To function at room temperature, a device size smaller than l_e (about 100 nm) at $T = 300$ K is required. It is very difficult to use wet chemical or dry etching to fabricate such small devices using a GaAs–AlGaAs heterostructure, due to the large depletion length close to etched device boundaries. The much shorter depletion length of the InGaAs–InP material system makes it possible to fabricate much smaller devices that work at room temperature [57]. The wafer that was used to fabricate the room-temperature ballistic rectifiers was a modulation-doped $In_{0.75}Ga_{0.25}As$–InP quantum-well structure [58] grown by a metalorganic vapor-phase epitaxy at a pressure of 50 mbar and a temperature of 600 °C. Si was used as the dopant because of its slow carryover effect. The structure consists of a semi-insulating (001) InP substrate, a 250 nm, not intentionally doped buffer layer, a 9 nm thick $In_{0.75}Ga_{0.25}As$ quantum well, a 10 nm thick, undoped InP spacer layer, and a 35 nm thick InP layer doped by Si to a level of about 6×10^{17} m^{-3}. On top of the doped layer, an additional 10 nm thick, undoped InP layer was grown. At room temperature, the carrier density of the two-dimensional electron gas in the $In_{0.75}Ga_{0.25}As$ quantum well is 4.7×10^{15} m^{-2} and the mobility 1.2 m^2/V · s, corresponding to $l_e = 140$ nm. Figure 6 shows the scanning electron microscope images of two room-temperature ballistic rectifiers with different sizes. Since l_e is only slightly shorter than the distance from the *S* or *D* channel to the triangular antidot, a large number of electrons can still travel through this distance without being scattered. As shown by Hirayama and Tarucha [23], if the electron transport is partially ballistic, the ballistic effect may still be observed, although weaker than that at low temperatures. Here, instead of a dc current, an ac voltage (1 kHz) was applied to the device, the dc (or average) voltage between the lower and upper terminals was measured. Indeed, a rectification efficiency of about 14% at room temperature, roughly half of that at 100 K, was observed in the smallest ballistic rectifier, as shown in Figure 7. This is one of the very few types of novel nanodevices that have so far been shown to work at room temperature.

Phys.* 40, L909 (2001). © 2001, Japan Society of Applied Physics.

Apart from meeting the criterion of functioning at room temperature, for possible real applications, any new type of nanodevice is desirable to function at gigahertz frequencies. To investigate the speed of the ballistic rectifiers, high-frequency experiments up to 50 GHz have been performed. Because of the in-plane nature of the ballistic rectifier—the electrical contacts are laterally separated rather than placed on the surface and the back side (substrate)—the parasitic capacitance between contacts is substantially lower than in a conventional vertical device of the same size. Furthermore, the new working mechanism does not rely on any minority carrier diffusion or barrier structure, two factors that often limit the speed of conventional semiconductor diodes. The ballistic rectifier was therefore expected to function at very high frequencies. Figure 8 shows the dc output of the device versus the power of 50 GHz signal at room temperature. The 50 GHz signal was transmitted to the device via a coplanar probe. The power (horizontal axis) in Figure 8 was the output power from the signal source. Due to the impedance

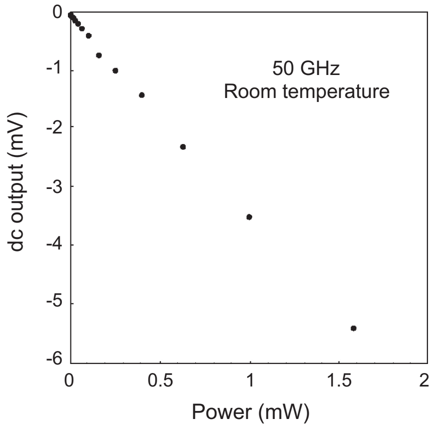

Figure 8. Output dc voltage of the smaller ballistic rectifier shown in Figure 6(b) versus the power of the applied 50 GHz signal at room temperature. Reprinted with permission from [57], A. M. Song et al., *Jpn. J. Appl. Phys.* 40, L909 (2001). © 2001, Japan Society of Applied Physics.

mismatch between the signal source (50 Ω) and the device (a few kiloohms), as well as some power loss due to the cables at 50 GHz, effectively only a small fraction of the power from the signal source was actually applied to the device. It was estimated that the real sensitivity of the device at 50 GHz was a few hundred millivolts of dc output per milliwatt input, which is virtually as high as that of a commercial microwave detection diode [57]. The ballistic rectifiers were, however, not specifically optimized. Much improvement can be expected in the future, by, for example, further reducing the device size. For a device about half of the one shown in Figure 7, one can expect not only a much higher efficiency, but also a stable performance that is insensitive to temperature changes up to room temperature.

As will be shown in the next section, theoretical studies on the ballistic rectifier yielded a quadratic response to input signals, which is very different from the exponential current–voltage characteristic of a conventional semiconductor diode. In Figure 7, a fit of $y = ax^2$ (where y represents the dc output voltage, x the ac input voltage, and a a constant) was performed. The remarkably good fit supports the theoretical prediction of the quadratic response to input voltage, Eq. (18), which will be derived in Section 2.2. This unique characteristic allows for generating second-harmonic signals without producing third or higher harmonics. The polarization of the generated second-harmonic signal (along the vertical direction) is perpendicular to that of the input signal (horizontal direction), which makes the separation of the second harmonic from the input signal much easier. Because of the quadratic characteristic, one also expects that the dc output is a linear function of the applied microwave power, which is demonstrated in Figure 8. Although we have not been able to test the devices at frequencies higher than 50 GHz so far, it is expected, from the working principle, that the cutoff frequency will be much higher, possibly up to hundreds of gigahertz or even in the terahertz regime. Recent numerical simulations confirmed this expectation, and showed excellent performance of the ballistic rectifier as a frequency doubler or power detector in the terahertz regime [59].

2.2. Semiclassical Model

As discussed in Section 1, Ohm's law does not hold in ballistic devices. Instead, the Büttiker–Landauer formalism [5–7], which treats transport in mesoscopic conductors as a transmission problem for carriers at the Fermi level, is widely used to describe the linear transport behavior of these conductors [13–15, 17–20]. For a multiterminal ballistic conductor at $T = 0$, the current in lead α in the linear transport regime can be written as

$$I_\alpha = \frac{2e}{h} \sum_{\beta \neq \alpha} T_{\beta \leftarrow \alpha}(\mu_\alpha - \mu_\beta) \tag{5}$$

Here, I_α is the current through lead α, and μ_α is the chemical potential of the electrons in contact (carrier reservoir) α. Such a standard formula is for linear electron transport only because the transmission coefficient $T_{\beta \leftarrow \alpha}$ for electrons from terminal (contact) α to terminal β is not considered a function of the applied voltage. To model the nonlinear (rectifying) effect observed in the ballistic rectifiers and the artificial nonlinear materials to be discussed in Section 3, the standard Büttiker–Landauer formula has been extended to the nonlinear regime. By doing so, a detailed model has been obtained, which provides analytical descriptions of the ballistic rectification effect in the framework of semiclassical ballistic electron transport [47].

Consider a general case where the electron transport is in the nonlinear regime, at a finite temperature, and in a finite magnetic field. The current through a lead α of a mesoscopic conductor, which is connected via perfect leads to a number of carrier reservoirs, can be written as

$$I_\alpha = \frac{2e}{h} \sum_{\beta \neq \alpha} \int [f(E-\mu_\alpha) - f(E-\mu_\beta)] \times T_{\beta \leftarrow \alpha}(E, B)\, dE \tag{6}$$

Here, $f(E-\mu_\alpha) = [\exp((E-\mu_\alpha)/k_B T) + 1]^{-1}$ is the Fermi–Dirac distribution function, and in general, the transmission coefficient for carriers from lead α to lead β, $T_{\beta \leftarrow \alpha}(E, B)$, is a function of the electron energy E and magnetic field B. At $k_B T = 0$ and $B = 0$, Eq. (6) becomes

$$I_\alpha = \frac{2e}{h} \sum_{\beta \neq \alpha} \overline{T}_{[\beta,\alpha]}(\mu_\alpha - \mu_\beta) \tag{7}$$

Here, $\overline{T}_{[\beta,\alpha]}$ equals $\int_{\mu_\beta}^{\mu_\alpha} T_{\beta \leftarrow \alpha}(E)dE/(\mu_\alpha - \mu_\beta)$ if $\mu_\alpha > \mu_\beta$, and $\int_{\mu_\alpha}^{\mu_\beta} T_{\alpha \leftarrow \beta}(E)dE/(\mu_\beta - \mu_\alpha)$ otherwise. This shows that only the transmissions from the reservoirs with higher chemical potentials to the reservoirs with lower chemical potentials need to be considered. Based on Eq. (7), the ballistic rectifying effect can be modeled in the framework of semiclassical ballistic electron transport.

Similar to the model for ballistic electron transport in a cross junction by Beenakker and van Houten [60], only the angular distribution of the ballistic electrons ejected from S and D was taken into account to determine the electron transmission probabilities into L or U leads. This is a particularly good approximation for this specific device geometry because the transmission probabilities for electrons from S (or D) to L and U are virtually completely determined by the ejection angles of the electrons.

