A recent paper on $Al_xIn_{1-x}As/Al_yGa_{1-y}As$ self-assembled QDs gives some insight on the effect of an electric field on the electronic properties of these systems [166]. Microphotoluminescence measurements have been performed on single QDs in the presence of an external field oriented along the growth direction (the field was considered positive when the field lines were oriented from top to substrate); the field, both positive and negative, has been varied in a wide interval. The most interesting result is an asymmetric Stark shift of the emission energy as a function of the applied field. In general, the single QD lines blueshift for increasing positive fields and this shift reaches a maximum; on the contrary, the emission is redshifted for negative applied fields. The results of theoretical calculations are quantitatively consistent with the experimental findings; in particular, the theory shows that the blueshift is mainly due to a strong increase in the electron confinement energy because the field displaces the electron toward the apex of the QD. Another interesting effect of the application of the electric field is that lines appear and disappear in the spectrum as the field is tuned. The effect is probably related to the modification of the emission selection rules [166].

The spectroscopy of single QDs in magnetic fields up to 8 T is discussed in [167], where a magneto-optical study of excitons, biexcitons, and charged exciton complexes in $Al_{0.36}In_{0.64}As/Al_{0.33}Ga_{0.67}As$ is presented. In particular, as the magnetic field is increased, the single exciton splits into σ^+ and σ^- polarized states, the splitting between the two states increasing linearly with the magnetic field. A slight diamagnetic shift of the order of 0.1 meV in the range 0 to 8 T is observed for the single exciton. Furthermore, the splitting of the biexciton is identical to that of the single exciton, despite the fact that the biexciton energy is not expected to split in a magnetic field, due to the singlet nature of the biexciton. In fact the final state of the biexciton transition is an exciton and thus the splitting of the biexciton emission is given by the Zeeman splitting of the exciton [167].

The use of magnetic field allows study of the presence of dark excitons in QDs. The concept of dark exciton refers to fine electronic structure of the electron–hole complex. Generally speaking, the e–h complex consists of a multiplet of states with different total angular momenta. The states are split (usually by few hundreds of μeV) due to the exchange interaction. Only the states with angular momentum equal to 1 can recombine radiatively; the other states are not coupled to the light field and are denominated dark exciton states. The presence of dark states has a strong influence on the recombination kinetics of bright excitons. In fact, dark states, due to their long lifetime, act as a reservoir for the bright exciton recombination.

A determination of the dark exciton states is quite difficult, first because a direct access by optical spectroscopy is allowed only if a symmetry breaking relaxes the conservation of the angular momentum. This occurs, for example, by using a magnetic field, which produces a mixture of dark and bright exciton states. A further complication in the study of dark excitons is related to the very small splitting between states of different angular momentum, which, in semiconductor structures, is usually much smaller than the inhomogeneous broadening. However, this last limitation is overcome in single QD spectroscopy. A spectroscopic study of dark exciton states in InGaAs single QDs under magnetic field has been reported in [168]. By varying the strengths and the orientation of the external magnetic field, the authors were able to resolve the full detail of the fine structure of the QD excitons, determining both the electron and hole g factors and the electron–hole exchange splitting.

4.2. Time-Resolved Photoluminescence

Ultrashort laser pulses below 100 fs are nowadays routinely generated and used for providing a sort of instantaneous optical excitation of semiconductor systems. The availability of laser sources with a large range of wavelengths, repetition rate, pulse duration, and energy has made it possible to explore a large variety of physical phenomena by means of time-resolved spectroscopy. After the excitation by an ultrashort pulse of a semiconductor in thermodynamic equilibrium, this undergoes several stages of relaxation before it returns to the initial condition. The investigation of these relaxation processes allows one to get information on the intrinsic time constant ruling the carrier dynamics. Time-resolved spectroscopic techniques with the appropriate time resolution are then largely exploited in order to follow, in real time, the relaxation paths of the photoexcited carriers. For a general review we refer to [169].

4.2.1. Experimental

Ultrafast Lasers Ultrashort laser technology is based on the mode locking method, in which the longitudinal modes of the laser cavity are locked in phase, in active systems with large gain bandwidth. Synchronously pumped organic dye lasers with a mode-locked Nd:YAG or Ar^+ ion laser, invented at the end of the 1970s, were the first efficient tool for ultrashort laser pulse generation. Enormous progress in tunability, stability, and quality of the laser pulses has been achieved with the development of solid state lasers and in particular with Ti:sapphire lasers. Generation of pulses shorter than 10 fs has been realized directly from the laser

oscillator without the need for laser amplification and compression. Optical parametric oscillators or amplifiers have recently increased the tunability range of ultrafast lasers.

PL Detection Several detection techniques have been so far developed for time-resolved PL spectroscopies. The most widely used method makes use of a streak camera. The PL photons, focused on a photocathode, extract photoelectrons that are deflected by time modulated electrostatic fields to be streaked, after multichannel plate amplification, across a phosphorescent screen. Therefore photoelectrons emitted at different times impinge onto the screen at different positions and the information on the time is transferred into a spatial distance. Picosecond resolution can be achieved in state-of-the art streak camera apparatuses. Higher time resolution, limited only by the pulse duration, can be achieved by nonlinear techniques like the parametric up-conversion. In this case the PL signal is combined in a nonlinear crystal, such as KTP or $LiIO_3$, with part of the laser pulse suitably delayed. Frequency sum generation can occur only during the laser pulse gate and its intensity as a function of the delay of the laser pulse directly gives the PL time evolution.

4.2.2. General Aspects

The carrier relaxation in semiconductors can be classified into three main temporally overlapping regimes.

Coherent Regime The excitation in the semiconductor created by a ultrashort laser pulse has a well defined phase relationship within the excitation and with the electromagnetic field of the laser pulse. In this situation, the system optical response is driven by the interaction of the field with the coherent macroscopic polarization induced by the laser pulse. This coherent regime shows several interesting phenomena, which are strictly related to the basic quantum mechanics in semiconductors. The time scale on which the coherent interaction relaxes is usually very short in semiconductor structures due to the scattering processes leading to a coherent loss. Typically, in semiconductor systems the dephasing processes are very fast (few picoseconds or even less). On the contrary, long dephasing times (in the nanosecond timescale) have been recently observed in semiconductor QDs.

Cooling Regime In this regime the photoexcited carriers lose their excess of energy, mainly by emission of phonons. In the first stages (few picoseconds) of this regime the distribution of the photoexcited carriers is very likely nonthermal (i.e., cannot be described by a temperature) Carrier–carrier scattering processes are very often responsible for the carrier redistribution within the accessible states leading to a thermalized distribution of the carriers. The related temperature can be higher than the lattice temperature for a long time scale (few tens of picoseconds). This stage is indeed denominated as a hot-carrier regime. In this regime the carriers lose their excess of energy mainly by emission of phonons. At the end of the intraband relaxation processes the photoexcited carriers eventually reach a thermalized distribution in equilibrium with the lattice vibrations. In the case of semiconductor nanostructures within the cooling regime the thermalization processes include also the carrier capture into the nanostructures because they represent the lowest energy states of the system.

Recombination Regime The carriers and the phonons are in thermal equilibrium with each other. However, there is an excess of electrons and holes with respect to the thermal distribution due to the laser pulse excitation. The photoinjected carrier population decays by either radiative or nonradiative recombination with a typical time constant of 100 ps–1 ns, in direct semiconductor nanostructures.

It should be stressed that often the relaxation processes in the different regimes occur simultaneously. For example, the electron–hole pair recombination can also occur during the cooling regime leading to the so-called hot PL. Nevertheless the description in terms of different relaxation regimes provides a useful framework for discussing the carrier dynamics in semiconductors.

4.2.3. Carrier Dynamics in Quantum Dots

Several experimental techniques have been so far developed for investigating different aspects of the carrier relaxation. Here we will focus our attention on the time-resolved PL originated by the thermalized distribution of electron–hole pairs (or excitons) in semiconductor QDs. Since the electronic levels in QDs are separated by tens of meV, low temperature PL measurements mainly probe the fundamental optical transition, unless state filling effects take place under large excitation power density. Generally speaking, the PL time evolution after short pulse excitation can be characterized by two time constants, that is, the rise time and the decay time. The rise time describes the delay after the excitation that occurs for the carriers to reach the levels from where the emission takes place and it contains information on the carrier capture and energy relaxation processes. The decay time is a direct measurement of the electron–hole pair recombination time by either radiative or nonradiative mechanisms.

It should be also noted that the carrier capture and recombination in QDs are random processes which are not adequately described by standard rate equation models. A theory of random population has indeed been developed for a correct description of the carrier dynamics in QDs [76]. Monte Carlo models have been developed for taking into account the random nature of the carrier capture in the QD recombination kinetics [170].

4.2.4. Carrier Relaxation and Capture in Quantum Dots

The nature of the mechanisms underlying the carrier relaxation in QD materials has been largely debated in the last years [171–175] and it is not yet completely understood. The relaxation processes in QDs attract much attention since they involve fundamental physical aspects of the zero-dimensional semiconductor systems, and also due to their relevance for device applications. In QD lasers the carriers are injected into the barriers embedding the QDs. After energy dissipation processes, the carriers are captured by the QDs and then relax to the fundamental lasing state. The efficiency of the relaxation cascade directly affects the device performances, such as threshold current, temperature

stability, and so on. The achievement of very fast capture rate is therefore a relevant aspect of the device optimization study. At the same time the interband phonon scattering in quantum confined electron gases is expected to show strong dimensionality effects [176]. Bockelmann and Bastard proposed a model calculating the theoretical emission rates for longitudinal acoustic (LA) phonons as a function of the lateral dimension L of the nanostructure in 0D, 1D, and 2D systems, corresponding to QDs, QWRs, and QDs, respectively. The model is based on weak phonon-coupling assumptions and Fermi's golden rule was used to estimate the carrier relaxation rate. In this model the initial electron state energy E_i was chosen in order to have the same energy difference from the fundamental level for the QD, QWR, and QW as illustrated in Figure 22. The initial electron states are the first excited level for the QD and the edge of the first excited subband for the QWR and the QW. For lateral sizes exceeding 200 nm the three scattering rates decrease and become very close, since the differences vanish when the confinement size becomes very large. In the presence of quantum confinement effects ($L < 100$ nm), a clear reduction of the LA phonon scattering efficiency is instead predicted when decreasing the dimensionality of the electron gas. In particular the LA phonon scattering rate in QDs is extremely small and exhibits strong oscillations. The oscillations are manifestations of the discrete atomiclike energy spectrum of the QD. Even more dramatic are the effects of the QD constraints on the allowed inelastic carrier scattering via LO phonons. In particular, single LO phonon emission is forbidden unless the energy separation between the QD levels exactly matches the LO phonon energy. The predicted inefficient carrier relaxation via phonon emission in QDs is usually referred to as phonon bottleneck.

From the experimental side, the characteristic carrier relaxation time from the barrier states to the fundamental QD level is found to be very fast, that is, of the order of few tens of picoseconds, and becomes even shorter for large injection of carriers. Several mechanisms have been invoked to explain the lack of phonon bottleneck. In the low injection regime, the fast relaxation time (30–70 ps) has been interpreted as a consequence of the presence of a continuum tail of defect states to which the carriers easily relax the excess energy [174]. Alternatively, resonant multiphonon processes can mediate the relaxation between the localized states [177]. The formation of vibronic (polaron) states, which might provide wide energy windows for efficient relaxation, has been also proposed [178]. In summary, a clear understanding of the origin of the fast carrier capture and relaxation in QDs has not yet been reached. On the contrary, there is evidence of the major role played by Auger-like processes in the carrier relaxation under large injection. This is shown in Figure 23 where the experimental PL rise time (equivalent to the relaxation time) is reported as a function of the excitation density and wavelength [179]. Increasing the carrier injection, the carrier–carrier interaction speeds up the energy relaxation rate. This effect has been assigned to Auger–like processes where an electron (or a hole) occupying an excited level of the dot relaxes to a lower state giving the excess of energy to another electron (or hole) [179, 180]. In particular, the Auger processes involving carriers localized in the 2D WL states have been claimed to increase the carrier relaxation rate inside the QD [181, 182]. Nevertheless recent experimental data unambiguously show that very similar phenomenology occurs also in GaAs/AlGaAs QD grown without WL, pointing out the relevance of internal Auger mechanisms in the QD carrier relaxation [183].

4.2.5. Spin Relaxation in Quantum Dots

The discrete nature of the electronic DOS of semiconductor QDs modifies the carrier spin relaxation dynamics with respect to the bulk or to quantum well structures [184]. The lack of available energy states is expected to inhibit both elastic spin flip mechanisms and inelastic phonon scattering. The possibility of very long spin relaxation time has been exploited for proposing the QDs as candidates for the implementation of spintronics [185].

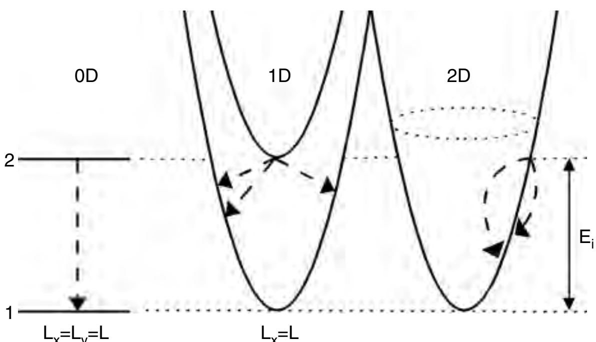

Figure 22. Schematic dispersion curves in the case of 0D, 1D, and 2D confinement.

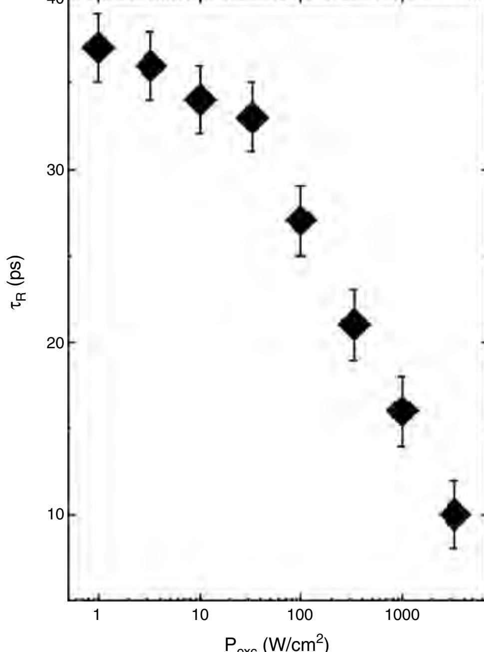

Figure 23. Dependence of the QD ground state PL rise time as a function of the laser excitation density in GaAs/AlGaAs QDs. After [183].

These predictions have stimulated large interest on the spin relaxation in QDs. In the study of natural QDs formed by interface fluctuations in GaAs QWs, it has been shown, by means of CW-PL experiment, that the rate of spin flipping was lower than the radiative recombination rate [130]. The same conclusions were obtained in [186] in the case of self-aggregated InAs QDs. On the contrary, longer spin relaxation times, almost twice the recombination time, have been observed in InGaAs quantum discs [187]. It should be noted that in all these studies the spin dynamics has been addressed via nonresonant excitation of the QD structures. This means that the carriers were photoinjected into the barriers. Therefore the observed polarization dynamics was the result of all the spin relaxation processes occurring during the relaxation path.

Recently the study of the QD spin relaxation has been performed by using strictly resonance conditions [188]. The laser excitation energy was exactly coincident with the detection energy. The use of up-conversion methods for detecting the QD-PL allowed not only a very good time resolution but also the elimination of the strong initial contribution due to Rayleigh scattering. The QD emission was analyzed both in the linear and in the circular polarization channel. The result was that spin relaxation was completely frozen on the carrier relaxation time scale. The discrepancy with the previous study was assigned to the relevant role of resonant injection in reducing carrier occupation of higher energy states which, via Coulomb exchange mechanisms, may produce a spin flip of the QD ground state [188].

4.2.6. Carrier Recombination in Quantum Dots

The measurement of the QD-PL lifetime τ_{PL} directly gives the recombination time of the electron–hole pairs inside the QD. Obviously τ_{PL} depends both on the radiative recombination time τ_{rad} and on the nonradiative recombination time τ_{nrad} via the well known relation $\tau_{\mathrm{PL}} = (1/\tau_{\mathrm{rad}} + 1/\tau_{\mathrm{nrad}})^{-1}$. It is commonly assumed that self-aggregated QDs are almost defect-free and that the parasitic nonradiative recombination channels do not play a major role in the low temperature PL emission. Therefore the experimental τ_{PL} is used as a direct measurement of the intrinsic QD radiative lifetime [189, 190], even if the presence of the nonradiative recombination affecting preferentially the small QDs has been reported in the case of high QD density [177]. The radiative decay rate $1/\tau_{\mathrm{rad}}$ can be evaluated by means of Fermi's golden rule in the dipole approximation [191]. In the limit of strong confinement conditions, where the carrier quantization energies are much larger than the exciton binding energy, $1/\tau_{\mathrm{rad}}$ is simply proportional to the atomiclike lifetime [192],

$$\frac{1}{\tau_{\mathrm{rad}}} = \frac{e^2 E_p \omega n}{2 m_0 \epsilon_0 h c^3} \phi^2 \tag{11}$$

where $\hbar\omega$ is the QD transition energy, m_0 and e are the electron vacuum mass and charge, E_p is the Kane energy, c is the speed of light in vacuum, and n is the index of refraction. The factor ϕ^2 is the overlap of the electron and hole wavefunctions. This expression predicts two relevant features. The first is the increase of the radiative recombination rate with the QD transition energy. Smaller QDs are expected to have shorter radiative lifetime. The second feature is that the radiative lifetime is proportional to the overlap of the electron–hole wavefunctions. The predicted dependence of the QD-PL lifetime on the QD size has been recently reported in a set of annealed InAs/GaAs QDs [190]. The thermally activated interdiffusion effect produces a large blueshift of the fundamental QD optical transition. Therefore the annealing induces a reduction of the effective QD size. As a consequence, the ground state radiative lifetimes are found to vary from 800 to 490 ps as the QD size is decreased. This variation is larger than the reduction predicted by the variation of the optical transition energy. The difference has been attributed to the increase of the overlap of the electron–hole wavefunctions [190].

The dependence of the radiative lifetime on the overlap of the electron–hole wavefunctions has been used to monitor the relative separation of the photogenerated carriers. Let us discuss two examples.

The first is related to the QDs grown on high index Miller substrates. As discussed in Section 4.1.6, the presence of piezoelectric fields in these QDs produces a spatial separation of the electron and hole wavefunctions which is expected to produce a reduction of the radiative recombination probability. The investigation of the carrier dynamics in InAs/GaAs (N11) QD performed in [156] by time-resolved (TR) measurements confirms this picture. The study of the time evolution of different spectral components of the PL band of (211)A QDs for increasing emission wavelengths evidences a progressive lengthening of the PL decay time. Of consequence, the PL emission peaks shift toward lower energy increasing the delay time after the exciting pulse, with minor variations of PL shape and linewidth (Fig. 24). In the long time limit the QD PL spectrum tends to recover the lineshape of the CW PL spectrum measured at low power density. Both the dynamic redshift of the PL band and the wavelength dependence of the PL decay times can be interpreted in terms of dynamic screening of the internal electric fields in the QDs. The electrons and holes injected by the optical excitation are spatially separated by the field resulting in a photoinduced screening of the internal field. Thus, in a TR-PL experiment, when increasing the delay time after the pulse excitation, an effective increase of the internal electric field is expected and the dynamic redshifts of the PL band can be attributed to the increase of the quantum confined Stark shift of the QD optical transition. The PL decay time dependence on the wavelength also reflects the same physical mechanism [156]. Note also that a large intrinsic nonlinearity in the carrier recombination kinetics [156] is associated with the described phenomenology. A detailed discussion of the influence of intrinsic internal fields on the recombination kinetics of high coverage (N11) InAs/GaAs quantum dots is reported in [193].

A second example is the possibility to tune the radiative lifetime in multilayer QD structures. The strain fields from the preformed islands induce vertical alignment in closely stacked QD layers and a self-organization of the QDs in vertical column occurs (see Sections 2.1.1 and 4.2). Whenever the barrier thickness is thin enough to allow tunneling, the carrier wavefunction becomes extended over many QD sites

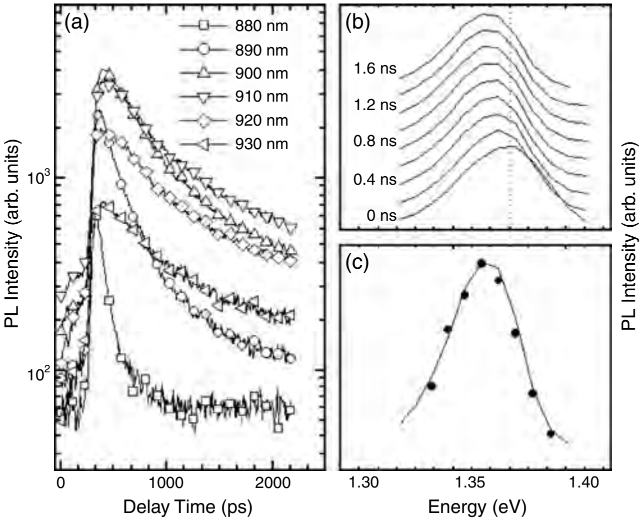

Figure 24. (a) PL intensity decay of the sample (211)A measured at various wavelengths: 880 (squares), 890 (circles), 900 (up-triangles), 910 (down-triangles), 920 (diamonds), and 930 nm (left-triangles). (b) Time-resolved spectra of the (211)A QDs. The step of the time delay between each spectrum is 200 ps. Each spectrum is normalized to its maximum. (c) Comparison between the time-resolved spectra of the (211)A QDs for an excitation power of 200 W cm^{-2} at 1.6 ns delay (corresponding to a reduction of nearly 1/10 of the PL integrated intensity at zero delay—continuous line) and the time-resolved spectrum for an excitation power of 20 W cm^{-2} at 0 ns delay (circles). along the column. However, the tunnel probability is larger for electrons than for holes. Therefore there exists a range of barrier thicknesses where the electrons are delocalized over the QD column and the hole are confined within a single QD. This induces a strong reduction of the electron–hole overlap and therefore an increase of the radiative recombination time [91].

An increase of the emission lifetime in stacked QDs increasing the number of layers has been observed [91, 92]. Data from [91] are reported in Figure 25. The emission

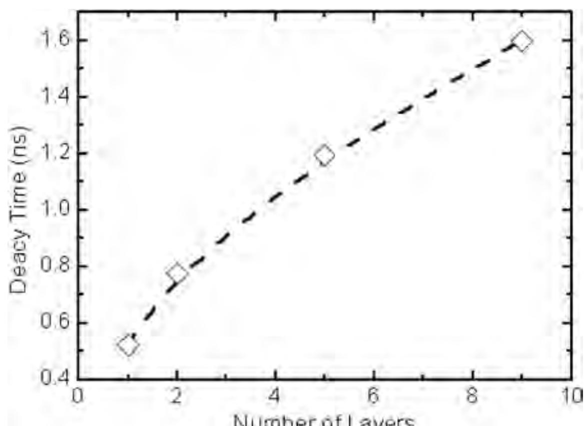

Figure 25. Dependence of the PL decay time at $T = 10$ K on the number of stacked QD layers (the solid line is only a guide for the eye). Courtesy of M. Colocci.

lifetime increases with the interlayer separation [160]. The interpretation relies in the reduction of the oscillator strength of the exciton inside the QD column [91], also due to the different delocalization between the wavefunctions of electrons and holes [91, 94].

Finally the excitation with ultrashort laser pulses has been used for the characterization of the QD excited state structure. [177, 189, 194, 195]. State filling in QDs, which is due to the exclusion principle, is effective when only a few carriers populate the lower states. Therefore the population of the excited states is easily achieved by photoinjection of carriers inside the barriers at excitation power exceeding few hundred W cm^{-2}, also due to the hindering of the interlevel relaxation. QD state filling has lead to the observation of a large number of excited state optical transitions. The measurement of the emission decay time of each transition was used to evaluate the excited state radiative lifetime, which was estimated to be of the same order of magnitude as the ground state lifetime [189].

5. APPLICATIONS

Significant technological improvements in the growth of nanostructures have been realized in the last decade. This opened the route to a new generation of QD devices taking advantage of the unique QD features arising from carrier quantization effects in all the three spatial directions. On one side, QDs have attracted large interest as possible efficient replacements of other quantum heterostructures for standard optoelectronic devices [196]. On the other side, a more general prospect has been recently addressed, aiming at exploiting the specific features of QDs for novel devices in the revolutionary field of quantum communication and quantum computation [197, 198]. Here we will touch on only two topics: the QD laser and QD based quantum cryptography.

5.1. Quantum Dot Lasers

Semiconductor lasers are nowadays key components in several widely used technological products, such as laser printers and compact disc players. At the beginning of the 1980s it was demonstrated that the use of quantum wells as the active layer in semiconductor lasers should result in more efficient devices. Even better performances can be obtained for lasers with quantum dot active layers [12]. This can be explained as follows. Stimulated recombination of electron–hole pairs occurs inside the nanostructure, where the confinement of carriers and also of the optical mode enhances the radiation–matter interaction. In particular, the change in the electronic density of states as a function of the nanostructure dimensionality is relevant, as discussed the Introduction. One relevant figure of merit of an active system is the optical gain spectrum [199]. Figure 26 reports a comparison between the optical gain of bulk and low dimensional semiconductors. The optical gain is enhanced in the case of QDs. It is clear that a QD laser will allow a reduction in threshold currents and an increase in differential gain. Other benefits of quantum dot active layers include less temperature dependence than other semiconductor lasers,

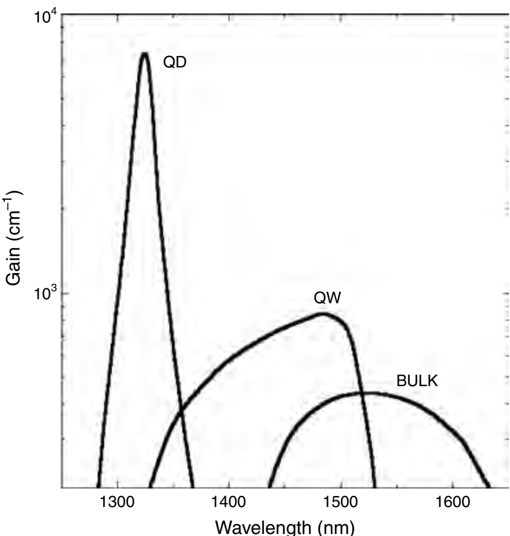

Figure 26. Calculated gain spectra at 300 K for a QD (a cube of 10 nm side), a QW (width of 10 nm), and bulk of $Ga_{0.47}In_{0.53}As/InP$. Data from [199].

reduced degradation at elevated temperatures, and larger tuning range.

However, the advantages in operation depend also on the uniformity of QD size. A large distribution of QD dimensions broadens the density of states, reducing the optical gain. Thus, the challenge in realizing QD lasers with operation superior to other semiconductor lasers was that of forming high density, high quality, and uniform quantum dots in the active layer. The first demonstration of a quantum dot laser with high threshold current density was reported by Kirstaedter et al. in 1994 [200]. QD lasers with improved operation were later achieved by increasing the density of the QD structures, stacking successive, strain-aligned rows of quantum dots and therefore obtaining vertical as well as lateral coupling of the QDs [196]. Nowadays 1300 nm GaAs-based and 1550 nm InP-based QD lasers are commercially available with performances not achievable with QW lasers. Nevertheless a number of critical issues on QD technology, involving the uniformity of size, the controllable achievement of higher quantum dot density, and a better understanding of loss mechanisms are still under study and will very likely improve the device characteristics in the next years.

5.2. Quantum Cryptography

The principles of quantum mechanics appear to offer novel degrees of freedom in the development of technological applications. Assuming to be able to organize and control a complex system governed by the law of quantum mechanics, it will be possible to engineer devices with revolutionary features. Among them quantum computational [197] and quantum cryptography [198] devices have been proposed to be realizable by means of QD technology. While quantum computing is still a dream, the realization of quantum cryptography seems to be very near. Let us briefly discuss the latter. Cryptography is the science of devising code to allow two users of a secret communication channel. The information generally takes the form of a string of bits that can be decoded only by the use of either a public-key encryption or secret-key encryption. Roughly speaking, in both cases the security of the communication channels is nowadays based on the assumed difficulty of factoring of extremely large prime numbers. Quantum information exchange is expected to provide a way of agreeing to a secure key without making this assumption [198]. The basic elements of quantum encryption are the measurements of a quantum state, typically the polarization state of a single photon. The quantum state is decided by the sender and then measured by the recipient. Due to the uncertainty principle, conjugate variables cannot be measured simultaneously. For example the photon polarization can be expressed in the linear or circular bases, but measuring the polarization in one specific basis will destroy the conjugates. Thus if the receiver do not know the basis used by the sender, the observation of the receiver can destroy the sender's information without understanding it.

The key technology for implementing quantum cryptography is the realization of a true single photon source. This cannot be realized simply by attenuating a standard light source since it has been predicted that even a very low rate of two–photon events makes the cryptography completely insecure. Recently the goal of a single photon source has been realized with QDs embedded in micropillar structures [201–203]. The QD layer placed inside a high Q planar microcavity, formed by two distributed Bragg reflectors, was fabricated monolithically using epitaxial growth techniques. Then the sample was patterned by electron beam lithography and etched through the microcavity leading to arrays of microposts with submicrometer diameters. This structure provides simultaneously the presence of very few QDs in the micropillar and fully three-dimensionally confined optical modes. Due to the quantum electrodynamical Purcel effect, the QD emission is enhanced and has preferential output direction [201]. It has been shown that, under these conditions, the QD generates one and only one photon from the fundamental optical transition for every excitation laser pulse [202, 203]. This demonstrates the realization of a quantum-dot single photon turnstile device.

GLOSSARY

Epitaxy The deposition of a crystalline substance, usually in a thin layer, upon the surface of a single crystal with a similar crystalline structure. The process does not involve a chemical reaction between the two materials.

Exciton Electron-hole pair bound by electrostatic interaction free to move in the semiconductor crystal. The exciton has no net electrical charge but it transports energy.

Heterostructure Synthetised crystalline system composed of more than one coherent material.

Phonon Quantum of lattice vibrational energy. The phonon can be viewed as a wave packet with particle-like properties.

Photoluminescence Emission of light as a result of absorption of electromagnetic radiation. The emitted light energy is usually lower that of the absorbed light.

Quantum structures Nanostructures capable of electronic quantum confinement in one (quantum well), two (quantum wire) or three (quantum dot) dimensions.

Self-assembling Generation of complex structures via atom organization driven by thermodynamics and kinetic processes.

Strain Relative deformation of elastic, plastic, and fluid materials under applied forces.

Quantum computer Device that employs properties described by quantum mechanics to enhance computational capabilities.

1. INTRODUCTION

The superior performances of quantum well (QWL) semiconductor devices over bulk devices have stimulated considerable interest in lower dimensional structures such as quantum wires (QWRs) and quantum dots (QDs) [1]. Carrier confinement to one or zero dimensions is expected to give rise to sharp peaks in the density of states (DOS). Figure 1 shows the DOS profile in energy of quantum nanostructures. The sharp peaks of the DOS can result in many interesting properties. For example, when used for optoelectronic devices, the sharp DOS peaks can lead to increased exciton binding, enhanced optical nonlinearities, narrower gain spectra, and higher differential gain.

The mature modern epitaxial techniques, such as metal-organic vapor-phase epitaxy (MOVPE) and molecular-beam epitaxy (MBE), provide the possibility of the fabrication of nanometer-sized semiconductor structures, including QWLs, QWRs, and QDs. In this chapter, we mainly review the advances in the growth, optical properties, and devices of semiconductor QWRs.

Several types of QWRs are realized by using III–V, II–VI, and SiGe semiconductor heterostructures, and also by using polymers and colloids. Here, we concentrate mainly on GaAs- and InGaAs-related QWRs produced by epitaxy, which are the two most mature kinds of semicondutor QWRs. Compared with others, these two kinds of QWRs have been well investigated, and several electronic devices have been realized, including QWR lasers, photodetectors, modulators, and transistors.

2. GROWTH OF QUANTUM WIRES

The current fabrication techniques of semiconductor QWRs make it difficult to obtain symmetric strong confinement from both dimensions. Most of the methods are based on the modified heteroepitaxial techniques, that is, QWRs are formed using the edges, corners, or intersections of two QWL layers. Therefore, one dimension confinement is from the potential barriers of heterostructures, while the other confinement is from the differences of the quantization energy, which is weaker. One aim to fabricate high-quality QWRs is to obtain large confinements from both sides. Two superior epitaxial methods of semiconductor QWRs are MOVPE and MBE.

2.1. V-Groove Quantum Wires

V-groove QWRs are one type of the most mature and promising QWR structures. The idea of V-groove QWRs was first proposed by Kapon and co-workers [3–5]. The idea is to grow QWL structures on a nonplanar substrate

to achieve lateral confinement by QWL thickness variation. V grooves are formed by two {111} facets. Figure 2 demonstrates the processing of the V grooves on GaAs (001) substrates. A (001) GaAs substrate wafer is processed using standard photolithography to obtain 2 μm wide photoresist-masked stripes with a 2 μm blank region between two stripes. Wet chemical etching is used to etch this patterned wafer. Because of the selectivity of the chemical etching to the different crystal facets, the {111} facets will be exposed to the surface. The V grooves are then formed by two {111} crystal facets, as demonstrated in Figure 2(a). Two kinds of chemical solutions are usually used to produce the V-groove patterned substrates: H_3PO_4:H_2O_2:H_2O (3:1:1), or

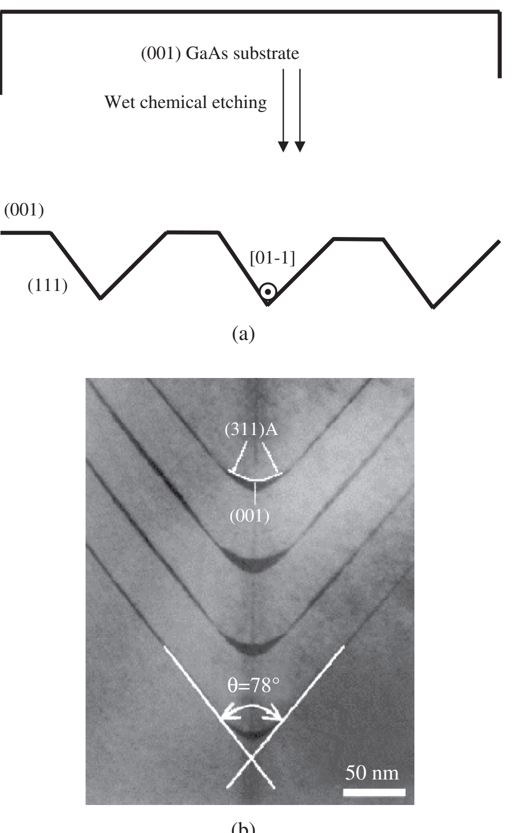

Figure 2. (a) Schematic of preparation of V-groove pitches. (b) TEM image of multiple AlGaAs/GaAs V-groove QWRs grown using flow rate modulation epitaxy method. Reprinted with permission from [16], X. L. Wang and M. Ogura, *J. Cryst. Growth* 221, 556 (2000). © 2000, Elsevier Science.

NH_3:H_2O_2 (1:5). The etching temperature can be at 0 °C or at room temperature. 4 μm pitch, [01–1]-oriented V grooves are formed after chemical etching of a 4 μm pitch photoresist patterned substrate wafer. To obtain a high density of the V grooves, the holographic lithography technique has been used. One short-wavelength laser beam interferes with its reflected beam on a substrate surface, which is coated with photoresist to obtain a high density of stripe patterns. This patterned substrate is also etched with the chemical solution. A 250 nm period V-groove array has been reported [6]. The growth on these V grooves will be self-limiting growth. When a GaAs or InGaAs QWL structure is grown on the patterned substrates, the well thickness at the V groove bottom is much thicker than that at the lateral side (so-called sidewall QWLs). Therefore, confinement can be obtained from the sidewall QWLs. At the bottom of the V grooves, a crescent-shaped QWR will be formed. Figure 2 shows a schematic illustration and a cross-section TEM image of a multiple GaAs/AlGaAs V-groove QWR structure grown on a 4 μm pitch V-groove grating substrate using the flow-rate-modulated epitaxy (FME) method [7]. The crescent shape is formed by different crystal facets, which is demonstrated in the schematic diagram. Because the diffusion length of the Al atom on the GaAs substrate is much smaller than those of Ga and In atoms, therefore the AlGaAs layer will not show much of a self-limiting profile; then the growth of the AlGaAs layer can maintain the V-groove shape. This property provides a chance to grow a thick AlGaAs buffer layer to recover the etching-induced damages on the surface without changing the V shape, and also to recover the V shape after the QWR layer.

2.1.1. Growth of V-Groove Quantum Wires with Conventional Epitaxy

AlGaAs/GaAs QWR MOCVD is preferred to grow V-groove QWR structures rather than MBE, which has been predicted in theory [8–9]. Here, conventional epitaxy means growing a QWL structure on the V-groove substrate as a conventional process of QWL growth on a planar substrate without interruption. Figure 3(a) shows a TEM image of multiple GaAs/AlGaAs QWRs grown with conventional epitaxy using low-pressure MOVPE on a 4 μm pitch V-groove patterned substrate. During the growth, a 0.1 μm GaAs buffer layer was grown before a 1 μm $Al_{0.5}Ga_{0.5}As$ layer. On the top of this thick $Al_{0.5}Ga_{0.5}As$ layer, a nominal multiple QWL structure was grown. All layers were grown at 750 °C. Multiple QWRs were then obtained at the V-groove bottoms. The thickness difference between the QWR and the lateral QWL is about three times. A dark vertical band in the TEM image is formed at the bottom of the V grooves as a low Al composition AlGaAs band due to the longer migration length of a Ga atom than that of an Al atom, and this low Al composition AlGaAs band forms a vertical quantum well (VQWL). Figure 3(b) shows the room-temperature PL spectra by using the micro-PL method. The dotted line is a Gaussian fitting. The sample is silicon doped in the wire region, which is for the purpose of photodetector devices using intersubband transition.

The lateral confinement of the QWR is always a limitation to obtaining the one-dimensional properties. To increase the

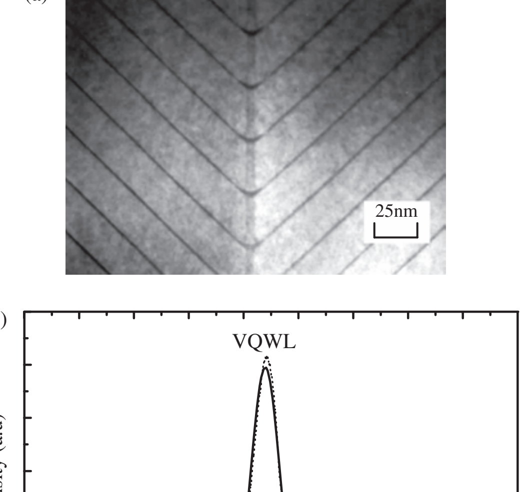

Figure 3. (a) TEM image of a multiple QWR structure grown by conventional MOVPE epitaxy. (b) Room-temperature micro-PL spectrum.

lateral confinement, the sublevel energy difference between a sidewall QWL and QWR should be enlarged. Liu et al. used dual self-aligned geometry to selectively implant the sidewall QWL, and then used thermal annealing to recover the damage. The sublevels of the sidewall QWL are then lifted from the interface intermixing [10, 11]. Figure 4(a) and (b) shows the CL images of the implanted and as-grown QWR structures. After implantation, the sidewall QWLs are disabled, and the CL from QWRs are clearly shown.

InGaAs/AlGaAs QWRs Indium atoms have a larger diffusion length than gallium and aluminum atoms. In the meantime, the InGaAs has a smaller bandgap than GaAs. Therefore, incorporation of indium in the wire region will benefit the lateral confinement. Figure 5 shows a TEM image of the cross section of an $In_{0.2}Ga_{0.8}As/Al_{0.5}Ga_{0.5}As$ QWR structure. The growth selectivity of the QWR to the sidewall QWL is obviously improved compared with GaAs/AlGaAs QWR structures. One difficulty for the growth of the $In_{0.2}Ga_{0.8}As/Al_{0.5}Ga_{0.5}As$ QWR structure is the difference of the growth temperature of the $In_{0.2}Ga_{0.8}As$ layer and the $Al_{0.5}GaAs$ barrier layer, which could be more than 150 °C. Asymmetric $Al_{0.5}Ga_{0.5}As$–$In_{0.25}Ga_{0.75}As$–GaAs QWR was successfully fabricated. Strain effects and the DOS were theoretically investigated [12].

High-Density QWRs To increase the planar density of QWRs, holographic lithography can be used to obtain a high density of stripes, then the high density of V grooves by using wet chemical etching. Figure 6 demonstrates the high density of an InGaAs/GaAs V-groove QWR structure. The distance between two QWRs is about 320 nm. This kind of high-density QWR structure will benefit optical devices, such as lasers and detectors.

2.1.2. Growth of V-Groove Quantum Wires Using FME

To achieve larger lateral confinement, one direct way is to increase the thickness difference of the sidewall QWL and the QWR layers, which needs stronger self-limited growth. Wang et al. used FME to achieve a larger lateral confinement [13–15]. Figure 7 shows the diagram of the flow rate control for the FME growth. We can see that Ga will have a larger diffusion length on the sample surface with arsine flow off. The TEM image in Figure 2 is a typical FME QWR [16]. It is clearly shown that the thickness ratio of the QWR to the sidewall QWL is increased compared with the QWR grown with conventional epitaxy (see Fig. 3). The enhanced lateral confinement can be seen in the optical properties, which will be described in the next part. Another key limitation to achieve real one-dimensional quantum structures is the strong interface effect, which is much stronger than that of QWLs because of the dramatically increased interface-to-volume ratio. Most of the QWRs are quantum box structures, which come from the monolayer fluctuation. The FME method dramatically improved the QWR interfaces [15].

TBA (tertiarybutylarsine) as Arsenic Source Wang et al. found that, when the TBA is used as an arsenic source in FME growth, the QWR interfaces were obviously

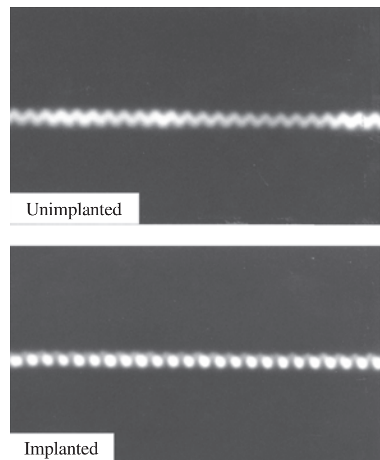

Figure 4. CL spectra of the as-grown (labeled as unimplanted) and the implanted samples.

Figure 5. TEM image of the cross section of an $In_{0.2}Ga_{0.8}As/Al_{0.5}Ga_{0.5}As$ QWR.

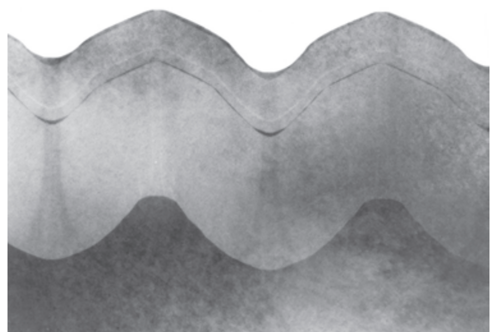

Figure 6. TEM image of high-density GaAs/$In_{0.2}Ga_{0.8}As$ QWRs grown on high-density V-groove substrates prepared by using holographic lithography. The distance between two QWRs is 320 nm.

improved compared with the conventional arsine source [16]. A comparison of V-groove structures by using arsine and TBA as an arsenic source in FME growth was demonstrated by AFM observation. Clear improvements were observed.

QWR Superlattice Buffer Layer One of the methods to improve the QWR interface is to use a QWR superlattice as a buffer layer. Microphotoluminescence (micro-PL) measurements showed that the number of exciton emissions within the excitation spot dramatically decreased (to be discussed in Section 3).

2.2. T-Shape Quantum Wires

The concept of the T-shaped QWR was originally proposed and investigated by Chang et al. [17]. The QWR is formed by using the cleaved-edge-overgrowth method, which is realized by cleaving a grown QWL structure in the MBE growth chamber followed by QWL growth over the cleaved edge. Two QWLs form a T shape; at the cross-section line, a QWR can be formed [18–20]. Figure 8 shows a schematic diagram of a T-shaped QWR. An $In_{0.17}Ga_{0.83}As$ T-QWR with $Al_{0..3}Ga_{0.7}As$ barriers is fabricated by the cleaved-edge-overgrowth method. The MQW layer consists of ten periods of $In_{0.17}Ga_{0.83}As$ QW and $Al_{0.3}Ga_{0.7}As$ barriers, and the total width of the MQW region is about 1 μm. Two 5 μm wide regions of the overgrowth QW were formed on both sides of the QWR region. This structure enables the unambiguous assignment of the PL peaks to QWR, QW1, and QW2 (after [20]). The T-shaped QWR has been extensively studied, particularly for the basic 1-D excitonic properties [21–23].

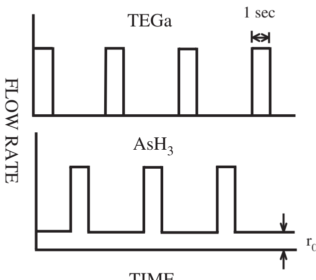

Figure 7. Schematic of the FME flow sequence during the epitaxy of QWR region.

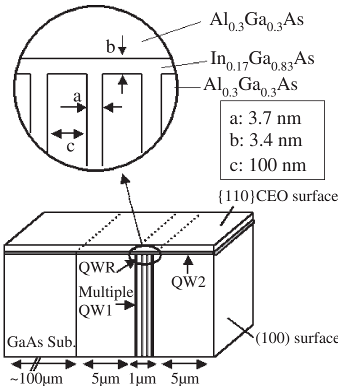

Figure 8. Structure of $In_{0.17}Ga_{0.83}As$ T-QWR with $Al_{0..3}Ga_{0.7}As$ barriers fabricated by the cleaved-edge-overgrowth method. The MQW layer consists of ten periods of $In_{0.17}Ga_{0.83}As$ QW and $Al_{0.3}Ga_{0.7}As$ barriers, and the total width of the MQW region is about 1 μm. Two 5 μm wide regions of the overgrowth QW were formed on both sides of the QWR region. This structure enables the unambiguous assignment of the PL peaks to QWR, QW1, and QW2. Reprinted with permission from [20], M. Yoshita et al., *J. Appl. Phys.* 83, 3777 (1998). © 1998, American Institute of Physics.

2.3. Sidewall Quantum Wires

Using the selectivity in (Al,Ga)As growth on patterned GaAs(311)A substrates, another kind of GaAs sidewall QWR can be fabricated by using MBE growth [24–27]. This concept is based on the intentional introduction of distinct lateral thickness variations of narrow quantum wells (QWs) in the x and/or y direction, in addition to the abrupt potential barrier in the z direction, which can be grown epitaxially with great perfection. These lateral thickness variations translate directly into bandgap variations via the transverse quantum size effect, that is, there is a strong variation of carrier confinement energy with well thickness. As a result, in addition to the vertical confinement in the z direction, there is a lateral 1-D or 2-D potential "well" in the (x; y) plane for electrons and holes at the thicker part of the (tapered) quantum well. By combining the lithographic patterning with self-organized growth during MBE growth, this kind of QWR can be obtained. Figure 9 shows a schematic illustration of the formation of lateral quasiplanar single (a) and multiple (c) GaAs QWRs in an (Al,Ga)As matrix at the fast-growing sidewall of shallow [01–1] mesa stripes on patterned GaAs(311)A. The one-dimensional confinement depicted by the real-space energy band diagram in (b) arises from the strong variation of the GaAs layer thickness along [−233].

2.4. Other Kinds of Quantum Wires

Quite a few other kinds of methods are used to fabricate the QWR structures, such as vicinal-substrate QWRs, etched QWRs, and so on. A vicinal-substrate QWR is achieved by making use of the step flow mode of growth on vicinal surfaces with MBE or MOCVD. The vicinal surfaces with small misorientation angles have an atomic step array with a well-defined periodicity in the 10 nm range. In this growth mode, the precursor atoms will preferentially adsorb at the edge of the steps. Based on this mode, the QWR structures are

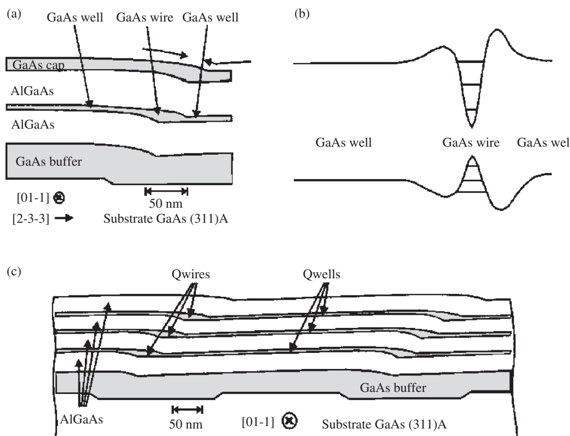

Figure 9. Schematic illustration of the formation of lateral quasiplanar single (a) and multiple (c) GaAs QWRs in (Al,Ga)As matrix at the fast-growing sidewall of shallow [01–1] mesa stripes on patterned GaAs(311)A. The one-dimensional confinement depicted by the real-space energy band diagram in (b) arises from the strong variation of the GaAs layer thickness along [−233]. Reprinted with permission from [27], K. H. Ploog and R. Nötzel, *Phys. E* 11, 78 (2001). © 2001, Elsevier Science.

formed by deposition of a superlattice structure on the tilted substrates, in which the lateral confinement is from the composition modulation [28–31].

Etched QWR is achieved by postgrowth etching of a QWL structure. The lateral confinement is from the vacuum potential when the stripe size is narrow enough. This requires a narrow stripe. To achieve nanometer stripes, electron-beam lithography or holographic lithography are necessary, followed by wet or dry etching. One great problem of this QWR is the strong lateral surface effects resulting from chemical etching, particularly for the optical properties [32–34].

3. OPTICAL PROPERTIES OF QUANTUM WIRES STRUCTURES

3.1. Light Emission from Real One-Dimensional Quantum Wires

PL is a direct way to study the one-dimensional properties of QWR. Also, it is a basic property (light emission) for application of the QWR to optoelectronic devices. As described in the first part, most of the QWR structures are quantum-box-like structures because of the monolayer fluctuation at the interface between the wire region and the barriers. The properties can be seen from micro-PL measurements at low temperature with low excitation power. Figure 10 shows low-temperature micro-PL spectra [15]. The structures are $Al_{0.45}Ga_{0.55}As$/GaAs single QWRs before and after improvements. The excitation laser spot diameter is about 1 μm. From Figure 11, we see that, within this 1 μm range, there are many quantum boxes before the interfaces are improved. Each individual sharp PL peak is from one quantum box. When the interface is improved, the quantum box number decreases dramatically, which means that the single QWR section is longer. Scanning near-field optical microscope (SNOM) experiments give a clear indication of a single QWR section. Figure 9 shows the PL emission from an 800 nm long single QWR section [35]. Within 800 nm, only one exciton emission line can be observed, which means that, within 800 nm, there is no interface fluctuation, 800 nm is very close to an ideal one-dimensional QWR. This promising quantum structure provides a good chance to investigate true one-dimensional quantum phenomena.

3.2. Thermal Stability of Quantum Wires Compared with Quantum Well Structures

The QWR was predicted to show higher thermal stability because of the sharp peak of the DOS. However, the increased ratio of the interface to the volume enhanced

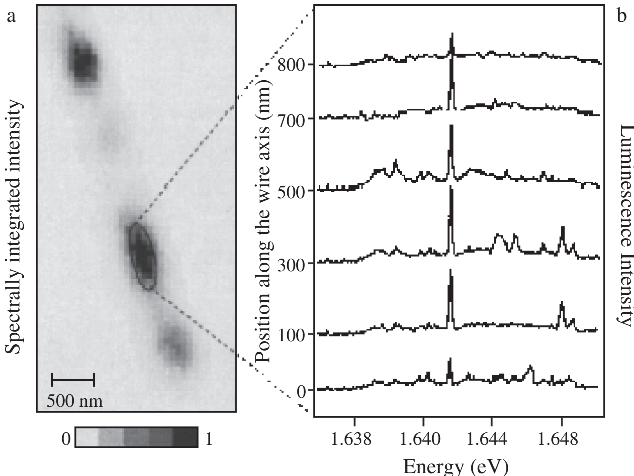

Figure 11. Real space image of PL intensity and the PL spectra corresponding to the long QWR section. Reprinted with permission from [35], A. Crottini et al., *Phys. Rev. B* 63, 121313 (2001). © 2001, American Physical Society.

the interface effects, and therefore decreased of the thermal stability of the QWR devices. Using a TBA source and special processing before the growth, the interface was tremendously improved, as discussed in Section 3.1. In the meantime, the nonradiative centers in the QWR structures are also dramatically reduced. Figure 12 shows the improvement of the thermal stability by using TBA as an arsenic source [36]. The intensity was increased about 1000 times at room temperature. Temperature-dependent lifetimes give further proof, as shown in Figure 13, in which the temperature of the maximum lifetime of the QWRs grown with TBA is about 100 K higher than that of those QWRs grown with arsine. The nonradiative centers are obviously reduced. We made a systematic comparison with QWL structures. Figure 14 shows the temperature-dependent PL intensities of 2, 5, and 9 nm single QWRs and single QWLs [37]. The PL intensities of a 9 nm QWR are larger than those of a 9 nm QWL at temperatures lower than 270 K. Our latest

Lett.* 79, 1622 (2001). © 2001, American Institute of Physics.

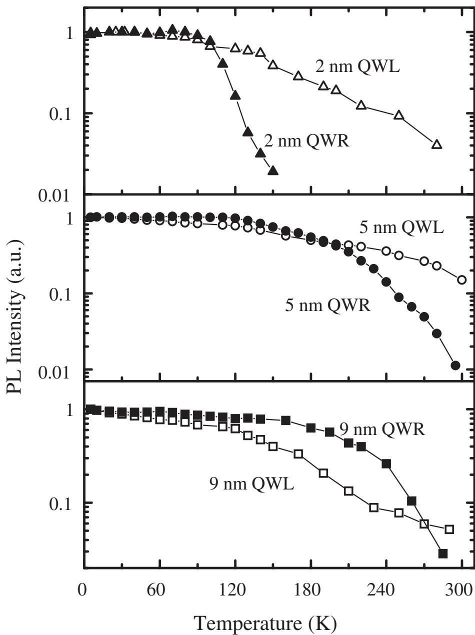

Figure 14. Comparison of the temperature-dependent integrated PL intensities of QWRs and QWLs with different thicknesses.

results show that stronger PL intensity of a QWR compared to that of a QWL structure is achieved at room temperature.

3.3. Piezoelectric Effects in High Quality Quantum Wires

Zinc-blende semiconductors are piezoelectric [38, 39]. Strain-induced piezoelectric effects have been shown to strongly affect the optical properties of quantum structures in strained III–V heterostructures [40–46]. Liu et al. demonstrated strong modification of optical properties by the tiny lattice-mismatch-induced piezoelectric field along the wire in ultrahigh-quality AlGaAs/GaAs V-groove QWR structures [47, 48]. In this study, a 5 nm thick $Al_{0.39}Ga_{0.61}As$/GaAs single QWR was grown using the FME method. To improve the quality of the interface, a short period superlattice buffer layer (AlGaAs (2.8 nm)/GaAs (1.4 nm) × 150) was grown before the growth of the AlGaAs barrier and the QWR structure. QWRs grown by this technique were proved to be of extremely high interface quality; the (001) center facets were composed of 1-D QWR sections with lengths of at least several 100 nm for one section, and the (113)A facets also became much smoother. Figure 15(a) illustrates TEM images of part of the superlattice buffer layer and the single QWR grown on it, (b) shows a schematic diagram of the axis, and (c) shows a schematic diagram of the potential profile along wires. The optical properties of the grown QWRs were characterized by photoluminescence, PL excitation (PLE), and time-resolved PL (TRPL) measurements. Figure 15(d) demonstrates the temperature-dependent PLE spectra and the 5 K PL spectrum. One striking feature shown in Figure 15 is that the PLE intensity of the ground state (e_1–hh_1) transition is almost zero at 5 K over an energy range as large as 20 meV. With increasing temperature, the e_1–hh_1 transition appears gradually, and clear e_1–hh_1 transition peaks can be observed when the temperature is higher than 100 K. The zero PLE intensity at low temperatures strongly suggests complete spatial separation of electron and hole wavefunctions, which might be caused by an internal electric field effect. With the temperature increased, the piezoelectric field is screened, and the PLE peak can be observed clearly.

3.4. Disordered Quantum Wires Superlattice Structures

In the last decade, much attention has been focused [49–57] on the two-dimensional disordered superlattice (d-SL) proposed by Sasaki et al. [58]. A d-SL is formed by disordered distribution of layer thickness and/or confinement potential, which causes carrier localization along one direction (growth direction). Superior optoelectronic properties resulting from the effects of strong carrier localization have been shown in d-SL as compared with ordered SL (o-SL), such as enhanced photoluminescence, particularly at higher temperatures, and slow PL decay with increasing temperature. Further stronger carrier localization, and thus further stronger PL intensities, are expected to result from a lower dimensional disordered structure, for example, a disordered quantum wire SL (d-QWR-SL) and a disordered quantum dot SL. To realize the lower dimensional disordered structures, accurate control of the size and multilayer potential profile, that is, energy bandgap engineering (EBE) in more than one direction, is required. The V-groove QWR is fabricated by direct epitaxial growth on a V-grooved substrate, during which the EBE can easily be realized in the growth and lateral directions. Liu and co-workers reported the first successful fabrication of the d-QWR-SL structures and the observation of significantly high thermal PL stability [59, 60]. PL properties and the carrier lifetimes in comparison with those of an ordered QWR-SL (o-QWR-SL) and a single QWR structure are systematically investigated. The results demonstrated superthermal PL stability of the d-QWR-SL structures, which probably comes from carrier localization phenomena resulting from artificial disorder effects. The samples were grown on a 4 μm pitch V-grooved substrate by means of MOVPE using the FME technique. The layer structures of the o-QWR-SL sample consist of a 200 nm thick GaAs buffer layer, a 900 nm thick AlGaAs barrier layer, a 32-period GaAs/AlGaAs SL layer, and a 200 nm thick AlGaAs barrier layer. The Al

composition of the AlGaAs barrier is different for different crystalline facets, which are about 0.425 and 0.336 for (111)A sidewall facets and the vertical quantum well (VQWL) formed at the V-groove center, respectively. All layers were grown at 630 °C. The nominal AlGaAs barrier thickness is 12 monolayers (MLs), and that of GaAs wire layer is 6 MLs. The d-QWR-SL structures consist of nominal 3(W_1), 6(W_2), and 9(W_3) MLs for wire layers and 7(B_1), 12(B_2), 17(B_3) MLs for barrier layers. Individual thicknesses appear randomly, but with equal probability. The average thicknesses of the wire and barrier in the d-QWR-SL structures are same as those in the o-QWR-SL. The sequence of the different thickness layers in d-QWR-SL sample is as follows:

$$W_3B_1W_1B_3W_1B_3W_2B_2W_1B_2W_2B_1W_2B_1W_3B_3W_2B_3W_3B_2 \\ \times W_3B_3W_1B_1W_1B_3W_2B_3W_1B_1W_2B_2W_2B_3W_3B_1W_2B_2 \\ \times W_3B_1W_3B_1W_1B_3W_3B_3W_1B_2W_1B_2W_2B_1W_1B_1W_2B_3 \\ \times W_2B_3W_3B_2W_3B_2W_1B_2.$$

The cross section was checked by TEM. Figure 14 shows the TEM image graphs. Figure 16(a) is of the o-QWR-SL, and Figure 16(b) is of the d-QWR-SL. The integrated PL intensity is shown in Figure 17, which demonstrates a much worse thermal stability of the o-QWR-SL than that of the d-QWR-SL. The thermal stabilities of single QWRs with thicknesses of W_1 and W_3 were also confirmed to be worse than that of the d-QWR-SL sample. Therefore, the thermal PL stability of the d-QWR-SL is indeed much better than those of a single QWR with a thick barrier or o-QWR-SL structures.

The carrier lifetime measurements confirmed the above PL results. Figure 16 shows the temperature-dependent lifetimes of the o-QWR-SL and the d-QWR-SL. For comparison, the lifetime of the single QWR is also shown in Figure 18. For the d-QWR-SL sample, the lifetimes of the low (labeled d-QWR-SL) and the high (labeled d-QWR-S_1) energy transitions reach maximums of 3.20 and 2.64 ns at about 170 and 180 K, respectively, and then decrease continuously. These temperatures are consistent with those of

the PL intensity maxima of the d-QWR-SL. On the other hand, for the o-QWR-SL sample, the lifetimes of the ground and the excited state transitions reach maxima at about 110 K, which is much lower than that of the d-QWR-SL, and then decrease continuously. In the temperature range from 60 to 110 K, in which the radiative recombination

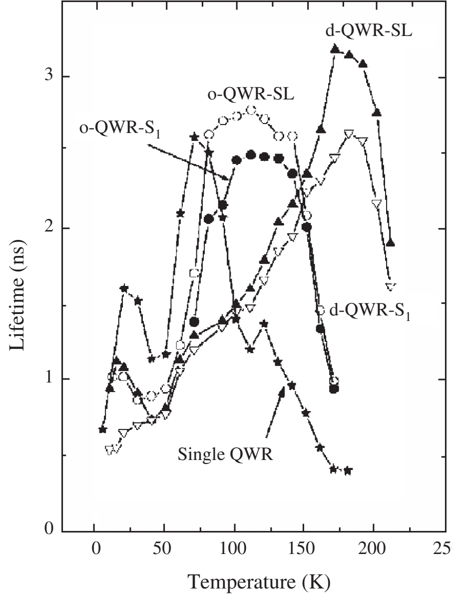

Figure 18. Temperature-dependent carrier lifetimes of the d-QWR-SL and o-QWR-SL structures. Reprinted with permission from [59], X. Q. Liu et al., *J. Appl. Phys.* 90, 6363 (2001). © 2001, American Institute of Physics.

is dominant for both the o-QWR-SL and the d-QWR-SL, the lifetimes of the d-QWR-SL are obviously shorter than those of the o-QWR-SL, while for the single QWR sample, the lifetime reaches a maximum of about 2.6 ns at about 70 K before decreasing, which is a temperature much lower than that of the d-QWR-SL. It is evidence of the contribution of the nonradiative recombination as the wavefunction penetrates into the barriers. These results demonstrate again the superior thermal stability of the PL of the d-QWR-SL.

4. QUANTUM WIRES DEVICES

4.1. Quantum Wires Laser

The interest in QWR laser structures is mainly focused on the predicted peaked density of states due to the lateral quantum confinement experienced by the charge carriers in such low-dimensional systems [1]. An extremely low threshold current is expected compared with QWL laser structures. However, the expectation for improved performance with such lower dimensional structures is difficult to realize because of fabrication difficulties. Kapon and co-workers reported lasing behavior in their pioneering papers [3, 5]; however, the laser emission is from excited states at low temperature. With the improvement of the QWR structures including the improved interfaces and the enhanced lateral confinement, the ground state QWR laser was demonstrated at room temperature [61, 62]. Figure 19 shows typical light output versus current characteristics (a) and stimulated emission spectra at various power levels (b) taken for the 600 nm long uncoated laser. Excitonic lasing behavior in a V-groove QWR was also reported at 10 K by optical pumping arising from a population inversion of localized excitons within the inhomogeneously broadened luminescence line [63].

4.2. Other Kinds of Quantum Wires Devices

The success of QWL infrared photodetectors [64–67] stimulated further interests in lower dimensional infrared quantum structures, such as photodetectors, including QWR and QD photodetectors, in which the photoabsorption will be enhanced, and also the normal incidence absorption can be realized. QD infrared photodetectors have been intensively investigated [68–70]; however, for QWR infrared photodetectors, it is not the case because of the difficulties of fabrication of the QWR structures. Liu and co-workers [71, 72] demonstrated a QWR photodetector device; however, the performances still need to be improved.

Another promising application of QWR structures is the single QWR FET [73–76], which can realize ballistic transportation. Sugaya et al. made an extensive study of the QWR FET, in which the QWR is a trench type grown by using MBE. The novel properties and promising prospects of the QWR FET are attracting great attention. The obvious improvement of the interfaces of QWR structures will speed up the application in electronic devices.

5. SUMMARY

In summary, we made a review of the growth, optical properties, and devices of semiconductor quantum wires. Different types of growth techniques and the structures associated with quantum confinement were reviewed. The optical properties were discussed in detail, followed by several kinds of devices.

GLOSSARY

Detector A kind of device, which can detect optical radiation, or other kind of signals.

Field effect transistor (FET) A kind of electronic device, which is used as electrical amplifier or switch.

Laser Light amplification by stimulated emission of radiation. A kind of optical device, which can emit light of ultrahigh density. The emitting media can be gas or solid.

Localization The carriers (holes or electrons) confined in a structure and the structure dimension is smaller than carrier mean-free length.

Metal organic chemical vapor deposition (MOCVD) A promising method to get high-quality semiconductor quantum structures for electronic devices.

Molecular beam epitaxy (MBE) An advanced method to grow semiconductor quantum structures. It can achieve mono-atomic layer control.

Nanometer One nanometer is 10^{-9} m.

Quantum well A structure that can confine the electrons or holes in a very thin layer. The electrons or holes will be free in two dimensions in the well plane. The well layer is generally around 10^{-9} to 10^{-7} m.

Quantum wire A structure that can confine electrons or holes in a very narrow line. The electrons or holes will be free along the line. The dimension of the line is generally about 10^{-9} to 10^{-7} m.

Superlattice When the confinement barrier is thin, and multiple quantum well stacked together, the carriers states in different quantum wells will couple with each other and form a new kind of quantum structure.

Transmission electron microscope (TEM) A method making use the electron beam to transmit a thin solid sample and can show up to atomic level image.

1. INTRODUCTION

The Si/SiGe:C heterostructures add a rich variety to the monotonic Si world. The misfit between Si and Ge, which is the initial obstacle to fabricating such material systems, becomes an advantage in tailoring the electronic properties of Si-based devices. Si/SiGe heterojunction bipolar transistors have a cutoff frequency of 210 GHz [1] and a maximum oscillation frequency of 285 GHz [2] with carbon incorporation in the base. The figures of merit of metal-oxide-silicon-field-effect transistors (MOSFETs) are also enhanced to some extent with the use of the strained Si on the relaxed SiGe buffers for both N and P channel devices [3, 4]. The reported peak hole mobility is 2700 cm^2/Vs in the strained Ge channel [5], and the reported peak electron mobility is 800 cm^2/Vs in the strained Si channel [6]. Heterojunction devices such as resonant tunneling diodes [7–9] and modulation-doped FETs [10, 11], which were only possible with III–V semiconductors in the past, can now be made from SiGe/Si heterostructures. Table 1 gives a summary of SiGe device performance.

$Si_{1-x}Ge_x$ material is a solid solution of Si and Ge with an intrinsic lattice constant larger than that of Si. A simplified way to look at $Si_{1-x}Ge_x$ is that it is made of "$Si_{1-x}Ge_x$ atoms" in a diamond structure, and the virtual "$Si_{1-x}Ge_x$ atom" inherits the characteristics from both Si and Ge, with the atomic fraction as a weighting factor. In most cases, a linear weighting assumption is good for applications. For example, the relaxed lattice constant of a $Si_{1-x}Ge_x$ crystal is a liner sum of the lattice constants of Si crystal and Ge crystal. The virtual $Si_{1-x}Ge_x$ atom approximation ignores the random nature of $Si_{1-x}Ge_x$, where the traveling carriers in the $Si_{1-x}Ge_x$ crystal visit Ge atoms with the frequency of x and visit Si atoms with the frequency of $1 - x$, but in the virtual $Si_{1-x}Ge_x$ crystal, the carrier sees only one kind of atom, the $Si_{1-x}Ge_x$. This kind of random alloy effect has to be taken into account when randomness is important. For example, the alloy scattering allows nonphonon radiative recombination in $Si_{1-x}Ge_x$, which does not occur in Si and reduces the carrier mobility. For a good approximation, $Si_{1-x}Ge_x$ is a diamond structure occupied by virtual $Si_{1-x}Ge_x$ atoms, and randomness has to be taken into account by alloy scattering in certain circumstances.

2. STRAIN EFFECT

Si and Ge have the same diamond lattice structures and are completely miscible for a full range of composition, but have different lattice constants. The misfit is defined as the lattice constant difference between Si and Ge with respect to the Si lattice constant and is around 4%. For a linear assumption, the misfit between $Si_{1-x}Ge_x$ and Si is $\sim 0.04x$. For example, the misfit between $Si_{0.75}Ge_{0.25}$ and Si is 1%, that is, the 100 Si lattice units have the same length as the 99 $Si_{0.75}Ge_{0.25}$ units. For device applications such as heterojunction bipolar transistors (HBTs), the misfit dislocation at $Si/Si_{1-x}Ge_x$ interface has to be avoided, and the virtual SiGe atoms have to bond with the Si atoms one by one in the underlying Si substrates. The dislocation-free strained $Si_{1-x}Ge_x$ is also described as "pseudomorphic." The $Si_{1-x}Ge_x$ on the Si is under compressive strain, since the lattice constant of Si is smaller compared with $Si_{1-x}Ge_x$. The strain causes changes in the crystal structures and electronic structure of $Si_{1-x}Ge_x$.

2.1. Critical Thickness

Since the Si substrate is much thicker (~0.7 mm for 200-mm wafers), the original cubic $Si_{1-x}Ge_x$ lattice with a lattice constant larger than that of Si has to be distorted into the

Table 1. The achieved performance of electronic and optoelectronic devices based on SiGe technology.

Device	Figure of merit	Growth technique
Strained NMOSFET	Peak effective electron mobility 800 cm^2/Vs [6]	Relaxed buffer
Strained PMOSFET	Peak effective hole mobility 2700 cm^2/Vs [5]	Relaxed buffer
NPN-HBT	$f_T = 210$ GHz [1], $f_{max} = 285$ GHz [2]	Pseudomorphic
PNP-HBT	$f_T = 59$ GHz at RT, $f_T = 61$ GHz at 85 K [12]	Pseudomorphic
Heterojunction phototransistors	1.47 A/W at 850 nm, bandwidth = 1.25 GHz [13]	Pseudomorphic
NMODFET	$G_m = 460$ ms/mm $f_T = 76$ GHz, $f_{max} = 107$ GHz at RT [14] $G_m = 730$ ms/mm $f_T = 105$ GHz, $f_{max} = 170$ GHz at 50 K	Relaxed buffer
PMODFET	$G_m = 300$ ms/mm $f_T = 70$ GHz, $f_{max} = 135$ GHz at RT [15]	Relaxed buffer
NRTD	P/V ≥ 7.6 at RT [7], 2 at 4.2 K [8]	Relaxed buffer
PRTD	P/V = 1.8 at RT, 2.2 at 4.2 K [9]	Pseudomorphic
Detector (IR)	1.3 μm, 1.5 μm [16]	Quantum dots
Detector (LWIR)	Schottky barrier: $\lambda_c = 10$ μm [17]	Pseudomorphic
LED	1.3 μm, 1.5 μm at RT [18, 19]	Pseudomorphic, quantum dots

Note: The last column indicates the growth techniques used to obtain device-quality material.

tetragonal symmetry with the built-up strain energy. The in-plane lattice constant of $Si_{1-x}Ge_x$ is reduced to that of Si, and the vertical lattice constant increases by 80% of the in-plane lattice constant reduction. $Si_{1-x}Ge_x$ under stress may yield to form dislocations if the compressive strain energy is high enough. Strained $Si_{1-x}Ge_x$ with dislocations grown on Si is shown schematically in Figure 1. The thickness of strained $Si_{1-x}Ge_x$ has to be thin enough to prevent the dislocation formation. The maximum thickness to have a defect-free $Si_{1-x}Ge_x$ epilayer is the so-called critical thickness. To minimize the sum of the strain energy and dislocation energy, the thermal equilibrium critical thickness (h_c) [20] can be derived as

$$x = 0.55 \ln(10h_c)/h_c \quad (1)$$

where h_c is in nanometers. For example, the critical thickness is ~13 nm and ~1.5 nm for strained $Si_{0.8}Ge_{0.2}$ and Ge on Si, respectively. This value is too small to be used in many applications. The meta-stable growth away from thermal equilibrium is desired to increase the critical thickness. The selective epitaxial growth [21] and the low temperature epi-growth are common meta-stable growth methods. The enhancement by a factor of at least 4 can be obtained for x less than ~0.5, but it really depends on the details of the growth conditions. Generally speaking, the smaller area of growth and the lower temperature of growth can have a larger meta-stable critical thickness. Most $Si_{1-x}Ge_x$ reactors have a growth temperature of 550–650 °C. However, metal-stable films will generate the defect if the thermal budget of the further process is too high. This is a challenge in the integration of $Si_{1-x}Ge_x$ into a CMOS process.

In ultra-large scale integrated circuits (ULSIs), the building devices are N-channel or P-channel MOSFETs. Strained channels can improve the device performance of MOSFET. $Si_{1-x}Ge_x$ grown on Si can be relaxed if it is much thicker than the critical thickness and/or is annealed at high temperature. Relaxed $Si_{1-x}Ge_x$ is not good enough for devices with vertical carrier transportation such as HBTs, since both the threading dislocations and misfit dislocations at the

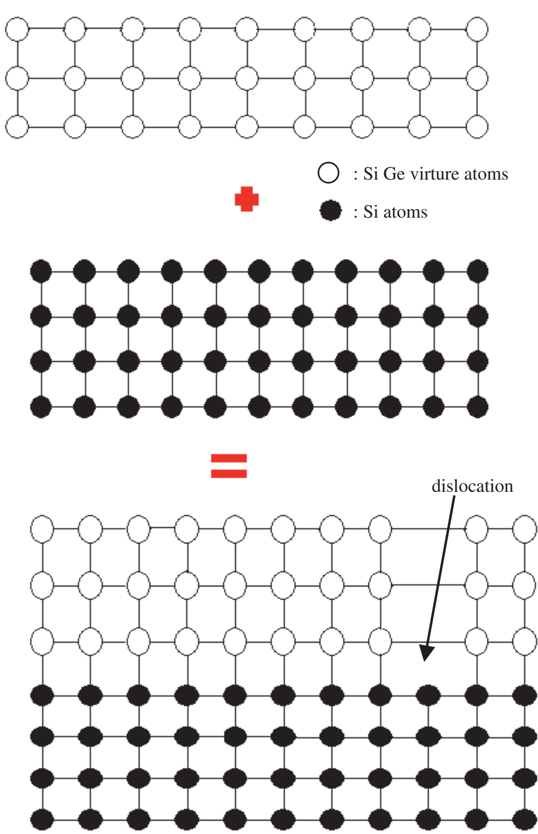

Figure 1. The strained SiGe grown on (100) Si. The misfit dislocation is the missing bond between the Si and SiGe atom.

$Si/Si_{1-x}Ge_x$ interface can act as recombination centers. The Si or Ge grown on relaxed $Si_{1-x}Ge_x$ is under tensile and compressive strain, respectively. The defects in the strained Si or Ge layer are the threading dislocation as shown in Figure 2, and most misfit network exists in the relaxed buffer layers. The threading dislocations in the strained Si and Ge channels have a small effect on in-plane carrier transport, especially for small feature devices, if the density is low enough (below 10^5 cm^{-2}). The strained Si and Ge channels increase the carrier mobility, and thus the device speed is enhanced in the same MOSFET technology node. For the Si or Ge grown on relaxed $Si_{1-x}Ge_x$ layers, the same critical thickness constraint is also applied. Note that the relaxed $Si_{1-x}Ge_x$ can be obtained with graded relaxed buffers [22], silicon on insulators (SOI) [23], and regrowth after smart cut [24]. Equation (1) can be used to estimate the critical thickness of strained Si or Ge, but x is the Ge fraction difference between strained Si (Ge) and relaxed $Si_{1-x}Ge_x$ buffers.

Because of the small lattice constant of diamond (made of carbon), the incorporation of carbon into SiGe on Si can compensate for the compressive strain from the large Ge atoms. A strain-free SiGeC film can be obtained if the ratio of the Ge fraction to the C fraction is ~11 (compensation ratio), obtained from the linear interpolation of the lattice constant between Ge and silicon carbide. Note that the silicon carbide is a compound with the same number of Si and C atoms in the face center cubic sublattices. However, only up to a few percent (~2.5%) of carbon can be incorporated into SiGe or Si [25, 26]. Note that Si and Ge can be mixed at any concentration.

$Si_{1-y}C_y$ and $Si_{1-x-y}Ge_xC_y$ alloys with tensile strain can be fabricated by incorporating carbon into Si and incorporating carbon content above the compensation ratio into $Si_{1-x}Ge_x$, respectively. In principle, the critical thickness concepts can still be applied to alloys with tensile strain. However, relaxation mechanisms in addition to the misfit dislocations, such as silicon carbide precipitation, and stacking fault formation, can also occur for thick and high-temperature annealed $Si_{1-y}C_y$ and $Si_{1-x-y}Ge_xC_y$ films.

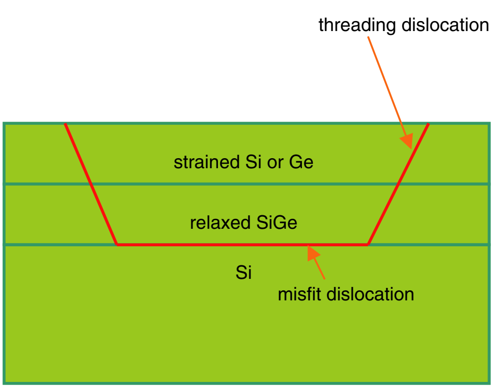

Figure 2. The misfit dislocation and threading dislocation. The misfit dislocation is at the Si/SiGe interface, and threading dislocation ends at the surface of the epilayers.

2.2. Growth Mode, Self-assembled Quantum Dots, and SiO_2 Dots

For $Si_{1-x}Ge_x$ layers thicker than the critical thickness, the relaxation is mainly apportioned by misfit dislocation generation at low Ge fraction (< ~0.4), although the morphology roughening can also lower the elastic energy [27]. For the high Ge fraction, the roughening is the dominant mechanism for relaxation, since the roughening barrier is sufficiently small in energy for most growth conditions. The roughening can be represented by the Stranski-Krastanow growth model. After the two-dimensional layer-by-layer growth reaches some critical thickness, the growth becomes three-dimensional island growth. Note that the critical thickness here can differ from the thermal equilibrium critical thickness (Section 2.1). The two-dimensional layer is also called the "wetting layer," and the islands are called "dots" or "quantum dots," depending on the size. The three-dimensional islands remain dislocation-free, but the top layers of the islands start to relax. This relaxation can stop the build-up of strain energy in the Ge islands. Further growth can cause the islands to coalesce, and misfit dislocations can occur.

Because of the different strain conditions on Ge layers, that is, the strained wetting layer and relaxed islands, the Si layer grown on the Ge dots has a tensile strain, whereas the Si layer on the Ge wetting layer is strain-free. If this Si layer is thinner than the correlation length [28], the strain condition remains, and the further Ge deposited on the Si layer (spacer) can vertically align with the underside of the Ge layers. The Ge dots of individual Ge layers are vertically self-assembled in a row in the same position [29] (Fig. 3). Ge quantum dots can also be fabricated with fine structures such as Ge/Si/Ge composite dots (Fig. 4) to improve uniformity, dot area coverage (Fig. 5), and photoluminescence efficiency. These Ge dot structures are used for photodetectors at wavelengths of 1.3, 1.5, and 10 μm (see Section 3.3.2).

To reduce the thermal budget of $Si_{1-x}Ge_x$-based devices, a low-temperature oxide is often used. Liquid-phase deposition can provide a low-temperature oxide on $Si_{1-x}Ge_x$. It is interesting that silicon dioxide dots can be deposited on the Si cap layers of self-assembled Ge dots with a liquid phase deposition method. The Si capping layer directly above the Ge dots has a tensile strain, whereas the Si cap on the wetting layer is not strained. The tensile strain can enhance the silicon dioxide nucleation and deposition on the Si surface, and SiO_2 dots are formed directly above the Ge dots with the SiO_2 wetting layers between the dots [29] (Fig. 3).

2.3. Electronic Structures

Because of the tetragonal distortion of strained $Si_{1-x}Ge_x$ grown on relaxed (001) $Si_{1-y}Ge_y$ layers, the energy bands of electrons and holes change according to the strain condition. For the compressive strain, the originally sixfold degenerate conduction band valleys split into a low-energy group of four valleys perpendicular to the growth direction and a high-energy group of two valleys along the growth direction. Similarly, the originally degenerate light and heavy hole bands split into the high-energy heavy-hole band and the low-energy light-hole band. For tensile strain such as that of

strained Si on relaxed $Si_{1-x}Ge_x$, the results are similar, but the energy levels switch between the degenerate groups. The two conduction valleys along the growth direction are lower in energy than the other four valleys in the strained Si. So are the valence bands. The effects are sometimes referred to as "uniaxial splitting."

The strained $Si_{1-x}Ge_x$ on Si has a smaller lattice constant in the two in-plane directions, and larger lattice constants in the growth direction as compared with originally relaxed $Si_{1-x}Ge_x$. The net volume decrease (hydrostatic term) of the tetragonal $Si_{1-x}Ge_x$ unit cell grown on Si leads to a shrinkage of the bandgap, that is, the valence band moves up and the conduction band moves down. Note that the strained Si on relaxed $Si_{1-x}Ge_x$ has the opposite effect, and the net volume increases. The bandgap of strained $Si_{1-x}Ge_x$ on Si is given in Figure 6 with the relaxed bandgap, and the optoelectronic devices for optical communication (1.3 and 1.5 μm wavelength) can be easily implemented by the strained $Si_{1-x}Ge_x$ bandgap. At low Ge concentration, the bandgap reduction is ~7.5 meV per % Ge for strained $Si_{1-x}Ge_x$ grown on Si. The conduction band discontinuity between strained $Si_{1-x}Ge_x$ and Si is often negligible. For strained Si grown on relaxed $Si_{1-x}Ge_x$ buffers, the bandgap reduction of Si is ~4 meV per % Ge. The smaller bandgap reduction of strained Si on relaxed $Si_{1-x}Ge_x$ as compared with the strained $Si_{1-x}Ge_x$ on Si is due to the fact that the tetragonal distorted lattice of strained Si has a net volume expansion to widen the conduction band edge and valence band edge. The conduction band edge of strained Si is lower than that of relaxed $Si_{1-x}Ge_x$ ($\Delta E_c \sim 6$ meV/%), and the electron confinement is possible in the relaxed $Si_{1-x}Ge_x$/strained-Si structures. The modulation doped devices can thus be made (Section 3.2.3). The bandgap of strained $Si_{1-y}C_y$ on Si is also reduced with respect to Si with the experimental value of 68 meV/% C [30].

There are two effects for carbon incorporation into $Si_{1-x}Ge_x$ on the bandgap:

1. Carbon can change the strain condition of the pseudomorphic film, and this effect on band structure can

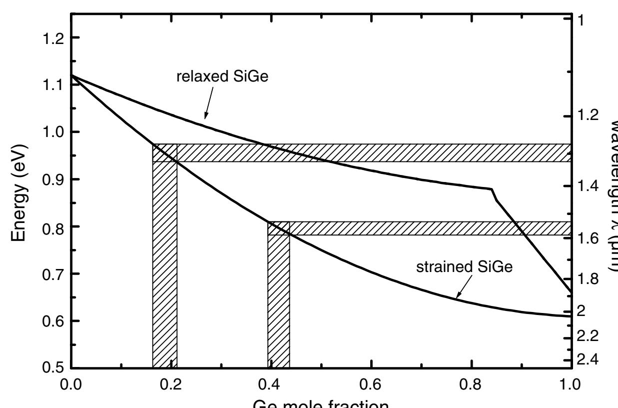

Figure 6. The bandgap of strained $Si_{1-x}Ge_x$ on a (001) Si substrate and relaxed bandgap of $Si_{1-x}Ge_x$ alloys. The shadow areas indicate the optical communication wavelength of 1.3 and 1.5 μm. Reprinted with permission from [16], B.-C. Hsu et al., "International Electron Device Meeting" 2002, pp. 91–94. © 2002, IEEE.

be taken account of in a manner similar to that of Ge incorporation.

2. Carbon also changes the fundamental bandgap [25, 31], and the relaxed $Si_{1-y}C_y$ bandgap decreases with carbon concentration initially because of the local lattice disorder, despite the large bandgap of diamond.

2.4. Mobility

2.4.1. Mobility in Relaxed and Strained $Si_{1-x}Ge_x$ alloys

The theoretical calculation [32] and experimental [33] values of the majority hole mobility in relaxed $Si_{1-x}Ge_x$ alloys are plotted in Figure 7. The decrease in mobility with Ge concentration is due to the alloy scattering, and an alloy scattering potential of 0.7 eV is used in the calculation to fit the measurement data.

Because of the impurity scattering, the mobility depends on the doping concentration. The in-plane and out-of-plane majority hole mobilities in strained $Si_{1-x}Ge_x$ layers for different doping concentrations are shown in Figure 8 [34]. Note that the hole mobilities in n-type material and p-type material are different from the terms of majority hole mobility and minority hole mobility, respectively. So are electron mobilities.

In the calculation, the alloy scattering potential determines the mobility value [37]. The majority hole mobilities in the strained $Si_{1-x}Ge_x$ alloys based on Monte Carlo simulation decrease by a factor of 2–3 if an alloy potential of 1.4 eV is used, as compared with 0.7 eV up to the doping concentration of $10^{19}cm^{-3}$. The hole mobility of strained $Si_{1-x}Ge_x$ calculated by different groups [31, 35, 36] is qualitatively similar. For a doping concentration of $\geq 10^{19}cm^{-3}$, the mobility depends weakly on Ge content, and the alloy scattering is not important. The majority hole mobility is important for the p-channel strained $Si_{1-x}Ge_x$ FET, where the current is made of the majority hole current.

Both in-plane and out-of-plane minority electron mobilities at different doping concentrations are plotted in Figure 9 [37, 38]. The out-of-plane mobility is especially

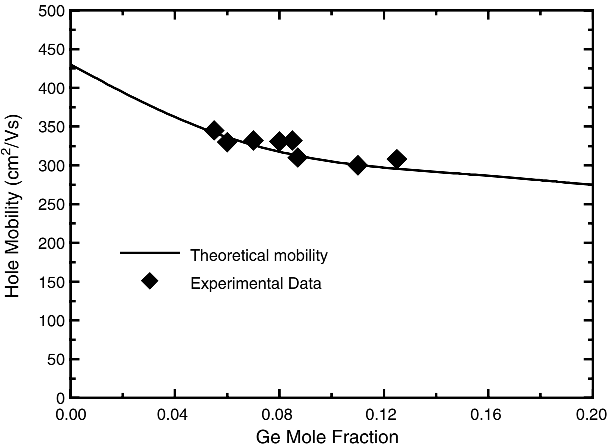

Figure 7. Theoretical values of the hole mobility in relaxed SiGe alloys at 300 K and a doping concentration of $N_A = 10^{16}$ cm^{-3}, with experimental results of Gaworzewski et al. [33].

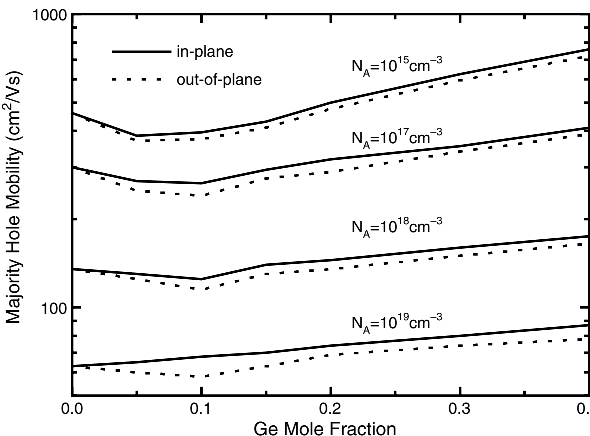

Figure 8. The in-plane and out-of-plane majority hole mobility of SiGe strained alloys for different doping concentrations.

important for npn Si/SiGe heterojunction bipolar transistor applications, where the electron transit time in the base is shortened by the electrical field generated by the graded Ge profiles. In-plane electron mobility decreases with increasing Ge fraction, whereas out-of-plane electron mobility increases with Ge fraction at small Ge content. The out-of-plane mobility is larger than the in-plane mobility.

Klaassen model [39, 40] is commonly used for minority and majority mobility. Klaassen's model takes into account four scattering mechanisms: lattice scattering, ionized impurity scattering, phonon scattering, and carrier-carrier scattering. The last mechanism makes the minority and majority carrier mobilities different.

2.4.2. Mobility in Strained Si

Figure 10 shows the in-plane electron and hole mobilities at 300 K in strained Si, based on [41]. Here the carrier-carrier scattering is neglected, and majority mobility and minority mobilities are the same. For tensile strain (positive strain value), the in-plane electron mobility increases rapidly, and electrons populate the two lower energy Δ valleys along the growth direction. The lower conductivity mass

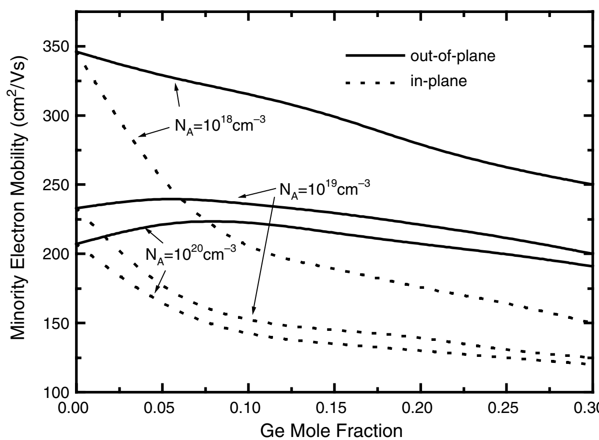

Figure 9. In-plane and out-of-plane minority electron mobilities of SiGe alloys at different doping levels at 300 K.

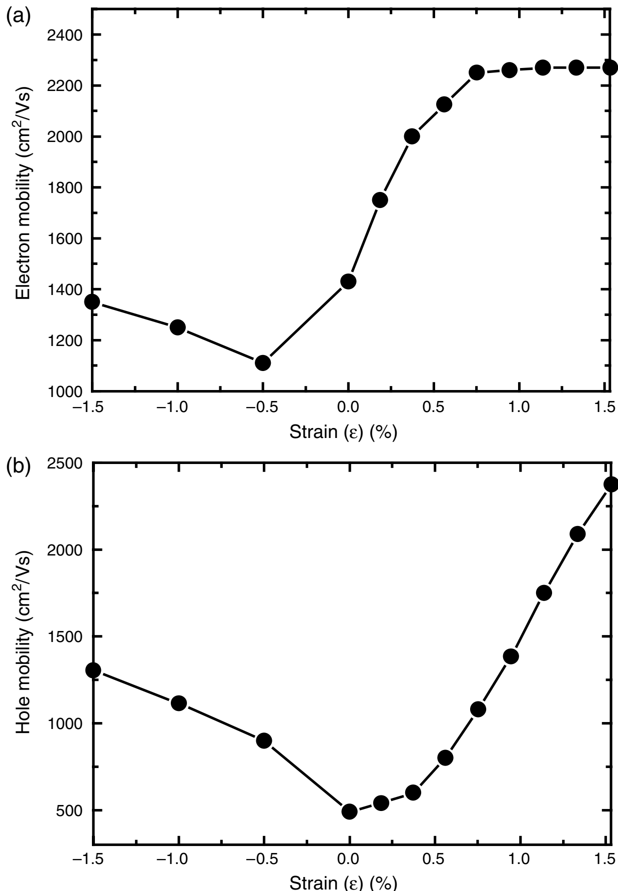

Figure 10. The in-plane (a) electron and (b) hole mobility in strained Si. Reprinted with permission from [70], F. Schafer, *Semicond. Sci. Technol.* 12, 1515 (1997). © 1997, Institute of Physics Publishing.

is the main cause of increased mobility with the help of the small decrease of intervalley scattering (the strong g-type process remains effective). The electron mobility reaches ~2300 cm^2/Vs at a tensile strain of about 0.8% (corresponding to a fully relaxed $Si_{.8}Ge_{.2}$ buffer layer). On the other hand, the out-of-plane mobility in Si with tensile strain drops rapidly with strain, since the conductivity mass is now the large longitudinal mass. However, only the in-plane mobility matters in the field effect device applications.

For the compressively strained Si, the in-plane electron mobility initially decreases with the strain, since electrons mainly populate the four Δ valleys perpendicular to the growth direction with a large effective conductive mass. With the further increase in compressive strain, the separation energy between the twofold degenerate valleys and fourfold degenerate valleys increases, and this reduces the intervalley scattering. The in-plane electron mobility increases again. Note that the out-of-plane electron mobility, controlled by the small transverse mass, remains high.

The hole mobility in strained Si increases for strain of either sign. The principal cause of the enhancement is the split of the degeneracy between the heavy-hole and light-hole bands at the Γ point in the reciprocal space and the reduction of the conductivity mass. For tensile strain, the light hole band has a much higher energy than the heavy-hole band, whereas for compressive strain the splitting of these two bands remains comparable to kT. This results in larger hole mobility in Si with tensile strain.

Tensile strain improves both electron and hole mobilities by reducing the effective transport masses and suppressing intervalley phonon scattering. For the MOSFET applications, the carrier in the inversion layers also suffers the oxide roughness scattering, which decreases the mobility value in the Figure 10. The calculated electron and hole inversion layer mobility enhancements in strained Si are plotted in Figure 11 [42, 43]. The amount of strain in Si is proportional to the Ge content in the relaxed SiGe buffer layer. The electron and hole mobilities are expected to increase with increasing strain and saturate at Ge concentrations of 20% and 40%, respectively, in the buffer layers. The saturation of mobility enhancement is related to the diminishing benefit of strain-induced energy splitting. The suppression of the intervalley scattering by energy splitting increases the mobility, but other scattering mechanisms, such as oxide roughness scattering and other phonon scattering, begin to dominate the low field mobility. At low temperature, there are fewer phonons, and the smaller energy splitting is enough to suppress the intervalley phonon scattering. Therefore, the mobility enhancement saturation is expected at even lower Ge content. Please note that both NMOSFET and PMOSFET can use the strained Si channel to increase the device speed.

2.4.3. Mobility in Strained Ge

Figure 12 shows the in-plane electron and hole mobilities at 300 K in strained Ge [41]. The electron mobility shows a noticeably complicated behavior. For tensile strain, electrons begin to populate the conduction states at the Γ point at strains larger than 1%. Because of the small in-plane effective electron mass in the Γ valley, there is a dramatic enhancement of mobility for strains larger than 1%. For compressive strain, the electrons mainly populate the L valleys at small strain, but the energy separation between

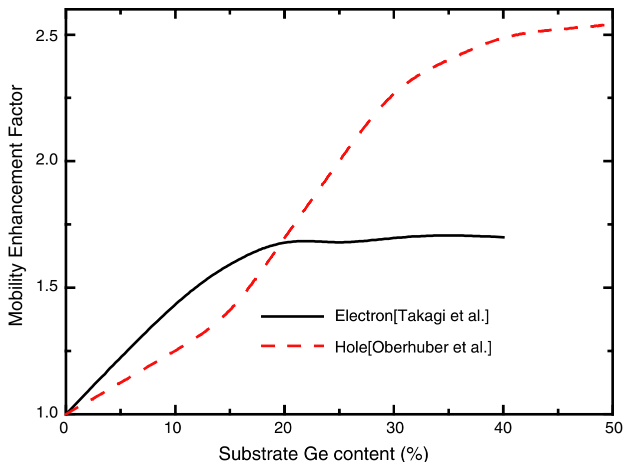

Figure 11. The calculated electron and hole mobility enhancement factor in MOS inversion layers of strained Si.

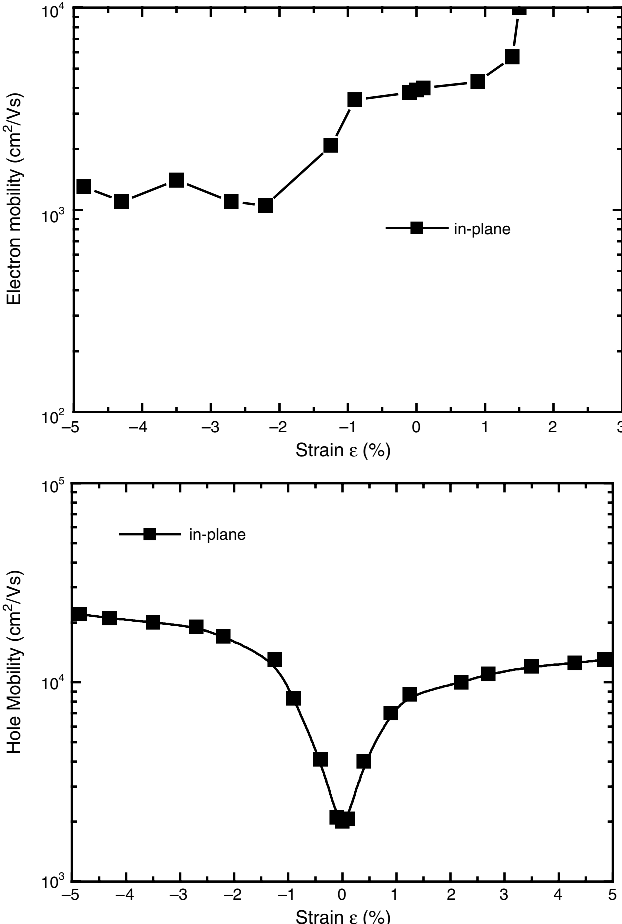

Figure 12. Electron and hole mobility in strained Ge.

L valleys and the four-fold Δ valleys perpendicular to the growth direction shrinks. The resulting larger intervalley scattering causes a lower mobility. At large compressive strain, all electrons stay in the Δ valleys. The mobility now approximates a constant value, nearly equivalent to the Δ valleys' electron mobility in relaxed Ge. In practice, only the compressively strained Ge can be grown. Therefore, there is no advantage to using the Ge channel in the NMOSFET, but it is interesting to note that the Ge with tensile strain can have a direct bandgap.

For in-plane hole mobility, the situation is qualitatively similar to that of strained Si. The compressive Ge has an in-plane hole mobility greater than 2000 cm^2/Vs and is beneficial for the PMOSFET application.

2.5. Relaxed SiGe on an Insulator

To have fully relaxed $Si_{1-x}Ge_x$ grown on Si, the $Si_{1-x}Ge_x$ thickness has to be much larger ($>10x$) than the critical thickness. The growth rate has to be high enough to ensure a reasonable growth time. The growth of films at low temperature takes a long time, but they might also have to be annealed at high temperature after growth to obtain sufficient relaxation.

The misfit and threading dislocations are generated in the relaxed films. All of the problems arise from the thick Si (500–800 μm) substrates. The thin epitaxial $Si_{1-x}Ge_x$ film has to fight with thick substrate to become relaxed with the pay-off of defects. It is unlikely that Si substrates can be thinned down far below 50 μm with mechanical stability. A smart way to effectively grow $Si_{1-x}Ge_x$ on thin Si is to use the silicon-on-insulator (SOI) substrates [44], and the Si can be as thin as 10 nm on the buried oxide (BOX, commonly used insulator). The SOI devices have the extra advantages of high speed, latch-up resistance, and radiation hardening. If the bonding force between Si and BOX can be small compared with Si and $Si_{1-x}Ge_x$, a $Si_{1-x}Ge_x$ thicker than SOI can easily be relaxed without any defect generation, and the thin SOI becomes strained. Several variations have been invented based on the basic idea.

The BOX layer can be created by separation-by-implanted-oxygen (SIMOX) technology after the $Si_{1-x}Ge_x$ layer is grown on conventional bulk Si wafers [45]. The implantation depth can reach Si or $Si_{1-x}Ge_x$. The relaxed films and BOX can be formed after high-temperature (>1100 °C) annealing. To obtain a relaxed $Si_{1-x}Ge_x$ layer with a large Ge fraction, the relaxed films can be further oxidized. The oxidation of $Si_{1-x}Ge_x$ can inject Ge into underlying $Si_{1-x}Ge_x$ films, and the underlying films can have a higher Ge fraction.

Bond-and-etch-back SOI (BESOI) wafers have the advantage of a cleaner silicon/oxide interface at the BOX than SIMOX. Oxidation of the seed and handle wafer, followed by bonding of the two wafers, generates the BESOI. The Si can be thinned down by the combination of CMP (chemical-mechanical polish) and etching to the desired film thickness. The relaxed $Si_{1-x}Ge_x$ can be grown on the BESOI wafers with thin Si (<100 nm) on the BOX.

The hydrogen ions implanted in Si at a sufficient dose (10^{16} to 10^{17} cm^{-2}) can break Si into two pieces after annealing at 400 °C to 600 °C because of the formation of hydrogen molecules (bubbles) in the implanted region. The way to cut Si by hydrogen implantation is called "smart cut." The splitting depth depends on the ion energy, and the splitting temperature depends on the ion dose. The combination of smart cut and wafer bonding can also yield relaxed $Si_{1-x}Ge_x$ with the use of one host wafer with oxide and the other handle wafer with hydrogen-implanted $Si_{1-x}Ge_x$ [46, 47]. Figure 13 shows one of the procedures for the smart-cut and layer transfer process to make strained Si on SiGe-on-insulator (SGOI) material, and Figure 14 is a transmission electron microscopy (TEM) picture of the resulting relaxed $Si_{1-x}Ge_x$ films with strained Si on the top. The as-split SGOI has a surface roughness of 5–12 nm (rms value); therefore a CMP process is needed to smooth the surface of the transferred layer. The relaxation of the $Si_{1-x}Ge_x$ layer is confirmed by X-ray diffraction measurement.

3. DEVICE PERFORMANCES

Advanced BiCMOS technology has fully utilized graded-base SiGe:C heterojunction bipolar transistors, which will dominate the radiofrequency (up to 10 GHz) and optical communication (up to 40 Gbit/s) markets. For mainstream Si technology, to increase the MOSFET speed with the same lithography feature, the strained Si MOSFET will be used in the 90-nm technology node and beyond. $Si_{1-x}Ge_x$ is one of

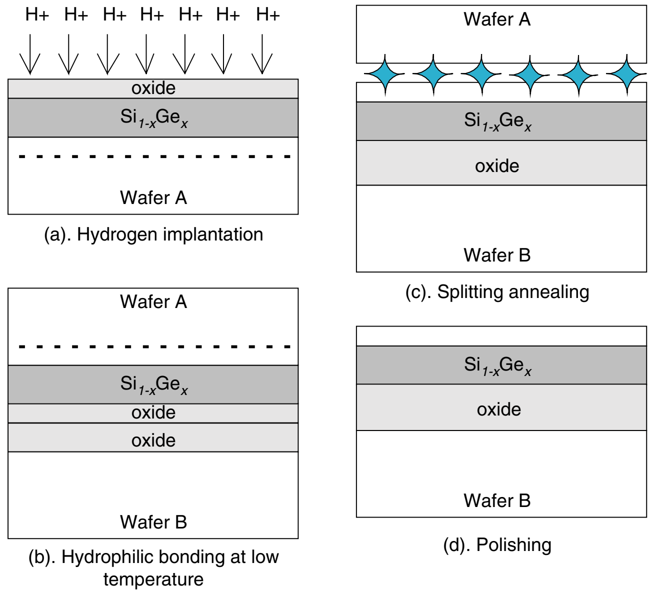

Figure 13. Smart-cut and layer transfer process flow for making strained Si on SiGe-on-insulator material.

the enabling technologies that can make Si prosperous for at least two more decades.

In addition to conventional Si devices, because of the heterostructures of $Si/Si_{1-x}Ge_x$, some III–V device structures, such as modulation doped FET and resonant tunneling diodes, can be made with Si. It is possible that these Si based quantum devices can outperform the original III–V devices.

The bandgap of Si (~1.1 eV) almost makes it impossible to have Si-based devices operating at 1.3-μm, 1.5-μm wavelengths and at the far-infrared region (~10 μm) for opto-electronic and defense applications. However, $Si_{1-x}Ge_x$ with a small bandgap can absorb the light of 1.3 and 1.5 μm, and Ge/Si quantum structures with intraband transition can have far-infrared absorption. For light emission devices, $Si_{1-x}Ge_x$ p-i-n light-emitting diodes are also demonstrated.

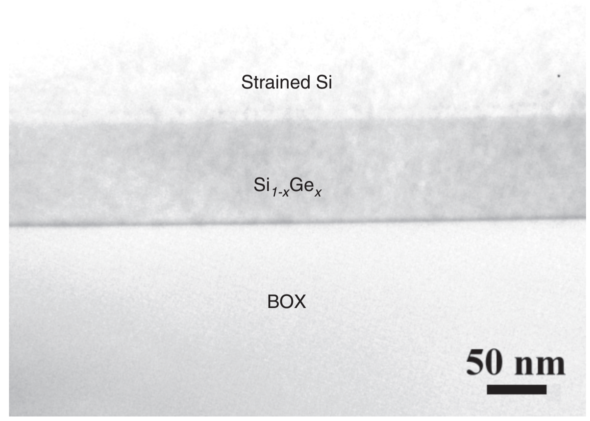

Figure 14. Cross-sectional TEM picture of relaxed SiGe on SOI from the smart-cut method.

3.1. Si/SiGe:C Heterojunction Bipolar Transistors

Since the first Si/SiGe heterojunction bipolar transistor (HBT) was reported in 1988 [48], tremendous progress of Si/SiGe:C HBTs has been achieved, reaching a maximum oscillation frequency of 210 GHz [1] and a cut-off frequency of 285 GHz [2], with circuit applications in wireless and optical communication.

In the NPN bipolar transistor, the collector current is controlled by application of a forward bias V_{BE} to the emitter-base junction [49]. In the forward active region, the base-collector junction is reverse biased by V_{CB}, as shown in Figure 15. More electrons are injected into the base region in HBT than in bipolar junction transistor (BJT) because of the lowering of the potential barrier ΔV_n. Note that the same base doping concentration is assumed in HBT and BJT, and therefore the separation between the Fermi level and the valence band edge is the same for HBT and BJT. This results in an increase in collector current as compared with Si BJT with the same base doping. In other words, to have the same barrier ΔV_n (same collector current), the HBT can have a heavy base doping, which moves the conduction band edge in the base upward. The narrow bandgap of the $Si_{1-x}Ge_x$ base can have a concentration of up to 2×10^{20} cm^{-3} [50], which significantly reduces the base resistance and hence leads to a high maximum oscillation frequency, high Early voltage, and a low noise figure, as compared with Si bipolar junction transistors.