First, consider the device at equilibrium, that is, when no voltage is applied. The angular distribution of the electrons ejected from a narrow constriction, for example, of the S and D channels, is given by

$$P(\theta) = \frac{1}{2}\cos\theta \tag{8}$$

Here, θ is the ejection angle with respect to the channel direction. Therefore, even at $V_{SD} = 0$, the electrons ejected out of S are, to some extent, collimated, as shown in Figure 9(c). This is actually a property of ballistic electrons, caused by the adiabatic electron transport at sufficiently low temperatures and in channels with smooth boundaries at the entrances and exits [14, 20, 61, 62].

Let θ_0 be the minimum ejection angle for an electron from S or D to be scattered by the triangular antidot to the lower lead. For the specific device in Figure 4, which is to

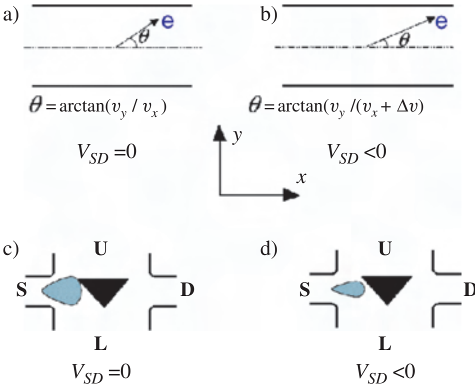

Figure 9. (a) The sketch shows that, at $I_{SD} = 0$, an electron is moving in the source channel with the angle $\arctan(v_y/v_x)$, where v_x and v_y are the velocity components along the direction of the channel and in the perpendicular direction. (b) When a negative voltage V_{SD} is applied, $I_{SD} < 0$, corresponding to a finite drift velocity Δv of the electrons in the source channel. This leads to a smaller ejection angle of the electron $\arctan[v_y/(v_x + \Delta v)]$. Overall, this results in a collimation effect induced by the applied voltage, and the angular distribution of the electron ejected out of S at $V_{SD} = 0$ shown in (c) becomes narrower at $V_{SD} < 0$, as schematically shown in (d). Consequently, the electrons more likely will be scattered by the triangular antidot to the lower lead, and have less chance to go through the gap between the antidot and the edge of the upper channel. This results in an accumulation of electrons in the lower lead, and consequently a negative voltage V_{LU}.

be modeled below as an example, $\theta_0 \approx \pi/4$. From Eq. (8), it is easy to obtain the transmission coefficients at zero bias:

$$T_{L\leftarrow S} = T_{L\leftarrow D} = T_{D\leftarrow L} = T_{S\leftarrow L} = N_{SD}\int_{-\pi/2}^{\theta_0} P(\theta)\, d\theta = \frac{N_{SD}(1+\sin\theta_0)}{2} \tag{9a}$$

$$T_{U\leftarrow S} = T_{U\leftarrow D} = T_{D\leftarrow U} = T_{S\leftarrow U} = N_{SD}\int_{\theta_0}^{\pi/2} P(\theta)\, d\theta = \frac{N_{SD}(1-\sin\theta_0)}{2} \tag{9b}$$

Here, N_{SD} is the number of occupied transverse quantum confinement modes at the Fermi level E_F in channels S and D.

To obtain an analytical description of the ballistic rectifying effect, certain approximations have to be taken. Ideally, the potential profile in the device at a finite I_{SD} should be calculated self-consistently in order to obtain the angular distribution of the ballistic electrons, and hence the transmission coefficients. Such a calculation is, however, very complex. Instead, it is noticed that the applied voltage mainly drops at the entrances and exists of the S and D channels [4]. Consider that, at $V_{SD} = 0$, the velocity components of a right-moving electron in the source channel are v_x and v_y, respectively, in the direction of the channel and in the perpendicular direction, as illustrated in Figure 9(a). The angle of ejection $\theta(I_{SD} = 0) = \arctan[v_y/v_x]$ will change if a finite V_{SD} is applied. For example, if V_{SD} is negative, the current in the source channel $I_S < 0$, meaning that the electrons in the source channel have a finite mean velocity or drift velocity, $\Delta v > 0$. As a good approximation, assume that the velocity component in the x direction of all of the electrons in channel S is increased by Δv, while the velocity component in the perpendicular direction v_y is essentially not affected. The ejection angle of the electron changes from $\arctan[v_y/v_x]$ at $I_{SD} = 0$ to a smaller angle $\arctan[v_y/(v_x + \Delta v)]$, as shown in Figure 9(b). Overall, this leads to a collimation effect induced by the applied voltage, which effectively narrows the angular distribution of the electron ejected out of S at $V_{SD} < 0$, as schematically shown in Figure 9(d).

The changes of the transmission coefficients, which fundamentally determine the output V_{LU}, can be directly evaluated once the angular distribution of the electrons is known. Since the angular distribution of the electrons ejected out of S becomes narrower, the electrons will have a greater chance to be scattered into the lower lead by the triangular antidot, and therefore the transmission probability for the ejected electrons to transmit from S to L will increase. In the mean time, the transmission probability from S to U will decrease since the probability for the electrons to have a large enough ejection angle to transmit through the gap between the antidot and the edge of the upper channel will reduce. The above analysis shows that the transmission probabilities of electrons could be directly linked to the electron drift velocity, and hence I_{SD}. It can be shown that

$$T_{L\leftarrow S}(I_{SD} < 0) - T_{L\leftarrow S}(I_{SD} = 0) = \frac{N_{SD}}{2}(\sin\theta_e - \sin\theta_0) \tag{10a}$$

$$T_{U\leftarrow S}(I_{SD} < 0) - T_{U\leftarrow S}(I_{SD} = 0) = -\frac{N_{SD}}{2}(\sin\theta_e - \sin\theta_0) \tag{10b}$$

In the equations, θ_e is determined by

$$\theta_e = \theta_0 + \arcsin\left[(\Delta v/v_F)\sin\theta_0\right] \tag{11}$$

where v_F is the Fermi velocity [47]. Assuming a hard wall potential for the source and drain channels because of the relatively large channel width, it can be shown that

$$\frac{\Delta v}{v_F} = -\frac{\hbar}{N_{SD} e E_F} I_{SD} \tag{12}$$

Here, the changes in the number of occupied modes in the source and drain channels with applied bias are neglected. This is, however, a good approximation for the four-terminal measurements of the ballistic rectifier. As will be shown by the following analysis, the output of a ballistic rectifier is determined by the relative changes of the transmission coefficients $\Delta T/T$ rather than the absolute values of the changes in the transmission coefficients ΔT.

Shown in Figure 10 is the dependence of the transmission coefficients on the electric current of the lead from which the electrons are ejected. Therefore, Eq. (7) can then be written as

$$I_\alpha \approx \frac{2e}{h}\sum_{\beta\neq\alpha} \overline{T}_{[\beta,\alpha]}(I_{[\beta,\alpha]})(\mu_\alpha - \mu_\beta) \tag{13}$$

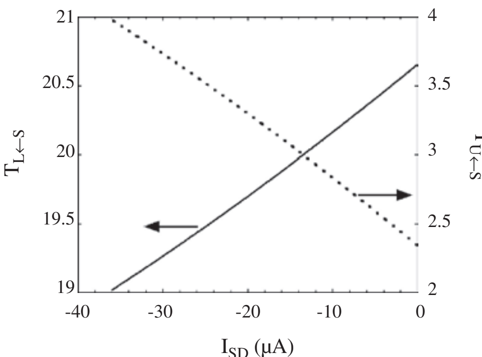

Figure 10. Calculated transmission coefficients $T_{L\leftarrow S}$ and $T_{U\leftarrow S}$ as a function of the negative source–drain current at $T = 0$. Adapted from [47].

where $\overline{T}_{[\beta,\alpha]}(I_{\{\beta,\alpha\}})$ equals $\overline{T}_{\beta\leftarrow\alpha}(I_\alpha)$ if $\mu_\alpha > \mu_\beta$ and $\overline{T}_{\alpha\leftarrow\beta}(I_\beta)$ otherwise [47]. With the values of the transmission coefficients determined, the V_{LU} versus I_{SD} characteristic is obtained by calculating the four-terminal resistance $R_{SD,LU} = V_{LU}/I_{SD}$. For the case of $V_{SD} < 0$,

$$R_{SD,LU} = \frac{h[T_{L\leftarrow S}(I_S)T_{D\leftarrow U}(I_U) - T_{D\leftarrow L}(I_L)T_{U\leftarrow S}(I_S)]}{2e^2 D} = \frac{h[T_{L\leftarrow S}(I_{SD})T_{D\leftarrow U}(0) - T_{D\leftarrow L}(0)T_{U\leftarrow S}(I_{SD})]}{2e^2 D} \quad (14)$$

where $I_S = I_{SD}$ and $I_L = I_U = 0$. Therefore, because the net current in L and U is zero, $T_{D\leftarrow L}$ and $T_{D\leftarrow U}$ are not sensitive to the applied current I_{SD}, and their values at zero bias are employed. In Eq. (14), D is a function of the individual transmission coefficients, and is found to be insensitive to the applied voltage or current [63]. For this specific device, $\theta_0 \approx \pi/4$, $T_{S\leftarrow D} = T_{D\leftarrow S} = 0$, and $T_{L\leftarrow U} \approx N_{LU}/3$, where N_{LU} is the number of occupied transverse quantum confinement modes in channels L and U. With these relations and taking into account $N_{LU} \gg N_{SD}$, it can be shown that

$$D = N_{SD}[2T_{L\leftarrow S}T_{U\leftarrow S} + T_{L\leftarrow U}N_{SD}] \approx \frac{N_{SD}^2 N_{LU}}{3} \quad (15)$$