A built-in electric field for electrons in the p-type base region can be obtained with graded $Si_{1-x}Ge_x$ (shown in Fig. 16). The electrical field accelerates the electron motion in the base and thus reduces the base transit time. The cut-off frequency f_t can be enhanced. Many studies [51–56] are focused on the optimal Ge profile of SiGe base HBT′ to minimize the base transit time. The narrow base also reduces the base transit time. However, because of the boron out-diffusion, especially by transient-enhanced diffusion (TED) in the fabrication process, the base width is limited. An ultra-high-speed HBT requires a heavily doped and extremely narrow base. The carbon incorporation in

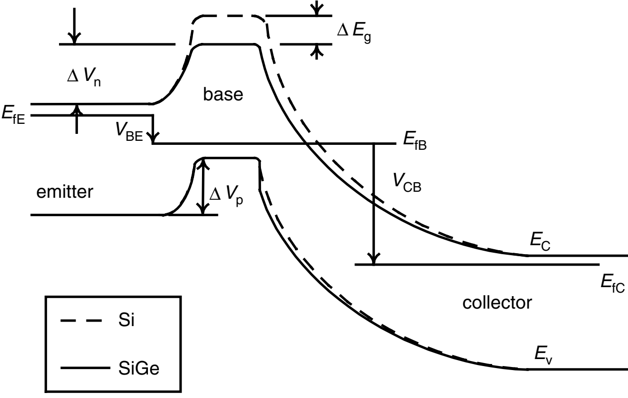

Figure 15. Band diagram of typical SiGe HBT. In the forward active region, the base-emitter junction is forward-biased (V_{BE}) and the base-collector junction reverse-biased (V_{CB}). E_{fC}, E_{fB}, and E_{fC} are the Fermi levels in the emitter, the base, and the collector, respectively.

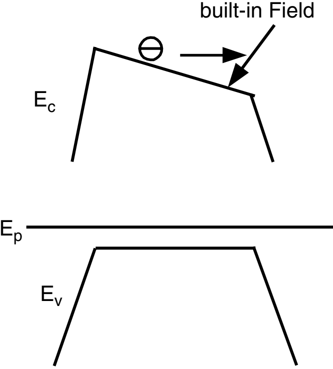

Figure 16. The compositionally graded $Si_{1-x}Ge_x$ can build an electrical field in the base of Si/SiGe HBTs.

the $Si_{1-x}Ge_x$ base can reduce the boron out-diffusion to a narrow base with small base resistance and without the parasitic barrier in the collector. A low concentration of carbon atoms ($\sim< 0.2\% = 10^{20}$ cm^{-3}) is introduced into the base region to effectively suppress the TED of boron [57]. The suppressed boron diffusion found in carbon-doped Si and SiGe is caused by an undersaturation of Si interstitials due to carbon out-diffusion from the base. However, it is reported that the addition of a carbon concentration higher than $\sim$1% can degrade the electron mobility by a factor of 2 [58].

3.2. Field Effect Transistors

3.2.1. N Channel Metal-Oxide-Semiconductor Field Effect Transistors

Very high electron mobilities in strained Si layers suggest a great potential for this material in high-performance N channel metal-oxide-semiconductor field effect transistors NMOSFETs. The low defect density buffers and high quality oxide at low temperature are key technologies for ensuring a mobility advantage in device performance.

The enhancement of effective electron mobility has been reported for long-channel MOSFETs with both surface and buried channels [59]. Figure 17 shows schematic diagrams of these two possible configurations of strained Si channel NMOSFETs [60]. Both structures have relaxed SiGe buffer layers grown on either a graded-Ge layer or SOI. The surface channel device (Fig. 17a) has a single layer of thin strained Si grown on top of a relaxed buffer layer. This layer is oxidized to form gate oxide. The buried strained Si-channel device (Fig. 17b) has a layer of strained Si buried beneath a thin layer of relaxed SiGe. An additional layer of strained Si is necessary to form gate oxide on top of the SiGe, and ideally this additional Si layer should be consumed during oxidation. If it is not, the residual sacrificial Si layer between the gate oxide and the SiGe barrier layer can act as a parallel conducting channel and strongly affects the device performance. Depending on the dopant type in the layers, these structures can also be used for PMOSFETs or NMOSFETs. The long channel ($W = 10\ \mu$m $\times 168\ \mu$m) surface and buried-channel NMOSFET devices fabricated on relaxed $Si_{0.7}Ge_{0.3}$ buffer layers showed well-behaved output characteristics. The effective low-field mobilities for these device structures [60] are shown in Figure 18. For the surface channel strained Si device, the effective mobility is enhanced with a similar dependence on the effective electric field as compared with a bulk-Si control device. The peak mobility value is 1000 cm^2/Vs, which shows 80% enhancement over the Si control device (550 cm^2/Vs). The peak mobility value of the buried channel device is over 1600 cm^2/Vs, which is almost 3 times that of the Si control device, but drops rapidly with increasing effective field. The enhancement of strained Si NMOSFET mobility becomes less significant, if the low Ge content buffer is used [60], since the strained Si mobility increases with increasing strain (more Ge content in the relaxed buffer layer). Note that buried channel devices with deep submicron length suffer from degraded threshold voltage roll-off and subthreshold characteristics.

Recently, IBM [6] has demonstrated current drive enhancements in the strained-Si NMOSFET with sub-100-nm physical gate lengths. Measured effective electron mobility characteristics are shown in Figure 19. For $\sim$1.2% strain (i.e., 28% Ge content in buffer layer), effective electron

mobility at high field was enhanced by 110% over that of the control Si. Note that to obtain a high current drive in extremely small devices (∼30 nm), the saturation velocity, in addition to the mobility, is also important.

3.2.2. P Channel Metal-Oxide-Semiconductor Field Effect Transistors

Strained-Si P channel metal-oxide-semiconductor field effect transistors (PMOSFETs) have been studied [61–67] through the use of high hole mobility. The tensile strain in silicon grown on relaxed SiGe buffer raises the light-hole band and lowers the heavy-hole band. This reduces an intervalley scattering and increases the low field hole mobility significantly. Recently, IBM [6] has demonstrated current drive enhancements in the strained-Si PMOSFET with sub-100-nm physical gate lengths. Measured hole mobility characteristics are shown in Figure 20. For ∼1.2% strain (i.e., 28% Ge content in the buffer layer), peak hole mobility was enhanced by 45% over that of the control Si. The hole

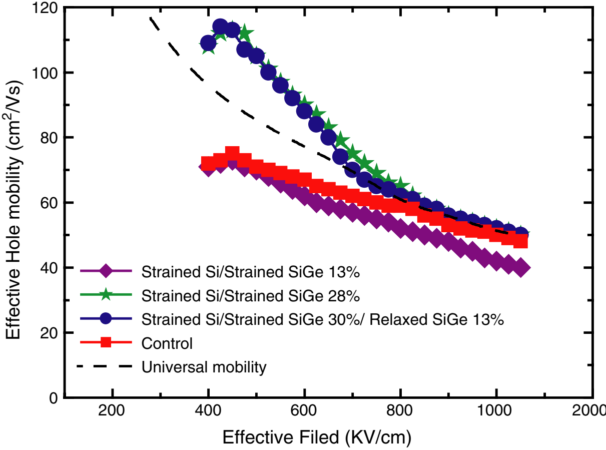

Figure 20. PMOSFET effective mobility versus vertical effective field. Adapted with permission from [6], K. Rim et al., "IEEE Symposium on VLSI Technology Digest, 98," 2002. © 2002, IEEE.

mobility enhancement diminishes at high effective electric field. For lower strain in Si (13% Ge content in buffer layer), hole mobility is slightly degraded compared with the control Si. Since the strained SiGe also has high hole mobility (Fig. 8), it is desirable to use a SiGe channel in the PMOSFETs. With a strained SiGe buried channel below the strained Si in the buried channel device (Fig. 21), the hole mobility has an enhancement comparable to that of the Si surface channel structure with high strain (28% Ge content in the buffer layer). The same strained Si structure suitable for NMOSFETs and PMOSFETs makes it possible to apply strained Si technology in CMOS circuits.

Since the compressively strained Ge has a large hole mobility (Fig. 12), Ge channel PMOSFETs with an effective mobility of 2700 cm^2/Vs have also been reported [5].

3.2.3. Modulation Doped Field Effect Transistors

Carriers can be separated from their parent donor or acceptor atoms for suitable band discontinuity. The impurity scattering can be further reduced if a spacer is inserted between the doped carrier-supply layers and undoped conduction channels. In principle, the modulation doped field effect transistors (MODFET) can have a much higher mobility than the MOSFET because of the lack of impurity scattering. With the band alignment requirement, NMODFETs have to use a strained Si channel on relaxed $Si_{1-x}Ge_x$ [68], whereas PMODFETs have to use strained $Si_{1-x}Ge_x$ on relaxed Si or strained Ge on relaxed $Si_{1-x}Ge_x$ [5, 69]. Figure 22 shows

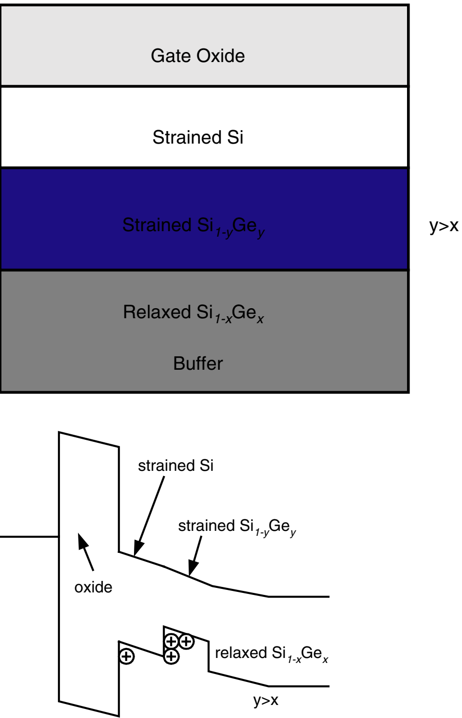

Figure 21. Schematic diagram of a buried strained-SiGe PMOSFET. Most current flow is in the strained SiGe channel. Adapted with permission from [6], K. Rim et al., "IEEE Symposium on VLSI Technology Digest, 98," 2002. © 2002, IEEE.

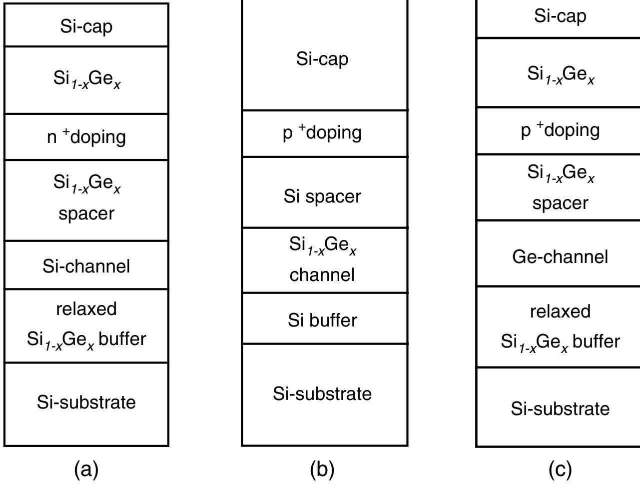

Figure 22. Typical MODFET structures. (a) NMODFETs with Si-channel on relaxed-SiGe buffer. (b) PMODFET with SiGe channel and (c) PMODFET with Ge channel on relaxed-SiGe buffer. Note that the doping layers and spacers can be located below the bottom of the channels (after [70]).

these three possible MODFET structures [70]. As in MOSFETs, the large defect density of these structures can seriously degrade the device performance.

An electron mobility up to 2700 cm^2/Vs at 300 K for a sheet carrier density of 7×10^{12} cm^{-2} in a strained Si channel NMODFET is reported [71], and a hole mobility of 1880 cm^2/Vs at 300 K for a sheet carrier density of 2.1×10^{12} cm^{-2} has been obtained with a pure Ge channel layer on a relaxed $Si_{0.4}Ge_{0.6}$ buffer [71]. All of the available data on effective electron and hole mobilities for MODFET are shown in Figure 23 [71–75]. From a comparison of Figure 19 and 23, it is evident the MODFETs have larger enhancement than MOSFETs.

3.3. Optoelectronic Devices

In the last decade, interest in silicon-based optoelectronic devices has grown rapidly [76]. The trend of optoelectronics is to integrate both high-performance optoelectronic and electrical devices on the same chips with silicon processing technology. Among silicon-integrable materials, Ge and SiGe are of great importance to the fabrication of optoelectronic devices because of their optical absorption wavelengths.

Many SiGe/Si devices operated in the 1.3–1.5 μm wavelength range have been reported and demonstrated [77–78]. In this section, we discuss Si/SiGe photodetectors, light-emitting diodes, and heterojunction phototransistors.

3.3.1. Absorption of SiGe

Because of the large absorption length ($\sim$16μm) of Si at 820 nm [79] and the forbidden absorption at 1300 and 1550 nm, Si-based photodetectors have limited detection efficiency and wavelength range. Not only can the incorporation of Ge into Si increase the cutoff wavelength (Fig. 6); it can also enhance the absorption efficiency (small absorption length). The strained Ge could have an absorption length of 0.1 μm or less at a wavelength of 820 nm. Figure 24 shows the absorption length at 820, 1300, and 1550 nm versus Ge mole fraction. The absorption length decreases as the Ge mole fraction increases. For the large Ge fraction, the shadowed areas indicate the uncertainty of the estimation. The incorporation of strained Ge/SiGe into optoelectronic devices makes devices particularly useful over the important fiber optic communications wavelengths.

3.3.2. Photodetectors

The figures of merit for light detection are high efficiency, high responsivity, low noise, low dark currents, and fast response. Previous studies have focused on metal-semiconductor-metal (MSM) diodes and p-i-n diodes.

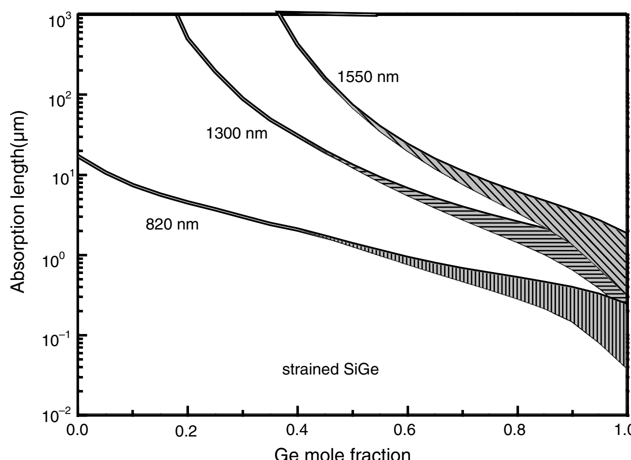

Figure 24. The absorption length at 820, 1300, and 1550 nm versus Ge mole fraction. The absorption length decreases as the Ge mole fraction increases. For the large Ge fraction, the shadowed areas indicate the uncertainty of the estimation. Reprinted with permission from [16], B.-C. Hsu et al., "International Electron Device Meeting," 2002, pp. 91–94. © 2002, IEEE.

In 1992, a metal-semiconductor-metal (MSM) diodes was reported by Splett et al. [80]. The measured responsivity at 1.3 μm is 0.2 A/W over a 1-mm detector length with 500 pA/μm^2 dark current at 5-V bias. In 1996, Huang et al. reported an epitaxial SiGeC/Si photodetector with a response in the 1.3–1.55-μm wavelength range [77]. The active absorption layer of the p-i-n photodiode consists of a pseudomorphic SiGeC alloy grown on a Si substrate with a Ge content of 55% and a thickness of 80 nm. In 2001, a p-i-n Ge on Si photodetector was reported by Masini et al. [78]. The photodiodes exhibit short-circuit responsivities of 0.3 and 0.2 A/W at 1.3 and 1.55 μm, respectively, reverse dark currents of 20 mA/cm^2, and response times of 800 ps.

In 1999, photodetectors and light-emitting diodes for 1.1-μm wavelength have been demonstrated with metal-oxide-silicon (MOS) tunneling structures on both n-type and p-type silicon substrates [81–84]. The ultrathin thickness ($<$3 nm) of thermal oxide is required in these novel photodetectors to provide sufficiently large tunneling probability. As biased in inversion region, the tunneling diode works in the deep depletion region with the soft pinning of oxide voltage, instead of pinning of surface potential, which is very different from the conventional MOS diode with thick oxide. The Ge MOS detector can operate at 1.3 and 1.55 μm with high responsivity [85]. To avoid material degradation such as strain relaxation and Ge out-diffusion, low-temperature liquid phase deposition (LPD) oxide is introduced [86].

A MOS Ge quantum dot photodetector is demonstrated [16]. The photodetector has responsivities of 130, 0.16, and 0.08 mA/W at detection wavelengths of 820 nm, 1300 nm, and 1550 nm, respectively. The dark current is extremely low (0.06 mA/cm^2). Si/Ge quantum dots are prepared by ultra-high-vacuum chemical vapor deposition (UHVCVD) on p-type Si (001) substrates. The structure is shown in Figure 25. With the careful design of intraband transition, the long-wavelength infrared (6–10 μm) can also be detected with the same devices.

3.3.3. Light-Emitting Diodes

Two different Si light emitters have been reported. A narrow-band infrared emitter at 1160 nm was implemented with a pn junction under forward bias with an external quantum efficiency of $\sim 10^{-4}$ [87]. A broad-band (450–850 nm) visible-light emitter was also realized with an avalanche pn diode with an external quantum efficiency of $\sim 10^{-8}$ [87] and $\sim 10^{-6}$ [88]. Recently, the band-edge (1.1 μm) electroluminescence (EL) of a MOS tunneling light-emitting diode has also been reported [83]. Because of the indirect bandgap of Si, additional momentum is required for the light emission process. The phonon provides the additional momentum in bulk Si and bulk SiGe [89]. In the MOS structure, the interface/surface roughness can seriously affect the carrier transport in the inversion layer [90]. This indicates that the interface/surface roughness can scatter the carrier and can change the carrier momentum. Therefore, the rough oxide can enhance the emission efficiency of MOS light emitting diodes [91].

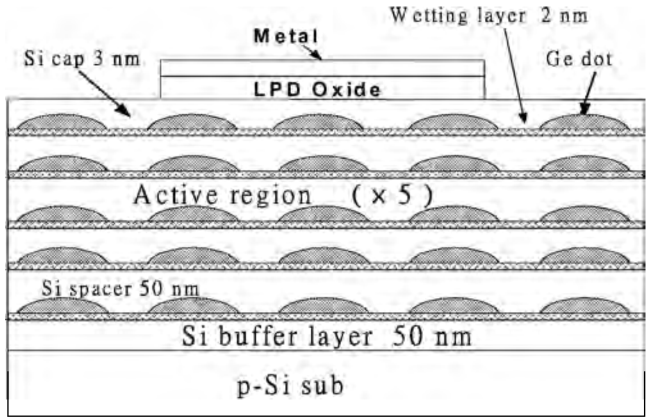

Figure 25. The MOS detector structure with five layers of Ge quantum dots.

The addition of $Si_{1-x}Ge_x$ to p-i-n diodes can increase the emission wavelength. Both 1.3-μm [18] and 1.5-μm [19] emissions with $Si_{1-x}Ge_x$/Si quantum wells and Ge/Si quantum dots, respectively, are demonstrated at room temperature, and erbium-doped $Si_{1-x}Ge_x$ can also have 1.5-μm emission [92]. However, MOS diodes with $Si_{1-x}Ge_x$ or Ge quantum dots are not reported to have long-wavelength emission so far.

3.3.4. Heterojunction Phototransistors

With high gain and low noise, the phototransistor can be used in the front end of an optical receiver. The $Si_{1-x}Ge_x$/Si multiple quantum well heterojunction phototransistor with an ultrahigh responsivity of 1.47 A/W and a bandwidth of $>$1.25 GHz at a wavelength of 850 nm has been reported at an operation voltage as low as $\leq$1.5 V [13]. The responsivity at 1310 nm is 0.15 A/W. The multiple quantum wells in the collectors can enhance the photon absorption and increase the cutoff wavelength. The current gain of the transistors can further amplify the optical current. Si/$Si_{1-x}Ge_x$ quantum well phototransistors with far-infrared (6–20 μm) response with low leakage current and high gain were also proposed [93].

4. FABRICATION TECHNOLOGIES

4.1. Growth of $Si_{1-x}Ge_x$ Films

$Si_{1-x}Ge_x$ can be epitaxially grown by chemical vapor deposition (CVD) and molecular beam epitaxy (MBE). Depending on the growth pressures, CVD has some variations: APCVD (atmospheric pressure), rapid thermal CVD (RTCVD, several torr with lamp heating), low-pressure CVD (LPCVD, several tenths of a torr), and ultrahigh vacuum pressure CVD (UHV/CVD). UHV/CVD [94] has a growth pressure of 10^{-2} to 10^{-3} torr and a base pressure of UHV ($\sim 10^{-9}$ torr). The designation UHV is sometimes confusing and only indicates the base pressure of the reactor chamber, not the growth pressure. The wafer temperature can be obtained by lamp heating or thermal equilibrium furnaces. For lamp heating, the wafer temperature can rise and fall very rapidly (on the order of 10 s), and is often called "rapid thermal CVD" [95]. The chamber used for RTCVD is often made of quartz to avoid contamination during growth. The quartz chamber does not absorb as much emission from the lamps

as Si wafers. A cold-wall RTCVD can be obtained, whereas a quartz tube with hot walls is used in the furnace-type reactor, such as that used for UHV/CVD. Because of the configuration of heating lamps, RTCVD can process only a single wafer at a time, whereas a furnace-type reactor such as that used for UHV/CVD can process a batch of wafers (more than 20 wafers). Silane (SiH_4) and dichlorosilane (DCS) are the common precursors of Si, and germane (GeH_4) is the precursor of Ge. Phosphine (PH_3) is used for n-type doping, and diborane (B_2H_6) is for p-type doping. Both RTCVD and UHV/CVD are used in semiconductor manufacturing laboratories as well as research laboratories.

MBE is a physical deposition system with a stainless chamber. The base pressure and growth pressure are about 10^{-11} and 10^{-9} torr, respectively. The electron beams are used to heat source materials such as Si and Ge, and the Si and Ge atoms are evaporated on Si substrates. The chamber is cold and substrates are heated by a local heater. Because of the difficulty of using large-diameter wafers and some process issues, MBE is used in research laboratories, and HBTs with ideal base currents are grown by MBE [96] after CVD.

4.2. Metal Contacts

As the microelectronics industry moves into the era of deep submicron devices, metallization has become the main performance-limiting factor. Metal silicides have been widely used to reduce the contact resistance of the source/drain of microelectronic devices. The self-aligned silicidation technique has become a crucial part of recent ultra-high-speed silicon device technologies [97]. $TiSi_2$ is currently the most commonly used silicide in the IC industry. In the deep submicron regime, a linewidth dependence of sheet resistance was observed for $TiSi_2$ [98, 99]. $CoSi_2$ has been introduced to replace $TiSi_2$ in sub-quarter-micron technology. However, its use in sub-0.1-micron devices is in doubt unless a raised source/drain scheme becomes feasible. NiSi is the only silicide left with resistivity comparable to that of $TiSi_2$ and $CoSi_2$. On the other hand, intensive efforts have been made to extend IC devices to other substrate frames, such as Si-Ge. Metal germanosilicide/$Si_{1-x}Ge_x$/Si heterostructures are promising for use in devices such as the heterojunction bipolar transistor and infrared detectors with high cutoff wavelengths [100, 101].

Metal germanosilicides may be used for making metallic contacts with $Si_{1-x}Ge_x$ alloys, and knowledge about the formation and stability of thin metal germanosilicide films is essential for such applications. The thermally induced metal/$Si_{1-x}Ge_x$ reaction has previously been studied for many metals. Various degrees of germanium segregation and/or the formation of segregated layered structures were observed in the reactions of these metal/$Si_{1-x}Ge_x$ systems. The difference in heats of formation of silicide and germanide offers the driving force for the segregation of Ge-rich Si-Ge alloy [102]. The phase formation paths were found to depend strongly on the composition of substrates. By extension from silicon to Si-Ge devices, the contact materials considered for Si-Ge devices have been focused on Ti, Co, and Ni contacts.

4.2.1. Co/Si-Ge System

Direct deposition of metal thin films on $Si_{1-x}Ge_x$ in a self-aligned silicide process would be an efficient technique and would take advantage of established technologies. However, the major difficulties in using Co as a contact material for $Si_{1-x}Ge_x$ appear to be the preferential reaction of Co with Si and the high consumption ratio of the Si to Co to form $CoSi_2$. The undesirable characteristics lead to Ge segregation, deterioration of the $Si_{1-x}Ge_x$ layer, degradation of junction integrity, and film agglomeration at low temperatures, resulting in poor thermal stability and high-resistivity contacts [103–105]. In addition, it has been demonstrated that $CoSi_2$ is formed at much higher temperatures on a $Si_{1-x}Ge_x$ layer than that on Si, owing to Ge expelled from the Co-Si-Ge compound, which blocks the Co diffusion paths, slowing down the reaction [106–108]. Successful formation of good quality $CoSi_2$ on epitaxial $Si_{0.7}Ge_{0.3}$ in the presence of a sacrificial a-Si layer has been achieved. $CoSi_2$ was previously found to form at a lower temperature on a-Si with a smoother interface than that on single-crystal Si [109].

For convenience, the two sets of samples Co(15 nm)/$Si_{0.7}Ge_{0.3}$ and Co(15 nm)/a-Si(50 nm)/$Si_{0.7}Ge_{0.3}$ are designated as samples A and B, respectively. Five hundred-nanometer-thick $Si_{0.7}Ge_{0.3}$ and 1-μm-thick strained layers of Si_yGe_{1-y} (y varies from 1 to 0.7) were grown on (001)Si wafers at 550 °C by MBE. A 50-nm-thick sacrificial a-Si layer was deposited on a $Si_{0.7}Ge_{0.3}$ substrate followed by the deposition of a 15-nm-thick Co thin film without breaking the vacuum at room temperature. Figure 26 shows the sheet resistance data of the two sets of samples after different heat treatments. For samples annealed at 600 °C, the sheet resistance of samples B is much lower than that of samples A. The low resistance is attributed to the early formation of low-resistivity $CoSi_2$, which is consistent with the X-ray diffraction data. In contrast, $CoSi_2$ was not detected in samples A annealed at a temperature as high as 800 °C. The further substantial increase in sheet resistance for Co(15 nm)/$Si_{0.7}Ge_{0.3}$ samples after 800 °C annealing,

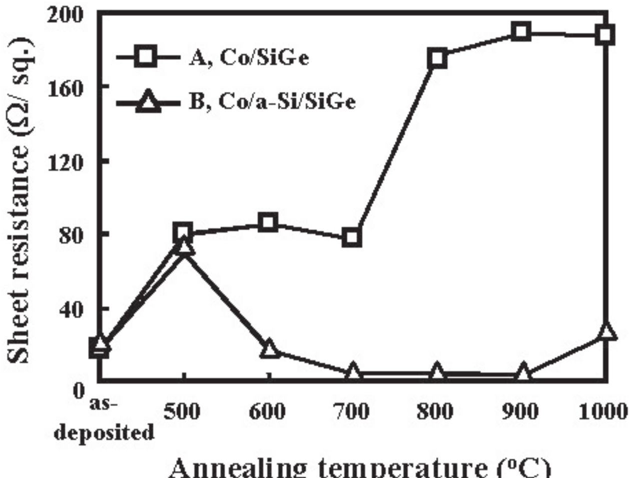

Figure 26. Sheet resistance versus annealing temperature curves for samples A and B after annealing at 500–1000 °C for 30 s by RTA. Reprinted with permission from [109], W. W. Wu et al., *Appl. Phys. Lett.* 81, 820 (2002). © 2002, American Institute of Physics.

as shown in Figure 26, is correlated to the agglomeration of $Co(Si_{1-x}Ge_x)$. Figure 27 is a plane-view TEM micrograph showing the formation of $Co(Si_{1-x}Ge_x)$ islands in a Co(15 nm)/$Si_{0.7}Ge_{0.3}$ sample annealed at 800 °C. On the other hand, for the Co(15 nm)/a-Si(50 nm)/$Si_{0.7}Ge_{0.3}$ samples, the formation of $CoSi_2$ was completed after 700 °C annealing. The sheet resistance maintained the same low level for samples B after annealing at 700–900 °C. In 900 °C annealed samples, the silicide films were found to be continuous with the smooth interface with $Si_{0.7}Ge_{0.3}$, as revealed by plane-view TEM and XTEM images shown in Figure 28. No Ge segregation was detected from the analysis of TEM direct images and electron diffraction patterns. In contrast with samples B, rough interface and Ge segregation in samples A are evident. An example is shown in Figure 29.

Previous study showed that the retardation of the silicidation process on $Si_{1-x}Ge_x$ is related to a higher effective Ge concentration at the reaction front, therefore causing an increase in the interface energy. The expelled and segregated Ge tends to diffuse to the surface and interface of the silicide layer [104, 105]. These Ge atoms can decorate the grain boundaries, resulting in an increase in the grain boundary energy, which makes the silicide film more prone to agglomeration. On the other hand, the sacrificial a-Si layer is shown to improve the interfacial roughness and thermal stability of a $CoSi_2$ film grown on $Si_{0.7}Ge_{0.3}$. The increased uniformity of the silicide/$Si_{0.7}Ge_{0.3}$ interface is speculated to result from small-grained $CoSi_2$. The average grain size is smaller for silicides formed on a-Si than that on single-crystal Si and poly-Si in samples subjected to the same heat treatment [110]. The results indicated that the reaction between Co thin films and a-Si incurs the formation of small-grained $CoSi_2$, which in turn enhances the morphological stability of $CoSi_2$. In addition, the formation of thermally stable $CoSi_2$ leads to a low sheet resistance value.

4.2.2. Ti/Si-Ge System

Titanium disilicide has been widely used for contacts to Si in microelectronics devices. Its use is complicated by the existence of two crystalline phases. The high-resistivity C49-$TiSi_2$ forms first on heating of Ti on Si above 500 °C, and additional heating above 700 °C is needed to transform C49 into the low-resistivity C54-$TiSi_2$. However, in the Ti/$Si_{1-x}Ge_x$ system, Ge segregation was observed near the C54 phase formation temperature [111]. In addition, the resistivity of C54-$Ti(Si_{1-z}Ge_z)_2$ forms on $Si_{1-x}Ge_x$ layer is higher than that of C54-$TiSi_2$. The appearance and agglomeration temperature of low-resistivity C54-$Ti(Si_{1-z}Ge_z)_2$ were both found to decrease with the Ge concentration [111].

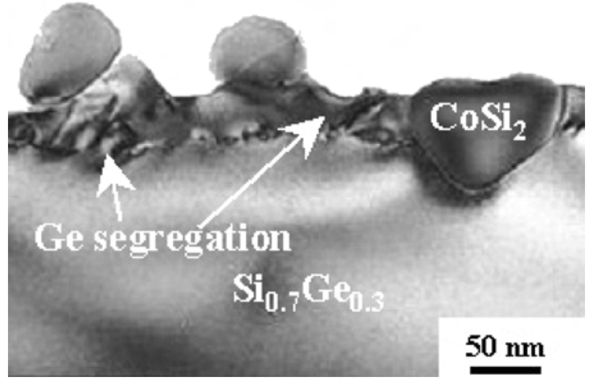

Figure 29. Cross-sectional TEM image of Co(15 nm)/$Si_{0.7}Ge_{0.3}$ samples after annealing at 900 °C for 30 s by RTA.

An amorphous Si was also successfully used to decrease the formation temperature of low-resistivity C54-$TiSi_2$ and alleviate the formation of islands as well as the segregation of Ge. For the Ti/a-Si/$Si_{1-x}Ge_x$ system, the thicknesses of Ti and amorphous Si were selected to be 15 and 30 nm, respectively. Figure 30 shows an XTEM image of a Ti/$Si_{0.7}Ge_{0.3}$ sample annealed at 900 °C, revealing the formation of C54-$Ti(Si_{1-z}Ge_z)_2$ islands and Ge segregation. An amorphous Si was used to alleviate the formation of islands as well as the segregation of Ge. The selection of the thickness ratio of Ti and a-Si was such that the a-Si was completely consumed in forming C54-$TiSi_2$. If the a-Si was too thin, Ti would start to react with the $Si_{1-x}Ge_x$ layer and accompanying problems in forming higher-resistivity $Ti(Si_{1-x}Ge_x)$ compound became troublesome [102]. Ge segregation [111], a rough interface [112], and strain relaxation of the $Si_{1-x}Ge_x$ layer are expected to occur [113].

GIXRD spectra of Ti(15 nm)/a-Si(30 nm)/$Si_{0.7}Ge_{0.3}$ samples revealed that low-resistivity C54-$TiSi_2$ was the dominant silicide phase above 650 °C. The formation temperature of C54-$TiSi_2$ was lowered by about 100 °C in samples with a sacrificial a-Si interlayer compared with that of the Ti/$Si_{0.7}Ge_{0.3}$ system [111]. Figure 31 shows the resistivity curves of the Ti(30)nm/$Si_{0.7}Ge_{0.3}$ and Ti(15 nm)/a-Si(30 nm)/$Si_{0.7}Ge_{0.3}$ samples (samples A and B) after annealing at different temperatures. For samples annealed at 700 °C, the resistivity of samples B is 23 much lower than that of samples A. It resulted from the formation of low-resistivity C54-$TiSi_2$ at low temperature. On the other hand, for samples A, as the annealing temperature was increased to 800 °C, a sharp drop in resistivity occurred. In samples B, the temperature range of low-resistivity C54-$TiSi_2$ was extended to 700–900 °C. From both resistivity and TEM data, it was concluded that the resistivity of C54-$TiSi_2$ in samples B is lower than that of C54-$Ti(Si_{1-z}Ge_z)_2$ in samples A. The magnitude of such differences will be affected by the homogeneity of the microstructures and will depend specifically upon the grain size [110]. On the other hand, with higher solute concentration, the electronic structure or phonon spectrum of the alloy will start to suffer from perturbation, and then the resistivity is expected to increase. For Ti(15 nm)/a-Si(30 nm)/$Si_{0.7}Ge_{0.3}$ samples, the a-Si was completely consumed in forming C54-$TiSi_2$, and the phase possesses lower resistivity than ternary C54-$Ti(Si_{1-z}Ge_z)_2$ phase. In addition, no Ge segregation was detected. The silicide films were also found to be continuous with the smooth interface with $Si_{0.7}Ge_{0.3}$, as shown in Figure 32. As a result, a sacrificial a-Si layer was found to decrease the formation temperature of C54-$TiSi_2$, prevent Ge segregation, lower the resistivity of silicide, and improve the morphological stability of C54-$TiSi_2$ on the $Si_{0.7}Ge_{0.3}$ layer. If the a-Si was too thin, Ti would react with the $Si_{0.7}Ge_{0.3}$ layer significantly and result in a rough interface.

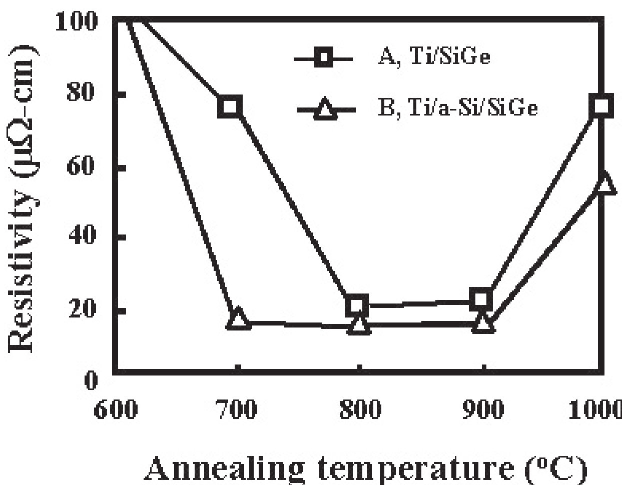

Figure 31. Resistivity versus annealing temperature curves for samples A and B after annealing at 500–1000 °C for 30 s by RTA.

4.2.3. Ni/Si-Ge System

Low-resistivity NiSi is currently one of the most promising silicides to replace $TiSi_2$ for the self-aligned technology of ULSI, owing to its favorable properties low resistivity, low silicon consumption, low processing temperature, and relative insensitivity to the linewidth of the silicide.

For the Ni/$Si_{0.7}Ge_{0.3}$ system, Ge tended to be less reactive with Ni than with of Si. Moreover, Ge was found to segregate to grain boundaries in 600 °C annealed samples, and $Ni(Si_{0.9}Ge_{0.1})$ islands were found to form in 700 °C annealed samples. In the XTEM image observation, the Ge segregation toward the grain boundary was evident. An example is shown in Figure 33. $Ni(Si_{0.9}Ge_{0.1})$ islands were observed to form in 700 °C annealed samples [114].

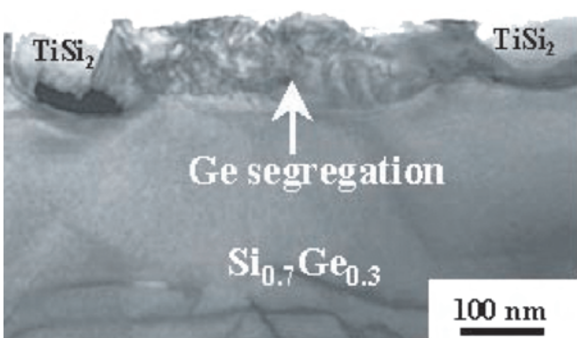

Figure 30. Cross-sectional TEM image of Ti(30 nm)/$Si_{0.7}Ge_{0.3}$ samples after annealing at 900 °C for 30 s by RTA.

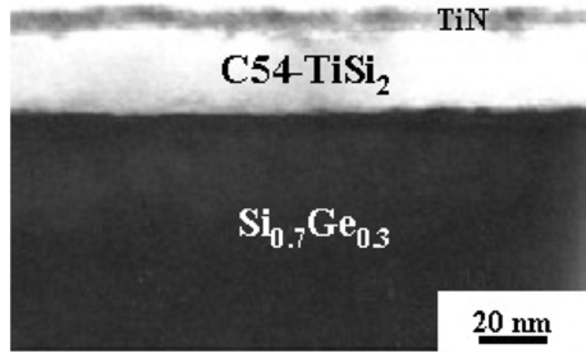

Figure 32. Cross-sectional TEM image of Ti(15 nm)/a-Si(30 nm)/$Si_{0.7}Ge_{0.3}$ samples after annealing at 900 °C for 30 s by RTA.

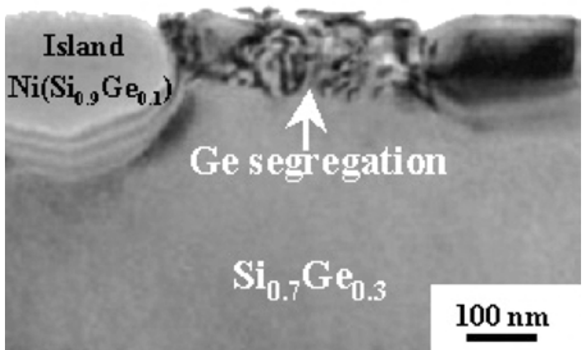

Figure 33. Cross-sectional TEM image of a Ni(30 nm)/$Si_{0.7}Ge_{0.3}$ sample after annealing at 700 °C for 30 s by RTA.

The scheme of an interposing a-Si layer was also attempted to overcome the detrimental effects of Ge segregation as well as island formation in Ni/Si-Ge systems. The thicknesses of Ni and amorphous Si were selected to be 15 and 27 nm, respectively. GIXRD spectra for Ni(15 nm)/a-Si(27 nm)/$Si_{0.7}Ge_{0.3}$ samples annealed at 300–700 °C indicated that low-resistivity NiSi was the only phase present in all samples annealed above 500 °C.

Figure 34 shows the sheet resistance data for Ni(30 nm)/$Si_{0.7}Ge_{0.3}$ and Ni(15 nm)/a-Si(27 nm)/$Si_{0.7}Ge_{0.3}$ samples (samples C and D). After annealing at 400 °C, low-resistivity NiSi phase was formed in both sets of samples. The apparent increase in sheet resistance for Ni(30 nm)/$Si_{0.7}Ge_{0.3}$ samples after annealing at 700 °C results from the formation of the island structure of $Ni(Si_{0.9}Ge_{0.1})$. On the other hand, even after annealing at 800 °C, the sheet resistance remained at the same low level for the Ni(15 nm)/a-Si(27 nm)/$Si_{0.7}Ge_{0.3}$ samples. Furthermore, the sacrificial a-Si layer was also seen to improve the interface roughness and thermal stability of NiSi film grown on $Si_{0.7}Ge_{0.3}$ from XTEM micrographs. In addition, no Ge segregation was observed. An example is shown in Figure 35. In the Ni thin films on the Si system,

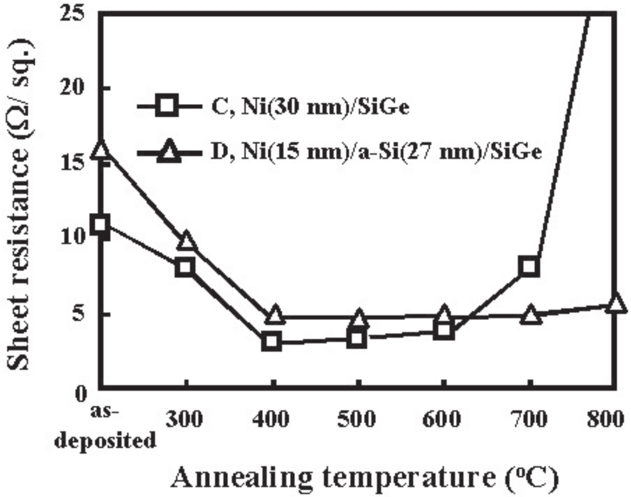

Figure 34. Sheet resistance versus annealing temperature curves for Ni(30 nm)/$Si_{0.7}Ge_{0.3}$ and Ni(15 nm)/a-Si(27 nm)/$Si_{0.7}Ge_{0.3}$ samples after annealing at 300–800 °C for 30 s by RTA.

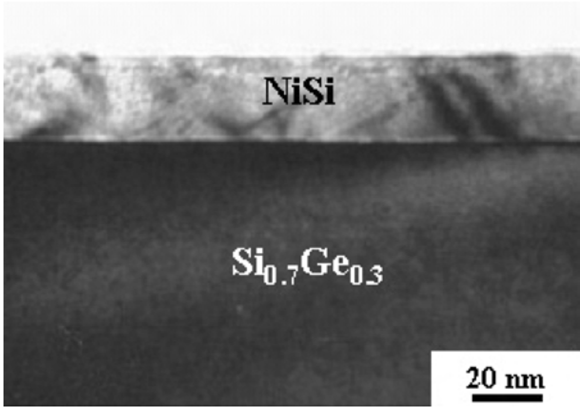

Figure 35. Cross-sectional TEM image of Ni(15 nm)/a-Si(27 nm)/$Si_{0.7}Ge_{0.3}$ samples after annealing at 800 °C for 30 s by RTA.

$NiSi_2$ is normally formed at 750 °C. The extraordinary stability of NiSi on $Si_{0.7}Ge_{0.3}$ with a sacrificial a-Si layer is likely due to the high consumption ratio of the Si to Ni to form $NiSi_2$, which requires the excess Ni atoms to react directly with the $Si_{1-x}Ge_x$ layer. Ge was then expelled from the Ni-Si-Ge compound and slowed down the reaction. The blocking of Ni diffusion paths by Ge atoms may also slow down the reaction and result in a delay of the formation of $NiSi_2$. The mechanism is similar to that of the formation of $CoSi_2$ on a $Si_{1-x}Ge_x$ layer. In contrast, if the a-Si is too thin, as in Ni(15 nm)/a-Si(22 nm)/$Si_{0.7}Ge_{0.3}$ samples, a rough interface is formed. The results indicate that a sacrificial a-Si layer with appropriate thickness works beneficially for Ni contacts on Si-Ge.

GLOSSARY

Chemical-mechanical polish (CMP) A chemical-mechanical method utilized to eliminate the surface roughness of a sample. This method is commonly used in ULSI processes.

Chemical vapor deposition (CVD) A method utilizing chemical gas to deposit film on substrates.

Dislocation A kind of line defect due to the lattice misfit between SiGe and Si. There are two segments. The segment parallel to the Si/SiGe interface is called "misfit dislocation," and the segment propagating to the surface is called "threading dislocation."

Heterojunction bipolar transistors (HBT) The narrow bandgap base in the bipolar transistor to enhance the device performance.

Metal germanosilicide A compound of metal, Si and Ge.

Strained Si-on-SiGe-on-insulator (SGOI) Introducing strained Si to the silicon-on-insulator (SOI) technology, which provides high-performance CMOS circuits due to combination of carrier mobility enhancement in strained Si with the advantage of SOI device/circuit.

Silicidation process The process used to form silicide.

Strained Si FET Strained Si field effect transistors. The tensile strained Si has higher carrier mobility than conventional Si. The new type of device can give larger current drive in VLSI circuits.

Universal mobility The carrier mobility in the field effect transistor depending only on effective transverse electrical field regardless of the doping concentration of the channel.

ACKNOWLEDGMENTS

The help of S. T. Chang (Department of Electrical Engineering, National Taiwan University, Taiwan) and W. W. Wu (Department of Materials Science and Engineering, National Tsing Hua University, Taiwan) in manuscript preparation are gratefully appreciated. The work on the composite quantum dots by Dr. P. S. Chen, ERSO/ITRI, Taiwan, is highly appreciated.

1. INTRODUCTION

Semiconductor nanocrystals, also called quantum dots (QD), show interesting properties, which are very different from those of the corresponding bulk materials. Their electronic structure is determined by the size and the chemical environment of the nanocrystals. The electronic structure is composed of discrete energy levels into the conduction and valence band of the bulk material. By decreasing the size of the nanocrystals, these confined states are shifted to higher values, and the electronic bandgap of the material increases. The atoms occupying the chemical bonds around a nanocrystal play an important role in the determination of the effective bandgap, by introducing interface states below the conduction band minimum or above the valence band maximum of the silicon nanocrystal. So, there is significant difference in the macroscopic properties of the QDs when their chemical environment changes.

Another interesting property of semiconductor QDs is that of the controlled charging, due to the Coulomb blockade effect. When one single charge is injected into a QD, it will occupy a confined state in the nanocrystal. The energy needed to inject a single charge into the QD is the confinement energy. The presence of one charge in the nanocrystal modifies the electrostatic potential within it, so that injection of a second charge needs to overcome the semiconductor charging energy. This means that under the same electric field, there is blockade of the injection of the next charge.

In this paper, we consider the case of silicon nanocrystal layers embedded in an SiO_2 matrix for application in memory devices or in light emission. Silicon dioxide is the dielectric used in current microelectronics technology both as a gate dielectric and as an isolation layer in different process steps. The use of this material as an insulating matrix of the QDs for the mentioned applications, offers important advantages, which concern not only the compatibility with silicon integrated circuit (IC) processing but also the advantage of a high-quality dielectric material with a high electronic quality interface to silicon, showing reduced interface states.

For memory devices, the basic memory structure consists of a sandwich of layers comprising a tunneling SiO_2 layer on bulk crystalline silicon, the silicon nanocrystal layer, a second thicker SiO_2 layer on top, and a metallic cap, used as electrical contact. The optimum nanocrystal size in the case of memory devices, is in the 5–6 nm range. For efficient light emission, on the other hand, much smaller nanocrystals are needed, with sizes necessarily below 2–3 nm. The efficiency of light emission is directly proportional to the number of luminescent sites so that it is necessary to increase, as much as possible, the number of light emitting nanocrystals in the structure. In this respect, periodic multilayers of silicon nanocrystals and SiO_2 are fabricated. If the SiO_2 layer that separates the silicon nanocrystals in these periodic structures is very thin, in the nanometer range, then the structure is called a nanocrystalline silicon superlattice (nc-Si SL).

Fabrication and fundamental properties of silicon nanocrystals in SiO_2, either arranged in one layer in between SiO_2 or in a nc-Si SL will be discussed in detail in this review paper. The fundamental properties of the Si QDs for application in light-emitting and in memory devices will also be discussed.

2. FABRICATION OF SILICON NANOCRYSTALS IN SiO_2

A composite material of silicon nanocrystals, capped with SiO_2, may be fabricated by using different techniques. One simple technique consists of fabricating porous silicon by electrochemical dissolution of bulk crystalline silicon and

then oxidizing it to produce silicon dioxide around the nanoscale silicon structures. Fabrication of porous silicon by anodizing p-type bulk crystalline silicon had been used for the first time by Uhlir in 1956 [1]. The size of the obtained silicon nanostructures depends on the anodization conditions used [2, 3]. Further reductions in size may be achieved by oxidation. Freshly prepared porous silicon, after exposure in air, appears contaminated by a native oxide, which may cover both its external and its internal surface. Controlled oxidation may be realized by anodic oxidation in a nonfluoride electrolyte [4, 5], by chemical oxidation [6, 7], or by thermal oxidation at high temperatures [8, 9]. Most of these processes result in the formation of a Si–SiO_2 interface of poor electronic quality, the best results being achieved by thermal oxidation at temperatures between 800 and 900 °C in diluted oxygen.

The composite material obtained by oxidizing porous silicon consists of a network of SiO_2-passivated silicon nanocrystals, interconnected and randomly oriented, with an important dispersion in their sizes. Size dispersion may be reduced by increasing the oxidation time or the porosity of the starting material before oxidation. This material is well suited for light emission by photoluminescence (PL), but its application in electroluminescent devices is limited by the difficulty of injecting carriers into the Si nanocrystals.

Another technique extensively used for the fabrication of silicon nanocrystals in SiO_2 is ion implantation of Si into SiO_2, followed by annealing at high temperature. Different groups used SiO_2 films thermally grown on silicon, which were then implanted either with high [10–13] or with low [14, 15] energy ions. Implantation with high-energy ions is, in general, combined with thick silicon oxide films (in the micrometer range). The material obtained after annealing is composed of silicon nanocrystals of different sizes, randomly oriented into the SiO_2 matrix. The control on the size of the nanocrystals and the nanocrystal packing density are limited. Many groups reported visible PL from this material at room temperature [10–13, 16], and some groups fabricated structures showing visible electroluminescence (EL) [17, 18]. For EL emission, however, as well as for memory applications, to get effective carrier injection into the nanocrystals by tunneling, the silicon oxide layer has to be very thin. Silicon ion implantation at high energy results in a low density of silicon nanocrystals in the oxide.

A reliable method to obtain a two-dimensional (2-D) array of silicon nanocrystals of high packing density in a very thin silicon oxide layer on silicon, suitable for memory applications [20], is to implant it into the thin oxide, very-low-energy ions (1 KeV and below) [14–19]. This technique has been used successfully to fabricate silicon nanocrystal memories with good characteristics [20].

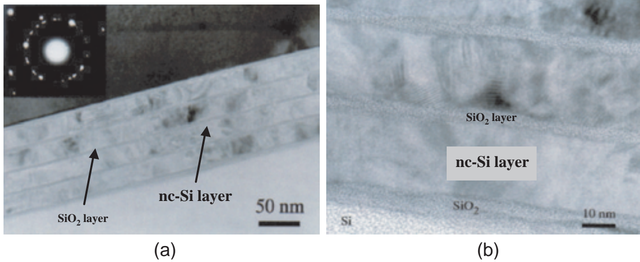
An alternative technique to ion implantation of silicon, by using ions, is ion-beam mixing of SiO_2–Si–SiO_2 layers [21]. The SiO_2 and Si layers in [21] were both amorphous and very thin (60 nm SiO_2/3 nm Si/100 nm SiO_2). They were deposited by ion sputtering of crystalline Si, by using Ar^+ ions for the deposition of amorphous Si (α-Si) and O_2^+ ions in an oxygen ambient for the deposition of α-SiO_2. Ion-beam mixing was performed by 80 KeV argon ions, and it was followed by annealing at 1100 °C.

Other techniques used to fabricate Si nanocrystals in SiO_2 include laser ablation of silicon targets in diluted oxygen gas under vacuum [22], or in an inert He ambient and subsequent exposure of the films to oxygen [23, 24]. Laser breakdown of silane gas in a vacuum chamber also was used [25, 26], followed by oxidation. Electron-stimulated desorption of SiO_2 in an ultrahigh vacuum field-emission transmission electron microscope was used to fabricate size- and position-controlled silicon nanocrystals [27].

SiO_2-capped silicon nanocrystals may be obtained from high-temperature aerosols produced, for example, by pyrolizing disilane [28–30]. A diluted aerosol of surface-oxidized Si nanocrystals is produced, which is bubbled through ethylene glycol to create a nanocrystalline colloid. Size-selective precipitation with tetrahydrofuran is used to reduce size dispersion of the nanocrystals (NCs). This technique is very interesting, since it has produced Si NCs with the highest PL efficiency in Si (quantum efficiency of 50% at low temperatures). However, the technological interest of this technique is limited, due to the very low production rate of the nanocrystals.

Two other promising techniques widely used for the fabrication of a 2-D layer of Si NCs in SiO_2 or a nanocrystalline silicon SL are: (a) direct current (DC) or radiofrequency (rf)-magnetron sputtering [31–37] and (b) low-pressure or plasma-enhanced chemical vapor deposition (LPCVD or PECVD) of silicon on an oxidized silicon wafer [31, 37–48]. Lu et al. [49] and Sullivan et al. [50] deposited ultrathin α-Si layers separated by α-SiO_2, with the aim to crystallize the silicon layer by annealing in a second step. However, crystallization of these thin silicon layers proved to be very difficult and even impossible for the thinnest layers [33]. This has been attributed to the high-strain fields within the layers. Crystallization has been achieved only for the larger layer thicknesses [31, 32], leading to relatively large Si NCs. A more complicated process of solid-phase crystallization of 4- to 20-nm-thick silicon layers, confined between amorphous SiO_2 layers, was used [33] to produce smaller NCs in the SL. It consisted of growing a disordered silicon–α-SiO_2 superlattice on silicon by rf-magnetron sputtering and plasma oxidation, followed by a two-step annealing process: rapid thermal annealing at 900 °C for 60 s, followed by quasi-equilibrium furnace annealing starting from 750 °C up to 1100 °C.

Silicon nanocrystal layers in SiO_2 may be produced in a more controllable way by deposition of a thin silicon layer on a thermally grown silicon oxide, by using LPCVD, followed by high-temperature oxidation [38, 39–41]. Silicon nanocrystals of sizes as small as 1–2 nm may be obtained, arranged in a 2-D layer in between SiO_2. By successive runs of silicon deposition and oxidation, multilayers and superlattices may be fabricated as shown in Figures 1–3. Figure 1 [39] is a TEM image of a multilayer structure with relatively large silicon crystals (10- to 20-nm thick), separated by thin SiO_2 layers. Figure 2 [41], shows a layer of smaller NCs in-between SiO_2 (sizes 2–4 nm), which were produced by oxidizing a much thinner silicon layer (12-nm thick). Figure 2a is a dark field, while Figure 2b is a bright field TEM image. In Figure 3, we see a nanocrystalline silicon superlattice, fabricated by successive runs of the process used in Figure 2. Figure 4a and b shows high-resolution TEM images of silicon nanocrystals in SiO_2, fabricated by the same technique,



(a) (b)

Figure 1. TEM images of Si–SiO_2 multilayers. The silicon nanocrystal layers are ≅20 nm thick and are separated by thinner SiO_2 layers. They were fabricated by successive runs of LPCVD silicon deposition and high temperature thermal oxidation [39]. The electron diffraction pattern from the nanocrystalline layers also is shown as an inset in (1a), while the image in (1b) was taken with higher magnification. while Figure 4c shows a bright field image of the same layer in between a tunneling oxide (bottom) and a thicker oxide on top. This structure is adequate for charge injection from the substrate and charge storage in memory applications.

This process of LPCVD deposition and oxidation is fully compatible with complimentary metal-oxide-semiconductor (CMOS) processing. The nanocrystals are capped with a high-quality silicon dioxide layer, with a reduced density of interface states at both the silicon substrate–SiO_2 interface and the interfaces of silicon nanocrystals with SiO_2. The only drawback of the technique is the complexity of the process in the case of SL fabrication (silicon deposition in the LPCVD system and *ex-situ* furnace oxidation for each superlattice period).

The material obtained by LPCVD deposition and oxidation is appropriate both for light-emission devices (LED) and for memory devices. As mentioned in the introduction, for efficient light emission, very small NCs are needed, of sizes preferably below ≅2 nm. The superlattice structure is used to increase the number of light-emitting sites. For memory devices, slightly larger NCs than those in light emission give optimum results (sizes in the range of 5–6 nm). In general, one single layer of silicon nanocrystals on a thin tunneling silicon oxide is used. In this case, to increase the number of silicon nanocrystals participating in the memory effect for a given device surface area, one has to increase

Figure 3. (a)(b) High-resolution TEM images of silicon nanocrystals in a 2-D layer in between SiO_2. The SiO_2 layer between the silicon substrate and the silicon nanocrystal layer is 4.3- to 4.6-nm thick. The diameter of the nanocrystal in (a) is 3.5 nm, while in (b), the nanocrystal is not spherical (d1, d2 equal 5.6 nm and 2 nm, respectively). In (c), the silicon nanocrystal layer in between SiO_2 is shown at lower magnification (A. G. Nassiopoulou, A. Travlos, and V. Ioannou-Sougleridis, unpublished results).

the packing density of the NCs in the layer, while keeping them isolated from each other. In this respect, different processes have been used. One method consists of modifying the surface chemistry of the SiO_2 layer before silicon deposition and in creating a high density of preferential nucleation sites for the growth of the NCs [51]. This is achieved by surface treatment of the oxidized surface in diluted HF to create surface silanol bonds (Si–OH) on SiO_2, which act as

nucleation sites for silicon nanocrystal formation by LPCVD [47, 48]. In non-HF treated surfaces, nucleation sites on SiO_2 probably are generated by the thermal dissociation of surface Si–O bonds, their density is, however, at least one order of magnitude lower than that of HF-treated surfaces. Another technique applied to promote lateral self-organization of Si QDs during CVD deposition of Si on a very thin SiO_2 layer was to use a buried array of dislocations, located at the bonding interface between an ultrathin silicon film and the silicon substrate [51]. Self-organized vertical QDs were produced in this way.

More recently, a technique consisting of seeding the SiO_2 surface with a submonolayer of silicon prior to chemical vapor deposition (CVD) was proposed [52]. An increase in Si NC density by one order of magnitude, compared to the nonseeded surface, may be achieved.

3. LUMINESCENCE PROPERTIES OF SILICON QUANTUM DOTS IN SiO_2

3.1. Photoluminescence

The different techniques described previously for the fabrication of SiO_2-capped silicon nanocrystals, result, in general, in a composite material composed of an amorphous SiO_2 matrix in which the Si nanocrystals are embedded. Depending on the technique used, the material is different as to the silicon nanocrystal sizes, size dispersion and their distribution and density in the matrix, the thickness and the quality of the SiO_2 film surrounding each nanocrystal, the strain fields within the material, etc. All these parameters significantly influence the PL properties of the material.

The following luminescence bands were, in general, obtained from silicon nanocrystals embedded in SiO_2 (see an example in Fig. 5):

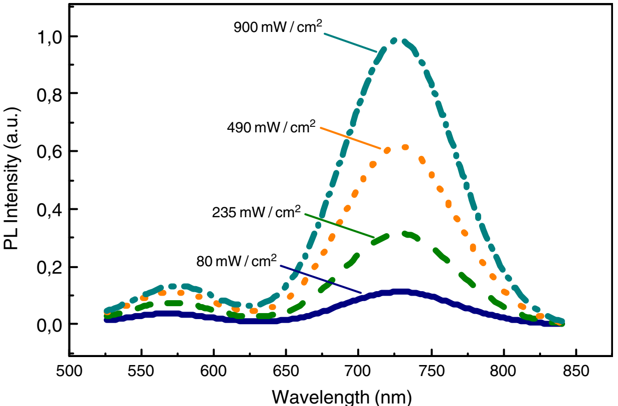

Figure 5. PL spectra from the nanocrystalline silicon superlattice of Figure 4 at different laser excitation intensities, obtained by using the laser excitation line at 457.9 nm. One broad band with a peak at around 720 nm is observed, due to quantum confinement in silicon nanocrystals and a yellow-green band at ≅575 nm, which is related to defects in SiO_2. 3.1.1. Defect-Related Blue-Green Band

This band is, in general, observed in samples grown by ion implantation of Si ions into SiO_2 or in samples prepared by CVD of silicon and oxidation, when the oxide is grown at relatively low temperatures, and it is not post-annealed at higher temperatures [39, 40, 53]. This is a weak PL band (see Fig. 5), and it has been observed both by PL and by EL. It is rapidly quenched under continuous wavelength (cw) laser illumination or under current stressing [39]. Its intensity increases linearly with increasing laser intensity. It does not saturate at high laser power. Its decay time is in the nanosecond range [40], and it can be resolved from the tail of the red PL band by gated photon counting techniques [39].

Due to the above characteristics, the red–green PL band is attributed to defects in SiO_2 or at the Si–SiO_2 interface, and it does not show any significant technological interest.

3.1.2. Tunable Red PL Band

3.1.2.1. General Characteristics This band is much more intense, and it is stable with time and under laser illumination. For large nanocrystals, the maximum of the emission is at about 900–950 nm, while it is blue shifted down to 680–700 nm by decreasing the size of the nanocrystals. This band is attributed to quantum confinement of electron-hole pairs in the nanocrystals. It has the general characteristics of PL observed in other low-dimensional silicon structures [54–70], starting from porous silicon in 1990 [54, 55] and including both zero-dimensional [54, 55, 59–70] and one-dimensional structures [56–58]. These characteristics are: (i) the tunability of the emission by changing the size of the nanostructure, (ii) the high quantum yield at room temperature, which is orders of magnitude higher than that of crystalline silicon (c-Si), and is due first, to the physical isolation of superimposed electron-hole pairs, and second, to the remarkably efficient suppression of nonradiative recombination, and (iii) the broad and featureless PL spectrum.

Suppression of nonradiative recombination in confined structures is due to the physical isolation of electron-hole pairs. This isolation suppresses Auger recombination at moderate excitation densities because a rare defect existing in the material is confined to just one nanocrystal containing the defect, so that nonradiative quenching of the PL is limited, and the luminescence is enhanced.

Photoluminescence tunability with the nanocrystal size is related to the important bandgap opening when the size is below ≈3–4 nm.

In the case of hydrogen-terminated Si nanocrystals, the nanocrystal bandgap E_g as a function of the nanocrystal diameter is fitted by the equation [71, 72]:

$$E_g(d) = 1.167 + \frac{88.34}{d^{1.37}}, \quad (eV)$$

where the effective diameter d is expressed in angstroms.

Experimental results from hydrogen-terminated silicon nanocrystals [73, 74] showed that PL emission follows the bandgap opening. In an experiment under controlled conditions of hydrogenation of porous silicon films, it was demonstrated that when the nanocrystal size is decreased, PL is tuned from the near infrared (IR) to the ultraviolet (UV) wavelength.

The size dependence of PL from silicon nanocrystals capped with SiO_2 was first demonstrated experimentally by Wilson et al. [70], by using size-selective precipitation and size-exclusion chromatography to separate the silicon nanocrystals from larger crystallites and aggregates. The optical spectra and photophysics of the nanocrystals provided direct evidence for quantum confinement. Quantum yields as high as 5.6% at room temperature and 50% at temperatures below 50 K were measured, which approach the yields obtained from direct bandgap semiconductors. However, their data indicated that although these nanocrystals had high luminescence yields, they behaved fundamentally as indirect bandgap materials with low oscillator strength. The measured high-emission quantum yields were attributed to the suppression of nonradiative recombination and the extremely efficient nanocrystal oxide passivation. The average lifetime of PL from their nanocrystals at 630 nm was found to be 50 μsec at room temperature and about 2.5 msec at 20 K. These values are typical for indirect gap semiconductors [73–75].

Photoluminescence tunability by size tunability of silicon nanocrystals in SiO_2 also was demonstrated in [41], where arrays of silicon nanocrystals of different sizes, arranged in a layer in-between SiO_2, were obtained by depositing a thin LPCVD silicon layer on a thermally grown silicon oxide on bulk silicon, followed by oxidation at a high temperature. The size of silicon nanocrystals was controlled by controlling the oxidation time. Silicon nanocrystal superlattices were obtained by successive cycles of silicon deposition and oxidation. By varying the size of nanocrystals from 3.5 to 1.5 nm, the PL peak intensity was shifted from 800 to 680 nm.

Tunable PL from silicon nanocrystals in Si–SiO_2 superlattices also was reported in [44]. The Si–SiO_2 superlattice was produced by depositing substoichiometric silicon oxide by PECVD, followed by high-temperature annealing. The nanocrystal size distribution was, in this case, tuned either by varying the annealing temperature or by changing the excess silicon content in the deposited layer. Tuning of the PL signal from 910 nm for a nanocrystal diameter of 4.6 nm to $\cong$800 nm for a nanocrystal diameter of 2.2 nm was reported.

Compared to hydrogen-terminated silicon nanocrystals, where the PL emission was tuned experimentally from the near IR to the UV, in the case of SiO_2–capped silicon nanocrystals, the emitted wavelengths do not go below 650–680 nm [41]. Below these wavelengths, there is no PL. The existence of this limit suggests that the luminescence is not related to free exciton recombination involving only silicon nanocrystal confined states in the conduction and valence band of the nanocrystal, but some localized states are involved in the recombination mechanism.

The existence of localized states also has been considered in a theoretical study for porous silicon by Allan et al. [75] to account for the large energy difference observed experimentally between absorption and luminescence. Porous silicon is a material composed of a network of silicon nanocrystals or nanowires terminated by hydrogen or silicon oxide or –OH, depending on whether the material is freshly prepared, aged in air, or oxidized. By using total energy calculations, they demonstrated the existence of self-trapped excitons at some surface bonds of silicon nanocrystals. These bonds are, for example, dimer bonds passivated by hydrogen atoms or by silicon oxide. Stretching of the covalent Si–Si bond stabilizes the self-trapped exciton. They attributed part of the observed luminescence to such surface states, while optical absorption is characteristic of quantum confinement, and it follows the bandgap opening when the nanocrystal size is decreased.

Figures 6, 7 and 8 illustrate the results of their calculations [75]. Figure 6 is a schematic configuration coordinate diagram, showing the energies of the ground state G, the normal excitonic state E, and the self-trapped exciton state as a function of the configuration coordinate Q, which corresponds to the stretching of the covalent bond. For a small Q, the ground and first exited states are delocalized over the crystallite and show a normal parabolic behavior. For Q larger than a critical value Q_c, the system localizes the electron-hole pair on one particular bond. Such a self-trapped exciton is likely to be favored at surfaces of nanocrystals where the elastic response of the environment is likely to be weaker than in the bulk. Calculations showed that in the case of Si–H surface bonds, it is always possible to trap an exciton when these bonds are sufficiently stretched. The stable situation corresponds to the broken bond that leads to hydrogen desorption. In the case of stretching of the Si–Si bond of a surface dimer, the stable situation for the excited state corresponds to the surface silicon atoms almost returned to their original lattice sites (see Fig. 7 from [75]).

Calculations by Allan et al. [75] were extended to the case of dimers at the Si–SiO_2 interface. It has been shown that the exciton can be trapped on the dimer. The Si–Si dimer distance was found to be 3.24 Å in the self-trapped state and the optical gap equal to 1.51 eV.

Later, a theoretical study of the electronic states of SiO_2-capped Si QDs has been published by the same group [73], combined with experimental results on the PL from oxidized

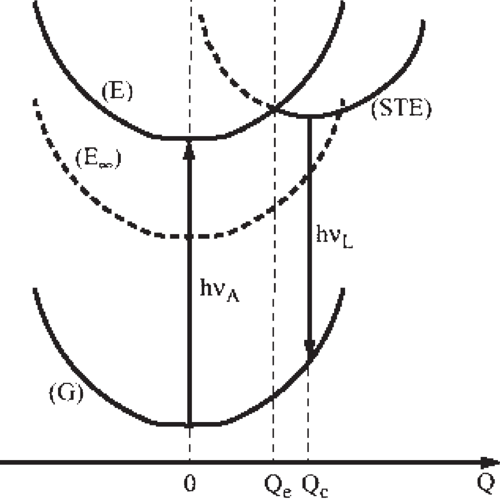

Figure 6. Schematic configuration coordinate diagram showing the energies of the ground state (E) and the self-trapped exciton state (STE) in silicon nanocrystals, The curve (E_∞) corresponds to a very large crystallite with no blue shift, showing that the STE state might not exist for large crystallites. porous silicon, obtained by a group from the University of Rochester [73]. The results of this study showed that the recombination mechanism in oxidized nanocrystals is different from that in hydrogen-passivated nanocrystals. It is proposed that in oxide-passivated nanocrystals, the carriers are trapped in an Si=O double bond, which is formed when a silicon nanocrystal is oxidized to stabilize the Si–SiO_2 interface. This bond does not require either large deformation energy or an excess element. It also terminates two dangling bonds. Depending on the size of the nanocrystals, the Si=O surface state is stable or unstable. In large nanocrystals, (size $\geq$3 nm), the bandgap is not wide enough to stabilize the Si=O state, and recombination occurs via free excitons, as in the case of hydrogen-terminated silicon nanocrystals. In the range of sizes between 1.5 and 3 nm, a p-type localized state on the silicon atom of the Si=O bond traps the electron, so recombination involves a free hole and a trapped electron. For sizes below $\approx$1.5 nm, both a p state localized on the Si atom and a p state localized on the oxygen atom are found, which localize, respectively, the hole and the electron. In this case, recombination is via trapped excitons. The calculated electronic states as a function of silicon nanocrystal size are illustrated in Figure 9 (from [75]).

The above simple model explains the red shift in the PL observed in oxidized silicon nanocrystals compared to hydrogen-terminated ones.

A detailed experimental investigation of PL from silicon nanocrystals in nc-Si–SiO_2 multilayers and superlattices, fabricated by successive runs of silicon deposition and high-temperature thermal oxidation, is found in [39–41] and [76]. Limited tunability of PL emission with silicon nanocrystal size was observed, and a clear red shift of PL, compared to the wavelength corresponding to the calculated nanocrystal bandgap. This discrepancy was more pronounced in the case of smaller nanocrystals. This result is in agreement with the theoretical calculations previously described. An example of PL spectra obtained at 70 and 300 K is given in Figure 10 (from [76]).

Another interesting result in [40] is the superlinear increase of PL intensity by increasing the number of periods in the superlattice. This is illustrated in Figure 11, where the PL signal from SLs with 1 to 5 periods is shown in (a), while,

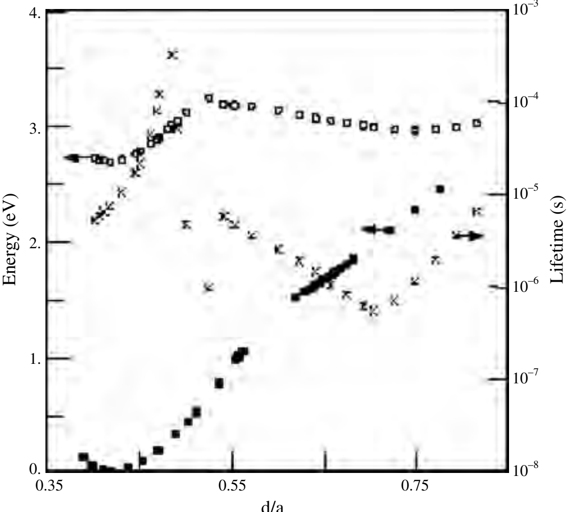

Figure 8. Energy of a spherical crystallite with 123 silicon atoms (diameter = 1.67 nm) in the ground state (■) and in the excitonic state (o) as a function of the interatomic distance d ($\alpha = 0.54$ nm). Crosses are the radiative lifetimes of the excitonic state. Reprinted with permission from [75], G. Allan et al., *Phys. Rev. Lett.* 76, 2961 (1996). © 1996, American Physical Society.

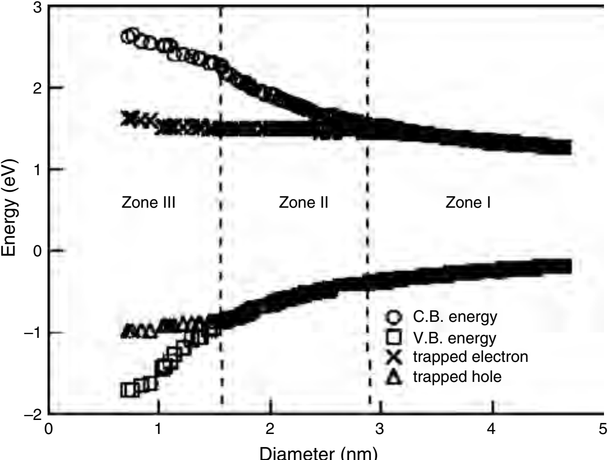

Figure 9. Electronic states in Si nanocrystals as a function of cluster diameter and surface passivation. When the silicon cluster is passivated by hydrogen, recombination is via free excitons for all sizes (symbols: “oo” for conduction band and “□□” for valence band). If the silicon cluster is passivated by oxygen, a stabilized electronic state may be formed on the Si=O bond. The trapped electron state is a p state, localized on the Si atom of the Si=O bond, and the hole state is a p state localized on the oxygen atom. Reprinted with permission from [73], M. V. Wolkin et al., *Phys. Rev. Lett.* 82, 197 (1999). © 1999, American Physical Society.

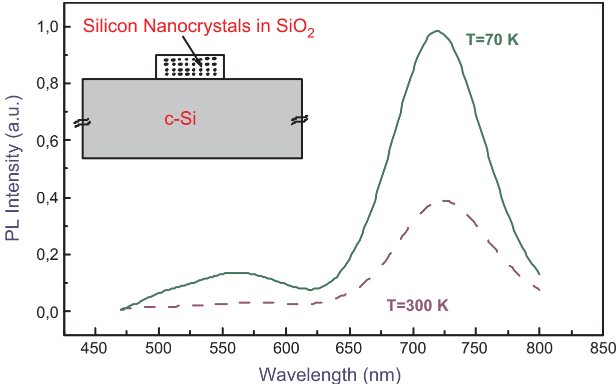

Figure 10. PL spectra from silicon nanocrystals in nanocrystalline Si–SiO_2 superlattice at two different temperatures. The size of silicon nanocrystals was ≅1.5 nm. Kamenev and A. G. Nassiopoulou, *J. Appl. Phys.* 90, 5735 (2001). © 2001, American Institute of Physics.

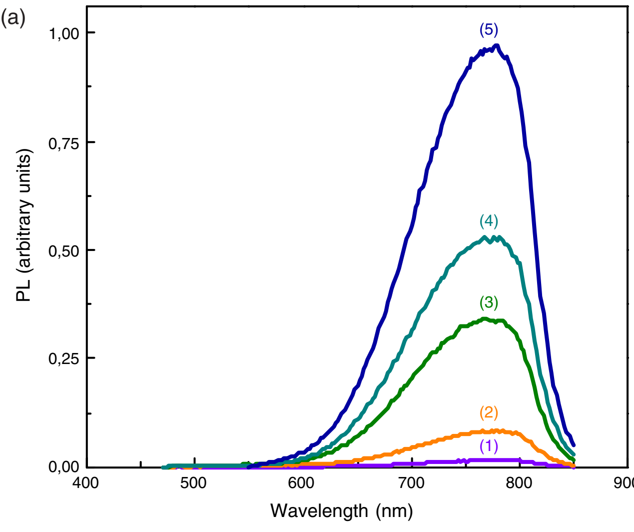
in (b), we see the PL peak intensity variation as a function of the number of periods. This interesting result may be attributed either to annihilation of defects during processing for the fabrication of the next SL period or to a decrease of silicon nanocrystal sizes and narrowing of their size dispersion after prolonged processing and thermal treatment. Smaller, defect free, silicon nanocrystals are more efficient light emitters. The hypothesis of decreasing the sizes of NCs in the first layers during formation of the next bilayers is evidenced in Figure 3.

3.1.2.2. Recombination Dynamics The recombination dynamics in silicon nanocrystals embedded in SiO_2 depend strongly on the characteristics of the sample used. This is because the radiative lifetime depends on silicon nanocrystal size, size dispersion, shape [77], and separation distance between the nanocrystals. As a result, different authors gave different experimental results for the radiative lifetimes of silicon nanocrystals. From Si nanocrystals produced by laser breakdown of silane gas [25], which were composed of a crystalline silicon core covered by a 1.6-nm-thick amorphous SiO_2 surface layer, the red PL decay profiles were described by a stretched exponential function, as follows:

$$I(t) = I_0\left(\frac{\tau}{t}\right)^{1-\beta} \exp\left[\left(-\frac{t}{\tau}\right)\right]^{\beta},$$

where τ is an effective decay time, β is a constant between 0 and 1, and I_0 also is constant. This stretched exponential decay usually is observed in the PL decay of disordered systems. It has been systematically observed in the case of porous silicon [78–80], and it was attributed either to size, shape, or crystallographic orientation [81] dispersion of the nanostructures. In the case of silicon nanocrystals in SiO_2 fabricated by ion implantation of silicon [62, 63], strongly nonexponential PL decay was obtained, which was associated with a nanocrystal–nanocrystal interaction. Multiexponential PL decay also was obtained from size-selected, surface-oxidized nanocrystals fabricated by size-selective precipitation and size-exclusion chromatography



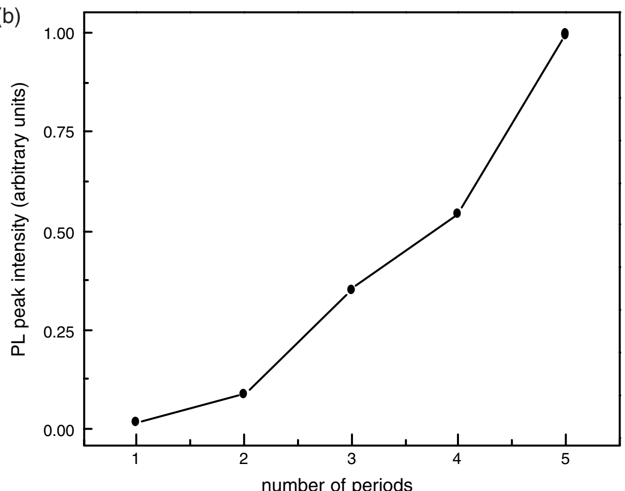


Figure 11. (a) PL spectra from nanocrystalline SiO_2 superlattices with one to five periods. (b) PL peak intensity as a function of the number of periods. Lett.* 76, 3588 (2000). © 2000, American Institute of Physics.

[82]. Since in that case, the size distribution was limited, the multiexponential PL behavior was attributed to the distribution of shapes and decay dynamics of nanocrystals for a given emission wavelength. The 630-nm average lifetime was found to be 50 nm at 293 K and about 2.5 nm at 20 K. On the other hand, single [44] or double [76] exponential PL was found in the case of well-separated silicon nanocrystals in Si–SiO_2 superlattices. This behavior was attributed to better size control and larger nanocrystal separation, which limited the nanocrystal–nanocrystal interaction. For example, in [44], it was found that for a nanocrystal diameter equal to 2.2 nm, the PL band was peaked at 790 nm and the radiative lifetime was in the range of 0.8 ms at 17 K and 0.25 ms at 250 K. The radiative rate, calculated by dividing the PL intensity by the decay time, was found to increase monotonically by a factor of 4 when the temperature was increased from 17 to 300 K. This increase has been explained by considering the model of Calcott et al. [83]for porous silicon.

According to this model, the exchange electron-hole interaction splits the excitonic levels by an energy Δ. The lowest level is a triplet state and the upper level is a singlet state, the triplet state having a radiative decay rate much smaller than that of the singlet. Once excited, carrier population in this state will be distributed according to a thermal equilibrium law. The temperature dependence of the radiative decay is, thus, deduced, and it is found that by increasing the temperature, the relative population of the singlet state, compared to the triplet state, will increase. As a result, since the radiative rate of the singlet state is much higher than that of the triplet state, the total radiative rate will increase with the increase of the temperature.

Slightly different behavior was found in the case of silicon nanocrystals of sizes below $\approx$1.5 nm, arranged in multilayers in between SiO_2, and studied in detail in [76]. The PL peak intensity was found to increase by increasing the excitation intensity, as illustrated in Figure 12. This increase was linear at low excitation intensity, and it saturated at higher intensities, both under cw and under chopped excitation. The PL saturation was observed both at room and at low temperatures (Fig. 13). This saturation is typical of systems with a finite number of light-emitting centers. In PL from silicon nanocrystals due to exciton recombination, PL saturation is attributed to the switching on of the fast nonradiative Auger recombination channel, which is due, at high excitation rates, to an additional carrier added to the first electron-hole pair within the nanocrystal [83–85].

The temperature dependence of PL intensity is different when we operate at low excitation than in the case of high excitation. As it was found experimentally in [76], at low

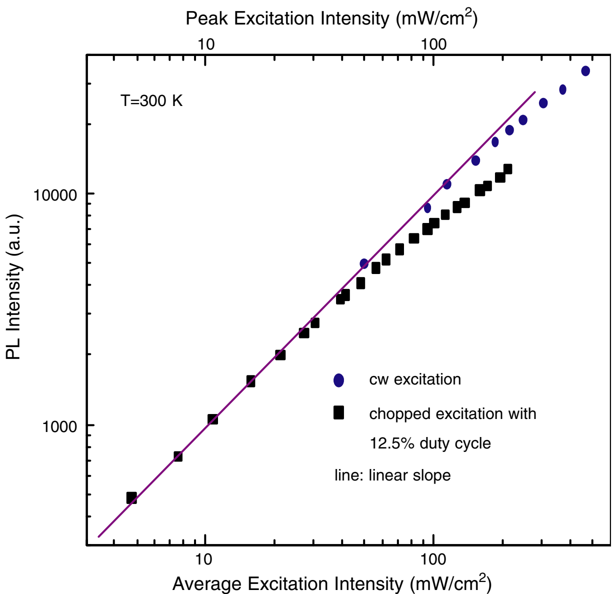

Figure 12. PL intensity from silicon nanocrystals in a nanocrystalline silicon superlattice as a function of the excitation intensity under continuous wave (cw) and chopped excitation with 12.5% duty cycle. The line is the linear slope at low excitation intensity. At high excitation intensity, there is saturation of PL. Reprinted with permission from [76], B. V. Kamenev and A. G. Nassiopoulou, *J. Appl. Phys.* 90, 5735 (2001). © 2001, American Institute of Physics.

excitation, PL intensity was increased by decreasing the temperature, and it saturated at temperatures below ~180 K. Under high excitation, PL intensity increased as the temperature was decreased down to 180 K, and it then decreased again at lower temperatures (Fig. 14).

The thermally activated behavior of PL emission is better understood if we consider PL intensity in combination with PL relaxation times. It was found that the PL decay time does not follow the stretched exponential law observed in the case of porous silicon, but it is fitted by two exponentials with relaxation times at room temperature equal, respectively, to 25–30 μsec (τ_F) and 80–100 μsec (τ_S). Typical PL transients at different temperatures are shown in Figure 15. By examining separately each term of the double exponential function of PL, it was found that while the temperature dependence of the two decay times was similar

Figure 14. (Fig. 16), the PL amplitude of each component showed different temperature dependence. The PL amplitude of the slower component, I_{PLS}, with decay time τ_S was independent of temperature, while that of the faster component I_{PLF}, with decay time τ_F, showed a maximum at around ~160 K. From room temperature down to 160 K the variation of I_{PLF} followed that of the decay time τ_F, while at lower temperatures, down to 70 K, I_{PLF} decreased (Fig. 17).

The increase of I_{PLF} from 70 to 160 K suggests that its excitation is thermally activated with small activation energy.

However, its decrease, by increasing the temperature in the range 160–300 K, which directly follows the decrease of the corresponding decay time, suggests that for this recombination channel, in this temperature range, Auger recombination is absent. This component was attributed to self-trapped excitons, related to Si–Si dimers at the surface or to the Si–SiO_2 interface of the very small silicon nanocrystals under investigation (size ≈1.5 nm). It also was suggested that the formation of self-trapped excitons on Si–Si dimers was in competition with the recombination mechanism of other active centers in the system, resulting in an apparent absence of Auger recombination in the case of this PL component. The slower PL component was ascribed to radiative recombination involving localized interface states in Si═O bonds [73, 76, 84].

3.1.2.3. Nature of Absorbing and Emitting States in Si Nanocrystals Bulk crystalline silicon is an indirect bandgap material. As a result, optical transitions are allowed only if phonons are absorbed or emitted to conserve the crystal momentum (phonon-assisted (PA) process). The relevant phonon modes include transversal optical (TO) phonons (E_{TO} = 56 meV), longitudinal optical (LO) phonons (E_{LO} = 56 meV), and transversal acoustic (TA)

Lett.* 66, 1114 (1995). © 1995, American Institute of Physics.

phonons ($E_{TA} = 56$ meV). In a nanocrystal, the situation is quite different. First, due to spatial confinement, both the absorbing and luminescing states are shifted to higher energies, thus the density of electronic states is changed, and second, this spatial confinement results in delocalization of carriers in K space, thus allowing no-phonon (NP) optical transitions to occur and significantly enhancing the oscillator strength of these transitions [86, 87]. A third result is that due to the better overlap of electron and hole envelope wavefunctions, one can expect a strong enhancement of the exchange interaction, inducing a splitting of the exciton levels [88].

The clear evidence that emitting states are driven to higher energies by confinement is coming from PL measurements. Photoluminescence tunability is obtained by changing the silicon nanocrystal size. Due to size distribution of the nanocrystals, a broad and featureless spectrum is obtained. A more detailed understanding of the nature of the absorbing and luminescing states in silicon nanocrystals is obtained from resonant PL emission (PLE) studies [89, 90], where the excitation energy approaches the detection energy. Under these conditions, only a small subset of nanocrystals is probed. It has been observed that the PL spectrum is no longer featureless, but it exhibits a set of onsets, whose energy separation corresponds to the energy of TO- and TA-momentum-conserving phonons of bulk silicon [89, 90]. Moreover, it has been found that phonon-related spectral features of the PLE signal are replicated in energy. This behavior is explained as follows: Spatial confinement partially breaks down the K-conservation rule. This allows NP transitions to be possible, and, therefore, in both absorption and emission, NP and PA processes coexist. At each particular energy, two groups of nanocrystals are contributing, one having an energy gap $E_{gap} = E_{det}$ and the other with a bandgap $E_{gap} = E_{det} + E_{TA}$ and $E_{gap} = E_{det} + E_{TO}$. The same is valid for the absorption, and this is why the related spectral features in PLE are replicated in energy [90].

Theoretically, it is predicted that the probability of NP transitions is increased by decreasing the size of the nanocrystals. Therefore, the optical properties of Si nanocrystals are governed by a competition between indirect and quasi-direct recombination channels. By using extremely energy-selective optical spectroscopy, Kovalev et al. [90] estimated the relative strengths of the NP transitions and phonon-assisted processes. It was found that in the vicinity of the crystalline silicon bandgap, in the weak confinement regime, TO-phonon-assisted processes dominate, while at 1.8 eV, NP processes begin to take over. The ratio between TO- and TA-phonon-assisted processes was estimated to be of the order of 10, independent of the confinement energy.

The above results were obtained from hydrogen-terminated silicon nanocrystals [90] in porous silicon. The authors claimed that SiO_2-capped silicon nanocrystals behave in a similar way, but, in this case, the strength of NP processes is significantly enhanced at the same emission energies. However, their overall conclusion was that even nanometer-size silicon crystallites do not become totally direct semiconductors. The more direct nature of the recombination leads to an increase of the oscillator strength, resulting in a shortening of lifetime of the optically active exciton state by two orders of magnitude over the whole spectral range.

3.1.3. Absorption Cross Sections

To estimate the quantum efficiency of PL, it is important to know the absorption cross sections for different excitation wavelengths. A detailed study has been made for porous silicon by Kovalev et al. [91] and for silicon nanocrystals embedded in SiO_2 by Priolo et al. [92] and Garcia et al. [93]. In [92] and [93], it was found that in SiO_2-capped silicon nanocrystals, the value of the absorption cross section per nanocrystal varies in the range of 10^{-16} to 10^{-15} cm^2 for excitation energies in the visible (457-, 488-, and 514-nm lines) and UV ranges (325 nm). The absorption cross section per nanocrystal increases as the nanocrystal size decreases for all excitation wavelengths, implying that the variation of the oscillator strength dominates over the reduction of the density of states.

Different results were obtained from porous silicon by Kovalev et al. [91], who found that absorption cross section depends both on the excitation and detection energy difference and it varies over nearly 5 orders of magnitude, from 10^{-19} cm^2 under low-energy resonant excitation to 10^{-14} cm^2 under excitation at higher energies above the bulk silicon direct bandgap. At resonant excitation, it was found that the value of the absorption cross section is a very strong function of the difference of the excitation and detection energy difference $\hbar\omega_{ex} - \hbar\omega_{det}$, this energy dependence reflecting the increase in the density of electronic states with increasing energy above the "gap."

3.1.3.1. Optical Gain in Silicon Nanocrystals For the practical use of silicon nanostructures for the fabrication of silicon-based optoelectronics, it is important to reach quantum efficiencies at least similar to those obtained from III–V

semiconductors. In an effort to demonstrate that this would be possible, experiments were carried out to investigate the possibility of obtaining stimulated emission from silicon nanocrystals. By using samples fabricated by ion implantation of silicon into SiO_2, Pavesi et al. [94] claimed, in the year 2000, that they observed optical gain from silicon nanocrystals. Other works then followed [95–97], reporting stimulated emission in silicon nanocrystals, in severe competition with fast nonradiative Auger processes. To explain the gain mechanism, it was suggested that interface states associated with oxygen atoms were involved in light emission. More recently, it was reported that either positive or negative gain could be observed [98], depending on the sample and on whether Auger fast processes or stimulated emission predominate. An effective four-level model was proposed to explain the obtained results.

However, although the above results on optical gain and light amplification seem to be promising, silicon LEDs still have a factor of 10 lower efficiencies than those required in optoelectronics. One important limiting factor seems to be the low density of light-emitting centers in the composite material, composed of an insulating matrix in which the nanocrystals are embedded.

3.2. Electroluminescence

Electroluminescence was observed both from silicon nanocrystals in SiO_2 [17, 18, 39, 43, 99] and from silicon nanowires [100–102] passivated by silicon dioxide. Compared to PL, the main issue in EL is carrier injection into the nanostructures.

3.2.1. Electroluminescence from SiO_2-Passivated Silicon Nanowires

Light-emitting silicon nanowires were fabricated by Nassiopoulou et al. [100, 102] and Grigoropoulos et al. [101] in 1995. These nanowires were in the form of nanopillars vertically standing on a silicon substrate, and they were fabricated by using lithography, combined with a highly anisotropic silicon-etching process [103], and followed by high-temperature thermal oxidation and oxide removal. The diameter of the wires was the same all along their length, and the aspect ratio of height to diameter after removal of the surface oxide was equal to 120. An example of these nanowires, arranged in line arrays on a silicon substrate, is shown in Figure 18. Figure 19 shows an example of PL spectrum from these nanowires. The PL intensity was limited because of the small number of light-emitting nanowires probed (their packing density was low). The characteristics of PL were similar to those of the red PL band from silicon nanocrystals, and they were attributed to quantum confinement.

To obtain EL from these wires, a device structure was fabricated as follows: The oxidized silicon nanowires were embedded in a nonconductive transparent polymer (polymethylmethacrylate), deposited by spinning on the silicon wafer containing the nanowires, which provided a matrix for planarization of the whole structure and extra electrical isolation of the nanowires, since both the wires and the silicon surface on which they were lying were covered by a thin SiO_2 layer. After planarization, the surface was slightly etched in an oxygen plasma to remove the resist from the top of the nanopillars. The oxide from the nanopillar top was removed by dipping the sample in diluted HF for a few seconds. A thin gold film, 15-nm thick, was then evaporated on top, which was used as gate metal. An ohmic contact was formed on the back side of the wafer, which was used as second contact. The process flow is schematically illustrated in Figure 20. Figure 21 shows EL spectra at two different polarization voltages. These results demonstrated clearly that light emission from silicon nanowires at room temperature is possible, both under optical and under electrical excitation, when their diameter is below few nanometers.

3.2.2. Electroluminescence from Silicon Nanocrystals in SiO_2

Samples fabricated by different techniques were used to investigate EL from silicon nanocrystals embedded in SiO_2.

Samples obtained by ion implantation of silicon into an oxide thin film on a silicon substrate showed, in general, EL at relatively high voltages. The main difficulty is carrier injection into the nanocrystals through the insulating oxide,

which leads to a low quantum efficiency. To improve carrier injection, two solutions were proposed, either (a) to grow a very high concentration of silicon nanocrystals into the oxide (close to the percolation threshold), implanted at high voltages [104]; or (b) to use very thin SiO_2 layers, implanted at low voltages, to get tunneling transport through the oxide. Song et al. [17] used 34-nm-thick SiO_2films on p-type silicon implanted with Si^+ ions of 25 KeV and annealed in a controlled nitrogen atmosphere at temperatures up to 1100 °C. Electroluminescence was observed at forward bias, with an onset at 8 V. The EL spectrum was broad and centered at 580 nm, with two weaker shoulders at around 470 and 730 nm. Song et al. [17] suggested that part of the 730 nm band was due to silicon nanocrystals, while some contribution was due to defects in SiO_2. The bands at 470 nm and 580 nm also were attributed to defects in the oxide. Valenta et al. [18] fabricated light-emitting diodes based on Si nanocrystals, by using thermal silicon oxides of thickness between 12 and 100 nm and covered by an amorphous silicon layer, 210-nm thick, which were implanted with Si^+ ions at 150 KeV. The EL band from radiative recombination in silicon nanocrystals was peaked at 800 nm. An external quantum efficiency of 3×10^{-5} was obtained.

More promising for EL emission were samples containing 2-D arrays of nanocrystals in between SiO_2 [80], fabricated by LPCVD deposition of silicon and high-temperature oxidation. The structure used for EL is shown in Figure 22. The substrate was p type, and a thin transparent aluminum film, ≈15-nm thick, was deposited on top of the SiO_2 layer containing the nanocrystals, and it was patterned to be used as gate metal. A variable voltage was applied between the gate and an ohmic contact on the backside of the wafer.

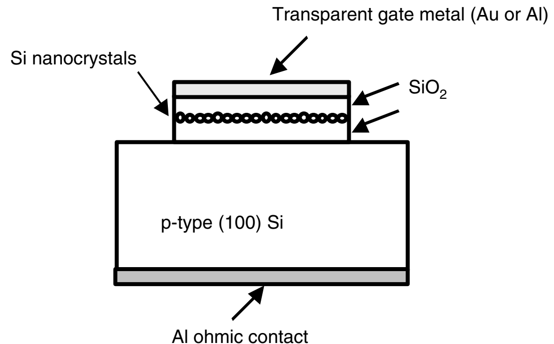

Figure 22. MOS structure with silicon nanocrystals in the SiO_2 layer, used to observe EL from silicon nanocrystals.

Figure 23 shows typical EL spectra at different temperatures, obtained with an applied voltage of 10 V, while Figure 24 shows EL spectra at different voltages. Figure 25 shows the evolution of EL intensity measured at two different emitted wavelengths as a function of the applied voltage, normalized by the electrical current through the structure. At low voltages, the normalized EL intensity increased linearly by increasing the voltage, while it saturated at higher voltages. Moreover, the normalized EL intensity at the two different emitted wavelengths (680 and 770 nm), showed that at low voltages, the intensity of the signal at 770 nm was

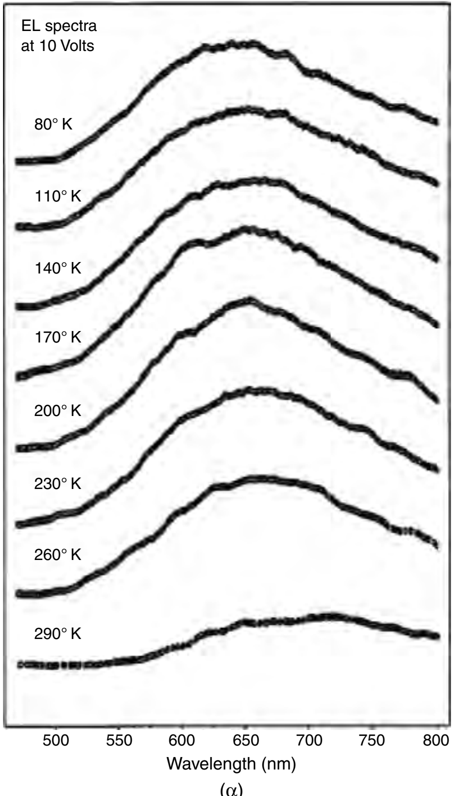

Figure 23. EL spectra from silicon nanocrystals in SiO_2 at different temperatures. Reprinted with permission from [99], P. Photopoulos and A. G. Nassiopoulou, *Appl. Phys. Lett.* 77, 1816 (2000). © 2000, American Institute of Physics.

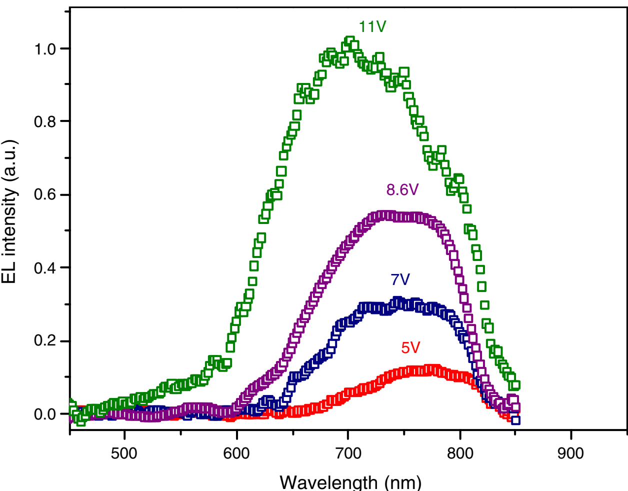

Figure 24. EL spectra from silicon nanocrystals at different applied voltages (P. Photopoulos and A. G.Nassiopoulou, unpublished results).

higher than that at 680 nm, while this was inverted at higher voltages. The saturation of EL at a high applied electric field occurs because part of the light-emitting nanocrystals are quenched, due to two different main effects: (a) the higher carrier injection when the applied voltage is increased and (b) the effect of the electric field itself (quantum-confined Stark effect, see [105]). The first effect also occurs in PL at high excitation power. It has been observed experimentally both in the case of nanocrystalline silicon SLs [105, 106] and in the case of porous silicon [83–85]. It is attributed to the fact that at high excitation power, it is more likely that more than one electron-hole pair is generated or injected into the nanocrystal [84, 85]. The presense of an extra carrier or a second electron-hole pair into the nanocrystal results in the fast opening of a nonradiative Auger recombination channel, which quenches PL and EL. This effect is expected to be more pronounced in larger nanocrystals, and this is why the PL signal at 680 nm (due to smaller nanocrystals) saturates at a higher voltage than that at 770 nm (due to larger nanocrystals). This is illustrated schematically in Figure 26.

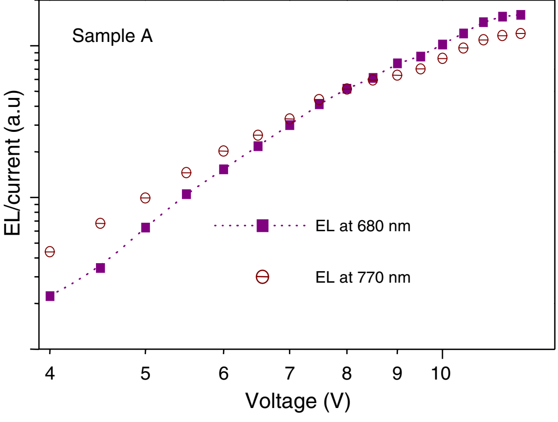

Figure 25. Variation of EL intensity from silicon nanocrystals, normalized by the current through the structure, measured at two different emitted wavelengths. Reprinted with permission from [99], P. Photopoulos and A. G. Nassiopoulou, *Appl. Phys. Lett.* 77, 1816 (2000). © 2000, American Institute of Physics.

The second effect, which is at the origin of EL saturation but is not present in the case of PL, is the effect of the electric field on the electron and hole of an electron-hole pair in the nanocrystal. This effect is known as the quantum-confined Stark effect, and it has been studied in detail in the case of quantum wells of III–V compounds [107–110]. For the case of $Si–SiO_2$ superlattices, a detailed study has been made by Quisse and Nassiopoulou [105] by means of a variational calculation. Due to the good dielectric properties of SiO_2, an electric field as high as 6–7 MV/cm can be applied to the $Si–SiO_2$ superlattice without causing a breakdown to the structure. This high electric field results in an increase of the separation between the electron and the hole of the electron-hole pair and, thus, exciton lifetime is increased. In [105], a cubic quantum box of size L with infinite barrier heights was considered and the possibility of carrier escape from the box was neglected. It was found that for a nanocrystal of a given size, as the electric field increases, the electron and the hole wavefunctions are gradually separated from one another, so that the radiative lifetime increases. Figure 27 schematically illustrates this effect. On the other hand, the transition energy decreases. At moderate electric field, the energy shift is proportional to the square of the electric field, as predicted by the second-order perturbation theory [105]. Also, to a good approximation (a few percentages), the dependence of the phonon-assisted lifetime on the applied electric field at room temperature is empirically given by:

$$\tau = \tau_0(1 + \gamma L^{5.25} E^2)$$

where $\gamma \approx 2.1 \times 10^{-8}$, if E is expressed in MV per centimeter, L is in angstroms, and τ_0 is the lifetime in the absence of an external electric field. The overall effect of the electric field on a nanocrystal of a given size is thus manifested by: (a) a red shift of the luminescence and (b) a quenching of the radiative recombination rate. This effect is size dependent, and it is more important for larger nanocrystals, as illustrated in Figures 26–28. Figure 28 shows the variation of the gap of cubic silicon nanocrystals versus the cube size and the electric field applied along the (100) crystallographic direction. Figures 29 and 30 show, respectively, the

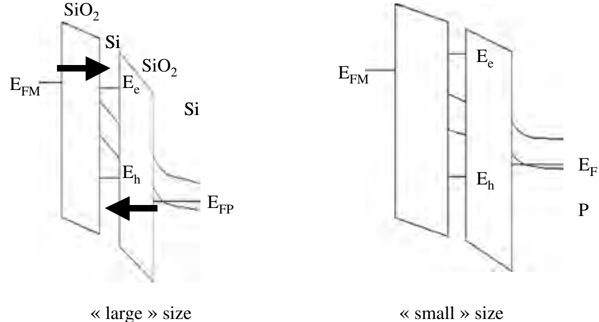

Figure 26. Effect of the applied electric field on energy levels in the case of a large and a smaller silicon nanocrystal, surrounded by two tunneling SiO_2 layers. Figure 27. Effect of an electric field on the electron and hole wavefunctions of an exciton in a silicon nanocrystal surrounded by two thin silicon oxide layers.

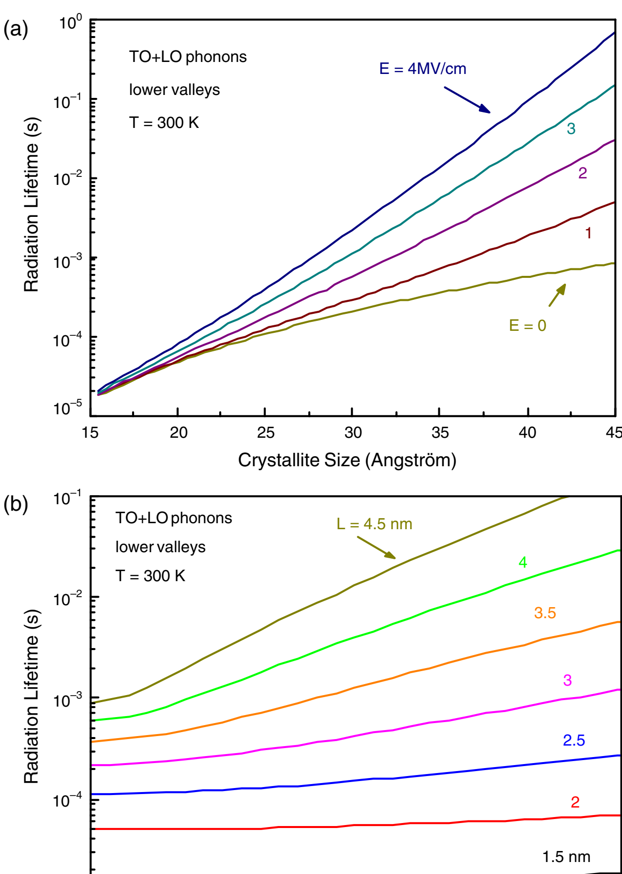

Figure 28. Variation of the radiation lifetime of silicon nanocrystals as a function of the crystallite size for different values of the electric field (a) and as a function of the electric field for different values of crystallite size (b) (T. Ouisse and A. G. Nassiopoulou, unpublished results)

direct and TO + LO phonon-assisted radiative recombination lifetime as a function of nanocrystal size and electric field along a (100) direction (lower valleys), at $T = 300$ K. As it is seen, the effect of the electric field is more substantial in larger nanocrystals. By increasing the electric field in these nanocrystals, the radiative recombination lifetime increases substantially.

3.3. Effect of a High Electric Field on PL and EL

3.3.1. Effect on PL

The effect of a high applied electric field on PL from silicon nanocrystals in SiO_2 has been systematically investigated in [111]. The structures used were MOS-type (metal–oxide–semiconductor) structures on silicon with the silicon dioxide layer containing 2-D arrays of silicon nanocrystals in SiO_2. The thickness of SiO_2 was chosen so as to minimize carrier injection into the oxide under the influence of the vertically applied electric field. The PL signal was excited by laser pumping at 457.9 nm. Two different samples were investigated, one with a mean nanocrystal size in the range of 1–2 nm and the other with a mean nanocrystal size in the 2–3 nm range. The PL was measured under the application of an increasing electric field at constant laser pumping. By current-voltage (I-V) and capacitance-voltage (C-V) measurements, it was found that there was no current flow through the structure if the electric field was kept below 2.5 MV/cm for the sample with the larger nanocrystals

and below 4 MV/cm for the sample with the smaller nanocrystals. The observed overall effect of the electric field on PL was as follows:

(i) In the sample with the larger nanocrystals, it was found that by applying an increasing electric field, the PL peak position was first slightly red shifted, and it was then blue shifted at a higher field, while PL intensity was continuously quenched by increasing the electric field. This is illustrated in Figures 31, 32, and 33.
(ii) In the case of the sample with the smaller nanocrystals, it was found that PL peak position was almost constant under the influence of an increasing electric field (slightly red shifted), up to an electric field of 2.3 MV/cm, while it showed a constantly increasing blue shift by increasing the electric field above this value. The PL intensity was also constant up to ≈2.3 MV/cm, while it was rapidly quenched above this value. This is illustrated in Figures 32–34.