Substituting Eqs. (9), (10), and (15) into Eq. (14) yields

$$V_{LU} = R_{SD,LU}I_{SD} = \frac{3h}{4e^2}\frac{\sin\theta_e - \sin\theta_0}{N_{LU}}I_{SD} < 0 \quad (16)$$

Note that θ_e is a function of I_{SD}, as shown by Eqs. (11) and (12). Combining the above with the case of $V_{SD} > 0$, where V_{LU} is also found to be negative, we have

$$V_{LU} = -\frac{3h}{4e^2}\frac{\sin\theta_e - \sin\theta_0}{N_{LU}}|I_{SD}| \quad (17)$$

The V_{LU} versus I_{SD} curve, calculated analytically for the device shown in Figure 4(a), is plotted with the solid line in Figure 11. It is in very good agreement with the experimental result (dashed line), especially in the low-current region. No adjustable parameters have been used at all in Eq. (17). At high currents, electron heating, not included in the above model, might reduce the rectifying effect. Moreover, the

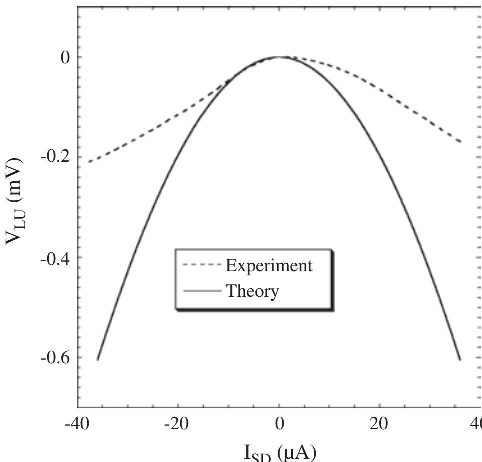

Figure 11. Theoretical (solid line) and experimental (dashed line, the same as that in Fig. 5) V_{LU} versus I_{SD} curves for the device shown in Figure 4(a). Although no fitting parameters have been used, the agreement between the experiment and the model is remarkably good. Reprinted with permission from [71], A. M. Song, *Appl. Phys. A* 75, 229 (2002). © 2002, Springer-Verlag.

length of the L and U channels (5 μm) is comparable to the electron mean-free path. This means that some electrons will be scattered by impurities or phonons, and change directions before they can travel through the channels and enter the electrical contact regions (carrier reservoirs). This certainly causes a reduced output.

The curves in Figure 10 display the dependence of $T_{L\leftarrow S}$ and $T_{U\leftarrow S}$ on I_{SD}. From $I_{SD} = 0$ to -37 μA, $T_{L\leftarrow S}$ increases by about 6.4%, while $T_{U\leftarrow S}$ decreases by about 34%. From Eq. (14), it is clear that, although the magnitude of the transmission from S to U is much less than that from S to L, it has a much stronger influence on $R_{SD,LU}$, and therefore contributes much more to the observed negative output V_{LU}.

It is also interesting to note that, in the limit as $I_{SD}| \to 0$, V_{LU} can be shown to have a quadratic response to I_{SD} [47]:

$$V_{LU} = -\frac{3\pi\hbar^2}{4e^3 E_F N_{SD} N_{LU}} I_{SD}^2 \quad (18)$$

Although the modeling was performed under the condition of $T = 0$, it has been shown that Eq. (18) holds as well at a finite temperature for sufficiently small currents [64], meaning that there is no threshold or turn-on voltage for the ballistic rectifier. With respect to applications, it is interesting to note that there are a number of practical advantages associated with the quadratic response, as have been introduced in Section 2.1 and will be discussed in Section 3. Based on the above picture, the nonlinear ballistic electron transport at finite magnetic fields can also be well described [65].

3. ARTIFICIAL FUNCTIONAL NANOMATERIALS

The concept of the ballistic rectifier has been extended from a single device to a new type of artificial functional material [66]. Figure 12 shows the atomic force microscope images

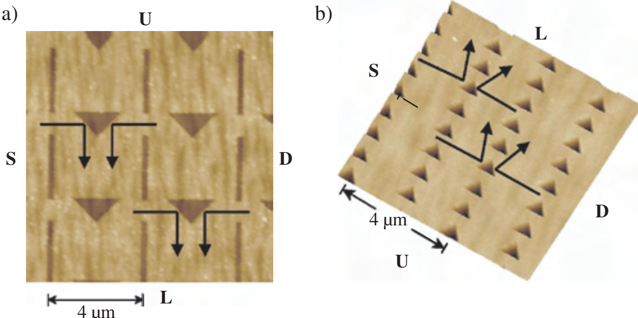

Figure 12. Atomic force microscope images of artificial functional materials of two different designs, fabricated using a GaAs–AlGaAs heterostructure. Note that the L terminal is on the upper-right side in (b). The arrows indicate the typical electron trajectories in the artificial materials.

of two examples of the artificial material that have been made. The working principle of the nonlinear materials is similar to that of the ballistic rectifier, and the materials were also fabricated using standard electron-beam lithography and wet chemical etching. In Figure 12(a), the artificial material was constructed by simply duplicating a ballistic rectifier over space. The duplicated individual rectifiers were connected in series and parallel, forming a network or an "artificial lattice." Apart from the above design, a material shown in Figure 12(b) was also fabricated, which only consisted of triangular antidots. In the material, not only is the intentionally broken symmetry by the triangular antidots important, but also the introduced offset between neighboring columns: the triangles were placed in such a coherent way that neighboring triangles support each other by simultaneously scattering electrons and forming channels through which electrons were ejected, as shown by the arrows in Figure 12(b).

In principle, these artificial materials can be made over a whole wafer. One apparent advantage is that the material is suitable for applications involving large signals, as a much higher voltage or current can be applied. Compared with the fabrication of a diode which involves multiple-step mask alignment, the production of the nanomaterial involves only one step of lithography. Therefore, the recently invented nanoimprint technology [67] can be used to mass produce these materials. It allows us to avoid the bottleneck of extremely long e-beam exposure time, a challenging problem in producing a large number of nanodevices efficiently and economically. With the nanoimprint technology, a master stamp (mold) with e-beam lithography can be used to replicate patterns over whole wafers of up to 6 in. in a matter of minutes [68]. Furthermore, for radio-frequency (gigahertz or even terahertz) applications, such as RF detection (the capability of the material to function at up to at least 50 GHz will be discussed later), it is often desirable to have a detector with a large active region in order to eliminate the need for building antennas. Moreover, as the nanomaterial is intrinsically nonlinear, individual devices can be made by simply cutting pieces from the material, according to the requirements for different applications.

The measurements on the artificial materials are very similar to those on the ballistic rectifier. An 80×80 μm^2 piece of the artificial material shown in Figure 12(b) has been measured at $T = 4.2$ K. To study how the nonlinear effect changes with the electron concentration or the electron Fermi wavelength, a layer of metal gate was evaporated on top of the artificial material after etching the triangular antidots. Negative gate voltages V_{GU} were applied between the gate and U to lower the carrier concentration of the 2DEG and increase the Fermi wavelength of the electrons. The lowered carrier concentration was directly indicated by the increase of the two-terminal source–drain resistance R_{SD}, as shown in Figure 13(c). From the figure, the pinch-off gate voltage is about -2.25 V. Figure 13(a) shows the V_{LU} versus I_{SD} curves measured at different gate voltages V_{GU} at $T = 4.2$ K. Similar to the experimental results of the ballistic rectifiers in Figure 5, the curves are not perfectly symmetric with respect to the vertical axis at $I_{SD} = 0$, which is a consequence of the imperfect device fabrication. The overall downward bending of the curves clearly indicates the expected rectifying effect. To better illustrate the influence of the gate voltage on the rectifying effect, the average output V_{LU} at $I_{SD} = +37$ μA and $I_{SD} = -37$ μA is plotted as a function of the applied gate voltage V_{GU} in Figure 13(b). The curve shows that the rectifying effect was enhanced dramatically by increasing the applied negative gate voltage. In particular, the average output increased rapidly when V_{GU} was approaching the pinch-off gate voltage of about -2.25 V.

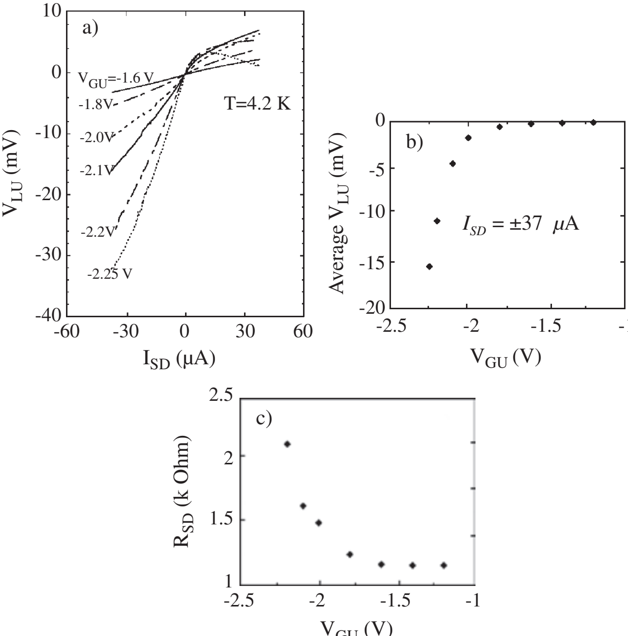

Figure 13. (a) V_{LU} versus I_{SD} curves at different voltages between the gate G and terminal U, V_{GU}, measured in an 80×80 μm^2 piece of the artificial material shown in Figure 12(b) at $T = 4.2$ K. (b) The average output voltage V_{LU} at $I_{SD} = +37$ μA and $I_{SD} = -37$ μA as a function of V_{GU}. (c) The two-terminal source–drain resistance R_{SD} as a function of V_{GU}.

The rectifying effect observed in the artificial material shown in Figure 13 can be qualitatively explained in the same physical picture. Similar to the voltage-induced collimation effect shown in Figure 9, the angular distribution of the electrons ejected out of the narrow gaps between neighboring triangular antidots at $V_{SD} = 0$ illustrated in Figure 14(a) becomes narrower at $V_{SD} < 0$, as schematically shown in Figure 14(b). The angular distribution is tilted upwards a little because of the asymmetry of the geometry [62, 69]. This leads to a higher probability for the electrons to be deflected downwards by the next triangular antidot on the side, as schematically shown in Figure 14(b), and fewer electrons will be able to transmit upwards. This induces an accumulation of electrons at the lower contact, and therefore a negative output voltage V_{LU}.

The pronounced gate–voltage dependence shown in Figure 13(a) and (b) is expected from the above model for the ballistic rectifier, although strictly speaking, Eq. (18) does not hold for the artificial material. However, since the working principle is the same, it could be used to qualitatively analyze the experimental results of the artificial material. For the material shown in Figure 12(b), by decreasing the voltage on the top gate, the electron density, and therefore E_F, reduces. From Eq. (18), the output voltage $|V_{LU}|$ will increase. Moreover, the lowered E_F also means less electron occupation of the transverse confinement modes in the gaps between neighboring triangular antidots. This can be regarded as reducing N_{SD} in Eq. (18), which also contributes to the dramatic increase of $|V_{LU}|$ in Figure 13.

Both of the artificial materials shown in Figure 12(a) and (b) could work only at temperatures below 77 K because of the large "lattice constants." It is possible to achieve room-temperature operations of the artificial material by fabricating nanomaterials with artificial lattice constants comparable to, or shorter than, the electron mean-free path [70]. Figure 15(a) is an atomic force microscope image of one of the nanomaterials that operates at room temperature, fabricated from the same InGaAs–InP heterostructure that was used to fabricate the room-temperature ballistic rectifiers. The lattice constants of the nanomaterial are $a_x =$ 800 nm and $a_y = 300$ nm in the lateral and vertical directions, respectively. Both the base and the height of the triangular antidots are 150 nm. The experimental data at room temperature are shown in Figure 15(b), in which the dc output between contacts L and U was measured as a function of the applied low-frequency (1 kHz) ac signal. The experiment

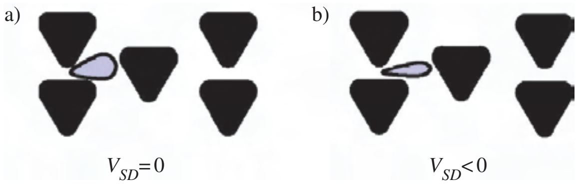

Figure 14. Similarly to the voltage-induced collimation effect shown in Figure 9, the angular distribution of the electrons ejected out of the narrow gaps between neighboring triangular antidots at $V_{SD} = 0$ (a) becomes narrower at $V_{SD} < 0$, as schematically shown in (b). The angular distribution is tilted upwards a little because of the asymmetry of the geometry.

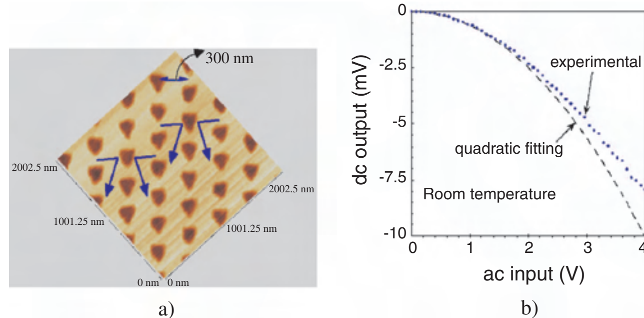

Figure 15. (a) Atomic force microscope image of one of the nanomaterials that operates at room temperature. The arrows represent typical electron trajectories. The lattice constants of the "artificial lattice" are $a_x = 800$ nm and $a_y = 300$ nm in the lateral and vertical directions, respectively. Both the base and the height of the triangular antidots are 150 nm. (b) Experimental data of a 30 μm × 30 μm piece of the nanomaterial shown in (a) at room temperature, in which the dc output between the lower and upper contacts was measured as a function of the applied low-frequency (1 kHz) ac signal. The dashed line represents a quadratic fit. Reprinted with permission from [71], A. M. Song, *Appl. Phys. A* 75, 229 (2002). © 2002, Springer-Verlag.

was performed using a 30 μm × 30 μm piece of the nanomaterial [71]. Note that the feature size of the nanomaterial is still far from ideal, that is, both a_x and a_y would ideally be shorter than l_e. The room-temperature operation shown in Figure 15(b) may be greatly improved by fabricating nanomaterials with a smaller feature size using the state-of-the-art nanolithography.

Similar to a ballistic rectifier, the in-plane nature of the nanomaterial ensures that the parasitic capacitance between contacts is much lower than in a conventional vertical device of the same size. The nanomaterial thus has an extremely high working speed, as is evident in high-frequency experiments. The curve in Figure 16 shows the output dc voltage between the contacts L and U as a function of the RF power of a 50 GHz signal, which was transmitted to the

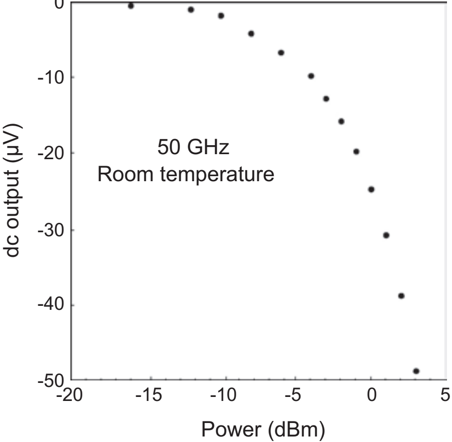

Figure 16. Output dc voltage of the nanomaterial versus the power of the applied 50 GHz signal at room temperature. The RF signal was applied to the material via coplanar probes. Reprinted with permission from [71], A. M. Song, *Appl. Phys. A* 75, 229 (2002). © 2002, Springer-Verlag.

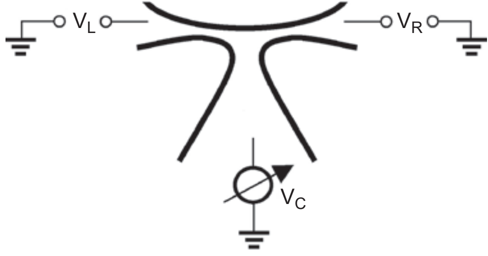
nanomaterial via coplanar probes. The ex periment was performed at room temperature. Similar results were obtained in other materials with different structural parameters.

Because of the experimental limitations, the material has not been tested at frequencies higher than 50 GHz. However, from the working principle, it is expected that the cutoff frequency will be much higher, possibly up to hundreds of gigahertz or even in the terahertz regime. The large area, in combination with the in-plane layout of the material, enables straightforward and efficient coupling to high-frequency microwaves. Moreover, microwaves traveling along the normal direction of the nanomaterial surface yield the most efficient coupling, while the coupling has to be achieved in specific ways (including using antennas) in a conventional vertical device. From the material point of view, this is the first artificial electronic nanomaterial that has been demonstrated to operate at room temperature.

The possibility of generating the dc output out of an external noise signal applied to the artificial material was also investigated. As expected, a guided net flow of electrons along the upward direction was induced, which generated a negative direct voltage between L and U [72]. In many aspects, such a ratchet effect in the artificial nanomaterial resembles the photovoltaic effect in some natural crystals [49–56, 66]. For the artificial crystals, however, one can design (adjust) the size and shape of the symmetry-breaking elemental units, as well as the lattice constants. Such flexibility may also provide a new route in further studies of the photovoltaic effect.

4. THREE-TERMINAL BALLISTIC JUNCTION DEVICES

The ballistic rectifiers and the artificial materials discussed in Sections 2 and 3 are four-terminal structures. Very recently, similar nonlinear functionalities were also discovered in another type of ballistic electron device which contained three terminals [38–40, 48]. Figure 17 schematically shows one such device. Referred to as a three-terminal ballistic junction (TBJ), Y-branch, or T-branch switch, the devices were fabricated by electron-beam lithography and chemical etching using either modulation-doped GaAs–AlGaAs heterostructures [40] or modulation-doped



A three-terminal ballistic junction

Figure 17. Sketch of a three-terminal ballistic junction device. The three branches are marked L (left), R (right), and C (center). In the experiment, a voltage V is applied to the left (L) and right (R) terminals in a push–pull fashion: $V_L = -V$ and $V_R = +V$. The output voltage V_C is measured at the lower terminal.