The observed shift in PL peak position and the PL quenching under the influence of an external electric field is explained in terms of the quantum-confined Stark effect, described previously. In the case of very small nanocrystals, PL was insensitive to the electric field, up to a certain field, while larger nanocrystals showed an important PL quenching under the influence of the same electric field, in agreement with theoretical calculations [105]. The fact that the observed shift in PL peak wavelength did not follow a constant red shift by increasing the electric field was attributed to the size distribution of silicon nanocrystals. The broad PL signal measured, contains the contribution from nanocrystals with different sizes, which show different behavior under the influence of the electric field. At a given electric field, PL from larger nanocrystals is quenched, while that from smaller nanocrystals is not affected by the field. The macroscopic effect observed is so manifested by a blue shift in PL position, accompanied by an important PL quenching. The obtained results were consistent with this explanation.

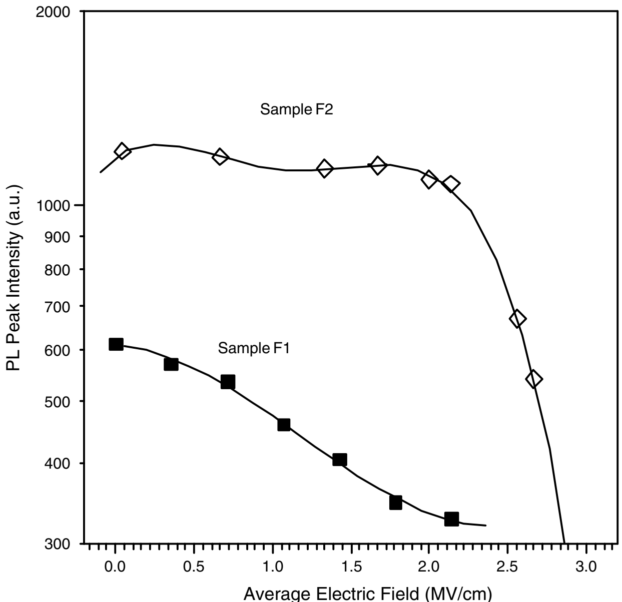

Figure 32. PL peak intensity from silicon nanocrystals in SiO_2 as a function of an applied electric field for two different sizes of silicon nanocrystals (2–3 nm [F1] and 1–2 nm [F2]). The influence of the electric field is more important in the case of larger nanocrystals. Reprinted with permission from [111], Ioannou-Sougleridis et al., *Mater. Sci. 3.3.2. Effect on EL

In the case of EL, there is no laser pumping, so carrier injection is necessary, to create electron-hole pairs into the nanocrystals. In the presence of carrier injection, the electric field has different effects on the EL signal:

(i) By increasing the electric field, carrier injection is increased, so we expect an increase in the EL signal proportional to the current. This is valid for low carrier injection, while at high carrier injection, Auger quenching of the EL signal occurs, which leads to saturation of the EL intensity.

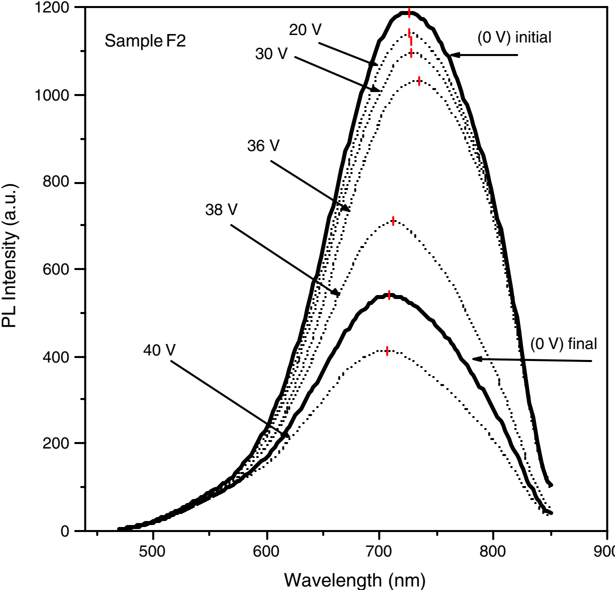

Figure 34. PL spectra from silicon nanocrystals, 1- to 2-nm thick, at different applied electric fields from zero to 40 V. The PL spectrum at zero voltage, obtained after the application of 40 V for some time, shows PL quenching and a slight blue shift compared with the initial spectrum before the application of the electric field. Reprinted with permission from [111], Ioannou-Sougleridis et al., *Mater. Sci. Eng., B* (to appear, 2003). © 2003, Elsevier Science.

(ii) The quantum-confined Stark effect plays an important role in EL quenching at high electric fields. The effect is more pronounced in larger nanocrystals.

(iii) Carrier injection into the nanocrystals is also a size-dependent effect. Smaller nanocrystals have a significantly smaller cross section for carrier injection.

The effect of an increasing electric field on EL was investigated in [99]. The EL intensity as a function of the applied electric field has been investigated at different wavelengths, and an example has been given in Figure 24 for two detected EL wavelength. The evolution of the EL position as a function of the applied voltage was given in Ref. [99] for nanocrystals of different sizes. The overall behavior was a blue shift in EL wavelength by increasing the applied field. This was observed in all samples. observed in all samples.

3.4. EL Efficiency

In the case of PL, it was demonstrated that the use of silicon nanocrystal–SiO_2 multilayers, instead of a single 2-D silicon nanocrystal layer in SiO_2, leads to a significant increase in PL emission, due to the increase of light-emitting centers. As mentioned, it was even found that a superlinear increase in PL emission is obtained when the number of multilayers is increased [40]. In the case of EL, however, the increase of recombination centers by increasing the number of silicon nanocrystal layers does not necessarily imply an increase in EL emission. This is because the main limiting factor in EL is carrier injection into the nanocrystals. By using vertical carrier injection, which was the configuration used in the literature [99, 104, 111] in light emitting devices, Quisse et al. [112] simulated the tunneling and recombination current in

$Si–SiO_2$ superlattices, to find the optimum conditions for EL. A p-type silicon substrate was considered for hole injection and an aluminum gate for electron injection. The basic assumptions used were that (i) the Si wells were thin enough to get an almost ideal 2-D system and (ii) quantization was represented by a square well approximation. They first simulated the one-well configuration, and it was found that in the absence of recombination, the hole-electron density product in the well is maximum for equal top and bottom oxide thickness ($t_{ox1} = t_{ox2}$). This is illustrated in Figure 35, where the density of electrons and holes in the well is plotted versus the top oxide thickness for a bottom oxide of thickness $t_{ox2} = 2.6$ nm, a well thickness $t = 1.5$ nm, a gate voltage $Vg = -2$ V, lower than the breakdown voltage of the Si well, and a temperature of 300 K. The optimum for a high density of both electrons and holes in the well is at ($t_{ox1} = t_{ox2}$). As it now concerns the optimum thickness for t_{ox1} and t_{ox2}, it was found that the thinner the insulating layers are, the higher are the currents and, therefore, the recombination rate.

In the presence of recombination, however, accumulation of holes is only possible if the top oxide thickness, t_{ox1}, is below a critical value t_{crit}. For accumulation of electrons, on the other hand, the necessary condition is $t_{ox1} = t_{crit}$. This means that it is impossible to get simultaneously both high-electron and high-hole density in the well in the presence of recombination. Another interesting result in [112] concerns the material of the injecting electrodes. The injection of carriers for radiative recombination in the well is difficult when the injecting material has the same or a similar work function as that of the confined layer, in the present case of silicon. Theoretically, to get acceptable electron injection currents in the direction of confinement, one has to use injection electrodes with a work function much lower than the electron affinity of Si. Similarly, one should inject holes from a material with a Fermi level as close as possible to the top of the Si valence band. For example, platinum could be used as a gate metal (chemical potential lower than the top of the Si valence band) and an n-type silicon substrate for electron injection. Compared with the $Al–SiO_2–Si–SiO_2$–p-Si structure, an improvement of a factor of 3 may be achieved.

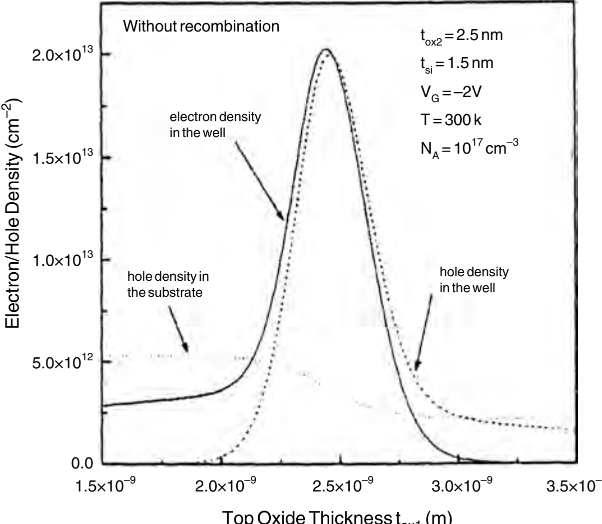

Figure 35. Variation of the electron and hole concentrations in an $Al–SiO_2–Si–SiO_2$–Si structure versus top oxide thickness $t_{ox2} = 2.5$ nm and voltage, without any recombination process in the single well. Reprinted with permission from [112], T. Quisse et al., *J. Phys. D: Appl. Phys.* 33, 2691 (2000). © 2000, Institute of Physics.

Coming back to the $Al–(Si–SiO_2)SL$–p-Si structure, a systematic investigation has been made in [112] by varying the number of wells and other parameters, for example, the voltage and temperature. The obtained results showed that almost all the recombination takes place in one well, the closest to the p-type substrate. There are no holes in all the other wells, and even the first well is almost empty, since both electron and hole concentrations are low. As in the case of one well, all the injected holes recombine with electrons, and they do not reach the metal electrode. In contrast, a non-negligible part of electrons tunnels into the silicon substrate.

In general, in contrast to what happens in PL, in EL, we do not expect any gain from the use of a multiple-well configuration.

Although the study in [112] concerns silicon wells in SiO_2, the obtained results could give a rough idea of what is expected in the case of 2-D arrays of nanocrystals in a nc-$Si–SiO_2$ superlattice. The use of a superlattice, instead of a single layer of 2-D arrays of nanocrystals does not offer any advantage in EL compared to PL. The obtained EL efficiency in the literature was, in general, low, below 10^{-5} [104], and this mainly is attributed to the intrinsic difficulty to inject carriers into the nanocrystals. The optimum case is expected to be a structure with a 2-D array of nanocrystals in a layer at a tunneling distance from the silicon substrate.

4. CHARGING OF SILICON NANOCRYSTALS SINGLE ELECTRON DEVICES

Silicon nanocrystals in SiO_2 constitute a very good candidate for use in single electron devices, due to material and process compatibility with the well-established IC technology (113–118). The IC compatible processes used involve either ion implantation of silicon into SiO_2 followed by annealing or LPCVD or PECVD deposition of silicon on a very thin SiO_2 layer, followed by high-temperature oxidation.

The active part in a single electron memory is a MOS capacitor, in which the oxide layer contains a 2-D layer of silicon nanocrystals at a tunneling distance from the silicon substrate, as shown in Figure 36. The top oxide is relatively thicker than the tunneling oxide, to prevent carrier injection from the gate electrode. The silicon nanocrystal memory uses, in general, two more electrodes (source and drain), and it operates as a three-terminal device. The MOS structure may be used to evaluate the quality of the nanocrystals. Single electron charging of the nanocrystals is evidenced by applying a vertical electric field between the gate metal and an ohmic contact on the backside of the silicon substrate. Capacitance-voltage (C-V) and current-voltage (I-V) characteristics may be used in this respect. The C-V curves show an hysteresis effect, due to charging of the silicon nanocrystals, while I-V curves show N-shaped behavior [119–121]. To correlate the observed hysteresis with charge trapping in the nanocrystals, one has to minimize all other causes

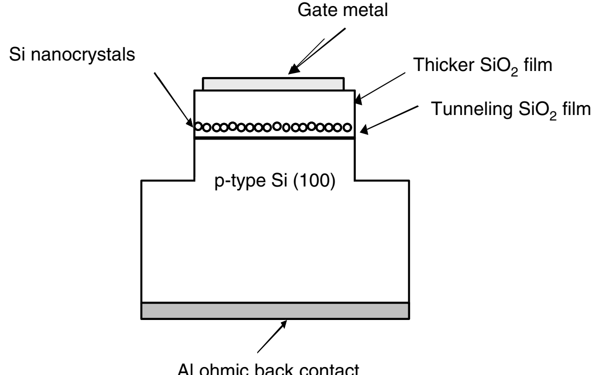

Figure 36. Basic structure used in a silicon nanocrystal memory. The bottom oxide is a tunneling oxide and the top oxide is thicker.

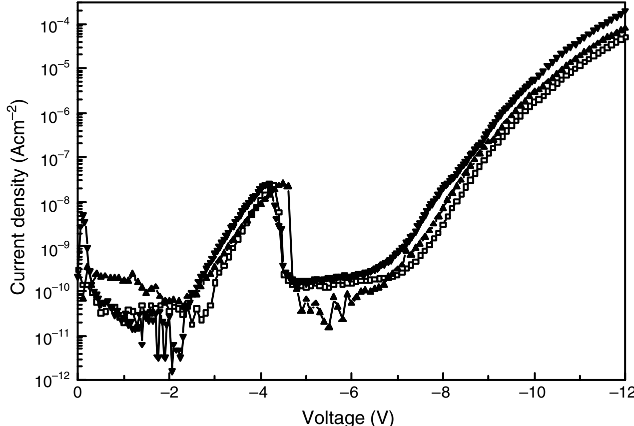

Figure 38. Current-voltage (I-V) curves from a MOS structure with silicon nanocrystals as in Figure 36. The I-V curves from three different samples are shown. These curves exhibit N-shaped behavior, attributed to charging of silicon nanocrystals. Reprinted with permission from [119], D. Kouvatsos et al., *Mater. Sci. Eng., B* (to appear, 2003). © 2003, Elsevier.

of hysteresis (defects within the oxide and at the different Si–SiO_2 interfaces, including the interface of silicon dioxide with the nanocrystals). The hysteresis ΔV due to the nanocrystals is observed when the voltage is swept from deep inversion to deep accumulation and back. An example is given in Figure 37 [119], where the substrate was p type and trapping of holes was observed (counterclockwise hysteresis). The measured hysteresis ΔV depends on nanocrystal size, being smaller for smaller nanocrystals. An example of a N-shaped I-V curve from the same sample is shown in Figure 38 for three different structures examined. The current shows a peak at a voltage of -4 to -5 V. This peak corresponds to hole charging of the nanocrystals. There is direct correlation between this peak in the current and the onset of C-V curves. This is illustrated in Figure 39, which shows C-V curves corresponding to successive voltage sweeps, starting from $+1$ V and going to negative values, with successively higher negative end voltage. The curves corresponding to sweeps from 1 to -2 V and back, and from 1 to -4 V coincide. The curve corresponding to a sweep from -4 to 1 V is considerably shifted with respect to the 1 to -4 V sweep. The sweeps with negative end voltage higher than -4 V are further shifted to more negative values. A capacitance drop also is observed at around -4 V, which also correlates with the peak in the current. However, the observed shift ΔV may be related not only to nanocrystal charging but also to charges at the interfaces between silicon nanocrystals and silicon oxide. By appropriate annealing, these interface states may be minimized to separate the nanocrystal charging effect [120, 121].

Silicon nanocrystal memory devices published so far are based on the threshold voltage shift, induced by the presence of nanocrystals in the gate dielectric of a field effect transistor [118, 120]. Compared to standard floating gate Flash electrically erasable programmable ready only memory (EEPROM), the difference is that in the case of silicon nanocrystal memories, the floating gate is not composed of a continuous nanocrystalline silicon layer, but it is composed of discrete nanocrystal dots, which are not electrically

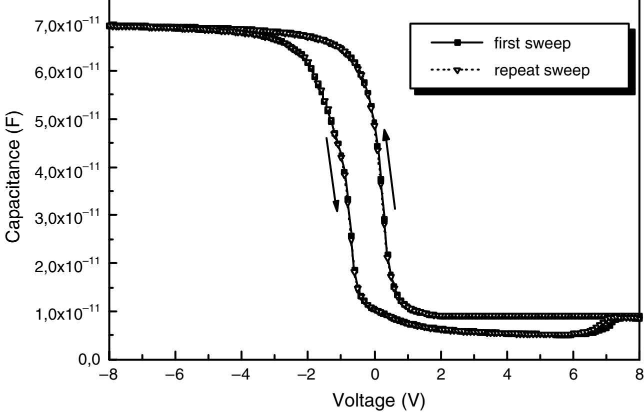

Figure 37. Double C-V curve from a MOS structure with silicon nanocrystals as in Figure 36. An hysteresis is observed, attributed mainly to silicon nanocrystal charging. Reprinted with permission from [119], D. Kouvatsos et al., *Mater. Sci. Eng., B* (to appear, 2003). © 2003, Elsevier.

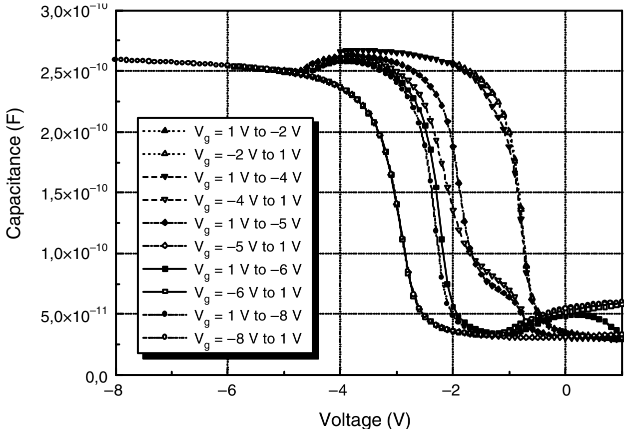

Figure 39. Multiple double C-V sweeps of MOS structure with silicon nanocrystals in SiO_2, biased from 1 V to increasing voltages into accumulation. Solid or open symbols are used for forward or reverse sweeps, respectively. The dip in the curves starting at $\cong$3 V is attributed to the silicon nanocrystal layer. continuous. In this way, a discrete defect in one of the nanocrystals does not lead to total charge leakage through the structure, and the memory device may still be functional. Moreover, there are other advantages of silicon nanocrystal memories compared to floating gate flash EEPROMs, such as the reduced degradation of the devices, faster write–erase times, lower operation voltage and lower power consumption.

To scale down the memory-device size, while increasing the stored charge, one has to maximize the density of silicon nanocrystals in the 2-D layer in-between SiO_2. In the case of LPCVD deposition of silicon on SiO_2, it was found that the silane (SiH_4) pressure, as well as the chemistry of the SiO_2 surface, influence significantly the silicon nanocrystal density [51], which decreases almost linearly with the increase in silane pressure. On the other hand, a chemical treatment of the SiO_2 surface before silicon deposition by 0.05% HF in deionized water, which creates surface silanol bonds (Si–OH), favorizes silicon dot nucleation and growth [51]. A QD density increase from 4×10^{11} cm^{-2} to 1.2×10^{12} cm^{-2} was measured by increasing the silanol density from 0.4 to 1.4 OH/nm^2.

5. CONCLUSION

Silicon nanocrystals in SiO_2 thin layers on silicon constitute a composite material with many interesting properties, the most important being the bright and stable PL at room temperature in the visible range and the controlled charging of the nanocrystals. These properties are size dependent and are significantly influenced by the chemical composition of the interface between silicon nanocrystals and silicon dioxide. They lead to very important applications, including light-emitting and memory devices and sensors.

GLOSSARY

Coulomb blockade effect The effect of blocking the injection of a second charge into a semiconductor under a certain electric field, due to modification of the electrostatic potential within it by the presence of the first injected charge. Injection of a second charge needs to overcome the semiconductor charging energy.

Ion implantation A technique used to incorporate different atoms into a solid at a certain depth from the surface. The atoms are ejected from different sources, they are ionized and accelerated by an electromagnetic potential under vacuum so as to be injected at high energy into the sample. Their depth distribution depends on their mass and energy.

Low-pressure chemical vapor deposition A technique used to deposit thin dielectrics or semiconductors on a solid surface from gas reactions under vacuum at high temperature.

Luminescence Intrinsic property of a material consisting in light emission at a certain wavelength under excitation by photons (photoluminescence) or under voltage excitation (electroluminescence).

Light-emitting devices Devices that emit light under electrical excitation.

Memory devices Devices used to store information. In conventional semiconductor memories, the information is stored in the form of charge.

Nanocrystalline silicon superlattice A structure consisting of ultrathin Si nanocrystal layers separated by nanometer-thick silicon dioxide.

Nanowires or quantum wires Wires with diameters below ~10 nm.

Optical gain Amplification (positive optical gain) or reduction (negative optical gain) of light from a source after interaction with a material.

Resonant photoluminescence emission Photoluminescence of the material with an excitation energy that approaches the detection energy.

Semiconductor quantum dots Semiconductor nanocrystals of diameter below ~10 nm.

Single electron devices Devices based on semiconductor nanocrystals, in which there is a possibility of controlling the injection of a single electron charge into each nanocrystal by controlling the applied electric field. Single electron devices are based on the Coulomb blockade effect.

1. INTRODUCTION

In the past decade there have been major advances in materials growth techniques as well as electron-beam lithography and reactive ion etching. Scanning probe microscopy manipulation became more advanced and able to form nanoscale structures. These developments made it possible to produce and study quasi-one-dimensional structures from metals and semiconductors.

The development of patterning and self-assembly procedure now allows fabrication of high-quality nanowires. Many techniques have been used to grow and fabricate nanowires in large quantities, from materials such as Si [1], Ge [2], GaAs [3], GaN [4], GaSe [5], Al_2O_3 [6], SiC [7, 8], Si_3N_4 [9], and various metals [10]. The nanowires not only allow the study of new physical phenomena characteristic for materials with reduced dimensions, but may also lead to future nanoscale device applications. In order to apply nanowires, one needs to study their physical and chemical properties and to understand the growth mechanism.

Semiconductor whiskers such as Si, Ge, GaN, etc. have been studied over 30 years. In recent years, however, the development of new techniques allowed much better control of size and structure of low-dimensional materials and the fabrication of nanowires. Among the nanowires from different materials, silicon nanowires (SiNWs) have attracted much attention because silicon is the most important semiconductor material as of now. Silicon nanowires differ significantly from bulk silicon and may find applications in the new emerging field of nanoelectronics.

A variety of techniques for synthesizing silicon nanowires has been developed, including lithography and etching techniques [11, 12], scanning tunneling microscopy [13], thermal evaporation [14], and laser ablation [3]. Yet it is still a challenge to control the morphology and diameter of silicon nanowires.

One of the most challenging tasks in recent years has been the synthesis of SiNWs on large scales. The well-known metal-catalyzed vapor-liquid-solid (VLS) growth model [10] was introduced by Wagner and Ellis for the unidirectional growth of silicon whiskers. In recent years, this technique has also been used for growth of silicon nanowires [3, 15, 16]. Large-scale synthesis of SiNWs has been achieved using the VLS process [17]. The preparation of bulk quantities of SiNWs makes it possible to study these materials in detail by various analytic techniques.

Bottom-up techniques deal with the growth of SiNWs from individual atoms. This can be performed with different approaches, for example by simple evaporation [18, 19], laser ablation [20], chemical vapor deposition [21], vapor-liquid-solid (VLS) growth [22], or epitaxial growth [23]. Some techniques, such as the template-directed vapor-liquid-solid growth [24] or magnetron sputter deposition [19], have been used to form aligned SiNWs.

SiNWs can also be fabricated by top-down approaches. These include electron-beam lithography with etching [25], pattern transfer [26], SiO_2 reduction under electron-beam radiation [27], or stress-limited oxidation [28].

In the area of scanning probe microscope (SPM) lithography, a variety of techniques has been developed: (1) local oxidation of silicon and metals [29–31], (2) superfine e-beam lithography using the tip of a STM as a low-energy electron source [32, 33], (3) direct movement of atoms and molecules [34], and direct mechanical modification of structures [35, 36].

SiNWs with different morphologies could be fabricated including amorphous and crystalline configurations. In particular, much attention has been given to single-crystalline SiNWs which are defect-free. Control of wire structure,

thickness, and surface layers has been achieved by various synthetic methods and post-treatments.

Noncrystalline but ordered structures, such as silicon nanotubes [37], superatom-stacking [38], and fullerene-structured SiNWs [19], have been proposed.

The surface of SiNWs has been studied in pristine form [19], hydrogen-passivated [39], silicon oxide sheathed [40], and SiC-coated [40].

SiNWs have been studied which were lightly doped with foreign atoms (such as boron [41] or lithium [42]) or had nanocrystallites such as copper silicide incorporated [43].

With most methods the SiNWs are grown or fabricated on solid supports. A few studies report on the fabrication of freestanding silicon nanowires [5, 44]. Other techniques were used to generate SiNWs incorporated in silicon oxide [45], in suspended form [46], as metal-silicon networks [47], or as composites with carbon nanotubes [48]. Silicon nanowires are widely considered to constitute the microstructure of porous silicon. Therefore, assemblies of SiNWs in parallel or other configurations have been investigated [49–52].

Various analytic techniques for structural investigation of SiNWs have been applied. Size, atomic structure, and morphology have been determined by transmission electron microscopy (TEM) [20], X-ray diffraction [14, 42], STM [41], and AFM [53]. Raman spectroscopy of silicon nanowires has been discussed with respect to bulk silicon [54, 55]. Field-emission has been studied under various conditions [56].

Electronic and thermal properties of silicon nanowires have been studied such as electron density of states [57], and phonon heat conduction [58]. In particular, the quantum confinement of charge carriers, excitons, and phonons is of interest. Charge transport is characterized by anomalous nonlinear behavior such as quantized conductance [59], negative resistance [60], hysteresis characteristics [60], and single-electron effects [61]. Optical properties, such as nonlinear behavior [62], photoluminescence [55], optical anisotropy [63], excitonic effects [63], and radiative lifetimes [64], have been studied. The results show that silicon nanowires have optical and thermal properties that differ significantly from bulk when their diameter is a few nanometers. This is mainly due to their one-dimensional electronic structure, which hardly resembles the bulk crystalline structure of silicon. The energy band structure of silicon nanowires depends on the reduction in dimension, morphology and atomic structure, and the surface conditions.

Theory of silicon nanowires was performed using the effective mass approximation (EMA) [65], first-principles techniques such as pseudopotential [65] or local density functional [39], empirical tight-binding [66], or semiempirical techniques [19]. Much attention has been given to understanding the electronic and optical properties related to the wire structures. Wires with crystalline or other network structures were considered and surfaces were either pristine or passivated. The bandgap, electronic density of states, and band edge electronic states were determined within first-principles calculations [49, 50, 57, 63, 65, 67–70] and the tight-binding method [71, 72].

The efforts in theory of silicon nanowires had intensified after in 1990 Canham [52] proposed that the observed efficient, visible photoluminescence in porous silicon is due to an array of silicon nanowires. This led to extensive theoretical studies focusing on the origin and mechanism of the luminescence and in particular on the quantum confinement in SiNWs. The two most important explanations of the photoluminescence are the quantum confinement (to Si nanoparticles and/or Si nanowires) and chemical luminescence models. There has been enormous work on porous silicon and other Si-based low-dimensional structures, in order to understand their unusual optical behaviors.

Most of the theoretical work has been done on nanowires cut out from bulk diamond-structure Si. Dangling bonds at the surface of the wires were usually passivated with hydrogen. Bandgaps and interband oscillator strengths were calculated [73]. Structural relaxation greatly improves the oscillator strength, which suggests that free nanowires are stronger light emitters than those embedded in porous silicon or other matrixes.

The strong interest in understanding porous silicon and other low-dimensional silicon structures is due to the possibility of developing Si-based optoelectronic integrated circuits (OEIC). In the past decade, many studies on porous-silicon-related nanotechnology have been stimulated by its potential applications in silicon-based optoelectronic devices.

SiNWs contain a quasi-one-dimensional electron gas which gives them novel properties for silicon-based electronic devices, such as the field-effect transistors [74], single-electron memory devices [75], silicon quantum wire lasers [76], metal-semiconductor junctions [77], or thermoelectric quantum wire arrays [78].

2. BOTTOM-UP FABRICATION

2.1. Vapor-Liquid-Solid Growth

For more than 30 years, the growth of silicon whiskers has been studied by using the vapor-liquid-solid (VLS) method. For the VLS method, small metal clusters are used to catalyze the whisker growth. The metal particle is either supported on a surface or produced in the gas phase. The diameters of the whiskers obtained from VLS are determined by the size of the metal particles. Variations of VLS techniques are solution-liquid-solid [79] and vapor-solid-solid [80] methods. All these techniques require the formation of nanoscale catalyst particles. Recently, the VLS method has been applied to grow silicon nanowires [3].

Silicon nanowires 15–35 nm in diameter were grown using SiH_4 chemical vapor deposition via Au and Zn particle-nucleated vapor-liquid-solid growth at 440 °C [81]. The Au-nucleated wires (Au-SiNWs) were grown by first evaporating 1 nm of Au onto a SiO_2 wafer. If the wafer then is annealed to 450 °C, Au particles form which will act as catalytic sites for the SiNW growth. The morphology and width of the wires critically depend on temperature and pressure used in the process [22]. At low pressure and high temperature, relatively thick nanowires grow, and thinner ones grow at higher pressure and lower temperature. The nanowires can be thinned further by oxidation. Surface oxidation can yield silicon cores as small as 5 nm.

Zn particles can also be used as catalysts but are fabricated with a different method [81]. For synthesis of Zn-catalyzed

silicon nanowires (Zn-SiNWs), a $ZnCl_2$/ethanol solution was deposited on a p-doped silicon substrate after removing the native oxide layer with HF. The wires then were grown using chemical vapor deposition from 5% SiH_4/He gas at 100 Torr. Wires in the diameter range 14–35 nm and length of 1–10 μm were grown. The wires are crystalline in the core with a 1-nm oxide coating.

The required synthesis temperatures for VLS growth of SiNWs range from 450–500 °C for gold and zinc to 950–1150 °C for transition-metal catalysts. By using low-melting-point metals low-temperature VLS growth of SiNWs can be achieved. Six-nanometer-wide SiNWs with uniform diameters were synthesized using gallium as a molten solvent, at temperatures less than 400 °C in hydrogen plasma [82]. Liquid-metal gallium has low solubility for silicon. Gallium forms a eutectic with silicon near room temperature.

2.2. Chemical Vapor Deposition

Ti-containing islands have been grown on silicon substrates by chemical vapor deposition using the decomposition of TiO_4 [83, 84]. When these islands are exposed to SiH_4 or SiH_2Cl_2, the metal catalyzes the decomposition of the silicon precursor and long SiNWs can grow. Exposing the wires to an ion beam after deposition promotes alignment of nanowires.

Quite straight SiNWs were grown using catalytic synthesis over Fe containing silica gel substrates by thermal chemical vapor deposition where silane is decomposed [85]. The fact that the nanowires are straight indicates that there are few defects and little growth stress. The nanowires are of uniform diameter of about 20 nm with a length of the order of 1 μm. A nanoparticle with a diameter of ~50 nm was found at the end of each nanowire. The center part of the nanowires is well crystallized and there is a thin amorphous surface layer, as revealed by high-resolution electron microscopy (HREM) and electron diffraction. The Raman spectrum of the wires has a prominent peak at 511 cm^{-1} with a shoulder at 490 cm^{-1}. The peak has a larger line width (about 15 cm^{-1}) and is down-shifted (about 9 cm^{-1}) as compared to that of bulk crystalline silicon. This is considered to be caused by the quantum confinement effects since similar behavior has also been found in porous silicon [86] and freestanding nanowires [87].

2.3. Laser Ablation

Laser ablation has become an important method for the synthesis of silicon nanowires [3, 88, 89]. Depending on the applied conditions, nanowires of different form and structural quality are produced. Of particular interest are long, uniform-sized and single-crystal wires, which can be fabricated in bulk quantities [90].

The internal structure of nanowires is closely related to the growth kinetics. SiNWs fabricated by laser ablation can have a high density of defects [20] and show various morphologies [91] which are closely related to the insertion of twins or the special twisting along the growth direction during the growth process. The nanowires can show morphological characteristics with straight, curved, kink, braided, and coiled shapes.

The combination of laser ablation cluster formation and vapor-liquid-solid (VLS) growth was used to synthesize SiNWs [3]. Laser ablation of a Si target with small Fe content was used to prepare metal catalyst clusters that determine the width of the silicon nanowires. The method produces bulk quantities of single-crystal silicon nanowires with diameters of 6 to 20 nm and lengths ranging from 1 to 30 μm.

It has been found that the addition of metal to the starting material has negligible effect on the yield of the SiNWs produced by laser ablation. Rather, the addition of SiO_2 powder to the Si target significantly increased the yield [17]. This suggests that silicon monoxide (SiO), which is produced by the reaction between Si and SiO_2, plays an important role in the growth of silicon nanowires (oxide-assisted growth model).

Silicon nanowires were synthesized by laser ablation of mixed SiC and SiO_2 powders at 1400 °C [92]. The SiNWs were about 14 nm in diameter and coexisted with a small amount of SiC nanoparticles. Such silicon nanowires have the diamond-type crystal structure and the nanoparticles are cubic SiC.

Silicon nanowires with high yield, uniform diameter distribution, and high purity were grown by excimer laser ablation at high temperature [88]. The target was made by mixing silicon powder with nano-sized Ni and Co powder (about 5 wt.% each). The mixed powder was hot-pressed at 150 °C to form a plate target. The target was ablated at a temperature of 1200 °C by using an excimer laser with a wavelength of 248 nm at pressure of about 500 Torr Ar. The ablated Si atoms self-organize into nanowires as a dark yellow colored deposit on a quartz tube wall [88]. For the ablation of targets containing a Co-Ni catalyst, most silicon nanowires have a curve-shaped morphology and some are largely coiled. More than 99% of the deposit is as silicon nanowires. Most of the silicon nanowires have diameters of 13 ± 3 nm. Their length ranges from a few tens of micrometers to hundreds of micrometers. Silicon nanowires produced from Co-Ni catalyst-free targets are different. Most of the nanowires have a diameter, which is not uniform at all, ranging from 15 nm to 60 nm.

Using laser ablation at high temperature, silicon nanowires were fabricated with very small diameters from 3 to 43 nm up to a few hundred microns long [16]. Twins and stacking faults have been observed in the silicon core of the nanowires.

By ablation of a silicon monoxide target with a pulsed KrF excimer laser at 1200 °C in an argon atmosphere, high-purity silicon nanowires were fabricated in bulk quantities [93]. The yield and linear growth rate can reach 30 mg/h and 500 μm/h, respectively.

Along with SiNWs, chains of silicon nanoparticles have also been formed. These were synthesized by laser ablation of a target containing metals over a temperature range 910–1120 °C [27].

2.4. Thermal Evaporation

Thermal evaporation of SiO powders was found to produce high-purity silicon nanowires in bulk quantity [94]. Growth of the SiNWs was studied in a closed system with different ambient conditions [95]. A silicon nanowire growth rate of

10 nm/h could be routinely obtained. With increasing ambient pressure, the yield of SiNWs decreased and the diameter of the SiNWs increased.

Thermal evaporation and laser ablation of SiO_2 powders were studied [17], by both methods separately and by combining the methods. The growth rate of silicon nanowires was higher with the assistance of laser ablation than with thermal evaporation alone. The solid source was pure silicon powder mixed with 70% of SiO_2 powder. After 12 hours of thermal evaporation, a silicon nanowire product (sponge-like, dark red in color) formed on the inside of the quartz tube. The method leads to two types of products, silicon nanowires with uniform and smooth surfaces (the major component) and silicon nanoparticles. Most silicon nanowires were very long, 10 microns and more, and randomly oriented. Most silicon nanoparticles appeared in form of chain [17].

Elevated temperature synthesis has been used to fabricate SiO_2-passivated (sheathed) crystalline SiNWs [80]. The nanowires were grown by heating a crucible with a Si-SiO_2 mixture in flowing argon gas. Condensation of nanowires as dark brown deposits was found in a narrow region on the wall of the tube enclosing the crucible. The central crystalline silicon core was $\sim$30 nm in diameter and the outer SiO_2 sheathing was 15 nm in thickness [80].

Thermal evaporation of a powder mixture of Si and SiO_2 [15, 40] was found to be an effective method for the growth of silicon nanowires on a silicon wafer [17]. They consist of a core of crystalline silicon clothed by a shell of silicon oxide with a thickness up to half of the wire radius [88]. Very weak photoluminescence at 630 nm (2 eV) was obtained for the as-grown sample. The as-grown SiNW sample was transferred to an ion-beam deposition chamber and a mixture of methane, hydrogen, and argon (mixture ratio 1:50:173) was used to deposit a thin film of SiC onto the sample. TEM analysis showed that the silicon dioxide layer was replaced by a cubic silicon carbide layer coating the silicon nanowires.

The synthesis of SiNWs on iron patterned silicon substrates has been performed by thermal evaporation of pure silicon powder [18]. This results in straight crystalline SiNWs with diameters of 10–60 nm. The growth of the nanowires can be controlled by positioning of iron squares on the silicon substrate using current semiconductor technology. For nanowire formation, p-type silicon(100) substrates were patterned with 5-nm-thick iron film by electron-beam evaporation through a shadow mask, which contains square-shaped openings of micrometer size. The substrates were then annealed in argon at 300 °C for 3 h. Thermal evaporation of silicon powder from a furnace was then used to grow the SiNWs.

Si nanowires have been grown by vapor deposition on various substrates including sapphire, Al_2O_3, and Si(111). Step-flow growth of silicon nanowires by gas-source molecular beam epitaxy on sapphire was used to fabricate parallel silicon nanowires [96]. The wires were aligned along the substrate steps and formed uniformly with 50 nm width and 1 nm height. Si nanowires were grown on an Al_2O_3 substrate at ambient pressure by using $SiCl_4$ as Si source [97]. Highly oriented amorphous SiNWs have been grown on Si(111) by a solid-liquid-solid (SLS) mechanism [98]. The length and diameter of the nanowires are almost uniform, 1 μm and 25 nm, respectively.

2.5. Magnetron Sputter Deposition

Bundles of parallel silicon nanowires were produced by using a magnetron sputter source for the deposition of pure silicon vapor onto highly oriented pyrolytic graphite (HOPG) [19]. The experiments were done in UHV at 10^{-10} torr and no catalyst particles were used. Therefore the nanowires grew from quenching the pure silicon vapor on the cold substrate. Since HOPG is atomically flat and chemically inert, the wires are formed by quasi-free growth. Uniform diameter for the wires in a bundle is found (Fig. 1).

2.6. STM-Induced Growth

In the setup of an STM, silicon nanowires were grown by applying a voltage at constant current between a heated silicon substrate (700 °C) and a gold tip [13]. Silicon atoms were deposited onto the apex of the gold tip by field evaporation. The applied sample voltage was 5 V and the tunneling current was 10 nA which yields a tip-sample distance of 0.6 nm. The voltage was applied for 15 minutes during which the deposition of silicon on the gold tip was monitored by *in-situ* scanning electron microscopy (SEM). The diameter and length of the wire were 20–150 nm and 3 μm, respectively. Growth of the silicon nanowire occurs due to atom transfer from the substrate to the tip. The maximum growth rate (for the maximum diameter of the wire of 150 nm) was 6.0 nm/s. The deposition rate was 2.1×10^7 atoms/s.

2.7. Template-Directed Growth

SiNWs have been synthesized in nanoporous alumina membranes using a combination of Au electrodeposition and vapor-liquid-solid growth at 500 °C using SiH_4 as the silicon source [24]. The diameters of the SiNWs were 200 ± 54 nm,

Figure 1. Several bundles of parallel silicon nanowires produced by magnetron sputter deposition of silicon on highly oriented pyrolytic graphite (HOPG) in UHV. Reprinted with permission from [19], B. Marsen and K. Sattler, *Phys. Rev. B* 60, 11593 (1999). © 1999, American Physical Society.

which was close to the pore size distribution of the membranes. The nanowires consist of a crystalline Si core, oriented in the (100) or (211) growth direction, with a thin (<3 nm) native oxide coating. The two ends of the nanowires are terminated by segments of gold, which result from the VLS mechanism of growth. This technique could also be applied for the synthesis of smaller diameter nanowires by using anodized aluminum oxide templates with pore sizes in the range of 10–100 nm [99].

3. TOP-DOWN FABRICATION

3.1. Lithography and Etching

Electron-beam or optical lithography combined with reactive ion etching are top-down methods for silicon nanostructure formation. These are conventional techniques employed in the microelectronic industry. SiNWs fabricated with these techniques are typically broader than 100 nm. However, by using sequences of sophisticated lithographic, etching, and oxidation techniques, much narrower SiNWs could be produced (Fig. 2). Crystalline SiNWs with diameters down to 10 nm and smooth surfaces have been fabricated by advanced procedures of electron-beam (EB) lithography and wet etching [100]. Amorphous SiNWs have been generated by optical lithography and reactive ion etching of a 9-nm-thick amorphous silicon film on a silicon crystal surface [58].

SiNWs were fabricated using an inorganic SiO_2 electron-beam (EB) resist process [25]. In this procedure, a conventional organic resist is substituted by an inorganic SiO_2 resist. The conventional EB lithography process using an organic resist shows relatively low resolution of around 30 nm. In the inorganic EB resist process, a resolution of 15 nm can be achieved. This is because the inorganic SiO_2 resist is hardly affected by the secondary electrons produced in the primary EB scattering. The technique was used to generate 15-nm-wide silicon nanowires and to fabricate a silicon nanowire memory transistor [25].

Linear windows 15 nm wide in a 0.3-nm-thick silicon oxide layer have been formed by focused electron-beam

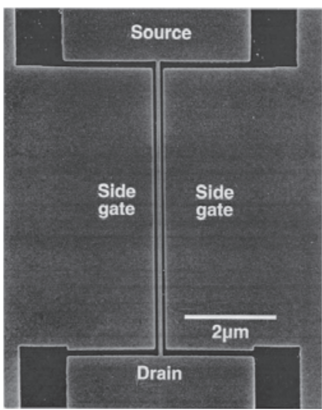

Figure 2. A silicon nanowire device fabricated with high-resolution electron-beam lithography. The wire is 70 nm wide over the 6-μm length of the side gates with a side gate separation of 80 nm. (EB) irradiation and successive HF-chemical etching [101]. Si-selective epitaxial growth (Si-SEG) with Si_2H_6 gas in the linear window of the mask has then been applied to fabricate silicon nanowires.

Silicon nanowires with SiO_2 boundaries were fabricated using a process based on SiGe/Si heterostructure [102]. First a Si/SiGe/Si heterostructure is grown on a silicon substrate with very low-pressure chemical vapor deposition. This is followed by lithography and reactive ion etching to form trench structures. Then SiGe is selectively etched over silicon and finally thermal oxidation is applied to obtain the silicon nanowires. A nanowire diameter of about 40 nm is obtained. The diameter can be controlled by the parameters used for selective chemical etching and thermal oxidation.

Orientation-dependent etching with subsequent oxidation has been applied to obtain silicon nanowires [12]. Silicon nanowires 2 nm wide were fabricated through a combination of a partly shifted resist pattern and orientation-dependent etching [53]. A $\{110\}$ silicon substrate is etched with KOH using a line pattern mask, which is shifted in the $\langle 111 \rangle$ direction at the line center position. The technique takes advantage of the fact that during silicon etching with KOH, the etching rate of the $\{111\}$ plane is more than 100 times lower than that of the other planes. Due to this selective etching property and to the shift technique, line patterns smaller than the beam diameter of lithographic tools can be formed.

SiNWs were generated by application of vertical ultrafine SiO_2 wall masks using oxidation of a polycrystalline silicon (poly-Si) layer [103]. For generation of a wall mask, electron cyclotron resonance (ECR) plasma etching and wet etching of the poly-Si layer after the sidewall oxidation has been applied. The wall masks are 10 nm wide and 90 nm high, and Si nanowires 10 nm wide and 18 nm thick have been obtained.

3.2. Selective Thermal Desorption

Silicon nanowires were fabricated using electron-beam-induced selective thermal desorption (EB-STD) of SiO_2 in silicon substrates [104, 105]. Electron-beam interference fringes have been used to form a 10-nm periodic surface structure of Si and SiO_2 by STD [104].

3.3. Pattern Transfer

Pattern transfer is an effective formation method for SiNWs. A process has been used for preparing high densities (up to 500 μm^{-2}) of well-passivated sub-5-nm diameter silicon nanowires [26]. In this formation process, a fine-grained natural mask is deposited. Subsequently, the pattern is transferred into the silicon substrate by reactive ion etching. The process was applied on silicon-on-insulator material, where the buried oxide layer acts as an etch stop. This isolates the nanowires from the bulk and from each other. The nanowire diameter was then brought below 5 nm by self-limiting oxidation. Subsequently, hydrogen-rich amorphous silicon nitride, prepared by plasma enhanced chemical vapor deposition, was deposited to act as a source of hydrogen for passivation of surface dangling bonds.

A resist film can be patterned in various ways in order to produce nanoscale structures on a substrate. Dots or

lines of small size or diameter can be written into the resist leaving openings to the substrate material. Applying such procedures, silicon nanowires have been fabricated using electron cyclotron resonance plasma deposition of a SiO_2 film through the openings of a patterned resist film [106].

3.4. Self-Limiting Oxidation

Self-limiting oxidation can be used to drastically reduce the active diameter of silicon nanowires. An initially broad diameter distribution can become much narrower and is significantly shifted to smaller diameters if the SiNWs are oxidized at elevated temperatures [26] (Figs. 3, 4).

Planar single-crystal silicon nanowires down to 8 nm in diameter were generated using self-limiting oxidation [28]. The SiNWs were formed on silicon-on-insulator (SOI) substrates with electron-beam lithography followed by a metal liftoff process and a silicon plasma etch. Oxidation was then used to shrink the wires to a sub-10-nm diameter. The stress generated by the expansion of the oxide during oxidation eventually stops the reaction, leaving a narrow silicon core. Extremely thinned SiNWs with 3–5 nm width were obtained by utilizing SiO_2 side-wall masks and self-limiting oxidation [107].

3.5. Electron-Beam-Induced Reduction of SiO_2

A thin film of SiO_2 can be directly reduced to Si under electron-beam irradiation [27]. If SiO_2 is irradiated with a high-intensity 100-keV electron beam with a dose of $\geq 3 \times 10^9$ Cm^{-2} of nanometer scale, silicon nanowires can be formed as small as 2 nm in diameter. No resist or chemical development is required.

3.6. Oxygen Implantation

Silicon nanowires embedded in SiO_2 have been fabricated using *in-situ* multiple low-energy oxygen implantation in combination with silicon molecular beam epitaxy [23].

A patterned silicon substrate was used for the formation of the nanowires. The starting substrate was a p-type on-axis Si(100). V-grooves along [011] with well-developed (111) facets were produced by electron-beam lithography and KOH etching at a 1-μm interval. Silicon nanowires can be generated by oxygen implantation at the bottom of the V-groove. Using silicon molecular beam epitaxy (MBE), SiNWs can be formed at the hilltop. Thickness and width of V-groove and hilltop-type nanowires are about 10 nm and 10 to 50 nm, respectively. In view of optoelectronic applications for these techniques, parallel SiNWs were formed and their use as Bragg reflector was studied.

3.7. AFM and STM Lithography

SiO_2 nanoscale structured layers on a silicon surface could be basic constituents for ultra-large-scale integrated (ULSI) nanocircuits. Silicon oxide pattern and SiNWs have been performed on the silicon surface by using STM and AFM [108–111]. Silicon nanowires were also fabricated by using mechanical atomic force lithography [112].

4. ANALYTIC TECHNIQUES

4.1. Microscopy and Electron Diffraction

There are various analytic techniques used to investigate the properties of silicon nanowires. Some of these are listed and discussed in the following paragraphs.

The most often used technique for a first study of silicon nanowires is high-resolution electron microscopy (HREM) [20, 88, 112–115], often combined with selected area electron diffraction (SAED) [42, 114]. The techniques are applied to determine the diameter distribution and morphology of the nanowires. The atomic structure of SiNWs, such as single-crystalline and amorphous, has been determined. Some growth techniques produce crystalline SiNWs, however, with a high density of defects, such as micro-twins and stacking faults [20]. These can well be studied with transmission electron microscopy (TEM). A profile projector has

been used to enhance the magnification for examination of the TEM micrographs [113]. A thin amorphous silicon oxide layer is usually visible on the surface of the SiNWs, determined by electron diffraction. In some studies, field-emission scanning electron microscopy (FESEM) [115] has been used for structural characterization.

A technique has been developed to improve imaging of SiNWs with the plane-view transmission electron microscope [107]. The nanowires are covered with a Si_3N_4 holding layer in order to fix them and to give high contrast in the TEM image of the crystalline fine structure. The lattice image of very fine (3- to 5-nm-wide) SiNWs could be studied.

The X-ray diffraction (XRD) spectrum of crystalline silicon nanowires [88] contains several peaks, which are clearly distinguishable. They all can be indexed to the diamond structure of bulk silicon, both by their peak position and by their relative intensity. The lattice parameter of the silicon nanowires is close to the value obtained for bulk silicon.

A scanning reflection microscope (SREM) has been used in combination with a scanning tunneling microscope (STM) for SiNW studies [105]. By applying the combined SREM/STM methods one can obtain the information on surface geometric and crystallographic properties at the same position on a sample.

A high-resolution electron microscope with energy dispersive X-ray fluorescence (EDAX) was used for morphology and composition analysis [88]. In the EDAX spectrum of pure SiNWs only one peak is visible, which corresponds to silicon.

Extended X-ray absorption fine-structure (EXAFS) studies are used for structural investigation, in particular to study short-range versus long-range order. EXAFS measurements showed a progressive degradation in long-range order going from bulk silicon to nanowires to porous silicon [116]. For silicon nanowires, various types of defects are observed, but EXAFS spectra show that the degree of disorder in SiNWs is usually relatively small and the nanowires are essentially crystalline.

Microprobe reflection high-energy electron diffraction (μRHEED) [105] and microprobe Auger electron spectroscopy (μAES) have been used to study the surface atomic structure and composition of silicon nanowires and oxide masks [101, 105].

Scanning tunneling microscopy (STM) has been applied both for structural analysis [41] and for the fabrication [13] of SiNWs. Si nanowires from a liquid suspension were deposited on highly oriented pyrolytic graphite (HOPG) and analyzed by STM [46]. Scanning tunneling spectroscopy (STS) has been applied for SiNW electronic structure studies [41]. STM and STS measurements have been performed on boron-doped and undoped silicon nanowires [41]. Regular nanoscale domains were observed on the silicon nanowire surface, which were attributed to boron-induced surface reconstruction. STS measurements in silicon nanowires showed an enhancement of electrical conductivity by boron doping [41]. An STM was used for nanofabrication by taking the gap between a gold-tip and a silicon substrate as active region to grow silicon nanowires [13].

The width of silicon nanowires was measured using atomic force microscopy (AFM) [53, 117]. SiNWs deposited on the substrate from a liquid suspension were studied. Different AFM modes can be applied and tuned to the specific applications. Tapping mode and contact mode AFM were used to image SiNWs on HOPG and mica [46] where the coupling to the substrate is weak.

4.2. Raman Spectroscopy

Raman scattering is very sensitive to the lattice microstructure and the crystal symmetry of microcrystalline materials. The Raman spectra of silicon nanowires, single-crystalline silicon (c-Si), and completely oxidized silicon nanowires were recorded and compared [16]. The first-order Raman peak of c-Si at 521 cm^{-1} is symmetrical with a full width at half maximum (FWHM) of 5 cm^{-1}. The Raman spectrum for fully oxidized silicon nanowires shows a very broad asymmetric peak. A redshift of the phonon frequency was observed in Raman spectra of SiNWs and assigned to the compressive stress from the oxide skin at the wire surface [55]. The Raman peaks are found to shift and broaden with decreasing diameter [54, 118] (Fig. 5). Similar results were obtained with Raman spectra that were taken from porous silicon layers with different confinement size [119]. Theoretical studies resulted in similar conclusions for Raman spectra of SiNWs [120].

Raman spectra of SiNWs were obtained for several phonon modes at room temperature [118]. In addition to the fundamental phonon mode, overtone and combination modes were observed. Phonon confinement is used to explain the results. The confinement effect becomes more obvious for wire width less than 22 nm. Silicon nanowires with average diameter of 15 nm and length from a few micrometers to millimeters were studied. Compared to bulk silicon, the silicon nanowires show redshift of all Raman peaks and a broadening.

Raman scattering has also been performed on silicon nanoparticle chains and showed that phonons are confined in the silicon nanospheres [121].

4.3. Electron Spectroscopy

X-ray photoelectron spectroscopy (PES) [113] and electron energy dispersive spectroscopy (EDS) [113] were used to perform chemical analysis on SiNWs. These techniques together with transmission electron microscopy and Raman spectroscopy showed that the wires consist of a crystalline silicon core with an amorphous silicon oxide surface.

Ultraviolet photoelectron spectroscopy (UPS) can be used to study both the crystalline structure and the chemical composition of a material. Silicon nanowires are essentially crystalline silicon encapsulated by silicon oxide [116] when some of the common fabrication methods are applied, a fact which can be obtained by the measurement of Si 2p and valence-band photoelectron spectra.

The bonding state and chemical composition of SiNWs were determined by parallel electron-loss spectroscopy (PEELS). It has been used to measure the concentration of Li ions in Li-doped SiNWs [42].

4.4. Optical Spectroscopy

UV-photoluminescence (UV-PL) spectroscopy was used to study the optical properties of nanowires and their electronic structures. Photoluminescence of porous silicon with varying confinement size was experimentally studied and explained by considering silicon nanowire and nanoparticle properties [119]. PL spectra have been taken, for example, for SiNWs fabricated on crystalline silicon (100). The wires emitted photoluminescence in the range of 500–600 nm [55]. Direct evidence of quantum confinement from size dependence of the PL of SiNWs was obtained [122]. The temperature dependence of the visible PL was determined over a wide range. For SiNWs on sapphire substrates the PL was observed at 9 and 300 K with a broad emission peak at 750 nm. The PL intensity at 9 K is over 20 times larger than that of 300 K. The PL peak barely shifts between 9 and 300 K [96].

4.5. Electrical Conductivity

In most studies of electrical conductivity, current-versus-voltage curves are taken, often at different temperature. Other techniques have been applied as well. Scanning Maxwell-stress microscopy (SMM) was used to investigate anomalous electrical conductance in a 100-nm-wide silicon wire [60]. SMM is capable of obtaining topographic and surface potential images simultaneously and gives the relationship between surface charging and electrical characteristics [123, 124].

5. MORPHOLOGY, SURFACE, DOPING

5.1. Form and Size

Most growth techniques yield nanowires with cylindrical shape, with a crystalline silicon core and an amorphous silicon oxide surface (Fig. 6). Theoretical expressions were derived for the calculation of energy eigenvalues in cylindrical and elliptic nanowires with finite potential barriers [125]. SiNWs with other cross sections, such as rectangular, have been obtained with top-down fabrication methods.

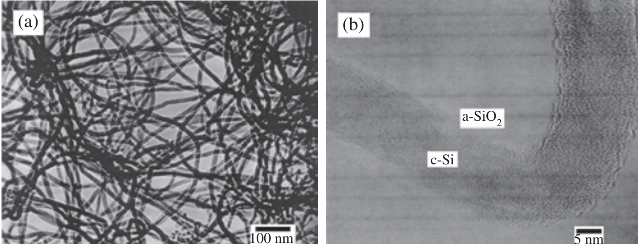

Figure 6. (a) TEM images of silicon nanowires with smooth surface. (b) Closer view TEM image showing crystalline core with amorphous oxide surface layer. Reprinted with permission from [139], Y. H. Tang et al., *J. Appl. Phys.* 85, 7981 (1999). © 1999, American Institute of Physics.

Such SiNWs have been used as model systems in several theoretical studies [63, 65, 126]. Pentagon-shaped silicon nanowires with widths around 300 nm were obtained by using Si/SiGe epitaxy technique, reactive ion etching, and subsequent selective chemical etching [127]. SiNWs with rectangular, triangular, and trapezoidal cross sections were studied using the effective mass approximation [128]. It was shown that the order of energy levels depends strongly on both the cross-sectional shape and the lattice orientation in wire direction.

For many experiments and applications it is desirable to have very thin and very long SiNWs. By using a sequence of procedures, the fabrication of such SiNWs can be achieved.

A combination of electron-beam lithography, NF_3 reactive ion etching, and dry thermal oxidation was used to fabricate 2-nm-wide silicon nanowires with an aspect ratio of more than 100 to 1 [129] (Fig. 7). The small width of the nanowires was realized by applying the self-limiting oxidation process. Fabrication of silicon nanowires as long as 10 μm has been reported [15].

An important property of SiNWs is the uniformity of their diameter and the smoothness of the wire surface. Many growth and fabrication techniques lead to SiNWs with well-defined and uniform diameters. However, under some experimental conditions, SiNWs with periodic instabilities of the diameter were found [130].

SiNWs were fabricated in different environments such as quasi-free [44], dispersed in liquid [46], parallel aligned in bundles [19], horizontally placed on substrates [18], perpendicular to a substrate [131], or inside a solid host (SiO_2 [45] or diamond nanocrystal [131]). An air-bridge-structured SiNW was made by micromachining a silicon-on-insulator (SOI) substrate [44]. Nanowires 20–100 nm in diameter and 300–600 nm in length were isolated from the substrate by an air bridge with a gap of about 300 nm. SiNWs have been dispersed in liquid using a mild etching treatment [46]. Subsequently, an electrophoresis mounting process was used to mount SiNWs onto electrodes of a prototype device. SiNWs were also fabricated perpendicular to the base of a substrate, analogous to the bristles of a brush [131]. The nanowire diameters were ~60 nm, the lengths were 500 nm, and the spaces between the wires were 130 nm.

Silicon nanoparticle chains can be formed together with silicon nanowires by using combined laser ablation and thermal evaporation of Si powder mixed with SiO_2 powder [17]. Using this method, bulk quantities of silicon nanoparticle chains have been produced [132] (Figs. 8, 9). The nanoparticle chains consist of equally spaced crystalline spherical silicon particles connected by silicon oxide bars. The transition from silicon nanowires to silicon nanosphere chains was determined by the annealing temperature, ambient pressure, initial silicon nanowire diameter, and the oxide-state of the outer layers of the silicon nanowires.

5.2. Width Reduction and Control

Various techniques for width reduction and control have been applied, for both the bottom-up and top-down techniques of synthesis. The growth techniques usually produce SiNWs with not exactly the same diameter but rather a distribution of diameters. It is desirable to have this distribution as narrow as possible. Also, one would like to have methods available to vary the size distributions.

Si nanowires with different diameters have been synthesized by laser ablation in different ambient gases [113]. SiNWs with the diameter distribution peaks at ~13.2 and ~9.5 nm have been obtained respectively in He and Ar (5% H2). SiNWs produced in N_2 had the smallest peak diameter at 6 nm.

For SiNWs produced by thermal evaporation in ambient gas, the diameter can be controlled by the ambient pressure. In one of these studies, the ambient pressure was changed between 150 and 600 torr and an increase of the average wire diameter from 12 to 23 nm was observed [133]. The mean diameter of the SiNWs was found to be proportional to the 0.4th power of ambient pressure.

Silicon nanowires with different diameters and morphologies were synthesized by laser ablation of a target containing metals over a temperature range 910–1120 °C [27]. SiNWs with larger diameters were formed in lower-temperature zone while silicon nanowires and silicon nanoparticle chains of smaller diameters were formed in higher-temperature zone. The study shows that the morphology and diameter of silicon nanowires synthesized by laser ablation not only correlate with the growth temperature of SiNWs, but also with the nature of the catalyst.

Diameter-controlled vapor-liquid-solid (VLS) synthesis of single-crystal silicon nanowires was reported [115]. Gold nanoclusters were used as catalysts. Starting with 5-, 10-, 20-, and 30-nm-sized gold clusters, silicon nanowires with mean diameters of 6, 12, 20, and 31 nm, respectively, have been grown. The nanowires have single-crystal cores sheathed with 1–3 nm of amorphous oxide and the cores remain highly crystalline for diameters as small as 2 nm.

The width of silicon nanowires grown by thermal evaporation of SiO at 1350 °C in a closed system depends on the applied ambient pressure [95]. With increasing ambient pressure, the diameter of the SiNWs increases.

In experiments where the nanowires are grown on a substrate, the type and temperature of the substrate may be important. It has been found [134] that the substrate temperature played a dominant role in controlling the diameter and morphology of SiNWs produced by evaporation.

Thickness of silicon nanowires can well be controlled by top-down techniques such as lithography with etching, using mask transfer, etc. For example, SiNWs of controlled width were obtained when fabricated by plasma deposition of a SiO_2 film through a mask with subsequent reactive ion etching [106].

5.3. Atomic Structures

Most preparation techniques for SiNWs lead to the formation of crystalline structures (Fig. 10). The degree of crystallinity and the lattice orientation have been determined for such SiNWs [114]. Defects inside such silicon nanowires could be significantly reduced by annealing the nanowires at 1100 °C for 6 h [135]. Stacking faults and twins were annihilated upon annealing. Raman spectra confirmed that the bulk specimen became almost defect-free by the heat treatment. Polycrystalline silicon nanowires were obtained by electron-beam lithography and thermal oxidation in standard polycrystalline silicon material [136].

Amorphous silicon nanowires have been grown using AuPd nanoparticles as catalysts [137]. The growth process appears to be the vapor-liquid-solid (VLS) mechanism. The controlled growth of oriented amorphous silicon nanowires on Si(111) was also reported [98].

Most applied synthetic techniques produce slightly curved or straight SiNWs. However, under some experimental conditions, uncommon shapes and structures have been obtained.

Silicon nanowires synthesized by laser ablation can exhibit straight, curved, kink, braided, and coiled shapes [91]. The formation of various morphologies of silicon nanowires is closely related to the insertion of twins or special twisting along the growth direction during the growth process. Flower-like and octopus-like forms of silicon nanowires were reported by heating a SiO_2 plate at 1600 °C under argon [138]. Spring-shaped, fishbone-shaped, and necklace-shaped silicon nanowires were observed after synthesis by laser ablation of silicon powder targets at 1200 °C [139].

The stability, morphology, and electronic structures of "hypothetical" silicon nanotubes were calculated with first-principles techniques based on density functional theory [37]. The band structure calculations show that, similar to carbon nanotubes, depending on their chiralities, silicon nanotubes may have metallic (armchair) or semiconductor (zigzag and mixed) properties (Fig. 11).

The electronic properties of silicon nanowires with "super-atom stacking structure" were investigated using a generalized tight-binding molecular dynamics scheme [38]. The nanowires are stable when the core consists of fourfold coordinated atoms and is surrounded by a threefold coordinated outer surface (Fig. 12).

Silicon nanowires were grown on highly oriented pyrolytic graphite in ultrahigh vacuum at 10^{-10} torr from pure silicon vapor [19]. No catalyst particles are used where the nanowires could start to grow. It was postulated that a fullerene-based structure with a Si_{24}-unit is the seed for nanowire growth under UHV conditions and that the wire formation occurs by adding further Si_{24} units in one direction. Such fullerene-structured silicon nanowires (Fig. 13) are calculated to be stable.

Highly pure SiNWs are required for many experimental studies. Among the various fabrication techniques, those without metal participation usually produce SiNWs with less impurities. High-purity silicon nanowires in bulk quantity, for example, have been grown from SiO in a high-temperature tube furnace [94]. Also, high-purity SiNWs of uniform diameters around 15 nm were obtained by sublimating a hot-pressed silicon powder target at 1200 °C in a flowing carrier gas [14]. A review of the synthesis of highly pure, ultralong, and uniform-sized semiconductor nanowires in bulk quantity by the methods of laser ablation and thermal evaporation of semiconductor powders mixed with metal or oxide catalysts has been given [140].

5.4. Surface Reactivity and Passivation

Silicon nanowires are usually made of a crystalline core of pure silicon with a surface layer of amorphous silicon oxide. Other types of coatings have also been studied. For example, a reaction of SiNWs with methane and hydrogen has been performed to produce a thin coating layer of cubic silicon carbide (beta-SiC) [40].

In theoretical studies the nanowires are often coated with hydrogen in order to saturate the silicon dangling bonds. Unpassivated and H-passivated SiNWs were compared [141]. The role of H-passivation has been explored by considering unpassivated, partially passivated, and fully passivated NWs. When one H atom is removed from a ring of 14 surface H atoms, one half-filled surface state is in the bandgap leading to metallic character. The removal of two hydrogen atoms leads to two dangling bond states (one occupied and one empty), separated by a small gap of ~0.2 eV. If all H atoms are removed, the unpassivated wire is metallic since a continuum of surface states fills up the bandgap. This result shows that good passivation is required for silicon nanowires to be efficient light emitters. The presence of even low concentration of H vacancies leads to localized states in the bandgap, which drastically change the optical wire properties. A similar result with respect to the bandgap has been obtained with scanning tunneling spectroscopy studies of unpassivated silicon clusters [142]. The pristine clusters, produced in ultrahigh vacuum, have none of their surface states passivated and can have bandgaps close to zero because the dangling bond states fill up the gap.

The chemical reactivity of H-passivated SiNWs with silver and copper ions has been studied [143]. Freestanding SiNWs with diameters of ~20 nm and millimeters in length were synthesized by laser ablation. Such wires had a polycrystalline silicon core and were coated by a thin layer of silicon oxide. The surface oxide layer was then removed and replaced by hydrogen after immersion of the SiNWs in HF solution. Then the etched SiNWs were exposed to silver (I) nitrate or copper (II) sulfate solutions. The formation of metal particles and other metal nanostructures at the surface of the SiNWs was observed as a result of the reductive deposition of the metal ions.

5.5. Doping

The transport properties of silicon are very sensitive to the concentration of foreign atoms. Controlled doping of SiNWs is a prerequisite for the realization of many applications as SiNW-based devices. Controlled Li-doping of SiNWs by electrochemical insertion method with different doping levels was reported [42]. Doping levels have to be low enough since the crystalline structure of the silicon nanowires is destroyed with increasing doping concentration. STS measurements in SiNWs showed an enhancement of electrical conductivity by boron doping. These nanowires were produced by oxide-assisted growth [144]. SiNWs with different bandgaps can be obtained by controlling the doping level [42]. Boron-doped silicon nanoparticle chains with 15 nm outer diameter were produced in bulk quantity by laser ablation of SiO powder mixed with B_2O_3 powder [145]. The nanoparticles had perfect lattices with an 11-nm crystalline core and a 2-nm amorphous surface oxide layer. Field-emission studies showed that the turn-on field of silicon nanoparticle chains was 6 V/μm, which was much lower than that of undoped SiNWs (9 V/μm).

5.6. Alignment

Parallel alignment or specific orientation with a substrate structure is desirable for the realization of many applications. Parallel SiNWs can be grown by deposition of silicon vapor on HOPG in UHV [19].

Alignment of SiNWs can be achieved by post-growth treatment such as exposure to an ion beam. Ti-containing islands, for example, have been grown on silicon substrates by chemical vapor deposition using the decomposition of TiO_4 [83]. When these islands are exposed to SiH_4 or SiH_2Cl_2, the metal catalyzes the decomposition of the silicon precursor and long SiNWs can grow. Exposing the wires to an ion beam after deposition promotes alignment of nanowires [83].

Interacting nanowires were considered in theoretical investigations in order to model the structure of porous silicon. One of the studies [146] deals with the effect of interwire interaction on the electronic structure and optical properties through two first-principles techniques: linear

muffin tin orbitals method in the atomic sphere approximation (LMTO-ASA) and norm-conserving pseudopotential. Silicon wires with rectangular cross section (5×4 and 7×4) with their axes along the [001] direction and the atomic structure of silicon bulk were used as model systems. Interwire interaction leads to the presence of localized interface states which strongly lower the bandgap energy, for example from 3.27 to 1.55 eV for two NWs considered [146]. As expected, the energy separation between the silicon core crystalline states of the two wires (i.e., the mobility gap) remains unchanged. However, localized interwire bonded states that emerge from the valence band appear and reduce the bandgap. The stability of the wire structures with respect to wire-wire interaction was also investigated and some reorganization of the structure was found. The Si-Si bond lengths in the wire remain practically unchanged, while there is a small lowering of the Si-H bond distance. When the wires are forced to get closer the bandgap strongly is reduced.

5.7. Composite Structures

Composites of carbon nanotubes and silicon nanowires in longitudinal [77] and transverse [48] have been synthesized. In the "transverse" process, first the silicon nanowires were produced by excimer pulsed laser ablation of a target made of a mixture of Si and SiO_2 powders under 9×10^4 Pa Ar atmosphere at 1200 °C. Then, by using hot filament chemical vapor deposition (HFCVD), carbon was evaporated on the SiNWs. Multiwalled carbon nanotubes were found to form on the SiNWs with good adherence.

Deposition of carbon on silicon nanowires can lead to another type of composite. Diamond crystallites were grown from the vapor phase onto arrays of silicon nanowires [131] (Fig. 14).

Two-dimensional aluminum-silicon alloy nanowire networks were fabricated on glass and silicon substrates by de-alloying an aluminum-silicon thin film through selective chemical etching [47]. The network consists of 3- to 6-nm diameter wires with lengths of 50–200 nm, and a wire density of 10^{10} wires/cm^2. Current-voltage measurements show that the nanowire network is metallic.

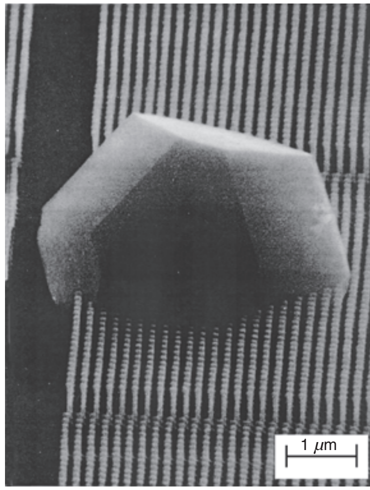

Figure 14. Scanning electron micrograph of a diamond crystallite grown on a silicon nanowire substrate, taken at 45°. The silicon nanowire obstructions have not disturbed the cubo-octahedral faceting of the diamond crystallites. Reprinted with permission from [131], P. A. Dennig et al., *Appl. Phys. Lett.* 67, 909 (1995). © 1995, American Institute of Physics.

Another type of composite was reported, which is composed of copper silicide nanocrystals in silicon nanowires [43]. Copper atoms have a high solubility in the silicon nanowires and precipitate in the nanowires.

6. ELECTRONIC AND OPTICAL PROPERTIES

6.1. Bandgap

Photoluminescence of porous silicon layers has been related to direct interband transitions in nanoparticles and nanowires of silicon [119]. Porous silicon samples with varying confinement size have been fabricated and a blueshift of the photoluminescence peak was observed for smaller confined regions, which is related to an opening of the energy bandgap with reduction of size. Fabricated silicon nanowires have shown unusual photoluminescence and Raman spectra [79, 118, 130] as well, implying a strong quantum size effect, which relaxes the k-selection rule. This leads to direct optical transitions in the SiNWs, which are not allowed for Si bulk crystals. Evidence of quantum confinement was given from the size dependence of the photoluminescence of silicon nanowires [122]. Following such observations, energy levels and charge density distributions have been calculated for silicon nanowires [141].

The bandgap up-shift of the wires with respect to bulk silicon was theoretically determined using effective mass theory (EMT) over a wide range of diameters [65]. It was found that EMT is valid for wires wider than $\sim$2.3 nm. The bandgaps are direct and at the zone center. From another study it was concluded that EMT describes the electronic structure of silicon nanowires well down to diameters of about 1 nm [147].

Nanowires have been considered in EMT studies where the wires either have a free surface or are incorporated in a solid host. The analysis of the electron states within the EMT is straightforward when the barrier potential is very large. It permits the infinite barrier approximation as in structures with free surfaces. However, the barrier potential is finite when the wire is surrounded by another semiconductor. An analytic solution of the equation for the envelope function is not possible for such wires. The wave function has to be expanded in terms of two-dimensional orthogonal functions and the differential equation is reduced to a matrix eigenvalue equation. Solutions to these equations were given [125] and the energy levels for nanowires with finite potential barriers were calculated.

First-principles pseudopotential calculations of band-edge electronic states of SiNWs have been performed [148]. The valence- and conduction-band-edge energies and effective masses of hydrogen-terminated silicon nanowires were calculated and the results were compared with EMT. It was found that the first-principles result for the ordering of states at the valence band maximum is different from the prediction of EMT. The EMT gives accurate values for the

bandgap up-shift for wire widths greater than about 3.3 nm, but it overestimates the bandgap up-shift by nearly 100% for wires of 2.0 nm width.

Using a full-potential linear-muffin-tin-orbital molecular-dynamics method, the geometric and electronic structure of very thin and short silicon nanowires were calculated [87]. Silicon nanowires consisting of tri-capped trigonal prism Si_9 sub-units and uncapped trigonal prisms were studied. These structures are found to be the thinnest stable silicon nanowires and have very small gaps of only a few tens of an electron volt.

The pressure dependence of bandgaps of 6 × 6 atoms (1.15 nm) and 10 × 10 atoms (1.92 nm) wide SiNWs has been calculated using a plane-wave basis and carefully fitted empirical pseudopotentials [149]. The pressure coefficient becomes more negative as the wire diameter increases, eventually approaching a value for the bulk of a = −1.90 meV/kbar. The pressure dependence of the photoluminescence of porous silicon has been measured by several groups [150–153]. It was found that as the pressure increases above ~25 kbar, the photoluminescence peak shifts to lower energies (redshift) with an average pressure coefficient of a~−3 meV/kbar. This value is more negative than the value for the indirect gap of crystalline Si (−1.4 meV/kbar) or that of amorphous silicon (−2.0 meV/kbar). At lower applied pressures, a blueshift is found for the shift of the photoluminescence peak [151, 153]. The crossover from blue- to redshift has been interpreted as a pressure-induced direct-to-indirect transition in the SiNWs of the sample [153]. Calculations of the coefficients for different applied pressures to silicon nanowires suggest that the redshift is an intrinsic property of the silicon wires but that the blueshift is rather a pressure-induced chemical reaction that takes place when alcohols are used as medium in the pressure cell [149].

6.2. Optical Activity

Optical activity and bandgaps have been calculated for SiNWs using an empirical tight-binding model [66]. Due to quantum confinement, the bandgap increases significantly for small wire diameters. The same technique applied to silicon nanowires [126] showed bandgaps equal to 3.29, 2.5, and 2.3 eV for square-shaped wires with diameters 0.77, 1.15, and 1.54 nm (4 × 4 to 8 × 8 atoms), respectively. These nanowires are optically active.

Ab initio electronic structure studies were reported for square-shaped silicon nanowires with 3 × 3, 4 × 4, and 5 × 5 structures and excitonic effects on the optical properties were calculated [63]. The SiNWs have a direct bandgap in the visible energy range. The allowed bandgaps are due to anisotropic effective masses and band mixing. The bandgaps are enlarged by 0.9, 1.3, and 1.9 eV with decreasing silicon wire widths from 1.53, 1.15, to 0.77 nm, respectively. A large optical anisotropy is found.

Blue-shifted electron states were calculated for 1-nm-wide (5 × 5 with $Si_{25}H_{20}$ per unit cell and 6 × 5 with $Si_{30}H_{22}$ per unit cell) H-passivated silicon nanowires using a first-principles approach, based on the self-consistent local-density approximation (LDA) [57] (Figs. 15, 16). LDA calculations [57, 65] as well as the effective mass theory [154] give strong size- and symmetry-dependent radiative times for optical interband transitions.

6.3. Photoluminescence

Photoluminescence (PL) spectra have been taken for silicon nanowires fabricated with various methods. SiNWs supported on crystalline silicon (100) emit photoluminescence in the range of 500–600 nm [55]. The PL efficiency and

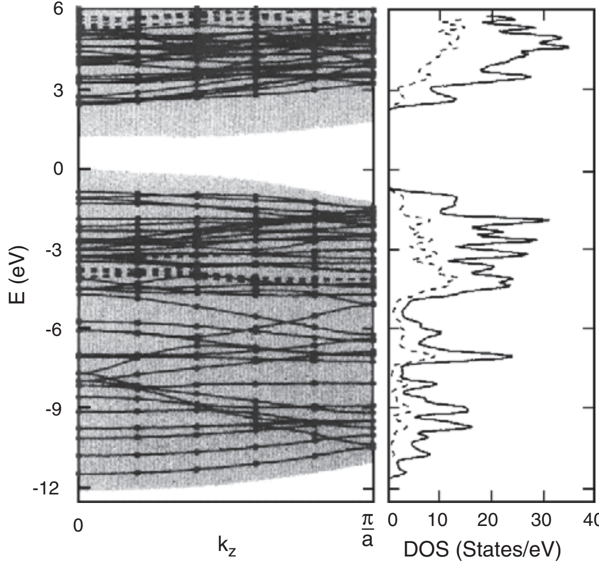

Figure 16. The band structure of a 5 × 5 silicon nanowire together with the projected bulk energy bands of silicon plotted against the wave vector along the wire and the associated density of states. B* 48, 4608 (1993). © 1993, American Physical Society.

energy position depend on the wavelength and polarization of the initial laser beam.

SiNWs produced in Ar (5% H_2) and N_2 atmospheres exhibit PL and spectral blueshift with diameter reduction, which was attributed to quantum confinement in the crystalline nanowires [113].

Silicon nanowires 50 nm wide formed by decorating atomic steps of an otherwise atomically smooth sapphire surface were found to exhibit visible PL. A broad PL emission peaked at 750 nm was found with an intensity at 9 K being over 20 times larger than at 300 K [155]. This is similar to what was observed for porous silicon and other nanostructured silicon [156, 157].

Strong multiple-peak emission in the visible spectral range was found for as-grown and partially oxidized silicon nanowires [122] (Fig. 17). The emission ranges from dark red to blue regions. The red light emission was ascribed to a quantum confinement effect originating from the crystalline core of the silicon nanowires.

Multiple-peak photoluminescence was also observed for silicon nanowires grown with $FeSi_2$ catalyst particles [130]. The nanowires were treated at high temperature with oxygen to obtain different diameters for the silicon core.

There have been problems in the past with degradation and low photoluminescence efficiency from silicon nanostructures. The degradation is usually accompanied with a blueshift of the PL peak. It is probably due to the chemical instability of the silicon surface [40]. When exposed to the atmosphere, the thickness of the silicon oxide layer at the surface increases, which leads to increased scattering and absorption of the incident light and to degradation of the PL intensity. The oxidation process also reduces the size of the core of nanowires or nanocrystals, which results in a blueshift. Various passivation methods have been applied to silicon nanostructures such as nitridation [158], and coating with a diamond-like carbon film [159] or a SiC film [40]. Silicon nanowires with SiC coating show stable photoluminescence with high efficiency.

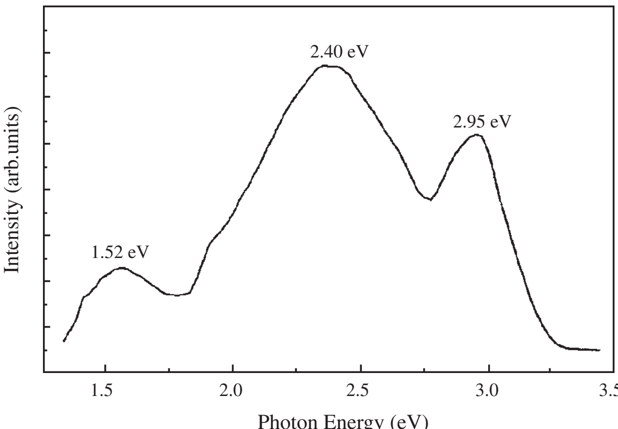

Figure 17. Photoluminescence spectra of silicon nanowires. Multiple emissions corresponding to red, green, and blue light are shown peaking at 1.54 eV (804 nm), 2.40 eV (515 nm), and 2.95 eV (429 nm), respectively. Reprinted with permission from [122], D. P. Yu et al., *Phys. Rev. B* 59, R2498 (1999). © 1999, American Physical Society.

The properties of small-width square hydrogenated silicon nanowires have been studied theoretically by a number of research groups with emphasis on energy level distribution, dispersion configuration, and optical transition matrix elements [63, 65, 67, 160]. A typical result is that SiNWs with diameters 1.0–2.5 nm are optically active in the visible range [146]. The energy gap becomes wider with decreasing wire diameter. Fully hydrogen-passivated 1-nm-wide SiNWs, for example, have a bandgap of about 2.7 eV.

The question has been addressed if the diamond structure is stable for extremely narrow silicon nanowires. It was found that ~1-nm-wide, H-terminated (5×5 and 5×6) silicon nanowires, fully relaxed within the local-density approximation, indeed can have the diamond structure of bulk silicon [57].

Bandgaps, effective masses, and optical matrix elements were studied with first-principles pseudopotential calculations for H-terminated silicon nanowires with thicknesses up to 1.6 nm [64]. For each wire structure the bandgap was found to be direct and at the zone center. Also, an upshift of the bandgap with decreasing wire thickness is a result of the calculations. For the narrowest possible hydrogenated silicon nanowire, a polysilane molecule, a direct bandgap at the zone center of 4.69 eV is calculated. A radiative lifetime of 560 μs for zero-phonon transitions is determined by calculating the zone-center interband optical matrix elements for a 1.6-nm-wide wire. This is close to what is measured for porous silicon. Porous silicon and silicon nanowires have the character of a direct bandgap semiconductor. The radiative transitions occur without phonon participation because the momentum rule is broken by quantum confinement.

The empirical pseudopotential method was used to study the electronic structure and the optical properties of [001] silicon quantum wires [141]. The wires have square cross sections ranging from 4×4 to 14×14 atoms (7.7×7.7 to 26.9×26.9 Å, respectively).

The influence of special orientation on the optical response of hydrogenated crystalline silicon nanowires with small width (0.55 nm) was calculated [69]. (111)-oriented silicon nanowires were studied and the results were compared to (001)-oriented wires [67]. It was found that both the (111)- and (100)-oriented nanowires exhibit a direct gap at $k = 0$. Therefore, if nanowires are present in porous silicon, they are optically active independent of their crystallographic orientation.

The spontaneous emission rate for direct and phonon-assisted transitions was calculated [161]. It was found that light emission from the wires has strong directional character if the wires are directed along the main crystallographic directions or along [110].

The band structure and luminescence properties of pristine and H-passivated SiNWs with three different diameters were compared [39]. The hydrogen-passivated SiNWs have wide bandgaps. For the nonhydrogenated nanowires the bandgap is very small because of the nonbonding nature of the dangling bonds, with the system remaining an insulator but with a minimum direct gap. For instance, calculations for Si_3H_4- and Si_3-based SiNWs give bandgaps of 3.2 eV and 0.3 eV, respectively. Similar results were obtained [66] with an empirical tight-binding approach. Mid-gap states act

as recombination centers for electron-hole pairs and therefore quench the photoluminescence. It explains the observed reduction of the PL intensity after desorption of hydrogen [162, 163].

The first step in a photoluminescence experiment is the optical absorption of ultraviolet photons. Nonorthogonal tight-binding calculations were used to determine the positional dependence of optical absorption of square-shaped 9×9-atom-sized SiNWs [164]. It is found that the optical absorption below 3.4 eV tends to occur at the inner silicon atoms of the nanowires.

7. TRANSPORT PROPERTIES

7.1. Electrical Conductance

The transport properties of silicon nanowires depend very much on the purity of the samples. Also, the wire diameter is important since it determines the sub-band electronic structures and the boundary scattering. It has been shown experimentally that electrical conductivity of SiNWs 15–35 nm in diameter can be varied by four orders of magnitude by doping and thermal treatment [81].

In electrical conductance measurements, air-bridge-structured silicon wires of 100 nm width showed anomalous behavior such as negative resistance and hysteresis at room temperature [44, 60] (Fig. 18). Charge accumulation in surface states is considered to be responsible for the nonlinear electric current behavior. Electrons are trapped in surface states and discharge very slowly, which causes the hysteresis behavior.

Narrow nanowires are expected to show quantized conductance at low temperatures. If the diameter of a nanowire is less than the Broglie wavelength of moving electrons, the band structure becomes divided into sub-bands and the moving electrons experience one-dimensional confinement. The Fermi level increases with the applied gate voltage and the channel conductance shows step-like increase every time when the Fermi level coincides with sub-band edges.

Single-electron effects have been observed at 4.2 K in heavily doped polycrystalline SiNWs with 20 nm $\times$ 30 nm active cross section [136]. The wires were fabricated by electron-beam lithography and thermal oxidation. A double period was seen and explained by grain boundary scattering and Coulomb blockade effects.

Silicon nanowires fabricated by orientation-dependent etching [12] show conductance steps with little fluctuations on plateaus at a temperature of 45 K. Conductance steps up to temperatures as high as 100 K have been observed for very narrow silicon nanowires in the sub-10-nm regime [53].

Step-like conductance was studied for silicon nanowires [61] with different wire widths and applied temperatures (between 25 and 160 K). The step-like conductance remains up to a temperature of about 100 K. The width of the wires was controlled from 20 to 70 nm.

Silicon nanowires have been fabricated using electron cyclotron resonance plasma deposition of a SiO_2 film through the openings of a patterned resist film. The nanowires show quantized conductance up to a temperature of 200 K. (Fig. 19).

A theoretical study [165] used computer simulation of electronic states in SiNWs to determine the conditions for quantum transport at room temperature. The goal is to get insight on the limits of device scalability for silicon. Depending on the configuration of nanowire, gate, and drain in

a device, the electrical transport properties were studied over a wide parameter space. This led to the prediction of conditions for quantum transport to be observable at room temperature.

For an amorphous silicon nanowire, single-electron effects with nonlinear current-voltage behavior at low temperature have been found [166]. A periodic step-like pattern was observed in the current-voltage curves with two periods. This was explained by two effects: hopping conductivity between trapping sites in amorphous regions or at grain boundaries and Coulomb blockade. The silicon nanowire for the I–V studies was 150 nm long, 9 nm thick, and 50 nm wide and at a temperature of 2 K. Short-period oscillations occur with a period of ~1.4 mV and are explained by single-electron scattering processes. The larger observed period of 10 mV is assigned to Coulomb blockade.

Nanowire-electrode contacts have been studied in experiments of charge carrier transport [81]. Al and Ti/Au contacts were investigated. SiNWs 15–35 nm in diameter were produced using SiH_4 chemical vapor deposition via Au or Zn particle-nucleated vapor-liquid-solid growth at 440 °C. The wires as produced were essentially intrinsic. Thermal treatment of the fabricated devices resulted in better electrical contacts, but also in the diffusion of dopant atoms into the nanowire and an increased nanowire conductance by 10^4.

Passivated silicon nanowires connected to aluminum electrodes were studied by large-scale local-density-functional simulations [167]. Short (~0.6 nm) wires have zero bandgaps due to metal-induced gap states (MIGS), which results in a finite electrical conductance. For longer wires (>2.5 nm) Schottky barriers develop and the conductance spectra exhibit size-dependent oscillations due to interference resonances from scattering of the ballistic electrons from the contacts.

7.2. Thermal Conductance

Heat conduction in one-dimensional structures such as nanowires has been studied only recently [168, 169]. There have been several approaches proposed for calculating the lattice thermal conductivity in nanowires [170–172]. Quantized thermal conductance has been predicted theoretically for nanowires at low temperature [169].

Various effects can influence the phonon heat conduction in a semiconductor nanowire with dimensions comparable to the phonon mean free path. Phonon relaxation mechanisms to be considered are phonon Umklapp scattering, mass-difference scattering, boundary scattering, and phonon-electron scattering. In a recent theoretical study [58], a model was used based on the solution of Boltzmann's equation, which takes into account (1) modification of the acoustic phonon dispersion due to confinement, and (2) change in the nonequilibrium phonon distribution due to partially diffuse boundary scattering. Phonon confinement and boundary scattering lead to significant decrease of the lattice thermal conductivity. In pure or lightly doped semiconductors, phonon-electron scattering has little influence on the lattice thermal conductivity. It becomes, however, important for high doping concentrations.

Similar results were obtained using molecular-dynamics (MD) simulations. The thermal conductivity of SiNWs with square cross sections are found to be about two orders of magnitude smaller than those of bulk silicon crystals in a wide range of temperature (200–500 K) [170]. The thermal conductivity is reduced due to boundary and internal phonon scattering. For nanowire cross sections from 2.58 to 28.62 nm^2, the thermal conductivity becomes length independent when the wire is longer than 8.56 nm.

A strong reduction of the thermal conductivity with decreasing size is a general property of nanowires. It has also been predicted (within the Boltzmann transport equation approach) for gold, sodium, and CdTe nanowires [173].

8. APPLICATIONS

8.1. Optoelectronic Devices

Silicon nanowires coated with SiC show stable photoluminescence at room temperature. Silicon carbide is an insulator with a wide bandgap, and high breakthrough electric field. It is durable at high temperature with high thermal conductivity and chemical stability. It has high tensile strength and high Young's modulus, which makes it an excellent coating material. Silicon nanowires coated with SiC show strong and stable photoluminescence [40], which makes them ideal components for integration in optoelectronic devices.

8.2. Quantum-Wire Transistor

The size of silicon devices has continuously been shrinking in order to obtain high integration and faster performance of electronic circuits. This scaling trend has put much attention on nanometer-scale devices with silicon nanowires as structural units.

Recent advances in formation methods allowed the fabrication of silicon quantum-wire transistors. A number of sophisticated successive fabrication steps are used for nanowire, source, and drain configurations.

One of these techniques uses silicon-on-insulator (SOI) technology, electron-beam lithography, anisotropic dry etching, and thermal oxidation [174]. The quantum wires have a width of 65 nm and are fully embedded in silicon dioxide. A Coulomb staircase, that is, step-like conductance versus gate voltage, was observed at temperatures below 4.2 K. This is typical for one-dimensional quantum conductance.

A silicon single-electron transistor (SET), showing an inverted voltage gain as high as 3.7, has been fabricated [175]. The device has staircase conductance oscillations at 4.2 K. The SET is formed in highly doped and oxidized SiNWs of less than 40 nm $\times$ 50 nm cross section and 1.5 μm length.

A combination of photolithography and side-wall patterning was used to fabricate a SET based on a 30-nm-wide SiNW, which can be operated at 77 K [176]. The device showed clear single-electron tunneling phenomena by an electrostatically well-defined single island and two tunnel junctions. The procedures are compatible with conventional metal-oxide-semiconductor process technology.

Detection of single electron and single holes was demonstrated at room temperature in silicon nanowire transistors [177]. Photogenerated carriers are stored in a quantum dot electrically formed in a silicon wire by a front gate. The

stored charges affect the current of the other type of carriers that flow along the silicon nanowire [177]. The silicon nanowire was cylindrical with a diameter of 20 nm. The device was a silicon-wire metal-oxide-semiconductor field-effect transistor (MOSFET) fabricated on a silicon-on-insulator wafer by electron-beam lithography.

An experimental setup was proposed that potentially allows a single-electron silicon quantum dot transistor to operate at room temperature [178]. The emitter and collector of the device consist of silicon nanowires and the base contains a single silicon dot buried in silicon dioxide. Split gates are added to better confine charge carriers perpendicular to the transport directions in the emitter and collector regions.

8.3. Single-Electron Memory

Single-electron memory cells with control over individual electrons would consume extremely low power and could be used in future integrated circuits [25, 75, 179]. A single-electron memory cell can be realized by using the Coulomb blockade effect. Important components of such a device are a silicon nanowire as a channel, a silicon nanodot as a storage node, and a silicon nanogate as a control gate. In addition, a single-electron read-out device needs to be attached. To realize single-electron or few-electron memory devices, narrow SiNWs need to be generated.

A compact single-electron memory cell has been fabricated in silicon [75]. The memory cell consists of a multiple tunnel junction (MTJ) and a memory node, which occupies an area of 0.5 μm^2. A second, connected device with another MTJ forms an electrometer for detecting the state of the memory node. Each MTJ has a side gate to trim its operating point. The amount of charge on the memory node is exactly defined by a control voltage. Memory operation is demonstrated by two distinct levels in the memory node voltage (Fig. 20). The device was tested at 4.2 K and showed memory operation with a >100-mV gap between "0" and "1" levels.

Applying the technology of an inorganic electron-beam resist process, a 15-nm-wide silicon nanowire was fabricated, together with a 10-nm-diam silicon nanodot, and used for a single-electron memory cell [25]. The observed memory behavior is caused by an electron charging effect.

8.4. Metal-Semiconductor Junction

The catalytic growth of metal-semiconductor junctions between carbon nanotubes and silicon nanowires was reported and shown that the junctions exhibit reproducible rectifying behavior [77]. To fabricate carbon nanotube–silicon nanowire (NT/SiNW) junctions, SiNWs were grown from the ends of the NT tips by using silane. Then, the electrical properties of individual NT/SiNW junctions were measured. While little current flow was measured for negative voltage, the current increased sharply above +0.8 V. This rectifying behavior is characteristic for a metal-semiconductor Schottky diode.

8.5. Proposed Applications

Nanoscale resonating devices could be of interest for sensing applications. The fabrication of such resonators, with low-mass and high-frequency response, could lead to a new generation of sensors. In order to test this idea, a harp-like array of 1- to 8-μm-long, 45-nm-wide silicon nanowires has been fabricated and the mechanical resonance has been measured [180] (Fig. 21). Resonance frequencies up to 380 MHz were detected. The Q-factor was studied as a function of wire width in order to understand the loss mechanism in nanosize structures. The Q-factor is found to decrease with

smaller wire dimensions, which is expected due to surface-related losses (Fig. 22).

Electron field emission was studied for 20-nm-wide SiNWs placed on a Si wafer with anode-cathode distances of 10–90 μm [56]. Smooth and consistent current-voltage curves were obtained. The turn-on fields of SiNW emitters with nominal diameter ~10 nm, ~20 nm, and ~30 nm are 4.5, 13, and 23 V/μm (Fig. 23). This is comparable to other types of emitters such as carbon nanotubes, diamond, amorphous carbon, and amorphous silicon nitride. It follows that silicon nanowire emitters could be used in future optical displays based on field emission.

9. SUMMARY

Silicon nanowires are a novel form of nanostructures with exceptional properties. A great deal of work has been devoted to find fabrication techniques to obtain thin, pure, and homogeneous SiNWs in bulk quantities. They have been produced by bottom-up and top-down fabrication techniques. Both approaches usually lead to crystalline SiNWs with an amorphous oxide surface. The crystalline core often has lattice imperfections and defects. Polycrystalline and amorphous SiNWs have also been fabricated. Other morphologies such as graphene and fullerene-like structures have been proposed.

Most bottom-up techniques use catalytic metal clusters for initiating the SiNW growth. This may lead to metal impurities in the nanowires, which can affect the transport properties. Methods have been developed where pure SiNWs are produced. SiNWs with diameters between 2 and several hundred nanometers and several millimeters long have been produced. The grown wires usually have cylindrical shape; the top-down fabricated nanowires have rectangular shape. Top-down fabrication is usually performed by lithography and etching, with many variations in these processes and various types of post-treatments.

SiNWs were usually first studied by electron microscopy and electron diffraction, which give size, length, shape, and atomic structure. Other standard techniques, such as Raman spectroscopy, electron spectroscopy, optical spectroscopy, and electrical conductivity, were subsequently applied. SiNWs are in many respects different from bulk silicon, due to their unique electronic structure, large surface area, optical activity, wide bandgaps, and confinement of electrons, excitons, and phonons. Photoluminescence is observed for SiNWs in the visible range while it is not allowed for bulk silicon. Narrow SiNWs show quantized conductance at low temperatures. Thermal transport through SiNWs is strongly reduced compared to the bulk.

As device dimensions in microelectronics approach the nanometer scale, conventional circuits will reach their operational limits. Low-dimensional electronic materials such as silicon nanowires could be among the solutions to this problem. SiNWs may find applications in optoelectronic devices, in single-electron transistors, and in single- or few-electron memory units. The wide range of novel properties may lead to many other applications for silicon nanowires.

GLOSSARY

Atomic force microscope (AFM) An instrument able to image surfaces to atomic accuracy by mechanically probing their surface contours.

Bottom-up fabrication Building larger objects from smaller building blocks.

Nanoelectronics Electronics on the nanometer scale.

Nanomanipulation The process of manipulating matter at an atomic or molecular scale in order to produce small structures.

Nanoscale 1–100 nanometer size range of structures.

1. INTRODUCTION

The current decade has seen great progress in the use of Si nanostructures for single-electron and quantum devices. There are two fields of research into the use of Si nanostructures. One field is their application in light-emitting devices used with large-scale-integrated (LSI) circuits, and the other is their application in ultimate low-power systems or new functional electron devices, such as single-electron or quantum-electronic devices.

With regard to light-emitting devices, considerable activity followed the first observation, in 1990, of intense, visible photoluminescence from porous Si at room temperature [1]. As well as the practical aspects, the mechanism underlying the photoluminescence itself is interesting because bulk Si has an indirect bandgap, which results in only weak photoluminescence in the infrared region. It goes without saying that these basic studies will be of great help in establishing various device applications for Si nanostructures.

Single-electron devices might be of use as elements of future solid-state circuits that require high integration and low power consumption. Single-electron charging effects are in themselves nothing new and have long been studied [2–5]. However, renewed interest has led to much theoretical and experimental work since the first proposal of their application to single-electron transistors (SET) in the mid-1980s [6]. Early work concentrated on proof of the basic operation and elucidation of the physical properties of SETs [7–9]. This involved experiments at temperatures at which the thermal energy was less than the single-electron charging energy of a Coulomb island. Accordingly, when observations were carrieds out at very low temperatures, it was unnecessary for the Coulomb island to be very small. In this early work, single-electron devices were mainly fabricated using metals or compound semiconductors, and the experiments were performed at very low temperatures. Owing to the relatively large device size used at these low temperatures, device fabrication could be achieved using conventional electron-beam (EB) lithography, the metal lift-off process, metal evaporation, and the shadow mask technique, which had already been used to produce metal gate structures for electron confinement in two-dimensional structures present in compound semiconductors.

In contrast, Si is the preferred material for single-electron and quantum-electronic devices from a practical point of view because we can use mature technologies for LSI circuits during the fabrication process. This is a definite advantage in developing commercial devices. One further requirement for the use of single-electron and quantum-electronic devices in future LSI devices is the ability to operate at room temperature. To achieve this using SETs, we need a nanoscale Coulomb island which reduces the total capacitance of the island so that the single-electron charging energy exceeds the thermal energy at room temperature. A similar structure is needed in quantum-electronic devices for electron confinement; the structure must be small enough for subband splitting to exceed the thermal energy at room temperature.

Research into the practical uses of Si single-electron and quantum-electronic devices began in the early 1990s [10, 11] when the fabrication of nanostructures in Si became possible owing to the continuous reduction of device size in LSI circuits for higher integration and performance. Room-temperature operation of Si single-electron memories and SETs was first reported in 1993 [10] and 1994 [11], respectively.

This article gives an overview of Si quantum dots along with their fabrication, microstructure, and optical and electrical characteristics. In this article, quantum dots include Coulomb islands, which are key elements in single-electron devices. In Section 2, natural and self-assembled formation as well as artificial fabrication of Si quantum dots are described. In Section 3, the optical properties and applications of Si quantum dots are reviewed. Their electrical properties and applications are reviewed in Section 4.

Finally, there is a summary of the remaining problems and some suggestions for the direction of future research (Section 5).

2. FABRICATION OF Si QUANTUM DOTS

With the aim of creating quantum devices or single-electron devices, many processes have already been proposed for the fabrication of Si quantum dots. These fabrication techniques can be divided into two broad categories: (1) self-organizing fabrication processes, and (2) artificial fabrication, with the most typical and direct method being EB lithography.

2.1. Natural and Self-Assembled Formation

While EB lithography has many advantages in nanostructure fabrication, its low rate of productivity is a serious drawback to the development of commercial devices. In contrast, the self-organizing fabrication process for nanostructures is a relatively simple and inexpensive method that is also highly productive.

In 1988, Furukawa and Miyasato first reported a quantum size effect in naturally formed Si nanocrystals surrounded by hydrogen atoms with diameters of 2–3 nm. They used a magnetron rf sputtering technique in hydrogen gas onto a low-temperature substrate [12]. Using optical absorption measurements, they observed a wider optical bandgap than that of bulk Si. Then in 1990, Takagi et al. fabricated Si nanocrystals, ranging in size from 2.8 to 5 nm, embedded in a SiO_2 matrix using microwave plasma decomposition of SiH_4 and H_2, or SiH_4, H_2, and Ar mixture [13]. They observed visible photoluminescence, which could be ascribed to the quantum confinement effect of electron-hole pairs.

Around the same time, visible photoluminescence in porous Si at room temperature was first reported [1]. After that discovery, most of the techniques for fabricating Si nanocrystals in the early 1990s were developed with the aim of studying their photo- or electroluminescence properties. In these optical studies, increasing luminescence intensity by increasing the number of Si nanocrystals responsible for it, size uniformity to produce a sharp luminescence line, and size controllability to change the position of the luminescence peak, are more important than achieving precise positional controllability of the nanocrystals. To achieve this, various techniques have been proposed, such as sputtering, gas evaporation, plasma-enhanced chemical vapor deposition (PECVD), and ion implantation followed by thermal annealing.

In the sputtering methods, Si nanocrystals were fabricated by means of an rf sputtering technique using hydrogen or argon plasma. The target materials are Si, SiO_2, or a mixture of Si and SiO_2. Si nanocrystals surrounded by hydrogen atoms were fabricated using a pure Si target with hydrogen plasma [12, 14]. Si nanocrystals embedded in a SiO_2 matrix were prepared by rf co-sputtering using argon plasma followed by N_2 [15] or vacuum [16] annealing at high temperatures. For targets in the co-sputtering, pieces of Si wafer were placed around or on pure silica. Si nanocrystals embedded in a SiO_2 matrix were also fabricated by sputtering from only a pure SiO_2 target using argon plasma followed by N_2 annealing above 1000 °C [17].

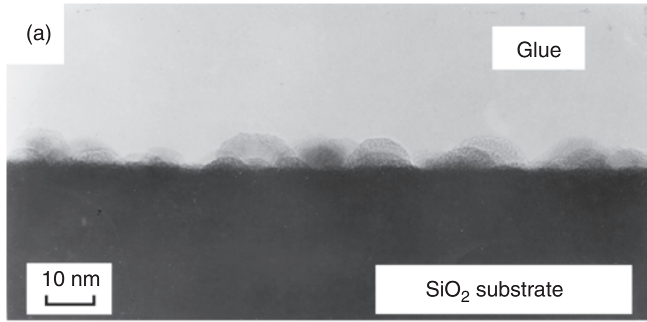
In the gas evaporation methods, high-purity Si powder was evaporated from a ceramic boat heated to high temperatures (about 2000 °C) in an inert gas, or an oxygen-containing inert-gas atmosphere under low pressure [18, 19]. Adding oxygen to the atmosphere during evaporation means that the surface of the deposited Si nanocrystals can be oxidized and the size of the Si core can be reduced [18]. The oxidized Si nanocrystals shows above-bandgap photoluminescence peak. The amount of the increase in the bandgap is 0.3 eV, which can be attributed to a quantum size effect. Also, Si nanocrystals and amorphous Si nanoparticles embedded in a SiO_2 matrix were prepared by evaporation of SiO followed by high-temperature annealing at 1303 K and 973 K, respectively [20]. Photoluminescence has been observed from both amorphous and crystalline nanoparticles and interpreted in terms of band-to-band recombination in nanoparticles with an average size of more than 2.5 nm and carrier recombination through defect states in smaller nanoparticles [20].

In the PECVD methods, Si nanocrystals surrounded by hydrogen atoms were produced using the decomposition of SiH_4 and H_2, or a SiH_4, H_2, and Ar gas mixture [13, 21, 22], or a SiH_4 and Ar gas mixture [23]. Si nanocrystals embedded in a SiO_2 matrix were produced using a SiH_4 and N_2 gas mixture with N_2O followed by thermal annealing in N_2 [24].

Thermal SiO_2 and bulk-fused silica were implanted with Si and Si nanocrystals formed after subsequent thermal annealing in an inert-gas ambient [25, 26]. To produce Si nanocrystals with a narrow size distribution throughout a thick SiO_2 film, Si implantation was carried out at multiple energies with varying doses [26].

Other typical fabrication methods for the synthesis of Si nanocrystals are gas-phase nucleation following pyrolysis of Si_2H_6, which uses an aerosol apparatus [27], and pulsed-laser-induced decomposition of SiH_4 in a flow reactor [28]. Si nanocrystals embedded in a SiO_2 and Si_3N_4 matrix were prepared using an approach based on the deposition of Si-rich Si-O and Si-N films by the ultrahigh vacuum chemical vapor deposition reactions of $O(SiH_3)_2$ and $N(SiH_3)_3$, respectively, followed by high-temperature thermal annealing [29].

However, the above techniques for producing Si nanocrystals are not always suitable for electron-device applications due to the inability to precisely control the position of the nanocrystals. The first clear demonstration of the practical application of a Si single-electron device was a single-electron memory with floating gates reported by Yano et al. [10]. They utilized nanoscale grains in an ultrathin poly-Si film as ultrasmall floating gates and ultranarrow channels in 1993 (three years after the discovery of visible photoluminescence in porous Si) [1]. Improvements in the methods of fabricating Si quantum dots for electron devices started from this point. Tiwari et al. fabricated a single-electron memory with floating dots utilizing Si nanocrystals produced by a specially designed ultralow-pressure CVD on a thin tunnel oxide [30]. Then, Nakajima et al. [31, 32] applied a conventional low-pressure CVD (LPCVD) technique using pyrolysis of SiH_4 to form Si quantum dots on a SiO_2 substrate. Figure 1 shows the transmission electron microscopy (TEM) micrograph of the fabricated Si nanocrystals. Owing to its wide



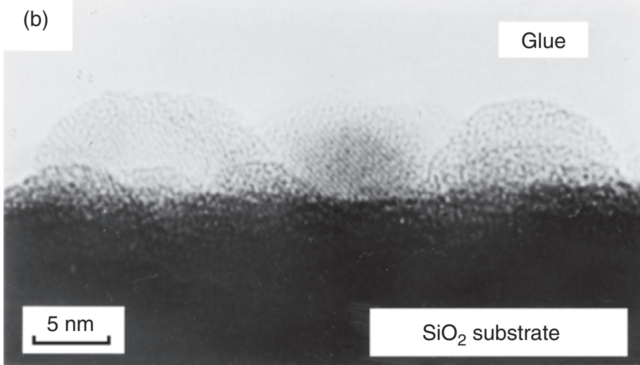


Figure 1. Cross-sectional TEM micrograph of a layer of Si nanocrystals for (a) an LPCVD deposition time of 60 seconds, and (b) a higher resolution micrograph. Phys.* 80, 4006 (1996). © 1996, Institute of Pure and Applied Physics; American Institute of Physics.

use in current ULSI technology and its convenience, Si quantum dots formed utilizing this technique are now extensively used not only for single-electron memories with floating dots [33] but also for Coulomb islands in Si SETs [34]. This technique is based on the early stages of Si film growth using conventional LPCVD on a SiO_2 film. It should be noted that Brownian motion of Si nanocrystals with diameters about 10 nm on SiO_2 was observed during the deposition. Though Brownian migration on KCl of Al or Au nanocrystals with diameters of less than 5 nm had previously been reported [35, 36], this was the first report regarding Brownian migration of such large Si nanocrystals on SiO_2.