InGaAs–InP quantum-well wafers [38, 39]. In Figure 17, the three branches are marked L (left), R (right), and C (center). In the experiment, a voltage V is applied to the left (L) and right (R) terminals in a push–pull fashion: $V_L = -V$ and $V_R = +V$. The output voltage V_C is measured at the lower terminal. For simplicity, here we consider a symmetric TBJ device. If the electron transport is diffusive, that is, if the device size is much larger than the electron mean-free path, one would expect $V_C = 0$, regardless of the value of the input voltage. However, this turned out to be not true if the electron transport is ballistic, and V_C was found to be always negative as long as $V \neq 0$. For small applied voltages, experiments showed that V_C was a quadratic function of the applied voltage V, which is in good agreement with the theory developed by Xu [48].

In his model, Xu applied the scattering theory, and obtained an analytical expression of the nonlinear effect. The key mechanism was identified to be the nonlinear properties of each of the three narrow constrictions or point contacts: the conductance of each point contact is a function of the applied voltage (or chemical potential difference) across it.

To illustrate this, we first take a look at an individual, ideal (so-called) saddle-point contact, which is connected to two reservoirs (numbered 1 and 2) at both ends, and is spatially separated from other point contacts. The electrostatic potential of the saddle point contact is expressed as

$$v(x, y) = v_0 - \frac{1}{2}m^*\omega_x^2 x^2 + \frac{1}{2}m^*\omega_y^2 y^2 \tag{19}$$

where v_0 is the electrostatic potential at the saddle, x along the channel direction, and y in the transverse direction. The transverse quantum confinement energy levels are equally spaced by $\hbar\omega_y$. If the etched device boundary is smooth, so-called the adiabatic approximation can be applied. At zero temperature, the electrons that have energies higher than $v_0 + (1/2)\hbar\omega_y$ may pass through this single point contact without being reflected, while electrons with lower energies will have a zero possibility of passing the point contact (total reflection). At zero applied bias $V = 0$, this leads to a multiple-step dependence of the total transmission coefficient $T_{1\leftarrow 2, V=0} = T_{2\leftarrow 1, V=0} \equiv T_{12, V=0}$ on the chemical potential μ_F, with $T_{12, V=0} = 1, 2, 3, \ldots$, when μ_F is equal to or higher than $v_0 + (1/2)\hbar\omega_y$, $v_0 + (3/2)\hbar\omega_y$, $v_0 + (5/2)\hbar\omega_y, \ldots$, respectively. This actually results in the experimentally observed quantized conductance in a single quantum point contact [8, 9].

At a relatively high temperature where the thermal energy $k_B T$ is larger than the level spacing between the transverse quantum confinement modes, semiclassical approximations can be applied. The multiple-step dependence of the transmission coefficient on μ_F is smoothed out, and at zero bias voltage, T_0 becomes a linear function of μ_F:

$$T_{12, V=0} = \frac{\mu_F - v_0 + \frac{1}{2}\hbar\omega_y}{\hbar\omega_y} = \frac{\mu_F - v_0}{\hbar\omega_y} + \frac{1}{2} \tag{20}$$

as schematically shown in Figure 18.

Under the nonequilibrium condition (at a finite bias voltage V), the electrochemical potentials on both sides of the single point contact μ_1 and μ_2 become different, that is,

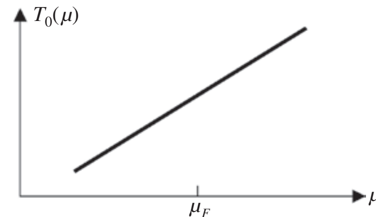


Figure 18. Linear relation between the transmission coefficients of a single, separated saddle-point contact and the chemical potential. This relation is obtained at relatively high temperatures, that is, the thermal energy k_BT is larger than the level spacing between the transverse quantum confinement modes, so that the semiclassical approximation can be applied.

$\mu_1 - \mu_2 = -eV$. Because of the linear dependence of the transmission coefficient on the chemical potential, the current can be expressed as

$$I = \frac{2e}{h}(\mu_1 - \mu_2)\overline{T_{12}} = -\frac{2e^2}{h}V\overline{T_{12}} \tag{21}$$

where $\overline{T_{12}}$ is the average transmission coefficient between μ_1 and μ_2:

$$\overline{T_{12}} = \frac{1}{2}\left[\frac{\mu_1 + \mu_2 - 2v_0}{\hbar\omega_y} + 1\right] \tag{22}$$

Clearly, if the applied voltage is dropped evenly on both sides of the point contact, which is a very good approximation of a single, symmetric point contact, then $\mu_1 = \mu_F - eV/2$ and $\mu_2 = \mu_F + eV/2$. Hence, such a simple model yields $\overline{T} = T_0$, and shows that the conductance is not sensitive to a change of the applied voltage. Note that this result is obtained under the conditions of a symmetric point contact, $|eV| < \mu_F$, and being at a relatively high temperature such that the thermal energy k_BT is larger than or comparable to the energy spacing between the transverse quantum confinement modes. Nevertheless, the above simplified model of a single point contact can be used to reveal the mechanism of the nonlinear effect of the TBJ devices, as will be discussed later.

For a TBJ device shown in Figure 17, the situation is not as simple because these three point contacts are closely connected. Even for a symmetric TBJ, as was observed experimentally, the voltage on branch C is not the average of the voltages applied to the left and right branches (which is zero in the push–pull fashion), indicating that the voltage drop in the whole device is neither even nor symmetric. Since a self-consistent calculation on the voltage drop in such an open system is very complex to perform, for simplicity, one may assume that the applied voltage is evenly dropped at the left and right terminals: $\mu_L = \mu_F + eV$, $\mu_R = \mu_F - eV$. Here, as was in the experiments, a push–pull bias fashion is assumed, and the total applied voltage is $\mu_L - \mu_R = 2\,eV$. Also, for simplicity, the potential at the saddle v_0 is assumed to be zero in all of these three point contacts, which is a good approximation if the channels are not very narrow.

If the terminal on the right is positively biased and the terminal on the left is negatively biased, that is, $V_L = -V$ and $V_R = +V$ (define such a bias polarity as $V > 0$), the net electron flows into the branch C are all from the terminal L, corresponding to a current

$$I_{C\leftarrow L} = \frac{2e}{h}(\mu_L - \mu_C)\left[\frac{\mu_L + \mu_C}{2\hbar\omega_{y(C,\,L)}} + \frac{1}{2}\right]t_{C\leftarrow L} \tag{23}$$

where $t_{C\leftarrow L}$ is the probability of the electrons transmitting from L to C. Here, $t_{C\leftarrow L}$ is assumed to be energy independent, which is a good approximation at a low applied voltage. $\hbar\omega_{y(C,\,L)}$ stands for the subband spacing of the transverse confinement modes in terminal L or in terminal C, of which $\hbar\omega_y$ is larger, and therefore of which the smaller number of occupied transverse confinement modes limits the current flow $I_{C\leftarrow L}$.

Because terminal C is a voltage probe, the net current flow in it is zero. Since $\mu_R < \mu_C, \mu_L$, the current by the electron flowing out of terminal C to R, $I_{R\leftarrow C}$, is equal to $I_{C\leftarrow L}$, and is given by

$$I_{R\leftarrow C} = \frac{2e^2}{h}(\mu_C - \mu_R)\left[\frac{\mu_C + \mu_R}{2\hbar\omega_{y(R,\,C)}} + \frac{1}{2}\right]t_{R\leftarrow C} \tag{24}$$

Similarly, here, $\hbar\omega_{y(R,\,C)}$ is the subband spacing of the transverse confinement modes in terminal C or terminal R, of which $\hbar\omega_y$ is larger, and therefore of which the smaller number of occupied transverse confinement modes limits the current flow I_{RC}.

The geometric symmetry of the device and the time-reversal symmetric lead to the relations $\hbar\omega_{y(C,\,L)} = \hbar\omega_{y(R,\,C)} \equiv \hbar\omega_{\max}$ and $t_{R\leftarrow C} = t_{L\leftarrow C} = t_{C\leftarrow L}$. Comparing Eqs. (23) and (24) yields very simple relations between the output voltage V_C, which is measured with respect to the electric ground, and the applied voltage:

$$V_C{}^2 - \frac{2\mu_F - \hbar\omega_{\max}}{e}V_C - V^2 = 0 \tag{25}$$

An analytical expression of the nonlinear effect in a symmetric TBJ device is obtained:

$$V_C = \frac{2\mu_F - \hbar\omega_{\max}}{2e} - \sqrt{\frac{(2\mu_F - \hbar\omega_{\max})^2}{4e^2} + V^2} < 0 \tag{26}$$

Similarly, it can be shown that the same result holds for $V < 0$ as shown in Figure 19. This explains the experimental discovery that the output voltage V_C is always negative. Remarkably, there are no geometric parameters of the device at all in Eq. (26) and the output voltage is only determined by the input voltage and the Fermi energy. The three-terminal ballistic junctions are therefore quite robust devices, and it is relatively easy to obtain a reproducible nonlinear behavior.

Note that, in the limit of a small applied voltage, $|V| \ll \mu_F/e$, the first term in Eq. (25) can be neglected because $|V_C| < |V| \ll \mu_F/e$. Therefore,

$$V_C = -\frac{e}{2\mu_F - \hbar\omega_{\max}}V^2 \approx -\frac{e}{2\mu_F}V^2 \tag{27}$$

by further assuming that $\mu_F \gg \hbar\omega_{\max}/2$, as derived by Xu in [48]. Equations (26) and (27) were obtained by assuming a parabolic confinement potential, Eq. (19), which is a good approximation for a narrow channel width. For

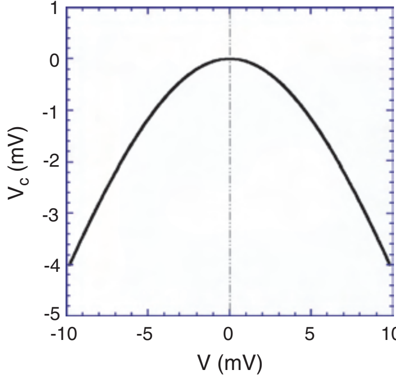

Figure 19. Theoretical results of the nonlinear output of a symmetric TBJ device. Typical parameters in the experiments were used in the calculation.

larger devices, however, a different V_C versus V relation is expected because of the different potential profiles in the device channels.

Similar to the ballistic rectifiers and nanomaterials discussed in Sections 2 and 3, TBJ devices are expected to be capable of high-frequency applications, allowed for by the ballistic transport nature and the low parasitic capacitance due to the planar device layout. This has been demonstrated in a number of experiments up to 20 GHz [73–75]. Recently, other interesting properties of the TBJ devices were predicted by Xu [76].

5. NEAR ROOM-TEMPERATURE OPERATIONS OF QUANTUM-EFFECT-BASED DEVICES

The above devices were demonstrated to function at room temperature, and the working principle is based on the semiclassical electron transport. Given the fact that the feature sizes of these room-temperture nanodevices are already comparable to the electron Fermi wavelength, it is expected to observe quantum effects not only at cryogenic, but also at elevated temperatures. In this section, we present the recent discovery of quantum effects associated with individual transverse confinement modes in some of the above devices at temperatures up to about 200 K. For the devices described in this chapter, the thermal energy k_BT at room temperature is comparable to or larger than the typical energy spacing of the transverse quantum confinement modes. It is therefore difficult to observe any quantum effect that is a direct manifestation of an individual transverse energy level at room temperature. However, it is worthwhile to point out that these devices reviewed in the previous sections are, even though not directly, fundamentally based on the wave nature of the electrons: the transverse quantum confinement levels in the narrow channels or point contacts. Otherwise, in the purely classical case, N_{SD} and N_{LU} in Eq. (18) would be infinity, leading to a zero output, even if the electron transport is ballistic. For the TBJ devices, it may appear that there was no evidence of the need for quantum transport in Eqs. (26) or (27). However, the derivations of these expressions are entirely based on Eq. (20), which actually represents the extent of the lateral quantum confinement in the point contacts. The nonlinear behavior is entirely based on the changes in the number of the occupied transverse quantum levels by the applied voltage.

Devices that display distinct quantum effects directly related to individual energy levels are expected to be ultrafast and sensitive because of the nature of the phase coherence of the electrons. A typical example of a superconductor counterpart is the superconducting quantum interference device (SQUID). Many types of semiconductor devices that directly manifest quantum effects have been realized at low (most often liquid helium) temperatures. However, it has not yet been possible to fabricate any such quantum semiconductor device that works at room temperature, largely due to the limitation in the device fabrication.

For the ballistic rectifier shown in Figure 6 and the nanomaterial shown in Figure 15(a), evidence of quantum behavior was recently observed at temperatures up to 200 K [72]. This suggests promising possibilities of realizing and operating quantum devices at room temperature in the near future by, for example, further reducing the device size. Figure 20(a) shows the experimental result of the ballistic rectifier shown in Figure 6(a), measured at a series of temperatures. Whereas, at room temperature, the negative output voltage V_{LU} was as expected in the physical picture of semiclassical ballistic transport, rather surprisingly, V_{LU} changed sign when the temperature was lowered to about 70 K. At even lower temperatures, the device generated a pronounced oscillatory output as a function of the

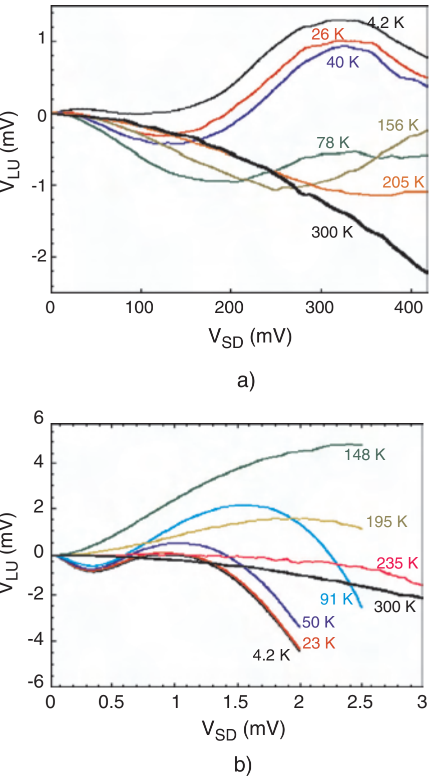

Figure 20. Normal (at room temperature) as well as reversed and oscillatory outputs (at low temperatures) of a small ballistic rectifier (a) and an artificial nanomaterial (b) as functions of the applied source–drain voltage.

applied voltage. Separate experiments showed that lower temperatures were needed to observe output reversal if the sample was illuminated by a light-emitting diode (LED) before the measurements. After the illumination, the electron concentration was increased by up to 30%, and the electron Fermi wavelength became shorter. A number of devices with different geometric parameters have also been measured, and the general trend is that, the larger the device, the lower the temperature at which the output reversal starts to be seen. Both facts suggest that quantum effects play an important role in causing the reversed and oscillatory output. This may be expected because the width of the source and drain channels, from which the ballistic electrons are ejected, is comparable to the electron Fermi wavelength (about 30–40 nm).

Recently, Fleischmann and Geisel developed a quantum model on a ballistic rectifier, and predicted reversed and oscillatory output [77–79]. The mechanism was attributed to the large difference between the channel widths of the upward and downward electron transmissions from S and D in the ballistic rectifier, that is, the gap between the triangular antidot and the edge of the upper channel is much narrower than the gap between the triangle and the edge of the lower channel. They argued that, when the applied voltage is small, the number of occupied modes of transverse quantum confinement in the (lower) wider gap may increase because of the applied voltage, while the number of occupied modes in the (upper) narrower gap remains constant due to the larger energy separation of the lateral confinement energy levels. This gives rise to the "normal" rectifying effect ($V_{LU} < 0$). If the applied voltage is high enough to open up a new mode in the upper gap, however, it was predicted that the output V_{LU} should undergo a change of sign, that is, output reversal.

While the result predicted by the model appeared to be in good agreement with the experimental data in Figure 20(a), such a mechanism for the output reversal does not seem to exist in the nanomaterials shown in Figure 15(a). This is because, in the nanomaterial, the width of the channel, which the electrons have to pass through to transmit upward after being ejected from a narrow gap between two neighboring triangles in a vertical column, is identical to the channel width of the downward electron transmission. As a result, the changes in the occupied lateral confinement modes in the channels of both the upward transmissions and the downward transmissions, induced by the applied voltage, are essentially identical. However, when measuring the nanomaterials with various geometric parameters, very similar reversed as well as oscillatory outputs were observed, which are unexpected from the model in [77]. This indicates that a different physical process is responsible for the observed oscillatory and reversed output.

Figure 20(b) shows the low-temperature experimental results of the artificial material, the geometric parameters of which are very similar to those shown in Figure 15(a). For this particular nanomaterial, the output reversal persists at up to about 200 K. Further observations, such as the dependence on device size and the influence of illuminations on the devices at low temperatures, also strongly suggest that the phenomena are a manifestation of quantum effects.

In Figure 20(a) and (b), the output is "normal" at room temperature, which has been understood in the framework of the classical ballistic transport in Section 2.2. To understand the output reversal and the oscillatory output, it was noticed that both the width of the source and drain channels in the ballistic rectifier and the width of the gaps between neighboring triangles in a vertical column in the nanomaterial are comparable to the electron Fermi wavelength, which is about 35 nm in the samples. By taking into account the finite depletion depth at the etched device boundaries, the real widths of the lateral quantum confinement are even narrower than those shown in the scanning electron micrographs. If temperature is lowered from room temperature, the electron transport may hence go from classical regime to the quantum transport regime.