Another approach to engineering the spatial position, size, and density of Si nanocrystals is the preparation of amorphous Si/SiO_2 superlattices [37–40]. Si nanocrystals were formed as a result of thermal recrystallization using high-temperature annealing [37]. The crystallization temperature increases rapidly with decreasing thickness of the amorphous Si layer. The size of the Si nanocrystals formed is limited by the thickness of the amorphous Si layer. A short period of steam oxidation was found to improve the surface passivation of Si nanocrystals. Amorphous Si/SiO_2 superlattices were grown using the PECVD method with alternating decomposition of SiH_4 and SiH_4/nitrous oxide [38], or by magnetron sputtering of amorphous Si followed by plasma oxidation [37, 38].

A severe drawback of this method is that most of the nanocrystals are touching. This clearly limits the luminescence efficiency due to the nonradiative processes that occur at the grain boundaries. An interesting development is the phase separation and thermal crystallization technique for SiO/SiO_2 superlattices used by Zacharias et al. [39]. Amorphous SiO/SiO_2 superlattices were prepared by reactive evaporation of SiO powders in an oxygen atmosphere. The SiO layers, ranging in thickness from 1 to 3 nm, were separated by SiO_2 layers of 2–3 nm. After deposition, the samples were annealed at 1100 °C for 1 hour under a N_2 atmosphere. The high-temperature annealing of such initially amorphous SiO film results in phase separation described by

$$SiO \rightarrow 0.5\ SiO_2 + 0.5\ Si$$

and in Si nanocrystals in a SiO_2 matrix. The phase separation of the SiO automatically ensures that the nucleated Si nanocrystals are separated from each other by a SiO_2 shell. Gourbilleau et al. also proposed a method for achieving good phase separation in a Si nanocrystal layer [40]. Si nanocrystals embedded in a SiO_2 matrix were formed by thermal annealing of a Si-rich layer/SiO_2 superlattice produced by magnetron sputtering. Instead of alternating Si target sputtering and plasma oxidation, the SiO_2 targets were sequentially sputtered by pure argon plasma for the deposition of a SiO_2 layer, and by a mixture of argon and hydrogen plasma to produce a Si-rich layer. The latter run made use of the ability of hydrogen to reduce the amount of oxygen originating from the SiO_2 target.

In a different approach, Si nanocrystals/amorphous Si superlattices were fabricated by Tong et al. [41] using the PECVD method. The layers of Si nanocrystals, surrounded by hydrogen atoms and amorphous Si, were prepared by changing some of the deposition parameters: (1) the gas ratio ($SiH_4/SiH_4 + H_2$), and (2) the application of a negative bias voltage to the sample substrate.

2.2. Artificial Fabrication

As mentioned above, the greatest advantage of using natural and self-assembling formation for Si quantum dots is high productivity. Although excellent uniformity of size and depth position was achieved using some of the formation methods described above, there was inadequate control over the number and lateral position of the dots. It is also often difficult to alter the size and position of the dots using natural and self-assembling formation methods. The most typical and direct method of overcoming these problems is to use EB lithography followed by various etching processes.

Using electrostatic confinement with a dual-gate device, Alsmeier et al. [42] fabricated periodic arrays of electron dots on Si, which were widely tunable in diameter and electron number. MOS devices with dual gates were fabricated. A metal (NiCr) bottom gate with a mesh structure was formed on a thermal oxide grown on *p*-type Si substrate. The mesh had circular openings of about 150 nm in diameter with a periodicity of 400 nm fabricated using EB lithography. PECVD was used to deposit the upper layer of SiO_2 on the mesh with a continuous thin metal (NiCr) gate on top. Positive and negative voltages were applied to the top and bottom gates, respectively. In the presence of bandgap radiation, electron dots were induced at the Si/SiO_2 interface underneath the bottom gate openings via the top gate voltage. The bottom gate voltage served to isolate the dots and

the top gate voltage determined the inversion layer electron density.

Nakajima et al. fabricated nanoscale Si dot arrays using EB lithography [43]. Following lithography, anisotropical dry etching and isotropical wet etching in $NH_4OH/H_2O_2/H_2O$ produces completely isolated crystalline Si dot arrays 10 nm wide and 10 nm high (Fig. 2). Since wet etching in $NH_4OH/H_2O_2/H_2O$ is a low-temperature process, problems such as a change in the doping profile can be ameliorated. After wet etching in $NH_4OH/H_2O_2/H_2O$, the expansion in volume caused by the growth of an oxide layer on the Si surface is much less than the dot size. This means that the stress induced by the expansion is low, enabling the integration and miniaturization of devices. The large reduction in device size is possible because the wet-etching process does not have any self-limiting characteristics in contrast to the oxidation of low-dimensional Si structures [44]. The extent of damage that occurs during dry etching can be greatly reduced by using wet etching. A further advantage of wet etching is that, since the technique is commonly used in the cleaning of Si wafers (RCA process), Si quantum dots can be fabricated using conventional Si LSI fabrication methods.

A self-limiting process combined with conventional EB lithography was proposed by Fukuda et al. to fabricate thin pillars consisting of multilayers of Si polycrystalline quantum dots with Si nitride tunnel barriers [44]. Vertically stacked Si dots with dimensions on the order of 10 nm in all three directions, connected by thin Si nitride layers (~2 nm thick), were fabricated using the saturation characteristics of the poly-Si core diameter during lateral pillar oxidation. During the fabrication, the multilayer structures were formed first by repeated deposition of amorphous Si film (~10 nm thickness) followed by thermal nitridation. Then the pillars were patterned using EB lithography followed by dry etching. The patterned pillars were oxidized in a dry oxygen ambient at 850~900 °C, yielding self-limiting oxidation of the Si pillars.

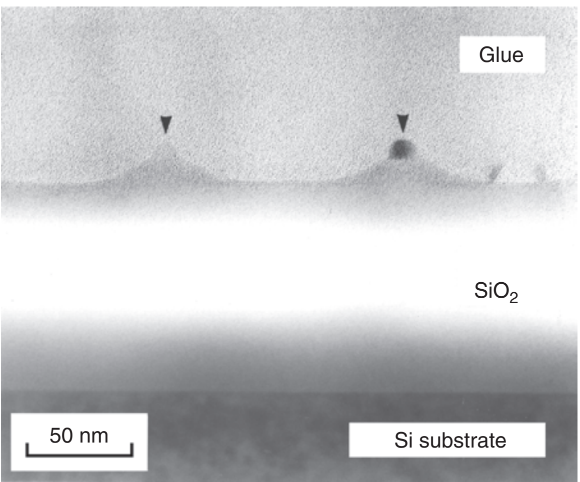

Figure 2. Cross-sectional TEM micrograph of Si dots 10 nm high and 10 nm in diameter (indicated by arrows) after the isotropic wet etching. The difference in contrast between the two dots is attributed to the difference in the crystal orientation of each poly-Si dot. Reprinted with permission from [43], A. Nakajima et al., *Jpn. J. Appl. Phys.* 33, L1796 (1994). © 1994, Institute of Pure and Applied Physics.

3. OPTICAL PROPERTIES AND APPLICATIONS

3.1. Quantum Size Effect

The quantum size effects of Si nanocrystals have been extensively studied using various optical measurements, such as measurement of optical absorption or photoluminescence.

Si nanocrystals surrounded by either hydrogen [12] or oxygen atoms [31, 32] indicate an increase in the optical bandgap due to the three-dimensional quantum confinement effect. Nakajima et al. measured the optical absorption of Si nanocrystals formed on a SiO_2 wafer [31, 32]. They showed that Si nanocrystals with a diameter of about 10 nm essentially maintain the properties of an indirect bandgap semiconductor, with the Si bandgap increasing due to the electron-hole quantum confinement effect. Figure 3 shows $(\alpha h\nu)^{1/2}$ as a function of the photon energy, $h\nu$, where α is the absorption coefficient. For each sample of nanocrystals with varying average sizes, $(\alpha h\nu)^{1/2}$ changes linearly with the photon energy, $h\nu$, near the absorption edge, which indicates that an indirect transition in the absorption is likely to occur for all samples. The bandgap energy of 1.7 eV obtained for a 60-second deposition time (average lateral diameter of 9.1 nm and average height of 4.0 nm including the outer surface oxide layer) showed reasonable agreement with the theoretical calculations of Takagahara and Takeda based on envelope function analysis [45]. A similar analysis also performed for the absorption coefficient of Si nanocrystals embedded in SiO_2 [24] and porous Si [46] indicated that Si nanocrystals maintain an indirect bandgap structure with an increase in the bandgap due to the electron-hole quantum confinement. This result is also consistent with that obtained from site-selective excitation spectroscopy for porous Si described in the Section 3.2.

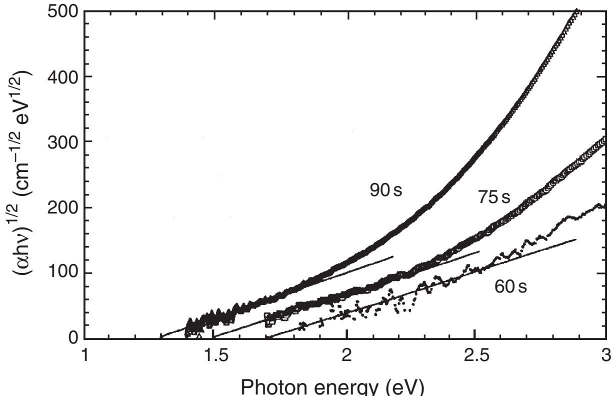

Figure 3. Square root of absorption coefficient (α) times photon energy ($h\nu$) vs. photon energy ($h\nu$) for Si dots with different deposition times. The sample with a 60-second deposition time consisted of isolated Si dots with an average diameter of 9.1 nm and an average height of 4.0 nm. At deposition times exceeding 60 seconds, not only does the diameter of each Si dot become larger, but also the dots tend to coalesce due to Brownian migration, leading to a rapid increase in the Si dot size over time. Reprinted with permission from [32], A. Nakajima et al., *J. Appl. Phys.* 80, 4006 (1996). © 1996, American Institute of Physics.

As described earlier, there seems to be a consensus at present that the photogeneration of electron-hole pairs mainly occurs in the Si core region of Si nanocrystals with an increased bandgap due to the quantum confinement effect. However, in regard to the radiative recombination process, there is still controversy as to whether the band-to-band radiative recombination of electron-hole pairs confined within nanocrystals is essential or whether the effect of the nanocrystal surface cannot be ignored.

Wilson et al. showed that the peak of the photoluminescence spectrum shifts towards a higher energy as the average size of the Si nanocrystals decreases [47]. They formed surface-oxidized Si nanocrystals using homogeneous gas-phase nucleation following pyrolysis of dilute Si_2H_6 in He. They used size-selective precipitation and size-exclusion chromatography to separate the nanocrystals into different groups with larger or smaller average particle size. There was no Stokes shift between the photoluminescence peak energy and the bandgap of the Si nanocrystals estimated from the photoluminescence excitation spectra.

Patrone et al. reported a photoluminescence study of Si nanocrystals produced using a conventional pulsed-laser ablation technique [48]. The Si nanocrystals were produced under an inert-gas ambient and the photoluminescence measurements were carried out *in-situ*. By selecting appropriate experimental parameters, they obtained significant condensation of the Si nanocrystals with reduced size dispersion. The photoluminescence band shifted from near-infrared to near-ultraviolet as the mean size of the nanocrystals varied from $\sim$4 to $\sim$1 nm. The size-dependent photoluminescence was explained by a discrete size model; that is, the spectral position of the photoluminescence band is essentially determined by the volume of nanocrystals with a complete outer atomic layer. The bandgaps of nanocrystals with discrete size differences, which were determined by the quantum confinement effect, corresponded to the photoluminescence peaks.

The above two groups insisted that photoluminescence occurs due to the band-to-band radiative recombination of electron-hole pairs confined within the nanocrystals and the bandgap is determined by the carrier quantum confinement effect.

Fernandez et al. found that the bandgap estimated by the photoluminescence excitation spectra and the photoluminescence peak energy shifted to a higher energy as the average size of the Si nanocrystals embedded in SiO_2 decreased [49, 50]. The Si nanocrystals were synthesized using ion implantation of Si^+ in a thick SiO_2 layer grown on a Si substrate followed by thermal annealing in N_2. The bandgap shifts measured are in good agreement with the model based on quantum confinement. Constant Stokes shifts of 0.26 eV, which is almost twice the energy of Si-O vibration, were observed between the photoluminescence peak energy and the bandgap. This finding suggests that absorption occurs between the quantum confinement states in the Si core and radiative recombination occurs at the Si/SiO_2 interface with the assistance of local Si-O vibration.

Dinh et al. described the optical properties of oxygen- or hydrogen-passivated Si nanocrystals [51]. These nanocrystals had an average core diameter of 2–7 nm and were synthesized by thermal vaporization of Si in an Ar buffer gas, followed by exposure to oxygen or atomic hydrogen. The visible component of the photoluminescence spectra showed blueshifts, which broadened as the size of the Si nanocrystals was reduced. There were differences in the photoluminescence spectra for the hydrogen- and oxygen- passivated nanocrystals. The authors explained the results using a model involving absorption in quantum-confined Si cores and emission due to the transition between surface and/or interface states. Namely, upon absorption of photons, electrons and holes were generated in the conduction and valence bands of the dots. In the emission process, the carriers were trapped and subsequently recombined through surface-related traps with energy levels extending into the energy gaps.

Iacona et al. also reported that the photoluminescence peak showed blueshifts as the size of the Si nanocrystals decreased with a quantitative discrepancy between the peak energies and the theoretically obtained values for the bandgap [52]. Si nanocrystals were formed by high-temperature annealing of substoichiometric Si oxide thin films prepared using the PECVD method. It was speculated that the photoluminescence results were due to absorption occurring as a result of the quantum confinement effect of the carriers in the Si nanocrystal cores, and that recombination occurred on the intermediate states, introducing energy levels inside the bandgap and corresponding to the Si/SiO_2 interfacial states of the Si nanocrystals.

Kanemitsu et al. described the size-independent peak energy of photoluminescence from oxidized Si nanocrystals [53]. The Si nanocrystals were produced by laser breakdown of SiH_4 gas followed by oxidation at room temperature in a clean air box. The average diameter of the Si nanocrystals formed varied from 7 to 13 nm with a constant SiO_2 surface thickness of 1.6 nm achieved by selecting appropriate experimental parameters. The peak position of the photoluminescence was 1.65 eV for all the Si nanocrystals, independent of their size. They also observed that photoluminescence intensity increased with a decrease in the average diameter of the Si nanocrystals in the size region. Photoluminescence intensity was observed to increase at temperatures below $\sim$150 K. The authors used a three-region model to explain these experimental findings. In the model, Si nanocrystals consist of three regions: (a) a Si core with a diameter of less than 5–7 nm, (b) a surface SiO_2 layer with a thickness of about 1.6 nm, and (c) an interfacial layer between (a) and (b). The interfacial layer contains nonstoichiometric amounts of oxygen, which leads to a much lower bandgap (calculated to be about 1.7 eV) than the outer surface SiO_2 layer. The bandgap of the Si core region is theoretically calculated to be higher than that of the interfacial layer when the core diameter is less than 5–7 nm. In this case, the exciton is confined in the interfacial spherical-shell region. This localized exciton increases the oscillator strength. The origin of the photoluminescence was therefore considered to be due to the localized exciton. In a three-region model, photogeneration of excitons mainly occurs within the Si core region. Some of the excitons in the core transfer to the interfacial layer by a thermally activated diffusion process. Then, strong photoluminescence is caused by the radiative recombination of excitons confined in the interfacial layer.

Kanemitsu [54] studied the dynamics of photoluminescence decay and photoluminescence under resonant excitation for these oxidized Si nanocrystals. The

photoluminescence behavior is characterized by a stretched exponential function. The radiative decay rate shows thermally activated temperature dependence with large activation energy (71 meV) at high temperatures, suggesting that the photoluminescence is produced by multilevel light-emitting states in a single nanocrystal. The cascade of carriers from higher to lower states means that the lifetime of the higher states is shorter and an exponential slope is then observed. At low temperatures, however, a long photoluminescence lifetime is mainly determined by the tunneling process. Clear phonon-related steplike structures are not observed in the photoluminescence spectra under resonant excitation of oxidized Si nanocrystals, in contrast to the case of porous Si described later. The large activation energy for radiative recombination and indistinct phonon-related structures indicate that the potential fluctuation in the surface states in oxidized Si nanocrystals is much larger than that in porous Si. The disordered potential of oxidized surface states causes a shallow tail or localized states. Thus, the photoluminescence properties in oxidized Si nanocrystals can be understood in terms of the localization of carriers or excitons in a disordered potential of the surface states.

The photoluminescence decay dynamics and site-selective excitation spectroscopy of surface-oxidized Si nanocrystals fabricated with a SiH_4 plasma cell reported by Kanemitsu et al. suggests that there are different luminescence bands in Si nanocrystals [55]. The photoluminescence decay dynamics show different dependence on monitored photoluminescence wavelengths at photon energies below and above ~1.65 eV for Si nanocrystals with an average core diameter of 4 nm. In site-selective excitation spectroscopy, the phonon-related structures are only observed under excitation levels below ~1.65 eV. Since a larger excitation energy selects smaller Si nanocrystals, the photoluminescence band under laser excitations above ~1.65 eV corresponds to the small Si nanocrystals where the effect of the surface becomes more important. Kanemitsu et al. speculated that the unclear phonon structures under laser excitations above ~1.65 eV are due to the localization of excitons near the disordered interface between the crystalline Si core region and the SiO_2 surface in these small Si nanocrystals. In large Si nanocrystals, on the other hand, excitons are delocalized in the core state, leading to clear phonon-assisted photoluminescence.

Linnros et al. studied the effect of interactions between Si nanocrystals on photoluminescence properties [56]. The decrease in the curvature of the photoluminescence decay curve with the increasing density of Si nanocrystals embedded in SiO_2 suggests a partially interconnected system of nanocrystals where excitons may migrate to and be trapped in large nanocrystals for a high density of nanocrystals.

3.2. Porous Si

Since intense visible photoluminescence was first observed at room temperature in 1990 [1], the mechanism underlying photoluminescence from porous Si has been studied intensively both from a purely scientific standpoint and from the point of view of its practical applications [57–59].

Porous Si samples are typically prepared by electrochemical anodization of the surface of a Si wafer. The microstructure of the porous Si very much depends on the fabrication conditions such as the doping type and resistivity of the Si wafer, current density, concentration of hydrofluoric acid (HF), and presence or absence of illumination. Cullis and Canham showed the existence of columnar Si wires undulating in width in porous Si that emits red light [60]. Nakajima et al. observed similar results for porous Si emitting red light [61]. Microstructures of lightly doped porous Si are shown in Figures 4 and 5 [61]. The existence of threadlike structures (a few nanometers wide) that undulated in width (Fig. 4) was confirmed by TEM. The porous Si also contained numerous spherical Si nanocrystals with diameters of a few nanometers (Fig. 5). This confirmed the existence of Si nanocrystals and undulating crystalline-Si wires with diameters of a few nanometers.

The quantum confinement model has been the focus of most attention in attempts to understand the photoluminescence of porous Si [1, 57–64]. Changes in the photoluminescence spectra were investigated after altering the size of the Si nanocrystals in porous Si and its surface composition. Size reduction was carried out by various methods such as changing the porosity of the porous Si by immersing it in an aqueous HF solution after anodization [1] or changing the anodization conditions by using different types of Si wafers [62]. The size and the surface composition of the porous Si were changed at the atomic layer level by alternately dipping it in an aqueous HF solution and an aqueous H_2O_2 solution (or aqueous HNO_3 solution) [63, 64]. Photoluminescence was measured before and after each step. These measurements confirmed the appropriateness of the quantum confinement model. However, other explanations have also been advanced, suggesting that the optical center may be chemical compounds on the surface of the porous Si [65] or amorphous-like structures in the porous Si [66].

More detailed information was obtained using selective excitation spectroscopy [67–71] and observing the lifetime of the photoluminescence [69, 72]. Two groups independently found a steplike vibronic structure using selective excitation spectroscopy, which indicates that in the photoluminescence of porous Si, phonon-assisted indirect transitions occur in

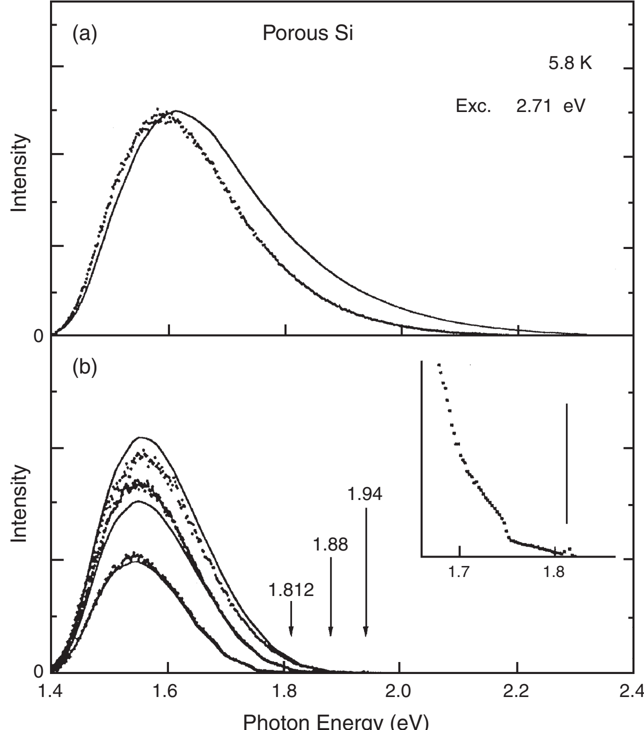

Figure 6. Photoluminescence spectra of porous Si taken at 5.8 K. The ordinate scale is proportional to the photon number per unit energy interval. (a) The dotted curves are the spectra excited by 2.71-eV line of an Ar laser. The solid curve is the distribution function $P(E)$ of the Si nanocrystal in the porous Si which has a bandgap of E deduced from this spectrum. (b) The dotted curves are the spectra excited at 1.812, 1.88, and 1.94 eV, and the solid curves are the best calculated fits to these spectra taking into account the multi-phonon processes. The inset shows the details of the spectrum with phonon structures near the laser line for 1.812-eV excitation. Reprinted with permission from [67] and [69], T. Suemoto et al., *Phys. Rev. Lett.* 70, 3659 (1993); *J. Phys. Soc. Jpn.* 63, suppl. B, 190 (1994). © 1993, 1994, American Physical Society.

the Si nanocrystal, with the bandgap increasing due to quantum confinement. This suggests that the optical centers in the porous Si retain the indirect bandgap characteristics of bulk crystalline-Si.

Figure 6 shows the results of Suemoto et al. [67]. Figure 6a shows the photoluminescence spectra of porous Si excited by an Ar laser at 2.71 eV; this corresponds to "nonselective" excitation and shows a broad peak at around 1.6 eV. Figure 6b shows the spectra under a selective excitation condition, where the excitation energy is within the luminescence band. Several notable features can be seen in Figure 6b: (1) with decreasing excitation photon energy, the intensity decreases substantially and the peak shifts to a lower energy, indicating the selection of luminescent species that emit light at energies lower than the excitation energy; (2) the line-narrowed resonant component is absent, suggesting that fast relaxation of the photoexcited state to a lower energy state occurs before light is emitted; (3) a steplike structure is visible, most clearly at 1.81 eV excitation (the spectrum near the laser line is shown in detail in the inset). Similar steplike structures were observed by Calcott et al. [71]. In regard to (2), they found that the fast relaxation is due to exchange splitting of excitons in porous Si based on the quantum confinement model. They observed that the onset of the luminescence does not occur exactly on the laser line in site-selective measurements, but shifts to a lower energy (the value varies from 23 meV under 2.410-eV excitation to 5 meV around 1.78 eV). They ascribed this energy shift to exchange splitting. In light absorption, the transition occurs mainly in the higher spin-allowed singlet state, but the fast exciton relaxation occurs from the singlet state to the lower triplet state at low temperatures. The emission occurred from the lower triplet state.

However, the steplike structure of the luminescence spectra in selective excitation spectroscopy can be basically interpreted by suggesting that multi-phonon-assisted indirect transitions in the Si nanocrystals occur with an increase in the bandgap of Si due to the quantum confinement of the electron and hole. The positions of the steplike features correspond quite closely to the energies of the momentum-conserving phonons in bulk crystalline Si [73]. The solid curves in Figure 6b are the best calculated fits assuming that the multi-phonon process involves up to two phonons. The calculated curves reproduce the experimental photoluminescence spectra well for all excitation energies (1.81, 1.88, and 1.94 eV). The calculated results reproduce not only the excitation energy dependence but also the temperature dependence of the experimental photoluminescence spectra [67, 69].

There have been a number of reports on the decay dynamics of luminescence at various time scales ranging from picoseconds to milliseconds [72, 74, 75]. Also, the

decay behavior is complicated by sample dependence. Therefore, there was no phenomenological model to provide consistent understanding of all the aspects of the reported decay dynamic until Suemoto et al. proposed a model based on the recombination of electron-hole pairs confined in Si nanocrystals in porous Si with radiative and nonradiative processes [69, 72]. In regard to the nonradiative process, the model takes into account both the tunneling and thermally activated escape processes of an electron (and/or hole) through a barrier. The model also explains the observed temperature dependence well along with the lifetime and nonexponential decay profiles of the photoluminescence [69, 72].

For a single Si nanocrystal, the luminescence intensity at time t after a pulsed excitation is given by

$$I(t) = C_o R_r \exp(-(R_r + R_n)t)$$

Here, R_r and R_n are radiative and nonradiative decay rates, respectively, and C_o is a constant. From the equation, $I(0) = C_o R_r$ is the initial amplitude of the luminescence and it is proportional to R_r, whether or not the nonradiative process exists. Suemoto et al. extracted the form of variations in the radiative decay rate with temperature from the measurement of this initial luminescence amplitude. They found that the decay rate obtained from the near-exponential gradient of the luminescence decay at long times agrees well with that obtained from the initial amplitude above. They concluded that the decay rate at long times represents radiatively dominated decay and that the decrease in the decay rate below the temperature where maximum luminescence intensity occurs is due to variation in the radiative decay rate. The activation energy obtained from the temperature dependence of R_r can be easily understood by considering the exchange splitting of excitons in porous Si as described previously.

In regard to the nonradiative process of electrons, the tunneling and thermally activated processes are shown in Figure 7. Here, E is the kinetic energy of an electron, and E_a is the barrier height from the lowest energy level of the confined electron. The total nonradiative recombination rate R_n becomes

$$R_n = f_0 p + f \exp(-E_a/k_B T)$$

where p is the tunneling probability of an electron through the barrier, and f_0 and f are, respectively, the attempt frequencies for the tunneling and thermally activated processes. Assuming a Gaussian distribution of the barrier, the calculated decay curves using this equation with appropriate fitting parameters show good agreement with the experimental results for every temperature, as shown in Figure 8. From the above analysis, it seems that thermal activation is dominant in carrier escape as the temperature increases above the maximum luminescence intensity, and tunneling becomes significant at very low temperatures with a low rate of radiative decay. The mean barrier height, E_a, obtained is 0.259 eV at a luminescence energy of 1.459 eV, which is one order of magnitude lower than the band offset between Si and SiO_2. They considered two possible reasons for this: (1) the existence of some material that differed from the simple oxide (a compound of Si, O, and H) on the surface of the Si nanocrystal; or (2) undulation in the width of the quantum wire. As the explanation mentioned above, the temperature dependence of the luminescence, and the lifetime and nonexponential decay profiles, can be successfully interpreted in terms of the quantum confinement model for porous Si that is not heavily passivated by oxygen. For heavily oxygen-passivated porous Si, coupling of excitons and local vibration at the surface have been suggested by several groups [76, 77].

3.3. Applications

Optoelectronic integrated circuits (OEICs) could have a significant impact on display and optical transmission in electronic data processing systems. OEICs with optical interconnections have already been realized in computer

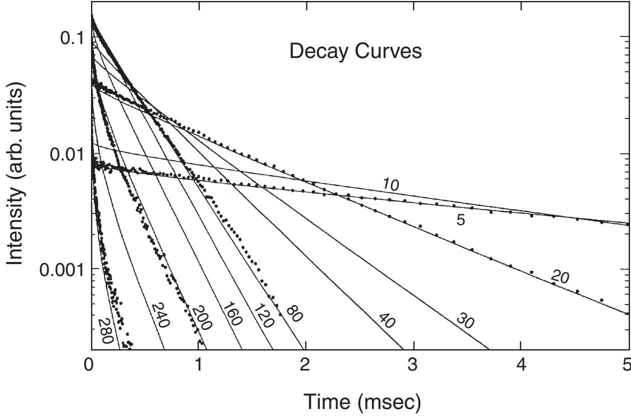

Figure 8. Typical observed decay curves of porous Si (dotted curves) taken at 5, 19, 80, 208, and 271 K. The solid curves are the calculated decay profiles. Reprinted with permission from [72], T. Suemoto et al., *Phys. Rev. B* 49, 11005 (1994). © 1994, American Physical Society.

networks and between computer boards. Many studies are now underway on optical signal transmission both between LSI chips on a board and within individual LSI chips.

An important factor in producing OEICs will be the ability to easily and inexpensively integrate optical and electronic devices on Si wafers. In this respect, the most satisfactory solution would be to create OEICs entirely from Si-based materials. Porous Si and Si nanocrystals have obvious potential in these light-emitting devices since they are forms of Si and emit intense visible photoluminescence. Preliminary versions of OEICs (including optical detectors and waveguides) have been already realized using Si-based materials. However, the major deficiency in current Si-based optoelectronic devices is the lack of suitable light-emitting devices such as light-emitting diodes (LEDs) and semiconductor lasers on Si wafers. At present, these light-emitting semiconductor devices are fabricated from direct-bandgap compound semiconductors. However, direct integration of compound semiconductor devices on a Si wafer has proved to be both complicated and expensive.

In recent years, the optical properties of Er-doped Si have generated intense interest because of the possibility of integrating electronic and optical devices using mature Si technology. Er emission at 1.54 μm, which arises from an internal 4f transition ($^4I_{13/2} \rightarrow {}^4I_{15/2}$) of Er^{3+} ions, is of particular interest because it overlaps the minimum loss region of the optical fibers employed in optical communication.

Recently, to improve the luminescence efficiency of Er-doped bulk Si, Er has been introduced into porous Si through ion implantation [78–81], electrolysis [82], or spin-on techniques [83]. The major advantages of porous Si as a host for Er ions are (1) the strong Er luminescence at 1.54 μm, (2) the weak temperature dependence of the Er luminescence, and (3) the long lifetime of the upper level $^4I_{13/2}$, which makes population inversion possible. The strong Er luminescence at 1.54 μm of Er-doped porous Si arises from the fact that the Er^{3+} ions are excited due to the energy transfer that results from the recombination of excess carriers confined in Si nanoscale grains in the porous Si near the incorporated Er. The quantum confinement of the carriers in Si nanoscale grains appreciably widens the Si bandgap and reduces the thermal quenching of Er^{3+} luminescence at 1.54 μm. The long lifetime of the upper level $^4I_{13/2}$ makes Er-doped porous Si very promising for a wide range of devices such as light-emitting diodes, optical amplifiers, and lasers.

Er-doped silica glass is already used in optical telecommunication technology as an amplification medium. Optical amplification at the 1.54-μm wavelength can be achieved if sufficient Er can be brought into the first excited state of $^4I_{13/2}$. Recently, Fujii et al. reported that the presence of Si nanocrystals in Er-doped SiO_2 considerably enhances the 1.54-μm luminescence of Er^{3+} [84]. Following this observation, a number of reports showed similar results for samples having Si nanocrystals and Er ions prepared using various means of Er doping including co-sputtering [85] and ion implantation [86–88]. All of these observations strongly suggest energy transfer from the Si nanocrystals to the Er. The currently accepted excitation model for Er^{3+} is as follows. First, a photon is absorbed by the Si nanocrystal, which results in the generation of an exciton inside the nanocrystal. This exciton can recombine radiatively, emitting a photon with an energy that depends on the size of the nanocrystal. If an Er ion is present close to the nanocrystal, the exciton can recombine nonradiatively by bringing Er into one of its excited states.

As described previously, the high luminescence efficiency of porous Si under optical excitation is quite remarkable. However, for its practical application as a light emitter, it will be necessary to obtain similarly high efficiency under electrical injection of carriers. Not surprisingly, attempts to observe electroluminescence (EL) began as soon as the high photoluminescence efficiency of porous Si had been reported [89, 90]. Initial results for devices with solid-state contacts were not very encouraging, while high EL efficiency was reported for liquid [91–93] or polymer contacts [94, 95]. Often, the reported quantum efficiency lay in the 10^{-6}–10^{-8} range for solid-state contacts in the initial stage [90]. A further complication hampering the use of EL devices is their poor stability. EL devices of porous Si with solid-state contacts typically fall into two categories: (1) Schottky type structures in which a metal contact deposited on the top provides a junction to the porous Si/bulk-Si structure [89, 90, 96, 97]. These devices often show limited rectification [89, 97]. (2) Vertical PN and PIN diode structures, on the other hand, yield EL only under forward bias [98–101]. This suggests the injection of both types of carriers. Several groups have recently reported the high quantum efficiency of such structures. Steiner et al. demonstrated a quantum efficiency of $\sim 10^{-4}$ in 1993 [100] and Linnros and Lalic demonstrated an even higher quantum efficiency of 2×10^{-3} in 1995 [101]. To improve the stability of EL devices, Tsybeskov et al. carried out light oxidation of porous Si and fabricated a stable PIN EL diode in 1996 [102]. They demonstrated a high quantum efficiency over 10^{-3}. EL was observed only in forward bias and at a voltage as low as 2 V. In addition, there was no degradation of EL during one month of pulsed operation. These results demonstrate fulfilment of many of the conditions required to make EL devices compatible with Si electronics. In 1996, Hirschman et al. demonstrated test structures that integrated Tsybeskov's EL devices (described above) with electronic devices [103]. There was also an attempt to fabricate EL devices consisting of Si nanocrystals by Toyama et al., who fabricated EL diodes showing visible EL emission with a peak energy of 1.8 eV in 1996 [104].

As mentioned above, porous Si, Si nanocrystals embedded in SiO_2, and Si nanocrystals in Er-doped SiO_2 are expected to play a key role in Si-based microphotonic application. However, there are still some obstacles to realizing this goal: (1) the need to further enhance the intensity of the luminescence; (2) the absence of directionality in the emission; and (3) the broad spectral shape of the luminescence (in the case of porous Si and Si nanocrystals). However, all of these problems can be overcome by microcavities. When a photon is confined in a microcavity in resonance with the emission of the active medium, the light emission becomes spectrally sharp and is strongly enhanced in the direction of confinement. Optical microcavities have been demonstrated for porous Si [105], for Si nanocrystals embedded in SiO_2, and for Si nanocrystals in Er-doped SiO_2 [106]. Pavesi et al. demonstrated porous Si microcavities based on distributed Bragg reflectors fabricated by alternating porous Si layers of

different porosities [105]. Iacona et al. fabricated Si nanocrystals embedded within a Si/SiO_2 microcavity [106]. They also realized Si nanocrystals in Er-doped SiO_2 sandwiched in Si/SiO_2 microcavities [106].

To realize laser operation, optical gain has to be achieved. Pavesi et al. demonstrated light amplification using Si nanocrystals dispersed in a SiO_2 matrix [107]. They realized a planar waveguide structure by Si nanocrystals formed by ion implantation into a SiO_2 matrix. A net optical gain was seen in both the waveguide and transmission configuration, with the material gain being of the same order as that of direct-bandgap quantum dots. They explained their observations using a model based on the population inversion of radiative states associated with the Si/SiO_2 interface.

4. ELECTRICAL PROPERTIES AND APPLICATIONS

4.1. Quantum Size Effects

From electrical measurement of the small Si dots sandwiched between tunneling barriers, it is difficult to assess the energy level due purely to the quantum size effect. This is because the contribution of the charging effect cannot be neglected in these small Si dots as quantum confinement energy is inversely proportional to the square of the dot size, while single-electron charging energy is inversely proportional only to dot size. Ye et al. investigated the discrete quantum levels of Si nanocrystals with SiO_2 barriers by observing their resonant tunneling characteristics at 77 K and at room temperature [108]. They fabricated diode structures with a layer consisting of laterally distributed Si nanocrystals. Compared with the theoretical results, they suggest it is necessary to recognize the charging effect to explain the large voltage separation between the resonant peaks.

Optical measurements are useful for assessing quantum energy levels only. Alsmeier et al. successfully obtained the quantum energy levels of Si dots using far-infrared transmission measurements [42]. They fabricated MOS devices with periodic arrays of electron dots on Si, which were widely tunable in diameter, employing electrostatic confinement with dual gates, as described in Section 2.2.

Several groups [109–111] reported the electrical measurements for diodes consisting of a SiO_2/Si nanocrystals/SiO_2 structure after Alsmeier's report; however, accurate separation of the effects of quantum size and single-electron charging has not yet been achieved.

The quantum size effect in a transistor structure is described in the section on single-electron transistors (Section 4.2.2) as it appears with single-electron charging effects in the transistor characteristics.

4.2. Single-Electron Effect

4.2.1. Single-Electron Charging Effect

Studies on the single-electron charging effect in solids originated in attempts to clarify the electrical conductivity of thin metal nanocrystal films. The importance of single-electron charging effects in the temperature and electrical field dependence of resistance in the plane of thin films composed of very small metal particles was first recognized in 1951 by Gorter [3]. In 1962, Neugebauer and Webb [112] confirmed these results experimentally. They measured electrical conduction in the film plane of ultrathin, evaporated metal films and obtained results that could be interpreted on the basis of the single-electron charging effect, that is, activation-type conductance, constant conductance in low electrical fields, and an increase in conductance in high electrical fields. In 1968, Giaever and Zeller [4] performed an interesting set of experiments designed to more clearly show the effect of single-electron charging on electron transport through extremely small metal particles in solids. They fabricated a diode structure of Sn particles with a diameter of about 20 nm and a double tunnel junction, and measured the electrical conductivity along the vertical direction to the plane at low temperature. They interpreted the high-resistance zero-bias anomalies by reasoning that the Coulomb-charging energies for the individual nanoparticles acted in such a way as to suppress electron tunneling to them. A detailed transport theory was later developed by Kulik and Shekhter in 1975 [113]. Much of our present understanding of the single-electron charging effect was developed in these early studies.

However, one drawback of these studies was inadequate control of the size and position of the nanocrystals. Consequently, the results obtained were the averages for the nanocrystals, leading to indirect proof of the existence of a single-electron charging effect. The lack of uniformity in their size and position also rendered these nanocrystals unsuitable for device application.

4.2.2. Single-Electron Transistor

Inversion-Type Si Single-Electron and Single-Hole Transistor Since the theoretical proposal of single-electron transistors (SETs) [6], there have been extensive experimental and theoretical studies on single-electron devices (SEDs). As previously mentioned (Section 1), SETs were initially fabricated using metal or compound semiconductors and measured at low temperatures to investigate the physics of the devices [7–9]. Reports of the use of Si in SEDs began appearing in the mid-1990s. The major reason for this timing was that the study of SETs was then more or less entering the practical phase of the research. From the point of view of down-scaling, the feature size of CMOS transistors would be comparable to that of SETs. Si-based SEDs have an advantage over those based on metal or compound semiconductors because of their compatibility with Si LSI technology. Another reason for the timing was that researchers were becoming aware of the potential to use the mature technologies used to fabricate Si LSI circuits (such as lithography, etching, and oxidation) in the fabrication of the extremely small structures required for high-temperature operation of SEDs. In addition, the ability to use fabrication technologies that required minimal changes to existing LSI device production facilities was a great advantage.

In the beginning, even for Si SETs, many of the fabricated Coulomb islands were rather large and single-electron effects were observed only at low temperatures. Coulomb oscillations and/or Coulomb gaps were observed for Si metal-oxide-semiconductor field-effect transistors

(MOSFETs) with a dual gate structure at 100 mK in 1994 [114], and at 4.2 K in 1995 [115] and 1996 [116]. In these devices, the lower gate formed a narrow inversion channel and the upper gate, which was made up of crossbars insulated by thick SiO_2, introduced potential barriers at constant intervals in a narrow channel. A Coulomb island was formed between two adjacent barriers in the channel. Another method of forming a Coulomb island is to use thin Si-on-insulator (SOI) materials since the thickness of the top Si layer of the SOI wafer can easily be reduced by oxidation and removal of the oxide. In 1994, SETs operating at up to 4 K were fabricated in thin SOI wafers using EB lithography and an isotropic dry-etching process [117]. Two EB lithography steps were used to form the Coulomb island. First, EB lithography and dry etching formed a narrow channel wire, and in the second stage, dry etching was applied for a short time to produce a narrow region in the channel for tunneling barriers. Also, using a thin poly-Si film on SiO_2 makes it easy to realize a size reduction in the vertical direction [118]. Using EB lithography and dry etching for patterning in the lateral direction, a Coulomb island was formed and operation of the SET was observed at 4.2 K (in 1995) [118].

From the point of view of its practical application, an important report was published by Takahashi et al. in 1994 [11]. They realized room-temperature operation of Si SETs using a pattern-dependent oxidation [PADOX] technique to achieve a very thin Si layer on SiO_2 [11, 119]. Conductance oscillations were observed at room temperature. Self-aligned processes usually have the drawback of insufficient controllability of the size and position of the structure formed. However, since the PADOX technique is a mixture of artificial and self-aligned fabrication methods, the size of the Si Coulomb island and its arrangement can be controlled to some extent. Using this PADOX technique or a modified PADOX technique (V-PADOX) [120], their group fabricated a Si SED that showed current switching at 30 K [121], two-input exclusive-OR gate function [122], and a CMOS-type inverter [123], for application such as in single-electron pumps and single-electron binary-decision-diagram (BDD) circuits. As well, a universal literal gate and a quantizer [124], which are basic components of multiple-value logic (MVL), were realized using the SETs fabricated by the above technique and MOSFETs fabricated on the same wafer. Since these MVL components are extremely compact, the number of elements can be greatly reduced by using merged SET-MOSFET devices.

After the report of room-temperature operation of a SET in 1994, various SETs operating at high temperatures were reported. By optimizing EB lithography and dry-etching techniques, Leobandung et al. [125] fabricated lithographically defined Si quantum dots with a diameter of about 20 nm. SETs and single-hole transistors (SHTs) that used the small island as a Coulomb island demonstrated quantum effects as well as Coulomb blockade effects at temperatures over 80 K. The SHTs [126] were fabricated using the same fabrication process except that the source, drain, and poly-Si gate were doped with a different type of species from those of the SETs.

Coulomb islands in the above SETs were fabricated (at least partly) with the help of dry etching. Thus, damage caused by dry etching had to be reduced by subsequent oxidation. In addition, the tunnel barriers between the Coulomb island and the source/drain regions were formed in the narrow Si wire where the quantum size effect raises the potential compared with that in the island. Oxidation after dry etching enabled the sizes of the Coulomb island and tunnel barriers to be further reduced. It should be noted that after dry etching, damage can be amended and the size of the Coulomb island and tunnel barriers reduced by using a wet-etching process [43, 127]. Nakajima et al. fabricated SETs showing clear Coulomb oscillation at 4 K using the wet-etching process [127]. In contrast, when Coulomb islands are formed using a deposition process, simple, damage-free fabrication is possible. In this case, the tunnel barrier usually consists of SiO_2 or air. Tunnel barriers made of SiO_2 have the advantage of greater barrier height, which is one of the conditions required for high-temperature operation of SETs [128, 129]. Choi et al. observed a Coulomb staircase and Coulomb oscillation at room temperature [34] using a conventional LPCVD method for Si nanocrystal formation, as described in the previous section [31, 32]. A few Si nanocrystals with a diameter of around 10 nm were positioned between ultrasmall metal pads with a gap <30 nm in the SiO_2 layer. However, with deposition methods, selecting only one Coulomb island and controlling its precise location present a difficult problem that has not yet been solved.

An interesting method has been proposed for realizing a high-temperature operating SET. A SET with a Coulomb island of a size beyond the limits of current state-of-the-art lithography was recently fabricated by Kim et al. [130, 131]. An amorphous Si side-wall was used as an etch mask for the formation of a SOI narrow channel wire. This method of side-wall patterning enables nanoscale patterning using a combination of conventional lithography and process technology. The SET has side-wall depletion gates on the narrow SOI channel, forming a small Coulomb island. The advantage of a side-wall structure is that it can implement a feature size below the limit of EB lithography. Periodic Coulomb oscillations have been observed up to 77 K and basic operation of a dynamic multifunctional SET logic circuit has been successfully demonstrated at 10 K by combining the fabricated SETs and a MOSFET.

Quantum Size Effects Quantum effects have more influence on the electrical characteristics of SETs and SHTs at higher operating temperatures since a smaller sized Coulomb island is required for stable operation at higher temperatures [125, 126, 132–136]. Roughly speaking, the quantum confinement energy is inversely proportional to the square of the dot size while the single-electron charging energy is inversely proportional to the dot size only. Therefore, the effect of quantum-level spacing increases and cannot be neglected as the island size decreases. To calculate the precise quantum-level spacing, it is necessary to know the confinement potential. However, precise potential profiles for the confinement have not yet been determined experimentally for SETs. Although experimentally obtained addition energy has been compared with calculated quantum confinement energy [125, 126, 132], the periodic drain current oscillations cannot be explained by assuming a simple potential well model for the confinement. However, more reliable values for quantum-level spacings were

obtained using the positions of the negative differential conductance and fine structures [134]. It has been suggested that in extremely small devices operating at room temperature it is very hard to predict the Coulomb oscillation peak positions due to these quantum confinement effects as well as the background charge since the energy spectrum fluctuates not only according to the size of the Si island but also according to the shape and orientation of the island [135]. Takahashi et al. proposed a method for adjusting the peak position after device fabrication by injecting charges into the Si nanocrystal floating gates [136].

Effect of High Doping Although various contingent phenomena, such as unintentionally introduced impurities or EB irregularities, can result in size reduction of the Coulomb island or tunnel barriers beyond the limits of state-of-the-art lithography, the controllability and reproducibility of the device fabrication method are extremely important in integrating the devices into circuits. Augke et al. suggested that highly doped SETs, nominally consisting of a single island and two Si tunneling barriers, act either as a SET with multiple Coulomb islands or as a SET with a single island corresponding to the geometric shape of the device, depending on the gate voltage applied [137]. The multiple islands are formed by the additional tunneling barriers introduced into the device as a result of fluctuations in the dopant concentration. These barriers can be removed by raising the Fermi level via the application of an appropriate gate voltage since the height of the barriers is usually less than that of a barrier defined by the geometrical shape. In another view, Sakamoto et al. [138] suggested that when the doping level is extremely high, fluctuations in the dopant concentration may be statistically very small, resulting in the electrical characteristics expected for a SET with a single island corresponding to its geometric shape.

System with Multiple Coulomb Islands Conversely, Coulomb islands can be self-assembled utilizing the dopant fluctuations discussed earlier. Frequently, Coulomb blockade phenomena have been observed in the conduction of highly doped narrow Si wires. Smith and Ahmed [139] observed the Coulomb blockade phenomena in highly doped (phosphorus) narrow Si wires (60–70 nm wide, 40 nm high, and 4–6 μm long) with a side-gate in a SOI configuration. They observed Coulomb oscillations with multiple periodicities as a function of the gate voltage and a minimum blockade size greater than zero. These phenomena are characteristic of single-electron tunneling in multiple-tunnel junctions of varying Coulomb island sizes, since the charging energy levels in each island in such a multiple island system can never be aligned with each other and the source-drain voltage at the same time. In this system, the gate coupling to the Coulomb island and the charging energies vary. There is speculation that the Coulomb islands and tunnel barriers are formed due to the dopant distribution. It is noted that in these high-doped narrow Si wires, equidistant peaks in the Coulomb oscillation have been reported. Tilke et al. [140] reported that 50-nm-wide Si wire fabricated on highly doped (As) SOI material shows equidistant peaks in the Coulomb oscillation at temperatures up to 100 K. They speculated that the pattern-dependent two-dimensional oxidation of laterally structured SOI wires is the reason for this. Another possible reason is the segregation effects of As dopants during thermal oxidation at the rough edge of the wire. They emphasize that the advantage of high doping is that it inhibits the separation of discrete energy levels, and that the charging energy for adding one electron to the SET is ideally not perturbed by the single-particle energy states.

Similar Coulomb blockade effects have been observed in the conduction of narrow poly-Si wires. The structural characteristics of the Si wires very much depend on the deposition method and conditions, and directly influence the electrical properties.

Ng et al. [141] examined the effect of wire length on the single-electron charging effect in ultrathin ($\sim$7 nm) wires of partly recrystallized poly-Si fabricated using electron-beam annealing of hydrogenated amorphous Si deposited by PECVD. In their work, long wires of micron-scale length and 50 nm in width were likely to exhibit Coulomb blockade effects at high temperatures of 70 K. Within the wires, Coulomb islands are speculated to be tapping sites in amorphous regions at grain boundaries. Another possibility is that a confinement due to potential fluctuations arising from dopant distribution forms Coulomb islands. In addition, the poly-Si grains may act as tunnel barriers. The larger Coulomb gaps observed with increasing wire length can be interpreted as quasi-one-dimensional multiple Coulomb island systems.

Solid-phase crystallized narrow poly-Si wires have exhibited single-electron charging effects. The wire was formed using thermal recrystallization of amorphous Si deposited by the PECVD method. After heavily doped (phosphorous) wire had been defined, thermal oxidation was performed, resulting in a minimum wire cross-section of 20×30 nm^2 [142]. In these wires, finer peaks are superimposed on the main peak in the Coulomb oscillation, suggesting the presence of a multiple tunnel junction along the poly-Si wires. The Coulomb islands are considered to be the poly-Si grains and the tunneling barriers are SiO_x created at the grain boundaries [143]. In the narrow wires, poly-Si grains form a one-dimensional chain of Coulomb islands, creating a multiple tunnel junction device.

Kawamura et al. [144] investigated narrow ($\geq$95 nm) and extremely thin ($\sim$7 nm) heavily phosphorous-doped poly-Si wires fabricated using LPCVD. The wire was fabricated in a two-step process: amorphous Si was deposited on the SiO_2 film at 520 °C by LPCVD and polycrystallized by annealing at 650 °C. The increase observed in the peak number of Coulomb oscillations with increased temperature (from 5 to 10 K) indicates that multiple Coulomb islands are connected in series in the narrow wire (120 nm wide). This is because, for electrical conduction to occur in a multiple Coulomb island system, the electrochemical potentials of each island must be at the same level within the limits imposed by thermal smearing. That is, kT determines the allowable mismatch between the electrochemical potentials of all of the islands. An increase in the peak number of Coulomb oscillations was also observed with increasing drain voltage in the narrow wire at 5 K, which indicates that the tunneling process occurs in the nonresonant inelastic tunneling mode. In nonresonant inelastic tunneling, an electron can tunnel through the multiple barriers between two adjacent islands nonresonantly by emitting

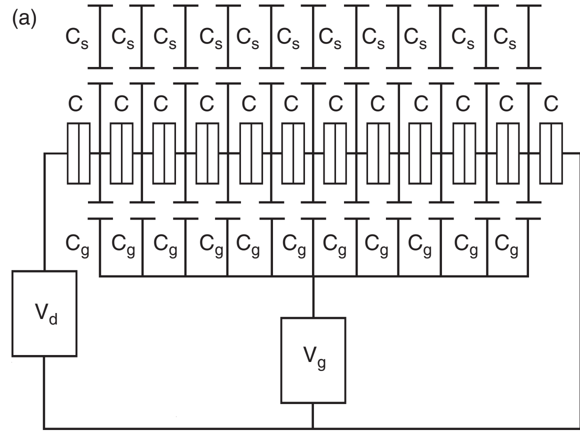
acoustic phonons. In the wires, the Coulomb islands are considered to be the small poly-Si grains and the tunneling barriers are the high potential barrier layer created at the grain boundaries due to the segregation of impurity atoms or the presence of a large number of trapping states in that region. The barrier height was estimated to be 26 meV from the activation energy of the conductance. The temperature dependence of the conductance within and outside of the Coulomb gap, suggested the generation of a charge soliton.

There are several advantages in using multiple tunnel junctions (MTJs). One is the ability to raise the operating temperature of the device in an MTJ system since the effective junction capacitance decreases due to the capacitances connected in series. This leads to a decrease in the total capacitance of the island inside the MTJ system and an increase in the charging energy of the island and a rise in the operating temperature. Another advantage of MTJs is the variety of their potential applications, such as to electron pumps and quantum dot cellular automata (QCA). To use such MTJ systems in SETs for practical purposes requires detailed investigation of the conduction mechanism.

Detailed descriptions of the fabrication procedure and measurements for SETs with one- and two-dimensional regular arrays of MTJs with metallic islands have been previously reported [8, 145, 146]. In such arrays, the presence (or absence) of one electron on an island induces the polarization of neighboring islands, described as a charge soliton (or antisoliton). However, for Si SETs with a MTJ system, most of the investigated arrays were naturally formed ones where junction size and position fluctuated, and they have not been evaluated precisely, as described earlier [34, 140, 144, 147]. Since the number of junctions is also unknown, the possibility of the contribution of solitons to conduction is suggested by Kawamura et al. [144], as mentioned above, only in these naturally grown systems.

To examine the conduction mechanism and the effect of solitons in detail requires the fabrication of a regular array of MTJs with numerous islands, in which the concept of solitons is important. Nakajima et al. [148] fabricated a Si SET with a one-dimensional regular array of MTJs with 11 islands for high-temperature operation and investigated the conduction mechanism in relation to solitons. A one-dimensional regular array of MTJs consisting of 11 islands was fabricated using EB direct writing in a SOI layer (Fig. 9). The tunnel barriers were formed in constrictions of silicon in between the islands due to the quantum size effect. The top layer of silicon and the buried oxide on the SOI wafers were 20 and 400 nm thick, respectively. Doping of the top silicon layer was carried out using $POCl_3$ diffusion (2×10^{20} cm^{-3}). The fabrication process included EB lithography and dry etching using an electron cyclotron resonance (ECR) etcher with the resist pattern as a mask. Subsequent isotropic wet etching in a $NH_4OH/H_2O_2/H_2O$ solution [43] reduced the dimensions of the device and amended damage that occurred during the dry-etching process. The widths of the barrier and island region were about 40 and 60 nm, respectively, as seen in Figure 9b.

For application to a QCA, Single et al. investigated a SET that included double islands with a regular array of junctions



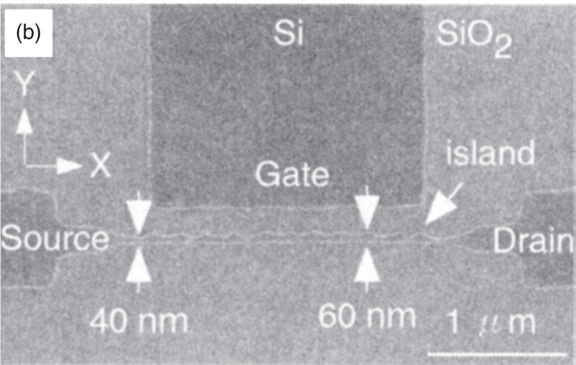


Figure 9. (a) Equivalent circuit of fabricated single-electron transistor (SET) with multiple tunnel junctions (MTJs) consisting of 11 islands. C_s, C_g, and C represent the substrate capacitance, gate capacitance, and tunnel junction capacitance of a Coulomb island, respectively. Parasitic capacitance C_0 of the island consists of C_s and C_g. (b) Plan-view scanning electron microscopy (SEM) micrograph of the SET. Reprinted with permission from [148], A. connected in series using EB lithography [149]. They confirmed the charge distribution between the dots on the system could be changed by the amount of one electron by measuring the drain current as a function of the two side-gates for each dot at 4.2 K.

4.2.3. Single-Electron Memory

Yano et al. reported the first room-temperature operation of a Si single-electron memory (SEM) in 1993 (Fig. 10) [10]. The SEM was based on a similar operating principle to that of a flash memory, except that the single-electron charging effect was utilized in the write/erase process [10, 150]. These reports were of great significance because they were the first to point out the potential application of single-electron devices to ultra-LSIs (ULSIs). The SEM uses very thin Si film (only about 3 nm thick), in which nanoscale grains form nanoscale Coulomb islands and a series of somewhat larger nanoscale grains forms the channel. Since there is a high statistical probability that one or more Coulomb islands are in the vicinity of the channel, the trapped charge in the Coulomb islands modulates the threshold voltage of the transistor section of the SEM. This concept overcomes

the main difficulty for SEMs in reading out small charges trapped in Coulomb islands at room temperature.

The most difficult problem in SEMs with naturally formed structures is the suppression of cell-to-cell scattering of the threshold voltage, which is essential for an acceptable error-rate memory system. To solve this problem, Ishii et al. introduced the concept of a verify process [151], which is described in detail later. A prototype of an ultralarge integrated SEM circuit (128 Mb) was demonstrated [152], in which the verify process was applied after both the writing and erasing processes, and a double-stacked memory cell structure was used. Utilizing the concept proposed by Yano et al., a Si single-electron memory with a structure more similar to that of flash memory was reported in 1995 by Tiwari et al. [30]. This device has a conventional MOSFET with Si nanocrystals acting as floating gates that are separated from the channel by a thin tunnel SiO_2 (Fig. 11) [30, 153–155]. In this device, single-electron transfer through the oxide was realized between the wide channel region and the Si nanocrystals by direct tunneling (DT) at 77 K. This SEM has several promising features over those of conventional flash memories, although the improvement of the SEM, such as the size of the Si nanocrystals, their uniformity, and density, is necessary for application to ULSIs. The advantages are as follows: (1) simple, low-cost device fabrication due to none of the complications associated with the dual poly-Si process used in a conventional flash memory; (2) better retention owing to the suppression of leakage currents between the nanocrystals and channel due to Coulomb blockade and quantum confinement effects [154]; and (3) again, better retention owing to the suppression of the leakage current between the nanocrystals and channel due to lack of conduction between the nanocrystals [153]. These improvements in retention time enable thinner tunneling oxides and lower operating voltages.

The next key research target for the nanocrystal memory described above is to further improve the threshold voltage characteristics and retention time. Refining the physical properties of the Si nanocrystals, such as crystal size and size distribution, and nanocrystal densities in the tunneling dielectrics, will directly contribute to this improvement. For this purpose, various tunneling dielectrics have been studied because the physical properties of the underlying layer largely influence the properties of the deposited Si nanocrystals. Kim et al. proposed ultrathin LPCVD Si_3N_4/SiO_2 double layers as tunneling dielectrics for use in a DT regime [156]. Because LPCVD Si_3N_4 has a rougher surface than thermal SiO_2, smaller and more uniform Si nanocrystals, at a higher density, can be deposited on LPCVD Si_3N_4 compared with those obtained on gate SiO_2. As a result of these features, clearer single-electron tunneling effects in the drain current versus gate voltage characteristics were observed for SEMs with double-layer tunneling dielectrics than for those with SiO_2 tunneling dielectrics at room temperature. In addition, Fernandes et al. proposed using atomic-layer-deposited (ALD) Al_2O_3/SiO_2 double layers as ultrathin tunneling dielectrics in a DT regime [157]. Better control of Si nanocrystal density against deposition conditions (SiH_4 pressure) was obtained for the deposition of nanocrystals on Al_2O_3 than on Si_3N_4. Better charge retention was also observed for double-layer tunneling dielectrics than for SiO_2 tunneling dielectrics.

To improve the physical properties of Si nanocrystals, a new formation process was introduced to SEM fabrication. De Blauwe et al. adopted a three-step aerosol process for Si nanocrystal fabrication and fabricated a floating-gate FET that acts in a Fowler–Nordheim (FN) tunneling regime [158]. The three-step process separates formation of Si nanocrystals, their surface oxidation, and their deposition onto the tunneling dielectrics.

The above reports of using SEM in a DT regime are all for *n*-channel nanocrystal memory. In contrast, the feasibility of *p*-channel nanocrystal memory was demonstrated

by Han et al. [159]. They observed V_{th} shifts due to hole tunneling in the Si nanocrystals through 4-nm-thick SiO_2 tunneling dielectrics. Since the barrier height of SiO_2 tunneling dielectrics for holes (about 4.7 eV) is larger than that for electrons (3.1 eV), the FN tunneling component due to holes is much smaller than that of electrons, leading to difficulties in using *p*-channel EEPROM devices in a FN regime. However, in a DT regime, the difference in gate tunneling current is less between *n*-channel MOSFETs and *p*-channel MOSFETs than in a FN regime. This suggests the possibility of using flash-type *p*-channel devices in a DT regime. They also observed better retention characteristics for holes than for electrons due to the higher barrier height of SiO_2 for holes than for electrons.

Interestingly, Ishii et al. proposed a new concept for utilizing a SEM with Si nanocrystals to replace a conventional nonvolatile memory with floating gates [160]. The devices they proposed are used in a FN regime with improvements in write/erase and retention characteristics. As charges are stored separately in multiple nanometer-size dots, only a limited quantity of nanocrystals are affected by weak spots in the surrounding insulator. This suppresses the generation of cells with an abnormally short retention time. Average write/erase operation between the nanocrystals sharpens the characteristic distribution of the device.

To attain long charge-retention characteristics without losing the high-speed write/erase characteristics of a DT regime, Ohba et al. proposed and fabricated a floating gate structure consisting of self-aligned double-stacked Si dots (Fig. 12) [161]. They showed that a SEM with double-stacked Si dots exhibited more than 10^2 times longer retention than a conventional SEM with a single-layer Si nanocrystal floating gate. This improvement in retention was attributed to quantum confinement and a Coulomb blockade in the lower Si dot. The trade-off between retention and write/erase speed is resolved by applying a high gate voltage for write/erase processes. Applying a high voltage enables a high write/erase speed. Since charge retention is carried out in the low gate voltage region, it is possible to obtain a long retention time without losing high-speed write/erase capability.

It should be noted that there have been attempts to use nanocrystals other than Si nanocrystals as floating dots in SEMs. Hanafi et al. fabricated a SEM with Ge nanocrystals

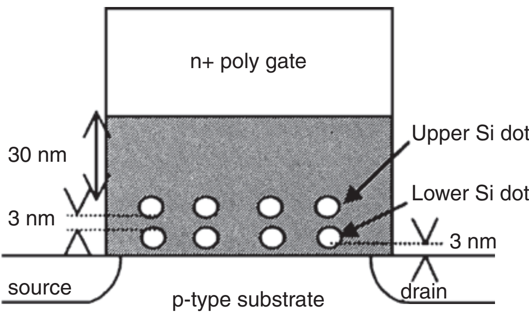

Figure 12. A schematic diagram of Si self-aligned double-dot memory fabricated by Ohba et al. Reprinted with permission from [161], R. Ohba et al., "IEEE International Electron Devices Meeting," 2000, p. 313. © 2000, Institute of Electrical and Electronics Engineers, Inc.

formed using a Ge ion implantation technique [155]. A high dose of Ge was ion implanted into thermal SiO_2 followed by annealing to introduce Ge nanocrystals into the oxide as floating gates. The drawback of this technique is the broader spatial distribution of the nanocrystals in the SiO_2, although it has the advantage that some of the nanocrystals are only a short oxide thickness away from the channel. King et al. developed a novel technique for fabricating Ge nanocrystals as floating gates that permitted more precise position controllability and uniformity of depth direction in SiO_2 [162]. The technique, which is based on thermal oxidation in combination with Ge segregation phenomena, provides excellent control of thickness for the top and bottom oxide layers that sandwich the nanocrystals. Taking another approach, Nakajima et al. developed a simple technique for fabricating metal nanocrystals as floating gates, which enables excellent uniformity of size and position, especially in depth direction [163–168]. The advantage of using metal nanocrystals as floating gates instead of semiconductor ones is the identical addition energy they provide because the contribution of the quantum confinement energy is negligible. Sn nanocrystals have been fabricated in thin thermally grown SiO_2 layers using low-energy ion implantation followed by thermal annealing [163–165]. The average diameter of the resulting Sn nanocrystals is 4.2 nm with a standard deviation of 1.0 nm. Sn nanocrystals preferentially reside in the SiO_2 layer at about 2 nm from the SiO_2/Si interface. This stable depth and excellent size uniformity are probably related to the transition region near the SiO_2/Si interface where compressive strain due to density mismatch occurs.

There may be an optimum nanocrystal depth and size that minimizes strain energy. Sb nanocrystals have also been fabricated in thin thermally grown SiO_2 layers using the same technique of low-energy ion implantation followed by thermal annealing [166–168]. Strictly speaking, the proposed method, which uses Sn in ion implantation, is not completely compatible with LSI fabrication since Sn is not typically used in conventional LSI device fabrication. However, Sb is one of the typical doping species used in conventional LSI fabrication. In contrast to the formation of Sn nanocrystals described above, when Sb nanocrystals are formed in a thin thermally grown SiO_2 layer, not only the effect of the compressive strain near the SiO_2/Si interface, but also the narrow as-implanted profile resulting from low-energy ion implantation contribute to uniform size and depth. When a narrow as-implanted profile is achieved with low-energy ion implantation, it results in an almost constant ion concentration in only a narrow region. If this narrow ion distribution can be adequately maintained during thermal annealing due to the slow diffusion of Sb in the SiO_2 region, the narrow profile will result in very uniform depth and size.

However, these devices used naturally grown Si nanocrystals as floating dot gates [10, 30] or even channels [10], leading to difficulties in controlling size, number, and position. This, in turn, led to poor uniformity and difficulties in analyzing the electrical characteristics. Hence, there was an urgent need for technology that could fabricate nanoscale features with precise control over size, number, and position. Thus, the next step in improving these devices was to artificially fabricate nanoscale floating dots and channels using

EB lithography. Consequently, in 1996 [169], a Si single-electron memory that could operate at room temperature was reported by Nakajima et al. with a nanoscale floating dot gate artificially fabricated using EB lithography and subsequent etching as described in Section 2.2. In this memory device [127, 169–171], a new technique was developed using a self-aligning process whereby a nanoscale floating dot gate was stacked exactly above a channel of nanoscale width (Fig. 13). This device thus allowed precise control over the size and the position of the floating dot gate, with the result that quantized threshold voltage (V_{th}) shifts due to single-electron transfer between the floating dot and channel were observed at room temperature (Fig. 14). Similar devices were reported around the same time [172].

Interestingly, the channel region beneath the floating dot is slightly wider than other channel regions in this device due to the lateral etching property of dry etching [127, 171]. This slightly wider channel region has been found to act as a Coulomb island at low temperatures. Consequently, this device can realize single-electron transfer not only between the floating dot and channel but also along the channel. If the Coulomb oscillation due to the single-electron transfer along the channel is combined with the quantized V_{th} shifts due to single-electron transfer between the floating dot and the channel, the possibility arises of producing a memory with ultralow power consumption.

It should be pointed out that the results of simulations have been published for the electrical characteristics of single-electron memories with a nanoscale floating dot gate [173, 174], and that the results obtained by Amakawa et al. provide a good explanation for the experimental results described in this section [174].

5. CONCLUSIONS

When the device size of MOSFETs decreases, the decrease in the mean number of carriers results in an increase in the thermal fluctuations of the carrier number relative to the mean value. This fluctuation in carrier numbers lowers

the reproducibility of the electrical characteristics for individual MOSFETs and between MOSFETs. Single-electron devices, which employ the Coulomb blockade effect, have the advantage of suppressing this fluctuation in carrier numbers [175].

To be considered as candidates for use in future LSI circuits, single-electron devices must be highly integrated and capable of operating at room temperature. It is therefore necessary to examine the reliability of the system at room temperature when single-electron devices are highly integrated. However, only a few reports have been published on this issue.

Two groups have anticipated the reliability of integrated single-electron memories at room temperature [175, 176]. Yano et al. [175] reported experimentally and theoretically on the time dependence of the probability distribution of the numbers of stored electrons for a single-electron memory with a floating dot gate. They showed that the probability distribution was clearly affected by the Coulomb blockade effect: the probability of a second-electron injection into the floating dot is much lower than the value expected for a Poisson distribution, which appears in the electron-tunneling process when the Coulomb blockade effect is absent. Due to the suppression of the second-electron injection into the floating dot gate (which was 10 nm in size), the probability of storing two electrons less than the average number of stored electrons is lower than the probability required by each memory cell for the operation of a 1-gigabit (Gb) memory chip with a 1000-fit error-rate. From this, they suggested that the average number of electrons required to achieve reliable operation is at least five, assuming that a 20% electron-count deviation is tolerable for each memory cell.

Usuki et al. [176] analyzed theoretically the basic trade-off between write errors and the number of stored electrons in a single-electron memory with a nanoscale floating dot gate at room temperature. They calculated the partition function from the charging energy of the floating dot, and then evaluated the mean number of stored electrons in the dot and the write error rate at room temperature. The write error rate was defined as the probability that the number of stored electrons is less than half the mean number of stored electrons. For a floating dot with a diameter of 10 nm, it was found that more than seven electrons are necessary at room temperature to maintain an error rate of 10^{-15}, which is the rate required by each memory cell to ensure reliable writing for a 1-Gb memory. The energy consumption of the memory cell was also estimated and found to remain low, even though each cell uses more than seven stored electrons. These results indicate that a memory with a small number n of stored electrons ($n > 7$) exhibits no disadvantages relative to single-electron memories with one stored electron.

These reports suggest that it is difficult to employ an integrated system when the write operation of the single-electron memory uses only a single-electron injection into a floating dot bigger than 10 nm. A simple calculation of the thermal fluctuation in the number of stored electrons (neglecting the discreteness of the quantum level in the floating dot) [176] shows that a floating dot with a diameter of less than 1 nm is required to obtain reliable write operation in an integrated system with only one stored electron in each memory. Since it is extremely difficult to reproducibly and uniformly fabricate a floating dot with a size of 1 nm with current fabrication technology, the development of single-electron memories that use a small number of stored electrons is probably a suitable objective for the next stage of research.

Another difficult problem encountered in the search for a memory that uses a small number of electrons is threshold voltage scattering due to background charges. To resolve this, Ishii et al., [151] proposed a new concept of applying the verify process, which has already been used in the operation of flash memory, to a single-electron memory. This process reduces not only the threshold voltage scattering due to stochastic variation and thermal fluctuation of the stored charge in the floating dot gate but also the scattering due to background charge. Threshold voltage and write time scattering between devices caused by the size and the positional fluctuation of nanoscale structures will also be suppressed by this verify process.

To produce memories that use few electrons, it is also necessary to investigate read and retention errors, since these also affect actual memories. It is equally necessary to continue efforts to improve the fluctuation in size and the productivity of nanoscale structures, and to control the distribution of background charge.

Unfortunately, the prospects for integration of the logic circuits of single-electron transistors (SETs) are not as bright as those for the memory devices described above. Kuwamura et al. [177] simulated the operation of complementary-SET (CSET) inverter circuits and pointed out that reliable operation at room temperature requires the total capacitance of the Coulomb island for each SET to be less than 0.16 aF (which corresponds to the self-capacitance of a Si dot with a diameter of around 1 nm in SiO_2) when CSET inverter circuits are highly integrated (a system of 10^{10} CSET inverters with an effective operating rate of 1% operates without error during a 10-year period with a clock rate of 100 MHz). When Shimano et al. [178] carried out simulations to test the reliability of CSET inverter circuits, they found that unless a 0.1-nm square tunnel junction of the Coulomb island is fabricated for each SET, at room temperature, it seems to be impossible for the CSET inverter circuit to meet the system specifications for reliability required by conventional Si ULSI systems (the system bit error rate is 10^{-10} during a 10-year operation period with a gate number of 100 kgates and a clock rate of 100 MHz).

Although several other logic circuits with SETs have been proposed [179, 180], no evaluation of their reliability in a highly integrated system have been performed at room temperature. The situation is further complicated by the fact that changes in the peak and valley positions of the Coulomb oscillation due to background charges increase the error rate of logic circuits with SETs [181]. In contrast to the case for memory (the verify process cannot be used for logic circuits), at present there are no reasonable solutions to the problem of background charge. Therefore, it is extremely important to clarify whether reliability can be maintained at room temperature when the logic circuits of SETs are highly integrated.

GLOSSARY

Addition energy Energy required to add or remove an electron to/from a dot. This energy generally includes both the contributions of charging energy and of quantum level spacing.

Charge soliton (antisoliton) In one- or two-dimensional regular array of multiple islands with multiple junctions, the presence (or absence) of one electron on an island induces a polarization of neighboring islands. The transfer of the charge distribution is called charge soliton (antisoliton).

Electron pump One of the single-electron devices categorized as a single-charge transfer device. Electron pump transfers exactly one electron from the source to the drain during one cycle of ac gate biases, even when the drain is reversely biased. Hence the name "pump."

Flash memory Electrically erasable and programmable read-only memory in which all the memory cells are erased in a lump.

Indirect bandgap semiconductor Semiconductor in which the minimum in the conduction band and the maximum in the valence band occur at different wave vectors.

PIN diode A diode in which a thin but lightly doped region is introduced between the *p*- and the *n*-side of a *p*-*n* junction. The lightly doped region can be assumed to be intrinsic.

Porous Si A Si layer consisting of many nanoscale structures and pores, formed by anodization of bulk Si in an aqueous HF solution.

Quantum cellular automata A machine consisting of identical cells, where each cell stores one bit of information and only talks to its nearest neighbors. A line of these cells can be used to transmit binary information and these cells can be arranged to form logic circuits.

Quantum size effect An effect in which the free electrons of holes occupy discrete quantum levels and have a discrete excitation spectrum when they are confined in a small region where their de Broglie wavelength is comparable to the size of the region.

Single-electron device A device that utilizes Coulomb blockade effect for the electron transfer.

Single-electron transistor A transistor having one or more Coulomb island(s) with tunnel junctions at both sides of each island. The electron tunnel through the island(s) is controlled by the gate voltage utilizing Coulomb blockade effect.

1. INTRODUCTION

In order to fabricate nanostructures, a technological process is needed, involving mask patterning followed by a surface machining. The final size of a device is mainly related to the mask size. Up to now, this size has regularly decreased from 15 to 0.18 μm over the last three decades. However, the manufacturing cost has followed the same type of variation, but in the way of an increase, leading to econonical limits toward 2010–2015. So, new low-cost approaches are under study: an-organic self-assembled layer for molecular electronics, nanoprinting, or scanning probe microscope (SPM) assisted lithography. SPM includes atomic force microscopy (AFM) and scanning tunneling microscopy (STM), two techniques based on a tip–surface interaction, with a nanometer range resolution. For the STM, the average tip–surface distance is on the order of 1 nm, and for AFM, in contact or noncontact mode (see other chapters of this encyclopedia for details on AFM and STM techniques), the tip is continuously or periodically in contact with the surface. If a few volts of polarization are applied between the tip and the surface, an electric field on the order of a few megavolts per centimeter is generated, leading to local electric-field-assisted oxidation of the surface. The subsequent oxide can be used as a mask in order to pattern the surface, under wet or dry etching. GaAs, SiGe, and Si semiconductors have been studied. Up to now, silicon has been the most popular, and this chapter is devoted to this material.

The aim of this chapter is to: (1) to present AFM and STM results for oxide generation, with the different physical parameters governing the oxidation kinetics; (2) to discuss the proposed models used to explain the oxidation process; (3) to show different nanodevices obtained using SPM-based lithography; and finally, (4) to discuss the throughput of SPM lithography, based on recent parallel approaches.

2. SILICON NANOOXIDATION

The first evidence of local nanooxidation of a silicon surface was presented by Dagata et al. in 1990 [1]. The authors used an STM on an Si(111) surface, preliminary passivated in dilute hydrofluoric acid after RCA cleaning [2]. The minimum definable feature was on the order of 100–200 nm size for an applied tip–surface voltage of 3.5 V and a tip velocity of 1 $\mu m \cdot s^{-1}$. Since STM images contain a convolution of topographic and electronic information, the STM-patterned features appear as 1–20 nm depressions. As silicon oxide is typically 1 nm high with respect to the silicon surface, this observation is in apparent contradiction with the observation of a locally oxidated region. In fact, as the silicon dioxide resistivity is higher than the silicon one, when the STM tip is over the oxide, the STM current tends to decrease, and in order to maintain a constant current, the STM feedback loop decreases the tip–surface distance. As the displacement of the tip perpendicular to the surface is interpreted as the local topography, the oxide thus appears as a depression. This observation shows us that the STM can realize local oxidation, but is not an adequate tool to accurently measure a local topography. However, as claimed by Dagata et al., this pioneer work shows that "STM-based nanotechnology is possible."

Modification of a silicon surface using an AFM with a conductive tip was demonstrated by a number of authors [3–6]. Figure 1 gives a schematic representation of the nanooxidation process. Day and Allee [7] used buffered hydrofluoric acid after the AFM oxidation process in order to reveal trenches in the silicon, consistent with silicon consumption in SiO_2 formation. By measuring the oxide height with the AFM, the authors showed that the oxidation is enhanced by the electric field and limited by the diffusion of oxidizing species. Fay et al. [8] examined a modified area of a silicon surface using Auger, electron spectroscopy, scanning

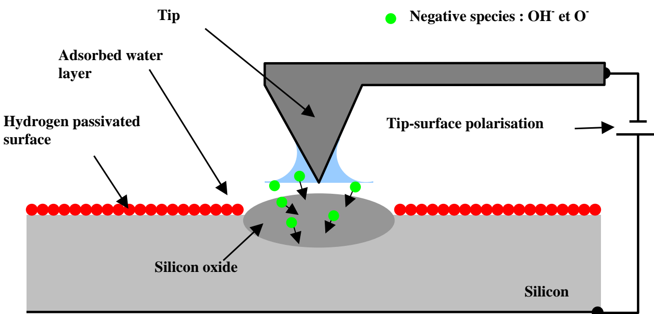

Figure 1. Schematic representation of the nanooxidation process.

electron microscopy, and atomic force microscopy. A comparison of these characterization techniques indicates that the features are both chemical and topographical in nature, and are the result of local oxidation of the silicon substrate.

These works have stimulated the research in the silicon nanooxidation field. A systematic study of the influence of the voltage and time [9–13] for STM and AFM in the contact mode has begun. The main results are that the oxidation is a tip-induced anodization and an electric-field-enhanced reaction.

As the tip–surface interaction is strong under STM or AFM in the contact mode, the tip reliability is poor. In 1995 and 1996, Pérez-Murano et al. [14] and Servat et al. [15] published a new approach using an AFM working in the tapping mode. They showed that a local oxidation is also possible, and realizes dots and lines. As the tip–surface interaction is smoother than in the case of the contact mode, the noncontact mode is more reliable than the contact mode, with high resolution (10 nm) and high speed (0.1 mm/s).

In order to clarify the performances of SPM techniques, Fontaine et al. in 1998 [16] investigated the three different SPM modes. They evaluated the efficiency of each technique in terms of reproducibility, spatial resolution, speed, and masking capability. Their results are summerized in Table 1.

The STM mode, despite reaching an optimum resolution of 10 nm, is not a suitable tool for nanolithography on silicon. In contrast, AFM in the contact mode allows high speed (up to 1 mm/s), and can provide thick oxide (8 nm). However, these performances are achieved at the expense of loss of spatial resolution, mainly associated with the tip shape. AFM in the tapping mode appears to be the best compromise between STM and CM–AFM, offering fine patterns as narrow as 20 nm with relatively high speed (10 μm/s). Similar results have been recently published by Tello and Garcia [17] in 2001.

In 1999, Legrand and Stiévenard [18] introduced an original method for better reliability of the oxidation process. Up to then, a continuous bias voltage was applied between the tip and the surface. Starting from the observation that the time required to obtain 1 nm oxide thickness is on the order of a few microseconds, they concluded that a continuous bias voltage is not necessary, and they proposed a pulsed voltage technique. In such a case, the interaction time of the tip with the surface under the electric field decreases. The frequency oscillation (in the noncontact mode) of the cantilever is taken as a reference, and pulsed voltages with variable phase and duty cycle are used. They show that the variation of the phase allows a 100% modulation of the oxide width. This work was later reinforced by similar results from Pérez-Murano et al. [19] and Calleja and Garcia [20].

The role of oxygen is obviously important for the oxidation process. By choosing suitable and controlled experimental conditions, Marchi et al. [21] proved that the oxide growth process is limited both thermodynamically (as evidenced by the voltage threshold) and kinetically (as shown by a considerable increase of the oxide growth by an ozone supply in the environmental gas). They proposed a qualitative three-step mechanism: (1) surface depassivation by desorption of hydrogen atoms assisted by the electric field above a threshold voltage; (2) the formation of oxyanions in the water meniscus between the tip and the surface, a complex step which may involve both electrolytic and dissolution processes, and (3) diffusion of the oxyanions assisted by the electric field toward the SiO_x–Si interface. More quantitatively refined models are discussed in the Section 3 of this chapter.

With regard to the role of water in the oxidation process, it has been mainly studied for the tapping mode. The formation of a water bridge between the tip and the surface is driven by the electric field [22–24]. Once a liquid bridge is formed, it provides the ionic species and the spatial confinement to pattern the silicon surface. The method was applied to write arrays of several thousand dots with a periodicity of 40 nm and an average width of 10 nm. Finally, Snow et al. [25] reported measurements of the kinetics of scanned probe oxidation under conditions of high humidity and pulsed bias. They concluded that the oxidation reaction is dominated by the production of OH ions for the case of moderate oxide thickness (a few nanometers) and exposure times (typically less than 10 ms). For long exposure times (typically more than 100 ms) and thick oxides, the effects of ion diffusion, space charge, and stress (as pointed out in Section 3) can eventually dominate the kinetics. In fact, for a hydrophobic silicon surface, the oxidation rate for short pulse duration is governed by the density of H_2O molecules

Table 1. Comparison of nanooxidation efficiency of STM, contact mode AFM, and tapping mode AFM.

Factors	STM	Contact mode AFM	Tapping mode AFM
Reproducibility	<50%	>50%	>75%
Maximum speed (μm/s)	8	128[a]	20
Better resolution (nm)	10	30	10
Maximum thickness oxide (nm)[b]	1.5	8	4

[a] In this case, limited by SPM equipment.
[b] Limited by a maximum 12 V polarization associated with the equipment.

in the ambient humidity surrounding the tip–surface interface. For a longer pulse duration, liquid H_2O bridges this interface, and the maximum oxidation rate increases by a factor of $\sim 10^4$ according to the increased density of H_2O molecules.

In the next part of this chapter, we discuss the different models proposed to explain the oxidation process.

3. MODELIZATION OF THE OXIDATION PROCESS

As the modelization of the oxidation process is a key parameter to predict and control the fabrication of nanostructures, the mechanism of tip-induced oxidation has been adressed by several authors since 1995.

The first attempt to understand the physical mechanism and its relevance to anodization layer and thickness was proposed by Gordon et al. [26], who pointed out that the initial density of the surface OH group is rate limiting. Moreover, using degenerated samples, they demonstrated that the presence of holes at the surface to recombine with the negative species (O^- or OH^-) is requested. Indeed, under illumination, the hole concentration increases, and consequently, an increase of the oxidation rate is observed.

Teuschler et al. [5] and Ley et al. [13] proposed an empirical power law ($h \propto t^{1/4}$) which fits experimental data well, but which is incompatible with classical models for oxide growth. However, they showed the existence of a doping-dependent threshold voltage under which no oxidation occurs.

The first quantitative model based on a physical basis was proposed by Stiévenard et al. in 1997 [27]. Their basic proposed idea was to use a Cabrera and Mott model [28] developed for field-induced oxidation, and to extrapolate it for very thin oxide. An analytical formalism fits a linear relation between h and V and $1/h$ versus $\log(t)$ well. Finally, the model allows the estimation of an activation energy associated with the oxidation process. An energy of 0.15 eV is found, far from the 4 eV involved for a high-temperature thermal oxidation process and not far from the one (0.15–0.4 eV) associated with plasma oxidation.

The previous approach is available only for the initial oxide layer, and cannot explain the formation of a thicker oxide layer. The same year, Avouris et al. presented new information [29]: first, he measured an electrochemical current during the oxidation. Its low value (a few 10^{-15} A) is associated with ionic transport, which confirms the role played by OH^- groups in the oxidation mechanism. Second, the rate of oxidation was found to decrease rapidly as the oxide films grow due to the self-limiting influence of the decreasing field strengths and the build up of the stress. A logarithmic time dependence of h versus t is found to fit the data for t ranging from 0.01 to 1000 s and h from a few nanometers to 50 nm well. An apparent contradiction arises from Stiévenard and Avouris's conclusions concerning the variation of h with time, between $1/h \propto -\log(t)$ and $h \propto \log(t)$, respectively. In fact, the two models are not comparable since the time ranges are not the same. In the case of Stiévenard et al., the oxidation time ranges from a few microseconds to a few milliseconds, whereas in the case of Avouris, the oxidation time ranges from a few milliseconds to a fraction of an hour. So, it is difficult to compare the two analyses since the physical events taken into account in the models are different (stress versus cutoff thickness, for example), and the Stiévenard model is only available for the initial thin oxide layer.

Dagata et al. [30, 31] present new data on the growth rate and electrical characteristic of nanostructures produced by scanned probe oxidation by integrating an *in-situ* electrical force characterization technique and a scanning Maxwell-stress microscopy during the fabrication process. Simultaneous topographical, capacitance, and surface potential data were obtained for oxide features patterned on *n*- and *p*-type silicon and titanium thin-film substrates. They proposed a model for the SPM oxidation reaction which complements existing kinetics descriptions derived from the Cabrera–Mott theory (Stiévenard et al.'s model). They show that space-charge effects are consistent with a rapid decline of high initial growth rates, and that oxide thickness and stress considerations alone cannot account for the observed doping and voltage–pulse dependencies, density variations, and SPM oxide growth rate enhancement by voltage modulation and other dynamic pulse-shaping techniques. The space-charge form leads to a 0.1 eV activation energy process, in agreement with the one (0.15 eV) deduced previously with the Cabrera–Mott model. However, their conclusion is that stress and space charge simply describe the same final outcome—an amorphous oxide—from two different points of view.

The more refined model was proposed by Dagata et al. [32] in 2000, followed by a similar approach of Dubois and Bubendorff [33] one month later. Dagata proposed a model that includes a temporal crossover of the system from transient to steady-state growth, and a spatial crossover from predominantly vertical to coupled lateral growth. Starting from a direct-log form for the SPM oxidation, they examined the assumptions used to derive it by Uhlig in 1956. He assumed that the rate-controlling step involves interaction of oxyanions with electronic species—holes or electrons—and defects at a metal–oxide interface. In particular, using the Uhlig model, it is possible to unify key concepts introduced by Stiévenard (a cutoff field associated with the potential at which space charge in the oxide nulls the externally applied field) and Avouris (by replacing the stress by space charge for a thickness-related change in activation energy) with Dagata's conjectures about the influence of space charge on SPM oxide growth. According to this approach, the production of charged defects leads to a build up of space charge within the oxide, inhibiting further growth over long pulse times. The power law of time for the variation of the oxide height is then derived. Dubois and Bubendorff [33] proposed a similar model based on the presence of a space charge due to nonstoichiometric states located close to the bulk/oxide interface. The main assumption in the model derivation is the occurrence of mutual Coulomb repulsions between traps and the control of the ionic transport by the region of lowest electric field. In fact, these assumptions are commonly used to treat transport phenomena in dielectrics. The presence of large trap density during the formation of the very thin oxide layer is questionable, and depends on the presence of a native oxide, which in principle does not exist on

a hydrogenated silicon surface. However, the observed fast oxidation rates are associated with the presence of a large amount of defects. This observation leads to the conclusion of a poor-quality oxide (plasma-like), in agreement with the low oxidation activation energy.

To return to the proposed models, the main parameters to take into account in order to describe the oxidation process are: (1) a field effect with a cutoff field, (2) a diffusion-limiting process, and (3) a space-charge effect associated with defects located at the Si/SiO_2 interface.

In the next section, we give some illustrations of silicon nanostructures obtained after a dry or wet chemical etching of a silicon surface. The nanostructure is obtained thanks to the SPM oxide, which is robust enough to act as a mask during the etching process.

4. NANOSTRUCTURES

One interesting aspect of the SPM-induced nanooxidation is the possibility to obtain low-cost low-dimensional structures. One of the first silicon nanostructures was obtained by Snow et al. [34] using an STM operating in air. The process involves the direct chemical modification of an H-passivated Si(100) surface and a subsequent wet etching. The chemically modified zones of the surface can withstand a deep (greater than 100 nm) wet etching of the unmodified regions with no degradation. Patterns with lateral feature sizes on the order of 25 nm were reliably fabricated. Typical results are given in Figures 2, 3 and 4. Figure 2 shows AFM images of oxide lines and silicon wires after KOH etching, with the associated cross section. Figure 3 shows a 3-D view of silicon nanowires and Figure 4 is a 3-D view of a 5.5 nm high wire on SOI substrate. The true full width at half maximum (FWHM) is estimated to be about 8 nm. The same results were obtained by Snow et al. [36] using an electron cyclotron resonance source for etching. Later, in 1994, the same authors presented a method for fabricating silicon nanostructures [37] with an air-operating AFM (also published by Morimoto et al. [38] and Sugimura and Nakagiri [39]). An electrically conducting AFM tip is used to oxidize regions of size 10–30 nm of an H-passivated Si(100) surface. This oxide acts as a robust mask for pattern transfer into the substrate by selective wet etching (KOH solution). In 1995, a step toward the fabrication of a nanodevice was achieved by Minne et al. [40]. Using an AFM, they fabricated a metal oxide semiconductor field-effect transistor on silicon with an effective 100 nm channel length. The lithography at the gate level was performed with the AFM tip: the gate was defined by an electric-field-enhanced selective oxidation of the amorphous silicon gate electrode. The device has reasonable characteristics (a transconductance of 279 mS/mm with a threshold voltage of 0.55 V). The same kind of result was obtained by Fayfield and Higman [41] and Ishi and Matsumoto [42], and a silicon field-effect transistor was fabricated by Campbell et al. [43] with critical features as small as 30 nm. Snow and Campbell [44] presented an improvement in the fabrication process: the width of the wires and the resistance of the junctions were controlled by real-time, *in-situ* measurement of the device resistance during fabrication. Because the properties of the nanometer-scale devices are very sensitive to size variations, such measurements bring a more accurate method of controlling device properties than by controlling geometry alone *a posteriori*. Structures with critical dimensions of less than 10 nm were fabricated.

In the last section, a comparison of the performances of SPM, optical, and *e*-beam lithographies is presented.

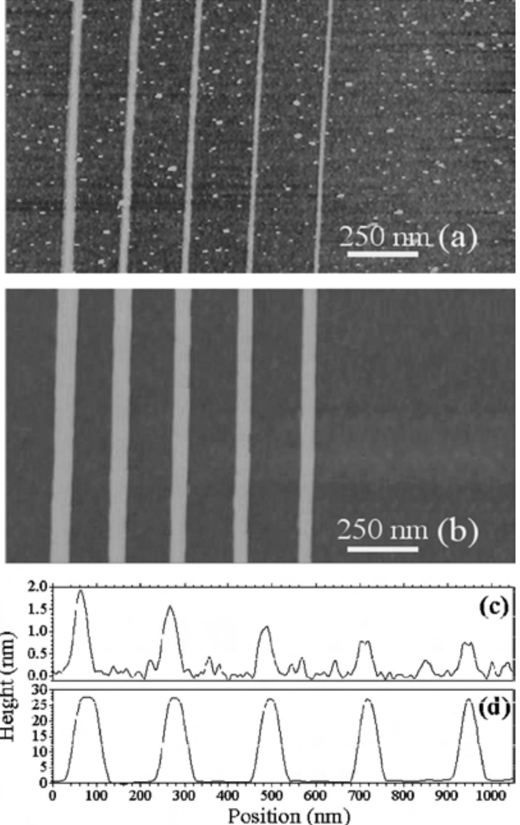

Figure 2. AFM images. (a) Top view of a set of five oxide lines of various widths and heights. (b) Resulting silicon wires after KOH etching. (c) Section across oxide lines of (a). (d) Section across silicon wires of (b) [35].

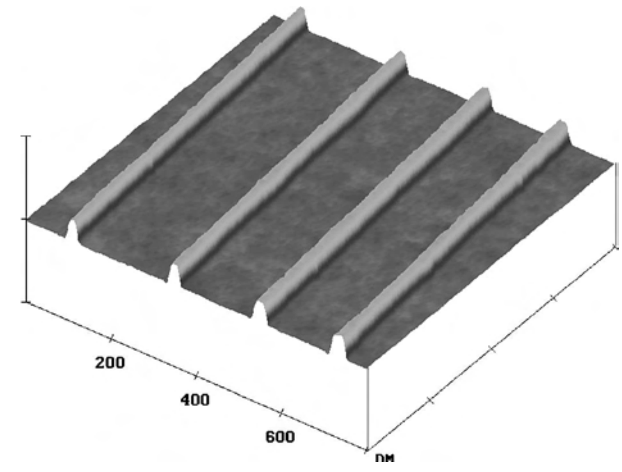

Figure 3. 3-D AFM view of silicon wires (height: 6 nm, width: 25 nm) [35].

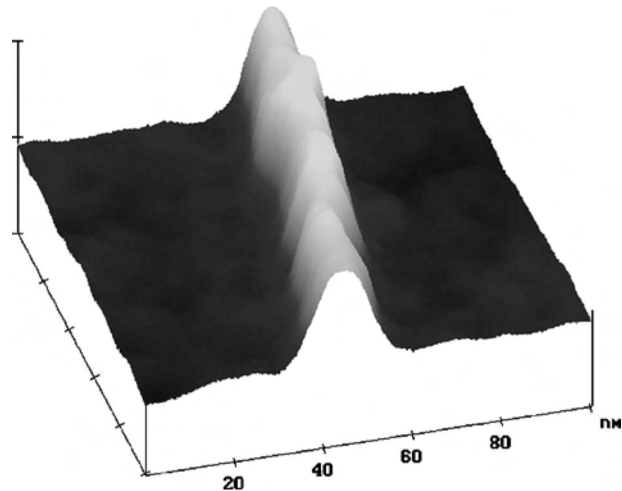

Figure 4. 3-D view of an AFM image (100 nm × 100 nm) showing a 5.5 nm high silicon wire with an FWHM estimated to be about 8 nm.

5. COMPARISON OF TECHNIQUES

Optical lithography has been used ubiquitously at the industrial level to define the patterns of integrated circuits for decades, and allows 0.18 μm resolution today. Projection optical lithography fulfills the five requirements for mass production: fine pattern formation capability, alignment accuracy, depth of focus, high throughput, and low cost. It will be used as long as possible, but theoretical limitations are on the verge of being resolved in the next decade. Indeed, it would be extremely difficult to delineate sub-100 nm fine patterns even by using short-wavelength light.

e-beam lithography could be an alternative since it is already employed for optical mask generation, and is at present the primary lithographic technique at the research level for nanometric device fabrication with 20 nm resolution. However, *e*-beam lithography suffers from a too slow wafer throughput. The exposure rate of an optical stepper is typically 10 cm^2/s, whereas it is less than 0.01 cm^2/s in the case of *e*-beam lithography, which is below the practical rate of 1 cm^2/s [45].

SPM lithography allows delineating down to 10 nm fine patterns, as shown before. The major drawback for practical applications is the very low exposure rate, on the order of 10^{-4} cm^2/s, for a single tip. Therefore, the only solution to fulfill the high-throughput requirement for mass production is the parallel lithography system. Using micromachining and microfabrication techniques, SPM tip arrays were built in the late 1990s. Following the work of Manalis et al. [46], who presented, in 1996, AFM cantilevers with an integrated actuator and sensor, Minne et al. [47] demonstrated lithography over a 100 mm^2 area using an array of 50 cantilevers. Up to a 1000 AFM tip array, called the "millipede," was built by IBM nearly at the same time [48]. Expected applications mainly concern ultrahigh-density data storage: using a thermomechanical process, each tip can write 30–40 nm sized bit indentations in a polymer film, and read them afterwards. On the other hand, Wada proposed in 1998 a lithography system including 10^4–10^6 micromachine SPMs in parallel [45]. Such a number of tips would allow reaching the practical exposure rate and the throughput required for mass production with a pattern minimum dimension of 10 nm. In order to ascertain the feasibility of the proposed system, these authors fabricated micro-STMs using technologies based on standard integrated-circuit fabrication technology. The total micro-STM size is about 100 μm, which is small enough to be integrated on a large scale.

6. CONCLUSION

As shown in this chapter, SPM-induced silicon surface oxidation is of prime interest for nanometer-scaled lithography. Many devices have already been demonstrated using SPM-based lithography, and several theoretical works have been devoted to the understanding and modelization of the SPM-induced oxidation mechanism(s). To realize prototypes (dots, wires, single electron transistors, etc.) with a nanometric size, such a technique is very low cost and powerful. It offers a unique way to study the physical properties of nanostructures. In the case of mass production, the low throughput is a major drawback. However, it can be partly overcome using a parallel system with up to a few thousand tips on the same support. Nevertheless, the poor tip reliability, even using pulsed voltage techniques, cannot be sufficiently increased for industrial applications. Only thermomechanical writing on polymer films is a possible route to low-cost and high-density data storage.

GLOSSARY

Atomic force microscope (AFM) Allows measurement of the topography of a surface with a nanometer resolution.

Etching During a technology process, the etching, wet or dry, allows the removal of materials in order to obtain 3-D structures.

Nanotechnology Technology using sub-100 nm resolution.

Oxydation Chemical reaction involving a material and oxygen.

Scanning probe microscope (SPM) Generic name for AFM or STM.

Scanning tunneling microscope (STM) Allows measurement of the topography and the local electronic structure of a surface.

Silicon on insulator (SOI) From bottom to top, materials made of a silicon substrate, an insulator, and a thin silicon top layer.

1. INTRODUCTION

The phenomenal success of semiconductor electronics during the past three decades was based on the scaling down of silicon field effect transistors (MOSFET) and the resulting increase of density of logic and memory chips. The most authoritative industrial forecast, the *International Technology Roadmap for Semiconductors* [1] predicts that this exponential ("Moore-Law") progress of silicon MOSFETs and integrated circuits will continue at least for the next 15 years. By the end of this period, devices with 10-nm minimum features (gate length L) should become commercially available. Recent experimental and results theoretical studies give grounds to believe that (given a proper economic climate) this frontier may really be reached. (For recent reviews, see [2, 3].)

However, prospects to continue the Moore law beyond the 10-nm frontier are much more uncertain. On one hand, recent theoretical modeling [4] of the most promising MOSFET species (double-gate transistors with an ultrathin undoped channel) indicates that the devices with a gate as short as ~3 nm still may provide performance high enough for use in most logic and memory circuits. On the other hand, the same studies show that such nanoscale MOSFETs would be extremely sensitive to very small variations of their physical dimensions. Figure 1 shows a typical result of such modeling; it implies that to keep variations of the transistor threshold voltage V_t below an acceptable limit (~50 mV), the gate length of a 5-nm MOSFET should be controlled better than ~0.25 nm, much tighter than the farthest ITRS projection of 0.7 nm for the critical dimension control accuracy at the 3σ level. Such high sensitivity to parameter fluctuations, and, hence, to the fabrication process as a whole, may lead to skyrocketing of chip fabrication facilities costs, very high even now. As a result, the Si-MOSFET-based Moore law may stop at $L \sim 10$ nm, i.e., long before fundamental physical limits have been reached.

These prospects give a strong motivation for the search for alternative devices that could replace MOSFETs beyond the 10-nm frontier, providing comparable performance but allowing less expensive fabrication. This search should start with a careful examination of the basic physics of transistor-like electron devices. Such an examination has to address, first of all, the famous particle-wave duality. Quantum mechanics show that electrons may behave either as discrete particles or continuous de Broglie waves, depending on experimental conditions. (Surprisingly enough, a sufficiently clear understanding of these conditions for conduction electrons in solids was achieved not so long ago, in the 1980s; for reviews see, e.g., [5, 6].)

Consider, for example, a generic situation where two parts of a conductor are separated by some interface, and ask whether the electric charge of each conductor is a multiple of the fundamental charge e at any instant (this is natural for the particle picture) or may be continuous (the wave picture allows this, because the wavefunction of each electron may be split between the two parts). The answer to this question turns out to depend on whether the effective tunnel resistance R of the interface is larger or smaller than the natural quantum unit of resistance

$$R_Q \equiv \hbar/e^2 \approx 4.1 \text{ k}\Omega \tag{1}$$

If the resistance is low, $R \ll R_Q$, the charge of each conductor may be continuous, but, in the opposite limit, it may be only a multiple of e.

This relation may be derived and explained in numerous ways [4–6]; perhaps the simplest interpretation is as follows. In a closed ("Hamiltonian") quantum system, the characteristic energy of quantum fluctuations per degree of freedom is $E_Q \sim \hbar\omega/2$, where ω is a characteristic frequency. In contrast, each part of the conductor we are discussing, concerning its electric charge degree of freedom, is an "open" system, strongly interacting with its environment (in classics,

corresponding to an RC relaxator, rather than an LC oscillator). For such a system, $\hbar\omega$ should be replaced by $\hbar/\tau$, with $\tau = RC$, where C is the capacitance between the two conducting parts. Transfer of a single electron between the parts causes an electrostatic energy change of the order of $E_C \sim e^2/2C$. Comparing E_C and E_Q, we notice that C cancels, and see that if $R \ll R_Q$, quantum fluctuations smear out the electrostatic energy difference that tries to keep the electric charge of each part constant.

To comprehend the importance of this result, let us combine it with the so-called Landauer formula for the interface conductance $G \equiv 1/R$ [5, 6]:

$$G = (e^2/\pi\hbar)\Sigma_i D_i \tag{2}$$

where D_i is the interface transparency (i.e., the probability of electron transmission) for a particular transversal mode of electron propagation; the sum is over all the modes. Comparison of Eqs. (1) and (2) shows that if the conductor cross section is so narrow that quantum confinement makes only one propagating mode possible, the condition of electric charge discreteness takes a simple and natural form: $D \ll 1$. However, for devices with a larger cross-section A, the restriction on the average transparency is much more severe: $D \ll 1/N$, where N is the transversal mode number. For a degenerate conductor, it is of the order of λ_F^2/A, where λ_F is the Fermi wavelength, typically of the order of 1 nm.

A MOSFET transistor is a good example of a device where the number n of electrons in the channel is never quantized, because the boundaries between the electrodes and channel are typically highly transparent ($D \sim 1$), and, in addition, the number of transversal modes is high ($N \gg 1$). As a result, these transistors do not exhibit single-electron charging effects (e.g., the Coulomb blockade) even if the average number of electrons in the channel is small. An adequate understanding of such devices may be achieved by using the wave language.

Theoretically, for nanoscale "wave" devices with $R \ll R_Q$, the FET-type control of transport is not the only possible mode of operation: the effects of quantum interference of electron de Broglie waves can be, as a matter of principle, used for this purpose as well. In the 1980s and early 1990s, numerous publications were devoted to the analysis and sometimes enthusiastic advertising of such "quantum electronic devices." However, later, the prospects for their practical applications (perhaps, with very few exceptions) have been recognized as rather dim, mostly for the following reason. In contrast to optical phonons (which obey Bose statistics), charge carriers in solids are fermions and, in particular, obey the Pauli principle: each of them must have a different energy, and, hence, a different de Broglie wavelength. Therefore, high-contrast interference patterns require operation with either a single transversal mode or a small number of modes.

The accuracy δL of size definition of the nanostructures that single out such a mode from a continuum, and then handle its interference, should be much better than the de Broglie wavelength $\lambda = h/(2mE)^{1/2}$ of the used electrons. Energy E should be well above the thermal fluctuation scale (typically, $\sim k_B T$) to avoid interference pattern smearing by thermal fluctuations. Combining these two requirements and plugging in fundamental constants, we may see that for room temperature, δL should be, as in nanoscale MOSFETs, well below 1 nm. This estimate shows that quantum interference devices do not have any substantial advantage over FETs for sub-10-nm scaling.

To summarize, besides some interesting memory cell ideas (which will be briefly discussed in Section 4.), in the category of "wave" electron devices ($R \ll R_Q$), we are still left essentially with field-effect transistors. In nanoscale structures with high impedance ($R \gg R_Q$), single-electron charging effects dominate and form the basis for single-electron devices. Their brief review will be the main subject of this article. (For earlier reviews see, e.g., [7–10].) Due to the space and time restrictions, I will not be able to cover the closely related superconductor, single-Cooper-pair devices [8–10] that may have some interesting applications in metrology and quantum computing, but can hardly make a large impact on broader electronics, due to the necessity of deep refrigeration (below the transition temperature of the superconductor material used).

2. BASIC SINGLE-ELECTRON DEVICES

2.1. Single-Electron Box

Physics of single-electron tunneling may be well explained on the example of the generic single-electron device, frequently called the "single-electron box" (Fig. 2a). The basic physics of this device was understood by Lambe and Jaklevic [11] as early as in 1969, on the basis of their experiments with disordered granular structures, while the first quantitative theory of the box was developed by Kulik and Shekhter [12].

The device consists of one small conductor ("island") separated from an external electrode by a tunnel barrier with high resistance,

$$R \gg R_Q. \tag{3}$$

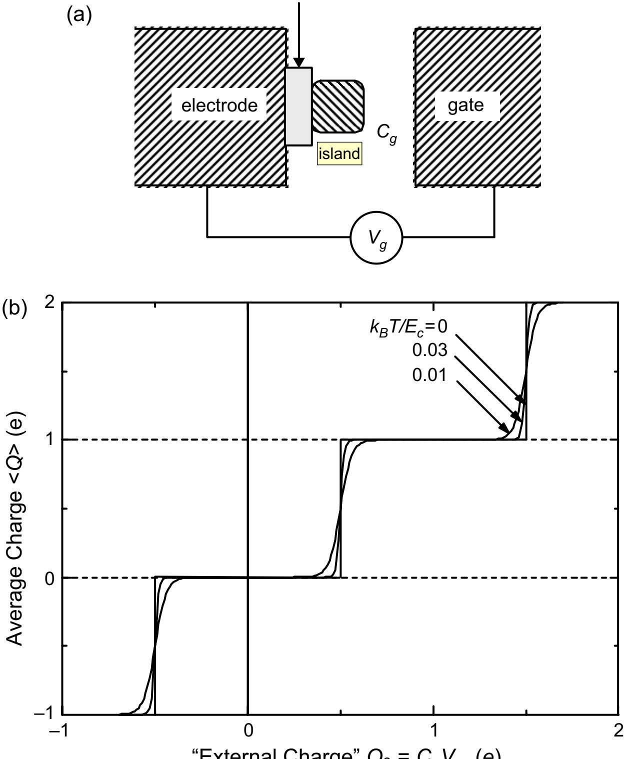

Figure 2. (a) Single-electron box and (b) its "Coulomb staircase," i.e., the steplike dependence of the average charge Q of the island on the gate voltage V_g, for several values of temperature.

An external electric field may be applied to the island by using a capacitively coupled gate electrode. The field changes the local Fermi level of the island and thus determines the conditions of electron tunneling. Elementary electrostatics shows that the energy of the system may be presented as

$$W = Q^2/2C_\Sigma + (C_0/C_\Sigma)QV_g + \text{constant} \quad (4)$$

where $Q = -ne$ is the island charge (n is the number of uncompensated electrons), C_g is the island-gate capacitance, while C_Σ is the total capacitance of the island (including C_g). It is convenient to rewrite Eq. (4) in another form,

$$W = (Q_0 - ne)^2/2C_\Sigma + \text{constant}, \quad Q_0 \equiv C_gV_g \quad (5)$$

where parameter Q_0 usually is called the "external charge." From its definition, it is evident that in contrast with the discrete total charge Q of the island, the variable Q_0 is continuous and may be a fraction of the elementary charge e.

At sufficiently low temperatures,

$$k_BT \ll E_C, \quad E_C \equiv e^2/C_\Sigma \quad (6)$$

the stationary number n of electrons in the island corresponds to the minimum of W; an elementary calculation using Eq. (5) shows that Q is a steplike function of Q_0, i.e., of the gate voltage (Fig. 2b), jumping by e when

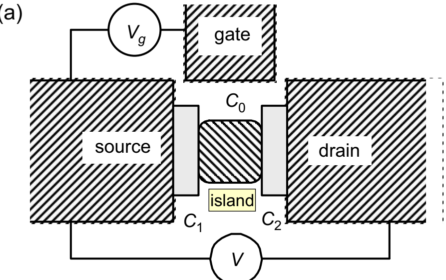
$$Q_0 = e\left(n + \frac{1}{2}\right), \quad n = 0, \pm 1, \pm 2, \ldots \quad (7)$$

If the temperature is increased to $k_BT \sim E_c$, the system has nonvanishing probability p_n will be in other states as well, with $p_n = \exp\{-W(n)/k_BT\}/\Sigma_n \exp\{-W(n)/k_BT\}$. A straightforward calculation of the average charge $\langle Q\rangle = -\Sigma_n enp_n$ yields the pattern shown in Fig. 2b: the steplike dependence of charge on gate voltage is gradually smeared out by thermal fluctuations. This is typical for all single-electron devices, so that the operation temperature of most of them should satisfy Eq. (6). (Notable exception are single–electron temperature standards—see Section 4.1.)

The physics of this "Coulomb staircase" is very simple: increasing gate voltage V_g tries to attract more and more electrons to the island. The discreteness of electron charge tunneling through low-transparency barriers (with $R \gg R_Q$, see the Introduction) necessarily makes this increase steplike.

2.2. Single-Electron Transistor

The single-electron box per se is still not a valuable device, but its simple modification, splitting its electrode into two parts, source and drain (Fig. 3a), turns it into a very important device, the single-electron transistor. This device, that was first suggested in 1985 [13, 14] and first implemented 2 years later [15], is clearly reminiscent of a MOSFET but with a small conducting island limited by two tunnel barriers, instead of the usual channel, connecting source and drain.



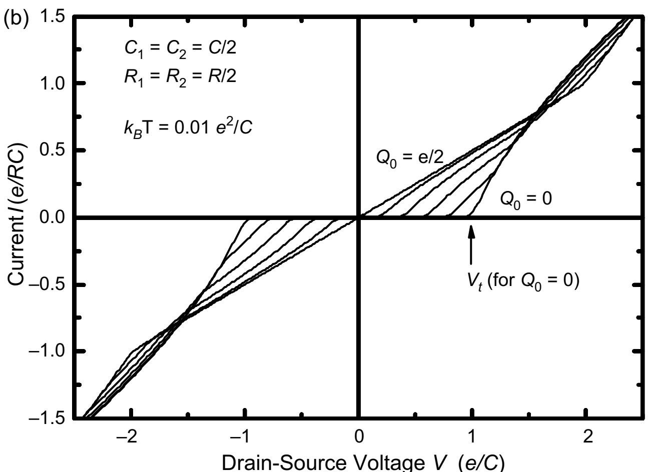


Figure 3. (a) Single-electron transistor and (b) a typical set of source–drain I–V curves of a symmetric transistor for several values of Q_0, i.e., of the gate voltage V_g, calculated by using the "orthodox" theory of single-electron tunneling.

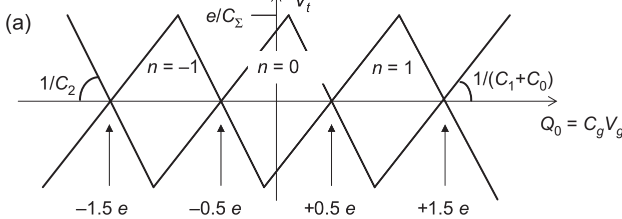
Figure 3b shows a typical set of direct current (dc) I–V curves of such a transistor, for several values of the "external charge" Q_0, defined in the same way as in the single-electron box [see Eq. (5)]. One can see that at small drain-to-source voltage V, there is virtually no current, besides the special values of Q_0 defined by Eq. (7). The physics of this phenomenon (the "Coulomb blockade") is easy to understand: even if $V > 0$, and, thus, it is energy-advantageous for a electron to go from source to drain, on its way the electron has to tunnel into the island first and change its charge Q it by $\Delta Q = -e$. Such charging would increase the electrostatic energy W of the system

$$W = (Q_0 - ne)^2/2C_\Sigma - eV(n_1C_2 + n_2C_1)/C_\Sigma + \text{constant},$$
$$C_\Sigma \equiv C_0 + C_1 + C_2 \qquad (8)$$

(where n_1 and n_2 are the number of electrons passed through the tunnel barriers 1 and 2, respectively, so that $n = n_1 - n_2$), and, hence, at low enough temperatures ($k_BT \ll E_C$), the tunneling rate is exponentially low.

At a certain threshold voltage V_t, the Coulomb blockade is overcome, and current starts to grow with V. The most important property of the single-electron transistor is that V_t is a periodic function of V_g, vanishing at special values of gate voltage, given by Eq. (27) (see Fig. 4). The reason for these so-called "Coulomb blockade oscillations" is evident from the previous discussion of the single-electron box: in the special points (7), one electron may be transferred to the island from either drain or source without changing the electrostatic energy of the system, even at $V = 0$. Hence, an electron can tunnel from the source to the island and then to the drain even at negligible V, so that $V_t = 0$. As can be readily shown from Eq. (8), at low temperatures the dependence of V_t on V_g is piecewise-linear, with its lower and upper branches forming the so-called "diamond diagram" (Fig. 4).



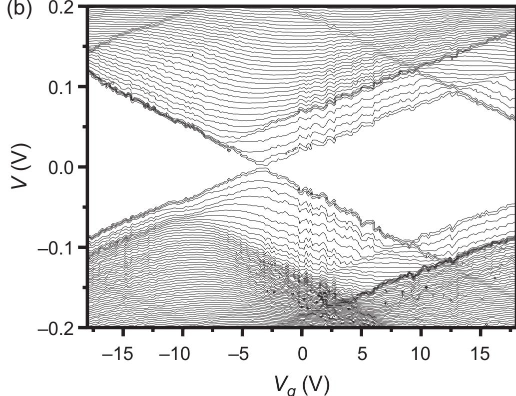


Figure 4. Threshold characteristics of single-electron transistors: (a) as given by the "orthodox" theory for $T \to 0$, and (b) experimental contour plots of constant current for an Al/AlO$_x$ transistor with $e/C_\Sigma \approx 0.1$ V, measured at $T = 4.2$ K. Reprinted with permission from [16], Y. A. Pashkin et al., *Appl. Phys. Lett.* 76, 2256 (2000). © 2000, American Institute of Physics.

Since the I–V curves of the transistor are continuous (Fig. 3b), if a small current is fixed by an external circuit (say, by a large resistor in series with the SET), V is close to V_t and also follows the diamond diagram (e.g., Fig. 4b). Thus, the voltage gain and transconductance of single-electron transistors may change sign depending on the gate voltage—an important difference in comparison with the usual field-effect transistors. The last mentioned property is very convenient for the design of SET analogs of (CMOS) circuits (see Section 5.3).

On the other hand, the same diamond diagram shows that the voltage gain is limited by a capacitance ratio: $(G_V)_{\max} = C_0/C_2$ [14]. It may be larger than unity (see, e.g., experiments [17–19]), but hardly much larger than that, especially in room-temperature transistors.

2.3. Single-Electron Trap

Another key device, the "single-electron trap," also may be understood as a generalization of the single-electron box. Let us replace the single tunnel junction in Fig. 2a with a one-dimensional (1D) array of $N > 1$ islands separated by tunnel barriers (Fig. 5a). (This device was first discussed explicitly in 1991 [20, 21], but, in fact, it may be considered just a particular operation mode of a more complex device, the single-electron turnstile, invented earlier [22].) The main

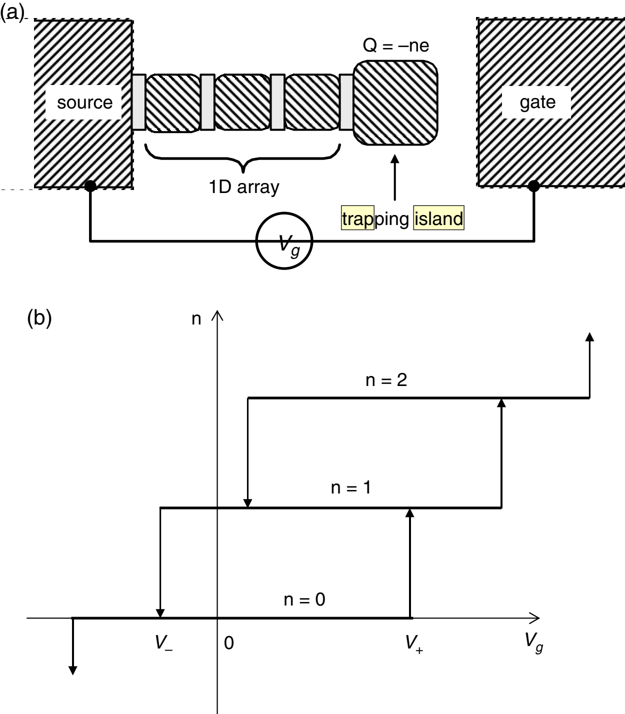

Figure 5. (a) Single-electron trap and (b) its static characteristic at $T \to 0$ (schematically).

new feature of this system is its internal memory (bi- or multistability): within certain ranges of applied gate voltage V_g, the system may be in one of two (or more) charged states of its edge island (Fig. 5b).

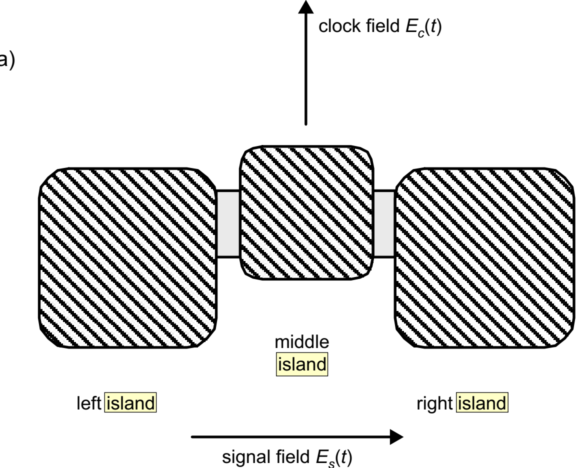
The reason for this multistability stems from the peculiar properties of an electron inside a 1D array; an electron located in one of the islands of the array extends its field to a certain distance [23, 24] and, hence, may interact with the array edges (is attracted to them). As a result, the electrostatic self-energy of the electron has a maximum in the middle of the array. By applying sufficiently high gate voltage $V_g = V_+$, the energy profile may be tilted enough to drive an electron into the edge island; if the array is not too long, other electrons feel its repulsion and do not follow. If the gate voltage is subsequently decreased to the initial level (0), the electron is still trapped in the edge island, behind the energy barrier. To remove the electron from the trap, the voltage has to be reduced further, to $V_g < V_- < 0$. As a result, the $n(V_g)$ dependence exhibits regions of bi- or multistability, in which the charge state of the trap depends on its prehistory (Fig. 5b).

The retention time of a certain charge state within the multistability region is fundamentally limited by the thermal activation over the energy barrier and a higher-order quantum process, cotunneling [25]. The first effect is exponentially low in E_c/k_BT, while the second effect falls exponentially with the array length N. As a result, electron retention time may be very long; experimentally, single electron trapping for more than 12 hr (at temperatures below 1 K) has been demonstrated [26–28].

2.4. Single-Electron Parametron

Single-electron parametron [29] is essentially a short segment of a 1D array of islands, galvanically detached from electron sources. The simplest version of the device uses three small islands separated by two tunnel barriers (Fig. 6a). For simplicity, I will describe its operation for the case when the system is charged by one additional electron, though such precharging is, in fact, unnecessary [30].

Let the parametron be biased by a periodic "clock" electric field $\boldsymbol{E}_c(t)$, oriented vertically, for example, by a slight vertical shift of the central island. (The same effect may be achieved in a strictly linear array, by using a special gate located closer to the central island [30].) This field keeps an extra electron in the central island during a part of the clock period. At some instant, the field E_c reaches a certain value E_t (Fig. 6b) at which electron transfer to one of the edge islands becomes energy advantageous. If the system were completely symmetric, the choice between the two edge islands would be random, i.e., the system would undergo what is called "spontaneous symmetry breaking." However, even a small additional field $\boldsymbol{E}_s$ applied by a similar neighboring device(s) may determine the direction of electron tunneling at the decision-making moment. Once the energy barrier created by the further change of the clock field has become large enough, the electron essentially is trapped in one of the edge islands, and the field $\boldsymbol{E}_s$ may be turned off. Now the device itself may serve as a source of the dipole signal field $\boldsymbol{E}_s$ for the neighboring cells. The sign of this field



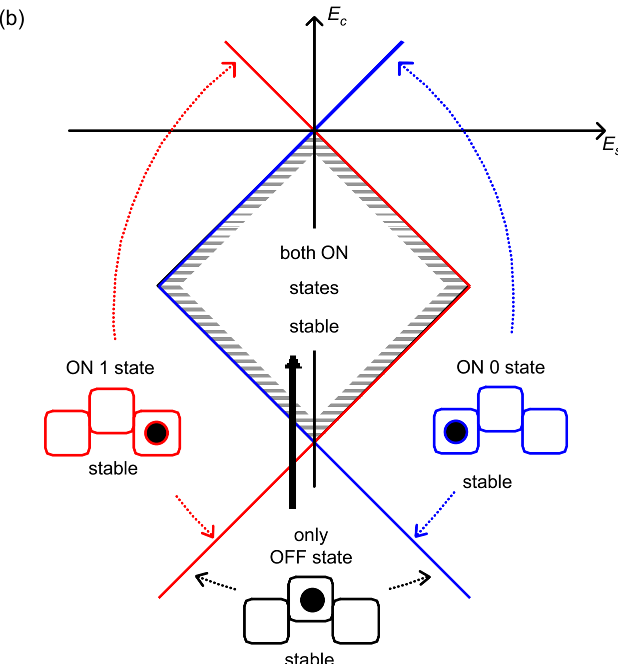


Figure 6. (a) Single-electron parametron (adapted from [29]) and (b) its phase diagram (adapted from [30]).

(i.e., of the electric dipole moment of the device) presents one bit of information.

Figure 6b shows the phase diagram of the parametron [30], which gives a quantitative description of the properties described previously. Each of "ON" states (with the extra electron in one of the edge islands) is stable within an angle-limited region. These regions overlap, providing the (hatched) diamond-shaped region of cell bistability. The route from "OFF" state (with the electron in the central island) to one of the ON states, as described, in shown by the bold arrow.

Recently, the parametron was experimentally demonstrated by two groups [31, 53] (albeit in one case under a different name).

3. SCALING AND IMPLEMENTATION

The most important conditions for operation of single-electron devices are given by Eqs. (3) and (6). The former condition, $R \gg \hbar/e^2 \approx 10$ kΩ, is relatively easy to satisfy experimentally, since resistance R of a tunnel barrier grows exponentially with its thickness. This relation shows that the output resistance of single-electron devices is unavoidably high, practically above ~100 kΩ. This feature frequently is cited as a drawback. However, what really is important for applications (e.g., interconnect recharging speed) is the maximum current density per unit width. For a room-temperature SET with $V \sim V_t \sim E_C/e \sim 1$ V, the total current would be below 10 μA. However, since the width of such transistor has to be very small, ~1 nm (see following), the available current density may be well above 1000 μA/μm, i.e., even higher than that of standard silicon MOSFETs [1].

The latter condition (6) makes the practical implementation of single-electron transistors operating at room temperature rather problematic. Figure 7 shows the energy E_a necessary to put an additional electron on a transistor island of a certain radius, calculated within the framework of a simple model. This energy is crudely a sum of the electrostatic contribution $E_C = e^2/C$, where C is the island capacitance, and quantum confinement energy E_k. While E_C dominates for relatively large islands, for 1-nm-scale islands with a size comparable with the electron de Broglie wavelength, E_k becomes substantial. Notice that at $E_k \gtrsim E_C$, the basic ("orthodox") theory of single-electron tunneling [8] (used in particular to calculate plots in Fig. 3b) should be modified [32, 33] (see also review [34]), although the device implications do not change significantly.

Both theory and experiment show that single-electron tunneling effects (i.e., some current modulation by gate voltage in single-electron transistors) become visible at $E_a \sim 3k_BT$.

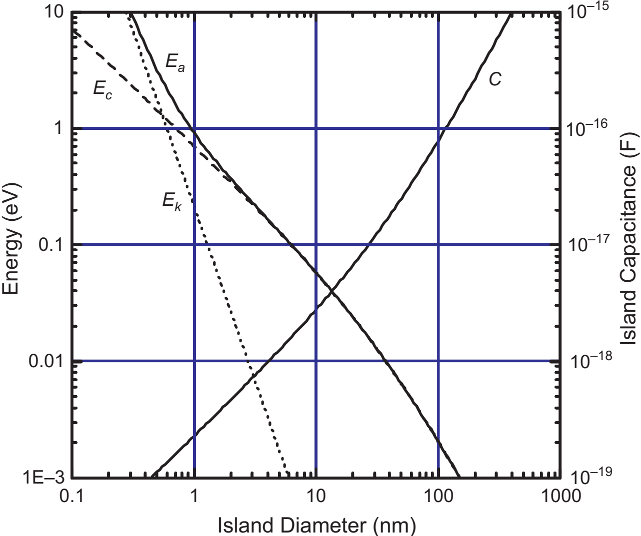

Figure 7. Single-electron addition energy E_a (solid line), and its components: charging energy E_C (dashed line) and electron kinetic energy E_k (dotted line), for a simple model of a conducting island. Reprinted with permission from [10], K. K. Likharev, *Proc. IEEE* 87, 606 (1999). © 1999, IEEE.

It means that to notice these effects at $T \sim 100$ mK (the temperature routinely reached in standard helium-dilution refrigerators), E_a should be above ~25 μeV, corresponding to the island capacitance $C \sim 5 \times 10^{-15}$ F and an island size of the order of 1 micron, with a tunnel junction area ~0.1 × 0.1 μm^2. Such dimensions can be reach routinely by several methods, including, notably, the now-classical technique of metal evaporation from two angles through a hanging resist mask (most typically formed by direct e-beam writing on a double-layer resist). This method was used, in particular, for the first experimental demonstration of a single-electron transistor [15]; later this technique, complemented with subsequent island oxidation, has been advanced to increase E_a to ~0.1 eV in certain samples [16]. This is sufficient to see a slight current modulation at room temperature.

However, for reliable operation of most digital single-electron devices (for exceptions, see Section 4.3.), the single-electron addition energy should be at least 100 times larger than k_BT. This means that for room temperature operation, E_a should be as large as ~3 eV. According to Fig. 7, this value corresponds to island size about 1 nm. Reproducible fabrication of integrated circuits with features so small presents quite a challenge. Most claims of success in this direction are based on studies of evidently irreproducible structures, for example, arrays of nanoparticles deposited between rather distant source and drain. (By chance, one of these particles may be tunnel-coupled to its neighbors much more weakly than are others, forming a single-electron transistor island, while strongly coupled particles effectively merge, forming its source and drain.) Of course, the parameters of such transistors are unpredictable, and there is no hope of using them in integrated circuits.

A more interesting option is fabrication of discrete transistors with scanning probes, for example, by nano-oxidation of metallic films [35, 36] or manipulation with carbon nanotubes [37, 38]. For the former devices, single-electron addition energies as high as 1 V have been reached [36], but unfortunately, the current in these transistors is very low (below 10^{-11} A). Moreover, these techniques are so slow that prospects for their use in the fabrication of circuits of any noticeable integration scale are very slim, though for discrete devices (e.g., Section 4.4.), this approach may be promising.

Several methods that are closer to standard CMOS technology also have been used to fabricate single-electron transistors, mostly by the oxidation of a thin silicon channel until it breaks into one or several tunnel-coupled islands (see the pioneering work [39] and recent results [40–43]). The highest values of E_a reached in those efforts (~250 mV [43]) are still not high enough for digital applications, but the necessary values $E_a \sim 3$ eV will probably be reached soon. A much larger problem with this approach is that the parameters of the resulting transistors are highly irreproducible, and there is little chance of changing this situation without the development of patterning technologies with a sub-nm resolution—a very distant goal indeed. (The use of carbon nanotubes [44] can hardly solve this problem.)

I believe that virtually the only promising way toward integrated circuits when using single-electron tunneling is the chemically directed self-assembly [45, 46] of molecular single-electron devices on prefabricated nanowires.

First, single-molecule single-electron transistors operating at room temperature already have been demonstrated experimentally [47–49]. Figure 8a shows the molecules used in experiments [49]. The obtained I–V curves (Fig. 8c) closely resemble the theoretical curves shown in Fig. 3b (though the adequate qualitative theory of these structures should depart considerably from the "orthodox" theory, by taking into account the electron motion quantization effects [32–34]). The main problem now is to synthesize molecules that would combine suitable device characteristics with the ability to self-assemble, with high yield, on a few nm gaps between prefabricated nanowires.

This approach can provide very high areal density of devices only if the wire pitch (wire width plus distance to the next wire) is of the order of the molecular device size. This would be a very tough task for usual lithography; however, if we put severe restrictions on the wire geometry, e.g., limit it by several layers of parallel wires, then special lithographic methods may be us, e.g., nanoimprinting [50] or an extension of the laser-assisted deposition techniques [51] to shorter wavelength (either EUV [52] or soft X-rays).

The nanowires may allow molecular single-electron devices to connect to larger and, hence, more sparse silicon nano-MOSFET devices (Fig. 9 [3]). The general idea of such "CMOL" (CMOS/nanowire/molecular) hybrid circuits is to combine the advantages of single-electron devices (very high density) with those of advanced field-effect transistors (high voltage gain and high reproducibility). A detailed discussion of this opportunity may be found in [3].

4. POSSIBLE APPLICATIONS

4.1. Analog and Metrology Applications

4.1.1. Supersensitive Electrometry

If the source-drain voltage V applied to a single-electron transistor is slightly above its Coulomb blockade threshold V_t, source-drain current I of the device is extremely sensitive to the gate voltage V_g. In fact, Figures 3 and 4 show that even the changes δV_g, corresponding to sub-single-electron variations δQ_e of the external charge, lead to measurable variations of I. This extremely high sensitivity has been suggested as a basis for supersensitive electrometry [14]. Calculations based on the orthodox theory have shown that the sensitivity of such an electrometer is not very impressive if the internal capacitance C_i of the signal source is large, on the scale of e^2/k_BT (at sub-1-K temperatures, above $\sim$0.1 pF) [66, 67]. On the other hand, if the source is so small and so close to the single-electron transistor that C_i, of the order of the capacitances of the transistor $C_{1,2}$, white noise limits the charge sensitivity at an extremely low level, $(\delta Q_e)_{\min}/\Delta f^{1/2} \sim 10^{-6} e/\sqrt{\text{Hz}}$, for the devices with routinely achieved 100-nm-scale islands (here Δf is the measurement bandwidth). This is some 7 orders of magnitude better than sensitivity of the best commercially available instruments, and about 4 orders of magnitude more sensitive than specially designed low-temperature MOSFETs (e.g., [83]).

Tunnel barriers and the electrostatic environment of single-electron devices always contain electron trapping centers and other two-level systems, each capable of producing "telegraph noise"—discrete, random low-frequency variations of the barrier conductance. An ensemble of these variations, with exponentially broad distribution of parameters, produces excess $1/f$-type noise; in single-electron transistors, such noise may be very high, typically limiting the charge resolution at the level of the order of $10^{-4} e/\sqrt{\text{Hz}}$ for a few Hertz signal frequencies. The sensitivity may be reduced radically (to a level below $10^{-5} e/\sqrt{\text{Hz}}$ [68]) by using special stacked geometry in which the single-electron island is lifted over the substrate that apparently hosts most of the $1/f$ noise sources. Another way to reach a similar sensitivity is to sense the transistor parameter change at a GHz-range

frequency [69, 70]. Such modulation cannot beat the white-noise imposed limitation of sensitivity [71] but helps to avoid most of the $1/f$ noise.

The high sensitivity of single-electron transistors has already enabled several groups to use them as electrometers in unique physical experiments. For example, they have made possible unambiguous observations [72–75] of parity effects in superconductors. The transistors also have been used in the first measurements of single-electron effects in single boxes and traps (e.g., [20, 26–28]). A modified version of the transistor has been used for the first proof of the existence of fractional-charge excitations in the fractional quantum Hall effect [76]. Another example is the sensitive measurement of local variations in the chemical potential of two-dimensional (2D) electron gas in GaAs/AlGaAs heterostructures [77, 78].

Further applications of these unique electrometers in scientific experimentation are imminent. For example, it has been suggested to use them, together with superconductor sensors, for submillimeter-wave photon counting [79]. A prototype detector of this kind for far-infrared photons (wavelength around 200 μm) has already been demonstrated [80].

Another exciting field is the fabrication of a single-electron transistor on the tip of a scanning probe and, with its help, implementation of a new type of scanning microscopy, combining submicron spatial resolution with sub-single-electron sensitivity [81]. This novel technique has already been used to observe single-charged impurities in GaAs/AlGaAs heterostructures.

4.1.2. Single-Electron Spectroscopy

Another useful spin-off of single-electron electrometry is the possibility of measuring the electron addition energies (and, hence, the energy-level distribution) in quantum dots and other nanoscale objects, pioneered by McEuen et al. [82].

There are two natural ways to carry out such measurements. The first is to use the quantum dot as the island of the single-electron box, capacitively coupled to the single-electron transistor or other sensitive electrometer [83]. The second is to use the quantum dot directly as the island of a weakly biased single-electron transistor ($V \to 0$) and measure the specific values V_n of the gate voltages V_g, which provide peaks of the source-drain conductance G (see Eq. (7) and its discussion). The latter method is technically simpler (only one small island is needed). Moreover, the height of the conduction peak gives additional information on the corresponding electron wavefunction distribution in the dot (e.g., [84]).

Single-electron spectroscopy has been applied to numerous objects, including laterally confined "puddles" of 2D electron gas in semiconductor heterostructures with lateral or vertical tunneling to source and drain, nanometer metallic clusters, naturally formed nanocrystals, C_{60} buckyballs, carbon nanotubes, and organic macromolecules and clusters. Presently single-electron spectroscopy is developing virtually independently of other applications of single-electron devices (for a detailed review, see [34]).

4.1.3. dc Current Standards

Another possible application of single-electron tunneling is fundamental standards of dc. The first suggestion for such a standard [13] followed the prediction that simple single-electron systems (e.g., a single small tunnel junction biased by a fixed dc I from a high-resistive source) should exhibit the so-called (SET) oscillations with frequency $f_{SET} = I/e$. Phase locking of these relaxation oscillations with an external radio frequency (rf) source of a well characterized frequency f would provide the transfer of a certain integer number m of electrons per period of external rf signal and thus generate dc, which is fundamentally related to the frequency as $I = mef$.

Despite the experimental confirmation of the existence of SET oscillations and the possibility of their phase locking [85], it turned out that better dc accuracy may be provided by other devices, the so-called single-electron turnstiles [22] and pumps [86], which do not exhibit oscillations in the autonomous mode. The following theoretical and experimental work has shown that better dc accuracy may be provided by the pumps, since these devices allow a more "gentle" (quasi-reversible) single-electron transfer. The best experimental effort so far gave a relative current accuracy of 1.5×10^{-8} [87], presumably limited by the photo-excitation of extra electrons by some electromagnetic radiation creeping into the system.

Unfortunately, the output current of single-electron standards is very limited (presently in the pA range), preventing a much broader application of these devices in metrology. A direct increase of the drive frequency f in pump-type devices runs into the problem of rapidly growing dynamic error rate. One way [10] to solve this problem is to use nanometer-scaled versions of charge-coupled devices [88] that would carry just a small, fixed number of electrons in each potential well, due to their Coulomb repulsion [89]. The first experimental step toward implementation of such devices has already been made [90].

4.1.4. Temperature Standards

An absolute temperature standard based on properties of 1D single-electron arrays has been proposed by J. Pekola and his collaborators [91–94]. At low temperatures, arrays with $N \gg 1$ islands exhibit dc I–V curves generally similar to those of single-electron transistors (see, e.g., Fig. 3b), with a clear Coulomb blockade of tunneling at low voltages ($|V| < V_t$) and approaching the linear asymptote $V = NRI+$ constant at $|V| \gg V_t$. If the temperature is raised above E_c/k_B, thermal fluctuations smear out the Coulomb blockade, and the I–V curve is almost linear at all voltages: $G \equiv dI/dV \approx G_n \equiv 1/NR$. The only remaining artifact of the Coulomb blockade is a small dip in the differential conductance around $V = 0$, with FWHM width $\Delta V = 5.44\ Nk_BT/e$.

Theoretical analyses have shown [92, 93] that this relation is surprisingly stable with respect to variations of almost any of the array parameters, providing a remarkable opportunity to use the arrays for absolute thermometry, since the fundamental constants are known with high accuracy. Each particular array may give a high ($\sim$1%) accuracy of T within less than 1 decade of temperature variations, but for arrays

with different island size (and, hence, different E_C), these ranges may be shifted and overlap. Thus it is possible to have an absolute standard of temperature with a very broad (say, 2 decade) total range from several circuits fabricated on a single chip.

This development is very encouraging, but further engineering work is needed to see whether these new devices will be able to compete with (or even replace) the more established temperature standards.

4.2. Random Background Charge Problem

The analog applications of single-electron tunneling previously discussed are very interesting, but, in terms of contemporary (predominantly digital) electronics, these are minor-niche applications at most. From the very formulation of single-electronics as an applied discipline [7, 95], the most intriguing question was whether single-electron devices will be able to compete with semiconductor transistors for use in digital integrated circuits. Any realistic discussion of this opportunity cannot ignore one more serious problem of single-electron devices.

Let a single-charged impurity be trapped in the insulating environment, for example on the substrate surface, at a distance r from a single-electron island, comparable to its size a. The impurity will polarize the island, creating on its surface a polarization ("image") charge of the order of $e(a/r)$. This charge effectively is subtracted from the external charge Q_0 [e.g., Eq. (5)]. This charge affects all characteristics of single-electron devices, for example, in the single-electron transistor, it determines the Coulomb blockade threshold V_t (see Fig. 4). For $r \sim a$, this shift may be large, in the order of $(V_t)_{\max}$, even from a simple impurity. By using even the most optimistic estimate compatible with experimental data, 10^9 cm^{-2} [54], for the minimum concentration of charged impurities, and assuming 1-nm island size, we can estimate that at least a 10^{-3} part of the chip area would be "poisoned," so that the same fraction of single-electron devices will have an unacceptably large background charge fluctuation, $\delta Q_0 \gtrsim 0.1\ e$.

A possible way to circumvent this problem is the use of single-electron transistors with resistive (rather than capacitive) coupling [14, 55, 56], which are insensitive to background charge. These devices require "ohmic" resistors with very high resistance (above $\sim$1 MΩ) and a quasi-continuous ("subelectron") transfer of charge that would provide the compensation for the fractional part of the random background charge. Such resistors have been demonstrated (e.g., [57]), however, their implementation for room temperature operation presents a problem. In fact, theoretical analyses [58–60] show that to provide the continuous transfer of charge, a diffusive conductor has to be much longer than the electron–phonon interaction length. For most materials at room temperature, this length is well above 10 nm (e.g., [61]), i.e., much larger than the desirable size of the whole device. Moreover, the stray capacitance of such a resistor would be much larger than that of the island itself, reducing its single-electron charging energy and making room-temperature operation impossible. As a matter of principle, electron hopping in quasi-insulators may ensure higher resistance at smaller resistor length; however, results of a recent analysis of quasi-continuous transport in this regime [62] also leads to pessimistic conclusions concerning the resistor size. For these reasons, prospects for room-temperature operation of resistively coupled single-electron devices do not look optimistic.

4.3. Memory Cells

The effect of random background charge randomness is easier to avoid in regular circuits, such as matrices of semiconductor memories [63, 64], that allow an access to each cell by selecting the corresponding "horizontal" (word) and "vertical" (bit) lines.

The published suggestions for single-electron memory cells are based mainly on two approaches:

- By using various modifications of the single-electron trap (Fig. 5) with either MOSFET or single-electron transistor readout,
- Direct scaling down of the cells of usual nonvolatile (e.g., flash) memories [64].

The latter approach includes an interesting proposal [96, 97] (see also [98–104]) for relatively large (multi-electron) memory cells, by using silicon nanocrystals rather than a single floating gate, in usual nonvolatile memories. The main advantage of this idea is that a single leaking defect in the tunneling barrier would not ground the whole stored charge but only its minor ($\sim 1/N$) part. This may allow very thin tunnel barriers (which would be unreliable in the ordinary case) to be used and thus decrease the characteristic time of Fowler-Nordheim tunneling, which presents the lower bound for the write–erase cycle. A potential drawback of nanocrystalline floating gates is that the electric field of the surface of each crystal, which determines the Fowler-Nordheim tunneling rate, depends on the size and exact shape of the crystal and is basically unpredictable. This may provide an undesirable broadening of the statistics of the electric field at the surface of nanocrystal surfaces and, hence, of write–erase thresholds, especially at any attempt to scale the cells to 10-nm scale size.

Returning to the two basic options outlined above, the physics of these two approaches is not much different: in both of them, insertion and extraction of a single electron to the trapping island ("floating gate"), i.e. write and erase operations, are achieved by the field suppression of the potential barrier separating the island from the electron source (word line). The only difference is that in the former case, the barrier is created by the Coulomb repulsion of electrons in a short 1D tunnel junction array, while, in the latter case, the barrier physics is the usual conduction band offset a single thick tunnel barrier (e.g., $\sim$8 nm of SiO_2).

Numerous experiments with single-electron cells of both types were useful for the development of the field; in particular, room-temperature operation of single cells has been demonstrated by several groups [65, 105–107]. However, because of the background charge randomness (see Section 4.2.), these cells can hardly be sufficiently reproducible. In fact, a single-charge impurity near the floating gate has an effect equivalent to an addition of (positive or negative) external charge $\Delta Q_0 \sim e$, and thus shifts the threshold for both write–erase, and readout operations from their

nominal values rather considerably. In the trap-type cells, the same effect, in addition, may change the array switching thresholds randomly. (Memory cells based on single- [or few-] electron trapping in grains of nanocrystalline MOSFET channels [108, 109] have even larger threshold spreads due to random locations of the grains and random transparency of tunneling barriers.)

However, due to the regular structure of memory arrays, several ways of avoiding the random background charge effects are available. The idea suggested first was to use the periodic character of the threshold characteristic of single-electron transistors for the cell contents readout [110]. In this approach, the memory structure may be very simple (Fig. 10a). Binary 1 is stored in a relatively large floating gate in the form of a positive charge $Q = Ne$, with $N \sim 10$, while binary 0 is presented by a similar negative charge. (Since $N \gg 1$, the effect of a random background charge on the floating gate is negligible.) The write–erase process is achieved by Fowler-Nordheim tunneling through a barrier separating the floating gate from the word line. Readout is destructive and combined with WRITE 1 operation—if the cell contents was 0, during the WRITE 1 process the injected electrons ramp up the electric potential U of the floating gate, so that the external charge Q_0 of the readout single-electron transistor is ramped up by $N'e$, with $1 < N' < N$. Due to the fundamental periodicity of the transconductance (Fig. 4), this ramp-up causes N' oscillations of the transistor current. (If the initial charge of the floating gate corresponded to binary 1, the transistor output is virtually constant.) The current creates oscillations of voltage between two bit lines connected to SET source and drain. These oscillations are picked up, amplified, and rectified by an FET sense amplifier; the resulting signal serves as the output. The main idea behind this device is that the random background charge will cause only an unpredictable shift of the initial phase of the current oscillations, which does not affect the rectified signal.

This concept has been verified experimentally [111] by using a low-temperature prototype of the memory cell. A very attractive feature of such SET–FET hybrid approach is a relatively mild minimum feature requirement: room temperature operation is possible with an electron addition energy of about 250 meV. Figure 7 shows that this level requires a minimum feature (SET island) size of about 3 nm, i.e., much larger than that required for purely single-electron digital circuits. The reason for this considerable relief is that in this hybrid memory, the single-electron transistor works essentially in the analog mode, as a sense preamplifier–modulator, and can tolerate a substantial rate of thermally activated tunneling events. One drawback of this memory is the need for an FET sense amplifier–rectifier. However, estimates show that since its input signals have already been pre-amplified with the SET, one FET amplifier may serve several hundred memory cells within the ordinary NOR architecture [63, 64], and, hence, the associated chip real estate loss per bit is minor. The next drawback is more essential: the signal charge swing $\Delta Q_0 = N'e$ at the single-electron island should exceed e. Since the gate oxide should not be too leaky to sustain acceptable retention time of the floating gate, its thickness should be at least a few nanometers. For silicon dioxide, this gives a specific capacitance

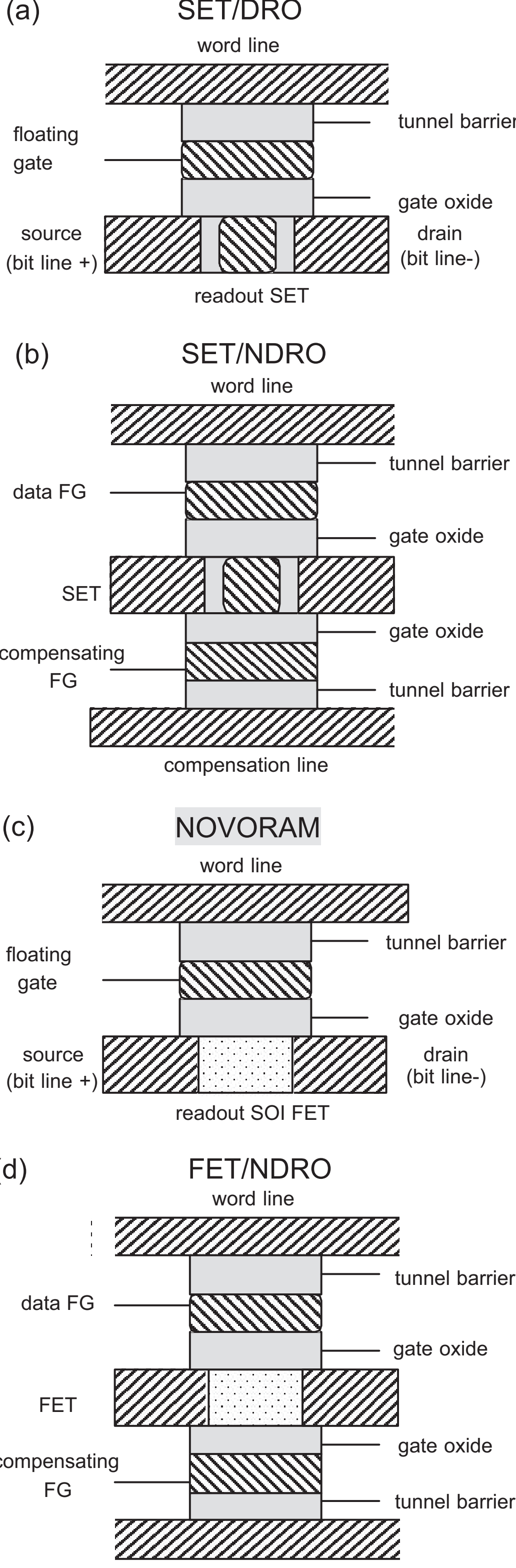

Figure 10. Suggested few-electron memory cells: (a) cell with destructive SET readout (SET/DRO, [110]); (b) SET-readout cell with background charge compensation, making non-destructive readout possible (SET/NDRO, [112]), (c) cell with nondestructive FET readout which may also be used in NOVORAM [113, 114], and (d) a similar cell with background charge compensation [3].

of approximately 1 μF/cm^2, corresponding to $\sim$10 nm^2 area per one electron (at 1 V). This prevents scaling of the island well below its maximum size ($\sim$3 nm).

Both these drawbacks may be avoided by using a more complex memory cell (Fig. 10b, [112]) in which the random background charge Q_0 of the island is compensated by weak capacitive coupling with the additional ("compensating") floating gate. The necessary few-electron charge of this gate may be inserted from an additional ("compensation") word line before the beginning of the memory operation, when special peripheral CMOS circuit measures Q_0 of each single-electron transistor (this may be done in parallel for all bits on a given word line) and develops an adequate combination of bit line signals. During the actual memory operation, the compensating charge is constant but may be adjusted periodically if necessary. Due to the compensation, the SET may be biased reliably at the steep part of its control characteristic (Fig. 14) and, hence, used for nondestructive readout of the cell state. Moreover, the signal charge swing may be relatively small, $\Delta Q_0 \sim (k_B T/E_a)e$, conveniently decreasing with the island size. This may allow the single-electron island to be scaled down to $\sim$1 nm, with the $\sim$3 nm floating gate storing just 2 to 3 electrons.

An alternative approach to few-electron memories is to scale down the generic structure of nonvolatile memory cells [64] by using a nanoscale MOSFET for readout (Fig. 10c). As was already mentioned in the Introduction, advanced MOSFETs with an ultrathin silicon-on-insulator channel may be scaled down to $\sim$10 nm, sustaining high performance and reproducibility. Further scaling down would lead to large random fluctuations of the threshold voltage, which again may be corrected by using a back floating gate (Fig. 10d).

Estimates of the maximum density of the SET–FET hybrid memories may be carried out under the assumption that the SET islands are fabricated by directed self-assembly, so their size is independent of the wiring line half-pitch F. In this case, the area of the cells shown in Fig. 10 is essentially independent of the island size and ranges between $6F^2$ and $8F^2$, where F is the minimum feature size of a given technology. The cell type determines the possible limits of this scaling. For the SET–DRO (Fig. 10a), it is confined in a narrow range around 3 nm, while for the SET–NDRO (Fig. 10b), F may be scaled down to $\sim$1.5 nm (line patterning permitting). For the FET–NDRO cells shown in Fig. 10c, *d*, the range of F does not have an upper bound; for the simple cell shown in Fig. 10c, the lower bound for F is about 5 nm, while the more complex cell with background charge compensation can be scaled down to $F \sim 2$ nm, i.e., to the cell area of about 30 nm^2. This should allow memories with a density well beyond 10^{12} bits/cm^2, enabling chips with a multiterabit integration scale. These exciting prospects are, however, contingent on the development of nm-scale fabrication technologies.

A possible problem with all the memory cells described is the slowness of the write–erase operations. In fact, they rely on the process of Fowler-Nordheim tunneling, similar to that used in the ordinary nonvolatile, floating-gate memories [64]. The standard 8-to-10-nm SiO_2 barriers used in such memories do not change transparency fast enough to allow floating gate recharging than in $\sim$1 μs even if the applied electric field is as high as $\sim$12 MV/cm, close to a breakdown threshold. (A reduction of the barrier thickness or height makes retention time too short.) Such a long write–erase cycle is acceptable for typical applications of flash memories [64] but is too long to replace (DRAM) in bit-addressable memories.

This problem can be solved by using special layered ("crested") barriers [113]. Calculations show [113–115] that trilayer crested barriers may combine a 1-ns-scale write time with a $\sim$10-year retention time, at apparently acceptable electric fields (about 10 MV/cm). This gives hope that such barriers may have the extremely high endurance necessary for RAM applications. Moreover, the ratio of the necessary write voltage (V_W) to the highest retention voltage (V_R) for such barriers may be well below 3. This condition ensures that the disturb effects on self-selected cells are small enough even in the simplest memory architectures [115].

Thus, if CMOS-compatible crested barriers are implemented, the few-electron cells shown in Fig. 10 may be used as random-access memories, replacing the (generically unscalable) DRAM. Moreover, crested barriers may enable the so-called nonvolatile random access memory (NOVORAM [115]) with a very simple cell structure (Fig. 10c) and architecture [105], which may be able to compete with DRAM and possibly SRAM even at the current technology level (minimum feature size F of the order of 100 nm), and be scaleable down to $F \sim 3$ nm. Some further decrease of F is possible by dropping the nonvolatility requirement and organizing cell refresh with period $\sim$1 s, because, in this case, the crested barrier and gate oxide may be thinned by $\sim$50%.

An alternative way to speed up the write–erase operation in floating gate memories is to replace the tunnel barrier with a transistor. Such two-transistor (2-T) memory cells were suggested long ago [116]; for a while they could not compete with DRAM because of the much larger cell size. The apparent impossibility to scale DRAM much below 100 nm has led to a recent revival of research and development work in this direction, and several new versions of the 2-T memories have been suggested (and some explored experimentally):

1) Single-electron trap with an additional gate controlling the potential profile high of the array and readout by using either a single-electron transistor [117] or nanoscale MOSFET [118–121]. Unfortunately, neither approach addresses the problem of random background charge. Notice that in experiments with semiconductor single-electron arrays, the Coulomb blockade mechanism of electron transport control coexists (and was repeatedly confused) with the usual field-effect mechanism. In this case, we are speaking about the effective replacement of the single-electron array by an MOSFET with very thin (and, hence, not very uniform) channel.
2) The authors of a recent work [122] have made this replacement conscientiously, arguing that their 2-nm-thick silicon channel should have lower parasitic source-to-drain leakage, because quantum confinement increased the effective bandgap. Indeed, their

MOSFETs exhibited leakage current as low as 10^{-19} A, sufficient to keep the cell retention time above 100 ms, i.e., the typical DRAM refresh time. A similar memory, but with a special "stacked" vertical FET [123] for fast write–erase (phase-state low electron drive memory [124]) (see also [125]). The channel of such a transistor incorporates three horizontal silicon nitride tunnel barriers partitioning the channel into several parts connected in series. Such separation improves transport control of the channel potential (and, hence, of the electron transport) by the surrounding gate; the considerable loss of ON current caused by these barriers is tolerable because the MOSFET should only recharge a very small capacitance of the charging node. Unfortunately, in such vertical MOSFETs, with their relatively large channel cross section, reaching acceptably small leakage current (and, hence, retention time) may be a difficult problem.

Though the last two approaches look interesting, I believe that the successful implementation of silicon-compatible crested barriers will make NOVORAM, with its simple structure, and small cell area, a more promising option.

The single- and few-electron memories will have to compete not only with each other, but with several other prospective memory concepts.

In ferroelectric memories, information is stored as a sign of electric polarization of a layer of a ferroelectric material. This polarization may be read out either destructively (as in DRAM) or nondestructively (e.g., if it controls a readout FET) [126]. Strong features of these memories include simple cell structure (and, as a result, small cell area), potential nonvolatility, and fast write–erase time (some materials have internal repolarization time well below 1 ns). In terms of an immediate practical introduction, the complexity of ferroelectric materials and their compatibility with the generic CMOS process is the main challenge. However, in the long term, scalability of these memories may be a larger problem. With the decrease in area, the height of the energy barrier $\Delta U \approx P_s E_c V$ separating two polarization states (where P_s is the saturation polarization; E_c, the coercive electric field; and V, the ferroelectric layer volume) decreases and should finally become comparable with the thermal fluctuation scale $k_B T$, resulting in random cell switching. For typical ferroelectric film parameters $P_s \sim 50\ \mu\text{C/cm}^2$ and $E_c \sim 5\ \text{V}/\mu\text{m}$ [126], such spontaneous switching should become rather noticeable ($\Delta U \lesssim 300\ k_B T$) at $V \sim 20 \times 20 \times 2\ \text{nm}^3$, even if P_s and E_c do not degrade with size. Thus, if no new breakthroughs are made, ferroelectric memory cells can hardly compete for terabit applications, which are the main promise of single- and few-electron memories.

In magnetic memories [127, 128], bits are stored in the form of thin-film magnetization. These memories share almost all the advantages and drawbacks of ferroelectric cells listed above (low 0/1 output signal value is an additional issue). However, because of the essentially similar physics, scaling of such cells to nanoscale may again be an issue. In this case, $\Delta U \sim B_s H_c V$ (where $B_s \sim 2$ T is the saturation magnetization and $H_c \sim 10$ Oe, the coercive magnetic field) drops below 300 $k_B T$ at even larger volume ($\sim 30 \times 30 \times 10\ \text{nm}^3$).

Memory cells based on structural phase transition include notably the Ovonics Unified Memory (OUM) [129, 130]. In an OUM cell, a chalcogenide alloy (GeSbTe) is switched from a conductive crystalline phase to a highly resistive amorphous phase under the effect of heating by current passed through a special heater. Though the chalcogenide materials are relatively complex, considerable progress in their deposition has been made in the course of development of CD-RW and DVD-RW technologies. As a result, OUM cells with surprisingly high endurance (up to 10^{13} cycles) have been demonstrated. Some OUM problems include relatively long write–erase time (reportedly, close to 100 ns, i.e., considerably longer than that of DRAM). Unfortunately, I am not aware of any published experimental data or reliable theoretical results sufficient to evaluate the dependence of the retention time on the storage region volume and, thus, to evaluate prospects of OUM scaling into the terabit range.

Finally, single-molecular memories may be based on various background physics. For example, they may be just the molecular implementation of single-electron memories as discussed previously. However, there is an alternative possibility: to use molecular conformation changes of the molecule for information storage. The studies of such single-molecular devices [131–135] are still in their infancy, and it is difficult to compare their prospects with the more mature approaches previously reviewed. I believe the most important issue to be addressed is the rate of thermally induced, spontaneous switching of a single molecule between its configurations. To keep the rate (and, hence, the soft error rate) sufficiently low, the potential barrier ΔU separating two possible states must be kept rather high, at least 100 $k_B T$. For room-temperature operation, this estimate yields ~3 eV, a pretty high energy scale. This requirement (together with those of fast electrical readout and reproducible directed self-assembly) will probably limit the list of possible candidate molecules rather severely.

4.4. Electrostatic Data Storage

A combination of single-electron transistors with crested barriers may be used not only in terabit-scale memories but also in ultradense electrostatic data storage systems [113] (Fig. 11). In this design, a single-electron transistor, followed by a MOSFET amplifier, a few microns apart, is fabricated on a tip-shaped chip playing the role of a READ–WRITE head. The data bits are stored as a few-electron charge trapped in a group of nanoscale conducting grains deposited on top of a crested tunnel barrier. It is important that since each bit is stored in a few (~10) grains, their exact shape and location are not important, so the storage medium production does not require any nanofabrication.

WRITE is performed by the application of the same voltage V_W to both input terminals, relative to the conducting ground layer of the moving substrate. The resulting electric field of the tip induces rapid tunneling of electrons from the ground through the crested barrier into a ~30-nm-wide group of grains. For READ, the single-electron transistor is activated by source–drain voltage $2V_R \geq V_t$. In this state, it is very sensitive to the electric field created by the group of charged grains it is being flown above.

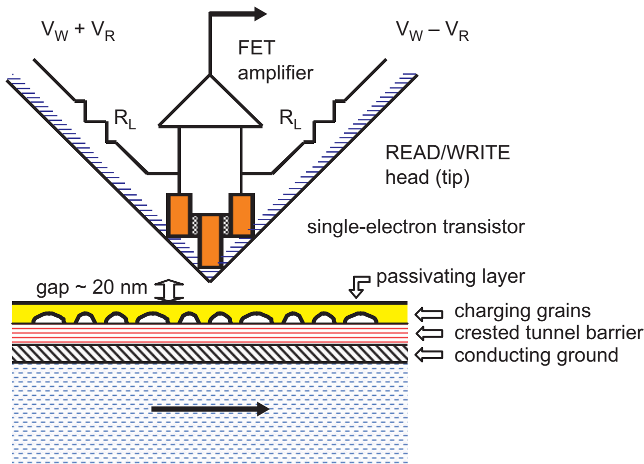

Figure 11. Proposed electrostatic data storage system with hybrid SET/FET readout [113], K. K. Likharev, *Appl. Phys. Lett.* 73, 2137 (1998). © 1998, American Institute of Physics.

Simple estimates show that with a 20-nm tip-to-substrate distance (close to those already implemented in the best present-day magnetic storage systems), the electrostatic system is capable of a density ~10 terabits per square inch, i.e., at least an order of magnitude more than the best prospects for the magnetic competition of which I am aware. The use of crested barriers may provide a very broad bandwidth of both WRITE and READ operations, up to 1 Gbps per channel, possibly quite adequate even for this enormous bit density.

Notice that for this particular application, the difficulty of fabrication of room-temperature single-electron transistors, outlined in Section 3, is not a major concern, because one would need just one (or a few) transistors per system, and slow fabrication techniques (like the scanning probe oxidation) may be acceptable. Moreover, as in single-electron memories, the transistor would work as an analog amplifier, so that the single-electron island size of ~3 nm would be sufficient.

The experiments [81], mentioned in Section 4.1., may be considered as the first step toward the implementation of this idea.

4.5. Logic Circuits

4.5.1. Voltage State Logics

Most suggestions of logic circuits based on single-electron devices may be referred to one of two groups. In circuits of the first, "voltage state", group (first considered in [14]) single-electron transistors (Fig. 3) are used in CMOS-like circuits. This means that the single-electron charging effects are confined to the interior of the transistor, while externally it looks like the usual electronic device switching persisting currents, with binary unity–zero presented with high–low dc voltage levels (physically not quantized). This concept simplifies the circuit design that may ignore all the single-electron physics particulars, except the specific dependence of the drain current I on the drain-to-source voltage V and gate-to-source voltage V_g (Figs. 3 and 4).

Analyses of this opportunity have shown that due to the specific shape of this dependence (oscillating transconductance), both resistively coupled [14] and capacitively coupled [136] single-electron transistors allow a very simple implementation of CMOS-type inverters, without a need for two types of transistors (like n-MOSFETs and p-MOSFETs in the standard CMOS technology). On the other hand, peculiarities of functions $I(V, V_g)$ make the exact copying of CMOS circuits impossible, and, to get substantial parameter margins, even simple logic gates have to be redesigned. The redesigned and optimized circuits (Fig. 12) may operate well within a relatively wide parameter window [137, 138]. Even after such optimization, the range of their operation with an acceptable bit error rate shrinks under the effect of thermal fluctuations as soon as their scale $k_B T$ reaches approximately $0.01E_a$. (For other suggested versions of the voltage state logic [136, 139], the temperature range apparently is even narrower). The maximum temperature may be somewhat increased by replacing the usual single-island single-electron transistors with more complex devices with 1D-array "channels" and distributed gate capacitances [140]. However, this would increase the total transistor area at the given minimum feature size.

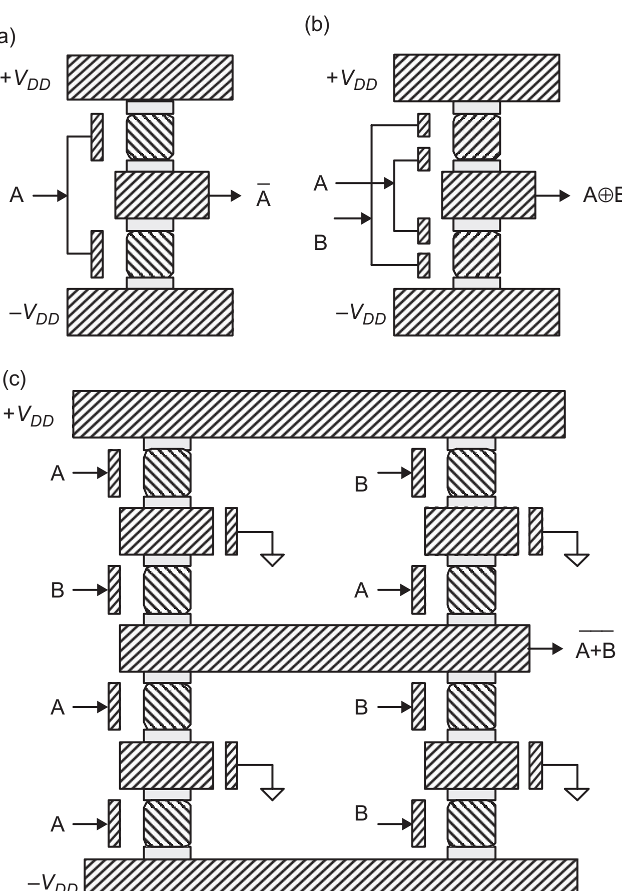

Figure 12. Basic gates of the complementary SET logic family using capacitively-coupled single-electron transistors: (a) inverter; (b) XOR, and (c) NOR/NAND [138], R. H. Chen et al., *Appl. Phys. Lett.* 68, 1954 (1996). © 1996, American Institute of Physics.

A disadvantage of voltage state circuits is that neither of the transistors in each complementary pair is closed too well, so that the static leakage current in these circuits is fairly substantial, of the order of 10^{-4} e/RC [137]. The corresponding static power consumption is negligible for relatively large devices operating at helium temperatures. However, at the prospective room-temperature operation, this power becomes on the order of 10^{-7} watt per transistor. Though apparently low, for the hypothetical circuits that would be dense enough ($>10^{11}$ transistors per cm^2) to challenge the prospective CMOS technology, this number gives an unacceptable static power dissipation density (>10 kW/cm^2).

4.5.2. Charge State Logics

The power dissipation problem may be avoided, to a large extent, by using "charge state" logic circuits in which single bits of information are presented by the presence or absence of single electrons at certain conducting islands throughout the whole circuit. In this case, the static currents and power virtually vanish. This approach has been explored theoretically since 1987 [141], and quite a few families of charge state logic circuits have been suggested [29, 30, 141–167]. In most suggestions, an electron is confined in a cell consisting of one or a few islands, while the logic switching is achieved via electrostatic (or spin [148, 154, 160]) coupling of the cells. Another classification of single electron logics may be based on where they take the energy necessary for logic operations: from dc power supply [141, 150, 158], ac power supply (also playing the role of a global clock) [29–31, 140, 145, 162, 166, 167], or just from the energy of an external signal [143–148, 154, 156, 160, 161, 163]. (The last category includes the so-called quantum (or quantum-dot) cellular automata based on ground-state computing. This concept has been controversial from the very beginning [149, 159–161], and, under the growing criticism [176, 177], it was eventually repudiated by its authors [31].)

Only a few of these concepts have been analyzed in detail, especially at finite temperatures. To my knowledge, the most robust charge-state logic circuits suggested till now are those based on the single-electron parametrons (see Section 2.4.). Figure 13 shows a possible shift register based on the parametrons. The direction of the shift of the central island of each next device is shifted by $\pi/3$ within the yz plane. The circuit is driven by electric field $\boldsymbol{E}_c(t)$ rotating in the same plane and providing the periodic switching on the SET parametrons, with an appropriate phase shift. As a result, each digital bit (one per three cells) is being shifted by 3 cells along the structure each clock period. Majority logic gates, sufficient for arbitrary logic circuits, may be implemented in the same way [30]. Geometric modeling and numerical simulation of these circuits within the framework of the orthodox theory have shown that they may operate correctly within approximately $\pm 20\%$ deviations from the optimal clock amplitude. Estimates show that the maximum operation temperature of these logic circuits is of the order of that of voltage mode circuits, i.e., of the order of $0.01E_c/k_B$, if the bit error rate is in the practically acceptable range (below $\sim 10^{-20}$).

A new, potentially useful feature of the charge state logics is the natural internal memory of their "logic gates" (more proper terms are "finite-state cells" or "timed gates"), thus combining the functions of combinational logic and latches. This feature makes natural the implementation of deeply pipelined ("systolic") and cellular automata architectures. The back side of this advantage is the lack of an effective means of transferring a signal over large distances; crudely speaking, this technology does not allow simple wires, just shift registers.

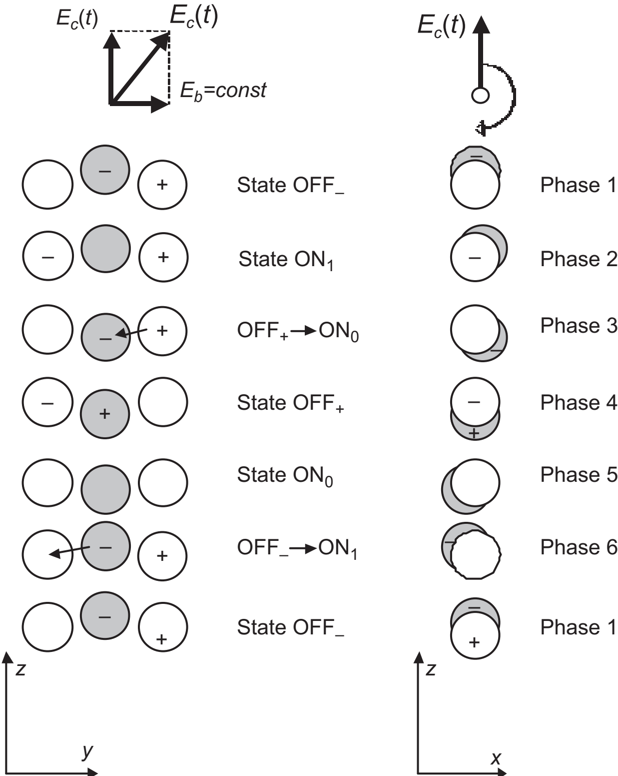

Figure 13. A shift register based on single-electron parametrons.

4.5.3. Phase-Mode Logic

Within the framework of our classification, the so-called phase-mode logic [168–171] should be placed in a separate category, because in these circuits the information-keeping cells are coupled by rf signals, carrying the binary information coded by either of two possible values of the rf signal phase. The elementary cell of this logic essentially is a relaxation oscillator generating SET oscillations with frequency $f_{SET} = I/e$ (see the discussion in Section 4.1.) phase locked by an external reference with frequency $2f_{SET}$. Such "subharmonic" generator has two possible phases of oscillations, which differ by π; the oscillation state with each phase has exactly the same amplitude and is locally stable, i.e., can be used to code a single bit of information. Moreover, the oscillator can impose its phase upon a similar, adjacent oscillator that had been turned off temporarily (e.g., by turning off its power supply current I) and is now being turned on. Thus information may be transferred along a row of oscillators, working as a shift register, very similar to that consisting of single-electron parametrons (see Fig. 13 and its discussion). Majority gates can be organized similarly, enabling the implementation of arbitrary logic functions.

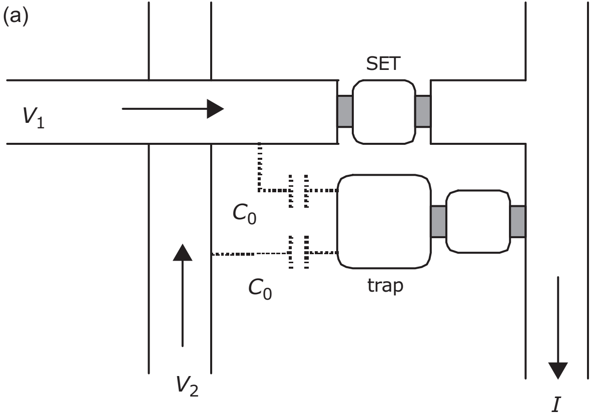
A theoretical advantage of this logic family is the potential insensitivity of its cells to the random background charges, if a resistor with quasi-continuous charge transfer is used for the insertion of dc current I. Unfortunately, as was discussed in Section 2, the known implementations of such resistors lead to very large size, making the implementation of practical (room-temperature) phase-mode logic circuits hardly feasible.

4.5.4. Devices for Defect-Tolerant Architectures

The main problem of all single-electron logic circuits is the effect of random background charge, described in Section 2. Until this problem has been solved, it is difficult to discuss seriously any of numerous suggestions of single-electron implementation of traditional logic circuit architectures (e.g., usual microprocessors, digital signal processors, etc.) based on number crunching.

I believe that the only way to make single-electron devices useful for large-scale electronic circuits is to introduce innovative architectures with high defect tolerance. The design of such architectures is especially natural for hybrid CMOL circuits combining CMOS components and single-molecule single-electron devices connected by nanowires (Fig. 9 and its discussion). In this case, single-electron devices may be used to perform only the functions that are natural for them (i.e., compact memory cells or externally controlled switches), leaving the more difficult functions (e.g., signal amplification with high voltage gain) for more sparse CMOS circuits.

Figure 14 shows a three-terminal version [173] of the earlier suggested [172] device that is a simple combination of the single-electron transistor and the trap, working together as a "latching switch." The device consists of three small islands connected by four tunnel junctions. Island 1, together with input and output wires serving as source and drain, forms a single-electron transistor. Islands 2 and 3 form a single-electron trap (cf., Fig. 5), with trapping island 3 capacitively coupled to the SET island 1, thus playing the role of a single-electron floating gate. If the effective source-to-drain voltage $V = (V_1 + V_2)/2$ applied from two inputs of the device is low, the trap in equilibrium has no extra electrons and its total electric charge is zero. As a result, the transistor remains in the Coulomb blockade state, and input and output wires are essentially disconnected. If V is increased beyond a certain threshold V_{inj} (which should be lower than the Coulomb blockade threshold voltage V_t of the transistor), one electron is injected into the trap. In this charge state, the Coulomb blockade in the transistor is lifted, keeping the wires connected at any V. However, if the node activity (voltage V) is low for a long time, either thermal fluctuations or cotunneling eventually kick the trapped electron out of the trap, and the transistor closes, disconnecting the wires. Figure 14b shows typical results of numerical simulation of the latching switch dynamics with a perfect background charge of the SET island (it may be adjusted by voltage applied to the SET gate). The trap injection threshold may be adjusted by voltage applied to an additional gate. Figure 15 shows a possible single-molecule implementation of such a device [174].



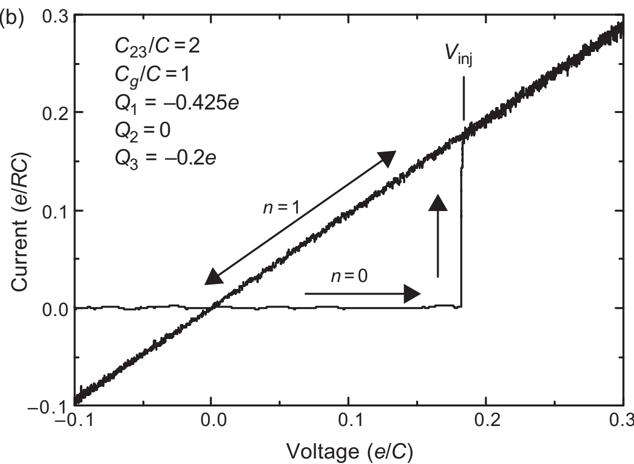


Figure 14. (a) Three-terminal single-electron latching switch and (b) its dc I–V curve calculated using the "orthodox" theory [172, 173].

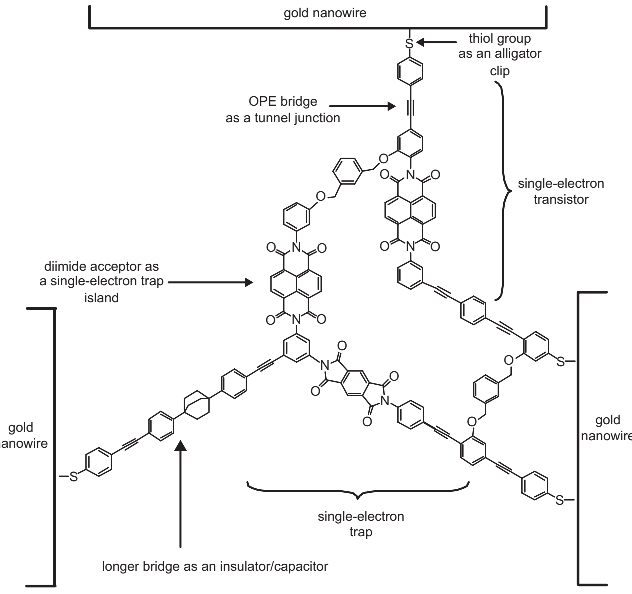

Figure 15. Possible molecular implementation of the three-terminal latching switch [174].

The latching switch is still sensitive to random charge impurities and, thus, should be used in redundant circuits that may tolerate at least a small percent of faulty devices. I believe that the architecture design space for such defect-tolerant circuits is very broad, and I will give just one example based on our recent Stony Brook work [172–175]. Figure 16 shows a possible structure of so-called distributed crossbar arrays for neuromorphic networks ("CrossNets") based on such switches. Cell bodies (which are supposed to be implemented in nanoscale CMOS technology) are embedded sparsely into a 2D array of single-electron latching switches working as single-bit-weight synapses. (Depending on the particular insertion rule, we distinguish several CrossNet species, e.g., FlossBar, InBar, and RandBar [173].) In each CrossNet, each cell body is hard-wired to a limited number $4M$ of other cells, with the discrete synaptic weights controlling which of these connections are currently active. Vice versa, signal activity of the network determines whether the synapses are open or closed, though the state of any particular synapse also is affected by the underlying randomness of single-electron tunneling.

Recent results of numerical simulation of limited fragments of the CrossNets on usual supercomputers have shown [173–175] that they may be taught to perform at least fast image recognition in the so-called Hopfield mode (Fig. 17). These results give hope that such self-adaptive

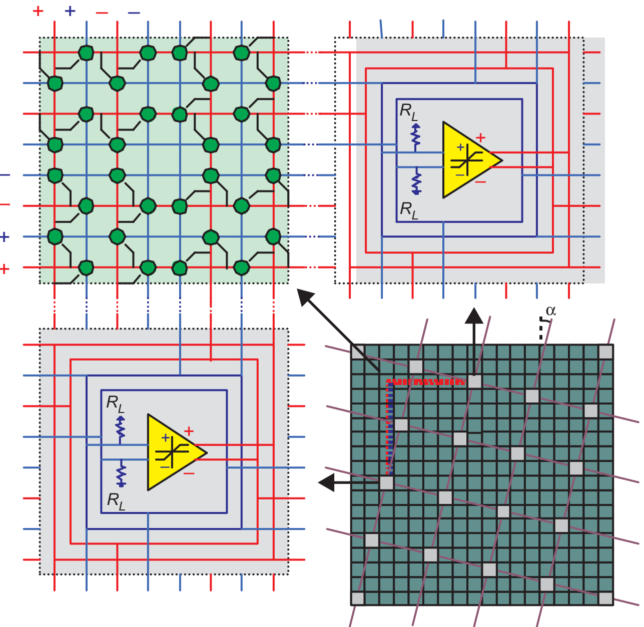

Figure 16. A Distributed Crosspoint Network ("CrossNet") and its basic components: synaptic plaquettes (green cells) and somas (gray cells) connected with axonic (red) and dendritic (blue) wires. On the synaptic plaquette (left upper panel), circles with arrows denote three-terminal latching switches (Fig. 14, 15). Solid points on the somatic cell borders show open-circuit terminations of the dendritic and axonic wires; due to these terminations the neural cells in the same row or column of the InBar do not interact. The bottom right panel shows the most explored CrossNet architecture, the Inclined Crossbar ("InBar"). In that panel, dashed red and blue lines show the particular connections show in the rest of the figure, while this violet lines indicate the square lattice formed by the somatic cells in InBar. These lines may be used for input/output of signals from individual cell.

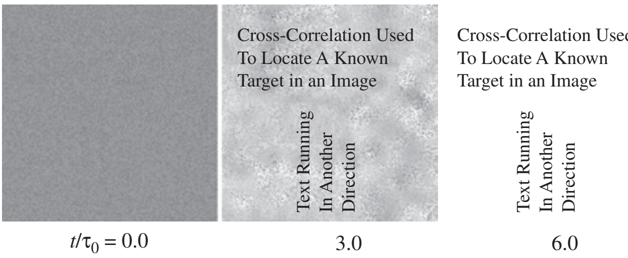

Figure 17. The process of recall (recognition) of one of three trained black-and-white images by an InBar-type CrossNet with 256 × 256 neural cells and connectivity parameter $M = 64$. The initial image (left panel) was obtained from the trained image (identical to the one shown in the right panel) by flipping 40% of pixels. $\tau_0 = MR_L C_0$ is the effective time constant of intercell interaction, where C_0 is the dendrite wire capacitance per one plaquette.

("plastic") networks also can be taught, by using global reinforcement training techniques, to perform more complex information processing. Moreover, it is expected that if a sufficiently large hierarchical, CrossNet-block-based system [174] will be able, after a period of initial training, to self-evolve and to self-improve on the basis of its interaction with the informational environment.

If these expectations are confirmed, CrossNets may have very impressive characteristics. Estimates show [172–175] that at the neural cell connectivity $M = 10^4$ (comparable with that of the human cerebral cortex) and a nanowiring pitch of 4 nm, neural cell density may be as high as 10^7 cm^{-2}, implying that brain-scale systems could be implemented on a silicon area of the order of 30 × 30 cm^2. The estimated speed scaling of this network is even more impressive, with time of signal propagation between the neural cells of the order of 100 ns, at acceptable power dissipation. This speed is nearly 4 magnitudes higher than that in biological neural networks. The systems capable of self-evolving at such a high speed would have a revolutionary impact on all information technology and possibly on the society as a whole.

5. CONCLUSION

Single-electron devices frequently are considered as the most probable candidates for the replacement of silicon MOSFETs as soon as the process of exponential improvement of the latter devices runs out of steam, apparently in about a decade. The most reasonable basis for these expectations is that the physics of single-electron device operation is basically material-insensitive, and, hence, these devices may be fabricated from a broad variety of materials. The most important corollary of this insensitivity is the possibility of self-assembly of chemically synthesized molecular devices on prefabricated metallic nanowire structures. Due to its potentially low cost, this technology may eventually replace lithography as the main road to future nanoelectronics.

However, working of these prospects, one has to take into account substantial problems of single-electron devices; first of all, their low voltage gain and high sensitivity to single charge impurities in the dielectric environment. Both these problems may be most readily circumvented in hybrid,

few-electron memory cells (see Section 4.3.). Such memory cells may be scaled down to a $\sim$30 nm^2 cell area, the range apparently out of reach of DRAM, ferroelectric, and magnetic memories. Complemented with crested tunnel barriers, the few-electron memories may also feature 1-ns-scale write–erase time. Moreover, the feature size requirements for single-electron devices in memory cells are more relaxed (for room-temperature operation, they should not be larger than $\sim$3 nm, instead of $\sim$1 nm for logic circuits). As a result, one may expect practical implementation of room-temperature few-electron memories, even by using the usual lithographic patterning methods or their straightforward future extensions.

For logic circuits, the random background charge effects are much harder to overcome. Nevertheless, the single-electron devices, used in CMOL hybrid circuits with nanoscale MOSFETs, may become the basis for implementation of novel, massively parallel architectures for advanced information processing, e.g., self-evolving neuromorphic networks (see Section 4.5.). In the most optimistic scenarios, such systems may eventually become more important for information processing than the traditional digital processors. Presently, the technologic and social consequences of such a breakthrough cannot be predicted in detail but would certainly be extremely significant.

GLOSSARY

CMOL circuit A hybrid VLSI circuit combining a CMOS stack and several levels of parallel nanowires connected by self-assembled molecular devices.

Coulomb blockade Suppression of electron transport through a system with a single-electron island(s) due to single-electron charging.

CrossNet A distributed crossbar circuit structure compatible with (i) neuromorphic network architectures and (ii) CMOL implementation.

Single-electron addition energy The minimal energy necessary to bring an additional electron from infinity into a single-electron island.

Single-electron box A system of two electrodes (source and gate) and one single-electron island connected to the source via a tunnel junction. Voltage applied to the gate changes electrostatic potential of the island and determines the equilibrium number of electrons in it.

Single-electron island A piece of conductor so small that injection/ejection of a single electron (e.g., through a tunnel junction) causes a substantial of island's electrostatic pontential that may affect transport of the following electrons.

Single-electron parametron A system of three (or more) single-electron islands connected by tunnel junctions but isolated galvanically from environment. External electric fields applied to the parametron may cause either a "soft" (reversible) switching of the electron configuration of the system and, hence, of its electric dipole moment or a "freeze" of the moment in one of two possible metastable states.

Single-electron transistor A system of three electrodes (drain, source, and gate) in which the source and drain are connected via two tunnel junctions and a single-electron island between them. Voltage applied to gate changes electrostatic potential of the island and, hence, the rate of electron transport between source and drain.

1. INTRODUCTION: SINGLE-ELECTRON DYNAMICS

Electrical current is microscopically a flow of large numbers of electrons, each of which carries an elementary charge, *e*. For instance, 1 A corresponds to a flow of approximately 10^{19} electrons per second. We generally do not care much about the transport of each electron for such a large current. However, as the electrical current becomes smaller and smaller, the flow of individual electrons becomes important. A commercially available current meter can measure down to a few femtoamperes (noise floor of a few fA/$\sqrt{Hz}$), which corresponds to about 10^4 electrons per second. Usually, we cannot observe the flow of individual electrons in an electrical conductor. However, recent developments in nanotechnology allow us to control and measure single-electron transport very accurately. An electron pump device, which carries exactly one electron during one cycle of voltage modulation, is considered a possible current standard with extremely high accuracy. A single-electron transistor has an extremely high charge sensitivity (about 10^{-5} electrons/$\sqrt{Hz}$) on a small conductive island. This device would detect individual electron transport of a current on the order of a few nanoamperes. With these techniques, various dynamical behaviors of single electrons can also be studied. Usually each electron moves randomly in a conductor. However, electron transport through a small conductive island, known as single-electron tunneling, can be somewhat correlated. An electron that has entered the small island leaves it before another electron is allowed to enter. Moreover, in a one-dimensional array of small islands, each electron is expected to transport more regularly. This research on single-electron transport has been started by understanding the dc and low-frequency transport characteristics, but now they are moving to more high-frequency dynamical single-electron transport characteristics, which we call *single-electron dynamics*.

Another important aspect of a single electron is that its behavior is governed by quantum mechanics. One of the nonclassical characteristics is the particle–wave duality. Although a single electron is a particle located somewhere when it is measured, it can behave as if it was located in two (or more) different places at one time. For instance, when an electron (the same is true for a photon or other single particles) is transmitted through and diffracted from a pair of small holes (a double slit), it appears randomly at a position on the screen behind the double slit. The probability of the appearance on the screen shows an interference pattern that is described by the wave characteristics of an electron (the quantum mechanical picture of an electron). One cannot determine the path (slit) an electron has taken without causing the interference pattern to disappear. This is an example of spatial interference, but similar interference can also appear in the time domain. Consider two conductive islands (a double quantum dot) located close to each other. When an electron is added to this double dot system, it occupies one of the two dots in the classical picture. However, quantum mechanics allows it to occupy both dots simultaneously. One cannot determine which dot the electron occupies at a given time, but one can determine the probability of finding the electron in each dot. When an appropriate electromagnetic field is applied to the system, the probability starts to oscillate. This *coherent dynamics of single electrons* is another interesting topic covered in this chapter.

A single electron rotates by itself (electron spin). Electron spin usually does not play an important role in nonmagnetic materials. However, it can determine the transport characteristics of a small island (a quantum dot) that contains a small number of electrons. Coulomb interactions of electrons confined in a small region induce different spin states, which give rise to spin-dependent transport. Single-electron spin in a quantum dot shows a long energy relaxation time and is expected to have a long decoherence time, which promises to provide the *coherent dynamics of single-electron spin*.

One challenging area of research in coherent single-electron dynamics is to realize quantum computing hardware, in which information processing is performed in the time evolution of quantum states. Quantum computing is expected to perform some sorts of calculations efficiently at an amazing speed that is unavailable in a classical computing scheme. The single-electron charge state and the single-electron spin state in quantum dots are good candidates for basic building blocks of a quantum computer.

2. STATIC CHARACTERISTICS OF A SINGLE ELECTRON

A *small conductive island* that accommodates a tunable number of electrons is often used to manipulate a single electron [1]. The electrons in the island can be controlled one by one. When the island is so small that the energy quantization is significant, the island is often called a *quantum dot* [2]. Electrons occupy discrete levels, each of which has twofold spin degeneracy. When a few electrons are confined in a well-defined potential, the quantum dot is often referred to as an *artificial atom*. Electrons occupy well-defined orbitals, as in a normal atom.

These islands, quantum dots, and artificial atoms are usually connected to the source and drain electrodes through tunneling barriers to allow transport measurements. A couple of gate electrodes are also used to control the electrostatic potential of the island and the tunneling barriers. In this section, we summarize the fabrication techniques of the devices and their dc transport characteristics.

2.1. Fabrication Techniques

The fabrication techniques for single-electron devices have been developed together with large-scale integration technology for solid-state devices. Electron beam lithography, which patterns arbitrary fine structures with a few nanometers resolution, is often used to fabricate small structures. Here, some typical fabrication processes are summarized.

Well controllable quantum dots are often fabricated from two-dimensional electron gas (2DEG) formed in a modulation-doped heterostructure [3, 4]. The heterostructure consists of a thick high-quality undoped GaAs layer, an undoped $Al_xGa_{1-x}As$ layer (an Al content of $x \sim 0.3$), and a Si-doped $Al_xGa_{1-x}As$ layer. The 2DEG accumulates at the interface of the GaAs and AlGaAs layers. Since the 2DEG is spatially separated from the doping layer, it shows a high electron mobility of 10^5–10^7 cm^2/Vs, with a typical sheet carrier concentration of $n = 2$–5×10^{11} cm^{-2} at low temperature (<4 K). The quality of the 2DEG has been improved for its application to high-electron mobility transistors as well as for the physical interest in integer and fractional quantum Hall effects. Small structures, like quantum dots, can be fabricated by processing the heterostructure. For a typical fabrication procedure, the first step is a wet etching process for device isolation and defining a conductive channel. Next, some Ohmic contacts (an AuGeNi alloy) are fabricated by metal evaporation, which is followed by a thermal annealing process. Then, fine Schottky gates (Au/Ti) are evaporated on the surface with the aid of electron beam lithography. Additional etching processes using a fine electron beam lithographic pattern can define the conductive channel more precisely. Considering that the 2DEG is depleted approximately 50–200 nm away from the edge of the etched pattern and about 10–20 nm away from the moderately biased gate electrode, a small conductive island (quantum dot) of 100–1000 nm can be routinely fabricated. This technique provides high-quality nanostructures with multiple gates.

Extremely clean quantum dots containing a very few electrons have been fabricated in a pillar structure of a resonant tunneling heterostructure [5]. An undoped InGaAs potential well separated from n-type GaAs electrodes by AlGaAs tunneling barriers can be designed to accommodate 2DEG even at zero voltage. A pillar structure with a diameter of $\sim$0.5 μm and a height of $\sim$0.5 μm is patterned and fabricated by using electron beam lithography and dry and wet etching. Then a gate electrode is deposited around the pillar structure. Electrons flow from the top of the pillar to the bottom of the structure. The electrons are confined in a square well potential in the vertical direction and in a two-dimensional harmonic potential in the lateral direction. The advantage of this structure is that the electron number can be reduced to zero. Since the confinement potential is well defined, the electronic state in the quantum dot can be predicted from theoretical calculations.

Another fabrication process often used for superconductor and normal metal islands is shadow evaporation [6, 7]. By using a double (or triple) layer of resists having different sensitivities for electron beam lithography, suspended or overhanging resist layers can be fabricated. Then metals are evaporated from different angles to the sample to form multiple metal layers that overlap in some regions. A thin insulating layer can be inserted between metal layers by using an oxidation process. For example, two aluminum evaporations with oxidation between provide $Al/AlO_2/Al$ tunneling junctions. Small metal islands, tunneling barriers, gate electrodes, and source and drain leads can be fabricated on a substrate by properly designing the lithographic pattern. High-quality Al islands show superconducting characteristics at low temperature and in a low magnetic field.

Much smaller islands, or quantum dots, can be fabricated by using various nanotechnologies. For instance, crystal growth of thin InAs on a GaAs substrate results in the formation of nanometer-scale islands (10–50 nm). This is known as the Stranski–Krastanov growth mode, which occurs when there is a large difference in the crystal lattice constants. Source and drain electrodes, as well as gate electrodes, can also be fabricated for transport measurements [8]. Moreover, a variety of materials, such as nanoparticles of magnetic, superconductor, and semiconductor materials as well as molecules of carbon nanotubes and fullerenes, can also be used as small quantum dots. However, as the islands becomes smaller, fabrication processes for transport measurement generally become difficult.

Generally, larger quantum dots have smaller characteristic energies and work only at lower temperatures. However, they can be fabricated together with multiple gate electrodes to control the characteristics of the dot independently. Therefore, the fundamental characteristics of quantum dots are investigated in relatively large quantum dots at

very low temperature (<0.1 K), while better characteristics are obtained in smaller quantum dots.

2.2. Coulomb Blockade and Single-Electron Tunneling

Here we discuss how an electron can be manipulated in a small island. Consider a conductive island connected to the source and drain electrodes via tunneling barriers and connected to a gate electrode with a small capacitor, as schematically shown in Figure 1a and in the equivalent circuit diagram of Figure 1b. We introduce the orthodox Coulomb blockade theory, which describes the Coulomb blockade (CB) effect and single-electron tunneling (SET) behavior [1]. For simplicity we assume zero bias voltage is applied between the source and drain electrodes, $V_{SD} = 0$. The total energy, $U(N)$, of the system, in which an island containing N electrons is affected by a gate voltage, V_g, via a capacitance, C_g, is given by [9]

$$U(N) = \frac{(-Ne + C_g V_g + q_0)^2}{2C_\Sigma} + E_{int}(N). \qquad (1)$$

The first term is the electrostatic energy approximated by the constant capacitance model, that is, constant Coulomb interaction in the island. In parentheses is the sum of the electron charge on the dot, the induced charge by the gate, and an offset charge, q_0. C_Σ is the total capacitance of the dot. The second term, $E_{int}(N)$, is the sum of the energies of the N occupied electron levels, measured relative to the Fermi energy of the leads, accounting for the internal degrees of freedom of the QD. Other corrections to many-body interactions can be included in E_{int}. We neglect the second term in this section, but discuss it in detail in Section 2.3. Ignoring this term corresponds to considering a relatively large island containing many electrons that occupy the continuum density of states. Even if an electron is excited to a higher energy state, the electron can relax quickly to the minimum energy, $E_{int}^{(\min)}$, which is almost independent of N.

Therefore, by neglecting E_{int}, the total energy of the system changes with V_g as shown in Figure 1c. The number of electrons, N, is determined to minimize the total energy and therefore becomes a well-defined integer ($N = N_0$, $N_0 + 1$, $N_0 + 2, \ldots$). The energy gap to neighbor charge states can be maximized to $e^2/2C_\Sigma$, for instance, at $V_g = V_{g0}$. When excitation energies, such as the thermal energy, are much smaller than this energy, an electron can neither enter nor leave the island. Therefore, transport through the island is blocked (Coulomb blockade). The energy gap can be made 0 by adjusting the gate voltage at $V_g = V_{g1}$, where N can fluctuate between N_0 and $N_0 + 1$ only by 1, but not more than 1. This means that electrons tunnel through the island one by one. This single-electron tunneling scheme is maintained unless the excitation energy exceeds the charging energy, $E_c \equiv e^2/C_\Sigma$. The Coulomb blockade and single-electron tunneling appear alternately by sweeping the gate voltage with a period given by e/C_g (CB oscillation).

When the source–drain voltage, V_{SD}, is applied, the CB region shrinks and the SET region expands, as shown in the charging diagram of Figure 1d. The maximum width of a CB diamond region is given by E_c/e in the V_{SD} direction and e/C_g in the V_g direction. The CB and SET appear in diamond (parallelogram) regions, as shown in Figure 1d. The number of electrons in the dot, N, can be controlled by changing V_{SD} or V_g.

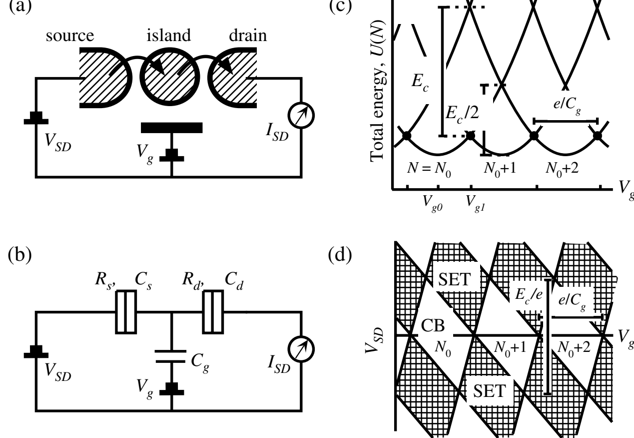

Figure 1. Coulomb blockade (CB) and single-electron tunneling (SET) in a single island. (a) Schematic diagram of the conductive region of a typical SET device (hatched regions). (b) Corresponding circuit diagram. The island is connected to the source and the drain via tunneling barriers and is connected to the gate electrode by a capacitor. (c) Total energy, $U(N)$, of the system as a function of the gate voltage, V_g. (d) The diagram of the CB and SET regions in the V_g–V_{SD} plane. Slightly asymmetric tunneling capacitances are assumed.

2.3. Energy Quantization and Many-Body Effects

When the size of an island (quantum dot) is so small that an electron wave can interfere, only the constructively interfering wave (electron orbital) can exist in the quantum dot, forming quantized energy levels [2, 10]. Each level can accommodate two electrons with spin-up and spin-down. In a very simple picture, electrons occupy levels starting from the lowest and making spin pairs. Therefore, the total spin, S, of the system is 0 for even N and $\frac{1}{2}$ for odd N. $E_{int}(N)$ in Eq. (1) is the sum of the occupied energy levels for all N electrons. For this quantum dot regime, the characteristic energy for CB and SET is the addition energy, E_{add}, which is the energy required to add one electron to the quantum dot. When an electron is added to an odd-N quantum dot, the addition energy is identical to the charging energy, $E_{add}(\text{odd-}N) = E_c$. However, when an electron is added to an even-N quantum dot, excess energy equivalent to the energy spacing, Δ, between quantized levels is required, $E_{add}(\text{even-}N) = E_c + \Delta$. The difference in the addition energy is reflected in the width of CB regions, which now show even–odd asymmetry (wider width for even N).

However, when N is relatively small, electrons in a quantum dot interact, and the width of the CB region exhibits more complicated variations with N. This comes from the Coulomb interactions between the electrons in a quantum dot. Electrons occupy different orbitals that have different spatial distributions in the dot. Electrons prefer to occupy

different orbitals in order to reduce Coulomb repulsion (the direct Coulomb interaction). Two electrons occupy different orbitals, rather than make a spin pair, if the energy gain is larger than the energy cost for taking a higher energy orbital. If electrons occupy different orbitals, their spins prefer to maximize the total spin in order to gain the exchange Coulomb energy. These Coulomb interactions determine the electron filling in a quantum dot (many-body effects). The width of CB regions changes with N in a complicated manner. In other words, one can study the many-body effects from the N-dependent addition energy.

The many-body effects can be clearly studied in a quantum-dot disk, in which electrons are confined in a two-dimensional harmonic potential [10–12]. In this case, the orbitals can be expressed analytically and can be identified as 1s, 2p, 3s, and 3d,... from the lowest energy to higher energy. Such a quantum dot is referred to as an artificial atom. The ground state of the one-electron quantum dot (artificial hydrogen atom) is one electron in the 1s orbital. This configuration does not change with the magnetic field. However, the ground state of the two-electron quantum dot (artificial helium atom) is the spin-singlet state having two anti-parallel-spin electrons in the 1s orbital, or the spin-triplet state having parallel-spin electrons in the 1s and 2p orbitals, depending on the strength of the Coulomb interactions and the level spacing. The transition from the spin-singlet state to the spin-triplet state occurs by applying a magnetic field ($B = 2$–6 T), which increases the Coulomb interactions and decreases the level spacing. Note that similar singlet–triplet transition in a normal helium atom is expected to occur at an extremely high magnetic field of 4×10^5 T. One can study simple atomic physics in moderate parameter spaces using an artificial atom (see Section 3.10).

2.4. Double Quantum Dot

A double quantum dot comprises two quantum dots separated by a tunneling barrier [13–16]. If a quantum dot is an artificial atom, a double quantum dot can be regarded as an artificial diatomic molecule. The two quantum dots can be coupled electrostatically (an ionic bond in the language of chemistry) as well as quantum mechanically (a covalent bond). Consider two quantum dots connected through a tunneling barrier with a capacitor, C_c, and tunneling coupling, T_c. Figure 2a is the schematic diagram of the double dot connected between the source and drain in series. For a moment, we neglect the effect of the source and drain contacts for simplicity. Figures 2b–2d show the charging diagram of the double quantum dot in different regimes [14]. The gate voltages, V_{gl} and V_{gr}, are swept to shift the potential of the respective dots; (n, m) represents the stable charge state in which n and m electrons occupy the left and the right dots, respectively. When there are no interactions between the two dots ($C_c \sim 0$ and $T_c \sim 0$), the charging diagram is just Coulomb blockade oscillations of the two dots [see Fig. 2b]. If only the electrostatic coupling is turned on, ($C_c > 0$, $T_c \sim 0$), charging of an electron on one quantum dot lifts up the potential of the other dot. And the gate voltage for one dot also affects the potential of the other dot

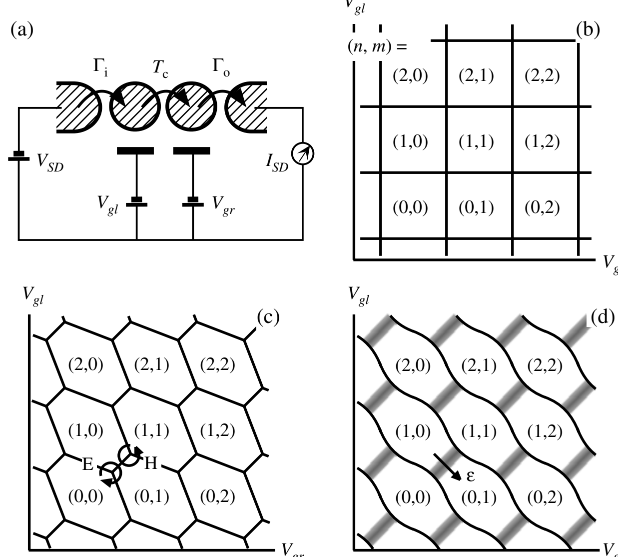

Figure 2. Charging diagram of a double quantum dot. (a) Schematic circuit diagram of a double dot. (b–d) Charging diagrams in the different regimes. (a) Both electrostatic and tunneling couplings are neglected. (c) Only electrostatic coupling is considered. Single-electron transport through the double dot with an electron-like process at the triple point, E, and with a hole-like process at H. Circled arrows are typical gate–voltage trajectories in the single-electron pumping operation. (d) Both electrostatic and tunneling couplings are considered. The charge state is no longer a good quantum state in the hatched regions.

via the coupling capacitor. In this case, the charging diagram becomes a hexagonal honeycomb structure, as shown in Figure 2c. Each crossing point in Figure 2b splits into two triple points [see E and H in Fig. 2c], whose spacing corresponds to the interdot coupling energy defined by

$$E_{id} = e^2 C_c / C_{\Sigma l} C_{\Sigma r} \tag{2}$$

Here $C_{\Sigma l}$ and $C_{\Sigma r}$ are the total capacitance of the left and the right dots, respectively. The transport through the double dot from the source to the drain is allowed only at these triple points, where three charge states are energetically degenerated. At the triple point indicated by E, an electron tunnels from the left to the right (the clockwise direction in the charging diagram) or the right to the left (the counterclockwise direction) sequentially. However, the tunneling sequence at the triple point H is somewhat peculiar. The electron tunneling process propagates in the reverse direction of the electron flow. It is easy to conceive that a hole, rather than an electron, tunnels sequentially.

Now we discuss the amplitude of current through a double quantum dot. We assume that electrons can tunnel between the two dots elastically, that is, only when the discrete energy states of the two quantum dots are aligned approximately within the lifetime broadening of the states. Then we expect a very sharp peak at the resonance, whose current profile is basically independent of the thermal distributions in the leads. In the vicinity of a triple point, only one energy state in each dot contributes to the transport [17]. At a large source–drain voltage, which saturates the current, the current profile is determined by the energy difference between

the two charge states, ε, and it is given by a Lorentzian function as

$$I(\varepsilon) = \frac{e}{\hbar} \frac{\Gamma_o T_c^2}{\varepsilon^2 + \Gamma_o^2/4 + T_c^2(1 + \Gamma_o/\Gamma_i)} \quad (3)$$

where Γ_i and Γ_o are the tunneling rate of the incoming and outgoing barriers, respectively [15]. Note that Γ_i and Γ_o appear asymmetrically, so the three parameters, T_c, Γ_i, and Γ_o, can be deduced from the current profiles obtained at different current directions. This is a convenient way to determine the parameters experimentally, if the inelastic current (see Section 3.11) and other currents from excited states can be neglected.

If the tunneling coupling, T_c, is made larger than Γ_i and Γ_o, coherent tunneling coupling (covalent bond) between the two dots is expected [14, 18, 19]. The charging diagram deforms as shown in Figure 2d. In the gray regions, one cannot distinguish whether a single electron is in the left or right dot. The localized states in each dot are mixed into bonding and antibonding states, which are energetically separated by $2\hbar T_c$ at the original triple points. The current peak is broadened and elongated into a crescent shape in the vicinity of the original triple point. Finally, if the tunneling coupling becomes too strong, the double dot becomes effectively a large single dot, in which just single CB oscillations are expected. In the intermediate and intriguing coupling regime, two dots are coupled strongly and coherently, but are weakly coupled to the source and drain electrodes just to measure the current. This double dot can be considered a tunable two-level system, which is discussed in Section 2.5.

2.5. Two-Level Systems—Electron Spin and Pseudo-Spin

The two-level system is the simplest system in which quantum mechanical characteristics can appear and provides an important model for the study of the quantum dynamics. After describing a single electron spin as a typical two-level system, we define a tunable two-level system in a double quantum dot.

An electron spin is fully described by quantum mechanics. The direction of an electron spin can be arbitrary in principle. However, electron spin takes spin-up, denoted here by $|0\rangle$, or spin-down, $|1\rangle$, when the z component of the spin is measured. An arbitrary spin state before the measurement is described by a linear superposition of these two states (bases) as

$$|\psi\rangle = \cos\frac{\theta}{2}|0\rangle + e^{i\varphi}\sin\frac{\theta}{2}|1\rangle \quad (4)$$

where θ and φ are mixing angles that determine the probability of measurement results. This representation is chosen to point out the spin orientation in spherical coordinate, and it is convenient for describing the state in the Bloch sphere of Figure 3.

Now, consider an electron spin in the presence of magnetic field $B = (B_x, B_y, B_z)$. The Hamiltonian of the system can be described as

$$H = -\frac{1}{2}\mu_s(\sigma_x B_x + \sigma_y B_y + \sigma_z B_z) \quad (5)$$

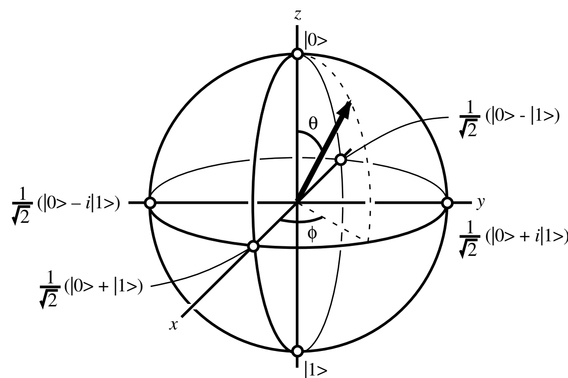

Figure 3. Bloch sphere of a spin 1/2 system. Any two-level system can be mapped onto the Bloch sphere. The arrow, θ and ϕ in the polar coordinate, indicates the state, $|\psi\rangle = \cos\frac{\theta}{2}|0\rangle + e^{i\varphi}\sin\frac{\theta}{2}|1\rangle$.

where σ_x, σ_y, and σ_z are the Pauli matrices, and μ_s is the magnetic moment of a spin. The stationary eigenstates of the system can be obtained by solving the time-independent Schrödinger equation, $H|\psi\rangle = E|\psi\rangle$. This gives the eigen energies

$$E_\pm = \pm\frac{1}{2}\mu_s\sqrt{B_x^2 + B_y^2 + B_z^2} \quad (6)$$

and the corresponding eigenstates of

$$|\psi_+\rangle = \sin\frac{\theta}{2}|0\rangle - e^{i\varphi}\cos\frac{\theta}{2}|1\rangle \quad (7)$$

$$|\psi_-\rangle = \cos\frac{\theta}{2}|0\rangle + e^{i\varphi}\sin\frac{\theta}{2}|1\rangle \quad (8)$$

where θ and φ are the directions of the magnetic field. This argument looks roundabout, since the z direction may be chosen as the direction of the magnetic field for simplicity. However, Eqs. (6) and (7) give general eigenstates for any two-level system under a Hamiltonian, which can be expressed by fictitious magnetic fields (Eq. 5).

Now, we define a two-level system in a double quantum dot [16, 18]. We choose the ground state of the charge state (1, 0) as one state $|0\rangle$ and the ground state of the charge state (0, 1) as the other state $|1\rangle$. Other excited states and other charge states can be ignored, if they are energetically much higher than the lowest two energy states, $|0\rangle$ and $|1\rangle$, that is, if the double quantum dot is properly adjusted somewhere in between a pair of triple points (gray regions in Fig. 2d). In addition, the double dot can be effectively isolated from the source and drain electrodes because the interdot charging energy can block the transport (see Section 2.4). The energy difference, ε, between the two states can be changed by the gate voltages, as shown by the arrow in Figure 2d. The coherent tunneling coupling, T_c, allows the system to change between $|0\rangle$ and $|1\rangle$. In this case, the Hamiltonian of the system is written as

$$H = \frac{1}{2}\varepsilon\sigma_z + \hbar T_c\sigma_x \quad (9)$$

where $\frac{1}{2}\varepsilon$ and $\hbar T_c$ can be regarded as fictitious magnetic fields in the z and x directions, respectively (compare with Eq. 5). Therefore, we can map the two-level

system of the double quantum dot onto the spin system (pseudo-spin model). Similarly any two-level system can be mapped onto the spin system, and its superposition can be represented in the Bloch sphere. The eigen energies of the double quantum dot are given by

$$E_{\pm} = \pm\frac{1}{2}\sqrt{\varepsilon^2 + 4(\hbar T_c)^2} \tag{10}$$

which is schematically shown in Figure 4a [18]. The corresponding wavefunctions, which are schematically shown in Figure 4b–d, are symmetric for energy E_- (often called the symmetric state or bonding state) and anti-symmetric for energy E_+ (antisymmetric state or antibonding state). And the eigenstates are always in the x–z plane ($y = 0$) of the Bloch sphere.

3. SINGLE-ELECTRON DYNAMICS IN NANOSTRUCTURES

In this section, we discuss the dynamical behavior of a single electron. In most of the phenomena, various types of potential modulations are included in the discussion of time-integrated tunneling current. When the modulation is relatively slow compared to the tunneling rate, the system changes adiabatically. We can still use the stationary states of quantum dots in the absence of the modulation. However, if the modulation frequency becomes higher than the tunneling rate, the system changes nonadiabatically, and the state is no longer the original stationary state. We have to use time-dependent Schrödinger equations, $i\hbar\, d\psi/dt = H\psi$,

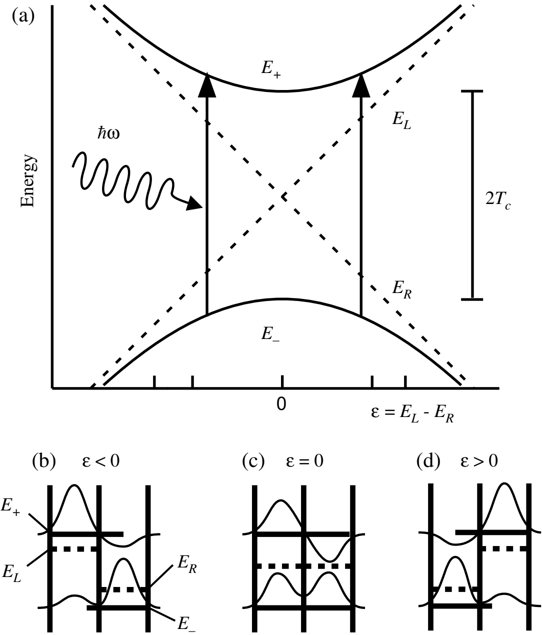

Figure 4. (a) Schematic energy diagram of a double quantum dot. E_L and E_R are the energies of the localized charge states (1, 0) and (0, 1), respectively. When the tunneling coupling is turned on, the bonding state with the energy E_- and the antibonding state with the energy E_+ are formed. (b–d) Schematic energy diagram and wavefunctions of the bonding and antibonding states for (b) $\varepsilon < 0$, (c) $\varepsilon = 0$, and (d) $\varepsilon > 0$.

to describe the dynamics. This section also describes the decoherence mechanisms, which are very important characteristics in the dynamics. Finally, measurement techniques for single electron states in a relatively short time domain are discussed.

3.1. Single-Electron Turnstile and Pump

Single-electron turnstiles and pumps are single-electron devices that carry exactly one electron from one electrode (the source) to the other electrode (the drain) during one cycle of the periodic potential modulation [20]. During the first half of the modulation period one electron tunnels from the source to the island, and the electron tunnels out to the drain during the second half of the cycle. By repeating the modulation at a sufficiently high frequency, typically $f \sim 10$ MHz, a reasonable electrical current, $I = ef \sim 1.6$ pA, is obtained. These devices have been discussed as a possible current standard for metrology [21]. The frequency-locked current in a single electron pump, the frequency-locked voltage generated by the Josephson effect, and the quantum resistance realized by the quantum Hall effect are expected to close the quantum metrology triangle formed by voltage, current, and frequency.