Consider the ballistic rectifier first. At sufficiently low temperatures, the transverse modes in the source and drain channels become well resolved. From the width of the source and drain channels, it was estimated that there were between one and four occupied modes at low temperatures. In this estimate, the depletion depth, about 10–20 nm at each edge of the etched channels, has been taken into account. Similar to the case of a quantum point contact in the adiabatic transport regime, each mode contributes to a specific angular pattern of the electron flow from S. The number of lobes (or branches) in the pattern of electron flow corresponds to the number of maximums in $|\psi|^2$ (where ψ is the electron transverse wavefunction), as a direct result of the adiabatic transport. Therefore, for the Nth transverse mode, the number of lobes is N. Such branch-like patterns of electron flow were recently imaged using a low-temperature scanning probe microscope [80, 81]. For simplicity, assume that there is only one occupied mode in the source and drain channels at zero applied voltage, which corresponds to the angular pattern of the electron flow shown in Figure 21(a), but the following discussion applies to other (if not too large) numbers of initially occupied modes. If a small negative source–drain voltage is applied, the voltage-induced collimation effect leads to a narrower angular pattern of the electron flow out of S, which is similar to the case at higher temperatures shown in Figure 9(d). As a result, the downward transmissions of the electrons deflected by the triangular antidot increase, resulting in a normal negative output V_{LU}. If the applied negative voltage is decreased further, however, the right-moving electrons from S will eventually occupy the second lateral confinement mode [25]. The second mode gives rise to a two-branch angular distribution on top of the single-branch pattern of the first occupied mode. In total, there are three lobes of electron flow, as shown in Figure 21(c). The widening of the angular distribution clearly results in an increased probability (or percentage) for the electrons to transmit upward, and a reduced probability of the downward transmissions. As shown by a detailed model and analysis in [47] (see Eq. (6) and the discussions), the output of a ballistic rectifier is determined by the relative changes of the transmission coefficients $\Delta T/T$, rather than the absolute values of the changes ΔT. Therefore, the increased probability for the electrons to transmit upward and the reduced probability of the downward transmissions, which are discussed above and illustrated in Figure 21(c), will lead to an increase in V_{LU}, and may even

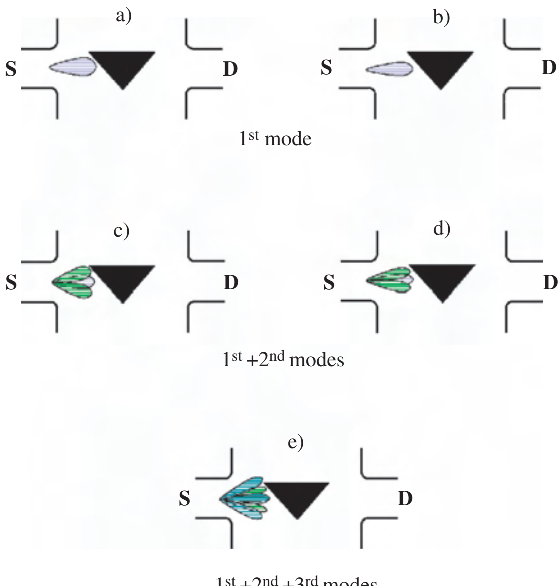

Figure 21. Schematic model for the output reversal and oscillatory output in the ballistic rectifier at low temperatures. As an example, suppose that there is only one lateral confinement mode occupied in the source channel when the applied voltage V_{SD} is zero. As a result of the adiabatic transport at low temperatures, the electrons ejected out of S have a narrow (rather than uniform) angular distribution (a). With decreasing V_{SD}, the angular distribution first becomes narrower due to the collimation effect induced by applied electric field, as shown in (b). By decreasing V_{SD} further (more negative), eventually the second lateral confinement mode becomes occupied, which gives rise to a two-branch angular distribution, on top of the single-branch pattern of electron flow of the first occupied mode. In total, there are three lobes in the electron flow (c). The total angular distribution will become narrower again with continuing decreasing V_{SD} because of the voltage-induced collimation effect (d), until at some point, the third transverse confinement mode starts to be occupied, giving rise to three additional lobes as shown in (e). Overall, by decreasing the applied voltage V_{SD} from zero, the angular distribution of the electrons ejected out of S changes alternately by subsequently narrowing (b), widening (c), narrowing (d), widening (e), and so on. Consequently, both the upward and downward transmission probabilities are oscillatory functions of V_{SD}, and this induces the oscillatory output V_{LU} which is shown in Figure 20.

cause output reversal (from negative to positive). If the negative applied voltage is decreased further (more negative), the applied voltage or electric field should again cause a narrowing of the overall angular pattern of the electron flow, as shown in Figure 21(d). The right-moving electrons hence have more and more chance to be scattered downward by the triangle on the right-hand side. This contributes again to a decrease in V_{LU}. A further decrease of the applied voltage will, at some point, cause the third transverse confinement mode to be occupied, giving rise to three additional lobes of electron flow, as shown in Figure 21(e), resulting in an increase in V_{LU}. Overall, by decreasing the applied voltage V_{SD} from zero, the angular distribution of the electrons ejected out of S changes alternately by subsequently narrowing (b), widening (c), narrowing (d), widening (e), and so on. Consequently, both the upward and downward transmission probabilities for the electrons ejected from S are oscillatory functions of V_{SD}, and this induces the oscillatory output.

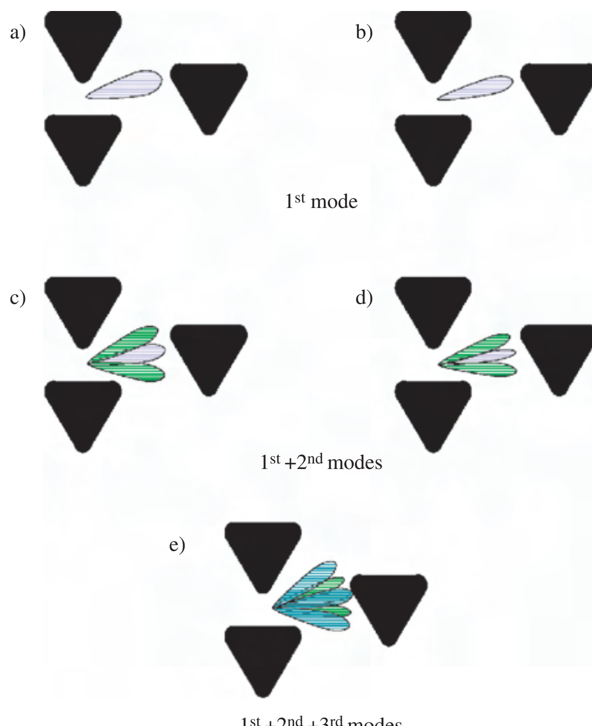

Figure 22. Schematic model for the output reversal and oscillatory output in the nanomaterial, which is similar to the case of the ballistic rectifier shown in Figure 21. For simplicity, only a small, representative part of the nanomaterial is sketched here. By decreasing the applied voltage to the nanomaterial V_{SD} from zero, the angular distribution of the electrons ejected right out of the gaps changes alternately by subsequently narrowing (b), widening (c), narrowing (d), widening (e), and so on because of the interplay between the voltage-induced collimation and the opening of additional lateral confinement modes in the gaps. As a result, the reversed and oscillatory output was observed in the experiments.

The reversed and oscillatory output in the nanomaterial can be explained very similarly, as sketched in Figure 22. At low temperatures, similar to the case of the ballistic rectifier, by reducing the applied voltage V_{SD} from zero (more negative), the angular distribution of the electrons ejected out of each gap changes alternately by narrowing (b), widening (c), narrowing (d), widening (e), and so on, as shown in Figure 22. This similarly results in an oscillatory modulation to the transmission probabilities for the electrons to be transmitted upward and downward, and hence leads to the oscillatory output V_{LU} in the nanomaterial, as shown in Figure 20(b).

The ballistic rectifier and the nanomaterials are still much larger than the smallest devices that can be fabricated with state-of-the-art nanolithography. By, for example, reducing the device size further, it is promising that these and other new types of room-temperature quantum devices would be realized in the near future, and lead to exciting applications.

6. CONCLUSIONS

Since the invention of the integrated circuit in 1959, the remarkable progress of the semiconductor industry has been described by Moore's law: every 12–18 months, the

integration density of integrated circuits doubles. While such a trend has been sustained for over three decades, it has been realized for many years that the miniaturization of conventional semiconductor devices will soon reach its limit, and the following generations of electronic devices will have to be built with nanoscience and technology, and be based on completely new concepts. From an application point of view, there is substantial industrial interest in new types of nanodevices that operate at room temperature, and at gigahertz or even terahertz frequencies. Despite great efforts in explorations of novel nanodevices that can be reproducibly fabricated for mass production, and that can function at room temperature, there has been very little success. One important reason is that, in order to work at room temperature, most electronic nanodevices proposed so far require a dimension of about a few nanometers, which is at the limit of even the best state-of-the-art facilities today. For example, although the first single-electron transistor (SET) was realized more than ten years ago [82], it is still very challenging to fabricate SETs that operate at room temperature [83–85]. Apart from the operation temperature, another key issue is the working speed, which is desired to be higher than 10 GHz for the next generation of integrated circuits. A great effort has been made to design SETs that operate at high speed [86].

The investigations on novel nanoelectronic devices reviewed above have provided working devices at room temperature, as well as gigahertz frequencies. Since the required device dimensions for ballistic transport are determined by the electron mean-free path of the host material, which is fairly long (about 150 nm) in III–V heterostructures, such and other room-temperature ballistic devices can be fabricated reproducibly with the currently available techniques in the industry. Although ballistic electron transport has been studied for more than two decades, new concepts of room-temperature ballistic devices are still being discovered, such as the devices discussed in this chapter. Currently, it is still very challenging to realize ballistic electron transport in silicon materials at room temperature because of the very short mean-free path (about 10 nm) [87]. Such a precision of device fabrication is nevertheless expected to be achieved by the industry in the near future. Apart from the bottom-up approaches, such as the promising possibilities of using nanowires to build novel room-temperature devices [88, 89], the top-down approach of design and fabrication of new types of ballistic devices such as the examples introduced in this Chapter, seems to be one of the most feasible routes to provide new building blocks for the next generation of electronics.