Current in a turnstile device is driven by an external dc bias voltage applied between the source and drain, and the current is regulated so that only one electron is allowed to pass through the device during one cycle [22]. The current direction is given by the polarity of the bias voltage, and the current vanishes at zero bias voltage. On the other hand, the current in single-electron pumps is generated by a pumping process from the source to the drain. The direction of the pumping current is independent of the applied bias voltage, and it works even at zero bias voltage [23]. Usually, the turnstile devices are operated with a single modulation voltage, while the pump devices are operated with more than two gate voltages modulated with different phases.

Consider pumping processes in a double quantum dot. The charge state of a double quantum dot is represented by (n, m), where n and m are the number of excess electrons in the double dot [see Fig. 2c]. If the system is initially in the (0, 0) state, modulation voltages are designed to move the charge state to the (1, 0) state, followed by the (0, 1) state, and return it to the initial state (0, 0). During this cycle, an electron moves from the left to the right sequentially. This trajectory is schematically shown by an arrow enclosing the triple point E in Figure 2c. The other trajectory in the reversed direction enclosing the other triple point H carries a hole (0 state) from the right to the left, which gives the same current direction. In this way, exactly one electron, or hole, is carried from one lead to the other in one cycle of the potential modulation.

For metrology, an extremely high accuracy of less than 10^{-8} errors per cycle is required. The deviation from the frequency-locked current arises from thermal activation, Poisson tunneling statistics, the cotunneling process, and so on. The probability of thermal excitation to other charge states can be suppressed below 10^{-8} at a dilution-refrigerator temperature of less than 50 mK for a typical double dot with interdot charging energy of about 100 μeV

[20]. The current error also arises from the Poisson statistics of tunneling events, whose interval is widely distributed. Even when an electron is allowed to tunnel, the tunneling may not happen during the finite period of the cycle. This error can be reduced by making the modulation frequency much smaller than the tunneling rate of the barriers.

The cotunneling process, which is the simultaneous tunneling over two (or more) tunneling junctions via an intermediate virtual state [24], is a serious problem. The cotunneling current survives even at zero temperature. Although the cotunneling current is much smaller than the frequency-locked current, cotunneling can easily degrade the accuracy of the current standard, especially when higher current is required. The cotunneling current can be reduced either by driving the pumping device with a high resistor located very close to the device or by using multiple tunneling junctions connected in series.

Other practical problems arise from low-frequency electrical noise and background charge fluctuations, which shift the effective operating gate voltage randomly, and high-frequency (microwave to far-infrared region) noise, which gives rise to photon-assisted tunneling processes [25]. By adjusting the operating parameters properly, a single-electron pump with seven tunneling junctions works very nicely with an error per pumped electron of 1.5×10^{-8} [26]. Single-electron pumps provide extremely accurate current of the order of $\sim$1 pA. Another way to achieve a possible current standard at a relatively large current is the moving quantum dot, which is discussed in Section 3.3.

The single-electron pump is a fundamental tool that allows us to manipulate electrons one by one. In principle, one can design the voltage waveform so that a single electron is injected into or extracted from an island *on demand* within the accuracy of the inverse of the tunneling rate. One can add any operation or manipulation during the interval.

3.2. Single-Electron Tunneling Oscillation

Single electron tunneling, in which electrons travel through an island one by one, is a sort of correlated tunneling process over the two junctions. In normal SET devices, tunneling events are uncorrelated *in time*, and the interval between them is distributed according to Poisson statistics. However, the distribution of the tunneling interval can be made narrower than Poisson statistics (sub-Poisson statistics), and each electron tunneling can take place more regularly (SET oscillation).

A very simple scheme for SET oscillation is a small tunneling junction driven by a constant current. When the tunnel junction with a small tunneling capacitance is driven by a small constant current, the voltage across the junction increases linearly in time due to the charging. Single-electron tunneling is allowed only when the voltage exceeds the charging energy of the junction and the voltage drops suddenly by discharging (tunneling of) an electron. Therefore, the voltage across the junction shows a sawtooth pattern in time. The charging and discharging should take place almost regularly as long as the junction is driven by a constant current. The constant current source can in principle be generated by a high-resistance resistor connected to the junction [27, 28]. However, it is not easy to fabricate such a resistor. A small parasitic capacitor in the vicinity of the junction smears the sawtooth pattern of the voltage difference, and the junction is then effectively driven by a constant voltage.

Another way to achieve SET oscillation is with a one-dimensional (1D) array of small islands connected by tunneling barriers. When an excess electron is injected into the array, potential distribution inside the array shows soliton characteristics (charge soliton). The soliton has a characteristic size, $M \sim \sqrt{C_T/C_0}$, in the unit of an island, where C_T and C_0 are the tunneling capacitance and the self-capacitance of an island, respectively. If the length of the array is longer than $2M$, transport through it is influenced by Coulomb repulsion between the solitons. The solitons line up in a Wigner lattice inside the array and propagate in a regular way (SET oscillation). This type of SET oscillation has been indirectly observed under microwave irradiation, where the SET oscillation is locked at the applied frequency [29]. The appearance of nonlinear characteristics under microwave irradiation indicates correlated transport in the one-dimensional array of islands.

The correlated tunneling process can also be studied in the shot noise of the single-electron tunneling current. When the current is carried by a Poisson process, the shot noise is given by $2e|I|$ (full shot noise), where I is the current. The suppression from the full shot noise indicates time-correlated tunneling and sub-Poissonian statistics. Even in a conventional single quantum dot device, the shot noise can be suppressed by half if the incoming and outgoing tunneling rates are almost the same [30, 31]. It is theoretically expected that shot noise in resonant Cooper pair tunneling can be suppressed significantly [32].

3.3. Moving Quantum Dots

In this section, we discuss the unique characteristics of moving quantum dots, in which an array of quantum dots each containing exactly one electron propagates from the source to the drain. When a high-frequency voltage (typically a few giga Hertz) is applied to a metal electrode on a piezoelectric material (such as GaAs), a surface acoustic wave (SAW) is generated and propagates on the surface. The propagating SAW deforms the crystal lattice, thus modulating the conduction band in the vicinity of the surface through the piezoelectric interaction between the lattice deformation and the electrons. Therefore, a sinusoidal potential for electrons propagates with the SAW velocity, $v = 2980$ m/s for GaAs. When a one-dimensional channel is prefabricated along the SAW propagation direction by conventional lithographic techniques, a moving 1D array of potential puddles (quantum dots) is formed. Each quantum dot carries a well-defined integer number of electrons, n ($= 1, 2, 3, \ldots$), which can be tuned by external voltages or the intensity of the SAW. The acoustoelectric current is quantized to $I = nef$ with the SAW frequency, f [33–37]. In this case, electrons are transferred with the propagating potential, and no tunneling processes are involved. The current amplitude can be on the order of nanoamperes (I $\sim$ 0.48 nA for $n = 1$ and $f = 3$ GHz), which is about 3 orders of magnitude larger than that in electron pump devices. Therefore, more practical current-standard devices are expected.

In order to obtain a sufficient potential modulation, the SAW is usually generated with a narrow-band interdigital transducer situated a few millimeters from the electrical channel [34]. The typical wavelength of the SAW is about 1 μm for $f_{SAW} = 3$ GHz and should be comparable to the length of the one-dimensional channel. Application of a few milliwatts of microwave power to the transducer gives a typical potential modulation of about 1 meV in the active region. Note that the modulation amplitude is significantly reduced by the screening effect from the existing electrons.

The accuracy of the current is expected to be excellent (less than 10^{-10} errors for a modulation amplitude of about 20 meV), when the electron transport is driven adiabatically [33, 38]. Practical error may come from insufficient potential modulation, background charge fluctuations, the existence of standing wave modes, thermal effects, and so on. Some devices show current accuracy of about 5×10^{-5} [35, 36], but this accuracy is not yet enough for metrology purposes. Further improvements are desired for this device.

3.4. Photon-Assisted Tunneling

In the previous sections, the energy states in quantum dots are assumed to be shifted adiabatically in proportion to the applied modulation voltages. This is a good approximation, provided the modulation frequency is much lower than the tunneling rate. However, when the modulation frequency exceeds the tunneling rate, a quantum mechanical description of the system is required in order to understand the nonadiabatic transport characteristics. In this and the next few subsections, we concentrate on sinusoidal potential modulation, in which the modulation can be regarded as a coherent photon field. Various kinds of electron–photon interactions analogous to those in quantum optics are expected. For instance, electrons can tunnel through a barrier by absorbing or emitting a photon. This photon-assisted tunneling (PAT) has been theoretically developed in the Tien–Gordon theory [39, 40] and experimentally studied in the transport through Josephson junctions [41] and resonant tunneling structures [42, 43], as well as quantum dots [44, 45]. Coherent electron–photon coupling is expected and has actually been demonstrated in double quantum dots and superconductor islands.

When a sinusoidal voltage, $V(t) = V_0 \sin \omega t$, is applied across a tunneling barrier, the wavefunction of an electron on one electrode acquires a phase shift, $\int eV(t)\, dt/\hbar$, relative to the other electrode. The wavefunction can be written as a superposition of a series of photon sidebands as

$$\psi(x, t) = \psi_0(x, t) \sum_{n=-\infty}^{\infty} J_n(\alpha) \exp(-in\omega t) \qquad (11)$$

where $J_n(\alpha)$ is the nth order Bessel function of the first kind, $\alpha \equiv eV_0/\hbar\omega$ is the normalized modulation amplitude, and $\psi_0(x, t)$ is the original stationary wavefunction in the absence of sinusoidal voltage. The energies of the photon sidebands are separated by the photon energy $\hbar\omega$, and the amplitude of each wavefunction is proportional to $J_n(\alpha)$ (as shown schematically in the inset of Fig. 3a). Therefore, the photon-assisted tunneling can be considered a normal tunneling process to one of the photon sidebands. The effective tunneling rate to the nth sideband state is given by

$$\Gamma_n = J_n^2(\alpha)\Gamma \qquad (12)$$

where Γ is the original tunneling rate in the absence of modulation. Here the energy dependence of Γ is neglected for simplicity; $n = \pm 1, \pm 2, \ldots$ corresponds to the tunneling with $|n|$ photon absorption (for positive n) and emission (for negative n). Equation (12) can also be applied in the case of intense microwaves, where nonlinear optical effects can appear. Figure 5a shows the function $J_n^2(\alpha)$, which indicates how the effective tunneling rate (or current) changes with the normalized modulation amplitude α. For a weak amplitude of $\alpha \ll 1$, Γ_n is proportional to the nth power of the photon power, that is $J_n^2(\alpha) \sim (\alpha^2)^n$. For a strong amplitude of $\alpha \gtrsim 1$, however, $J_n^2(\alpha)$ is an oscillating function of α. At a specific amplitude where $J_1(\alpha) = 0$, for instance at $\alpha \sim 2.8$, tunneling through a one-photon sideband should vanish even in the presence of an intense oscillating potential. It should be noted that the zero-photon tunneling rate Γ_0 for $n = 0$ is also affected by the photon field, and the total sum is always conserved, $\sum_{n=-\infty}^{\infty} J_n^2(\alpha) \equiv 1$.

The Tien–Gordon theory explains very well the I–V characteristics of Josephson junctions and other tunneling devices, such as resonant tunneling structures and superlattices, in the presence of microwaves, millimeter waves, THz waves, and far-infrared light [40–43]. Here we focus on the photon-assisted tunneling in single-electron systems

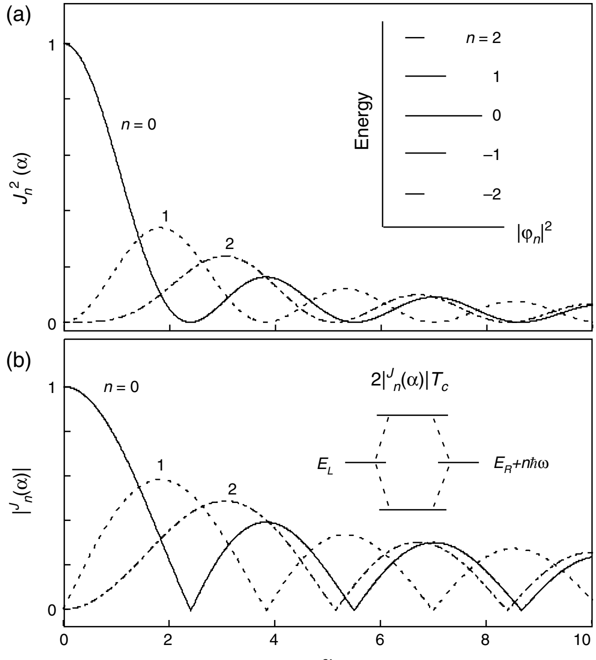

Figure 5. (a) The square of the Bessel function. The photon-assisted tunneling current is proportional to the square of the Bessel function. The inset shows the sideband structure in the presence of oscillating potential. The length of the bars schematically indicates the amplitude of the wavefunctions. (b) The absolute value of the Bessel function. The energy splitting of the two states separated by n times the photon energy is proportional to the absolute value of the Bessel function.

[44, 45]. A microwave (photon energy of 4–200 μeV for microwave frequency of 1–50 GHz) is often used as a coherent photon source. Application of a microwave on a gate or source–drain electrodes induces photon-assisted tunneling on the two tunneling barriers. Since the two tunneling barriers are close to each other, it is technically difficult to control the modulation amplitude across each barrier independently, and photon-assisted tunneling can occur at either barrier. Nevertheless, the flow of current through the device can be quantitatively explained by the Tien–Gordon theory. The photon-assisted tunneling from the continuum density of states in the electrode to a discrete energy state in the quantum dot produces a pumping current. A broad pumping current with a width corresponding to the photon energy appears in the vicinity of the SET current peak.

When a microwave is properly applied to modify the potential of the quantum dot, coherent tunneling through one of the photon sidebands is expected. An electron can tunnel into the dot by absorbing one photon through one barrier and simultaneously tunnel out from the dot by emitting one photon through the other barrier. Distinct resonant PAT current peaks have been observed [46], indicating a coherent PAT process. In this case, the PAT current peaks are separated from the SET current peak by the photon energy. Furthermore, when the photon energy is made higher than the energy spacing in the quantum dot, one can excite an inner electron in the quantum dot to the reservoir. This process is analogous to the photoionization process of atoms.

3.5. PAT in a Double Quantum Dot

A more interesting case is the electron–photon interaction in a double quantum dot, where an oscillating potential is applied between two discrete energy states [47, 48]. Note that a similar situation can be realized in a superconducting island, where photon-assisted tunneling of a Cooper pair is observed between superconducting charge states in the island [49]. In this subsection, we restrict ourselves to a weakly coupled double dot, where an electron tunnels sequentially through three barriers (see Section 3.6 for the strongly coupled double dot). In this case, we can still use the Tien–Gordon theory to describe the pumping current. The photon-assisted tunneling current appears as a very sharp peak because of the discrete energy states. The peak appears when the two energy states are exactly separated by the photon energy. The current profile is given by Eq. (3) by substituting $J_n(\alpha)T_c$ for T_c [47]. In the weak coupling limit, the width of the peak is determined by the tunneling rate of outer barriers, in principle, or by the effective electron temperature in some cases. In a low-temperature cryostat with a low-noise measurement system, the width can be reduced to a few microelectron volts, corresponding to a frequency of about 1 GHz. The double dot is expected to act as a good microwave and millimeter wave spectrometer [50]. The current increases linearly with microwave power in the low-power limit, as expected from Eq. (12) [18, 51].

Furthermore, the double dot is a unique system in which population of each quantum dot can be controlled by external voltages [48]. In the normal population, the occupied state is energetically lower than the empty state, and excitation from the lower state to the higher state takes place by a photon absorption. However, in the *inverted population*, the occupied state has a higher energy than the empty state, and the microwave stimulates the transition from the higher state to the lower state by emitting a photon (*stimulated emission*). One can study microwave emission and absorption spectra just by changing the voltages.

3.6. Coherent Electron–Photon Interaction

Here we discuss the coherent electron–photon interaction in a strongly coupled double quantum dot, where the simple Tien–Gordon theory cannot be applied [52, 53]. In this case, the double dot can be considered a two-level system. In order to generalize the problem, we use the pseudospin model introduced in Section 2.5. We consider that a microwave is applied to the two-level system to modify the energy difference, ε, between the two charge states, (1, 0), denoted by $|0\rangle$, and (0, 1), denoted by $|1\rangle$; $\varepsilon(t) = \varepsilon_0 + \varepsilon_1 \cos \omega t$. Then the Hamiltonian of the system is time dependent and given by

$$H(t) = \frac{1}{2}(\varepsilon_0 + \varepsilon_1 \cos \omega t)\sigma_z + \hbar T_c \sigma_x \tag{13}$$

where T_c is the tunneling coupling. When the Hamiltonian is periodic, $H(t+T) = H(t)$, with the period $T = 2\pi/\omega$, the eigenstates have the form $\psi(t) = e^{-iEt/\hbar}u(t)$, where E is the quasi-energy and $u(t)$ is a periodic function (Floquet function) with the period T. E and $u(t)$ are the eigenenergy and eigenstate of the one-period evolution operator $U(T)$, which can be obtained by integrating the equation

$$i\hbar \frac{\partial}{\partial t} U(t) = H(t)U(t) \tag{14}$$

numerically [54].

Figure 6 shows the numerical calculation of the eigenenergy, E, for different normalized modulation amplitudes,

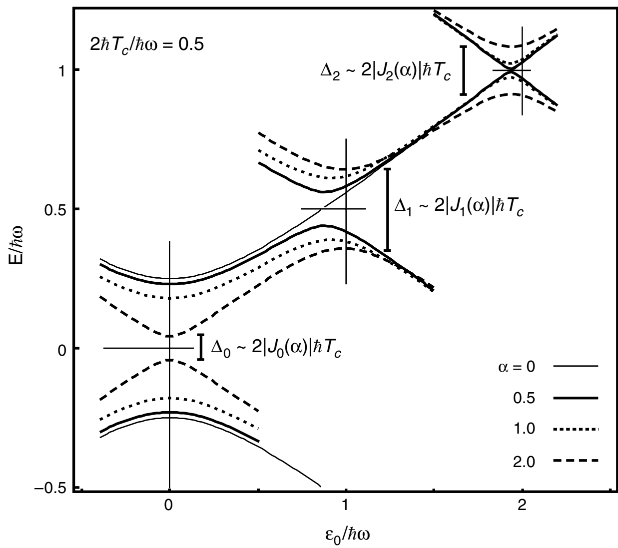

Figure 6. Quasi-energy, E, of the two-level system in a double quantum dot in the presence of microwave modulation. The numerical calculation is done for $2\hbar T_c/\hbar\omega = 0.5$ and $\alpha = \varepsilon_1/\hbar\omega = 0, 0.5, 1$, and 2.

$\alpha = \varepsilon_1/\hbar\omega$. The trace for $\alpha = 0$ is identical to that in Figure 4a, which schematically illustrates photon excitation from the bonding state (lower energy) to the antibonding state (higher energy). When the microwave amplitude is very weak, $\alpha \ll 1$, the application of the microwave does not perturb the energy states of the double dot. A current peak appears when the bonding and antibonding states are exactly separated by the photon energy, $\varepsilon = \sqrt{(\hbar\omega)^2 - 4(\hbar T_c)^2}$ see arrows in Figure 4a. So there is a minimum frequency, T_c/π, to observe the microwave excitation current. This is an accurate measurement to experimentally determine ε and T_c, since it can be deduced from the frequency. Actually, the anticrossing behavior has been demonstrated in a strongly coupled double dot and in a superconducting island [18, 49].

However, eigenstates of the system are influenced by microwave modulation, as shown in Figure 6. As the amplitude increases, the original bonding and antibonding states, $|\psi_+\rangle$ and $|\psi_-\rangle$, are coherently coupled with the aid of n photons, and a new energy gap, Δ_n, appears at the energy spacing close to the integer multiple of the photon energy, $\varepsilon_0 \sim n\hbar\omega$ [53]. The appearance of the gap indicates the coherency of the system, and the absorption and emission can take place coherently and oscillatory (Rabi oscillations, see next subsection). In the limit $T_c \ll \omega$, where analytical solutions can be obtained, the nth energy gap, Δ_n, is approximately given by

$$\Delta_n = 2|J_n(\alpha)|\hbar T_c \tag{15}$$

at $\varepsilon_0 = n\hbar\omega$ [53]. Figure 4b shows the Bessel function, $|J_n(\alpha)|$, to illustrate how the energy gap changes with α (compare with the square of the Bessel function for Tien–Gordon theory in Fig. 4a). As is also seen in Figure 6, the energy gaps change with α. It should be noted that the position of the gap also changes. The energy gap with one photon appears at $\varepsilon = \pm\sqrt{(\hbar\omega)^2 - 4(\hbar T_c)^2}$, in the case of weak microwave amplitude, $\alpha \ll 1$, while it shifts toward $\varepsilon = \hbar\omega$ for strong amplitude. This shift is also observed as a shift of the current peak in a double quantum dot device [55]. Strong nonlinear electron–photon coupling can be studied in quantum dot systems.

3.7. Coherent Oscillations in the Time Domain

In this subsection, we discuss some coherent oscillations in the time domain. First, we describe Rabi oscillations in a double quantum dot under microwave irradiation. Then, a slightly different type of charge oscillation induced by abruptly changing a gate voltage and spin rotation in the microwave magnetic field are discussed.

In order to simplify the problem, we consider that the two levels in the double quantum dot are separated by ε in the limit of $\hbar T_c \ll \varepsilon$ and the microwave is irradiated at the resonant condition, $\varepsilon = \hbar\omega$, with the same notations as in the previous subsection. Therefore, the localized state, in which an electron occupies the left or the right dot, gives a good picture of the system. Suppose an electron occupies the left dot before microwave irradiation at $t < 0$ and the microwave is turned on for the period $0 < t < t_p$. If microwave absorption and emission take place coherently during the microwave irradiation, the probability of finding the electron in the dot should oscillate in time,

$$P_{l/r}(t) = \frac{1}{2}[1 \pm \cos(\Delta_1 t/\hbar)] \tag{16}$$

where the frequency, $\Delta_1/\hbar$, is given by Eq. (15). This is analogous to Rabi oscillations in atomic systems [56]. One cannot directly observe the oscillation by detecting the location of the electron, since the measurement itself causes the decoherence of the system and makes the oscillation cease. Instead, one can measure the location of the electron after turning off the microwave at $t > t_p$. A simple measurement scheme is a current measurement. The gate voltages can be adjusted so that an electron in the right dot, for example, can escape to the lead to measure as a current. This tunneling rate must be much smaller than the oscillation frequency to reduce the decoherence. However, this measurement yields only one electron at most per pulse. Since a typical current meter requires about 10^5 electrons to detect a signal, a reasonable current can be obtained by repeating identical measurements (microwave pulses) many times. Then the current is proportional to the probability, $P_r(t_p)$. The oscillation pattern appears if the current is measured at various pulse lengths, t_p, or strengths of electron–photon coupling, $\Delta_1 = 2|J_1(\alpha)|\hbar T_c$.

Practically, the coherent oscillation does not continue forever due to dissipation and decoherence (Section 3.8) and ends up with a stationary ground state. In order to obtain the oscillations, higher oscillation frequency and less decoherence are required. However, the observation of Rabi oscillations in a single-electron system is difficult, because of technical difficulties in obtaining a short microwave pulse compared to the relatively short decoherence time of single charge states. Successful oscillations have been observed in an exciton (electron–hole pair) system, in which ultrafast optical excitation is used [57] .

A slightly modified technique is coherent charge oscillation induced by a high-speed voltage pulse, instead of a microwave pulse [58, 59]. A localized state is prepared before the pulse, and the two levels are aligned during the pulse ($\varepsilon = 0$) so that the electron can go back and forth between the two dots coherently.

Neglecting the source and drain electrodes, the Hamiltonian of the system, by using the same notation as in Section 2.5, changes from

$$H(t) = \frac{1}{2}\varepsilon_0\sigma_z + \hbar T_c\sigma_x \quad (t < 0) \tag{17}$$

before the pulse, where $|\varepsilon_0| \gg T_c$ is chosen to give a localized state in the steady state, to

$$H(t) = \frac{1}{2}\varepsilon_1\sigma_z + \hbar T_c\sigma_x \quad (0 < t < t_p) \tag{18}$$

during the pulse, where $\varepsilon_1 \sim 0$ is the situation we are interested in. The dynamics of the pseudo-spin can be understood well using the Bloch sphere introduced in Section 2.5. The system is initialized in the ground state of Eq. (17) (at the north pole in the Bloch sphere of Fig. 7e) at $t = 0$ and then precesses about the x axis during the pulse.

In a way similar to the microwave-induced Rabi oscillations, the electron in the right dot can be detected as a current, which is proportional to the probability of finding an electron in the right dot, $P_r(t_p)$. This is the projection of the quantum state in the Bloch sphere onto the z axis and is given by

$$P_{l/r}(t_p) = \frac{1}{2}[1 \pm \cos(2T_c t_p)] \tag{19}$$

at $\varepsilon_1 = 0$.

Figure 7 shows the coherent oscillation pattern in the $t_p - \varepsilon_1$ plane. As $|\varepsilon_1|$ grows larger, the oscillation amplitude and the oscillation period decrease. For $\varepsilon_1 \neq 0$, the Hamiltonian of Eq. (18) contains an additional fictitious magnetic field in z directions. The pseudo-spin rotates about the direction of the total fictitious magnetic field, which is illustrated in the trajectories in Figure 7d–f. It is important that any position (state) in the Bloch sphere can be prepared by adjusting ε_1 and t_p in a single pulse. By using a fast pulse generator with a rise time of 50–60 ps, successful charge oscillations have been observed in superconducting charge states in a single Cooper-pair box [58, 59] and more recently in single electron states in a double quantum dot [60].

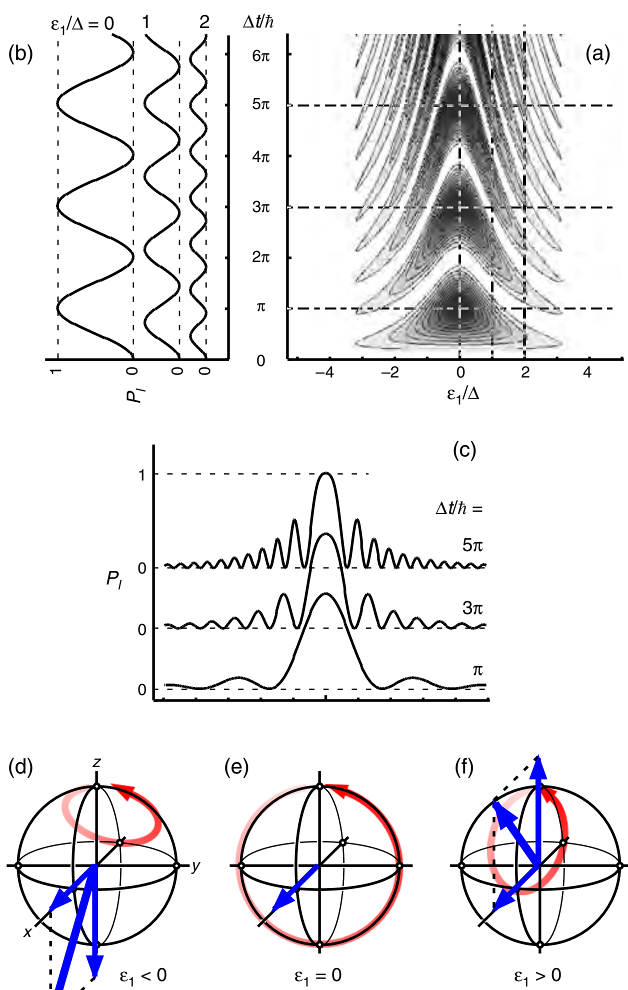

Figure 7. Time evolution of the two-level system in a double quantum dot. (a) Probability of finding the system in the excited state, P_e (white for 0 and black for 1) as a function of the normalized time, $\Delta t/\hbar$, and the normalized offset energy, ε_1/Δ. (b) Oscillations in the time domain appear at $\varepsilon_1/\Delta = 0$, 1, and 2 (they are offset for clarity). (c) The interference fringe in the offset energy for $\Delta t/\hbar = \pi$, 3π, and 5π. (d–f) Schematic trajectories of the oscillation in the Bloch sphere for (d) $\varepsilon_1 < 0$, (e) $\varepsilon_1 = 0$, and (f) $\varepsilon_1 > 0$.

Another important coherent oscillation is the electron spin resonance, in which the real electron spin precesses in the presence of a static magnetic field, B_0, in the z direction and an oscillating magnetic field, B_1, in the x direction. The Hamiltonian of the system is given by

$$H(t) = -\frac{1}{2}\mu_s(B_0\sigma_z + B_1 \cos \omega t \sigma_x) \tag{20}$$

which is similar to Eq. (13) by exchanging the x and z directions. When the frequency of the oscillating magnetic field is adjusted at the Zeeman splitting energy, the spin direction goes up and down with a precession about z direction. This is known as the electron spin resonance, and many kinds of coherent effects have been investigated in many systems. However, because of insufficient measurement sensitivity for electron spin, the electron spin resonance has to be obtained from an ensemble of many spins. Dynamical measurements on a single electron spin are desired (see Section 4.3).

3.8. Decoherence in Quantum Dots

Loss of coherence, which arises from the interaction between a quantum system and the environment, kills the coherent oscillations of the quantum system. There are two or three characteristic times to describe the coherency. Longitudinal relaxation time, which is often called T_1, is the characteristic time by which energy of the system is dissipated into the environment (dissipation). The transverse relaxation time, T_2, is the time by which the phase of the system becomes uncertain (decoherence). If the transverse relaxation time originates from the inhomogenity of an ensemble of the quantum system, it is often referred to as T_2^* (dephasing). Since dissipation also kills the phase information, generally $T_2^* \leq T_2 \leq 2T_1$.

Electrons in a quantum dot have orbital and spin degrees of freedom. These degrees of freedom are actually influenced by the environment surrounding the quantum dot, such as photons in the electrical leads and vacuum, phonons of the crystal lattice, other electrons in the electrodes and impurities, nuclear spin of the crystal, and noise and other fluctuations in the control signal. Moreover, spin and orbital degrees of freedom are coupled with relativistic correction (spin–orbit interactions). The quantum system has to be well isolated from the environment to maintain the coherency of the system.

The characteristic times (T_2^*, T_2, and T_1) of a system depend on the material, devices, and measurements and their parameters. In the next few subsections, we describe some dissipation and dephasing mechanisms that appear in a single-electron system.

3.9. Momentum Relaxation in a Single Quantum Dot

We start from the energy relaxation process from an excited state to the ground state of a single quantum dot without changing spin. The dominant interaction in this case is the coupling with acoustic phonons for a typical quantum dot whose energy spacing is less than ~10 meV. Because of the discrete energy states in a quantum dot, the quantum dot only couples with a phonon whose energy is identical to the energy difference of the ground and excited states. At very low temperature, where no phonons are excited, only spontaneous emission of a phonon is important. It should be noted that the wavelength of the phonon can be close to the size of the QDs. This is a notable difference when compared to electron–photon coupling, in which the wavelength of the photon is usually much longer than the size of the system. The strength of electron–phonon interaction becomes maximum when the half wavelength is about the size of the quantum dot [61, 62].

We have to consider different types electron–phonon couplings to fully understand the mechanisms. In addition to the normal bulk phonon modes, surface acoustic waves have to be taken into account, if the quantum dot is close to the surface within the phonon wavelength, and interface phonon modes if it is close to the interfaces. Moreover, for polar semiconductors, for example, GaAs, there are two types of couplings. One is the deformation type, in which the deformation of the lattice shifts the potential for electrons, and the other is the piezoelectric type, in which the deformation gives an electric field. Generally, the piezoelectric type coupling is more efficient for low energy phonons (less than ~1 meV for GaAs).

The electron–phonon interactions for optical characteristics are intensively studied because inefficient optical properties (the phonon bottleneck effect) are expected for a QD whose energy spacing is relatively large [63]. The phonon bottleneck effect is undesirable with respect to optical characteristics, but it is desired in order to reduce the decoherence of the quantum system. The energy relaxation time is expected to become significantly long, if the energy spacing is not right at the optical phonon energy and if the corresponding phonon wavelength is longer than the size of the QDs. There are still many questions about its influence on the efficiency of luminescence, but recent studies indicate that the phonon bottleneck effect does exist when other relaxation mechanisms, which may be related to holes or other electrons, are well suppressed [64–66]. Optical techniques are often restricted by their generated electron–hole pairs, which open other relaxation channels.

As for the transport measurement, in which no holes are generated, the suppression of phonon emission appears more clearly. Excitation spectra in single-electron tunneling characteristics indicate relatively long relaxation time; however, conventional transport characteristics do not give quantitative information about the relaxation time [67]. The recent discovery of time-dependent transport through a QD in the Coulomb blockade regime allows us to measure the energy relaxation time in a QD that contains just one electron (an artificial hydrogen atom). The energy relaxation process from the 2p orbital (the first excited state) to the 1s orbital (the ground state) is schematically shown in Figure 8a. The relaxation time, $T_1 = 3$–10 ns, slightly increases with increasing energy spacing (1.5–2.5 meV) by changing the magnetic field ($B = 0$–5 T) [68]. This behavior is understood as the spontaneous emission of an acoustic phonon and indicates the phonon bottleneck effect. It should be noted that the observed T_1 time is close to the minimum condition, where the half wavelength is about the size of the quantum dot (maximized electron–phonon interaction). The strength of electron–phonon coupling could be reduced by tailoring the structure of the quantum dot.

3.10. Spin Relaxation in a Quantum Dot

When the energy relaxation involves a spin–flip, simple photon or phonon emission cannot contribute to the relaxation. Spin–flip mechanisms, such as spin–orbit or hyperfine interactions, have to be considered together with the phonon emission that is required for energy conservation. Spin–orbit interaction, which mixes the spin and orbital degrees of freedom, is known to be a dominant spin–flip mechanism in 2D electron systems in semiconductors. Causes of spin–orbit interaction include the lack of crystal inversion symmetry, the electric field of the confinement potential, and impurities and interfaces of the structures. However, the spin–orbit interaction does not contribute to the spin relaxation in a QD to the first order if the energy spacing is much larger than the spin–orbit-induced spin splitting

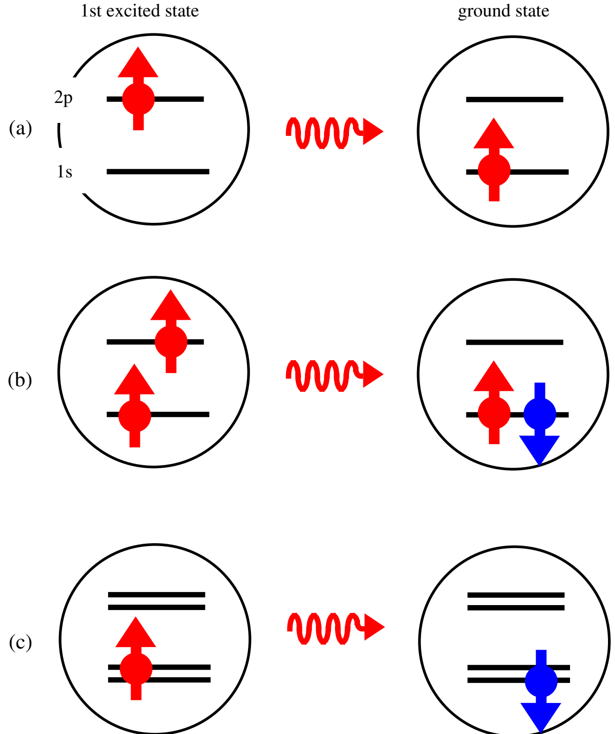

Figure 8. Energy relaxation processes in a quantum dot. The upper and lower horizontal lines in each circle represent the 2p and 1s orbital states, respectively, in a quantum dot. (a) Momentum relaxation from the 2p state to the 1s state. (b) Spin and momentum relaxation in a two-electron quantum dot. (c) Spin relaxation in a one-electron quantum dot. The double line indicates Zeeman splitting in a magnetic field.

energy (a few microelectron volts for GaAs). Higher order spin–orbit interactions give rise to a small effect on the spin–flip energy relaxation, whose relaxation time is expected to be longer than 1 ms for a typical GaAs QD [69–72]. Nevertheless, spin–orbit coupling is theoretically predicted to be a major source of the spin–flip energy relaxation process.

The spin–flip energy relaxation time has also been intensively studied in optical measurements. However, the observed relaxation time strongly depends on the excitation conditions. When the QD is excited resonantly, a very long relaxation time ($\gg$20 ns, which is even longer than the experimental limit of the optical technique) has been reported at low temperatures ($<$20 K) [73, 74]. However, it is not as long as the theoretical predictions. The optical measurement is restricted by its electron–hole recombination lifetime.

Single-electron transport measurements with time-dependent gate voltage allow us to measure extremely long relaxation times (the electrical pump and probe technique) [68, 75, 76]. The energy relaxation from the spin-triplet state to the spin-singlet state in a two-electron quantum dot (artificial helium atom) involves a spin–flip, as schematically shown in Figure 8b. This inelastic spin relaxation time is found to be about 200 μs for a specific device. From a detailed analysis, this relaxation was found to be dominated by the cotunneling process, which exchanges the spin and the energy with the electrode [68]. For instance, a spin-up electron leaves the dot, and simultaneously a spin-down electron enters it. During this process, the QD loses energy and the electrode gains the same energy. Since the strength of the cotunneling process is determined by the tunneling rate, the cotunneling process can be easily reduced by increasing the tunneling barrier. Then, the resulting relaxation time should become longer than 200 μs and may be dominated by spin–orbit interactions.

The inelastic spin relaxation time ($>$200 μs) is more than 5 orders of magnitude longer than when no spin–flip is involved ($\sim$10 ns) [68]. The ratio of the relaxation time can be larger than 3×10^4, which is close to the theoretical expectation of 5×10^5 for this structure [70]. It is interesting to compare this ratio to that of real atoms. Quantum dots, or artificial atoms, couple to lattice vibration modes (phonons), while real atoms couple to electromagnetic fields (photons). The strength of the optical transition in real atoms strongly depends on the characteristics of the state, known as selection rules [77]. The typical transition lifetime, or relaxation time, of allowed transitions for electric dipole coupling is on the order of nanoseconds, e.g., 1.6 ns for the Lyman α transition line from the 2p state to the 1s state in a hydrogen atom. However, some transitions have an extremely long relaxation time, for example, 7860 s for the relaxation from the two-electron spin-triplet excited state to the spin-singlet ground state in a helium atom. In this case, the transition is forbidden by spin conservation and parity [77]. The huge ratio of the relaxation times, more than 10^{12} for hydrogen and helium atoms, indicates the high quality of the quantum numbers, spin, and angular momentum. The ratio decreases with increasing atomic number, because spin–orbit interaction increases and the Russel–Saunders approximation becomes worse. The ratio in a GaAs artificial atom is $>3 \times 10^4$, which is comparable to the ratio of 10^5 for potassium and calcium atoms, which are located in the same row as gallium and arsenide in the periodic table. This crude comparison implies that the spin–orbit interaction in the nanostructure is almost comparable to an atomic property.

Another important spin relaxation process is the transition between Zeeman sublevels in a magnetic field (see Fig. 8c). This relaxation time has been measured with the electrical method, and is also longer than the experimental limit of about 50 μs [78]. However, this spin relaxation time is expected to be longer than 1 ms, based on consideration of only the spin–orbit interaction [68].

The long spin relaxation time in quantum dots gives rise to spin-dependent tunneling. Since an electron has spin 1/2, a single-electron tunneling changes the total spin of the dot by 1/2. Other tunneling transitions that change the total spin by more than 1/2 should be blocked (spin blockade) [79, 80]. Moreover, the long spin relaxation time induces nonequilibrium transport that cannot be explained by the orthodox CB theory [9, 81].

3.11. Energy Relaxation in a Double Quantum Dot

In contrast to single dots, the energy states in a double quantum dot are spatially separated. Here we discuss the energy relaxation between the two charge states in the double dot defined in Section 2.5. Suppose two quantum dots are weakly coupled by a tunneling barrier, and consider an energy relaxation between two localized states, that is, $\varepsilon \gg T_c$. By changing ε, the overlap of the wavefunctions can be modified, as schematically shown in Figure 4(b–d). The transition rate, W, is given by $W = (T_c/\varepsilon)^2 J(\varepsilon)$, where $J(\varepsilon)$ is a spectral function that describes the interaction with its environment. As is the case for momentum relaxation in a single quantum dot, the energy relaxation without spin–flip is dominated by electron–phonon interactions. In the double quantum dot case, the spectral function can be studied by changing ε.

In single-electron transport measurements through a weakly coupled double quantum dot in a series configuration, the current through the device, I, can be directly related to the transition rate, that is, $I = eW$ for $\varepsilon > T_c$, if the outer tunneling barriers are made more transparent than the inelastic transition of interest [82, 83]. Measurements on GaAs double quantum dots indicate a spectral function close to the ohmic interaction in this system. Because of the relatively small energy ($\varepsilon = 4$–100 μeV), piezoelectric interactions with acoustic phonons are the dominant mechanisms.

In some cases, $J(\varepsilon)$ in a double quantum dot shows some structures, which come from the relation between the phonon wavelength and the spacing between the dots [82, 83]. The phonon emission between the two states is enhanced when the spacing is half of the phonon wavelength, but suppressed when the spacing equals the wavelength. The electron–phonon interaction might be strong to renormalize the single-electron tunneling [84]. Even though there is no confinement of phonons, such oscillatory behavior is observable in the current spectrum of a double quantum dot.

3.12. Decoherence of a Double Quantum Dot

In contrast to the energy relaxation processes, decoherence is a loss of phase information over the ensemble of measurements. In the discussions of coherent oscillations in the time domain (see Section 3.7), we completely neglect the decoherence and dissipation. However, in reality, oscillation does not continue forever, but is dampened over a duration characterized by the decoherence time, T_2. It is convenient to assume an exponential decay of the oscillation amplitude, but the amplitude can decay in a Gaussian shape in some cases [85].

The decoherence of the two-level system in a double quantum dot may be dominated by fluctuations of ε and T_c. The fluctuation changes the frequency of the coherent oscillations and smears out the oscillation in the ensemble measurement. According to a detailed study of coherent oscillations in superconducting charge states, the $1/f$ noise in the background charge fluctuations is the decoherence mechanism [85]. Although the power spectrum decreases with a $1/f$ dependence at higher frequency, the integrated contributions come from a wide frequency range. A single-electron state has the advantage of high controllability, but this means that it can easily couple to the environment. The mechanism of the charge fluctuations is not well understood, and the reduction of the noise may not be easy.

One way to avoid the influence of fluctuations is to design the quantum state to be less sensitive. As seen in Figure 4a, the energy spacing between two eigenstates is insensitive to the fluctuation of ε at $\varepsilon = 0$ to the first order, while it is sensitive at $\varepsilon > T_c$. Therefore, longer decoherence time is expected at $\varepsilon = 0$. In a superconducting island with a SQUID interferometer to control the Josephson coupling (equivalent to T_c), the quantum system can be set at the saddle point where the energy spacing is insensitive to the fluctuation of ε and T_c. A very long decoherence time of a few microseconds compared to the precession period of $\sim$50 ps has been realized [86].

3.13. Radiofrequency Single-Electron Transistor

The single-electron transistor is known to work as a highly sensitive electrometer. In principle, the operating frequency can go beyond 1 GHz if it is determined by the intrinsic RC time constant of the tunneling resistance and capacitance. However, the practical operating frequency is limited to a low-frequency range (a few kiloHertz at most) in conventional dc current measurements. The capacitance of the electrodes, including the measurement instruments, is so large that the frequency range is restricted by the RC time constant of the electrode capacitance and the tunneling resistance.

The radiofrequency (rf) single-electron transistor (RFSET), which works as a wide-band and highly sensitive electrometer, is a SET combined with an impedance transformer (LC resonator) [87]. The capacitance of the problem can be canceled by an external inductor located close to the SET device if it is operated at the resonant frequency, f_{res}. The maximum frequency of the RFSET is approximately given by f_{res}/Q_{LC}, where Q_{LC} is the quality factor of the resonator. The external LC resonator placed close to an SET device has a typical bandwidth of about 100 MHz, with $f_{res} \sim 1$ GHz and $Q_{LC} \sim 10$. Better performance (higher f_{res} and larger Q_{LC}) may be obtained using an on-chip resonator. The conductance of the SET is measured by the reflection or the transmission of the rf carrier signal at f_{res} [88, 90]. The transmission amplitude, or the small change in the reflected signal, is, in principle, proportional to the admittance (the inverse of the impedance) of the SET [90].

The sensitivity of a charge respective to the island can be about $10^{-5}\text{e}/\sqrt{Hz}$, which is usually restricted by the noise of the high-frequency amplifier. This means that the intrinsic noise of the RFSET (shot noise) is very low at high frequency (>10 kHz), while it suffers from $1/f$ noise at low frequency. Theoretically, the noise of the RFSET is expected to be very close to that of the conventional SET [89]. The charge sensitivity can be as low as $2 \times 10^{-6}\text{e}/\sqrt{Hz}$ for an optimized device using a practical superconducting island, and better sensitivity is expected by using a smaller island [87].

The RFSET technique is very attractive and can be used as a highly sensitive fast-response electrometer for many applications [91]. If the RFSET is attached to another quantum dot located in another conductive channel, each single-electron tunneling process would be detected with a high sensitivity [92]. This would be an extremely sensitive current meter, in which current flow could be detected by counting tunneling electrons. If a RFSET is attached to a two-level system in a double quantum dot (see Section 2.5 and 3.7), the charge state can be detected in a short time [93]. This is desirable for further investigation of quantum dynamics and correlations in single-electron systems.

4. TOWARD QUANTUM INFORMATION PROCESSING

Quantum information processing is digital data processing with the aid of coherent time evolution of quantum states. Analogous to a bit that is the unit of digital information, the unit of quantum information is the quantum bit (qubit), which is basically realized in any single two-level system. Quantum information processing would provide various advantages that have never been obtained in the conventional classical approach [94, 95]. For instance, quantum cryptography would provide secure telecommunications because any unknown single quantum state cannot be duplicated and because any unknown single quantum state cannot be determined completely. A quantum nondemolition measurement scheme improves the measurement accuracy by avoiding back action. Quantum computation is programmable interferometry in which only one or a few desired answers can be efficiently obtained from an extremely large number of candidates. Recently, quantum information processing has become attractive for realizing very specific tasks.

4.1. Concept of Quantum Computation

First, we stress that quantum information processing is completely different from so-called "quantum devices." Quantum devices are designed to transform a classical input, like a voltage, into another classical output, like a current, with excellent transfer characteristics with the aid of quantum mechanics. The resonant tunneling diode, which is a typical quantum device that works even at room temperature, shows negative differential resistance in the current (output)–voltage (input) characteristics. Although quantum mechanics is required to design the diode, one can use the diode without considering the quantum mechanics, if the characteristics are known. In quantum information processing, however, the quantum state is the carrier of information. The quantum state is transformed from an input state to an output state by applying an external field, for example, an electromagnetic field, in a certain period. The transformation of the quantum state is called a quantum logic gate and should be a unitary transformation to keep coherency. The quantum state changes by applying a series of quantum logic gates necessary for quantum computation from the beginning, at which some classical values are input to the quantum state, until the end of the computation, at which the output states are finally measured as classical values. One may not measure the intermediate state, which would result in the collapse of the quantum state. Quantum computing requires a high degree of quantum coherence for a long enough time to complete the computation.

In principle, any calculation that can be performed in a conventional classical computer can also be performed in a quantum computer. But this is not a good idea because quantum computation requires extremely high accuracy and coherency in the quantum logic gates and because computation errors are unavoidable. However, one can design the algorithm of quantum computation in such a way that a series of data processings are performed at once in a parallel fashion (quantum parallelism). Then, quantum computation is expected to provide extremely efficient calculations for specific problems that cannot be solved efficiently with conventional classical computers. For instance, factorization of a large number is a formidable task for conventional computers. There are no efficient algorithms for this in classical computers, and one has to check sequentially whether the number to factorize is divisible by a number from 2 to the square root of the number to factorize (actually, there is a better way using a probabilistic algorithm). Nevertheless, factorization of a 1000-digit number would require 10^{25} years (longer than the history of the universe) by using 1000 workstations in parallel [96]. In Shor's factoring algorithm for quantum computing, the factorization problem is attributed to how efficiently a Fourier transformation is calculated. The quantum Fourier transform can be constructed from a few kinds of quantum logic gates, and can be calculated very efficiently. Factoring a 1000-digit number would require only a few 10^6 steps in the quantum computation [96]. The factorization (quantum Fourier transformation) is just an example of quantum computation. There are many algorithms, such as database search and quantum simulations, that would solve some problems very efficiently.

Although the potential of quantum computing is fascinating, only a few small-scale quantum computers have been realized. The solution nuclear magnetic resonance (NMR) quantum computer is the most advanced quantum computer. The nuclear spin of an atom is used as a qubit, and a single molecule that contains distinguishable atoms (nuclear spins) works as a quantum computer. The NMR quantum computer works by applying a sequence of radiofrequencies (quantum logic gates) to many molecules (quantum computers) in a solution. Recently, factorization of 15, whose prime numbers are 3 and 5, was demonstrated using a solution NMR QC with 7 qubits [97]. However, the solution NMR QC has problems integrating large numbers of qubits and thus may not be a practical quantum computer. It is generally accepted that solid-state quantum computers are good candidates for scalability. There are many proposals based on the charge state or flux state in a superconducting island, the charge state, electron spin state, or exciton state (electron–hole pair) in a semiconductor quantum dot, and the nuclear spin state of impurities or crystals. One-qubit operations have been demonstrated in some solid-state systems, and two-qubit operations has recently been studied in superconducting system [98].

To construct a quantum computer, single quantum states would have to be prepared physically, manipulated coherently, preserved for a long enough time, measured individually, and integrated in large quantity [99]. Each of these points requires further development. Decoherence is one of the major problems in solid-state systems. Fundamental research has been conducted to reduce the decoherence problems and to devise the best quantum logic gates. In the following two subsections, we briefly summarize the strategies for realizing quantum computers using single-electron dynamics.

4.2. Single-Electron Charge Qubit

As we discussed in Section 2.5, a single electron in a double quantum dot can be used as a two-level system, serving as a qubit (charge qubit) [18, 100]. A similar charge qubit has been realized in a superconducting island, in which the two-level system is represented by an extra Cooper pair occupying or not occupying the island (a superconducting charge qubit). The coherent oscillations induced by microwave irradiation or by a high-speed voltage pulse can be used as a rotation gate for one-qubit operation (Section 3.7). The qubit state can be controlled to any state [θ and ϕ in the Bloch sphere, see Figure (7d–f)] by tailoring the pulse shape. The NOT gate, which reverses the classical information, can be obtained by applying a π pulse (a half cycle of the oscillation at $\varepsilon = 0$). The Hadamard gate, which creates a superposition state from an eigenstate, is achieved by a $\pi/2$ pulse (a quarter cycle of the oscillation).

When two sets of double quantum dots (two qubits) are fabricated to couple electrostatically, any superposition of four bases $|00\rangle$, $|01\rangle$, $|10\rangle$, and $|11\rangle$, where the first and second numbers indicate the location of electron in respective double dot, can be prepared. The dipole coupling between the two qubits affects the total energy of the states. The controlled-NOT gate, which is a typical two-qubit operation, can be performed by applying a voltage pulse to degenerate two states, say $|00\rangle$ and $|01\rangle$, for a certain period that exchanges the two states. This means that the state of the

second qubit (target qubit) is reversed (NOT operation) only when the first qubit (control qubit) is 0. If this is performed coherently, the controlled-NOT gate should work for any superposition state as well. For instance, starting from the initial state $|00\rangle$, the Hadamard gate on the fist qubit followed by the controlled-NOT gate brings an entangled state

$$|00\rangle \rightarrow_H |00\rangle + |10\rangle \rightarrow_{CNOT} |01\rangle + |10\rangle \tag{21}$$

in which the first and second qubits are correlated [95].

The qubit state can be measured by an electrical current, as explained in Section 3.7. In this case, ensemble averaging over many measurements is required due to small current sensitivity. In some cases, for example, when the correlation between the two qubits is essential, it is desirable to measure a single qubit state without any ensemble averaging. The RFSET technique discussed in Section 3.13 would provide a single shot measurement without averaging for the charge qubit. If the electrostatic coupling between the qubit and the RFSET can be made sufficiently large, the qubit state can be measured in a relatively short time (hopefully ~10 ns). Of course, the RFSET can be turned off by switching off the carrier rf signal during the quantum computation to minimize the decoherence from the measurement.

4.3. Single-Electron Spin Qubit

The spin degree of freedom is an alternative way to construct a qubit [101]. If the charge qubit is an artificial qubit, electron spin is a natural qubit. The coherency and manipulation of electron spins have been studied in many systems. The spin coherence time of conductive electrons in bulk GaAs crystal can be longer than 100 ns [102], and electron spin bound to a donor in silicon shows $T_2 \sim 300$ μs [103]. Electron spin based quantum computation is motivated by the long decoherence time. However, in contrast to the countless studies of the ensemble of spins, little work has been done on the manipulation of single-electron spin. In order to address each electron spin (qubit) in a quantum computer, single-spin manipulation and measurement techniques are essential.

A simple scheme for one-qubit operation is the electron spin resonance discussed in Section 3.7. The effective g factor of each electron spin can be made different for different quantum dots by using g-factor engineering, so that each qubit is addressed by a corresponding microwave frequency [101]. Or a moderate magnetic field gradient in the device may be useful in changing the Zeeman splitting energy. However, a typical one-qubit operation using an electron spin resonance will require a relatively long time, ~100 ns, because of the weak magnetic dipole transition. Alternative ways using the optical Stark effect in a specific band structure [104] or exchange coupling among three electron spins constituting one qubit [105] are promising for much faster operations Two-qubit operation can also be performed by the exchange coupling between two quantum dots [106].

Single shot spin measurement is a challenging technique for quantum information technology. One proposal is based on the spin-dependent tunneling between two quantum dots combined with an RFSET [107]. When each of the two quantum dots possesses one electron spin before the measurement, tunneling from one dot to the other is allowed if the two electron spins can make a spin pair (spin-singlet state) [108]. This spin-dependent tunneling could be measured with an RFSET in a short time.

GLOSSARY

Adiabatic approximation When the Hamiltonian of a quantum system changes slowly, the wave-function can be approximated by an eigenstate of the instantaneous Hamiltonian (adiabatic approximation). However, when the Hamiltonian changes very fast (nonadiabatically), the wave-function becomes a nonstationary superposition state.

Bloch sphere Any linear superposition of two orthonormal bases can be expressed in a form, Eq. (4), which indicates a point on the unit sphere (Bloch sphere). This representation is very useful for visualizing a quantum state.

Cotunneling Cotunneling is two or more tunneling processes that occur successively in a short time. The intermediate state may have a high energy if the energy cost is within the energy uncertainty given by the interval of the corresponding tunneling processes.

Coulomb interaction Coulomb interaction between two or more electrons can be described by a direct integral, which comes from the direct overlap of the two wavefunctions, and an exchange integral, which depends on the spin state.

Poisson statistics Poisson statistics describe frequency distribution when the probability of an event is very small. The probability for n events happening is given by $p(n) = a^{-n}e^{-a}/n!$, where a is the average number of events. When the distributions are narrower than Poisson statistics, they are described by sub-Poisson statistics.

Rabi oscillation When a coherent electromagnetic field is resonantly applied to a two-level system, emission and absorption take place coherently and with oscillation (Rabi oscillation).

Spontaneous/stimulated emission When a transition from a higher energy state to a lower energy state occurs by the emission of a boson (photon or phonon), it consists of spontaneous emission, which always occurs due to vacuum fluctuation of the bosonic system, and stimulated emission, which is proportional to the number of existing bonons.

1/f noise $1/f$ noise has a power spectrum close to $1/f$ frequency dependence. In electrical noise, $1/f$ noise comes from an ensemble of many electron traps, each of which emits or captures an electron independently (Poisson statistics).

1. SINGLE-CHARGE-TUNNELING MECHANISMS

1.1. Introduction

It is well known that classical mechanics provides an accurate description of the behavior of macroscopic objects. On the other hand, the physics of microscopic systems involving electrons, atoms, and molecules is exclusively quantum mechanical. With the advances of fabrication techniques, the crossover region between these two fundamental regimes has been the subject of intense experimental and theoretical investigations. Systems that fall into this crossover region are called mesoscopic—although they contain a macroscopic number of particles, these systems are small enough in physical size that their behavior reveals quantum-mechanical effects. The characteristic length scale of mesoscopic samples varies from nanometers to tens of micrometers.

Several new effects have been observed in mesoscopic devices. The wave nature of electrons is apparent in the interference effects which produce quantum conductance fluctuations and weak localization effects [1–3]. In addition, it has also given rise to the Aharonov–Bohm effect in ring geometries [4]. In contrast, the ballistic transport of electrons through short and narrow channels results in quantized conductances [5]. The discreteness of the electron energy spectrum has been probed in semiconductor heterostructures [6] and small metal particles [7]. It is in this last category of charging effects that this chapter belongs.

The discreteness of the electronic charge is usually not evident in conventional electron devices, in which the current is regarded as a continuous charge flow. However, if electrons are confined to small isolated regions (called islands) that are weakly coupled to its surroundings, the discreteness of the electronic charge can significantly influence the electrical properties of the system. The capacitance of the island to the external circuit can be so small that the charging energy required to add a single electron becomes the dominant energy. This phenomenon is called the "single-electron-charging effect."

Single-electron-charging effects have been widely studied on double oxide-tunnel-junction systems, also called single-electron transistors (SETs). Such a sample is conventionally fabricated by electron-beam lithography and shadow evaporation techniques. It consists of a metallic island which is weakly coupled to two bias leads through small-capacitance and high-resistance tunnel junctions, and capacitively coupled to a gate electrode. The islands and the leads are separated by thin oxide-tunnel barriers, through which electrons can only be transported by quantum-mechanical tunneling. The gate is used to control the average number of electrons on the island. This chapter will emphasize the current transport mechanisms in SETs with a normal metal island or a superconductor island, and describe the fabrication and application of SETs.

1.2. Theoretical Framework

1.2.1. Electron Tunneling

The field of single-charge tunneling was formulated in the middle of the 1980s. The Orthodox theory [8–12] of the correlated single-charge tunneling was shown to be extremely successful in describing most experimental results. The general operating principle of SET is to control the tunneling of a single charge. Such a system must have small islands that connect to other metallic regions via tunnel barriers, with a total tunneling resistance R_Σ exceeding the quantum resistance $R_Q = h/e^2 \approx 25.8$ kΩ. The criterion for this requirement can be derived by noting that, to observe a Coulomb blockade, the charging energy $E_c = e^2/2C_\Sigma$ must exceed the quantum energy uncertainty $\hbar/R_\Sigma C_\Sigma$ associated with

the lifetime due to tunneling. Essentially, it means that the wavefunction of an excess electron on the island is localized so that quantum fluctuations of the electric charge are negligible. Another criterion to observe single-charge-tunneling effects is $E_c \gg k_B T$, so that the energy E_c required to add a charge onto the island far exceeds the available energy of thermal fluctuations. These two conditions ensure that the transport of charges through the island is governed by the Coulomb charging energy.

To understand the electron transport through the SET, let us start by considering the tunneling between two normal metal electrodes separated by a barrier (NIN junction), as illustrated in Figure 1. The Fermi energies of the two electrodes are offset from each other by an amount eV. (The symbol e represents the magnitude of the electron charge, i.e., $e = |e|$.) The basic idea is that there is a nonzero probability of charge transfer by quantum-mechanical tunneling of electrons between two metals separated by a thin insulating barrier, which classically forbids tunneling. This probability falls exponentially with the distance of separation, and it depends on the properties of the insulating material. Electrons can tunnel across the barrier via an energy-conserving horizontal transition, from the filled states in electrode 1 to the empty states in electrode 2. The Hamiltonian describing this system is written as [13]

$$H = H_0 + H_T \tag{1}$$

where H_0 is the unperturbed Hamiltonian of the metals when they are completely isolated from each other, which can be expressed as

$$H_0 = \sum_{k,\sigma} \varepsilon_k c^+_{k\sigma} c_{k\sigma} + \sum_{q,\sigma} \varepsilon_q c^+_{q\sigma} c_{q\sigma} \tag{2}$$

where the first term corresponds to electrode 1 and the second corresponds to electrode 2. ε_k and ε_q are the electron energies measured with respect to the Fermi energies of electrodes 1 and 2, respectively. c^+ and c are the creation and annihilation operators. σ is a spin index, and k and q are the electron wavevectors.

H_T is the perturbing Hamiltonian which is a result of the electron wavefunctions "leaking" from one electrode into the other. It is referred to as the transfer or tunneling Hamiltonian, and is given by [13]

$$H_T = \sum_{k,q} T_{k,q} c_{1k} c^+_{2q} + \text{h.c.} \tag{3}$$

where $T_{k,q}$ is the tunneling matrix element which accounts for the wavefunction overlap between the two electrodes. The first term denotes taking an electron from electrode 1 to electrode 2; the Hermitian conjugate (h.c.) term transfers an electron in the opposite direction.

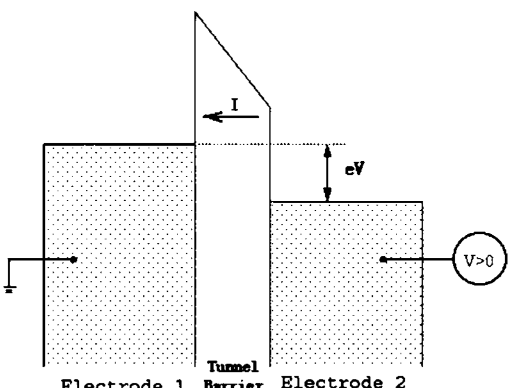

Figure 1. Tunneling diagram for an NIN junction at $T = 0$. An applied voltage produces a difference in the Fermi energies of the electrode. Electrons can tunnel horizontally through the barrier from filled states (shaded) in one electrode to empty states in the other.

Let us assume that the coupling due to tunneling between the two electrodes is sufficiently weak, so that it is reasonable to consider H_T as a first-order perturbation. According to Fermi's golden rule, the transition rate from a single initial state k to a set of final states q is given by [14]

$$\Gamma_k = \frac{2\pi}{\hbar} \sum_q |T_{k,q}|^2 \delta(\varepsilon_k + eV - \varepsilon_q) \tag{4}$$

The Dirac delta function ensures that energy is conserved in the tunneling process, that is, $\varepsilon_q = \varepsilon_k + eV$. One can transform the sum over q states to an integral over the energy ε_q by substituting the density of states (DOS) of electrode 2, $D_2(\varepsilon_k + eV)/2$ at $\varepsilon_k + eV$, and obtain

$$\Gamma_k = \frac{2\pi}{\hbar} |T|^2 \frac{D_2(\varepsilon_k + eV)}{2} \tag{5}$$

Note that the DOS of electrode 2, $D_2(\varepsilon_k + eV)$, has already included the spin degeneracy factor of 2. The division by 2 reflects that only states with the same spin as the original can be tunneled into, that is, no spin flips are allowed. Let us also assume that the average tunneling matrix amplitude $|T|$ is independent of the wavevectors k and q, and therefore, it is independent of the energies ε_k and ε_q.

At thermal equilibrium, the occupation probability of the electronic state is given by the Fermi distribution function

$$f(\varepsilon) = [1 + e^{\beta\varepsilon}]^{-1} \tag{6}$$

where $\beta = 1/k_B T$, and the probability of the unoccupied state is $1 - f(\varepsilon)$. Tunneling can only occur if the initial state is occupied and the final state is unoccupied. Thus, summing over all initial occupied states ε_k, including the factor $D_1(\varepsilon_k)$ for the DOS of electrode 1, one obtains the rate for tunneling from electrode 1 to electrode 2:

$$\Gamma_{1\to 2} = \sum_k \frac{2\pi}{\hbar} |T|^2 \frac{D_2(\varepsilon_k + eV)}{2} [1 - f(\varepsilon_k + eV)] \tag{7}$$

Replacing the sum over initial states k by an integral over ε_k, one gets

$$\Gamma_{1\to 2} = \frac{\pi}{\hbar} |T|^2 \int_{-\infty}^{\infty} D_1(\varepsilon) f(\varepsilon) D_2(\varepsilon_k + eV) \times [1 - f(\varepsilon + eV)]\, d\varepsilon \tag{8}$$

Since the bias energies are much less than the Fermi energies in the normal electrodes, one can assume that the

DOS is independent of energy, that is, $D_1(\varepsilon) = D_1$ and $D_2(\varepsilon) = D_2$. In this way, the forward tunneling rate becomes

$$\Gamma_{1\to 2} = \frac{\pi}{\hbar}|T|^2 D_1 D_2 \int_{-\infty}^{\infty} f(\varepsilon)[1 - f(\varepsilon + eV)]\, d\varepsilon \quad (9)$$

Using mathematical identities for the Fermi functions,

$$f(\varepsilon)[1 - f(\varepsilon + eV)] = \frac{f(\varepsilon) - f(\varepsilon + eV)}{1 - e^{-\beta eV}} \quad (10)$$

one can express Eq. (9) as

$$\Gamma_{1\to 2} = \frac{eV}{e^2 R_T (1 - e^{-\beta eV})} \quad (11)$$

with

$$R_T = \frac{\hbar}{\pi |T|^2 e^2 D_1 D_2} \quad (12)$$

The tunneling rate in the reverse direction $\Gamma_{2\to 1}$ is simply obtained by reversing the sign of the bias voltage, that is,

$$\Gamma_{2\to 1} = \frac{eV}{e^2 R_T (e^{\beta eV} - 1)} \quad (13)$$

The net current through the junction is then obtained by subtracting the reverse tunnel current from the forward tunnel current:

$$I(V) = e(\Gamma_{1\to 2} - \Gamma_{2\to 1}) \quad (14)$$

After inserting the tunneling rates, one gets

$$I(V) = V/R_T \quad (15)$$

recovering the ohmic relationship, with R_T being the normal state resistance of the tunnel junction.

One can also write the tunnel rates in terms of a more general energy change ΔF. Let us define ΔF as the change in the system free energy in going from the initial state to the final state. The electron travels from electrode 1 to electrode 2 in the direction favored by the applied bias, the bias source does an amount of work eV. Assume that the tunneling electron rapidly relaxes to the Fermi level, since the tunneling process is essentially irreversible, it leads to a decrease in the system free energy by this amount. Thus, $\Delta F = -eV$. Then one can express the tunneling rate in terms of ΔF:

$$\Gamma(\Delta F) = \frac{1}{e^2 R_T} \frac{\Delta F}{e^{\beta \Delta F} - 1} \quad (16)$$

Figure 2 plots the tunneling rate as a function of ΔF for various temperatures. This rate equation forms the basis of the Orthodox theory of single-electron tunneling [8–12].

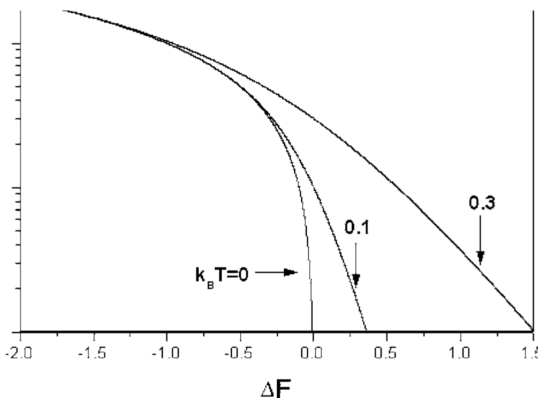

Figure 2. Forward tunneling rate of an NIN junction as a function of ΔF at different values of $k_B T$.

1.2.2. Coulomb Blockade of Tunneling

As discussed before, when the capacitances of the junctions become sufficiently small, and the Coulomb charging energy E_c of a single electron is large enough, then the discreteness of the electronic charge becomes very important. Let us first look at a single tunnel junction with small capacitance. The electrostatic energy of an isolated capacitor C with charges $Q(>0)$ and $-Q$ on the two electrodes is $Q^2/2C$, or $CV^2/2$, where $V = Q/C$. If an electron tunnels from the negative electrode to the positive one, the charge on the capacitor becomes $\pm(Q - e)$, so that the energy of the capacitor becomes $(Q - e)^2/2C$. (Here it is assumed that the single junction does not form a closed circuit, so that the capacitor charges do not come to equilibrium with the rest of the circuit.) This indicates an increase in the system energy unless the initial charge $Q \geq e/2$, that is, $V \geq e/2C$. This implies that electron transfer is energetically forbidden for voltages $V < e/2C$. This regime of zero tunnel current, despite a finite voltage across the junction, is called the Coulomb blockade [1].

Since the relevant time scale for tunneling is set by the tunneling resistance and the capacitance $\tau = RC$, which is on the order of 10^{-10} s, the effective shunting resistance is determined by the high-frequency properties of the leads near the junction, not the dc bias resistance. Hence, unless ultracompact resistors are inserted right at the junction [1], the effective impedance seen will be the high-frequency impedance of the leads, $Z \approx 100\ \Omega$, which is much less than R_Q. Thus, it is difficult to observe the Coulomb blockade effect in a single tunnel junction, no matter how low the temperature gets. One way to circumvent this problem is to make a double-junction system in which each junction is effectively isolated from the low-impedance environment by high tunnel resistance and low capacitance of the other junction (see Fig. 3).

1.2.3. Energy Considerations in the Single-Electron Transistor

In this section, the energetics of the double-junction system made of only normal metals will be considered. The energetic considerations are important because, if one knows how to calculate the change in the system free energy ΔF for a tunneling event, then one can calculate the rate at which

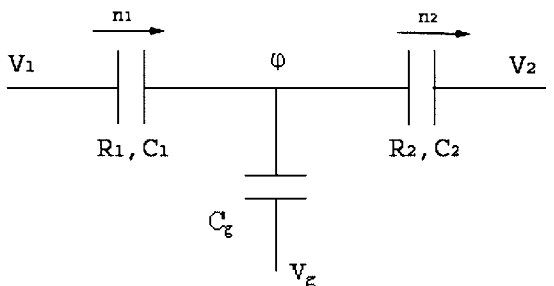

Figure 3. Schematic of a single-electron transistor showing two small capacitance tunnel junctions and a capacitively coupled gate. The region between the two tunnel junctions and the gate capacitor forms the island. By varying the gate voltage, the number of electrons on the island can be controlled.

this particular process occurs. When the leads and the island are normal metals, this rate is determined by Eq. (16). Once all of the tunneling rates are known, the tunneling current through the device can be determined.

The total capacitance of the island to its surroundings is given by the sum of the capacitances to the three electrodes:

$$C_\Sigma = C_1 + C_2 + C_g \tag{17}$$

The self-capacitance of this island is negligibe, and its effects could be included by merely renormalizing the other capacitances. Since charge is quantized in units of e, the total charge on the island is always discrete. However, continuously increasing the gate voltage is mathematically equivalent to continuously adding charge to the island. Thus, the effective charge of the island is continuous. This shows how the gate can tune the strength of the charging energy barrier.

To calculate the system free energy for the single-electron transistor, let us define n_1 and n_2 to be the number of electrons that have tunneled forward across junctions 1 and 2, respectively, and the integer $n = n_1 - n_2$ to be the excess number of electrons on the island. If ϕ is the electrostatic potential of the island, then with the voltages and capacitances defined in the schematic diagram of Figure 3, one has (let $C_3 = C_g$ and $V_3 = V_g$) [15]

$$\sum_{i=1}^{3} C_i(V_i - \phi) = ne \tag{18}$$

From this, one can find the electrostatic potential of the island:

$$\phi = \frac{\sum_{i=1}^{3} C_i V_i - ne}{C_\Sigma} \tag{19}$$

where ϕ is measured with respect to the same reference as V_1, V_2, and V_g. The electrostatic energy U of the system is given by summing the field energies of the three capacitors. Thus,

$$U = \frac{1}{2}\sum_i C_i(V_i - \phi)^2 \tag{20}$$

If one uses Eq. (19) and substitutes for φ in Eq. (20), after some algebra, one obtains

$$\begin{aligned} U &= \frac{(-ne)^2}{2C_\Sigma} + \frac{1}{2C_\Sigma}\sum_i \sum_{j>i} C_i C_j (V_i - V_j)^2 \\ &= \frac{(-ne)^2}{2C_\Sigma} + \Lambda \end{aligned} \tag{21}$$

where Λ is a constant independent of n. Since only the changes in the system free energy associated with tunneling events need to be considered, the exact value of Λ is not important.

When considering the tunneling of an electron onto or off the island, one must include not only the change in the charging energy U from Eq. (20), but also the work done by the bias voltage sources. The total work done by the voltage sources when an electron tunnels onto the island across junction j is

$$W_j = e\sum_i \frac{C_i}{C_\Sigma}(V_i - V_j) \tag{22}$$

In the case of the symmetric voltage bias, that is, $V_1 = -V/2$ and $V_2 = +V/2$, for an electron tunneling onto the island across junction 1, the voltage source does work:

$$W_1 = \frac{e}{C_\Sigma}[(C_2 + C_g/2)V + C_g V_g] \tag{23}$$

and similarly, for junction 2, the voltage source does work:

$$W_2 = -\frac{e}{C_\Sigma}[(C_1 + C_g/2)V - C_g V_g] \tag{24}$$

The system free energy can then be calculated by subtracting the work done by the voltage sources from the electrostatic energy, that is,

$$F_{\text{sys}}(n_1, n_2) = U - n_1 W_1 + n_2 W_2 \tag{25}$$

Substituting Eqs. (23) and (24) into Eq. (25), one obtains

$$\begin{aligned} F_{\text{sys}}(n_1, n_2) = \Lambda + \left[\frac{(-ne)^2}{2C_\Sigma} - n\frac{eQ_o}{C_\Sigma}\right] - n_1\frac{e}{C_\Sigma}(C_2 + C_g/2)V \\ - n_2\frac{e}{C_\Sigma}(C_1 + C_g/2)V \end{aligned} \tag{26}$$

where $Q_o = C_g V_g$ is the induced gate charge, which is a continuous variable as compared to the discrete change ne from tunneling events. This offset can be suppressed by shifting the zero of the gate voltage. In practice, naturally occurring random charged impurities near the island shift the polarization charge by an amount independent of V_g, and may drift or change discontinuously in time.

If the integer $m = n_1 + n_2$ is defined as the total number of electrons that have tunneled forward through either junction, then after completing the square of the term in brackets in Eq. (26), one finds (up to a constant which is independent of n and m)

$$F_{\text{sys}}(n, m) = \frac{(Q_o - ne)^2}{2C_\Sigma} - \left[m + n\frac{C_2 - C_1}{C_\Sigma}\right]\frac{eV}{2} \tag{27}$$

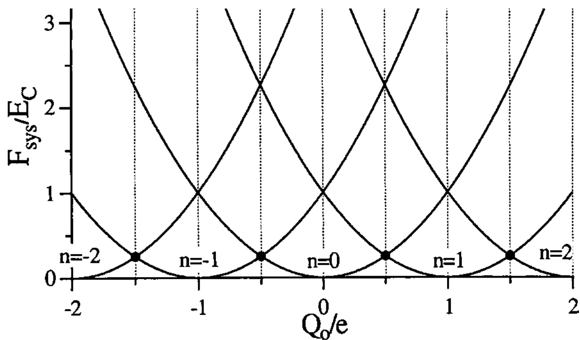

Figure 4. System free energy as a function of Q_o/e for various numbers n of excess electrons at $V = 0$. For fixed n, changing Q_o moves along the appropriate parabola.

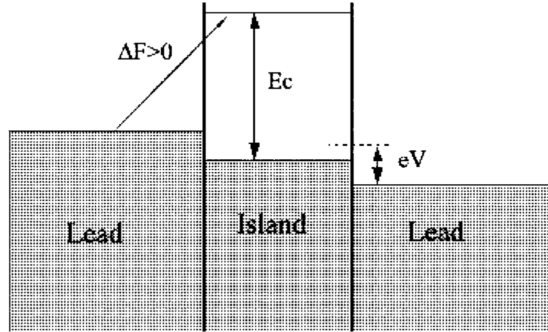

Figure 5. Energy diagram of an NNN SET with symmetric junction capacitances. The Coulomb blockade exists when the tunneling process is energetically unfavorable below the threshold voltage e/C_Σ.

The first term is conventionally called the charging energy, with an effective island charge of $Q_o - ne$. The second term represents the total work done by the voltage sources. Because the effective charge of the island influences the strength of the charging energy barrier, the gate voltage can be used to tune this barrier, and therefore modulate the current through the device. Since n must be an integer, the minimum energy for given Q_o is obtained if n is the integer closest to Q_o/e. That implies that the n giving the lowest charging energy must lie in the range

$$\frac{Q_o}{e} - \frac{1}{2} \leq n \leq \frac{Q_o}{e} + \frac{1}{2} \tag{28}$$

In Figure 4, the system energy is plotted as a series of parabolas for $V = 0$. Each curve corresponds to a different number of n excess electrons on the island. As the gate voltage varies, that is, changing the gate charge Q_o, the system favorable energy level can be changed. The parabolas for n and $n \pm 1$ cross at $Q_o = (n \pm \frac{1}{2})e$ at energy $E_c/4$. At each crossing point, one electron tunnels onto or off the island, changing the number of excess electrons on the island from n to $n \pm 1$. Because the system energy is periodic in Q_o, the current is also periodic in Q_o with period e, and with current peaks occurring at half-integer values of Q_o/e. In other words, in one modulation period of the current, that is, the gate voltage increases by $\pm e/C_g$, a single electron is added or removed from the island. The current through this device is a function of both the bias voltage V and the gate voltage V_g, exhibiting transistor action. Thus, varying the gate voltage can manipulate the tunneling of electrons one by one. Therefore, this system is given the name single-electron transistor.

1.2.4. Energy Diagrams for Single-Electron Tunneling

It is useful to draw simple energy diagrams to illustrate how the Coulomb blockade arises, and how it can be tuned away. Figures 5–7 show the energy diagram for tunneling in a normal metal SET (NNN system) with symmetric junctions, that is, $C_1 = C_2$. The energy that can be supplied by the bias sources is represented by shifting the Fermi level of one of the leads with respect to the other by an amount eV. The change in the charging energy due to tunneling is represented by the distance between the Fermi level in the island and the solid line above it. This solid line represents the position of the Fermi level after the tunneling event.

Consider symmetrically biased junctions at $V_g = 0$; in order to overcome the Coulomb blockade, the bias voltage has to exceed a threshold value at which $\Delta F_{n \to n+1} = 0$. This yields

$$eV \geq (2n+1)\frac{e^2}{C_\Sigma} = 2(2n+1)E_C \tag{29}$$

Figure 5 shows the case for $n = 0$; tunneling from the left lead onto the island increases the charging energy by E_c. For $V < e/C_\Sigma$, this tunneling process is energetically unfavorable ($\Delta F > 0$), and occurs with an exponentially suppressed rate for $T \ll E_c$, so very little current will flow through the system, and thus tunneling is blocked. On the other hand, for $V > e/C_\Sigma$, the bias source provides enough energy to overcome the charging energy barrier, and the Coulomb blockade is overcome and current flows through the system, as shown in Figure 6.

Figure 7 shows that, when $Q_o = e/2$, the Coulomb blockade is completely tuned away, and current will flow through the system for any nonzero bias voltage. The I–V characteristic for $Q_o = 0$ and $Q_o = e/2$ is shown in Figure 8 for two junctions of equal tunnel resistances.

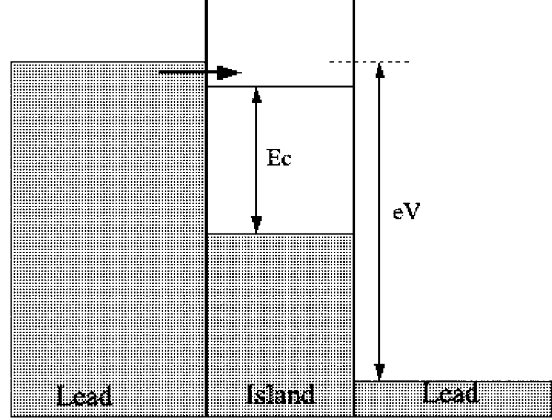

Figure 6. When $V > e/C_\Sigma$, that is, bias voltage sources provide enough energy to overcome the Coulomb barrier, single-electron tunneling occurs.

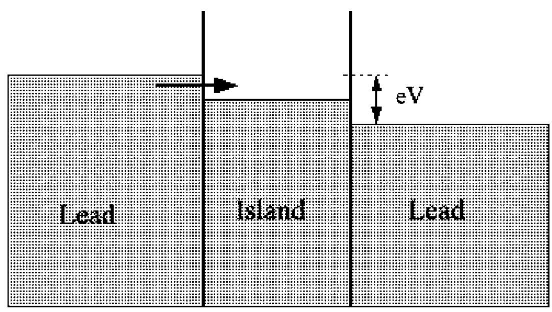

Figure 7. At $Q_o = e/2$, the Coulomb blockade is lifted at infinetesimal voltages as the charging energy barrier diminishes.

Considering electron tunneling across junctions 1 and 2, respectively, one can calculate the energy changes in the transition from the n to $n \pm 1$ state [15]:

$$\Delta E_1^{\pm} = \frac{e^2}{C_\Sigma}\left\{\left[\frac{1}{2} \pm \left(n - \frac{Q_o}{e}\right)\right] \mp \frac{(C_2 + C_g/2)V}{e}\right\} \quad (30)$$

$$\Delta E_2^{\pm} = \frac{e^2}{C_\Sigma}\left\{\left[\frac{1}{2} \pm \left(n - \frac{Q_o}{e}\right)\right] \pm \frac{(C_1 + C_g/2)V}{e}\right\} \quad (31)$$

For a transition to occur at $T = 0$, it is necessary that the relevant energy change ΔE is negative. For net current through the device, both tunneling on across one junction (charging step) and then off across the other (discharging step) must be allowed. The sum of the two ΔE values for a through passage of charge is always exactly eV, so that the energy would always be lowered by $e|V|$. The essence of the Coulomb blockade is that the energy must be lowered on each of the two successive transitions of charging and discharging the island. Actually, as long as the first step becomes energetically favorable, the second step will always become favorable. For the case when an electron tunnels off from the island to the right electrode first, followed by an electron from the left onto the island, it is the same as considering a hole which tunnels from the right electrode onto the island, then off to the left electrode.

From ΔE_1^+ and ΔE_2^-, one can determine the voltage thresholds for the charging step across junction 1 and for the discharging step across junction 2. ΔE_1^+ for the charging step becomes negative for positive bias voltage above the threshold $V_{1,\text{th}}^+$, and ΔE_2^- becomes negative for positive bias voltage above $V_{2,\text{th}}^-$ [15]. The extent of the Coulomb blockade is determined by whichever is the lesser of the two thresholds:

$$V_{1,\text{th}}^+ = \frac{e}{C_2 + C_g/2}\left[\frac{1}{2} + \left(n - \frac{Q_o}{e}\right)\right] \quad (32)$$

$$V_{2,\text{th}}^- = \frac{e}{C_1 + C_g/2}\left[\frac{1}{2} - \left(n - \frac{Q_o}{e}\right)\right] \quad (33)$$

Therefore, the Coulomb blockade can be overcome by a combination of the tunnel voltage V and gate voltage V_g. In the case of symmetric junctions (i.e., $C_1 = C_2$), tunneling is blocked when the following condition is fulfilled:

$$C_\Sigma |V|/e < (2n + 1) - 2C_g|V_g|/e \quad (34)$$

For $n = 0$, one sees that the Coulomb blockade occurs for the area within the diamond of Figure 9. If the junctions are asymmetric, then the diamond shape will be skewed. From the slopes, the capacitance of each junction can be extracted.

1.2.5. Current Through the Single-Electron Transistor

This section will describe how one can calculate the tunneling current through an SET in which the leads and the island are normal metals. Let us first assume that the electrons cannot tunnel across both junctions simultaneously. This process is referred to as cotunneling, which will be discussed in the next section. One can calculate the ΔF associated with transitions from charge state n to charge state n' using Eq. (27). Once ΔF are known, all tunneling rates can be calculated using Eq. (16).

Let us define a steady-state probability $\sigma(n)$ to be the ensemble distribution of the number of electrons on the island. $\sigma(n)$ can be viewed as the classical analog of the diagonal elements of the quantum-mechanical density matrix. Assuming no charge accumulation on the island at steady state, one can determine $\sigma(n)$ by requiring the total probability of tunneling into a state to be equal to the total probability of tunneling out of it.

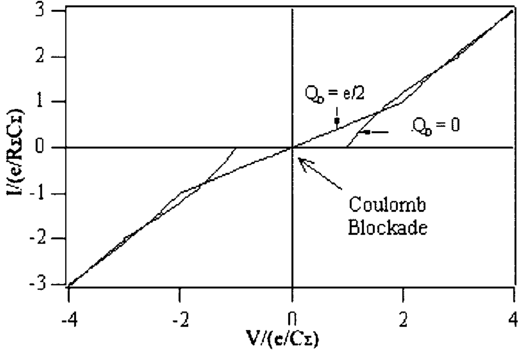

Figure 8. The current through a normal metal SET with identical junctions, calculated as a function of gate-induced charge for the cases of $Q_o = 0$ and $Q_o = e/2$ ($T = 0$).

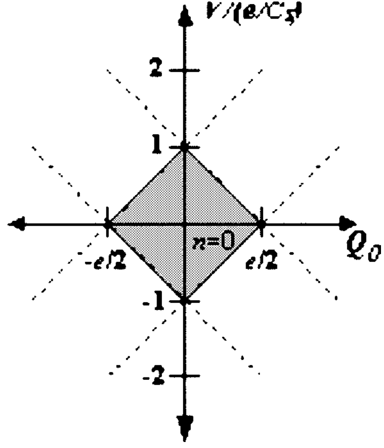

Figure 9. V–Q_o diagram illustrating Coulomb blockade for $n = 0$ state (shaded area).

The master equation to determine $\sigma(n)$ is [10–12]

$$\sum_n \sigma(n)\Gamma(n \rightarrow n') = \sum_{n'} \sigma(n')\Gamma(n' \rightarrow n) \tag{35}$$

Here, $\Gamma(n \rightarrow n')$ includes both the rates $\Gamma_1(n \rightarrow n')$ and $\Gamma_2(n \rightarrow n')$ for going from state n to state n' by tunneling through either junction, and the summation runs over all possible island charges. In the case of normal metals, only adjacent n states are connected via tunneling, and the distribution satisfies detailed balance:

$$\sigma(n)\Gamma(n \rightarrow n+1) = \sigma(n+1)\Gamma(n+1 \rightarrow n) \tag{36}$$

Thus, $\sigma(n)$ can be solved subject to the normalization condition $\sum_n \sigma(n) = 1$. When either the lead or the island is superconducting, the current mechanism changes to two-electron tunneling at low bias voltages, that is, from n to $n \pm 2$. In these cases, the full matrix equation of (35) must be solved.

From the determination of the island charge distribution function $\sigma(n)$, one can calculate the steady-state current through the transistor by considering transitions across a single junction for any possible island charge. For normal metals, taking account of the forward and reverse tunneling across each junction, the net current can be written as

$$I(V) = -e\sum_n \sigma(n)[\Gamma_1(n \rightarrow n+1) - \Gamma_1(n \rightarrow n-1)] \tag{37}$$

$$= -e\sum_n \sigma(n)[\Gamma_2(n \rightarrow n-1) - \Gamma_2(n \rightarrow n+1)] \tag{38}$$

Since there is no charge accumulation on the island in the steady state, the currents in the two junctions are equal. The finite probablity of occupying higher energy n states for voltages above threshold results in a nonlinear I–V curve called the "Coulomb staircase," which is most pronounced in the case of asymmetric junction resistance. This overall approach to calculate the current is referred to as the Orthodox theory of single-electron tunneling [10–12].

1.2.6. Cotunneling in the Single-Electron Transistor

Consider a Coulomb blockade region, where the sequential tunneling of an electron from the left electrode to the island is energetically unfavorable ($\Delta F > 0$), and thus forbidden, even in the presence of a finite bias voltage. Therefore, from what has been previously discussed, it is impossible to transport an electron from the left to the right electrode by sequential single-electron tunneling across the junctions. However, the cotunneling or macroscopic quantum tunneling processes make the transport possible. There are two types of cotunneling processes: [16, 17] (1) an inelastic process, in which two different electron states are involved, and there is an electron–hole excitation left on the island; and (2) an elastic process, in which the same electron state is involved in both tunneling processes, and there is no excitation left over.

Figure 10 illustrates the inelastic cotunneling process. The energy–time uncertainty relation of quantum mechanics results in the quantum fluctuation of electric charge on the island within a short period of time associated with the tunneling event. This implies that, when one electron tunnels onto the island and a second electron tunnels off the island within the time $\hbar/E_c$, the net result is that an electron has tunneled through the whole system. This process involves electrons tunneling simultaneously (here, "simultaneous" is used to distinguish cotunneling from sequential tunneling, in which two tunneling events are separated by a time interval great than $\hbar/E_c$) through the two junctions via a virtual intermediate state with increased electrostatic energy, and leaving an electron–hole excitation on the island [16]. This inelastic cotunneling process transfers the electrostatic energy of the system into the energy of the electron–hole excitations. Since the process is of the second order, the rate of the cotunneling is small compared to the rate of the sequential tunneling, but nevertheless, this process is dominant in the Coulomb blockade regime, where the sequential tunneling is suppressed.

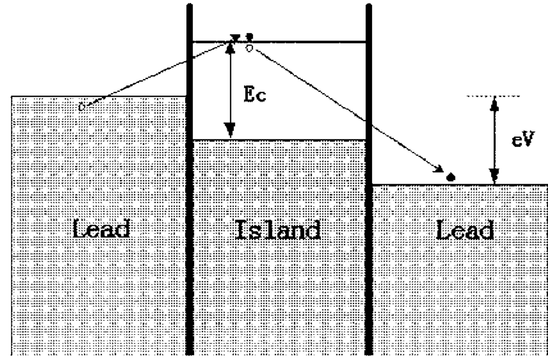

Figure 10. Schematic of the inelastic cotunneling process. Although single-electron tunneling is blocked, charge can be still transported through the system by simultaneous tunneling of electrons across both junctions.

The rate for inelastic cotunneling can be calculated by applying Fermi's golden rule for the higher order transitions. At low temperatures, the current due to this process is [17]

$$I_{\text{elastic}} = \frac{\hbar}{12\pi e^2 R_1 R_2}\left(\frac{1}{\Delta E_1} + \frac{1}{\Delta E_2}\right)^2 \times \left[(eV)^2 + (2\pi k_B T)^2\right]V \tag{39}$$

where ΔE_1 and ΔE_2 are the energy changes associated with the sequential tunneling in the first and second junctions as given by Eqs. (30) and (31). Here, $\Delta E_1, \Delta E_2 \gg eV$. The current varies as the third power of the voltage V, and it causes rounding in the I–V curve right near the voltage onset of the single-electron tunneling.

Cotunneling is elastic if the same electron state is involved in both tunneling processes, and the coherence of the tunneling electron is maintained in the tunneling event. Elastic cotunneling can also be viewed as a process in which an electron tunnels onto the island, virtually diffuses through it, and tunnels off across the opposite junction [18].

Inelastic cotunneling is an important charge-transport mechanism in the SET. It was first observed experimentally by Geerligs et al [19] in a lithographically patterned SET. In contrast, elastic cotunneling has only been observed

in tunneling through extremely small metal particles (~1–10 nm) in a double-junction system using a scanning tunneling microscope. Elastic cotunneling occurs with a negligible rate in lithographically patterned SETs because it takes an electron much longer than $\hbar/E_c$ to virtually diffuse from one junction to the other.

2. SUPERCONDUCTING SINGLE-ELECTRON TRANSISTOR

2.1. Subgap Charge-Transport Mechanism in an NSN System

Let us first consider the charge-transport mechanisms in an SET with normal metal leads and a superconducting (Al) island (NSN system). Charge transport at low temperatures and at low bias voltages in the NSN system occurs by two sequential Andreev steps, which is refered to as the Andreev cycle. (Andreev considered a normal metal and a superconductor in good metallic contact. But his physical picture can be generalized to tunnel junctions.) The first is the charging step, in which one electron incident on junction 1 is Andreev reflected into a hole on the same side of the junction. It can be regarded as an event in which two electrons tunnel onto the island to form a Cooper pair [20, 21]. The second is the discharging step, in which a hole incident on junction 2 is Andreev reflected into an electron. This can be regarded as an event in which a Cooper pair breaks up and forms two electrons tunneling off the island, and the island returns to the original state. The two steps of the Andreev cycle are analogous to the sequential single-electron tunneling, except that two electrons now tunnel in each step. Andreev reflection is subject to the same energetic considerations as is single-electron tunneling in the NNN system. Thus, it also exhibits a Coulomb blockade.

To calculate the Andreev reflection rate, Hekking et al. [21] model each step of the Andreev cycle as a second-order process, and break it down as follows. In the first transition of step 1 (step 2), an electron (hole) tunnels onto the island, and takes the system from the initial state to an intermediate state in which a virtual quasiparticle exists on the island. In the second transition, another electron (hole) tunnels onto the island through the same junction to a state paired with the existing quasiparticles. This leads to immediate recombination, and returns the system to the BCS ground state. By summing over appropriate initital, intermediate, and final states, the Andreev reflection rate across junction i is

$$\Gamma^{i}_{\text{Andreev}}(\Delta E_i) = \frac{G^{i}_{\text{Andreev}}}{e^2} \frac{\Delta E_i}{e^{\beta \Delta E_i} - 1} \tag{40}$$

where ΔE_i corresponds to the energy change in transfering both electrons and G^{i}_{Andreev} is the Andreev conductance of junction i. Note that this rate equation is analogous to that of single-electron tunneling in an NNN SET [refer to Eq. (16)], except that the Andreev conductance of the junction appears in place of the normal tunnel conductance of that junction. Unlike the normal conductance, however, the Andreev conductance depends on the specific geometry and the electronic mean free path in the leads [22–24]. Since Andreev reflection is a second-order process and the junctions are tunnel barriers with very low transparency, the Andreev conductances are expected to be much smaller than the normal tunnel conductance. A first-order estimate, which is based on ballistic electron motion near the junctions and ignores the effects of phase coherence between the tunneling electrons [21], gives Andreev conductances on the order $5 \times 10^{-12}\ \Omega^{-1}$, which are indeed much smaller than $1/R_{\Sigma}$. However, the experimentally determined Andreev conductances are approximately 10^3 times larger than this value. Since the elastic mean-free path in the leads is much smaller than the junction dimension, the ballistic picture assumed is not applicable, and one must consider directly the effects of phase coherence [25]. The magnitude of enhancement of the Andreev conductance by phase coherence is expected to depend on the precise geometry near the tunnel junctions, as well as the location of impurities and other scattering sites.

2.2. Subgap Charge-Transport Mechanisms in an SSS System

Figure 11 shows experimental data at low temperature and zero magnetic field for a sample when both the island and the leads are in the superconducting state (SSS system) [26]. In this figure, the current is measured while slowly sweeping V and quickly sweeping V_g, forming the envelope of all possible $I(V, V_g)$ curves. The upper graph in Figure 11 shows a sharp rise at 960 mV. Since this is an SSS system, this rise should occur at $V = 4\Delta/e$, which yields superconducting gap $\Delta = 240$ meV. The current peaks appearing at approximately 660 mV arise from a "$2e$–e–e" Josephson-quasiparticle (JQP) cycle in which the tunneling of a Cooper

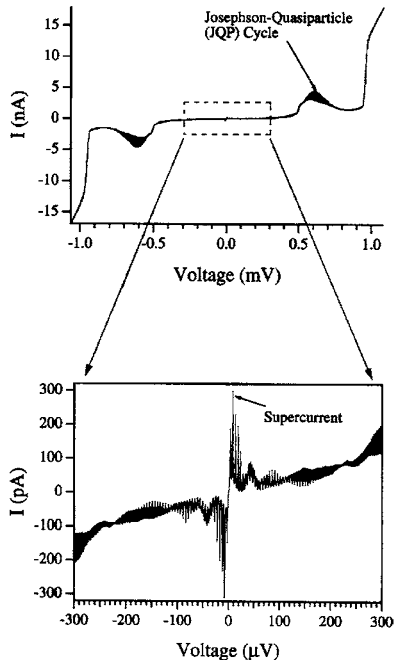

Figure 11. $I(V, V_g)$ data for an all superconducting SET. The upper graph shows the JQP peaks, and the lower graph shows the supercurrent peak which depends strongly on the value of Q_o.

pair in one junction is followed by two sequential quasiparticle tunneling events across the other junction [27–29]. Here, let us focus on the behavior of the system around zero bias voltages, shown enlarged in the lower graph of Figure 11.

In the SSS system, another energy scale, the Josephson coupling energy E_j, becomes important in addition to E_c and Δ. There are three distinguishable regimes [15]. If $E_c \ll E_j$, the charging energy effects are small, and the system has essentially the classical Josephson effect. If $E_c \gg \Delta$, single-electron charging energies dominate, observed phenomena show e periodicity, and Cooper-pair tunneling is unimportant. The most interesting regime is $E_c < E_j < \Delta$, in which there exists a supercurrent that is modulated by the gate charge Q_o with period $2e$.

If one considers junctions in which $R_\Sigma \gg R_Q$, then $E_j \approx (R_Q/R_\Sigma)\Delta \ll \Delta$, so there is a considerable range of E_c for which the two inequalities hold. The fact that Δ is larger than all other energies allows us to restrict our attention (at $T = 0$) to states of the island containing only an even number of electrons, which form Cooper pairs. At zero bias voltage, one can express the total energy of the system by the Hamiltonian [15]

$$H = \frac{(-en + Q_o)^2}{2C_\Sigma} - E_{j1}\cos\varphi_1 - E_{j2}\cos\varphi_2 \tag{41}$$

where n is the number of electrons, E_{j1} and E_{j2} are the Josephson coupling energies of the two junctions which couple the island to the superconducting leads, and φ_1 and φ_2 are the phase differences across each junction. A high conductance of the voltage source makes the phase sum $\vartheta = \varphi_1 + \varphi_2$ behave as a classical variable. On the contrary, the factor $\varphi = (\varphi_1 - \varphi_2)/2$ measuring the departure of the phase on the island from the midpoint between the phases of the two leads can behave as a quantum variable [10].

If one uses ϑ and φ to eliminate φ_1 and φ_2 in Eq. (41), and to simplify with trigonometric identities, one can reduce this equation to [15]

$$H = \frac{(-en + Q_o)^2}{2C_\Sigma} - E_j(\vartheta)\cos(\varphi - \chi) \tag{42}$$

where the parameters

$$E_j(\vartheta) = \sqrt{E_{j1}^2 + E_{j2}^2 + 2E_{j1}E_{j2}\cos\vartheta} \tag{43}$$

and

$$\chi = \arctan\left[\frac{E_{j1} - E_{j2}}{E_{j1} + E_{j2}}\tan\frac{\vartheta}{2}\right] \tag{44}$$

are determined by the fixed values of E_{j1}, E_{j2}, and ϑ. Since the eigenvalues of Eq. (42) do not depend on the reference phase χ, one can suppress it in the following equation, and rewrite it as

$$H = \frac{(-en + Q_o)^2}{2C_\Sigma} - E_j(\vartheta)\,\cos(\varphi) \tag{45}$$

This expression is then the same as the Hamiltonian of a single junction.

In the case when C_Σ is so large that the charging energy term in Eq. (45) can be neglected, the ground state has $\varphi = 0$, so that the supercurrent can be calculated [15]:

$$I_s = -\frac{2e}{\hbar}\frac{\partial E_j}{\partial\vartheta} = \frac{2e}{\hbar}\frac{E_{j1}E_{j2}\sin\vartheta}{E_j} \tag{46}$$

For identical junctions, that is, $E_{j1} = E_{j2} = E_i$, Eq. (46) reduces to

$$I_s = \frac{2e}{\hbar}E_i\sin\frac{\vartheta}{2} \tag{47}$$

which agrees with the classical result for two identical Josephson junctions in series, splitting equally the total phase difference ϑ.

In the other limit, $E_c > E_j$, in which the charging energy term is dominant, it has been shown [8] that the supercurrent at the degeneracy points between even-n states (i.e., at odd-integer values of Q_o/e) is

$$I_s = \frac{2e}{\hbar}\frac{E_{j1}E_{j2}\sin\vartheta}{2E_j} \tag{48}$$

This is exactly half of the value found in Eq. (46) for the classical case in which E_c is negligible [15]. And for midway between the degeneracy points, the supercurrent decreases to a minimum value of

$$I_s = \frac{2e}{\hbar}\frac{E_{j1}E_{j2}\sin\vartheta}{4E_c} \tag{49}$$

In summary, the Josephson current varies periodically with the gate charge. At odd-integer values of Q_o/e, it reaches a maximum value given by Eq. (48), comparable to the classical values for the supercurrent in individual junctions. And in between the degeneracy points, the current is depressed by a factor on the order of $E_j/E_c \ll 1$. It should be noted that thermal and quantum fluctuations can result in phase diffusion, characterized by a finite resistance of the supercurrent. As a result, it leads to a switching current lower than the nominal critical current.

2.3. Parity Effects in a Superconducting Island

One knows that thermodynamic properties of small systems depend on the parity of the number of particles N in the system. The best known example of such a dependence is provided by atomic nuclei, where the binding energy of nuclei with an even number of protons and neutrons is systematically larger than the binding energy of nuclei with an odd number of nucleons [30]. A similar phenomenon is expected to occur in small metallic clusters and tubes. Because of the spin degeneracy of the single particle states, the properties of clusters and tubes with even and odd numbers of electrons are quite different [31–33].

In both of these examples, however, the even–odd asymmetry, specifically the ground state energy difference, decreases with an increasing number of particles and vanishes in the thermodynamic limit. It has been found [34, 35] that superconductivity amplifies the parity effect in such a

way that it takes place even in a superconducting island with a macroscopically large number (10^9) of conduction electrons. Before the experiments described in this section were performed, it was widely believed that the strength of even–odd effects in superconductors would be suppressed as $1/N$. Thus, it was generally agreed that a superconductor with $N \gg 1$ would not exhibit parity effects in its macroscopic properties. However, the strength of the parity effect at very low temperatures is not governed by $1/N$, but rather, is in principle independent of N. Its strength is directly related to the difference between the number of quasiparticle excitations in the island when N is even and when is N odd. Since this difference is in principle equal to 1 at $T = 0$ regardless of the size of the system, at very low temperatures, the parity effect should not weaken as the system is made larger.

2.4. Experimental Observation of the Parity Effect

This section will show the temperature dependence of the parity effect in an NSN SET system. When the bias voltage V is close to zero, the system free energy is simply the electrostatic energy

$$U = \frac{(-en + Q_o)^2}{2C_\Sigma} \tag{50}$$

which depends on n, the number of excess electrons on the island. As V_g is swept, n changes by unity every time Q_o passes through a half-integer value. This leads to a variation of the populations, and hence the current $I(V_g)$ at fixed bias V is e-periodic with peaks at half-integer values of Q_o/e, corresponding to single-electron tunneling.

When the island is superconducting, it was found that the I–Q_o curve taken under similar conditions becomes $2e$-periodic. Figure 12 shows a series of I–Q_o curves for an NSN sample (with $T_c \approx 1.5$ K) at different temperatures and zero magnetic field [36]. At the lowest temperatures, the curves are strongly $2e$-periodic, with two-electron tunneling (Andreev peaks) occurring at odd-integer values of Q_o/e. This $2e$ periodicity indicates that the number of electrons on the island changes by two as Q_o is swept through one current peak. This in turn suggests that the island prefers to have a total number of conduction electrons of a certain parity. As the temperature rises, the Andreev peaks decrease in size, and gradually, each Andreev peak splits apart into a subtle double maximum. The two maxima eventually move farther apart in Q_o, and develop into well-separated peaks, with the current slightly higher at odd-integer values of Q_o/e than at even-integer values. Finally, the current becomes completely e-periodic with equal peaks at all half-integer values of Q_o/e, and the magnitude of the current modulation grows with a further increase in the temperature. From observation, these I–Q_o curves in Figure 12 are $2e$-periodic at temperatures up to and including 275 mK. The dashed line on the I–Q_o curve at 275 mK is drawn to assist viewing the existence of $2e$ periodicity. At 285 mK and above, only e periodicity can be distinguished in these curves. Thus, the crossover temperature from $2e$ to e periodicity can be estimated, $T^* \approx 285$ mK, which is surprisingly only about one fifth of the critical temperature T_c of the sample.

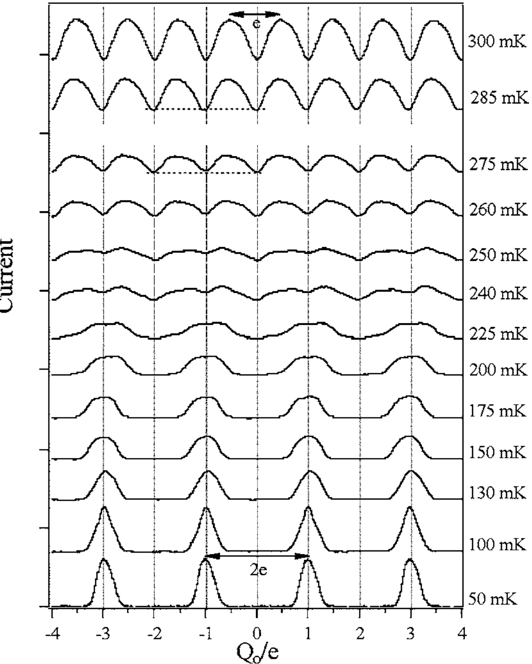

Figure 12. Experimental I–Q_o curves for an NSN sample at a small bias voltage ($V = 125$ μV) with temperatures ranging from 50 to 300 mK. The curves are displaced upward successively for clarity. The current axis is 1 pA per division. At low temperatures, the curves are strongly $2e$-periodic. As the temperature is gradually increased, the curves evolve until they become completely e-periodic above a crossover temperature T^* ($\approx$285 mK for this sample).

2.5. Equilibrium Model

To thoroughly understand the parity effect, it is necessary to make a kinetic calculation [37, 38], solving a master equation to find the self-consistent steady-state nonequilibrium populations of all relevant states, and the resulting current as a function of the bias voltage and the gate voltage. However, in the limit of low bias voltage, state populations will be near the $V = 0$ equilibrium values. At sufficiently low bias voltages, it is expected that the current through the device is proportional to V with a coefficient which is a function of V_g and T, dependent on the equilibrium populations. Thus, the period (e or $2e$) of the current will be determined by the period with which the populations vary with V_g. Therefore, one can simply use the periodicity of the equilibrium populations as a proxy for the periodicity of the current at low bias voltages. The simple approach is very useful, even if it is limited to finding the period of $I(V_g)$, without finding the exact magnitude and waveform.

The equilibrium model explains the origin of the parity effect and the temperature T^* at which it disappears. The basic idea of this model is that, since the BCS ground state of a superconductor consists of a coherent superposition of Cooper pairs, there is necessarily exactly one unpaired electron which appears as a quasiparticle excitation if the number of conduction electrons N is odd. The minimum energy of this excitation at $T = 0$ is given by the superconducting energy gap Δ. Thus, the ground-state energy of the system is higher by an amount Δ when N is odd (one quasiparticle excitation) compared to when N is even (all electrons

are paired). As a result, the states of even N become energetically favorable over those of odd N, giving rise to the even–odd parity effect. Averin and Nazarov [34] introduced to the system free energy an explicitly additive energy term, which has the value Δ in odd-N states and zero in even-N states.

The energy arguments of Averin and Nazarov apply only for the case of $T = 0$ and $H = 0$. At finite temperatures, a number of states become available for quasiparticle excitation. This gives entropy contributions which diminish the free energy difference between the even and odd states. On the other hand, for nonzero magnetic fields, the reduction of the minimum quasiparticle excitation energy also yields a smaller energy difference. Thus, one can generalize the model of Averin and Nazarov by defining a parity (or even–odd)-dependent free energy difference $F_0(T, H)$. The system free energy for $V = 0$ is thus expressed as

$$F_{\text{sys}} = \frac{(-en + Q_o)^2}{2C_\Sigma} + p_n F_0(T, H) \tag{51}$$

with

$$p_n = \begin{cases} 0, & \text{if } n \text{ is even} \\ 1, & \text{if } n \text{ is odd.} \end{cases} \tag{52}$$

2.5.1. Even–Odd Free Energy Difference

The even–odd free energy difference F_0 is calculated using equilibrium statistical mechanics. The grand canonical partition function Z for quasiparticle excitations on the superconducting island is [39]

$$Z = \prod_k (1 + e^{-\beta\xi_k}) \tag{53}$$

where ξ_k is the energy of a quasiparticle excitation in state k relative to the Fermi energy. In zero magnetic field,

$$\xi_k = \sqrt{\varepsilon_k^2 + \Delta^2} \tag{54}$$

where ε_k is the individual electron energy in the normal state relative to the Fermi energy. The grand canonical partition function can be separated algebraically into terms corresponding to an even or an odd number of quasiparticle excitations:

$$\begin{aligned} Z &= \left(1 + \frac{1}{2!}\sum_k \sum_{l\neq k} e^{-\beta\xi_k} e^{-\beta\xi_l} \ldots\right) \\ &\quad + \left(\sum_k e^{-\beta\xi_k} + \frac{1}{3!}\sum_k \sum_{l\neq k} \sum_{m\neq k,l} e^{-\beta\xi_k} e^{-\beta\xi_l} e^{-\beta\xi_m}\right) \\ &= Z_{\text{even}} + Z_{\text{odd}} \end{aligned} \tag{55}$$

If the number of electrons on the island is fixed, only Z_{even} or Z_{odd} is used since quasiparticle excitations can only be created two at a time. Only the tunneling of a quasiparticle from the leads onto the island can change the parity. The even–odd free energy difference is then defined as the difference in free energy calculated for the two parity cases:

$$F_0 = k_B T \ln\left(\frac{Z_{\text{even}}}{Z_{\text{odd}}}\right) \tag{56}$$

2.5.2. Low-Temperature Approximation of $F_0(T)$

At low temperatures, there are rarely any thermally excited quasiparticles. Consequently, the first term of Z_{even} and the first term of Z_{odd} dominate, yielding [39]

$$F_0 \approx -k_B T \ln\left[\sum_k e^{-\beta\xi_k}\right] \tag{57}$$

Making the continuum approximation and using the quasiparticle density of states $\rho_s(\xi)$ which includes the spin degeneracy, one gets

$$F_0 \approx -k_B T \ln\left[2V_I \int_0^\infty \rho_s(\xi) e^{-\beta\xi} d\xi\right] \tag{58}$$

V_I is the volume of the superconducting island, and the factor of 2 on the right-hand side is needed to count quasiparticles with $|k| < k_F$ and $|k| > k_F$. It is expected that $F_0(T = 0, H) = \Omega_G(H)$ since, at zero temperature, the remaining quasiparticle will reside at the minimum excitation energy, that is, the spectroscopic gap $\Omega_G(H)$, which is a decreasing function of the magnetic field. Thus, it is useful to rewrite Eq. (58) as

$$\begin{aligned} F_0 &\approx -k_B T \ln\left[e^{-\beta\Omega_G} 2V_I \int_{\Omega_G}^\infty \rho_s(\xi) e^{-\beta(\xi-\Omega_G)} d\xi\right] \\ &= \Omega_G - k_B T \ln(N_{\text{eff}}) \end{aligned} \tag{59}$$

with

$$N_{\text{eff}} = 2V_I \int_{\Omega_G}^\infty \rho_s(\xi) e^{-\beta(\xi-\Omega_G)}\, d\xi \tag{60}$$

Here, N_{eff} is the number of statistically significant states available for quasiparticle excitation. It roughly equals the number of quasiparticle states within $k_B T$ of the superconducting gap edge. The corresponding entropy is $k_B \ln(N_{\text{eff}})$. Note that the average number of thermally excited quasiparticles in the superconducting island is given by

$$\langle N_{qp}(T)\rangle = 2V_I \int_0^\infty \rho_s(\xi) f(\xi, T)\, d\xi \tag{61}$$

where $f(\xi, T)$ is the Fermi distribution function. For $k_B T \ll \Omega_G$, one can show that

$$\langle N_{qp}(T)\rangle \approx 2V_I \int_{\Omega_G}^\infty \rho_s(\xi) e^{-\beta\xi}\, d\xi = N_{\text{eff}} e^{-\beta\Omega_G} \tag{62}$$

In the low-temperature approximation, Eq. (59) shows that F_0 falls nearly linearly with temperature, becoming zero at a temperature determined by the criterion

$$T^* = \frac{\Omega_G}{k_B \ln(N_{\text{eff}}(T_0))} \tag{63}$$

This can be regarded as a first-order approximation of the $2e$ to e periodicity crossover temperature. The temperature dependence of N_{eff} only contributes weakly because it appears within a logarithm.

2.5.3. Crossover Temperature in Zero Magnetic Field

For zero magnetic field and low tempeartures, one can ignore the temperature dependence in Δ, and set $\Omega_G = \Delta$, so it is appropriate to use the BCS form of the superconducting density of states:

$$\rho_s(\xi) = \begin{cases} 0, & \text{for } \xi < \Delta \\ \rho_n(0)\frac{\xi}{\sqrt{\xi^2-\Delta^2}} & \text{for } \xi > \Delta \end{cases} \tag{64}$$

where $\rho_n(0)$ is the normal density of states in the island per unit energy and per unit volume (including spin). Substituting these zero-field expressions into the low-temperature approximations of Eqs. (59) and (60) gives

$$F_0 \approx \Delta - k_B T \ln(N_{\text{eff}}) \tag{65}$$

$$N_{\text{eff}} \approx V_I \rho_n(0)\sqrt{2\pi\Delta k_B T} \times \left[1 + \frac{3}{8}\frac{k_B T}{\Delta} + O\left(\frac{k_B T}{\Delta}\right)^2\right] \tag{66}$$

As an example, for the NSN sample (whose $I - Q_o$ curves are shown in Fig. 12) with $\Delta \approx 240\ \mu$eV, $E_c \approx 100\ \mu$eV, and island volume $V_I \approx 3.2 \times 10^{-15}$ cm^3, one can estimate N_{eff} to be approximately 10^4. Using the BCS value of $\Delta = 1.76 k_B T_c$, the first-order estimate of the $2e$ to e periodicity crossover temperature is

$$T^*(H = 0) = \frac{\Delta}{k_B T \ln(N_{\text{eff}})} \approx T_c/5 \tag{67}$$

which is in good agreement with the experimental data which gives the crossover temperature to be around 285 mK.

In summary, the nonzero F_0 results in a system free energy which is $2e$-periodic in Q_o. As the temperatures or magnetic fields increase, F_0 gradually decreases, causing a transition from $2e$ to e in the I–Q_o characteristics. To illustrate this point, Figure 13(a) shows the system free energy diagram of the NSN system at $T \approx 0$ and $T \geq T^*$. Physically, two distinct energies are competing with the thermal energy: the energy gap Δ opposes creation of quasiparticles, and the Coulomb energy E_c tries to make the electron number match the gate charge Q_o [36]. When $\Delta > E_c$, the ground state contains the even number of electrons closest to that specified by Q_o. The only accessible degeneracy points between even-n states occur at odd-integer values of Q_o/e. These degeneracy points are associated with the Andreev peaks as in Figure 13(b). As the temperature increases, F_0 decreases according to Eq. (65), and the odd-n states move downward in the system free energy diagram. Because the even–even crossing is the degeneracy point of the lowest energy, the Andreev peak maintains a single maximum as long as $F_o(T) > E_c$. When the temperature becomes T^*, the free energy difference between the even and odd states disappears, that is, $F_o(T^*) = 0$, as illustrated in Figure 13(c). At the degeneracy points where adjacent n states cross at half-integer values of Q_o/e, single-electron tunneling dominates, giving rise to the e-periodic I–Q_o curve as shown in Figure 13(d).

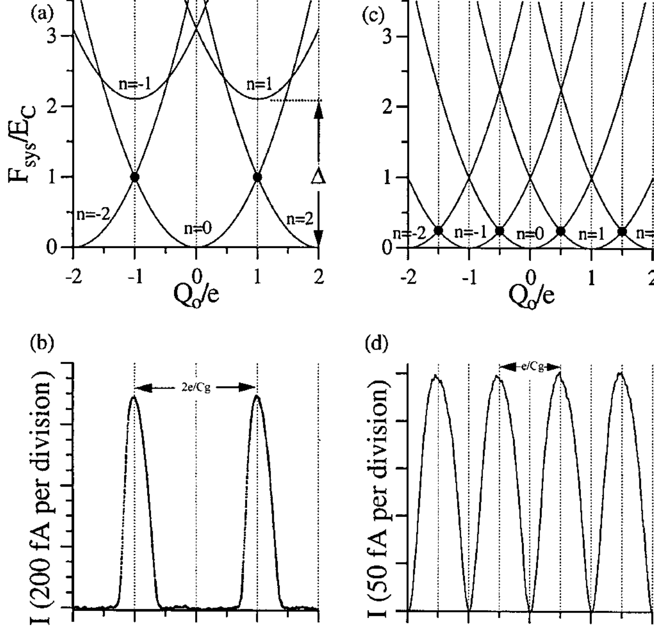

Figure 13. System free energy diagrams and corresponding I–Q_o curves measured at 125 μV for an NSN SET at $T = 50$ and 300 mK, respectively. (a),(b) For $T = 50$ mK, at the lowest lying degeneracy points where adjacent even-n states cross, two-electron tunneling occurs giving rise to the Andreev peaks that are $2e$-periodic in Q_o with peaks at odd-integer values of Q_o/e. (c),(d) For $T = 300$ mK $> T^*$, at the degeneracy points where adjacent n states cross, single-electron tunneling occurs giving rise to the current that is e-periodic with peaks at half-integer values of Q_o/e.

2.5.4. Calculation of a General Form of $F_0(T)$

For T near or above T^*, the presence of a thermally excited quasiparticle in the island becomes important. As a result, in order to accurately calculate the even–odd free energy difference in this temperature regime, one must consider higher order terms in Eq. (55). To simplify the calculation, let us model the quasi-continuum of excited states above the superconducting gap by a single level at energy Ω_G with degeneracy N_{eff}; then the partition sums of Eq. (53) can be written as

$$Z = (1 + e^{-\beta\Omega_G})^{N_{\text{eff}}}. \tag{68}$$

Let us assume that the island is in weak tunneling contact with a particle reservoir at $V = 0$, so that the island can contain either an even or odd number of electrons. By constructing forms in which either the even or odd terms cancel, one can then write partial partition sums as [36]

$$Z_{\text{even}} = \frac{[(1 + e^{-\beta\Omega_G})^{N_{\text{eff}}} + (1 - e^{-\beta\Omega_G})^{N_{\text{eff}}}]}{2} \tag{69}$$

and

$$Z_{\text{odd}} = \frac{[(1 + e^{-\beta\Omega_G})^{N_{\text{eff}}} - (1 - e^{-\beta\Omega_G})^{N_{\text{eff}}}]}{2} \tag{70}$$

At this point, it is helpful to make use of the approximation

$$\left(1+\frac{a}{b}\right)^{b} \approx e^{a} \tag{71}$$

which is valid for $b \gg 1$ and $|a| \ll b$. Applying this relation, for $e^{-\beta\Omega_G} \ll 1$ and $N_{\text{eff}} \gg 1$, one obtains

$$(1+e^{-\beta\Omega_G})^{N_{\text{eff}}} \approx e^{N_{\text{eff}}e^{-\beta\Omega_G}} \tag{72}$$

and

$$(1-e^{-\beta\Omega_G})^{N_{\text{eff}}} \approx e^{-N_{\text{eff}}e^{-\beta\Omega_G}} \tag{73}$$

One can thus write

$$Z_{\text{even}} \approx \cosh\left(N_{\text{eff}}e^{-\beta\Omega_G}\right) = \cosh(\langle N_{qp}\rangle) \tag{74}$$

$$Z_{\text{odd}} \approx \sinh\left(N_{\text{eff}}e^{-\beta\Omega_G}\right) = \sinh(\langle N_{qp}\rangle) \tag{75}$$

Substituting Z_{even} and Z_{odd} into Eq. (56), one finds that

$$\begin{aligned} F_0(T) &\approx k_B T \ln\left[\coth\left(N_{\text{eff}}e^{-\beta\Omega_G}\right)\right] \\ &= k_B T \ln[\coth\langle N_{qp}\rangle] \end{aligned} \tag{76}$$

which asymptotically approaches zero. Figure 14 plots the low-temperature approximation and the high-order form of $F_0(T)$ at zero magnetic field. The temperature dependence of N_{eff} gives the slight downward bending of $F_0(T)$ for temperatures below T^*.

Now, it is appropriate to describe the physical origin of the crossover temperature. According to T^* in Eq. (63), Eq. (62) at $T = T^*$ becomes

$$\langle N_{qp}(T^*)\rangle = N_{\text{eff}}(T^*)e^{-\Omega_G/k_B\left[\frac{\Omega_G}{k_B \ln(N_{\text{eff}}(T^*))}\right]} = 1 \tag{77}$$

Thus, in simple physical terms, the parity effect disappears at the temperature T^* (which is much less than T_c), at which there is on average one thermally excited quasiparticle in the entire island.

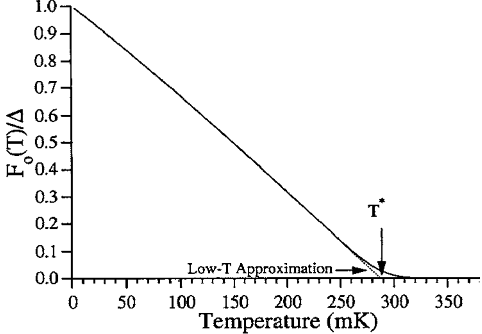

Figure 14. Temperature dependence of the even–odd free energy difference for the NSN sample ($T^* \approx 285$ mK). Dotted line shows the first-order approximation for low temperatures.

3. IMPLEMENTATION APPROACHES OF NANOSCALE OXIDE JUNCTIONS

SETs can be made using a wide variety of metals, semiconductors, or conducting polymers. This section will discuss the implementation of SETs using a lithographically fabricated ultranarrow thin film as an island in an $Al/Al_2O_3/Al$ three-layer process. Since aluminum is a superconductor, this device can be operated either in the superconducting state or in the normal state.

Typically, this kind of SET device is fabricated by electron-beam (e-beam) lithography, followed by a shadow evaporation technique. This fabrication technique was pioneered by Dolan [40]. The fabrication procedure consists of a series of steps. The first is to start with a polished Si wafer, which has a thin layer (~30 Å) of native oxide. The Si wafers are first coated by a bilayer resist, which is an e-beam-sensitive polymer. A scanning electron microscope (SEM) is used to write the device patterns on the wafer chips. Then they are developed so that the electron beam exposed areas are removed. After metal evaporation, the remaining resist gets removed in the liftoff step in acetone. In the following sections, we will take a closer look at the fabrication steps of resist film preparation, electron-beam writing, and metal evaporation.

3.1. Resist Film Preparation

In preparation for resist coating, the Si wafer is ultrasonically cleaned in trichloro-ethylene (TCE), followed by acetone and methanol. The wafer is then blown dry with compressed, dry N_2 gas, ensuring that no solution droplets remain. It is then placed on a spinner for resist coating.

E-beam resist is a polymer consisting of a long linear chain to which a number of side groups are attached. Often positive resist is used, which means that, when writing, the high-energy electrons break chemical bonds and sever the side groups of the resist. These side groups are easily removed, leaving behind a highly porous mass which the developer can infiltrate and dissolve.

The resist has two layers, a sensitive bottom layer and a less sensitive top layer. When coating each resist layer, a few drops of resist solution are applied to the wafer and spun to produce a thin and uniform film. The bottom resist layer consists of a copolymer of methyl methacrylate (MMA) and methacrylic acid (MAA), which has 8.5% by weight MAA. The top resist layer consists of a 1.5% by weight solution of 950K PMMA/MAA copolymer in chlorobenzene. As the electrons travel through the resist and reach the substrate, they backscatter into the resist, interacting with the resist molecules, and broadening the exposed area to form an undercut in the bottom layer. This undercut serves two important purposes. First, a good undercut profile helps to avoid tearing the deposited metal thin films in the liftoff phase of the fabrication. More importantly, sufficient undercut is required in order to create a suspended resist bridge (illustrated as RB in Fig. 17), enabling the formation of tunnel junctions by shadow evaporation. In the small gap between the lithographic lines of the island and the lead, the bottom resist layer is completely developed away, leaving only the top resist layer bridging the gap, forming the resist

bridge. Usually, the bottom layer should be at least three times as thick as the total thickness of the metal deposited. Figure 15 shows a schematic of the resist profile.

3.2. Electron-Beam Lithography—SET Patterning

E-beam lithography is a technique which takes advantage of the extremely small electron probe size in an SEM to create high-resolution patterns. The electron beam is finely focused to produce a probe as small as 50–100 Å in diameter. Such a small probe supplies a current in the range of 1–10 pA, suitable for submicron features. The probe is scanned along the resist to write the device pattern.

To facilitate e-beam lithography, an SEM running the Nanometer Pattern Generation System (NPGS, from Nabity Lithography Systems, Inc.) is often used to control the x and y deflections and the beam blanking. Using digital-to-analog converters connected to the SEM scan coils, the NPGS program controls the electron beam to write each pattern. It takes the designed pattern as input, and the writing parameters include beam current, center-to-center spacing, line spacing, dosage, and magnification. Figure 16 shows a design pattern for e-beam writing.

An accelerating voltage is applied to the SEM filament. Decreasing the accelerating voltage increases the fraction of primary electrons that are backscattered near the surface of the substrate. Since the intensity of the exposure due to backscattered electrons is higher in the bottom resist layer than in the top layer, the backscattered electrons affect the amount of undercut. Thus, a relatively low accelerating voltage is chosen in order to increase the amount of undercut. It is found that 12 kV is sufficiently low for electrons backscattered from the substrate to produce an adequately large undercut.

When e-beam writing is complete, the wafer is developed in an MIBK:IPA solution. MIBK stands for methyl isobutyl ketone, and IPA stands for isopropyl alcohol. The developers usually consist of two ingredients. The first is the solvent, and the faster it can infiltrate the resist mass, the faster it will dissolve it. The second is a nonsolvent which affects the rate at which the resist goes from a gel to a liquid, by adjusting the enthalpy of the solution. After developing, the chip is

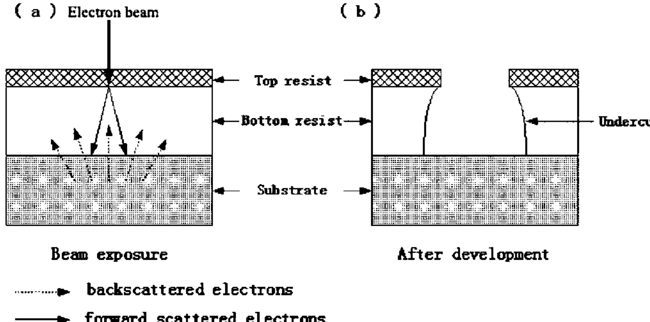

Figure 15. Resist profile. (a) View of the resist being exposed by the electron beam. (b) Because of the backscattered electrons and the higher sensitivity of the thick bottom layer, more of the bottom layer is removed in the developing procedure, thus creating a large undercut.

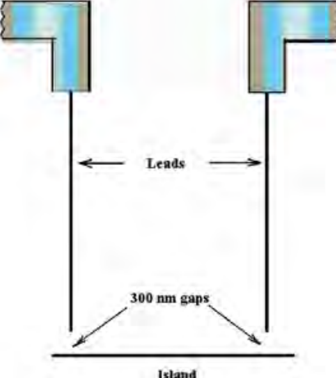

Figure 16. Example of an SET design pattern for e-beam patterning. The island has a length of 2 μm. The 300 nm spacing between the island and the leads produces resist bridges.

gently agitated in an IPA solution stop bath, and blown dry with dry N_2 gas.

3.3. Metal Evaporation and Liftoff

The samples are mounted on a rotatable sample stage in the evaporator. Here, we will show an example of a double-angle evaporation procedure for an SSS SET sample consisting of only aluminum. The first evaporation is straight down, which deposits approximately 250 Å of Al onto the substrate. As shown in Figure 17, this forms the island. This layer of Al is then oxidized in dry O_2 at ~50 mtorr for 3–5 min. The oxide insulating layer is about 1 nm thick. A second evaporation is done at a 45° angle along the two lead channels in the direction of the island. In this evaporation, 550 Å of Al are deposited.

Following the evaporation step, the samples are placed in acetone for liftoff. This dissolves most of the remaining resist. The samples are then rinsed with acetone and methanol to remove the unwanted metal that was originally deposited on top of the resist.

3.4. Sample Measurement

In order to observe the single-electron effects, the SETs must be measured at low temperatures. This is because the energies of these phenomena are lower than 0.1 meV for a system capacitance on the order of 10^{-15} F, which approximately equals the thermal energy at 1 K. Typically, four-probe current transport measurements are performed on samples which are cooled in dilution refrigerators.

SETs are usually very sensitive to noise [41], so a measurement is often taken inside an electromagnetically shielded room, and sufficient lead filtering is needed. High-frequency noise in the leads must be attenuated before it reaches the sample. Otherwise, the noise can lead to an RF heating of the sample, enabling photon-assisted tunneling which can dramatically change the current transport behavior. And for superconducting SETs, it can change the phase dynamics of the Josephson junctions.

Double Angle Evaporation

(d)

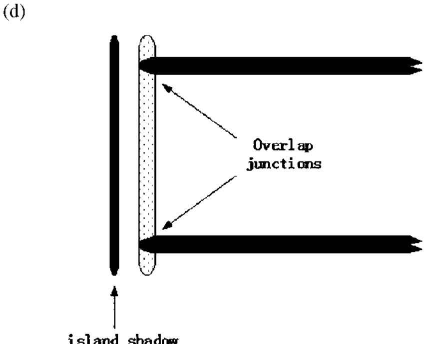

Figure 17. (a) Cross-sectional view along one of the lead channels showing where metal is deposited in the first evaporation. Because of the suspended resist bridge (RB), the first layer of the lead does not connect to the island. (b) Metal pattern after the first evaporation. (c) Cross-sectional view of the second evaporation at an angle 45° toward the island. (d) Two junctions are formed after the second evaporation.

4. APPLICATION OF SINGLE-ELECTRON TRANSISTORS

In the semiconducting industry, it is now possible to produce MOSFETs and integrated circuits with gate oxides less than 10 atoms across. Such thin films are required to maintain the current response of the transistor to lower voltages at the gate electrode. Manufacturers need to lower the power supply to individual components in order to pack more devices onto a chip. The roadmap projects that, by 2012, the gate oxide must be reduced to a thickness of five Si atomic layers as the device size miniaturizes [42]. Such scaling down of the gate oxide will eventually reach its fundamental physical limit, as the quantum-mechanical tunneling of electrons will cause the breakdown of electrical insulation. There are also other limitations associated with device miniaturization. For example, the power dissipated will be too high to allow the realization of integrated circuits with about 10^{11} devices per cm^2, high electric fields will cause device breakdown, and the shrinkage of depletion regions causes leakage. As a result, nanoscale devices become an attractive option for the development of integrated circuits with dimensions and performances beyond the ultimate roadmap. Among them, SET presents promising features such as reduced dimension, extremely low power consumption, and high charge sensitivity.

Many measurements have been made studying charge transport in the SETs. As we have discussed, by adding electrons to the island of an SET transistor, one can study the interaction of electrons on the island, the coupling of states in the leads to states in the island, and how superconductivity changes the system behavior. The remarkable capability to control the current allows SETs to be used in metrological applications such as ultrasensitive electrometer and current standard. The low power dissipation makes them potentially useful in high-density memory and logic circuits. SETs are also very sensitive to applied radiation. Photon-assisted tunneling has been observed, and the absorption of individual photons of microwave radiation can be detected. Furthermore, SETs have potential applications in the magnetic recording industry and developing new spintronics devices. In this section, we will discuss some possible applications of SETs.

4.1. Metrological Applications

4.1.1. Precision Measurements

Because of their charge sensitivity, SETs are excellent for making precision charge measurements. SET can be used to measure charge either in the normal state or in the superconducting state. Typically, it is voltage biased at a point where there is a large modulation of the current as a function of the gate charge Q_o. The charge that is to be measured is coupled to the gate, and the current modulated by the gate is monitored. Thus, charges much smaller than the electron charge e can be measured. The charge resolution that can be achieved is $8 \times 10^{-6} e/\sqrt{Hz}$ at 10 Hz [44]. SETs offer by far the best charge resolution among the available charge measurement devices.

SETs have also been capacitively coupled to a variety of systems so that the charge motion of those systems could

be monitored. Metallic SETs have been coupled to semiconductor quantum dots to observe the charge fluctuations in the quantum dot [45]. They have been coupled to superconducting particles where it is possible to observe whether the particle has an even number or an odd number of electrons on it [46]. SETs have also been scanned over semiconductors to measure fluctuations in the dopant distribution [47].

4.1.2. Current Standard

One of the applications of SET devices is a fundamental current standard. In such a device, a known current is established by transferring individual electrons through the device with a frequency f. This results in a current $I = ef$. A number of different designs have been made. They include modulating the gates coupled to the islands in an array of tunnel junctions, [48, 49], modulating the tunnel barriers in a semiconducting quantum dot [50], and transferring Cooper pairs in a superconducting circuit [51]. The most intensively studied current standard is called an electron pump. It consists of a number of tunnel junctions in series with a gate connected to each island between the junctions. By modulating the gates successively, one can draw a single electron through the array of tunnel junctions. The accuracy that has been achieved with this current standard is 15 parts per billion [52].

4.2. Information Technology

4.2.1. SET Memories

The small size and low power consumption of SETs make them a promising candidate for the information technology industry. In comparison with single-electron logic, single-electron memory is much easier for implementation, and therefore more promising from the practical point of view. All major problems of single-electron logic (operation temperature, background charge fluctuations, and power dissipation.) can be solved much easier for single-electron memories [53]. Here, we will discuss two memory schemes. The first is an offset-charge-independent DRAM cell which was described by Likharev and Korotkov [54]. In their circuit, a bit is represented by the presence or absence of the charge of a few electrons which are stored on an island. The charge on the island is monitored by an SET. When the memory cell is read, if there are charges on the island, the current through the SET undergoes oscillations as each electron tunnels off the island. The current oscillations through the device occur for any value of the offset charge. If there are no charges stored on the island, there will be no current oscillations.

Another SET memory type, called a single-electron MOS memory (SEMM), is also based on the motion of individual electrons [55]. This device is very similar to a conventional floating-gate MOS memory, which has a floating gate between a channel and a control gate. Information is represented by storing charges on the floating gate, which modulates the conduction through the channel. The ultimate limit is to use a single electron to represent a bit.

In the silicon SEMM design by Chou's group [56], there are two key features: (1) the silicon channel width (~10 nm) is narrower than the Debye screening length of a single electron, and (2) the floating gate is a nanoscale polysilicon dot (~7 nm × 7 nm) embedded between the control gate and the channel. The narrow channel ensures that the storage of one electron on the floating gate is sufficient to screen the entire channel width from the potential on the control gate. The tiny floating gate significantly increases the electron quantum energy and electron charging energy, so that the threshold voltage shift and the charging voltage become discrete and well separated at room temperature. When a single electron is added to the floating gate, the conduction through the channel significantly changes.

In the fabrication of this Si SEMM [66], a polysilicon film 11 nm thick was deposited on an Si wafer that had a 35 nm thick top layer of crystalline Si. The polysilicon film and the Si layer were separated by a layer of 1 nm thick native oxide. The first procedure of e-beam lithography and chlorine-based reactive ion etching (RIE) patterned the width of the floating gate and the narrow Si channel. The initial channel width ranges from 25 to 120 nm. Then, a second procedure of e-beam lithography and RIE patterned the length of the floating gate. An 18 nm thick layer of oxide was then thermally grown, reducing the thickness of the polysilicon dot by ~9 nm, and the lateral size of the dot and the width of the Si channel by 18 nm. The polysilicon dot functions as the floating gate. Then a thick layer of oxide was deposited by plasma-enhanced chemical vapor deposition. Polysilicon was then deposited, and the control gate was patterned to a length of 3 mm, which covered the floating gate and part of the narrow channel. In order to allow fast charging and to minimize the potential difference between the channel and the floating gate during the charging process, no tunnel oxide was intentionally grown between the channel and polysilicon floating gate. However, a potential barrier still exists between the channel and the floating gate because of the grain boundary in polysilicon and the thin native oxide. The devices were characterized at room temperature. With the drain voltage fixed at 50 mV, a positive voltage pulse was first applied to the control gate, causing the electrons to tunnel from the channel to the floating gate. The drain current was then measured as a function of the gate voltage. It was found that the charge stored at the floating gate could be held for ~5 s after the control gate potential was set back to the ground.

4.2.2. SET Logic Circuits

In the application of logic circuits, quite a number of logic designs based on SET circuits have been proposed. Some of the designs are very similar to CMOS, where bits are represented by voltage levels [57, 58]. Some logic designs resemble superconducting single-flux quantum logic [8]. In this case, bits are represented by the presence or the absence of individual electrons. Other logic designs contain elements that act like electron pumps for transferring charges [59].

Hadley's group at the Delft University of Technology fabricated a CMOS-like SET inverter using two capacitively coupled single-electron transistors [60]. This inverter has a voltage gain of 2.6 at 25 mK, and remained larger than 1 for temperatures up to 140 mK. Inverters can be used as a fundamental building block of SET logic circuits and memory

elements. NAND and NOR gates are realized by making slight variations of the inverter. With two inverters, a static RAM memory cell can also be constructed.

4.3. Microwave Detector

It has been shown that, when the island is superconducting, the effects of photon-assisted tunneling (PAT) in the SET greatly enhances the rates of some energetically forbidden tunneling processes. The most dramatic effect, the emerging of a secondary peark near $Q_o = 0$, is directly linked to superconductivity in the island. It results when PAT introduces a single quasiparticle to the island, a process which is otherwise forbidden at low voltage and temperature. This switches on the two-electron tunneling process, which continues until the single quasiparticle escapes from the island after a relatively long time, $\sim$1 μs. Consequently, the effect of PAT is magnified because many electrons tunnel through the system for each absorbed photon. It has been demonstrated that, in an all-superconducting SET sample, approximately 100 electrons can tunnel through the system per absorbed photon, giving rise to a secondary peak up to $\sim$1 nA [43]. In the presence of very small amounts of microwave radiation, the secondary peak provides a direct measure of the absorbed power. Therefore, the superconducting SET can be used as an extremely sensitive microwave detector.

4.4. Magnetoelectronics

There has been much interest in the past few years to study the spin transport and dynamics in ferromganetic SETs with ferromagnetic electrodes. [61–63]. Here, let us consider a double-junction system where the two electrodes are ferromagnets and the island is a normal metal. Such a tunnel junction can be used in ferromagnetic alignment (the magnetizations of the two electrodes are parallel) and in antiferromagnetic alignment (the magnetizations of the two electrodes are antiparallel, as shown in Fig. 18). Already for relatively large junctions (where the Coulomb blockade can be neglected), the anti-ferromagnetic alignment is interesting because a tunnel current generates a spin accumulation on the island. For nanoscale double-junction systems with ferromagnetic leads, it has been calculated that spin accumulation caused by cotunneling squeezes the Coulomb blockade in the antiferromagnetic configuration. And the tunnel magnetoresistance (TMR) is strongly enhanced by the cotunneling process in the Coulomb blockade region [64–66] in which the sequential tunneling is suppressed.

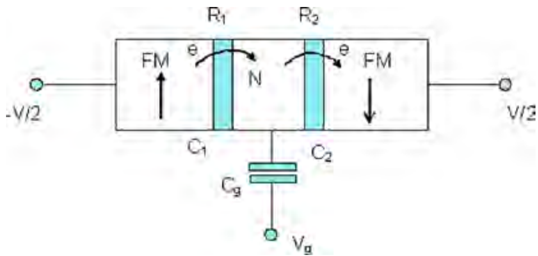

Figure 18. A ferromagnetic SET in the antiferromagnetic configuration. Insulating barriers are shown by the shaded areas.

As discussed earlier, cotunneling is a higher order process of tunneling through both junctions via a virtual intermediate state with increased electrostatic energy. The cotunneling process is energetically favorable since the cotunneling lowers the electrostatic energy by eV. One can calculate the TMR using the perturbation theory, and obtain the TMR ratio in the case of a symmetric junction:

$$\frac{R_A - R_F}{R_F} = \frac{2P^2}{1 - P^2} \qquad (k_B T \gg E_c) \tag{78}$$

$$\frac{R_A - R_F}{R_F} = \frac{4P^2}{(1 - P^2)^2} \qquad (k_B T \ll E_c) \tag{79}$$

where R_A and R_F are the resistances when the electrodes are in antiparallel and parallel alignments, respectively, and P is the polarization of the magnetic electrodes. Therefore, the TMR for $k_B T \ll E_c$ in the cotunneling regime is enhanced by $2/(1 - P^2)$ compared with TMR for $k_B T \gg E_c$ in the absence of the Coulomb blockade effect [67].

Extending the result to a superconducting island, it is found that the spin accumulation signal is strongly enhanced since a superconductor is a low carrier system for spin transport, but not for charge [68]. These aspects lead SET into new spin electronic devices useful for the magnetic recording industry as read head sensors and magnetic memory elements.

5. SUMMARY

We have discussed the charge-transport mechanisms in single-electron transistors, with primary concentration on the normal state SETs and superconducting state SETs. We have shown that superconductivity in the island leads to very interesting even–odd electron number effects, even if there are as many as one billion conduction electrons in the island. Single-charge-tunneling effects play an important role in devices with very small dimensions as device miniaturization continues for dense integrated circuits. Because the phenomena of single electronics that most groups have been studying manifest themselves at low temperatures, the main drawback of SET for applications is the necessity for low-temperature operation. However, the demonstration of a silicon-based SET operating at room temperature, the recent demonstration of carbon nanotube- and nanowire-based logic circuits operating at room temperature, and ongoing advances in nanofabrication to make even smaller feature sizes indicate that SET circuits can operate at room temperatures. Therefore, it is highly promising for single-electron devices to realize their practical industrial applications.

GLOSSARY

Coulomb blockade Electron transfer is energetically forbidden for voltages below a threshold voltage, showing a zero tunnel current region in the I–V characteristics.

Coulomb charging energy Energy required for adding a single electron onto an island.

Even–odd free energy difference Difference in free energy between two parity cases.

Inelastic cotunneling In the Coulomb blockade region, where sequential tunneling of an electron is energetically unfavorable, electrons can tunnel simultaneously across two junctions via a virtual intermediate state, leaving an electron-hole excitation on the island.

Island A region (for example a piece of metal, superconductor, or semiconductor), that is weakly coupled to its surrouding high resistance tunnel junctions. Charges can be transferred only through tunnel junctions.

Orthodox theory Formalism to calculate the current through the single electron transistor by determining the island charge distribution function and by considering the transitions across a single junction for any possible island charge.

Parity effect In a superconductor island, due to electron pairing, the ground state energy of the system is higher when the total number of electrons on the island, N is odd compared to when N is even. As a result, the states of even N become energetically favorable over those of odd N. This effect is also called even–odd electron number effect.

Single-electron charging effects When the capacitance of the island to the surrounding is very small, the charging energy required to add a single electron becomes the dominant energy, and current transport is significantly influenced by the discreteness of the electronic charge.

Single-electron transistor A double tunnel junction system in which the island is weakly coupled to the bias leads through small capacitance and high resistance tunnel junctions, and capacitively coupled to a gate electrode.

Total capacitance of the island Sum of the capacitances of the island to the three electrodes in a double junction system.

1. INTRODUCTION

Single wall carbon nanotubes (SWCNTs) are very thin (0.7–2 nm in diameter) and very long (lengths exceeding 10 μm are not uncommon) hollow tubules made up of a covalently bonded network of sp^2 carbon atoms. The main difference between SWCNTs and carbon fibers is that in principle one SWCNT is one giant molecule while fibers consist of entities significantly smaller than the fiber itself, held together by secondary bonding forces. Their exceptionally high aspect ratio makes SWCNTs the perfect one-dimensional model compound and results in many special physical properties. Besides being fascinating materials in their own right, there is considerable interest in nanotubes in the plastic, automotive, and nanoelectronics industries.

Advances in carbon nanotubes were reviewed by several authors since their discovery in 1991 [1–12]. In this chapter our goal is to give an overview of the SWCNT field for nonspecialists and to summarize the new results of the last few years for specialists.

1.1. Single Wall Carbon Nanotubes Timeline

Carbon soot containing a host of pyrolysis products has been around ever since mankind started using fire. Industrial-scale interest in artificial carbon forms was raised at the end of the 19th century by paint, adsorbent, and especially rubber manufacturers and was boosted by the spreading of cars running on black tires. Carbon fibers have been researched intensively since the 1950s. In the 1970s and 1980s vapor grown fibers with diameters below 10 nm were grown catalytically [13, 14] and in 1985 fullerenes were discovered [15]. Even though it is rather likely that carbon nanotubes were also produced in these experiments, the nanotube field started only in 1991 with Iijima's discovery of multiwall carbon nanotubes in the product soot of a dc arc discharge experiment utilizing graphite electrodes [16].

SWCNTs were discovered in 1993 simultaneously by Iijima and Ichihashi [17] and Bethune et al. [18]. SWCNT research increased in the second half of the 1990s as substantial amounts of nanotubes became available thanks to the optimization of the dc arc discharge by Journet et al. [19] and to development of the laser ablation process by Thess and co-workers [20]. Later, the chemical vapor deposition (CVD) SWCNT synthesis method was developed [21–24] and the first method offering feasible up-scaling of production was described [25, 26].

The end of the 1990s also brought the functionalization of carbon nanotubes [27–29], nanotube field effect transistors [30], and nanotube based chemical force microscopy tips [31] as well as nanotweezers [32]. Focal points of contemporary research are (i) achieving full control over the diameter and purity in nanotube synthesis, (ii) utilizing nanotubes in nanoelectronic devices like transistors, sensors, and actuators, (iii) bringing nanotube-based field emission devices (e.g., flat panel displays, lamps) and composites to the commercial market, and (iv) using nanotubes in the energy sector to improve batteries, fuel cells, and H_2 storage devices.

1.2. Single Wall Carbon Nanotubes Structure

This chapter introduces the basic concepts and vocabulary necessary for newcomers to understand the language of current SWCNT research papers. The formalism used for the presentation of the material here is adopted from the work of Saito et al. [2] and Dresselhaus and Eklund [33].

1.2.1. Geometry

Graphite is a three-dimensional (3D) material consisting of several 2D layers (graphene sheets) of hexagons of sp^2 carbon atoms arranged in a honeycomb lattice. SWCNTs can be derived by taking a long, thin strip of hexagons out of one graphene sheet and rolling it up to make the opposite long edges meet. As-synthesized tubes are always capped by fullerene hemispheres on both ends which can be opened later by chemical reactions. The present lower limit for SWCNT diameter is 0.4 nm for tubes confined into the channels of a zeolite host and 0.7 nm for freestanding tubes [25]. Although there is no theoretical upper limit for tube diameter or length, most SWCNT samples produced today fall into the range of $d =$ 0.9–2.5 nm and $l =$ 0.2–10 μm.

The beauty and the complexity of nanotube science both originate from the same ground: that one has nearly complete freedom in choosing the strip width and cut direction when slicing the graphene sheet. Each choice results in a nanotube with a different orientation of hexagons in the cylindrical wall (different *helicity*) and, consequently, with different electronic properties. It is therefore mandatory to understand Figure 1, which summarizes the geometrical quantities characterizing a nanotube. By connecting the crystallographically equivalent points O and A this strip can be rolled up into a (4, 2) SWCNT. Relocating point A to A* or A** would result in different armchair (4, 4) and zigzag (4, 0) nanotubes, respectively. Each tube is unambiguously identified by its *chiral vector* $\mathbf{C_h}$ (also called the *Hamada* vector [34]) which is perpendicular to the tube axis and is connecting O and A. $\mathbf{C_h}$ can be expressed as the sum of integer multiples of the real space unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ of the unrolled honeycomb sheet,

$$\vec{a}_1 = \left(\frac{\sqrt{3}}{2}a, \frac{a}{2}\right) \qquad \vec{a}_2 = \left(\frac{\sqrt{3}}{2}a, -\frac{a}{2}\right) \tag{1}$$

where $a = 1.44$ Å $\times\sqrt{3} = 2.49$ Å is the lattice constant of the unrolled honeycomb lattice [35]:

$$C_h = n\vec{a}_1 + m\vec{a}_2 \equiv (n, m) \quad (n, m \in \mathbf{Z} \quad \text{and} \quad 0 \leq m \leq n) \tag{2}$$

Tubes possessing identical mirror images are called *achiral*; these are the so-called *armchair* ($n = m$) and *zigzag* ($m = 0$) SWCNTs while the general (n, m) tube is always *chiral*. The *diameter* d of a SWCNT is given by

$$d = \frac{a}{\pi}\sqrt{n^2 + m^2 + nm} \tag{3}$$

The *chiral angle* Θ denotes the tilt angle of the hexagons with respect to the direction of the SWCNT axis and can be expressed from

$$\cos\Theta = \frac{2n + m}{2\sqrt{n^2 + m^2 + nm}} \tag{4}$$

The *translational vector* $\mathbf{T}$ points from O to B which is the first lattice point through which a line normal to $\mathbf{C_h}$ passes from O:

$$\vec{T} = t_1\vec{a}_1 + t_2\vec{a}_2 \equiv (t_1, t_2) \qquad (t_1, t_2 \in \mathbf{Z}) \tag{5}$$

The *unit cell* of the nanotube is the OAB'B rectangle. Let d_H denote the highest common divisor of n and m and let us define d_R as

$$d_R = \begin{cases} d_H & \text{if } (n - m) \text{ is not a multiple of } 3d_H \\ 3d_H & \text{if } (n - m) \text{ is a multiple of } 3d_H \end{cases} \tag{6}$$

The N number of hexagons in the unit cell is then obtained as

$$N = \frac{2(m^2 + n^2 + nm)}{d_R} \tag{7}$$

The unit cell contains $2N$ carbon atoms.

The Brillouin zone (the reciprocal space counterpart of the unit cell) of 2D graphite is a regular hexagon. There are three highly symmetric points in the zone: the $\Gamma = (0, 0)$ point in the center, the $\mathbf{K} = (0, \frac{4\pi}{3a})$ point in the corner, and the $\mathbf{M} = (\frac{2\pi}{\sqrt{3}a}, 0)$ at the center of the edge. The reciprocal unit vectors are defined as

$$\vec{b}_1 = \left(\frac{1}{\sqrt{3}}, 1\right)\frac{2\pi}{a} \qquad \vec{b}_2 = \left(\frac{1}{\sqrt{3}}, -1\right)\frac{2\pi}{a} \tag{8}$$

where a is the lattice constant of the graphene sheet. The Brillouin zone of SWCNTs is derived from that of 2D

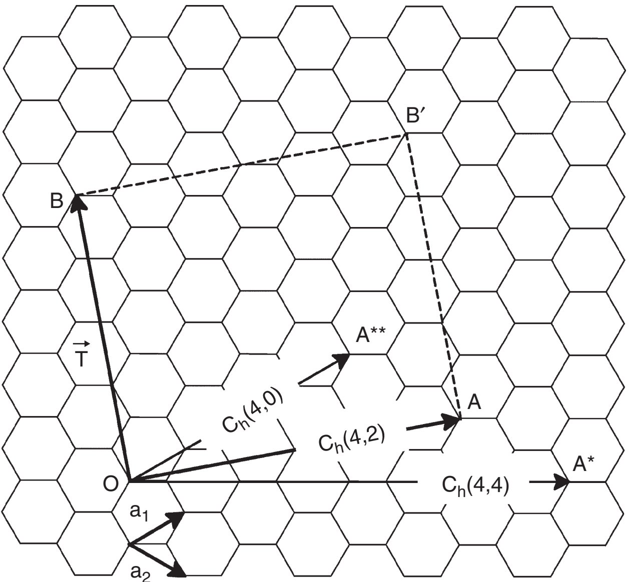

Figure 1. A graphene sheet can be folded into a SWCNT by connecting points O and point A. The resulting (4, 2) tube will have the translation vector **T** and unit cell OAB′B. Relocating point A to A* or A** yields the armchair (4, 4) and zigzag (4, 0) SWCNTs, respectively. The real space unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ are also shown.

graphite by calculating the nanotube reciprocal lattice vectors $\mathbf{K}_1$ and $\mathbf{K}_2$ corresponding to $\mathbf{C_h}$ and $\mathbf{T}$, respectively as

$$\vec{K}_1 = \frac{1}{N}(-t_2\vec{b}_1 + t_1\vec{b}_2) \qquad \vec{K}_2 = \frac{1}{N}(m\vec{b}_1 - n\vec{b}_2) \quad (9)$$

Since the single wall carbon nanotube is a one-dimensional system, only $\mathbf{K}_2$ is a true reciprocal unit vector. The Brillouin zone is a $|\vec{K}_2|$ long line segment passing through the Γ point parallel with $\mathbf{K}_2$. $\mathbf{K}_1$ gives discrete values for the wave vector $\mathbf{k}$ in the direction of the Hamada vector.

The symmetry of SWCNTs is determined by the geometry of the unit cell. The achiral (n, n) armchair and $(n, 0)$ zigzag nanotubes possess one inversion center (i) and one n-fold (C_n) axis and one $n \times C_2$ rotational axis in the directions parallel and perpendicular to the nanotube axis, respectively. The $n = 2k$ $(k \in \mathbf{Z})$ achiral tubes have an additional horizontal mirror plane (σ_h) and thus belong into the point group D_{nh} while the $n = 2k + 1$ $(k \in \mathbf{Z})$ tubes belong into D_{nd}. The basic symmetry operation of chiral (n, m) SWCNTs is a rotation around the tube axis followed by a translation along the axis. This operation corresponds to the $\mathbf{R} = p\mathbf{a}_1 + q\mathbf{a}_2$ vector where p and q are calculated from

$$d_H = mp - nq \quad \text{with the conditions } p < \frac{n}{d_H} \quad q < \frac{m}{d_H} \quad (10)$$

Let us define Ω as

$$\Omega = \frac{p(m+2n) + q(n+2m)}{d_H/d_R} \quad (11)$$

The point group of the chiral (n, m) tube is $C_{N/\Omega}$ if $d_H = 1$ and is obtained as a direct product $C_{d_H} \otimes C'_{N/\Omega}$ if $d_H \neq 1$.

SWCNTs are seldom found alone; rather, they stack together and form bundles which may contain from a few up to a few hundred tubes. Thess et al. provided experimental [transmission electron microscopy (TEM) and X-ray diffraction (XRD)] evidence [20] that the bundles are quasi-crystalline arrays of nanotubes arranged into a trigonal lattice of space group *P6/mcc* [36]. It is yet uncertain if the arrays are made up of all identical (n, m) tubes or of SWCNTs with similar diameters but different helicities. The number of tubes in a bundle can be increased by functionalization [37] or decreased by ultrasonication in aqueous ionic [38, 39] or nonionic [40] surfactant solutions. However, it is quite difficult to separate a macroscopic SWCNT sample into truly individual tubes. Therefore, most of the macroscopic nanotube-related studies reported so far in the literature refer to work on SWCNT bundles even if not stated explicitly.

1.2.2. Electronic Structure

The electronic structure of SWCNTs is obtained simply by applying periodic boundary conditions in the $\mathbf{C_h}$ direction to 2D graphite. Thus the wave vector perpendicular to the nanotube axis becomes quantized while the parallel one remains continuous [41]. Following Saito et al., for a SWCNT with N hexagons in the unit cell we can think of the quantization as making N cross-sections in the energy dispersion surface of 2D graphite, resulting in N pairs of one-dimensional energy dispersion curves of the nanotube:

$$E^{\pm}_{\mu}(k) = E^{\pm}_{g2D}\left(k\frac{\vec{K}_2}{|\vec{K}_2|} + \mu\vec{K}_1\right) \qquad \mu = 0, \ldots, N-1$$
$$\text{and} \qquad -\frac{\pi}{|\vec{T}|} < k < \frac{\pi}{|\vec{T}|} \quad (12)$$

Here, $k \equiv |\vec{k}|$ is the magnitude of the wave vector, $E^{\pm}_{g2D}(k)$ denotes the energy dispersion relation of 2D graphite, and the "+" and "−" indices correspond to the π and π^* bands, respectively. The cross-sections are made along $\mathbf{K}_1$ spaced, $|\vec{K}_2|$ long line segments in the hexagonal Brillouin zone. If for a particular nanotube a segment happens to go through a $\mathbf{K}$ point where the π and π^* bands of graphene are degenerate, than there will be a zero gap between the valence (+) and conduction (−) branches of the corresponding one-dimensional energy dispersion curve. Since the degenerate point matches the Fermi energy where in such cases the electronic density of states has a nonzero value, these SWCNTs are *metallic*. On the other hand, if none of the N segments passes through a $\mathbf{K}$ point then the corresponding SWCNT will possess a finite gap, its electronic density of states will be zero at the Fermi energy, and therefore the tube will be *semiconducting*. It can be shown that tubes with $(n - m) = 3k$, $k \in \mathbf{Z}$ are the metallic ones and all others (the remaining 2/3 of all possible helicities) are semiconducting. It is useful to remember that armchair SWCNTs are always metallic and zigzags are metallic only if n is a multiple of 3.

The electronic density of states (DOS) of SWCNTs is calculated as

$$D(E) = \frac{|\vec{T}|}{2\pi N}\sum_{\pm}\sum_{\mu=0}^{N-1}\int \frac{1}{\left|\frac{dE^{\pm}_{\mu}(k)}{dk}\right|}\delta(E^{\pm}_{\mu}(k) - E)\,dE$$
$$[\text{States/C atom/eV}] \quad (13)$$

It is clear from this equation that very high $D(E)$ values can be expected close to the minima and maxima of the 1D energy dispersion curves as defined in Eq. (12). These peaks in the DOS are called *van Hove singularities* (vHs) and they play a crucial role in several SWCNT spectroscopies. The singularities are indexed as $i = 1, 2, \ldots$ from the Fermi energy to both directions (valence vs conduction band) and optical transitions between the ith valence and jth conductance band vHs are denoted as E_{ij}. The energy separation between the highest valence band vHs and the lowest conduction band vHs (the gap size of semiconducting SWCNTs) is independent of the chiral angle as shown in the formulae

$$E^{m}_{11} = \frac{6a_{\mathrm{C-C}}\gamma_0}{d} \qquad \text{and} \qquad E^{sc}_{11} = \frac{2a_{\mathrm{C-C}}\gamma_0}{d} \quad (14)$$

for metallic and semiconducting SWCNTs, respectively. In Eq. (14) $a_{\mathrm{C-C}} = a/\sqrt{3}$ is the nearest neighbor C–C distance in 2D graphite, $\gamma_0 \cong 2.5$ eV is the C–C transfer energy, and d is the diameter of the nanotube. These equations are valid strictly only within the so-called "linear k approximation" [42] which fails for small SWCNT diameters. In thin tubes the equienergy contour lines of the energy dispersion surface of 2D graphite are distorted from circles into trigonal shapes

for large k values. This phenomenon is called the *"trigonal warping effect"* [43] and is responsible for the splitting of DOS peaks in zigzag and in metallic chiral nanotubes. Armchair and semiconducting chiral nanotubes do not suffer any splitting due to the warping effect.

2. SYNTHESIS OF SINGLE WALL CARBON NANOTUBES

With nanotube research being a very young science, the issue of nanotube synthesis has not yet settled down so well as, for example, in the case of the six years older fullerenes. Authors of all research papers are still expected to provide details about their nanotube source and purification procedure because these have a considerable effect on the properties of the material. Several extensive reviews are available on the topic of SWCNT synthesis [44–46].

2.1. Synthesis Using Arc discharge

The temperature in an electric discharge may reach as high as 4000 °C. Under its operation material transfer takes place between the electrodes. In 1990, successful fullerene [47] and in 1991 successful carbon nanotube syntheses [16] were performed using this method.

Lozovik and Popov [48] divided the operation mode of electric discharge systems into noisy and quiet ones. Continuous transition between the two modes can be regulated simply by changing the current density. It was found that high current density and low inert gas pressure result in the formation of fullerenes, while for low current density and high pressure nanoparticles and nanotubes are predominately formed. Ebbessen and Ajayan [49] developed a technique suitable for large scale production. He gas was run through the reactor with controlled rate and pressure. Generally the anode graphite rod contained a hole filled with the metal catalyst. The product formed on the cathode was composed of various matter including nanotubes, fullerenes, carbonaceous nanoparticles, and catalyst. After purification only 1% of the initial deposit remained as final product. Journet et al. [19] reported a novel technology leading to yields of nanotube production as 70–90%. Bundles of a few tens of tubes and only a few isolated tubes were formed. Bethune et al. [18] reported that co-vaporizing carbon and Co under He atmosphere resulted in the formation of SWCNTs of very small diameter (around 1.2 nm). They proved that no nanotube formation was found when using Fe, Ni, or a mixture of Ni–Cu. Seraphin and Zhou [50] have reported an efficient synthesis of SWCNTs in the presence of bimetallic catalysts such as Fe–Ni, Fe–Co in argon atmosphere. They obtained gram quantities of SWCNTs. Iijima and Ichihashi [17] prepared SWCNT by co-vaporization of graphite and Fe in an Ar–methane atmosphere. Here, the atmosphere contained a hydrocarbon component reactive at the temperature of arc discharge. The average diameter of the tubes centered at around 1 nm. No tube was formed in absence of iron catalyst. Kiang and Goddard [51] proved that various additives such as S, Bi, and Pb increased the yield of nanotube production and substantially modified the diameter distribution of SWCNTs.

There is no a well defined mechanism describing the formation of SWCNTs in the arc discharge process. *Ab ovo* there are two main ways of formation: the noncatalytic and the catalytic. For the noncatalytic process one of the most probable methods of generation suggested by several authors [52] is as follows. The tube grows from an empty fullerene cage by repeated additions of C_2 units to the open ends. The growth by this mechanism lengthens a closed tube. According to other authors [53–55] the tubes are open during the growth and the carbon atoms bond to the active dangling bond edge sites. Iijima [54] assumed that the axial growth predominated over the shell growth for SWCNTs.

More and even complex mechanism assumptions are reported on the growth of SWCNTs in the catalytic version of arc discharge. Here, the metal atoms generated by evaporation of catalyst parallel with the carbon electrode should agglomerate to small clusters, and simultaneously (while growing the metal particles) or after forming agglomerates of a suitable size the carbon nanotubes should be generated. Alternatively, SWCNT formation takes place on the metal nanoparticles deposited on the cool reactor parts and counterelectrode surface.

Iijima and Ichihashi [17] assumed that Fe particles act as a homogeneous catalyst in the gas phase assisting in some way the formation of SWCNTs. Kiang et al. [56] described a model in which small catalytic particles rapidly assemble in a region of high carbon density. SWCNTs nucleate and grow very rapidly on these particles as soon as they reach a critical size. By other authors [51] planar polyyne rings serve as nuclei for the formation of SWCNTs. They assumed that C_{32} and C_{38} monocyclic rings lead to SWCNTs with diameters of 1.25 and 1.5 nm, respectively. Co_mC_n type compounds are assumed to act as catalysts. Seraphin and Zhou [50] found that there is no strict correlation between the diameter of SWCNTs and that of the catalyst particle and that the tubes do not grow out from the metal particles. They concluded that the metal acts at the atomic level rather than acting as a heterogeneous catalyst in the growth of SWCNTs. Summarizing the described mechanisms, the following generalized picture can be drawn. The plasma generated by arc discharge of catalyst containing carbon sources, electrons, and other charged species, together with the atoms of catalyst and carbon, is a rather complex reacting system. When a metal catalyst is evaporated with carbon, the metal and carbon atoms may condensate and form alloy particles. As the particles are cooled, carbon dissolved in the particles starts to segregate on the surface of particles since the solubility of carbon in the metal decreases with decreasing temperature. In general the Baker et al. [57, 58] mechanism may be regarded as a realistic description even for the formation of carbon nanotubes. In short, they suggested that the first step is the decomposition of hydrocarbons on the metal surfaces and dissolution of carbon in the metal. Upon this generally exothermic procedure the metal warms up. The dissolved carbon moves to the cooler part of the metal particle and leaves the metal there. The carbon moved from the metal initiates the growth of carbon fibers and/or nanotubes. In this process the diffusion of carbon in the metal is the rate determining step. Opposite to this, Oberlin et al. [59] concluded that the diffusion of carbon in the metal is negligible and diffusion takes place dominantly on the surface of metal

particles. However, Baker et al. [57] have found a correlation between the carbon diffusion in the metal particle and the rate of the growth of the carbon fibers. Baker et al. [60] answered an additional important question concerning the interaction of metal particles to the support material. They classified this interaction into two groups. For the weak interaction the growing tube pushes the catalytic metal particles from the support surface into the gas phase. This way carbon fibers or nanotubes with metal particles in their tips are formed. When the interaction is strong, metal particles remain bonded to the surface and nanotubes are growing on these metal islands. In both cases there are free surfaces toward the gas phase, not covered by carbon fibers or tubes, where the carbon transport may occur from the gas phase. Surface species formed by nucleation may catalyze the growth of SWCNTs. While the tube is growing carbon is supplied from the metal that dissolves carbon coming from the adsorbing carbon atoms. Theoretical calculations [61, 62] have also been performed to clarify the formation mechanisms of SWCNTs. A more complex mechanism has been proposed by Kanzow and Ding [63]. They divided the procedures into three main streams depending on the correlation between the carbon supply and the kinetic energy of the carbon source. These procedures take place at different temperature ranges. The condition with rich carbon supply and insufficient kinetic energy can be represented by significantly lower temperature than for insufficient carbon supply and high kinetic energy. For the former case MWNTs dominate, while under the latter conditions SWCNT formation dominates.

2.2. Synthesis of Single Wall Carbon Nanotubes with Laser Ablation

When a laser beam is used for evaporation of a carbon target generally containing transition metals as catalyst components, procedures similar to those for arc discharge take place [20]. In a typical laser ablation experiment, the second harmonic of a Nd:YAG laser pulse is focused on a graphite target containing 1–2 at% catalyst metal [64–66]. The target is kept in inert atmosphere and the system is heated to 800–1400 °C by an electric furnace. The result of laser ablation is also plasma. Dal et al. [67] concluded that by the application of this direct evaporization method better control over the growth of tubes can be achieved and also the quality of SWCNTs is better. Furthermore, this method allows quasi-continuous production and consequently the yield is much higher as well. Bimetallic catalysts such as Co/Pt, Co/Ni, etc. also gave nice nanotubes. They assumed that SWCNTs form on such a metal particle whose diameter is too small for generation of second and further walls. Kataura et al. showed that varying the type of catalyst metals and the furnace temperature can control the diameter of the grown nanotubes rather well [68]. Since SWCNT formation takes place in the plasma generated by the laser pulse [69], it is thought that nanotube growth in a laser ablation experiment follows essentially the same mechanisms as those detailed for the dc arc discharge [70]. The laser ablation method is often referred to as pulsed laser vaporization (PLV) method as well.

2.3. Chemical Vapor Deposition Synthesis of Single Wall Carbon Nanotubes

There are several studies focused on the decrease of the temperature of CVD. In these works either novel catalyst systems or new carbon sources are applied in the synthesis. Harutyunyan et al. [71] found that addition of 20% of molybdenum to the alumina supported Fe catalyst is beneficial to the SWCNT production, since it lowered the reaction temperature and eliminated the reduction of catalyst prior to the synthesis. The catalyst was active as low as 680 °C. No multiwall nanotube formation was observed.

The generation of SWCNTs is one of the most intriguing questions. Several attempts aimed at the particle size of the metal catalysts, turbulent flow of the carbon source around the catalyst, the role of metal carbide generally detected by instrumental methods, etc. have been made. The role of the size of catalyst metal particles was investigated by Li et al. [72] applying 1–2 or 3–5 nm particles in apoferritin. The instrumental characterization involving atomic force microscopy (AFM), TEM, and Raman spectroscopy proved that the diameter of SWCNTs is strictly correlated to the size of metal particles. Furthermore they proposed a mechanism for the formation of tubes from methane. According to their TEM measurements the metal particles are sitting on the substrate and the isolated carbon nanotubes are growing from them toward the gas phase.

Colomer et al. [24] reported on the production of single wall carbon nanotubes by CCVD of ethylene over Co, Ni, and Fe or their mixture on various supports. They assumed that the support helps to disperse the metal particles. The reaction carried out at 1080 °C gave a significant amount of SWCNT bundles on the Co–Fe, Fe–Co–Ni catalysts.

A real breakthrough was achieved in CVD nanotube production when the silica, zeolite, and alumina types of catalyst supports were replaced by alkaline earth oxides or carbonates [73–75]. In this latter case the removal of support became much easier.

2.4. Gas Phase Catalytic Single Wall Carbon Nanotubes Growth

Industrial scale carbon nanotube applications can only be expected if economic industrial scale SWCNT production methods become available. Arc discharge and laser ablation are extremely power hungry batch methods. It is unlikely that they can ever be scaled up to deliver large quantities of SWCNTs at a reasonable price [e.g., in kg/(unit × day) magnitude]. CVD methods use continuous carbon feedstock but require an additional purification step to separate the synthesized carbonaceous deposit from the catalyst support (SiO_2, Al_2O_3, MgO, etc.). A promising alternative is to eliminate the support and generate the metal catalyst particles *in-situ* in a continuous flow gas phase reactor. This approach has been shown to work utilizing metallocenes and $Fe(CO)_5$ as catalyst precursors and hexane, benzene, C_2H_2, CH_4, and CO as carbon sources. Since most hydrocarbons pyrolize at 6–700 °C which is in all cases below the required operating temperature of the reactor, nanotubes grown from hydrocarbon sources often show an undesired amorphous carbon coating. The most successful gas phase

catalytic SWCNT production method uses carbon monoxide as the carbon source and $Fe(CO)_5$ as the catalyst precursor. It was developed by Bronikowski et al. at Rice University and is called the HiPco® (high pressure CO decomposition) process [25, 26].

In a typical HiPco® synthesis a flow of CO (1–2 standard dm^3/min) dosed with 4–8 ppm $Fe(CO)_5$ is led through a quartz tube kept at 800–1200 °C. Iron nanoclusters formed by Fe atoms from the thermal decomposition of $Fe(CO)_5$ serve as catalyst particles on which SWCNTs can grow from the carbon produced by the Boudouard reaction from CO. Carbon nanotubes are collected from the reactor walls and from a filter placed into the flow at the reactor outlet. SWCNT yield can be increased by raising the CO pressure (30–50 atm) and the temperature (1100–1200 °C) and by introducing a little (<1 vol%) CH_4 into the feedstock. Bronikowski et al. [26] optimized the process parameters and obtained SWCNTs of up to 97 mol% purity at 450 mg/h yield. An extensive analysis of HiPco® kinetics was performed by Dateo et al. [76, 77]. The end product of the HiPco® process contains remarkably little non-SWCNT carbon material and almost no nanotubes exhibit an amorphous carbon coating. The dominant contamination (4–5 at% Fe in the raw product) comes from the iron catalyst particles which are encapsulated in the SWCNT cap in the closing step of the growth process. Chiang et al. [78] described a purification protocol consisting of two wet air oxidation and two HCl sonication steps which could decrease the iron content of a raw HiPco® sample from 5.06 to 0.05 at%. High temperature (800 °C) annealing of the purified material in Ar results in better quality SWCNTs because defects introduced during the synthesis and oxidation steps are partially healed. It is still debated if the annealing improves also the crystallinity of HiPco® samples [78] or not [79].

Although the diameter distribution of HiPco® SWCNT samples can be controlled to some extent by changing the CO pressure, the currently available typical HiPco® materials are characterized by a broader distribution peaking at a lower mean diameter than those obtained by, for example, arc discharge. Diameters of HiPco® tubes were found to fall between 0.79–1.2 and 0.8–1.4 nm by Yudasaka et al. [80] and Zhou et al. [79], respectively. In a recent study [81] Kukovecz et al. reported the values $d = 1.05$ nm, $\sigma = 0.15$ nm for Gaussian distribution mean diameter and variance, respectively. The observed discrepancies between measured and simulated HiPco® Raman spectra suggested that the diameter distribution of HiPco® materials could also be non-Gaussian. HiPco® nanotubes have proven to be excellent subjects for diameter selective observations because of their broad diameter distribution. The oxidation rate of SWCNTs scales roughly with $1/d$ allowing the selective oxidation of thin tubes while leaving the thicker ones intact. Reported selective oxidation conditions are: (i) 425 °C/1 h in flowing wet air [78], (ii) 460–650 °C/10 min in stagnant dry air [79], (iii) oxidation in a reduced O_2 atmosphere [82], and (iv) focused laser pulse at ambient conditions [83]. Similar to the coalescent diameter doubling phenomenon [84] the mean diameter of a HiPco® SWCNT sample could also be increased by heating it to 1600–1800 °C for 5 hours in high vacuum [80]. The diameter enhancement itself was evidenced by Raman and TEM measurements as well as by the increased burn-off temperature of the sample, but the mechanism for this remarkable reaction is yet unclear.

2.5. Other Single Wall Carbon Nanotubes Synthesis Methods

Two additional catalytic SWCNT synthesis methods should also be mentioned here, even though they are not as widespread as the ones detailed previously at present. The solar route [85, 86] focuses the beams of the sun on a catalyst-containing graphite target. The growth dynamics inside the solar furnace are thought to be similar to those in laser ablation [87] and the product obtained is high quality nanotubes containing little amorphous carbon [88]. SWCNTs can also be prepared in low pressure hydrocarbon (e.g., C_2H_2, C_2H_4) flames by mixing catalyst precursors [e.g., $Fe(CO)_5$ or ferrocene] into the feedstock [89, 90]. The principle of this method is quite similar to the gas phase catalytic decomposition detailed previously and, similarly, the best results for SWCNTs are obtained when using CO as carbon source [91, 92]. However, the chemical engineering side of flame reactors is well known and instruments from the laboratory to the production plant scale are already available commercially. Therefore, once the optimal conditions are found [93], flame pyrolysis could rapidly become the dominant large scale supplier of carbon nanotubes in the future.

Under special conditions SWCNTs can also be synthesized without metal catalysts. The thermal coalescence of C_{60} molecules within a SWCNT (peapod system; see Section 3.1) produces a thin SWCNT inside the larger diameter outer tube which acts as a nanoreactor in this case. Another example of SWCNT growth in a confined environment is the pyrolysis of organic template molecules in freshly synthesized $AlPO_4$-5 zeolite pores [94, 95] which gives uniform 0.4 nm diameter SWCNTs superconducting below 20 K [96]. Interestingly, the lowest diameter (0.33 nm) SWCNT reported so far was not produced under steric restrictions. This (4,0) SWCNT was grown from a larger nanotube under electron beam irradiation from a TEM field emission gun [97].

2.6. Single Wall Carbon Nanotubes Purification

The raw product of a single wall nanotube synthesis contains various forms of carbon, that is, amorphous, active carbonlike matter, carbon nanoparticles including fullerene-like material, SWCNTs, as desired product and the catalysts particles. Depending on the preparation method the catalyst component may be the simple metal nanoparticle itself or more complex, supported metal nanoparticles. The aim of the SWCNT purification is the removal of the amorphous carbon forms and the catalyst as completely as possible. A number of purification methods have been suggested; however, they can be classified into four main groups: acidic oxidation, gas phase oxidation, filtration and chromatography, and their combination.

In the acid treatment, first described by Rinzler's group [98], the raw product is refluxed in nitric acid in order to oxidize the metal and the amorphous carbon. This base method has been modified several times suggesting alternative acid

concentrations and reflux times. However, the characteristics of the resulting, purified materials were very similar. Generally upon acid treatment the ends of nanotubes have been decapped and the open ends were terminated by carboxyl groups. Furthermore, structural imperfections closed by hydroxyl and/or carboxyl groups must have been generated as well. The appearance of these functional groups is advantageous for those samples that are to be applied to polymers as a strengthening material; however, they are disadvantageous when the nanotubes are to be utilized in nanoelectronic devices. Zimmerman et al. [99] discussed an oxidation technology for purification of SWCNTs using HCl, Cl_2, and H_2O. A multistep purification procedure was discussed in the paper by Li et al. [100]. The method was developed for purification of SWCNT samples produced by catalytic decomposition of hydrocarbons. The yield of the treatment is 40% with a purity of about 95%. The first step of the procedure is an extraction. Using benzene as solvent the soluble material is removed from the sample. The next step is the acid leaching to remove the iron catalyst particles. The procedure is enhanced by ultrasonication. After filtering the sample was frozen at −196 °C for 10 h followed by further ultrasonication. Finally the sample was washed with deionized water and dried. Starting from 200 mg of raw product 75 mg of purified sample was obtained.

Gas phase oxidation is the most commonly used method for purification of SWCNTs [101–103]. Dillon's group [104] described a method that produces >98 wt% pure SWCNTs. First they subjected the carbonaceous matter to a nitric acid treatment at reflux temperature followed by the gas phase oxidation at 550 °C, for 30 min. They proved that SWCNTs purified in this way are stable as high as 600 °C in oxygen. The acid treatment prior to the gaseous oxidation procedure is obligatory in order to oxidize or dissolve the metal content of the raw product since several metals used for nanotube production by catalytic methods catalyze also the oxidation of carbon nanotubes. Chiang et al. [105] reported a high efficiency purification method for SWCNTs produced by laser oven growth. They investigated the influence of the metal content of the tubes as well and found that with increasing metal content (the origin of which is the catalyst) the oxidation rate of carbon nanotube is enhanced. By the method proposed by Moon et al. [106] high-yield purification of SWCNTs can be achieved. They designed a rotating oven for annealing the nanotube samples in the first step of the procedure. The second step consists of acid leaching for 24 h in order to dissolve the metal impurities. They claim a product with very low, less than 1 wt%, metal content.

Microfiltering proved to be an advantageous procedure for purification of carbon nanotubes. Shelimov et al. [107] developed an ultrasound assisted ultrafiltration method resulting in as high as >90% pure SWCNTs.

Nanotubes of high purity and rather uniform length distribution were obtained by Duesberg et al. [108] using column chromatography for separation of aqueous solution of SWCNTs. Niyogi et al. [109] reported a gel permeation chromatographic method for purification of soluble single wall carbon nanotubes. Two columns, Styragel HMW7 and PLgelMIXED-A, were used and the effluents were analyzed by AFM, ultraviolet-visible (UV-vis), near-infrared (NIR), fluorescent, and Raman spectroscopies. The first fraction of effluent contained 74% of soluble SWCNTs. The authors have claimed that the refinement of this chromatographic technique gives a promise of SWCNT products separated by their length, diameter, and even chirality [109].

3. FUNCTIONALIZATION OF SINGLE WALL CARBON NANOTUBES

Adapting the notation of fullerene chemistry we may classify SWCNT functionalization methods into three groups: (i) endohedral functionalization takes place when materials are admitted into the hollow interior of the nanotube, (ii) exohedral functionalization refers to sidechains chemically bound to the outer surface of the tube, and (iii) lattice functionalization occurs if the SWCNT properties are changed because agents are introduced into the intertube channels of the nanotube lattice. As a limiting case of exohedral functionalization one must also mention the in-wall chemistry of SWCNTs when a number of carbon atoms are substituted by boron and/or nitrogen.

3.1. Endohedral Functionalization

Several groups reported considerable success in forming 1D single crystals of metals, metal carbides, metal oxides, and metal halides within the nanospace inside the SWCNT. These materials are expected to show interesting electrical and magnetic properties like quantum wire effects. Utilized encapsulation methods are based on (i) the capillary effects, (ii) wet chemical techniques, (iii) one-step synthesis of the filled tube by arc dischare, (iv) condensed phase electrolysis, and (v) pyrolysis. Reportedly introduced materials are various metals [110], carbides [111], oxides [112], and halides [113–116]. The reader is referred to some recent extensive reviews for more details on the topic [117, 118].

Fullerenes can be encapsulated within SWCNTs if the tube diameter is adequate [119]. The resulting materials form a subclass of endohedrally functionalized SWCNTs called "peapods" (e.g., C_{60}@SWCNT). A spectacular high resolution TEM (HRTEM) image of a C_{60} peapod is presented in Figure 2a. Peapods were first described in 1998 as spontaneously formed by-products of the purification of PLV derived SWCNTs [120–122]. They quickly gained popularity within the nanotube community and their large scale synthesis was worked out by Smith et al. at the University of Pennsylvania [123, 124] and Kataura et al. at Tokyo Metropolitan University [125]. Since C_{60} favors the inner space of wider nanotubes [126, 127] the synthesis principle is simple: the purified fullerene and a buckypaper of opened SWCNTs are heated together in an evacuated quartz ampoule at 600 °C for 2 hours and then the excess C_{60} is removed by washing the formed peapod buckypaper with toluene. The method is sensitive to the purity of the starting materials and especially to the opening of the nanotubes which can be achieved by selective oxidation of the caps with, for example, H_2O_2, HNO_3, or hot wet air. In the ideal case 90–100% of all available SWCNTs can be filled with fullerenes. Besides direct TEM observation the filling factor can also be determined by electron energy loss spectroscopy (EELS) [128] and Raman spectroscopy [129]. To now peapods have been characterized

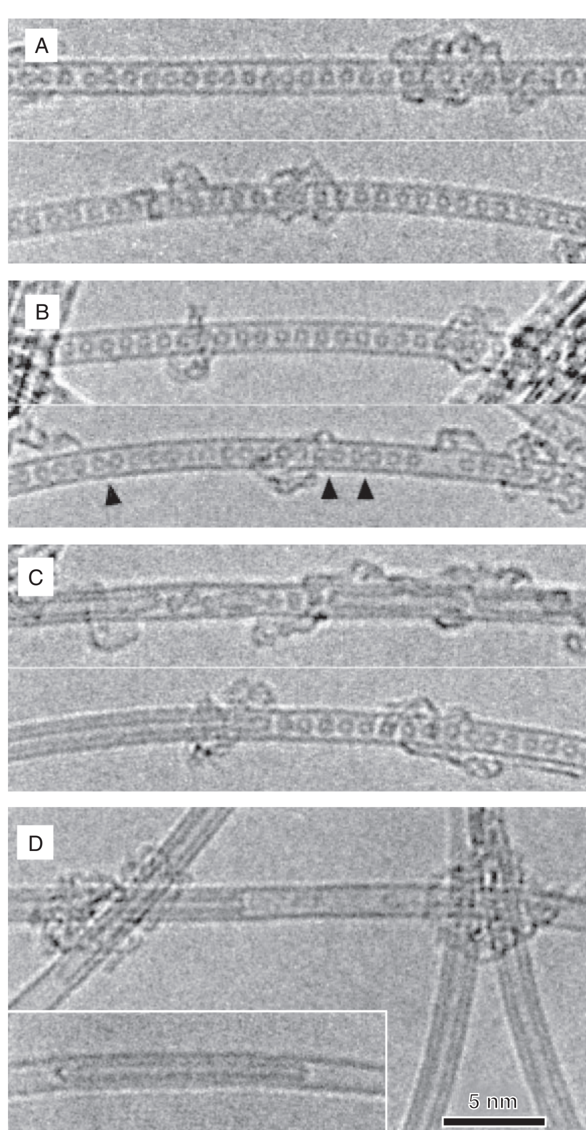

Figure 2. HRTEM images showing a C_{60}@SWCNT peapod (a) and the formation of a double wall carbon nanotube by the coalescence of fullerenes within the nanotube as the peapod is heated to 800, 1000, and 1200 °C (b, c, and d) respectively. Black arrows in (b) indicate locations where the first step of coalescence is observable. Reprinted with permission from [135], S. Bandow et al., *Chem. Phys. Lett.* 337, 48 (2001). © 2001, Elsevier Science.

by electron diffraction [130], EELS [131], optical absorption, and Raman spectroscopy [132, 133] as well as TEM and scanning tunneling microscopy (STM) [134].

Peapods are expected to outperform both fullerenes and empty SWCNTs in applications demanding mechanical strength, H_2 storage [136], and tunable electronic properties [137]. Especially promising studies were reported on metallofullerene peapods [138], for example, on the Gd@C_{82}@SWCNT system [139, 140] which can perform as an ambipolar transistor [141]. The fullerene molecules polymerize inside the SWCNT upon doping [142] and coalesce to yield a thin inner nanotube within the parent SWCNT when heated [135, 143]. This latter process is very visible in Figure 2, where (b)–(d) show the formation of a double-wall carbon nanotube as the peapod depicted in (a) is heated to 800, 1000, and 1200 °C in vacuum, respectively.

3.2. Exohedral Functionalization

Just like fullerenes, the perfect SWCNT is without functional groups and is therefore chemically quite inert. On the other hand, doing addition-based covalent chemistry on nanotubes is considerably easier than functionalizing graphite. The two main sources of reactivity in SWCNTs are (i) the curvature-induced strain arising from the nonplanar geometry of sp^2 carbons and (ii) the misalignment of the π orbitals. The former is more pronounced (i.e., the pyramidalization angle is larger) at the capping fullerene hemispheres while the latter affects mainly the sidewalls. All in all the most reactive places in any nanotube sample are found in the cap of the thinnest tube and least reactive are the bonds running perpendicular to the axis of the largest diameter SWCNT. Recent reviews on the covalent chemistry of SWCNTs are available [12].

Derivatization reactions can be roughly divided into two categories: (i) direct attachment of the required functional groups onto the nanotube and (ii) building bridgeheads by oxidizing some atoms in the tube wall and then proceeding with the functionalization using substitution reactions on the simple (-F, -OH, -COOH) groups formed. Reactions falling into the first category are the 1,3-dipolar cycloaddition [144], the Birch reduction [145], and reactions with nitrenes, radicals, and carbenes [146]. In the second case the first reaction step is usually an aggressive treatment, for example, (i) oxidation in refluxing cc. HNO_3 (yields carboxyl groups) [147–149], (ii) ozone treatment [150, 151], (iii) ball milling in reactive atmosphere [152] or together with solid KOH (hydroxyl groups) [153], and (iv) HF reaction (-F groups) [154, 155]. Then in the second step these bridgeheads are converted to more reactive groups (e.g., carboxyl groups are replaced by acyl chlorides after $SOCl_2$ treatment) and finally, conventional organic synthesis reactions like the Grignard reaction [156] are applied to build the desired functionality onto the anchor sp^3 carbon in the nanotube wall.

Covalent functionalization opens new routes for SWCNT applications. Most important of all, functionalized tubes are often soluble in organic solvents [157, 158] or even water [159, 160]. Georgakilas et al. suggest that a nanotube purification protocol could be based on the solubility difference between functionalized tubes and unharmed carbon/metallic species [161]. Sidegroups may also serve as covalent anchors for fixing SWCNTs onto surfaces [162] or within a polymer matrix [163]. Nanotube–polymer composites have superb mechanical properties and are expected to become a major SWCNT application field in the near future [164, 165].

By heating a SWCNT-B_2O_3 mixture in nitrogen containing atmosphere to ~1600 K it is possible to substitute some of the carbon atoms forming the nanotube wall itself by boron and nitrogen [166, 167]. This reaction—a limiting case of exohedral functionalization—yields $C_xB_yN_z$ tubes. Finally, we should note that investigations on the stacking-based, noncovalent functionalization of SWCNTs are also in progress [168–170].

3.3. Lattice Functionalization (Doping)

The properties of a SWCNT sample can be modified by introducing electron donors or acceptors into the trigonal nanotube lattice [171, 172] to get the nanotube analogs of graphite intercalation compounds. In the former, n-type doping can be achieved by, for example, alkali metals and in the latter, p-type doping can be achieved by, for example, Br_2 or $FeCl_3$. The conductance of doped samples increases [173] and their optically allowed transitions are quenched which causes characteristic changes in their optical [174] and Raman spectra [175]. The extent of intercalation depends on the type of doping species and on the diameter distribution of the nanotube sample [176]. It is possible to dope one-half of a single SWCNT n-type and the other half p-type which leads to an intramolecular nanoelectronics device [177]. The occupancy of the valence/conduction bands can also be modified without doping agents by electrochemical means [178, 179]. A recent review of doping is available from Fischer [180].

4. CHARACTERIZATION OF SINGLE WALL CARBON NANOTUBES

In spite of the significant research effort invested [68, 82, 181–183] it is still impossible to synthesize one selected (n, m) SWCNT in macroscopic quantities. Synthesis products are always obtained as mixtures of different helicity nanotubes. These mixtures cannot be separated into SWCNT fractions using the currently available techniques. Therefore, the reader should be aware that the macroscopical SWCNT studies published so far all investigate a set of different (n, m) nanotubes. It is common to characterize SWCNT samples by estimating the parameters of their diameter distribution from TEM, AFM, or Raman measurements. The distribution function is usually close to a Gaussian, though notable exceptions are also found.

Even though idealized nanotube geometries and detailed electronic models are readily available, experimental SWCNT characterization is no simple task. The main reasons for this are: (i) no well-defined reference tube samples are available, (ii) the sample to be characterized is always a mixture of various (n, m) chiralities, (iii) the sample is often contaminated by non-SWCNT carbon and leftover catalyst particles, and (iv) because of its low atomic number ($Z = 6$) carbon exhibits small cross-section for electron and X-ray diffraction. In this section we discuss the various techniques applied in nanotube research.

4.1. Calculations on Nanotubes

The relationship between SWCNTs and calculations performed on them is a unique one. Since the ideal nanotube structure is well defined but pure and monodisperse samples are scarce, experiments in nanotube science were not *initiating* first principles calculations but quite often *verifying* them. The special physics caused by the one-dimensional character of SWCNTs was well understood by 1995 [184]. The Dresselhaus group at MIT has systematically studied the electronic [185], magnetic [186], and phonon [187] band structure of SWCNTs. Nanotubes were shown to be thermodynamically stable [188] and to favor hexagonal packing [36] with only weak intertube coupling [189].

Currently structural *ab initio* calculations are mostly used to explore the effects of deviations from the ideal cylindrical sp^2 carbon network due to sp^3 defects [190, 191], B and/or N substitution [192], and doping [193–196]. Molecular dynamics simulations are used continuously to suggest nanotube formation mechanisms [62, 197–202]. Some other fields of nanotube research where calculations are making important contributions are: (i) the refinement of our understanding of the special quantized nature of nanotubes [203–208], (ii) H_2 storage related simulations [209–215], and (iii) studies on functionalized SWCNTs [127, 216–218].

4.2. Nanotube Microscopy

Single wall carbon nanotubes were first observed by TEM. Low resolution TEM is regularly used to detect non-nanotube carbon and leftover catalyst contamination in SWCNT samples. Images of nanotube bundles curving through the TEM focal plane provided evidence for the trigonal lattice of SWCNT quasi-crystals and several interesting carbon nanostructures like nanotube coils [219], nano-onions [220], nanocones [221], bamboo-shaped rods [222, 223], etc. were also found as side products of SWCNT electron microscopy. HRTEM can be used to directly measure tube diameters and observe various cap shapes. Iijima et al. [53] published HRTEM images of the continuous junction between tubes of two different diameters proving that heptagon–pentagon defect pairs may occur even in otherwise undamaged nanotube walls. Young's modulus of multiwall [224] and single wall carbon nanotubes [225] was estimated for the first time from intuitive TEM experiments by Treacy et al.

The scanning probe microscopy techniques complement TEM in SWCNT research well [226–229]. Though it was shown theoretically that AFM is capable of reaching atomic resolution on nanotubes [230], AFM is typically used at low magnification levels as a fast and economical means to acquire nanotube length, bundle diameter, and sample purity data. STM, on the other hand, has been applied with considerable success to SWCNT atomic structure elucidation. The first low temperature measurements by Wildoer et al. [231] and Odom et al. [232] showed that the nanotube walls are made of hexagonally arranged carbon atoms and that metallic and semiconducting tubes coexist in SWCNT samples. This was further confirmed by the room temperature results of Hassanien et al. [233]. The chiral angle Θ can often be precisely measured on atomically resolved STM images. Several different angles were observed and this put an end to the early TEM based assumptions that SWCNT samples are dominated by achiral (10,10) tubes. However, neighboring nanotubes of the same apparent helicity (zigzag) were observed in a SWCNT bundle by Hassanien et al. which argues in favor of the "one rope—one helicity theory." Nevertheless, care must be exercised when extracting helicity information from STM images since (i) distinguishing between the intrinsic chirality of the SWCNT and a large scale axial twisting of the tube is not

straightforward [234] and (ii) the geometry of the interaction of the STM tip with a thin nanotube cylinder is rather complex [229, 235].

The electrical conducting properties of nanotubes can be directly measured by scanning tunneling spectroscopy (STS), an STM modus where the tip is held fixed above a chosen sample point and the tunneling current is measured as a function of the bias voltage [236, 237]. The distinction between metallic and semiconducting tubes is then readily made on the basis of the measured I–V characteristics. It is even more useful to study the $\frac{\partial I}{\partial V}/\frac{I}{V}$ vs V curve which is the measure of the electronic DOS. STS experiments on isolated SWCNTs proved the existence of van Hove singularities [238] and made it possible to measure the bandgap of nanotube semiconductors. It was possible to probe the local density of states near the tip of SWCNTs by STS and find sharp resonant valence band states filling the bandgap [239, 240]. While most of the available STS data support the predictions of the simple model described in Section 1.2.2, in a recent report Ouyang et al. [241] argued that only isolated armchair SWCNTs are true metals. Bundled armchair tubes have a pseudogap whose width scales roughly with the inverse tube diameter, and "metallic" zigzag SWCNTs in fact do possess real energy gaps scaling with the inverse square root of tube radius [242].

Scanning probe microscopy is suitable for measuring the mechanical properties (Young's modulus, toughness, strength) of SWCNTs [243–245]. It can also be used for manipulating individual SWCNTs to create, for example, nanotube junctions [246] or field effect transistors (FETs) and to cut nanotubes [247]. The laborious pushing–rolling cycles of moving a nanotube around a surface can be avoided by using the new technique described by Cheung et al. [248]. Nanotubes themselves make superior SPM tips for high resolution topography imaging [249, 250]. Lieber's group pioneered the use of nanotubes as probes for individual biomolecules [31, 251–253]. The best results are achieved when the tubes are grown directly on the SPM cantilever [254–258]. An exciting new field is the utilization of covalently functionalized nanotubes as tips for chemical force microscopy [259, 260].

Some recent advances in SWCNT microscopy include the introduction of Fresnel projection microscopy [261, 262] and near field spectroscopy.

4.3. Optical Spectroscopy

Optically allowed transitions (OATs) from the ith valence to the jth conduction band follow the selection rules $(j - i) = 0$ and $|j - i| = 1$ for electric fields polarized parallel and perpendicular to the nanotube axis, respectively. Since in the latter case the OAT is suppressed because of the depolarization effect, in practice we only have to consider the symmetric E_{ii} transitions between the equidistant van Hove singularities below and above the Fermi energy. Each transition gives rise to a peak in the nanotube UV-vis–NIR absorption spectrum. Peaks at around 0.7, 1.2, 1.8, and 2.5 eV come from the E_{11}^{sc}, E_{22}^{sc}, E_{11}^{m}, and E_{33}^{sc} OATs where "*sc*" and "*m*" denote semiconducting and metallic tubes, respectively. The exact position, shape, and width of the peaks are determined by the diameter distribution of the sample and the DOSs of the individual tubes. Bachilo et al. have suggested a method for rapidly surveying the (n, m) composition of bulk SWCNT samples using bandgap fluorescence spectroscopy [39, 263].

Optical absorption measurements have provided the data to estimate the diameter distribution [264, 265], the bandgap size, the γ_0 transfer energy, and the dielectric function of SWCNTs. Kazaoui et al. [266, 267] conducted an optical absorption study on the n- and p-type doping of a SWCNT sample using Cs as electron donor and Br_2 as electron acceptor partners. In both cases, the intensity of the first few (low energy) absorption peaks decreased with increasing dopant concentration. This could be explained by the gradual filling of the conduction band or the valence band with electrons/holes in n- and p-doping, respectively. Both effects extinguish van Hove singularities gradually, decreasing the possibility of an OAT involving that particular vHs which manifests as a loss of absorption band intensity in the spectrum. Close to saturation the authors observed new peaks at 1.07 and 1.30 eV for Br- and Cs-doping, respectively. They tentatively assigned these to intersubband transitions in the valence (for Br) and the conduction (for Cs) bands. Finally, the presence of the characteristic peaks in the UV-vis–NIR spectrum can be used to demonstrate that the sample retained its special one-dimensional electronic structure even after performing purification and/or functionalization chemistry on it.

4.4. Raman Spectroscopy

Raman spectroscopy is a very potent SWCNT characterization technique. High resolution spectra can be collected from practically all sample forms, at any sample temperature, even *in-situ* while, for example, monitoring the progress of a chemical reaction. Moreover, the SWCNT Raman spectrum is relatively simple to interpret yet informs us about the diameter distribution, electronic properties, and purity of the sample. This section discusses the major components of the spectrum and refers the reader to the available reviews [33, 268, 269] for more details.

4.4.1. Basics of Single Wall Carbon Nanotubes Raman spectroscopy

Phonon dispersion relations and phonon densities of states of SWCNTs are calculated by zone folding of a graphene sheet with special attention to certain nanotube specific differences [187]. A SWCNT with N hexagons in its unit cell [Eq. (7)] has altogether $6N$ possible phonon modes. The number of actual distinct phonon branches is usually much smaller because of mode degeneracies, for example, 66 (54 doubly degenerate plus 12 nondegenerate) instead of 120 in the case of the $(10, 10)$ tube. Four phonons are always acoustic: two degenerate transverse acoustic modes corresponding to x and y displacements perpendicular to the nanotube axis, a twisting acoustic mode for the rigid rotation around the tube axis, and a longitudinal acoustic for displacement along the axis. These four give rise to a constant nonzero phonon DOS at very low energies, which increases stepwise with the energy as the optical phonons enter. Each new subband introduces a 1D van Hove singularity into the phonon DOS.

Only a small portion of the $6N - 4$ optical phonon modes is Raman active because of symmetry reasons. As only k vectors very close to $k = 0$ can couple to the incident light, one has to consider only the symmetry of the vibrations at the center of the Brillouin zone (Γ point). Therefore, the point group of the unit cell can be used to find the Raman active vibrations which are $\Gamma^{\text{vib, Raman}}_{(n,n)|n=2k} = 4A_{1g} + 4E_{1g} + 8E_{2g}$, $\Gamma^{\text{vib, Raman}}_{(n,m)|n\neq m\neq 0} = 4A + 5E_1 + 6E_2$, and $\Gamma^{\text{vib, Raman}}_{\text{others}} = 3A_{1g} + 6E_{1g} + 6E_{2g}$. It is important to note that the number of Raman active modes (16 for even n armchair tubes, 15 for all others) is independent of the tube diameter and chirality, even though the number of total optical phonon modes ($6N - 4$) varies a lot. The *frequency* of a particular mode, however, may or may not be sensitive to the tube diameter. For example, the low frequency (below 500 cm^{-1}) modes soften quasi-linearly with $1/d$ [270] while other modes between 1000 and 1200 cm^{-1} show an opposite behavior and the highest frequency modes around 1580 cm^{-1} are not very diameter sensitive [271–273]. Some Raman active modes have only a very small Raman cross-section and therefore, only 6–7 modes are typically observable experimentally. On the other hand, SWCNT samples are always [274] mixtures of different helicities. Consequently, it is rather common to find several (even more than 16) peaks in a measured spectrum since the same symmetry mode could appear at j different positions for j different tubes.

Perhaps the most striking feature of SWCNT Raman spectroscopy is the enormous *resonance enhancement* of the signal at selected laser wavelengths. The scattering intensity is enlarged by orders of magnitude when the energy of the incident (laser photon) or the scattered (laser photon–absorbed phonon) light matches the energy of an OAT between a vHs pair in the electronic DOS. The enhancement is so strong that even fifth order Raman spectra could be observed with its help [275]. Since the position of the vHs's and, accordingly, the E_{ii} OAT energies are helicity dependent, it is possible to measure only a few desired (n, m) tubes selectively even in heterogeneous samples by selecting the excitation laser to match the corresponding OAT frequency [276]. The large enhancement factor will then ensure that most of the Raman signal comes from the chosen tubes and the others remain "silent." In an inverse experiment Jorio et al. succeeded in focusing the laser beam on one SWCNT and fine-tuned the excitation laser around an OAT frequency [277]. They plotted the intensity of a selected Raman peak as a function of laser energy and thus were able to directly map the singularities in the SWCNT joint DOS. Their results indicate that a vHs may be significantly narrower ($\sim$1 meV) than previously estimated from STS data ($\sim$100 meV).

In Figure 3, the Fourier transform (FT)-Raman spectrum of an arc discharge derived SWCNT sample is depicted. It can be seen that all the theoretical considerations mentioned previously boil down to an admirably simple spectrum which has only three main first order components: the so-called radial breathing mode (RBM) at around 180 cm^{-1}, the D-line at 1330 cm^{-1}, and the G-line between 1560 and 1600 cm^{-1}. Typical second order and combination bands are also depicted. In the following sections we will discuss the

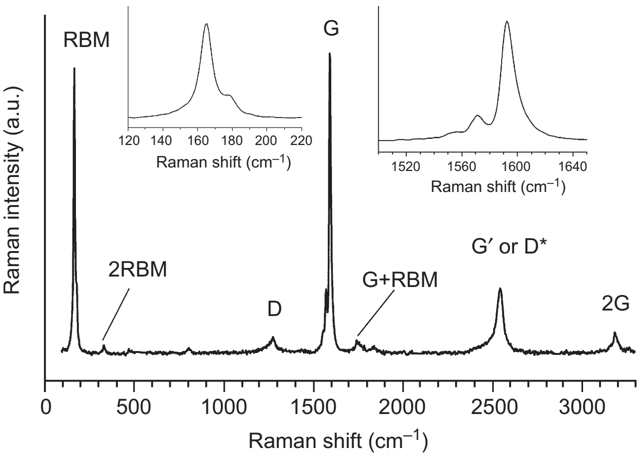

Figure 3. FT-Raman spectrum of a SWCNT sample showing the characteristic first and second order bands as well as the G+RBM combination band. The insets reveal the typical detailed shapes of the RBM and the G-line.

information one can get from each of these bands. Unless indicated otherwise, all experiments refer to Stokes Raman spectra ($E_{\text{scattered}} = E_{\text{laser}} - E_{\text{phonon}}$).

4.4.2. Radial Breathing Mode

The radial breathing mode is a low frequency (150–300 cm^{-1}) A_1 mode corresponding to the total symmetric in-phase motion of all carbon atoms in the SWCNT wall perpendicular to the tube axis. It has a large Raman cross-section and its position is sensitive to the tube diameter (d). Therefore, it is a valuable tool for SWCNT research. The RBM Raman shift ω_{RBM} scales linearly with $1/d$ as

$$\omega_{\text{RBM}} = \frac{C_1}{d} + C_2 \qquad C_1, C_2 \in \mathbf{R}$$
$$[C_1] = \text{cm}^{-1}\,\text{nm} \qquad [C_2] = \text{cm}^{-1} \tag{15}$$

It should be noted that although the RBM frequency is a reliable means of investigating SWCNT diameters in the d =0.7–2.0 nm range, its cross-section is itself a function of d and decreases rapidly with increasing tube diameter, complicating studies on thick tubes. In Eq. (15) C_1 is the proportionality constant and C_2 compensates for intertube interactions. Choosing the right values for these two is the key to get accurate tube diameter estimates and has been frequently addressed in the literature. Suggested (C_1, C_2) pairs based on fitting experimental data are (224, 14) [278] (232, 6.5) [279] (214, 6) [280], and (239, 8.5) [81]. Values based on theoretical calculations were reported as (234, 0) [203] and (223.75, 0) [281]. Jorio et al. have found (248, 0) to describe their single tube experiments the best [282].

A remarkable feature of the RBM is that its position varies with the energy of the excitation laser in an oscillatory fashion even when measuring the very same SWCNT sample [283, 284]. The phenomenon can be explained by considering that (i) SWCNT samples are always made of several different diameter tubes and (ii) the position of the van Hove singularities in the DOS and, consequently, the E_{ii} energies of the OATs responsible for the resonance Raman

enhancement are dependent on the diameter (helicity) of the SWCNT. Each laser line brings different (n, m) nanotubes into resonance. The contribution of these few tubes to the total RBM will be dominant and the spectrum will show a peak at the $\omega_{\mathrm{RBM}}(d)$ frequency determined by Eqs. (3) and (15). Tuning to another laser wavelength brings a new set of tubes into resonance, and therefore the dominant RBM peak will appear at a different position. It is quite useful to study the so-called *Kataura plot* depicted in Figure 4 to visualize the events for ourselves. Each point in this plot corresponds to an OAT energy (ordinate) for a chosen nanotube diameter (abscissa). Let us now consider a sample containing SWCNTs in the $d = 1.0$–1.5 nm diameter range and excite it with a laser emitting $E_{\mathrm{laser}} = 2.0$ eV photons. This energy matches the first optical transition of $d \sim 1.3$ nm metallic nanotubes found in the sample, and therefore the dominant RBM peak will appear at $\omega \sim 190$ cm^{-1} (top x axis). By increasing E_{laser} slowly we hit the $E_{11}^{\mathrm{metallic}}$ OAT of thinner and thinner metallic tubes so the RBM peak will wander to higher and higher frequencies. At a certain point the E_{laser} energy will be high enough to excite the $E_{33}^{\mathrm{semicond}}$ transition of the thickest semiconducting SWCNTs in our sample; thus there will be two major RBM peaks: one corresponding to the diameter of the thinnest metallic (at $\omega \sim 248$ cm^{-1}) and one to the thickest semiconducting tube ($\omega \sim 190$ cm^{-1}). The former will disappear when increasing E_{laser} any further, the latter will start wandering upward, and the process will repeat itself again when the excitation energy reaches the $E_{44}^{\mathrm{semicond}}$ OAT and so on. Even though the overall result is apparently a RBM peak moving between 190 and 248 cm^{-1} the reader should remember that this is a resonance effect and that the position of the RBM peak of any given SWCNT depends neither on E_{laser} nor on tube conductivity. Kataura plots can be used to do approximate (n, m) assignments [284, 285]; however, the accuracy of such calculations is limited by the accuracy of the underlying DOS

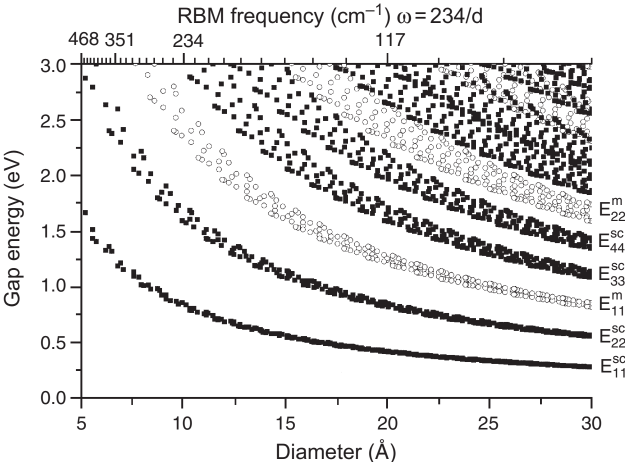

Figure 4. A plot of the bandgap energy vs nanotube diameter for all possible nanotubes within the diameter range 0.5–3.0 nm ("Kataura plot"). Black squares and open circles denote semiconducting and metallic tubes, respectively. The calculated position of the Raman RBM peak for each diameter is given on the top x axis. Public domain data from the homepage of Dr. S. Maruyama (University of Tokyo, Tokyo, Japan) were used for creating this figure.

calculation as well as by experimental issues like intertube interactions and spectral resolution.

The positions of the RBM peaks inform us about individual tubes only. In order to obtain the more useful *diameter distribution* parameters it is advantageous to analyze the oscillations of the first and second spectral moments [286] of the whole radial breathing mode band measured at several different laser energies to avoid biasing the distribution toward a certain diameter via the resonance effect. The required formalism has been recently reviewed by Kuzmany et al. [287].

4.4.3. Defect Induced Mode (D-Line)

The so-called D-line is a weak to medium intensity peak observed between 1300 and 1350 cm^{-1} in visible excitation SWCNT Raman spectra. Its most striking feature is that it upshifts approximately 50 cm^{-1}/eV when increasing the laser excitation frequency. The position of the D-line is not particularly sensitive to the diameter distribution of the sample. In the early SWCNT Raman investigations the D-line was usually assigned to the unidentified graphitic/amorphous carbon contamination accompanying the nanotubes. The SWCNT D-line has a similar counterpart in graphite which itself has puzzled researchers for decades and initiated several incorrect interpretations. Finally, Thomsen and Reich succeeded in explaining the graphitic D-line by developing a double resonance theory for it [288]. The authors have shown that the double resonance model is applicable to SWCNTs as well and that only the $(n - m)/3d_H \in \mathbf{Z}$ [see Eq. (6)] nanotubes contribute to the D-line [289]. Single tube measurements by Souza et al. verified that the position of the D-line is sensitive to the chirality of the nanotube and explained this with a resonance effect between the van Hove singularities in the SWCNT DOS [290]. The most comprehensive theory of the SWCNT Raman D-band is that of Kürti et al. who take both the double resonance process and the van Hove singularities into account [207]. This theory is able to predict the small deviations from linearity in the dispersion of the SWCNT D-line reported by Grüneis et al. Kürti et al. suggest that the fine structure of the D-line dispersion profile could be sensitive to the diameter distribution.

The message of these theoretical advances is that it is not necessary to have macroscopic impurities in a nanotube sample to observe the D-line. However, the presence of a defect site is certainly required by all double resonance models. It is therefore correct to regard the D-line as an overall indicator of defects: sp^3 carbon atoms, holes in the SWCNT walls, attached functional groups, and, indeed, non-nanotube graphitic domains may all contribute to the D-line. It is customary in the nanotube literature to report the intensity ratio of the D-line to the G-line as an indicator of sample purity ("pure" meaning both "amorphous carbon-free" and "defect-free" as discussed previously). As a rule of thumb we can say that the larger the G/D ratio, the higher the sample quality.

An interesting feature in the second order SWCNT Raman spectrum is the G′-line (also called the D*-line by some authors) found between 2500 and 2900 cm^{-1} [291]. The G′-line shows a dispersion of ~100 cm^{-1}/eV with E_{laser}. This first overtone of the D-line is generally more intense

than the D-line itself because the G′ is symmetry allowed. The recent work of Souza et al. indicates that the fine structure of the G′-line is rather informative and should be studied in detail [292].

4.4.4. Tangential Modes (G Band)

The most intense lines of the SWCNT Raman spectrum are found between 1560 and 1600 cm^{-1} in the so-called the G-band which corresponds to the tangential C–C stretching vibrations. The band consists of non- or weakly diameter dispersive phonons of A_1, E_1, and E_2 symmetries. It is rather insensitive to E_{laser} as long as the character of the dominant, resonantly enhanced nanotubes is the same (i.e., either semiconducting or metallic). When the main spectral contribution comes from semiconducting SWCNTs (e.g., 2.1 eV < E_{laser} < 2.7 eV for a typical sample with Gaussian diameter distribution $d = 1.35$ nm, $\sigma = 0.15$ nm) then the G-band is dominated by a sharp peak at ~1592 cm^{-1} accompanied by a sideband at ~1560 cm^{-1}. G-bands of semiconducting SWCNTs can be fitted very well with six Lorenztian oscillators [one longitudinal (LO) and one transversal (TO) mode for each of the three allowed symmetries] [293].

Although peaks from semiconducting tubes are always present in the G-band to some extent, the characteristic features of G-bands dominated by metallic nanotubes (1.7 eV < E_{laser} < 2 eV for the aforementioned distribution) are three new, broader peaks at ~1515, 1540, and 1580 cm^{-1}. The 1540 cm^{-1} peak is intense, broad, and asymmetrically elongated toward the lower frequencies. Unlike the other peaks which are well fitted with Lorentzian oscillators, the 1540 cm^{-1} one has a Breit–Wigner–Fano (BWF) lineshape [264],

$$I_\omega = I_0 \frac{[1 + (\omega - \omega_{BWF})/q\Gamma]^2}{1 + [(\omega - \omega_{BWF})/\Gamma]^2} \tag{16}$$

where I_0, ω_{BWF}, $1/q$, and Γ denote the maximum intensity, the renormalized frequency, a coupling parameter, and the full width at half maximum, respectively. BWF lineshapes have been reported previously for several metallic carbon species like alkali metal intercalated graphite [294] and C_{60} [295]. They arise from the coupling of a phonon mode (in the case of SWCNTs an A_1(LO) [208] or A_1(TO) [273, 296] phonon) to the electron continuum and can be regarded as a telltale signal of the presence of metallic nanotubes. The intensity ratio I_{1540}/I_{1592} is routinely used as a semiquantitative indicator of the relative contribution of metallic SWCNTs to a given Raman spectrum. The position of the BWF line has been found to be more sensitive to the diameter of the investigated nanotubes than other components of the G-band [208].

The main semiconducting G-line peak found at 1592 cm^{-1} at room temperature shifts about –0.012 cm^{-1}/K with increasing sample temperature [297, 298]. This effect can be used to estimate the local temperature experienced by the sample hit by the Raman laser and to characterize sample purity [299]. The former effect is particularly useful since the usual temperature sensor of Raman spectroscopy, the Stokes/anti-Stokes intensity ratio, fails for SWCNTs because of the resonance effect. Charge transfer to and from the nanotube (n- and p-type doping) also shifts the G-band to lower and higher frequencies, respectively [172, 175]. Maultzsch et al. examined the dispersion of the various G-band components with E_{laser} and suggested that the G-band could also result from a double resonance process similar to the D-line [206].

4.4.5. Other Raman Features of Interest

Although understanding the RBM, the D-line, and the G-band should enable the reader to benefit from the majority of the SWCNT Raman research papers available, one should not forget about developments that took place in more specialized fields of nanotube Raman spectroscopy. Peaks showing strong energy dispersion have been found in the intermediate (600–1200 cm^{-1}) frequency range of the spectrum [300]. Differences between semiconducting and metallic tubes were found when studying the anti-Stokes Raman spectra [301–303] and when performing surface enhanced resonant Raman experiments [304–306]. Polarized Raman experiments helped in identifying the symmetry of the components of the G-band [307–310]. UV Raman studies uncovered notable differences between the RBM and D-line intensities in UV ($E_{laser} = 4.8$ eV) and visible SWCNT Raman spectra [311]. The possibility of helicity assignment based on the splitting of the van Hove singularities in the DOS due to the trigonal warping effect was suggested by Saito et al. [43].

4.5. Other Characterization Methods

Even though SWCNTs are very thin and beam-sensitive, some groups have managed to calculate [312] and measure nanotube electron diffraction (ED) patterns [313, 314] and in some cases even succeeded in ED (n, m) assignment [315, 316]. The parameters of the trigonal SWCNT lattice in bundles have been obtained from X-ray diffraction studies [20, 281]. Rols et al. have recently shown that diameter distribution estimates based on XRD agree sufficiently with, for example, TEM results if the finite size of the nanotube bundle is taken into account upon XRD evaluation [317, 318]. Inelastic neutron scattering is a powerful alternative to Raman spectroscopy for studying the SWCNT phonon structure because in contrast to optical probes, all phonons are active to neutrons [319–321]. Rayleigh scattering was utilized by Yu and Brus [322] to study the interband transitions of SWCNTs and by Puretzky et al. to investigate the dynamics of the PLV synthesis method [323].

Investigations based on magnetic interactions [electron paramagnetic and nuclear magnetic resonace (EPR, NMR)] in SWCNTs are generally not as informative as for other materials. Pure SWCNTs do not show any intrinsic EPR features; the formerly reported $g = 2.002$ asymmetric line [324] is now thought to be due to charge transfer effects. On the other hand, SWCNTs do have their own ^{13}C MAS NMR signature: a broad isotropic line at 126 ppm (relative to TMS) which can be deconvoluted into Lorentzian semiconducting and metallic contributions [325, 326]. The recent increased interest in SWCNT functionalization, however, has opened up new fields of application for ^{13}C NMR in nanotube research. Functional groups are anchored to the nanotube via sp^3 carbons giving a signal at 29 ppm and also show their own chemical shifts (e.g., 182 ppm for –COOH groups) [327].

Although SWCNTs do have infrared (IR) active phonons that can be described as $\Gamma^{\text{vib, IR}}_{(n,n)|n=2k} = A_{2u} + 7E_{1u}$, $\Gamma^{\text{vib, IR}}_{(n,m)|n\neq m\neq 0} = 4A + 5E_1$, and $\Gamma^{\text{vib, IR}}_{\text{others}} = 2A_{2u} + 5E_{1u}$, infrared spectroscopy is seldom used for characterizing pure SWCNT samples because all IR active modes are very weak. IR reflectance studies on untreated SWCNT samples are available in the mid-IR regime from Kuhlmann et al. [328, 329] and in the far-IR from Ugawa et al. [330, 331]. In a mid-IR transmission experiment Kastner et al. found one broad and asymmetric line at 1575 cm^{-1} and a weaker line at 868 cm^{-1} [332]. On the other hand, once the symmetry of the SWCNT structure is broken, IR spectroscopy becomes a rather helpful tool. Several authors used the IR spectrum of sidewall functionalized nanotubes to prove the presence of, for example, carboxylic acid [37, 148, 157, 333], ester [334], amide [335, 336], quinone [333], and fluoride [337] groups as well as the formation of more complex heterostructures [338] and physisorbed complexes [339]. Substituting carbon atoms in the SWCNT wall can also be studied by IR spectroscopy as it was shown for boron [340] or nitrogen [341, 342] substitution recently.

The EELS of SWCNTs was measured in 1994 by Kuzuo et al. [343] to be different from that of multiwall carbon nanotubes [344] and of graphite. According to Knupfer et al. [345] the two strongest peaks in the loss function arise from the π plasmon (the collective excitation of the π system) and the $\pi + \sigma$ plasmon (the excitation of all valence electrons) at 5.8 and 21.5 eV for $q = 0.15$ Å^{-1}, respectively. Another set of low intensity, low energy (0.6, 1.2 eV) nondispersive peaks could be assigned to interband transitions between the van Hove singularities in the SWCNT electronic density of states. These peaks can be correlated with optical absorption peaks after performing Kramers–Kronig analysis and could be used for studying alkali metal intercalation into SWCNT bundles [346–349]. EELS was successfully applied for detecting chemical bonds between SWCNTs and Pt nanoclusters [350] and for identifying endohedral metallic oxide functionalization [351]. Finally, EELS has become an indispensable tool in B- and N-doped SWCNT research since it allows the simultaneous determination of atomic composition and heteroatom hybridization state [167, 352–354].

The gas adsorption properties of SWCNTs received much attention because of their potential application for H_2 storage [104]. Isotherms are available for, for example, N_2 [355–359], O_2 [356], Ar [359, 360], Kr [361], Xe [333, 362–365], CH_4 [361, 366, 367], CF_4 [364], SF_6 [364], C_6H_6 [355], and CH_3OH [355]. Small molecules are predicted to adsorb both within open tubes and in the interstitial space while large molecules clearly prefer adsorption inside the nanotube [368]. As expected, single wall carbon nanotubes are essentially microporous adsorbents with BET surface areas exceeding 400 m^2/g [369]. However, it is important to realize that closed (as synthesized) and opened (oxidized) SWCNTs have different sorption properties. In the latter adsorbates enjoy a favorable potential within the tubes and thus the tube interior is filled up completely before adsorption starts in the interstitial channels [356]. Ohba and Kaneko argue that the BET analysis is inapplicable for nanotube surface area determination [370]. According to Du et al. the diameter of the open pores can be reliably analyzed using the Horvath–Kawazoe method [359].

5. PROPERTIES OF SINGLE WALL CARBON NANOTUBES

One should always be aware of the heterogeneity of the SWCNT samples used for determining the physical properties of the material. While the SWCNT as a molecule is a well-defined entity, bulk nanotube samples available currently are mixtures of various different helicities at best. Samples reported in the literature come from different sources, may contain amorphous carbon impurities and/or leftover catalyst particles, and may have been subjected to different postsynthetic treatments. In this section we report on what appear to be the basic common characteristics of SWCNTs. The most important parameters are summarized in Table 1.

5.1. Macroscopic Properties and Handling

A SWCNT sample usually appears as a fluffy black powder with very low apparent density. It cannot be dissolved in any solvent and does not melt or sublimate in vacuum up to 1400 °C. Apart from irritating the respiratory system if inhaled, it is a nontoxic material. However, samples may contain harmful contaminants like carcinogen polyaromatic hydrocarbons and also the intrinsic carcinogenety of nanotubes cannot be ruled out at the present state of knowledge. For ease of handling the powder is often transformed into a randomly oriented mat of entangled SWCNTs (*buckypaper*) by dispersing the nanotubes in a solvent and filtering the dispersion through a ~0.4 μm pore filter. The dried buckypaper can be investigated by Raman spectroscopy and scanning

Table 1. A summary of the physical properties of single wall carbon nanotubes.

Property	Value	Ref.
Length	50 nm–1 mm	[371, 372]
Diameter	0.4–5.6 nm	[94, 373]
Density	0.040–2 g/cm^3 (buckypaper—individual tube)	[374, 375]
Lattice	trigonal *P6/mcc* space group	[20, 36]
Melting point	>1400 °C in vacuum	[2]
Specific surface area	151–1315 m^2/g	[376]
Specific heat	~610 mJ/(gK)	[377]
Thermal conductivity	35 W/mK (disordered) 200 W/mK (aligned)	[378, 379]
Debye temperature	960 K (in-tube) 13 K (intertube)	[377]
Dc conductivity at 300 K	6.9×10^4 S/m	[375, 380]
Dielectric constant at 10 kHz	$\sim -1.8 \times 10^4$	[375]
Susceptibility	$\sim -10 \times 10^{-6}$ emu/g (anisotropic)	[381]
Maximum electric current density	$>10^9$ A/cm^2	[382, 383]
Bandgap	~0.7 eV (semiconducting)	[384]
Young's modulus	1.25–0.35/+0.45 TPa	[225]
Tensile strength	~45 GPa	[243]

electron microscopy or used in electrochemical experiments without further treatment.

Though not soluble in the classical sense, SWCNTs can be finely dispersed in liquid phase by ultrasonication. Care must be exercised when setting the parameters as tubes may break during the process [107, 385]. The right solvent is chosen by trial-and-error because the dispersability of a certain nanotube sample in a given solvent depends largely on the type and parameters of the SWCNT synthesis method, the sample morphology, and also the postsynthetic treatments (e.g., purification) applied. In general 1,2-dichlorobenzene, CS_2, N,N-dimethyl-formamide, and 2-propanol are worth trying before others. Recently Walters et al. [386] succeeded in preparing aligned nanotube membranes by filtering a SWCNT solution in a strong magnetic field. Dispersions containing individually separated SWCNTs can be obtained by ultrasonicating nanotubes in an aqueous detergent solution. Ionic (e.g., alkali-dodecylsulphates) [39, 387] and nonionic [388] surfactants were both shown to perform adequately. Surfactant assisted suspensions are the only systems where successful high pressure liquid chromatography separation of unfunctionalized nanotubes was reported [38, 108, 389]. Nanotube dispersions can be directly studied by techniques like UV-vis–NIR spectroscopy or light scattering. When a SWCNT film is more appropriate for the measurement it can be obtained by drop-, spin-, or spray-coating substrate. Such samples are used in optical absorption spectroscopy and IR spectroscopy. In the former case the substrate is quartz, and in the latter it is a gold mirror which is measured in reflection–absorption geometry. Samples for nanotube microscopy are generally produced by drop-coating an adequate substrate (e.g, highly oriented pyrolitic graphite, gold, Si) with a highly diluted nanotube suspension.

5.2. Mechanical Properties

Nanotubes have exceptional mechanical properties [390–392]. Walters et al. [243] measured the tensile strength of SWCNTs and found a maximum elastic strain of $5.8 \pm 0.9\%$. Taking 1.25 TPa as the Young's modulus of a SWCNT [225] they calculate the yield strength of a SWCNT rope to be 45 ± 7 GPa—an order of magnitude better than that of high quality steels. Chesnokov et al. found that the reversible work done in compressing a nanotube sample to 29 kbar is 0.18 eV/C atom and suggested that nanotubes could be applied as strings for mechanical energy storage [393].

5.3. Electronic and Heat Conductance

SWCNTs are one-dimensional conductors with only two open conduction channels in the case of armchair tubes, and therefore it was expected that their conduction electrons should localize with increasing length. However, White and Todorov showed that SWCNTs could in fact be ballistic conductors with localization lengths over 10 mm [394]. Experimental evidence for the ballistic conductance of MWCNTs [395] and SWCNTs [396] was also found. Very thin SWCNTs synthesized within the pores of aluminosilicates were reported as superconductive [96] with a transition temperature of 15 K. Another interesting feature of SWCNTs is that they exhibit strong electron–electron correlation effects (Luttinger liquid behavior) [397, 398]. For some recent work on nanotube transport properties, see, for example, [399–402].

The thermal properties of SWCNTs are determined by the 1D quantized phonon band structure [403–406]. The specific heat of SWCNTs is very close to a graphene sheet above $T = 50$ K but is significantly smaller at lower temperatures [377]. Macroscopic thermal properties were found to be rather sensitive to the alignment of SWCNTs in the sample: the room temperature thermal conductivity of a random nanotube mat is 35 W/mK while that of an aligned sample is ~200 W/mK [379].

5.4. Optical Properties

The linear polarizability α and third-order nonlinear polarizability γ of SWCNTs was calculated for several finite length SWCNTs by Wan et al. [407, 408]. They found both parameters to be heavily chirality and size dependent. Narrower tubes and tubes with a higher helical degree have larger polarizability [409]. Semiconducting SWCNTs have smaller α and much smaller γ values than metallic ones. The calculations indicate that SWCNTs are promising nonlinear optical materials. Vivien et al. recently published a study on the optical limiting properties of SWCNT suspensions [410]. Ruzicka et al. measured the optical reflectivity and dc resistivity of pristine and potassium doped SWCNT mats [374].

6. APPLICATIONS OF SINGLE WALL CARBON NANOTUBES

In the first decade of SWCNT research efforts were mainly focused on synthesizing nanotubes in sufficient quantity and quality and on understanding their unique physical properties. While there is certainly a lot left to do in these fields as well, it is expected that in the second decade the spotlight will move to nanotube-based applications, devices, and marketable items. In this section we present a brief overview of the current mainstream SWCNT application themes [411].

6.1. Nanoelectronic Devices

The traditional silicon-based electronics industry is quickly approaching the limits of miniaturization where size reduction is no longer possible because of inevitable quantum effects. Nanoelectronics or "single-molecule electronics" therefore became an extensively researched field in the 1990s. Because of their unique properties SWCNTs are regarded by many as potential building blocks for nanoelectronic devices. The three major research directions are currently nanotube semiconductors, sensors, and field emission displays.

FETs utilizing a single carbon nanotube as the active element were first reported in 1998 [30, 412] and have been extensively researched ever since [413–415]. Other elementary electronics units like diodes [177, 398], logical gates [416, 417], and random access memory cells [418] were also prepared from carbon nanotubes. Establishing good contacts between the nanotube and other parts of the circuitry is crucial for the performance of such devices. In fact it was

recently shown by Heinze et al. [419] that transistor action may occur primarily on the contact resistances (Schottky barrier transistors). For a recent review on nanotube semiconductor applications see, for example, Avouris [420].

SWCNT based chemical sensors were first reported in 2000. Collins et al. observed the extreme oxygen sensitivity of the electrical resistance of SWCNTs [421] and Kong et al. used a similar setup to detect small amounts of NO_2 and NH_3 [422]. The detection limit of nanotube based gas sensors already matches or exceeds that of conventional solid state sensors. However, recovery time and the number of duty cycles are still to be improved. The selectivity of nanotube sensors can be enhanced by using a two-layered construction where the outer layer interacts specifically with a target molecule and the inner layer transmits the changes induced by this interaction to the SWCNT in the core of the sensor. Nanotubes were also successfully tested as biosensors [423–425]. Mechanical and thermal strain experienced by a SWCNT containing polymer can also be measured on the basis of specific Raman shifts [426, 427]. An up-to-date review on nanotube based sensors is available from Dai et al. [428].

The market of flat panel displays (FPDs) is rapidly expanding. Active TFT screens can be manufactured cost-effectively only up to approximately 20 inch diagonal and plasma or projection displays are built with diagonals starting at 40 inches. Therefore, the demand for economical FPDs in the size of a normal home TV set is not yet satisfied. One possible solution is the field emission display (FED) which keeps the phosphorescent coating of the old cathode ray tube but uses a separate electron emitter for each pixel. The excellent field emission properties of carbon nanotubes were realized as early as 1995 [429, 430]. The first working display was reported in 1998 [431, 432] and commercial devices are expected to be introduced in 2004. Nanotube FEDs work at quite low turn-on voltages (0.7–4 V/μm) where nanotubes still follow the conventional Fowler–Nordheim model (up to a critical current density [433]). Nanotube FEDs generally utilize aligned nanotube arrays [434–436] grown by the CVD technique directly on the back plate of the display [437, 438].

6.2. Hydrogen Storage

Due to the environmental hazard caused by car exhaust gases an enormous effort is focused to the production of car engines working by combustion of hydrogen with oxygen. If hydrogen fuel cells were used to power automobiles and other vehicles, air pollution would be reduced. Such a fuel cell would be practical only if the hydrogen could be stored on board the vehicle in a safe, efficient, compact, and economical manner. For this purpose, metal hydrides and various carbon materials were investigated [439]. After the discovery of carbon nanotubes they became the most attractive materials for hydrogen storage since they were tubular, the interior of the tubes might be filled with hydrogen, and they are lightweight materials more suitable for preparing adsorbents than metals or metal oxides and hydrides [104, 440].

Optimistic calculations predict that SWCNTs are capable of exceeding the U.S. Department of Energy (DOE) target for H_2 storage; for example, Lee et al. calculated 14 wt% for a (10, 10) tube [441, 442]. While certain studies warn that gases cannot be adsorbed in the interstitial channels of SWCNT bundles [443] Ren and Price interpret their neutron scattering data as evidence for H_2 adsorption in the interstitial space [444]. Wang and Johnson argue on the basis of geometric considerations that it is impossible the meet the DOE target (6 wt%) using SWCNTs at ambient temperature [445, 446]. Recent calculations indicate that the hydrogen storage capacity could be a function of nanotube diameter and chirality [209, 447]. Some published experimental H_2 uptake values for SWCNTs are: (i) 4.2 wt% at room temperature (RT) [448], (ii) 0.932 wt% at RT [449], (iii) 4 wt% at RT [450], and 8 wt% at 77 K [451]. Typically 70–78% of the total hydrogen adsorbed can be released under ambient pressure at RT. Alkali doped SWCNTs appear to perform considerably better: Chen et al. report 14–20 wt% H_2 uptake [452]. Froudakis explains this observation by suggesting that charge transfer from the alkali metal to the H_2 polarizes the latter and the charge-induced dipole interaction makes higher hydrogen storage capacities possible [453]. On the other hand, some doubt has been raised recently that some of the weight increase in the earlier experiments was due to H_2O and not to H_2 uptake [454].

Summarizing, H_2 storage in SWCNTs is at present more of a controversial scientific challenge than a mature technology. Possible future research directions were recently sketched by the experts of the field [439, 455–458].

6.3. Other Applications

Incorporating 0.2–5% nanotubes into plastics [459] offers considerable benefits in two major areas: (i) conducting polymers and (ii) enhanced durability plastics. Nanotube–polymer composites are available with conductances in the 0.01–0.1 S/cm range which is more than enough to dissipate electrostatic charge in, for example, pipelines and filters threatened by static discharge induced explosions. Qian et al. reported that 1% multiwall nanotube incorporation can increase the elastic modulus and the break stress of a polystyrene matrix by 36–42% and ~25%, respectively [460]. Biercuk et al. observed a monotonic increase up to 350% (at 2 wt% SWCNT content) in the Vickers hardness of SWCNT–epoxy composites as a function of nanotube loading as well as a 125% increase (at 1 wt% SWCNT) in the thermal conductivity of the composite [461]. The performance of composites is governed by the quality of the nanotube–polymer interface [218, 462]. It is expected that even better results could be obtained by anchoring functionalized tubes into the matrix through covalent bonds [463, 464].

Some other fields with large potential for development in carbon nanotube applications are nonlinear optics [410, 465–467], heterogeneous catalysis [468–470], and biotechnology [471–474].

7. CONCLUSIONS

Since Iijima's discovery in 1991 carbon nanotube science has developed from a peculiar side branch of fullerene research into a discipline of its own with well over 100 genuine papers published monthly. Though a good deal of the basic physical

and chemical properties is known already, there is still a lot of exciting science left waiting to be explored. It is expected that SWCNT-based devices will make it from the laboratories to the consumer market in the next 5–7 years. The most promising candidates for this seem to be nanotube-based gas sensors, field emission displays, lamps, and nanotube-enforced composites at the moment. The most important challenge today is preparing monodisperse (n, m) samples in macroscopic quantities as this would open the road for manufacturing single-molecule nanoelectronic devices with SWCNTs as active elements. In the long run, the hollow inner space of nanotubes might also be utilized at an industrial scale as a "nano cleanroom" for a whole new chemistry. One thing is certain: this coming second decade of SWCNT research is bound to be lots of fun so be sure to follow it as closely as you can!

GLOSSARY

Buckypaper A thin mat of randomly oriented carbon nanotubes obtained by filtering a carbon nanotube suspension, much like normal paper is obtained by filtering cellulose fiber suspension.

BWF peak A peak with a characteristic Breit-Wigner-Fano lineshape occuring in the low wavenumber branch of the tangential Raman band (G-band) of metallic carbon nanotubes. The asymmetric BWF lineshape is the result of the coupling of a phonon to the electronic continuum and is reduced to a symmetric Lorentzian if there is no such coupling.

Catalytic chemical vapor deposition (CCVD) A gas-solid heterogeneous catalytic synthesis reaction. The carbon source molecule mixed into the gas feed decomposes on the heated solid catalyst particles and forms carbon nanotubes. Sometimes also referred to as CVD.

Density of states (DOS) A characteristic function of a solid which shows the number of available electronic states at a certain energy relative to the Fermi level.

Hamada vector The folding vector along which a hypothetical graphene sheet can be rolled up into itself to form a particular SWCNT. Also referred to as "chiral vector", the Hamada vector determines all of the properties of the nanotube.

Kataura plot A plot of the energies of all optically allowed transitions between the valence and the conduction band of SWCNTs as a function of nanotube diameter. The Kataura plot is very helpful in understanding the peculiar resonance behavior of SWCNTs.

Peapod A nanostructure consisting of fullerenes ("peas") filled into the hollow core of a SWCNT ("pod").

Pulsed laser vaporization (PLV) A synthesis method for preparing carbon nanostructures by evaporating a part of a graphite target using a laser pulse. The nanostructures are formed in the plasma during cooling.

Radial breathing model (RBM) A totally symmetric vibrational modus of SWCNTs when all carbon atoms move in-phase perpendicular to the tube axis.

Single wall carbon nanotube (SWCNT) A quasi one dimensional form of carbon which can be visualized as a very long (above 1 μm) and thin (1–2 nm diameter) rolled-up graphene sheet.

41. Actually, the wave vector along the nanotube axis is also quantized for finite length SWCNTs. However, because of the large aspect ratio of carbon nanotubes this quantization becomes important only when examining transport properties at low temperatures.
42. The so-called "small (or linear) k" approximation holds near the K point of the graphene Brillouin zone. In this approximation the valence and the conduction bands are symmetric and the energy dispersion relation is a linear function of k.

274. The Raman excitation laser is usually focused into a spot with diameter 1–2 mm (macroscopic measurements) or a few micrometers (microscopes). Even the latter is large enough to cover several SWCNTs in the sample. Thus, the measured Raman spectrum is really a weighted average of the various individual tube spectra. The averaging can only be avoided by sophisticated experiment design like depositing dilute SWCNT suspensions onto grids with microscopic markers or that used in the single tube measurements of Jorio et al.

Sliding, Rotation, and Rolling of Nanoparticles

K. Miura

Aichi University of Education, Kariya, Japan

CONTENTS

1. Introduction
2. Sliding, Rotation, and Rolling of Single-Walled Carbon Nanotubes (SWNTs) and Multiwalled Carbon Nanotubes (MWNTs)
3. Sliding of Flakes
4. C_{60} Molecular Bearings
Glossary
References

1. INTRODUCTION

This chapter describes the sliding, rotation, and rolling of nanoparticles on the nanometer scale using scanning probe microscopy, in particular, an atomic force microscope (AFM) and a frictional force microscope (FFM). Nanoparticles described in this chapter are single-walled carbon nanotubes (SWNTs), multiwalled carbon nanotubes (MWNTs), graphite flakes, and MoS_2 flakes. Motions of nanoparticles on the nanometer scale depend strongly on the substrates where nanoparticles perform, exhibiting translational and zigzag sliding, rotation around a pivot, and rolling. The sliding, rotation, and rolling of nanoparticles exhibit novel phenomena, which are different from macroscopic events.

There exist tremendous developments of scanning probe microscopy including an AFM and a scanning tunneling microscope, in the background where one can study the movement of nanoparticles on the nanometer scale. Over the past decade, atomic and molecular manipulations have become possible through techniques derived from scanning probe microscopy, which makes a tip travel on a surface on the order of an angstrom and controls arbitrarily the motions of atoms and molecules. Thus, the technique makes nano- and microlithography possible, thereby leading to applicability for nano- and microdevices. Furthermore, simultaneous measurements of forces during manipulation give crucial knowledge of the changes of materials occurring on the nanometer scale. Hence, it becomes possible to investigate the similarity and difference of behaviors between nanoscopic and macroscopic particles.

The forces needed to manipulate atoms and molecules are consequently equivalent to the lateral force (or frictional force) of atoms and molecules on the nanometer scale when moving atoms and molecules along the surface. Hence, this study leads to that of the friction on the nanometer scale. It is interesting to note that the relationship between nanoscopic and macroscopic sliding, rotation, and rolling is similar to that between nanoscopic and macroscopic friction.

In the second section, sliding, rotation, and rolling of SWNTs and MWNTs are described, where the sliding of the SWNTs on graphite does not occur because the SWNTs form a bundle of self-assembled cables and a nanotube array in the bundle contacts with graphite. In contrast, the SWNTs on a KCl(001) surface slide easily. Natural rolling of MWNTs appears in commensurate contact with a graphite surface. This strongly means that the substrate where nanotubes perform influences their movements.

In the third section, it is also shown that graphite and MoS_2 flakes move so as to keep in commensurate contact with a substrate. The graphite flake moves on graphite such that the stacking of graphite layers is maintained. The MoS_2 flake also moves on MoS_2 such that the stacking of the sulfur basal plane of MoS_2 is maintained. In the case where the flake movement is parallel to the pulling direction, the frictional force is smallest. Furthermore, the appearance of the zigzag movement would originate in the rotation of the flake around a pivot point in addition to translation.

In the last section, C_{60} molecular bearings are described. In this section, the applicability and realization of C_{60} molecular bearings, and the detailed mechanism of their movement, are described. C_{60} molecules grow on graphite such that the hexagonal face of a C_{60} molecule pairs with the hexagonal face of the second graphite layer, so as to continue the natural stacking of the graphite. Thus, we can construct a system confining a C_{60} monolayer between graphite plates, which forms the nanogears of six-membered rings between C_{60} molecules and graphite. C_{60} molecules roll by their nanogears. Then, the novel frictional mechanism is realized in the graphite/C_{60} monolayer/graphite system, in which static frictional forces have a finite value but mean dynamical frictional forces are zero. It is emphasized that

the graphite/C_{60} monolayer/graphite system is very promising for the realization of nano- and micromachines.

2. SLIDING, ROTATION, AND ROLLING OF SINGLE-WALLED CARBON NANOTUBES (SWNTs) AND MULTIWALLED CARBON NANOTUBES (MWNTs)

Carbon nanotubes have attracted increasing interest due to their mechanical as well as electronic properties. Because of their high tensile strength, flexural rigidity, and high aspect ratio, they are promising candidates for strong fibers. SWNTs are known to be arranged mostly in the form of fibers with closely packed stacking [1], which thus form self-assembled cables on the nanometer scale. The elastic and shear moduli of SWNTs are measured to be of the order of 1 TPa and 1 GPa, respectively [2]. Consequently, we expect large elastic and shear moduli for SWNTs. Because of their shapes, which are similar to those of C_{60} and C_{70} fullerenes, the nanotubes are also promising as an ideal means of lubrication. We need to control the alignment of nanotubes to enable their use as a lubricant. Sliding and rolling behaviors of nanotubes including fullerene molecules depend strongly on their interactions with the substrate [3–8]. For example, SWNTs are bent on a KCl(001) surface but are aligned on graphite resulting in a threefold symmetry [8]. This is the reason why six carbon rings of the nanotube pair with those at the basal graphite surface, in the same manner as the stacking of graphite layers. In this case, the sliding of the SWNTs on graphite does not occur because the SWNTs form a bundle of self-assembled cables and a nanotube array in the bundle contacts with graphite. In contrast, the SWNTs on a KCl(001) surface slide easily, resulting in a shear stress of 3 MPa. Falvo et al. [3, 4] show the stick-slip lateral force behavior for rolling of MWNTs. Let us show in detail sliding, rotation, and rolling of SWNTs and MWNTs in this section.

2.1. Bundle Structure of SWNTs and their Sliding

2.1.1. Bundle Structure of SWNTs

FFM images of nanotubes on the KCl(001) surface and of those on the graphite (highly oriented pyrolytic graphite: HOPG) surface are shown in Figure 1a and b, respectively. An appreciable difference between these images appears in the configuration of the nanotubes on the substrate. Many nanotubes on the KCl(001) surface (Fig. 1a) are usually observed to be bent. In contrast, many nanotubes on the graphite surface (Fig. 1b) are aligned. The periodic lattice image of the graphite substrate is shown in the inset of the FFM image in Figure 1b. The crystallographic direction of the graphite surface is estimated from the periodic lattice image (which roughly means hollow site contrast) of the graphite [9, 10] and is illustrated on the right-hand side (top) of Figure 1b. The angle between the axial direction of the nanotubes and the $[12\bar{3}0]$ direction of the graphite substrate is estimated to be 60°. The geometrical relationship between the nanotubes and the graphite substrate is found

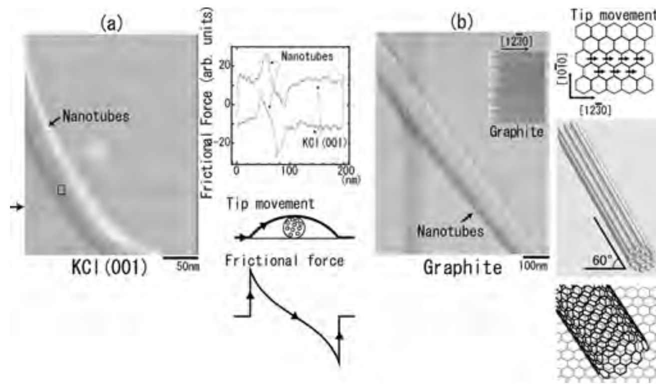

Figure 1. FFM images of nanotubes on a KCl(001) surface (a) and on a graphite surface (b). The periodic lattice image of the graphite substrate is shown in the inset of the FFM image in (b). The line profile (indicated by an arrow) of the FFM image of the nanotubes on KCl(001) is shown on the right-hand side (top) of (a). The line profile consists of components from the nanotubes and the KCl(001) substrate. The FFM contrast due to surface corrugations is described by the slope (on the right (bottom)) of tip movement (on the right (middle)).

to exhibit threefold symmetry from many samples. It is of interest to note that the angle between the axial direction of the nanotubes and the $[12\bar{3}0]$ direction of the graphite substrate becomes 60°, when the lower hexagonal faces of nanotubes of the armchair type become commensurate with the hexagonal faces of the second graphite layer of the graphite substrate, in the same manner as the stacking of graphite layers, where only a single nanotube in a bundle is illustrated on the right-hand side (bottom) of Figure 1b. This consideration is consistent with the result that the hexagonal face of a C_{60} molecule pairs with the hexagonal face of the second graphite layer [11, 12]. The line profile of the FFM image of the nanotubes on KCl(001) is shown on the right-hand side of Figure 1a. The line profile consists of components from the nanotubes and KCl(001) substrate, as illustrated in the figure. The FFM contrast consists of a component produced by surface corrugations without energy dissipation and one produced by intrinsic friction with energy dissipation [13]. The contrast due to surface corrugations is described by the slope of tip movement. Assuming the tip shape and the shape of nanotubes to be a sphere and a cylinder, respectively, the tip movement and its FFM contrast when the load is constant are illustrated in the figure.

An enlarged image of the local area (square) shown in Figure 1a is shown in Figure 2. The enlarged FFM image exhibits stripe structures representing the periodic spacing w of 2.1 nm along the scanning direction. Thus, the periodic spacing between stripes a is estimated to be 1.8 nm using $a = w\sin\theta$, where $\theta = 60.1°$ is the angle between the axial direction of the nanotubes and the scanning direction. The line profile in Figure 2 can be discussed in the same manner as Figure 1a and indicates nanotubes of the same diameter. Assuming the bundle of closely packed SWNTs to be as shown on the right-hand side of Figure 2, the height of the bundle H is given as follows using the radius of SWNT, R:

$$H = 2R + \frac{\sqrt{3}}{2}a(\mathrm{N}-1) = \left(\frac{\sqrt{3}}{2}(\mathrm{N}-1)+1\right)a - b \quad (1)$$

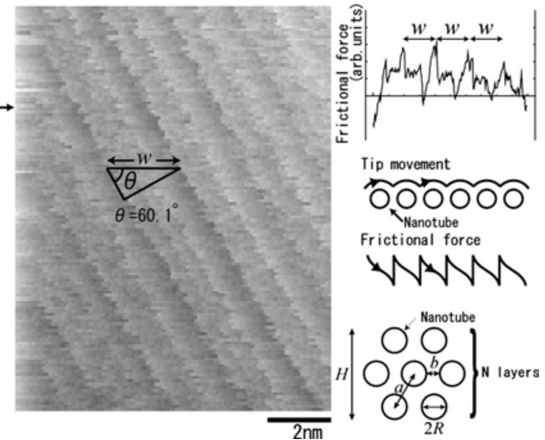

Figure 2. Enlarged image of the local area (square) shown in Fig. 1a. The enlarged FFM image exhibits stripe structures representing the periodic spacing w of 2.1 nm along the scanning direction. Thus, the periodic spacing between stripes a is estimated to be 1.8 nm using $a = w \sin\theta$, where $\theta = 60.1°$ is the angle between the axial direction of the nanotubes and the scanning direction. The line profile (indicated by an arrow) in the figure can be discussed in the same manner as in Fig. 1a and indicates nanotubes of the same diameter. A schematic view of the closely packed SWNTs is shown on the right (bottom), where $2R$, N, a, and b are the diameter of a nanotube, the layer number of nanotubes, the nearest distance between any two nanotube centers, and the nearest distance between any two nanotubes, respectively.

where N, a, and b are the layer number of nanotubes, the nearest distance between any two nanotube centers, and the nearest distance between any two nanotubes, respectively. Here, H and a were estimated to be 9.2 nm based on AFM data and 1.8 nm based on the periodic spacing of stripes, respectively. Thus, taking N = 6, the diameter of the nanotubes $2R$ and the nearest distance between any two nanotubes b are estimated to be 1.4 nm and 0.3 nm, respectively.

2.1.2. Rotation of SWNTs

Next, the sliding of the nanotubes on the KCl(001) surface and the graphite surface is described. Only on the KCl(001) surface is the sliding of the nanotubes observed. The FFM image that shows the sliding of the nanotubes on KCl(001) is shown in Figure 3. As in Figure 2, stripe features due to nanotubes are again observed. At point A, sliding is found to occur because the stripe features do not change. If rolling occurs, the striped rows of nanotubes will not coincide at sliding point A with the increase in sliding distance. The sliding distance d and the rotation angle around pivot point B, θ, are estimated to be 6.8 nm and 3.5°, respectively. Thus, the distance between sliding point A and pivot point B, l, is estimated to be 111.2 nm using $l = d/\tan\theta$. Then, the frictional force during sliding is estimated to be about 11 nN from scan line (b) where sliding occurs. Thus, the threshold value of the torque for rotation around pivot point B is estimated to be 1.2×10^{-15} Nm (11 nN × 111.2 nm). The energy loss for rotation, or the energy dissipation, is also estimated to be 0.75×10^{-16} J (11 nN × 6.8 nm), which is much smaller than that in the case of MWNTs on mica (3×10^{-16} J) [3]. This sliding occurs very often on the KCl(001) surface but not on graphite. Thus, this demonstrates that the nanotube-KCl(001) shear stress

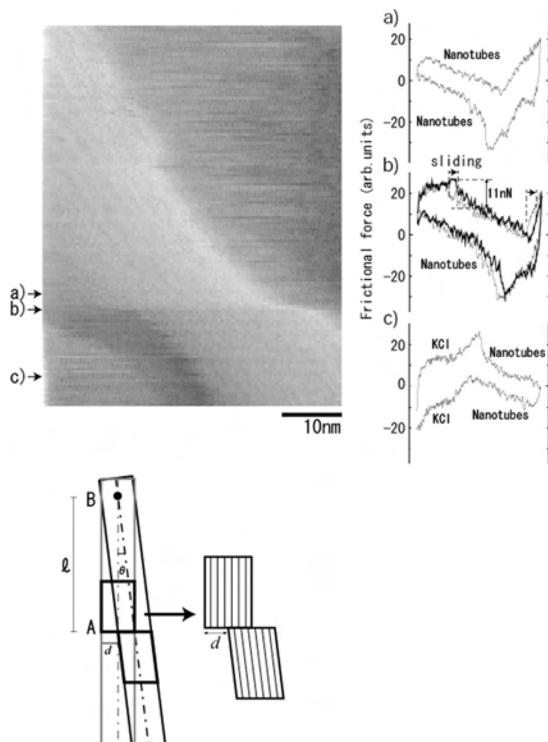

Figure 3. FFM image of the sliding of nanotubes on KCl(001). As in Fig. 2, stripe features due to nanotubes are again observed. On the right, line profiles (a) before, (b) during, and (c) after sliding are given. In line profile (b), both the scan line during sliding (thick line) and that before sliding (thin line) are depicted. At point A, sliding was found to occur. The sliding distance d and the rotation angle around pivot point B, θ, are estimated to be 6.8 nm and 3.5°, respectively. Thus, the distance between sliding point A and pivot point B, l, is estimated to be 111.2 nm using $l = d/\tan\theta$.

$\tau_{\text{nanotube-KCl(001)}}$ would be smaller than the nanotube-graphite shear stress $\tau_{\text{nanotube-graphite}}$; $\tau_{\text{nanotube-KCl(001)}} < \tau_{\text{nanotube-graphite}}$. However, the sliding and/or rolling often occurs in the case of MWNTs on graphite, as shown in the next subsection [14]. It should be noted that strictly speaking, the sliding discussed above indicates in-plane rotation around a pivot point, that the shear stress around the pivot point is not uniform, and that the essential quantity in the control of in-plane rotation movement is not the sliding force F but the moment of force Fl. In the case of a large shear stress, such as for nanotubes on graphite, it is reported that rolling is preferred over sliding due to in-plane rotation [3, 5].

2.2. Rolling of MWNTs on Graphite

2.2.1. Type of MWNTs

The FFM image of a MWNT on graphite is shown in Figure 4. Many MWNTs on graphite are aligned, resulting in a threefold symmetry, in a manner similar to SWNTs. The enlarged images of local area **a** in the graphite substrate and local area **b** in the MWNT are shown on the bottom. The enlarged image of local area **a** exhibits a one-dimensional stick-slip motion, which shows that the scanning direction of a tip is identical with the $[12\bar{3}0]$ direction of the graphite substrate [10]. Also, it is noted that the enlarged

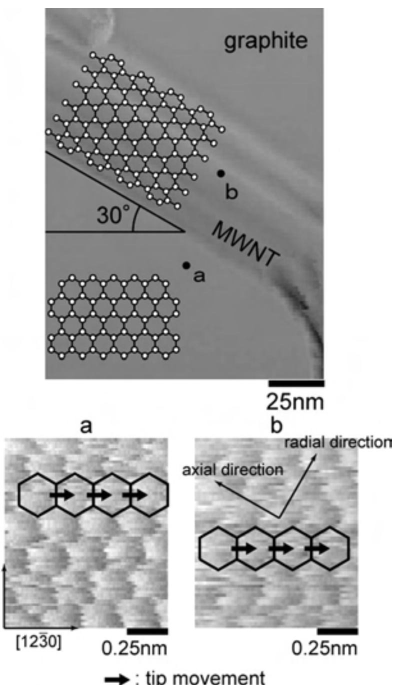

Figure 4. FFM image of the MWNT on the graphite surface. The enlarged images of local area **a** in the graphite substrate and local area **b** in the MWNT are shown on the right-hand side of the figure. The enlarged image of local area **a** exhibits a one-dimensional stick-slip motion, which shows that the scanning direction of a tip is identical with the $[12\bar{3}0]$ direction of the graphite substrate. Also, it is noted that the enlarged image local area **b** exhibits is the same as that of local area **a**.

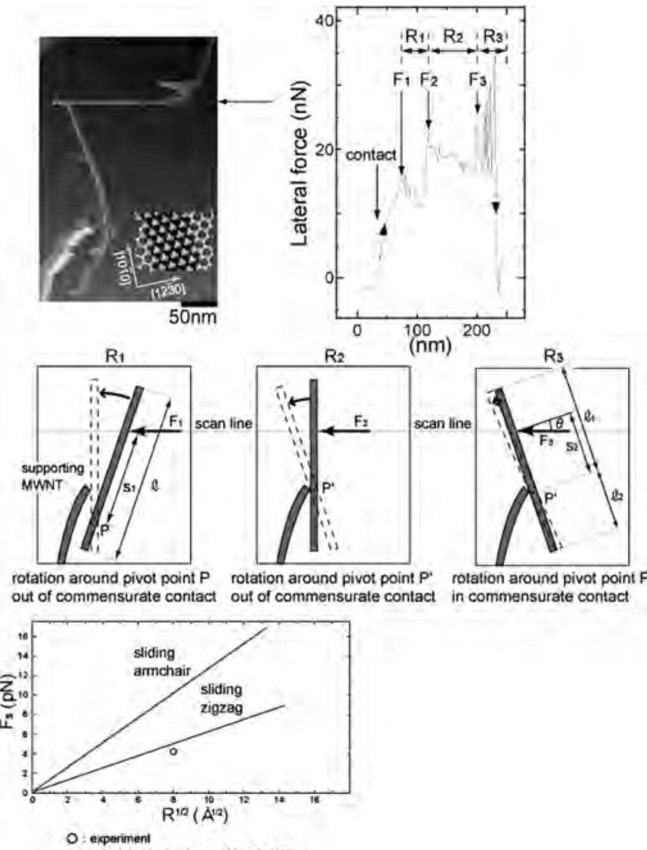

Figure 5. FFM image from the zigzag MWNT on graphite. The line profile (indicated by an arrow) is depicted on the right-hand side of the figure. First, a tip approaches the MWNT from the right and then comes into contact with it. The MWNT begins to rotate around the pivot point P out of commensurate contact (R_1). After rotating about 14°, the MWNT begins to rotate around the pivot point P′ (different from pivot point P) out of commensurate contact (R_2). Furthermore, the MWNT begins to rotate around the pivot point P′ in commensurate contact (R_3). The bottom figure shows the forces (solid lines: Buldum and Lu [5]) per angstrom needed to slide the armchair and zigzag nanotubes and one (circle) estimated from experimental data.

image of local area **b** exhibits the same image as that of local area **a**. It is of interest to note that the angle between the axial direction of the nanotube and the $[12\bar{3}0]$ direction of the graphite substrate is 30°. This reveals that the chirality of this MWNT is a zigzag type. Assuming that the interaction between the MWNT and graphite relies on the outer graphene sheet of the MWNT, it is possible that the MWNT stacks on the graphite substrate in the same manner as the stacking (AB stacking) of graphite layers. This assumption is consistent with those of other cases such as C_{60} molecules on graphite [7], SWNTs on graphite [8], and a graphite flake on graphite [15].

2.2.2. Rotation of MWNTs

Figure 5 shows the FFM image from the zigzag MWNT on graphite. First, a tip approaches the MWNT from the right and then comes into contact with it. The MWNT begins to rotate around a pivot point P out of commensurate contact (R_1). After rotating about 14°, the MWNT begins to rotate around a pivot point P′ (different from the pivot point P) out of commensurate contact (R_2). Furthermore, the MWNT begins to rotate around the pivot point P′ in commensurate contact (R_3). Vibration behavior shown in figure R_3 is probably due to fluctuations in a supporting MWNT building up the pivot point P′. Thus, this in-plane rotation of the MWNT consists of both rotations out of commensurate and in commensurate contacts. It is noted that the force needed to begin rotating in commensurate contact is larger than that out of commensurate contact. Now, assuming that the shear stress σ between the MWNT and graphite is constant around the pivot point P′, the force per unit length required to rotate the MWNT, F_l, is given as follows:

$$Fs_2 = \int_0^{l_1} \sigma l \, dl + \int_0^{l_2} \sigma l \, dl \tag{2}$$

$$F_l = \sigma d = \frac{2Fs_2}{l_1^2 + l_2^2}, \qquad l = l_1 + l_2 \tag{3}$$

where d, s_2, and l are the contact width between the MWNT and graphite, the distance between the push point and the pivot point P′, and the length of the MWNT, respectively. In commensurate contact, F_l is estimated to be approximately 4 pN/Å using $F = 25$ nN ($F_3 \times \cos 17°$), $s_2 = 189$ nm, $l = 600$ nm, and $l_1 = 433$ nm, where the radius of this MWNT is 6.5 nm. This value is in excellent agreement with that of theoretical calculation [5] for a zigzag nanotube. Using $\sigma = 0.2$ GPa [7], d is estimated to be approximately 0.2 nm, which corresponds to the lattice constant of graphite.

2.2.3. Rolling of MWNTs

Figure 6 shows the FFM image for rolling of the zigzag MWNTs on graphite. The upper two figures, A and B, show the characteristics of natural rolling. Both cases show that the original position and the final position keep in parallel after rolling. First, a first peak (F) appears which exhibits the lateral force required to push the MWNT. Then, the energies for MWNTs A and B used to push MWNTs are estimated to be 9.6×10^{-17} J and 3.4×10^{-17} J from the first peak area, respectively. After being pushed, the MWNT rolls naturally without a driving force. After rolling about two revolutions, the MWNT loses kinetic energy and stops. The tip catches up with the MWNT and scans over the MWNT, which is denoted by S in Figure 6 [14]. However, the lower figure C in Figure 6 exhibits stick-slip features. Even in this case, the MWNT translates in parallel. As reported by Falvo et al. [3, 4], the stick-slip features reveal that the tip again pushes the MWNT which, however, continues to roll. Even in this case, the rolling is about two revolutions. In the atomic force microscope (AFM) mode where a scan direction is parallel to the axis direction of a cantilever, the stick-slip features very often appear. Also, natural rolling only occurs under an argon atmosphere although the stick-slip behaviors little change under the relative humidity (0–30%). Thus, rolling behaviors seem to depend on the relative humidity and the relative coordinate between the scanning direction of a tip and the axial direction of a MWNT, which controls the chance or probability where a tip again comes into contact with a MWNT during rolling. Furthermore, the fact that natural rolling only occurs under an argon atmosphere indicates that the adsorbed water molecules on graphite and/or a MWNT influence the distance of natural rolling; for example, a MWNT easily loses kinetic energy and easily stops at a higher relative humidity.

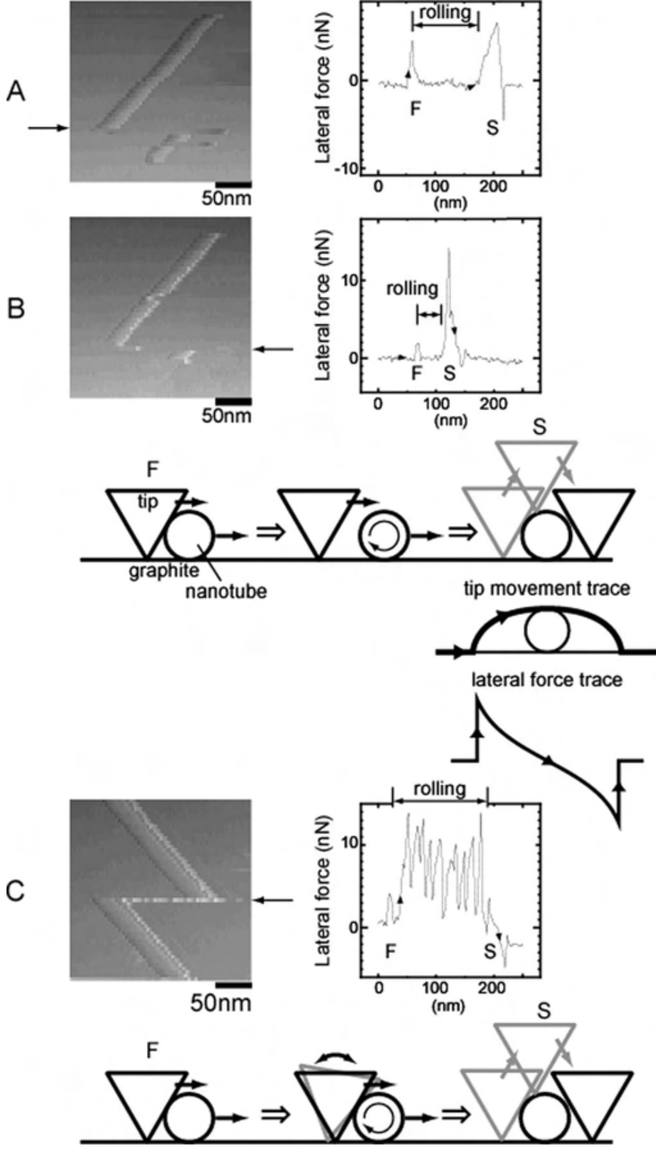

Figure 6. FFM image for rolling of the zigzag MWNTs on graphite. The line profile (indicated by an arrow) is depicted on the right-hand side of the figure. The upper two (A and B) and the bottom (C) figures show the characteristics of natural rolling, and rolling with the several contacts with the tip during rolling, respectively.

3. SLIDING OF FLAKES

In this section, we describe the sliding of a graphite flake on graphite and a MoS_2 flake on MoS_2. The graphite flake moves on graphite such that the stacking of graphite layers is maintained. In the case where the flake movement is parallel to the pulling direction, the frictional force is smallest. The MoS_2 flake also moves on MoS_2 such that the stacking of the sulfur basal plane of MoS_2 is maintained. The frictional forces between MoS_2 surfaces are clearly proportional to loading force although they depend strongly on the movement of the MoS_2 flake. The Amontons–Coulomb law is excellently satisfied at loading forces in the range of 1 to 120 nanonewtons.

3.1. Sliding of a Graphite Flake on Graphite

Figure 7 shows two x frictional force maps at different areas from a graphite flake on graphite scanned along the x direction. It should be noted that these exhibit a scaled pattern, clearly different from that of a tip on graphite from the standpoint of a periodic pattern and contrast [10, 15, 16]. Noting that this system consists of the friction between a tip and a graphite flake and that between a graphite flake and graphite, it is revealed that the friction from this system includes two different frictional mechanisms. However, it is reasonable that the frictional features from a flake on graphite exhibit only the friction between a graphite flake and graphite because they do not include the frictional force map from a tip on graphite. This indicates that the friction between a tip and a graphite flake is larger than that between a graphite flake and graphite. Thus, the graphite flake moves together with the tip when the tip is scanned. It is noted that the frictional force maps from a flake on graphite exhibit various patterns. The three types (A–C) of movement of the graphite flake are illustrated in Figure 7. These maps are transient during scanning from top to bottom. The size of the unit cell of the lower pattern is larger

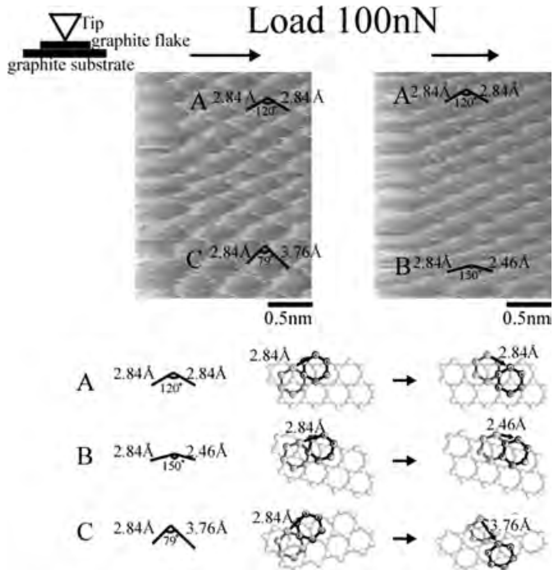

Figure 7. Two x frictional force maps from a graphite flake on graphite obtained by scanning along the x direction, where the arrows mean the scanning direction. The three types (A–C) of movement of the graphite flake are shown in the lower part of figure.

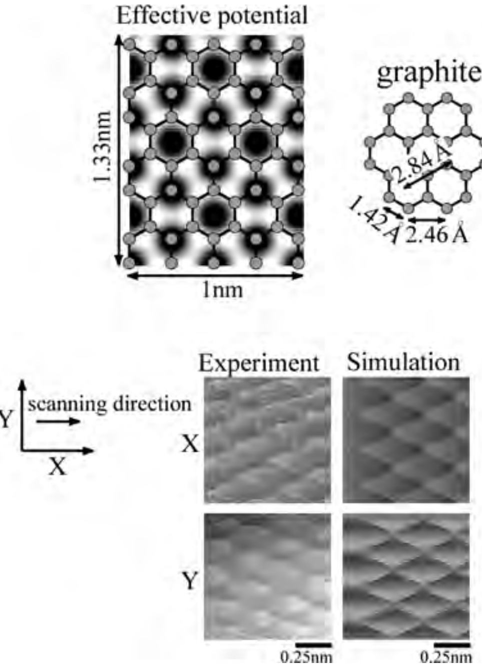

Figure 8. Experimental data and theoretical simulation for type A of Fig. 7.

than that of the upper ones. Now, we consider type A of the frictional force map, which is the standard pattern appearing in this experiment. The movement of the flake on graphite is substituted into the movement of a single particle moving with a constant velocity in the effective potential as follows:

$$V = V_0\left\{2\cos\left(\frac{2\pi}{a}x\right)\cos\left(\frac{2\pi}{a\sqrt{3}}y\right) + \cos\left(\frac{4\pi}{a\sqrt{3}}y\right)\right\} \quad (4)$$

where $a = 0.142$ nm $\times$ 2 = 0.284 nm. This effective potential is determined so that it takes the minimum values at the natural stacking relation of graphite. This simple preliminary simulation is in excellent agreement with the experimental data, as shown in Figure 8. Here, the spacing of $a = 0.284$ nm indicates a movement to the next stable position holding AB stacking of graphite. Similarly, the other patterns reveal that their movements are carried out so as to maintain the natural stacking relation (AB stacking) of graphite, as shown in Figure 7. It has been reported that the energetic barrier (the energetic difference between AA stacking and AB stacking of graphite) to the interlayer sliding is approximately 12 meV per carbon atom [17]. Assuming that the energetic barrier to the interlayer sliding in this experiment is on the order of electronvolts because the frictional force in flake friction appears on the order of nanonewtons, the number of carbon atoms contributing to the interlayer sliding is on the order of hundreds, leading to tens of unit cells of graphite. Thus, it is expected that the actual contact area between the flake and graphite becomes very small and only occupies an extremely small part of the flake. In order to observe flake movement, the relationships between the flake position and the lever support position are shown in Figure 9. Compared to the tip movement on graphite, that of the flake exhibits sharper peaks. This feature is also identical with the pattern theoretically given by Tomanek et al. and Weiss et al. [18, 19], which indicates no jump (or no energy dissipation) when the flake moves on a graphite substrate. This suggests that a driving force (a static frictional force) appears when the flake moves on a graphite substrate but a dynamical force (a dynamical frictional force) disappears. We think that this gives an explanation to the problem why the friction of the system including various flakes is generally small; for example, a friction force acting on many flakes with different movements may be close to zero.

The frictional forces in relation to loading force for a tip on graphite (D and E on the left-hand side) and for a flake on graphite (F and A on the right-hand side) are shown in Figure 10. The case F exhibits that the flake movement is parallel to the pulling direction or scanning direction, in which the frictional forces are very weakly proportional to the loading force. Thus, the proportional coefficient μ_F for case F is estimated to be approximately 0.001, which corresponds to the frictional coefficient $\mu_{12\bar{3}0}$ because the movement of case F is along the crystallographic direction [$12\bar{3}0$]. However, in case A (which is the same as case A in Fig. 7)

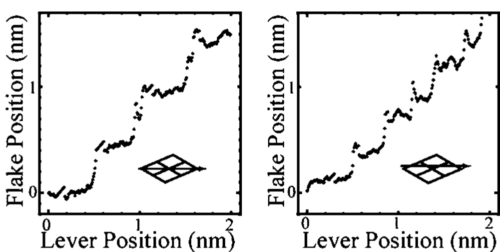

Figure 9. The relationships between the flake position and the lever support position at different lines in scaled patterns.

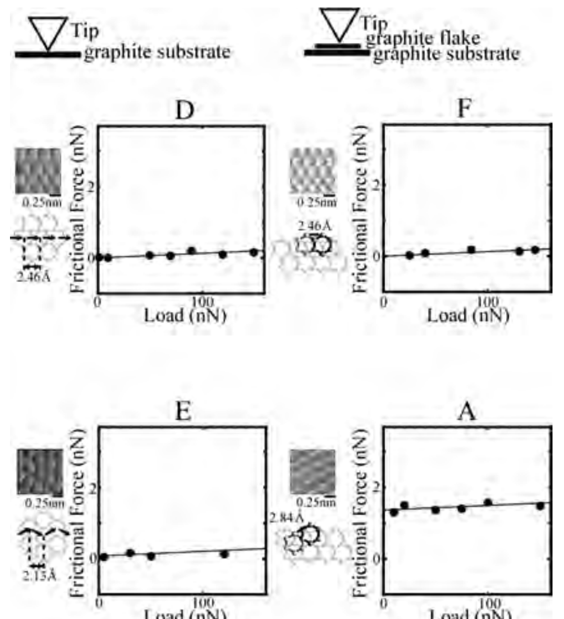

Figure 10. The mean frictional forces in relation to loading force for a tip on graphite (D and E on the left-hand side) and for a flake on graphite (F and A on the right-hand side). Images and arrows on the left-hand side represent frictional force maps and the tip movement, respectively. Image and arrows on the right-hand side represent frictional force map and the flake movement, respectively.

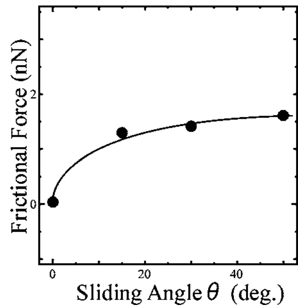

Figure 11. The mean frictional forces versus sliding angle at a loading force of 100 nN.

where the direction of flake movement is not parallel to that of the pulling force, the frictional forces satisfy the relationship that $\alpha + \mu_A F_n$, where $\alpha = 1.3$ nN, $\mu_A = 0.001$, and F_n represents the loading force. Here, it is expected that the graphite (0001) flake is easy to shear along the direction $[12\bar{3}0]$ of the graphite (0001) surface because the path to the next stable point in this case does not take the path of AA stacking and its energetic barrier is the smallest. However, cases A, B, and C always occur. The proportional coefficients μ_D and μ_E for cases D and E are also together estimated to be approximately 0.001. Now, it is interesting to note that the difference between case D(E) and case F(A) reveals the change in the frictional behavior when the frictional mechanism is transient from a single-atomic tip to a large-area flake tip. When the flake does not move parallel to the scanning direction, there exists the difference between a tip on graphite and a flake on graphite (compare E with A). However, when the flake moves parallel to the scanning direction, it is found to be identical with that from a tip on graphite (compare D with F).

Now, the anisotropy of the frictional force for different directional movement of the flake versus pulling direction is shown in Figure 11 from the results of Figure 10, which appears depending on the sliding angle θ, denoted as the angle between the direction of flake movement and the pulling direction. The frictional forces are found to increase with increase of the sliding angle, which, interestingly, appears similar to the behavior of the frictional mechanism between flat surfaces discussed by Gyalog and Thomas [20]. These results conclude the following two points: (i) in the case where the flake movement is parallel to the pulling direction, the frictional force is smallest; (ii) in the case where the direction of the flake movement is not parallel to that of the pulling force, the flake does not move toward the next stable point until the projection of the pulling force is coincident with the force to begin moving toward the next stable point. Thus, the larger the sliding angle, the larger the pulling force. Here, it should be noted that preferred slidings have been observed in other cases of MoO_3 nanocrystals on MoS_2 surfaces [21] and MoS_2 flakes on MoS_2 surfaces [22]. Thus, it is very interesting to note that these findings provide us important information of how to decrease friction between surfaces.

3.2. Sliding of a MoS_2 Flake on MoS_2

Figure 12 shows three different x frictional force maps from a MoS_2 flake on MoS_2 scanned along the x direction. It should be noted that these exhibit scaled (types A and B) and square (type C) patterns, clearly different from that of a tip on MoS_2 from the standpoint of a periodic pattern and contrast (see figures on the left-hand side of Fig. 14). Noting that this system consists of friction between a tip and a MoS_2 flake and that between a MoS_2 flake and MoS_2, it was found that the friction from this system includes two different mechanisms. However, it can be concluded that the frictional features of a flake on MoS_2 exhibit only the friction between a MoS_2 flake and MoS_2 because they do not include the frictional force map from a tip on MoS_2. This means that the friction between a tip and a MoS_2 flake is greater than that between a MoS_2 flake and MoS_2. Now, we consider type A of the frictional force map, which is the standard pattern appearing in this experiment. The movement of the flake on MoS_2 is substituted into the movement of a single particle moving with a constant velocity in the effective potential for type A, as follows:

$$V = V_0\left\{2\cos\left(\frac{2\pi}{a}x\right)\cos\left(\frac{2\pi}{a\sqrt{3}}y\right) + \cos\left(\frac{4\pi}{a\sqrt{3}}y\right)\right\}$$

where $a = 0.316$ nm. The result of this simple preliminary simulation is in excellent agreement with the experimental data, as shown in Figure 13. Here, the spacing of $a = 0.316$ nm indicates a jump to the next stable position maintaining the stacking of MoS_2. Similarly, it is also revealed that the movements for the type B and C are performed such that the natural stacking relation of MoS_2 is maintained, as shown in Figure 12.

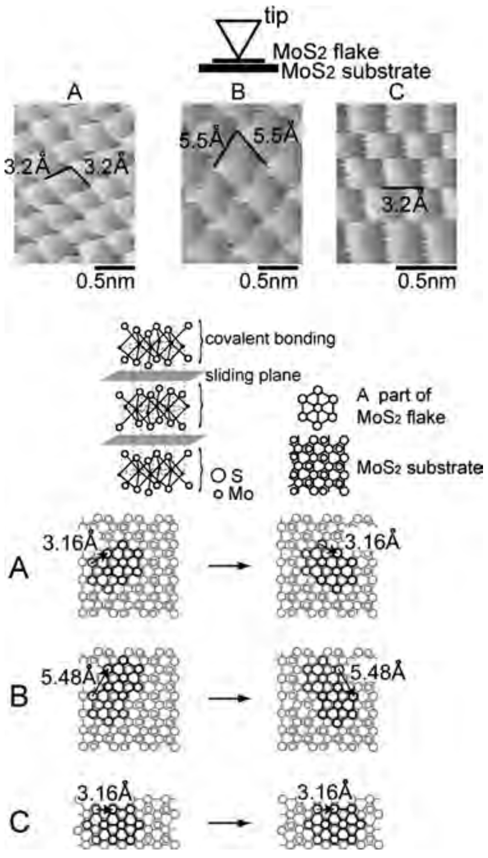

Figure 12. Three x frictional force maps at different areas from a MoS_2 flake on MoS_2 obtained by scanning along the x direction, where the arrows represent the scanning direction. The three types (A, B, and C) of movement of the MoS_2 flake are shown in the lower part.

The frictional forces for different movements in relation to loading force are shown on the right-hand side in Figure 14. These are all proportional to loading force although they depend strongly on the movement of the MoS_2 flake. Thus, the proportional coefficients defined as μ_A, μ_B, and μ_C for cases A, B, and C are estimated to be approximately 0.01, 0.02, and 0.003, respectively. The proportional coefficient μ_C for case C is much smaller than μ_A and μ_B for cases A and B because the flake movement in case C is parallel to the pulling direction or scanning direction. However, in the cases A and B where the direction of flake movement is not parallel to that of the pulling force, the frictional forces become larger than those for parallel movement. Thus, anisotropy of the frictional force for different directional movements of the flake in relation to the pulling direction prominently appears as shown in Figure 15, where the angle between the direction of flake movement

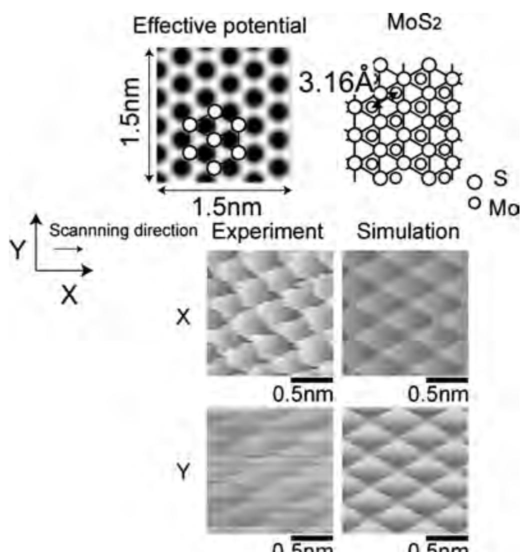

Figure 13. Experimental data and theoretical simulation for type A of Fig. 12.

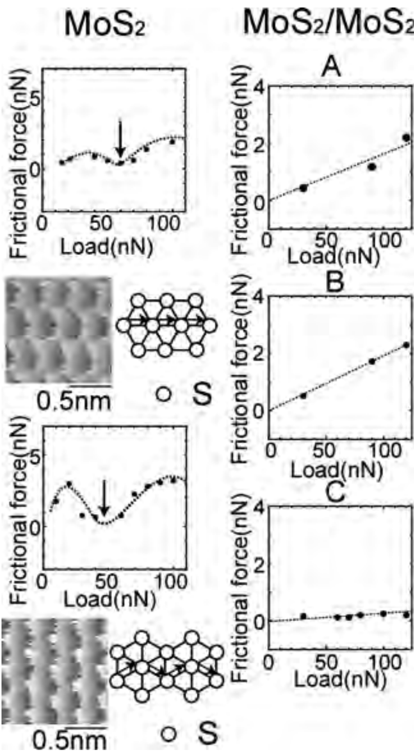

Figure 14. The frictional forces in relation to loading force for surface friction (right-hand side) and for tip friction (left-hand side). Images and arrows on the left-hand side represent frictional force maps and the tip movement, respectively.

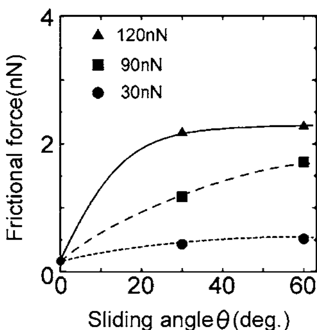

Figure 15. The frictional forces versus sliding angle deduced from the data of Fig. 14, where the sliding angles for cases A, B, and C are 30°, 60°, and 0°, respectively.

and the pulling direction is denoted as the sliding angle θ. One notes that the frictional forces versus sliding angle increase and increase strongly with higher load. Interestingly, this behavior is consistent with the frictional mechanism between flat surfaces discussed by Gyalog and Thomas [20] and Hirano et al. [23]. Since the movement of case C is along the crystallographic direction $[10\bar{1}0]$, the frictional coefficient $\mu_{10\bar{1}0}$ (the sliding angle $\theta = 0°$) where the $MoS_2(0001)$ surface shears along the crystallographic direction $[10\bar{1}0]$ of the $MoS_2(0001)$ surface is estimated to be 0.003, which is close to the experimental value (below 0.002) obtained by Martin et al. [24]. Thus, it is found that the $MoS_2(0001)$ flake is easy to shear along the direction $[10\bar{1}0]$ of the $MoS_2(0001)$ surface. Surprisingly, the frictional coefficient for case B is eight times larger than that for case C. Here, we suppose that case C is preferred over cases A and B because its energetic barrier is the smallest. However, cases A and B occur very often. This is the reason why the size of a flake is very large and the movement such as rotation of a flake would occur in addition to the parallel movement. Proportionality of the frictional forces in relation to loading force also reveals that the contact area between MoS_2 surfaces S is proportional to the loading force F_N, using the relationship $F = \mu F_N = \tau S = \tau\alpha F_N$, where α represents the proportional constant. This indicates that surface deformation is significantly smaller in MoS_2 than in graphite because the lamellar MoS_2 consists of covalent bonding, which behaves like a hard plate. Also, it should be noted that frictional forces for tip friction are quite different from those for surface friction. Along the different scanning directions of the $MoS_2(0001)$ surface, a tip performs one-dimensional stick-slip and zigzag stick-slip motions, shown on the left-hand side in Figure 14. This behavior is similar to that of ionic surfaces [25]. In the case of an ionic surface, the minimum points (shown by the arrows) appear before large distortions of the surface occur. Thus, it is inferred that large distortions of the surface occur even in MoS_2 triple layers.

This result reveals the change in the frictional behavior when the frictional mechanism is transient from a single-atomic tip to a large-area flake tip (compare data on the left-hand side with those on the right-hand). There is a prominent difference between frictional force maps of tip friction and those of surface friction. Similarly to graphite, the MoS_2 flake moves on MoS_2 such that the stacking of sulfur basal plane of MoS_2 is maintained. However, the frictional forces between MoS_2 surfaces are proportional to loading force and depend strongly on movement of a MoS_2 flake. The frictional coefficient $\mu_{10\bar{1}0}$ at the sliding angle $\theta = 0°$ is estimated to be 0.003, which indicates that a MoS_2 flake is easy to shear along the direction $[10\bar{1}0]$ of the $MoS_2(0001)$ surface. These findings also show us how to decrease friction between MoS_2 surfaces.

4. C_{60} MOLECULAR BEARINGS

The mechanical properties of fullerenes have attracted much attention in a materials science field. Especially, C_{60} and C_{70} solids have been expected to be good lubricant materials because of their nearly spherical shape and low surface strength. Okita et al. [6] have reported the nanotribological behavior on the C_{60} islands on KCl(001). Along different scanning directions of $\langle 1\bar{1}0\rangle$ and $\langle 11\bar{2}\rangle$ of a $C_{60}(111)$ surface, a tip has displayed one-dimensional stick-slip and zigzag stick-slip motions on the order of a load of nanonewtons, respectively, although at a larger loading force it destroys the $C_{60}(111)$ surface. Also, water adsorption on C_{60} films gives a lower frictional force, indicating that C_{60} molecules rotate or translate at the (111) surface. Thus, the C_{60}films are expected to exhibit various behaviors depending on loading forces, scanning direction, and relative humidity. C_{60} molecules on graphite also begin to grow with a monolayer. Then, a shear force between a single C_{60} molecule and graphite is shown.

In this section, the frictional behavior of C_{60} films on an ionic crystal and graphite is described, and furthermore the applicability and realization of C_{60} molecular bearings is described first. A rolling stick-slip model with a step rotation of a C_{60} molecule is proposed. The novel frictional mechanism is realized in the graphite/C_{60} monolayer/graphite system, in which static frictional forces have a finite value but mean dynamical frictional forces are zero. The C_{60} film thicker than the C_{60} bilayer, sandwiched by graphite plates, behaves as an elastic body. It should be emphasized that the graphite/C_{60} monolayer/graphite system is very promising for the realization of nano- and micromachines and opens a new field of molecular bearings.

4.1. C_{60} Films on Ionic Crystals and Graphite

Normal and lateral forces are measured simultaneously under humidity controlled conditions at room temperature. The C_{60} films are prepared by evaporation on a KCl(001) surface from a boron nitride (BN) crucible. The temperature of KCl(001) substrate is kept at about 200 °C. The growth mode is island growth. The C_{60}films had face-centered cubic symmetry, and the (111) facet surrounded by (001) facets is parallel to the KCl(001) surface. The C_{60} films on highly oriented pyrolytic graphite (HOPG) and KCl(001) are prepared by evaporation from a BN crucible. The temperatures of their substrates during evaporation are kept in the range of 150 °C to 200 °C.

First, we show in Figure 16a and b the normal force (NF) and lateral force (LF) images taken simultaneously for scans along the $\langle 1\bar{1}0\rangle$ and $\langle 1\bar{1}2\rangle$ directions at a load of 0.024 nN at 20% RH, respectively. The scanning area corresponds to the (111) facet surrounded by the (010) facets. It is found that the images are periodic but are quite different from each other depending on the scanning direction. In order to analyze the images quantitatively, it is necessary to calibrate the tip displacements for NF and LF images. If we take, as shown in Figure 16a, the geometrical relationship between the x, y, and z axes and cantilever, the NF profile and the LF profile are determined by the bending of the cantilever in the y or z direction, and by the torsion of the cantilever in the x direction, respectively. For calibration of the LF profile we plotted lateral force increment versus scanning distance at the first stacking point in the y direction of scanning because the bending of the cantilever in the y direction is dominant in the NF mode. Figure 16a shows the line profiles from scans 1 to 5 for a single-period area of the $\langle 1\bar{1}0\rangle$ image. Lines 1, 3, and 5 exhibit the same profiles in both

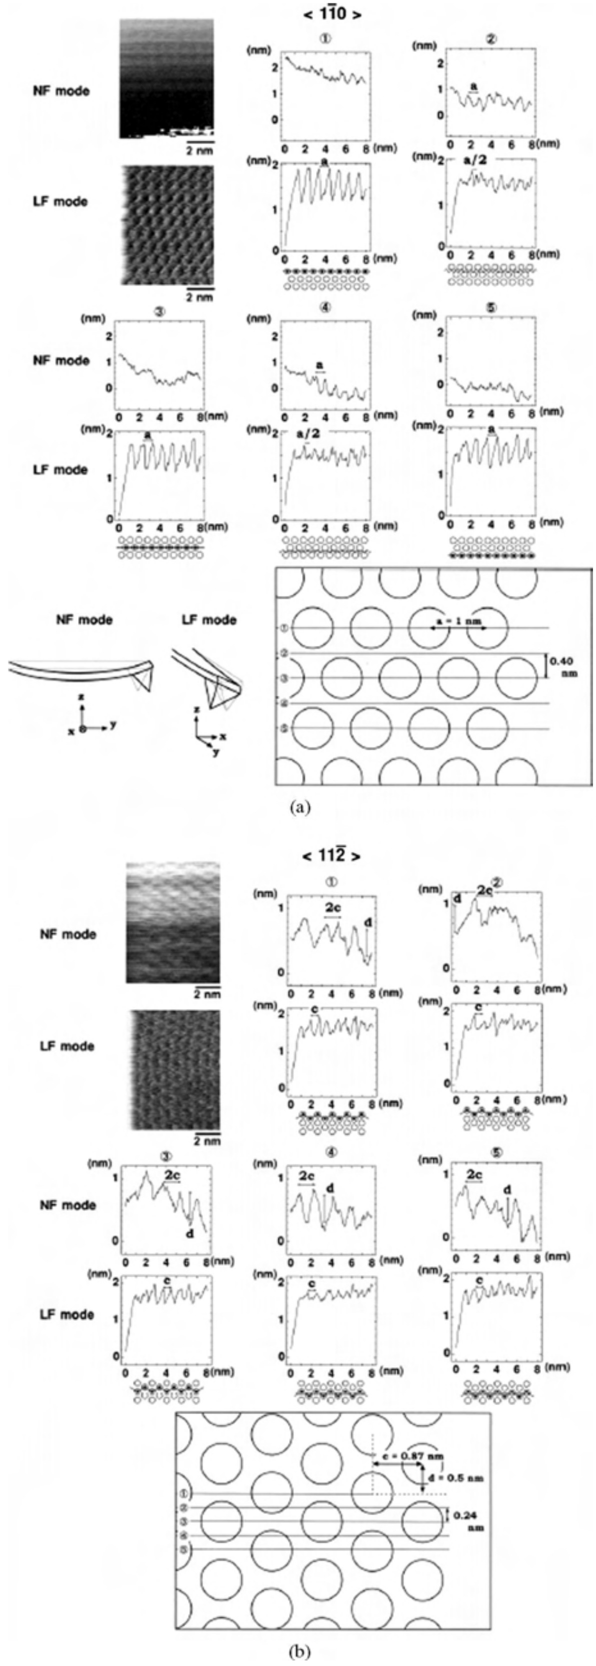

Figure 16. The normal force (NF) image and lateral force (LF) image taken simultaneously for scans in the (a) $\langle 1\bar{1}0\rangle$ and (b) $\langle 11\bar{2}\rangle$ directions at relative humidity (RH) of 20%. The line profiles from scans 1 to 5 were taken for one-period areas. The circles represent molecules.

the NF and LF profiles; the LF profile clearly has peaks with a period of 1-nm but the NF profile has no periodicity. In the LF profile of lines 2 and 4, the 1-nm period peaks become unclear and include small 0.5-nm period peaks, but in the NF profile 1-nm period peaks appear. Thus, lines 1, 3, and 5 indicate that sticking points of a tip always occur on molecules lying in a row in the $\langle 1\bar{1}0\rangle$ direction. However, lines 2 and 4 indicate that sticking points of a tip occur at zigzag positions between the neighboring molecular rows. This is consistent with small 0.5-nm period peaks in the LF profile and 1-nm period peaks in the NF profile. In the same manner as for scanning in the $\langle 1\bar{1}0\rangle$ direction, Figure 16b shows the line profiles from scans 1 to 5 for a single-period area of the $\langle 1\bar{1}2\rangle$ image. All NF profiles from lines 1 to 5 have 1.7-nm period peaks, although all LF profiles have 0.9-nm period peaks. Note that the amplitudes of 1.7-nm period peaks in the NF profiles are about 0.5-nm. Thus scans in the $\langle 11\bar{2}\rangle$ direction reveal zigzag stick-slip motions between neighboring molecular rows along the $\langle 11\bar{2}\rangle$ direction.

In Figure 17, we show frictional loops for a scan in the $\langle 1\bar{1}0\rangle$ direction at 20% RH and in dry argon, where the load was 0.024 nN for both cases. Note that the mean frictional force at 20% RH is about a quarter that in dry argon. Furthermore, the amplitude at dry argon is about three times that at 20% RH. However, both frictional loops have a typical sawtooth profile due to stick-slip motion, because they have a hysteresis during the loop, and accordingly accompany dissipation. One note is that the prominent difference between the dry argon case and the 20% RH case comes from the slope change of the sticking part, because the periodic spacing of stick-slip is the same. In general, the lateral effective spring constant, K_{eff}, which corresponds to the slope of the sticking part, is combined with the lateral contact stiffness between the tip and the sample, $K_{contact}$, the lateral stiffness of the tip, K_{tip}, and the torsional spring constant of cantilever, K_{lever}, as follows [26]:

$$K_{eff} = (1/K_{contact} + 1/K_{tip} + 1/K_{lever})^{-1} \tag{5}$$

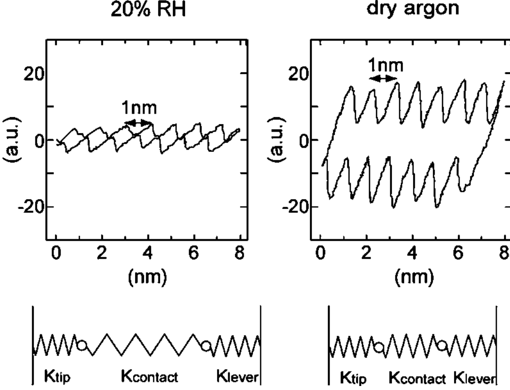

Figure 17. The frictional force loops for scanning in the $\langle 1\bar{1}0\rangle$ direction at relative humidity (RH) of 20% and in dry argon. Note that the mean frictional force at 20% RH is about one quarter than in dry argon. The change of tip-sample contact stiffness is illustrated below. The softening contact stiffness appears at 20% RH, where $K_{contact}$, K_{tip}, and K_{lever} show the lateral contact stiffness between the tip and the sample, the lateral stiffness of the tip, and the torsional spring constant of the cantilever, respectively.

If K_{tip} and K_{lever} are constant (this assumption is reasonable because the same tip is used), the decrease in lateral contact stiffness between the tip and the sample links directly to the decrease in effective spring constant. Thus, the decrease in slope of the sticking part means a softer spring for tip-sample contact. It has been shown [27] that water adsorption makes the molecules more mobile. Thus, it is now supposed that the adsorption of water molecules helps the mobility of C_{60} molecules. Here, the 'rolling' and/or 'translation' effects of a C_{60} molecule with lower resistance is considered for the mobility of C_{60} molecules, but it may be reasonable to prefer rolling rather than translation at the area of minimum energy around a C_{60} lattice point.

Figure 18 shows AFM images of C_{60} islands on a KCl(001) surface, respectively. Their islands consist of scores of molecular layers. The (111) facets appear in the C_{60} islands which form parallel to a KCl(001) substrate. Such an island growth occurs in the case where an intermolecular interaction is stronger than a molecule–substrate interaction. Thus, it is concluded that C_{60}-C_{60} interactions are stronger than C_{60}-KCl(001) interactions, respectively. Figure 19 shows AFM (topograph) images of C_{60} films on a graphite surface, respectively. Height of the C_{60} films in Figure 19 becomes about 1 nm, exhibiting a monolayer. As shown on the bottom of Figure 19, the high-resolution FFM image has a periodicity of 0.9 nm, which shows a zigzag motion along a $\langle 11\bar{2}\rangle$ scanning direction of the C_{60} monolayer [6]. Thus, an existence of the monolayer exhibits an epitaxial growth on graphite. As shown by Gravil et al. [12], the growth of this monolayer indicates that C_{60} molecules grow on graphite such that the hexagonal face of a C_{60} molecule pairs with the hexagonal face of the second graphite layer, so as to continue the natural stacking of the graphite.

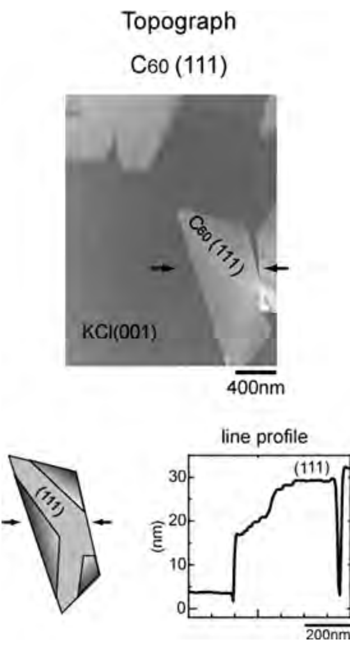

Figure 18. Atomic force microscope (AFM: topograph) images of C_{60} islands on a KCl(001) surface, respectively. The (111) facets appear in C_{60} islands which form parallel to a KCl(001) substrate. On the bottom of figure, line profiles depicted by the arrows are illustrated.

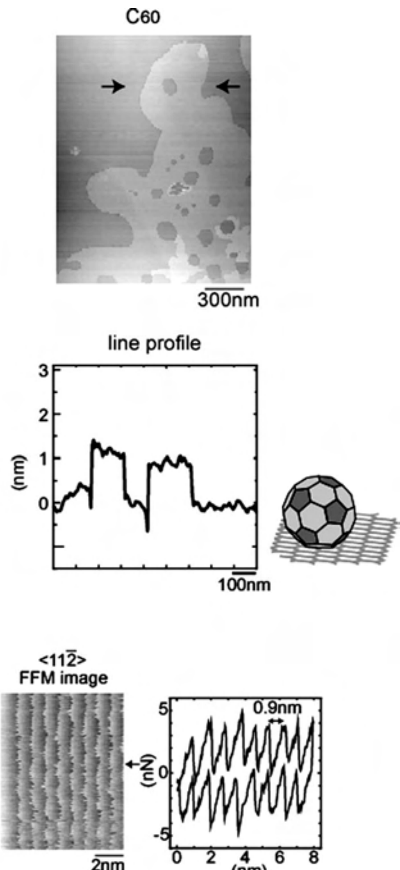

Figure 19. AFM (topograph) image of C_{60} films on a graphite surface. On the middle of figure, line profiles depicted by the arrows are illustrated. Height of C_{60} films becomes about 1 nm, exhibiting a monolayer. As shown on the bottom of figure, the high-resolution frictional force microscope (FFM) image has a periodicity of 0.9 nm, which shows a zigzag motion along a $\langle 11\bar{2}\rangle$ scanning direction of the C_{60} monolayer.

Figure 20 shows how AFM images of Figure 19 change by increasing a loading force. One notes that the C_{60} monolayer on graphite is swept up by increasing up to a load of 0 nN. Using Herztian continuum theory [11, 28], a contact radius versus a tip load estimated using a pull-off force of −10 nN and a tip radius of 15 nm is shown on the bottom of Figure 20. At a loading force of 0 nN, a contact radius between the tip and the C_{60} monolayer surface was estimated to be about 1.3 nm, exhibiting that the contact area between the tip and the C_{60} monolayer becomes a seven molecular dimension. Then, a mean lateral force was about 3 nN. Thus, assuming that seven molecules are moved by a lateral force of 3 nN with a tip, a shear force between a single C_{60} molecule and graphite is estimated to be about 0.4 nN, indicating that a shear stress between a C_{60} monolayer and graphite is estimated to be about 0.2 GPa.

Figure 21 shows the high-resolution FFM images of (111) surfaces of C_{60} films. For $\langle 1\bar{1}0\rangle$ and $\langle 11\bar{2}\rangle$ scanning directions, both films exhibit one-dimensional stick-slip and two-dimensional zigzag motions, respectively [6]. In case of a $\langle 11\bar{2}\rangle$ scanning direction of the C_{60}(111) films, it should be interesting to note that the image of a $\langle 11\bar{2}\rangle$ scanning direction of the C_{60}(111) films at a loading force of −9 nN (pull-off force: −10 nN) changes from one-dimensional

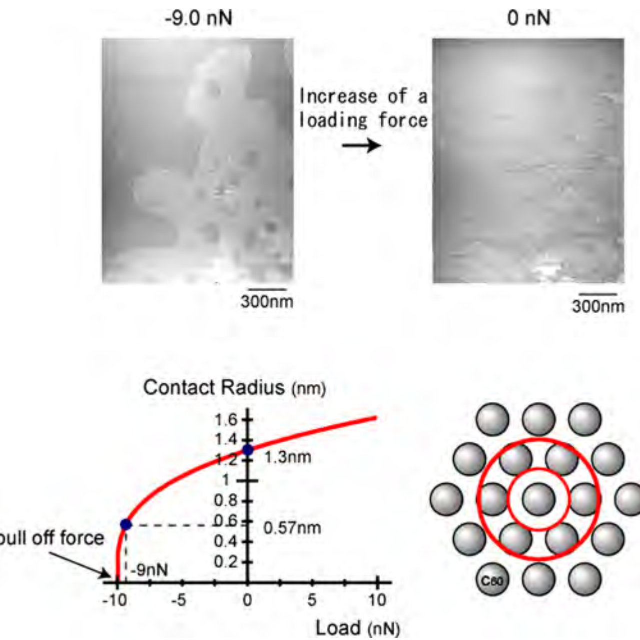

Figure 20. A change of AFM (topograph) image of Fig. 19 by increase of a loading force. One notes that a C_{60} monolayer on graphite is swept up by increasing up to a load of 0 nN. Using Herztian continuum theory, a contact radius versus a loading force was estimated and is shown on the bottom of figure, where the pull-off force is −10 nN. Contact radiuses at loading forces of 0 nN and −9 nN are 1.3 nm (large circle) and 0.57 nm (small circle), respectively.

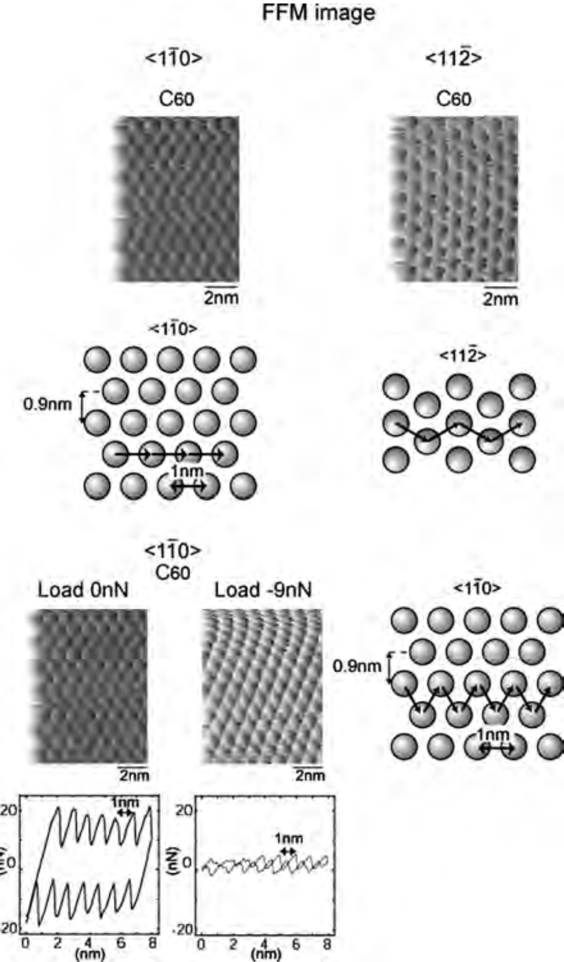

Figure 21. High-resolution FFM images of (111) surfaces of C_{60} films. For $\langle 1\bar{1}0\rangle$ and $\langle 11\bar{2}\rangle$ scanning directions, both samples exhibit one-dimensional stick-slip and two-dimensional zigzag motions, respectively. In case of a $\langle 11\bar{2}\rangle$ scanning direction of the C_{60} (111) films, it should be interesting to note that the image of a $\langle 11\bar{2}\rangle$ scanning direction of the C_{60} films at a loading force of −9 nN (pull-off force: −10 nN) changes from one-dimensional stick-slip to clear two-dimensional motions, exhibiting a single molecule contact with a tip, which gives a mean frictional force of 1 nN.

stick-slip to clear two-dimensional motions, exhibiting a single molecule contact with a probe tip, which gives a mean frictional force of 1 nN. In other words, this is a phase transition of stick-slip motion due to a change from a multimolecular contact to a single molecular contact. Thus, a shear force between a tip and C_{60} molecule is estimated to be 1 nN. This confirms that a tip scanning at the C_{60} monolayer is unstable and it is difficult to obtain a high-resolution FFM image of the C_{60} monolayer because the shear force (1 nN) between the tip and the C_{60} molecule is larger than that (0.4 nN) between the C_{60} molecule and the graphite.

4.2. Graphite/C_{60} Monolayer/Graphite System

Nano- and micromachines have been expected to trigger the creation of a future prominent industry. As first suggested by Feynman [29], molecular bearings have been expected to be a fundamental component of many molecular mechanical devices performing a frictionless system and to be very effective for the realization of nano- and micromachines. However, previous work on micromachine bearings has produced poor results, both experimentally and theoretically. Thus far, micromachines have been considered “machines incapable of movement.” Here, we describe C_{60} molecular bearings. It has been reported [6, 7, 14] that C_{60} molecules on graphite can grow in monolayer form, which consists of close-packed C_{60} molecules. Since the six-membered ring of a C_{60} molecule stacks on that of graphite such that the AB stacking of graphite is maintained, a graphite flake placed on the C_{60} monolayer on graphite is expected to stack in the same way as the C_{60} molecules on graphite. Thus, we can construct a system confining a C_{60} monolayer between graphite plates, which forms the nanogears of six-membered rings between C_{60} molecules and graphite.

Figure 22 shows a topograph (atomic force microscope image) of graphite (A, area S_A), and C_{60} monolayers (B, area S_B) and C_{60} bilayers (C, area S_C) on graphite. When a graphite flake is placed on areas S_A, S_B, and S_C, the graphite flake on graphite (D), the graphite flake on the C_{60} monolayer/graphite (which we call graphite/C_{60}^{mono}/graphite: E), and the graphite flake on the C_{60} bilayer/graphite (graphite/C_{60}^{bilayer}/graphite: F) are obtained, respectively. As shown in Figure 22, frictional force maps for graphite (A) show that the tip exhibits one-dimensional stick-slip and two-dimensional zigzag stick-slip motions for $[12\bar{3}0]$ and $[10\bar{1}0]$ scanning directions, respectively [10], although they exhibit significant load dependence at small loads [10]. Frictional force maps for B and C show that the tip exhibits

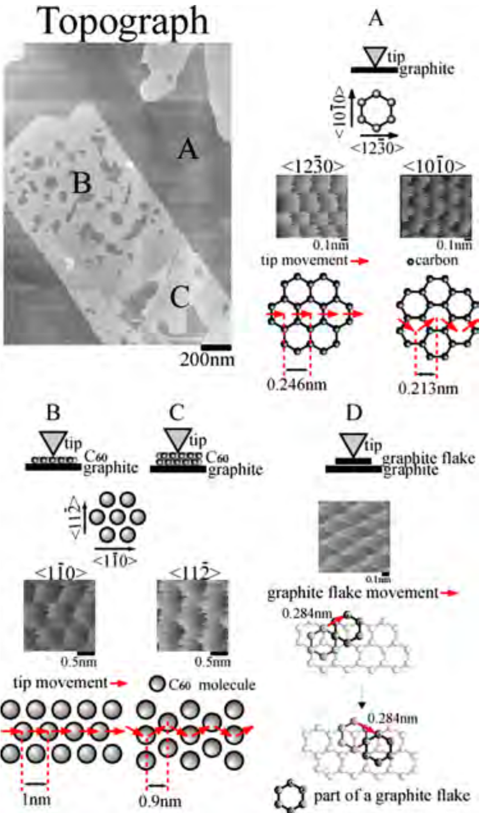

Figure 22. Topograph (atomic force microscope image) for graphite (A, area S_A), and C_{60} monolayers (B, area S_B) and C_{60} bilayers (C, area S_C) on graphite. Frictional force maps for graphite (A), C_{60} monolayers on graphite (B), C_{60} bilayers on graphite (C), and graphite flake on graphite (D) are shown in the figure.

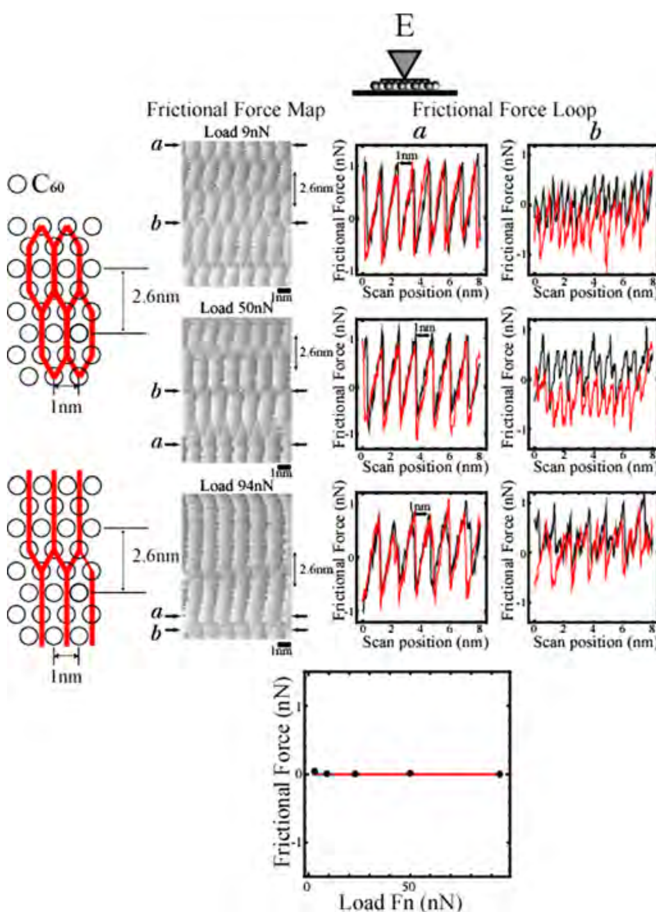

Figure 23. Frictional force maps versus loading force for graphite/C_{60}^{mono}/graphite (E). Frictional force loops obtained from line profiles shown by the arrows *a* and *b* in the frictional force maps are also represented, where the black and red lines indicate one direction and in the opposite direction, respectively. Super cell structures of the frictional force maps are illustrated on the left-hand side. Mean frictional forces versus loading force shown by the arrow *a* are shown on the bottom.

one-dimensional stick-slip and two-dimensional stick-slip motions for the $[1\bar{1}0]$ and $[11\bar{2}]$ scanning directions of a $C_{60}(111)$ surface, respectively [10]; it is more difficult to obtain clear frictional force maps for a C_{60} monolayer than for a C_{60} bilayer because the C_{60} monolayer is unstable for a tip contact. The frictional force maps for B show that the C_{60} monolayer consists of close-packed C_{60} molecules. This indicates that a six-membered ring is stacked on the graphite such that the AB stacking of graphite is maintained, and thus the six-membered ring is situated at the top of C_{60} molecules [7, 14]. The frictional force map for D shows that the graphite flake moves on the graphite such that the AB stacking of graphite is maintained [15]. Assuming that the graphite flake stacks on C_{60} molecules in the same way as C_{60} molecules stack on graphite, the projection of the first-layer six-membered net of the graphite flake is expected to be completely coincident with that of the graphite substrate through a C_{60} monolayer.

Figure 23 shows frictional force maps versus loading force for the graphite/C_{60} mono/graphite (E). It should be noted that the maps of E show transient patterns in relation to loading force, clearly different from those for graphite (A) [10], $C_{60}(111)$ surfaces (B and C) [6, 7], and the graphite flake on graphite (D) [15] from the standpoint of periodic pattern and contrast, as shown in Figure 22. Noting that this system includes friction between a tip and a graphite flake and that between a C_{60} monolayer and two graphite plates, it is considered that the friction from this system involves two different frictional mechanisms. However, it is reasonable that the frictional features of this system show only friction between the C_{60} monolayer and the two graphite plates because they do not show a frictional force map like that obtained for graphite (A) at all. This leads to the conclusion that the friction between the tip and the graphite flake is greater than that between the C_{60} monolayer and two graphite plates. Thus, the graphite flake moves together with the tip during scanning. At this point we note that the frictional force map at a load of 9 nN has a periodicity of 1 nm along the x direction and a periodicity of 2.6 nm along the y direction. This reflects the close-packed C_{60}molecular arrangement, as shown in Figure 23, but, has a superstructure (a periodicity of 2.6 nm) along the y direction. Furthermore, these maps exhibit a vertical chainlike transient pattern related to loading force. It should be noted that the frictional loops obtained from line profiles shown by the arrow *a* in the frictional force maps do not exhibit hysteresis in both directions, which indicates

that the mean frictional forces are zero and thus there is no energy dissipation, although those shown by the arrow *b* accompany some hysteresis, in which two-dimensional zigzag motions of a graphite flake exhibit. As shown on the bottom of Figure 23, the mean frictional forces at the position *a* are zero up to a high load, although the frictional forces have a finite value. Then, the maximum frictional force in this experiment is estimated to be below 1 nN, which is comparable to the shear force (0.4 nN) between a C_{60} single molecule and graphite [7].

If the nanogears of a six-membered ring between C_{60} molecules and the upper and lower graphite plates are formed in this system, it is found to be easy to apply torque to C_{60} molecules via their gears as shown in Figure 24a. Thus, it is possible that C_{60} molecules roll by means of torque, which is estimated to be approximately 1.0×10^{-19} Nm. This indicates that the rolling of C_{60} molecules occurs easily along the $[12\bar{3}0]$ direction using one side of a six-membered ring. However, there exist only four six-membered rings along a great circle of a C_{60} molecule, which does not always mean that the six-membered ring situates on the top of the C_{60} molecule after rolling. Now, the energetic barrier for rotation of a C_{60} molecule around the [0001] axis of a graphite substrate is estimated to be a few mili-electron-volts by Gravil et al. [12]. Therefore it is possible that the discrete step rotations of a C_{60} molecule

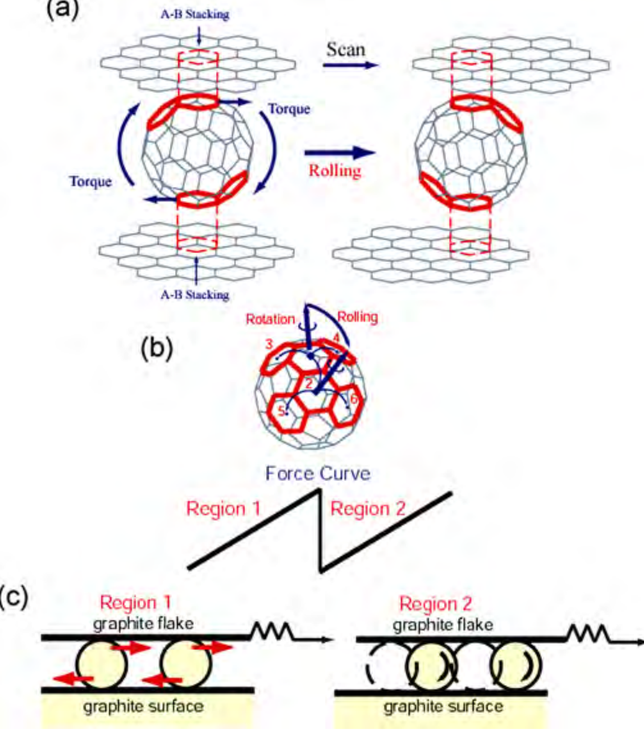

Figure 24. The stick-slip rolling model with a step rotation of a C_{60}molecule. (a) C_{60} molecules roll by means of torque, which is produced by the nanogears of six-membered rings between C_{60} molecules and the upper and lower graphite plates. (b) The discrete step rotation of a C_{60} molecule around the [0001] axis is illustrated. (c) In the region 1, C_{60} molecules stick but thermal rotations around the [0001] axis occur. In the region 2, C_{60} molecules slip in both rolling and translational motions (bottom figure).

between the positions holding AB stacking around this axis are induced by thermal excitations at room temperature. This step rotation allows C_{60} molecules to roll so that a low friction force generates. For example, when the rotation around the [0001] axis occurs, the rolling of the C_{60} molecule with the step rotation at the six-membered ring 1 occurs equivalently toward rings 2, 3, and 4. Assuming that the C_{60} molecule rolls toward the ring 2, the next rolling occurs equivalently toward rings 1, 5, and 6. Assuming that the C_{60} molecule rolls toward the ring 5, the six-membered ring of the C_{60} molecule facing to the graphite surface advances such as $1 \rightarrow 2 \rightarrow 5$ as shown in Figure 24b. Thus, a stick-slip process for rolling and translational motions is given as follows. In the region 1 in Figure 24c, C_{60} molecules stick but thermal rotations around the [0001] axis occur. In the region 2 in Figure 24c, C_{60} molecules slip in both rolling and translational motions. Then, nearly all the potential energies stored by a cantilever transform into rolling and translational motions. Thus, it should be noted that friction heat does not generate in this system. It can be expected that the van der Waals interaction between C_{60} molecules gives significant influences on the collective motion of C_{60} molecules, which can produce the super cell structure in frictional force maps.

The appearance of the vertical chainlike pattern with larger loads indicates the increase of the deformations of C_{60} molecules which leads to the vertical chainlike pattern by decreasing C_{60} nearest-neighbor distances. Here, it may be interesting to note that the deformations of the C_{60} monolayer induce a transition from a semiconductor phase to a metal phase [30].

As shown in Figure 25, the frictional force maps for graphite/C_{60}^{bilayer}/graphite (F) are also clearly different from those for graphite (A), C_{60}(111) surfaces (B and C), the graphite flake on graphite (D), and graphite/C_{60}^{mono}/graphite (E) from the standpoint of periodic pattern and contrast, as shown in Figures 22 and 23. The frictional force maps for graphite/C_{60}^{bilayer}/graphite (F) do not exhibit clear load dependence although they feature periodic patterns. As shown on the right-hand side of Figure 25, plots of mean frictional force versus loading force for graphite/C_{60}^{bilayer}/graphite (F) are shown. The curve of frictional force versus loading force from graphite/C_{60}^{bilayer}/graphite behaves in the same manner as does the Herztian contact, because the solid line is defined as $\alpha(F_n^{2/3} - \beta)$ in relation to the loading force F_n with α and β estimated to be 0.068 and 30 nN, respectively. Thus, this indicates that the C_{60} bilayer confined by graphite plates behaves as an elastic body. Furthermore, it should be noted that as C_{60} molecular layers become thick, the frictional force maps from E and F disappear but the frictional force map from graphite is reproduced. This indicates that the tip executes stick-slip motions on the graphite flake so that the C_{60} molecules and graphite substrate situated below the graphite flake do not move as well as the graphite flake because the combined shear force between the C_{60} layers and the shear force between the C_{60} molecules and graphite plate become larger than the shear force between the tip and the graphite flake.

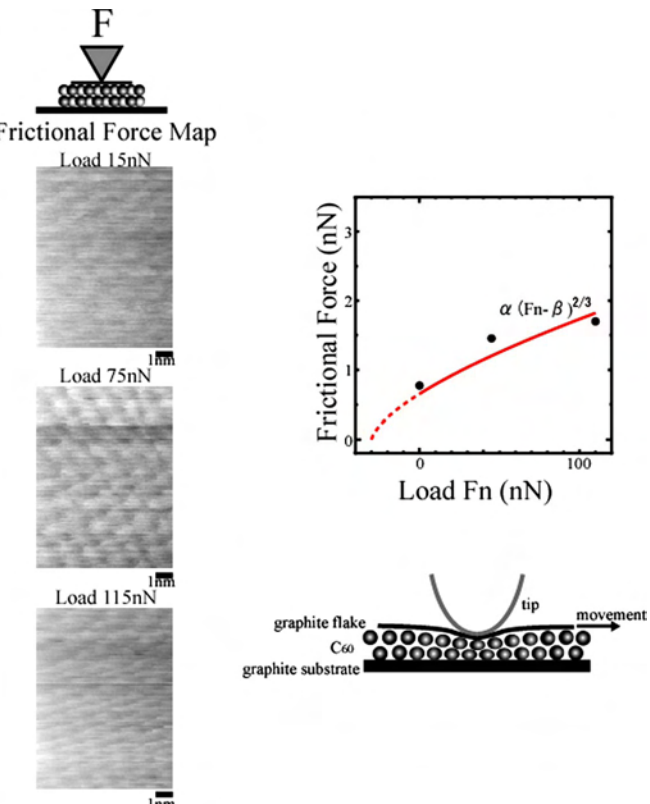

Figure 25. The frictional force maps and the curve of mean frictional force versus loading force for graphite/C_{60}^{bilayer}/graphite (F). The frictional force maps for graphite/C_{60}^{bilayer}/graphite (F) do not exhibit clear load dependence although they feature periodic patterns. The curve of mean frictional force versus loading force from graphite/C_{60}^{bilayer}/graphite behaves in the same manner as does the Herztian contact, because the solid line is defined as $\alpha\ (F_n^{2/3} - \beta)$ in relation to the loading force F_n with α and β estimated to be 0.068 and 30 nN, respectively.

GLOSSARY

AB stacking The way in which graphite layers stack up.

Amontons–Coulomb law The classical law of friction, that is, the relationship that the friction force is proportional to a loading force.

Atomic force microscope (AFM) The apparatus capable of investigating the surface topography on the atomic scale.

Frictional force microscope (FFM) The apparatus capable of investigating the lateral force on the atomic scale.

Micromachine Microscale machine.

Molecular manipulation The technique to make a molecule manipulate arbitrarily.

Multiwalled carbon nanotube (MWNT) Multiwalled nanotube consisting six-membered carbon ring network.

Nanogears Nanoscale gears.

Nanomachine Nanoscale machine.

Single-walled carbon nanotube (SWNT) Single-walled nanotube consisting of six-membered carbon ring network.

Stick-slip Periodic phenomena of sticking and slip.