GLOSSARY

Ballistic rectifier A new type of nanometer-scale nonlinear device that functions like a bridge rectifier. Unlike a conventional diode, the working principle is based on the ballistic electron transport and symmetry breaking, and does not require the use of a doping junction or barrier structure to achieve nonlinear functionality.

Ballistic transport A type of electron movement contrary to the diffusive transport. If the dimension of an electronic device is smaller than the electron scattering length (mean-free path), electrons may travel from one electrode to another without encountering any scattering event from randomly distributed scatterers, such as impurities. Instead the electrons are scattered only at the device boundary, that is, moving like billiard balls. Such an electron movement is called ballistic transport.

Electron-beam lithography A standard process to create nanometer-scale structures. The resolution is generally much higher than optical lithography, well below 100 nanometers. The pattern definition is achieved by a high-energy electron beam focused on a thin layer of resist that is chemically sensitive to an electron beam. The resist layer is then developed in a suitable solution, in which either the exposed areas or the unexposed areas are selectively dissolved.

Electron mean-free path An important quantity to describe the electron transport in a material. Also often referred to as the electron scattering length, it stands for the average distance between the randomly distributed scatterers in a semiconductor material, such as defects, impurities, and phonons.

Heterostructure A multilayer semiconductor material created by growing two or more different types of semiconductors on top of each other. Each layer is normally quite thin, around tens of nanometers, and the degree of the interface homogeneity can reach the atomic level by using epitaxial growth technique, such as molecular beam epitaxy.

Mesoscopic scale The dimension between the atomic scale and macroscopic scale, typically shorter than one micron but longer than one nanometer. Ballistic electron transport devices, for instance, normally require mesoscopic dimensions.

1. INTRODUCTION

In recent years a number of experiments have been performed utilizing scanning probe techniques for the investigation of the electronic properties of semiconductor nanostructures and similar systems like two-dimensional electrons on metallic surfaces or carbon nanotubes and other molecular nanostructures. Most of these experiments fall into one of the following three classes:

- Scanning tunnelling microscopy experiments, in which the tunnelling current between the conducting tip of a scanning tunnelling microscope and an electronic system is measured. Prominent examples are local density-of-states measurements on two-dimensional electron gases on metallic surfaces [like on the silver (111) surface] or semiconducting surfaces (like InAs surfaces), or even on individual carbon nanotubes.
- Scanning near field optical microscopy experiments, which allow one to measure optical excitations of individual nanostructures.
- Local probe experiments coupling a metallic sensor capacitively to a buried electronic system (e.g., the electrons in semiconductor heterostructures in which the two-dimensional electron gas is laterally patterned into quantum point contacts, quantum wires, or quantum dots). Examples for such experiments are scanning gate measurements, subsurface charge accumulation experiments, measurements with a scanning single-electron transistor, or experiments related to the Kelvin probe force microscopy.

This chapter concentrates on the last class of experiments and tries to give an overview of this field of experimental research in solid state physics. Most of these experiments had to be performed in a cryogenic environment at temperatures below 4.2 K. The reason for this lies in the relevant quantum mechanical energy scales in semiconductor nanostructures, like the Fermi energy (typically of the order of 10 meV), electrostatic charging energies (typically below 1 meV), and confinement energies (typically below 100 μeV). In addition, magnetic fields of up to about 10 T have been applied in order to be able to investigate systems in the quantum Hall regime.

In conventional low-temperature magnetotransport experiments on mesoscopic systems the measured conductance does not give direct insight into microscopic properties within the system. Within the Landauer–Büttiker description of the conductance in nanostructures the conductance is determined from the *asymptotic* behavior of the scattering states in the leads (i.e., from the corresponding transmission coefficients). This means that no microscopic information about the states *within* the nanostructure can be directly obtained from such measurements. On the other hand, detailed microscopic theories (e.g., based on the complete scattering wave functions) have to be invoked for the calculation of the conductance. These theories have to make assumptions about local potential landscapes in the structures in order to lead to quantitative results.

Scanning probe techniques can give more detailed information about the interior of a mesoscopic system, help to find the right model parameters for theoretical calculations, confirm theoretically predicted microscopic details of quantum systems, or even reveal theoretically unanticipated microscopic features.

Although this combination of magnetotransport experiments and scanning probe techniques seems to be a straightforward extension of the available experimental techniques,

Volume 9: Pages (391–413)

it turned out that the realization of these experiments is nontrivial and the number of successful experiments is smaller than one might have expected a couple of years ago. In the following, we try to review these experiments and related theoretical approaches.

In the second section the required scanning probe microscopy (SPM) instrumentation will be discussed. This includes the design criteria and a particular implementation of a suitable cryo-SFM (scanning force microscope) operating down to 300 mK and in magnetic fields up to 9 T. The third section describes a basic Kelvin probe force experiment on a two-dimensional electron gas in a GaAs/AlGaAs heterostructure. It serves as an example how a metallic tip couples capacitively to a buried electronic system and gives an exemplary demonstration of the effects that have to be taken into account. The fourth section covers scanning gate experiments on semiconductor nanostructures. As an example, scanning gate measurements on a quantum wire are discussed in detail. The last section reviews the investigation of edge channels in the quantum Hall regime with scanning probe techniques.

2. INSTRUMENTATION

2.1. Low-Temperature Scanning Force Microscopes

Since its invention by Binnig et al. [1], the SFM has become a standard tool for the investigation of conducting and insulating surfaces on the atomic scale. On the instrumentation side many low temperature SFMs have been built for more than a decade by researchers (see [2] for a historical overview). The first cryo-SFMs have become commercially available only recently, reaching base temperatures around 5 K under ultra-high-vacuum (UHV) conditions. Lower temperatures have been reached with home-built microscopes in non-UHV setups [3–7]. Such cryo-SFMs are desirable for many applications in physical research. The physics of mesoscopic semiconductor structures is a particular field of application.

2.2. Design Criteria

Here we discuss cryo-SFMs needed for the investigation of buried two-dimensional electron gases and laterally defined nanostructures on the microscopic scale. The required lateral resolution is given by the Fermi wavelength of the electrons which is 30–50 nm in typical structures. Only one or two nanostructures with a size of about 1 μm are located on a large 5 mm$\times$5 mm chip. Finding such a structure at low temperatures without optical access to the microscope is a major challenge. Large scan ranges of several μm are therefore important and a positioning system is needed for coarse positioning the structure at low temperatures.

The low temperatures are needed due to the small energy scales relevant for such structures. Elastic impurity or boundary scattering dominates the transport properties of electrons at temperatures below 4.2 K. At these temperatures quantum phenomena in electron transport such as the Shubnikov–de Haas effect or the quantum Hall effect can be observed. For the investigation of phase-coherence effects such as weak localization or conductance fluctuations temperatures below 1 K are typically required. Charging effects in quantum dots (i.e., the Coulomb blockade effect) become important at even lower temperatures. However, the cooling power of cryostats decreases with base temperature that can be achieved. While the cooling power of a ^{4}He cryostat is typically many mW at 2 K, a ^{3}He cryostat has a cooling power of the order of 0.1 mW and the cooling power of dilution refrigerators can be even smaller. Operating an SFM requires a large number of cables leading to a significant heat load which may diminish the time for scanning at base temperature in single shot systems (e.g., most ^{3}He-systems) or may not allow one to reach base temperature in dilution refrigerators, if thermal anchoring of the cables is not efficient.

Low-dimensional semiconductor structures show a rich variety of phenomena such as the quantum Hall effect only at elevated magnetic fields. Therefore a transport setup with a cryo-SFM has to include a superconducting magnet supplying magnetic fields of the order of 10 T and all the SFM components have to be made of nonmagnetic materials.

A feedback mechanism is needed for keeping the local sensor at a well-controlled distance from the sample surface. Typical semiconductor nanostructures are sensitive to light (persistent photoeffect) and therefore a nonoptical cantilever deflection detection method is needed. Such a method has the additional advantage that it leads to less involved setups.

The whole microscope has to be small enough in order to fit into the cryostats. While the sample space needed for a transport experiment at cryogenic temperatures is of the order of 1 cm^3, a SFM is much bigger. The size constraint is mainly dominated by the magnet bore which in turn is a main factor entering the prize of the magnet.

A modular design for such a microscope has to be preferred. Several components with different functionality and maintenance requirements are combined in an SFM. Easy access and exchange possibility has to be provided for all the components. Mechanical stability of the whole assembly is crucial for stable operation. Only the highest quality of all components will warrant satisfying performance of the SFM at cryogenic temperatures.

2.3. SFM Operated in a ^{3}He System

In the following we describe a SFM operating at temperatures between 350 K down to 300 mK and in magnetic fields up to 9 T. The microscope is operated in vacuum; however, samples and tips cannot be prepared and exchanged under UHV conditions, in contrast to other setups [2, 8]. Piezoelectric quartz tuning forks were employed for nonoptical tip–sample distance control in the dynamic operation mode. Faster response is achieved by employing a phase-locked loop for driving the mechanical oscillator.

Figure 1 shows a schematic drawing of the cryostat setup in which the microscope is implemented. The cryostat is sitting in a hole in the concrete lab foundation. The whole concrete block is mechanically decoupled from the rest of the building thereby providing a mechanically very quiet environment. Effective insulation of the cryostat from remaining vibrations is achieved by suspending the whole ^{3}He insert

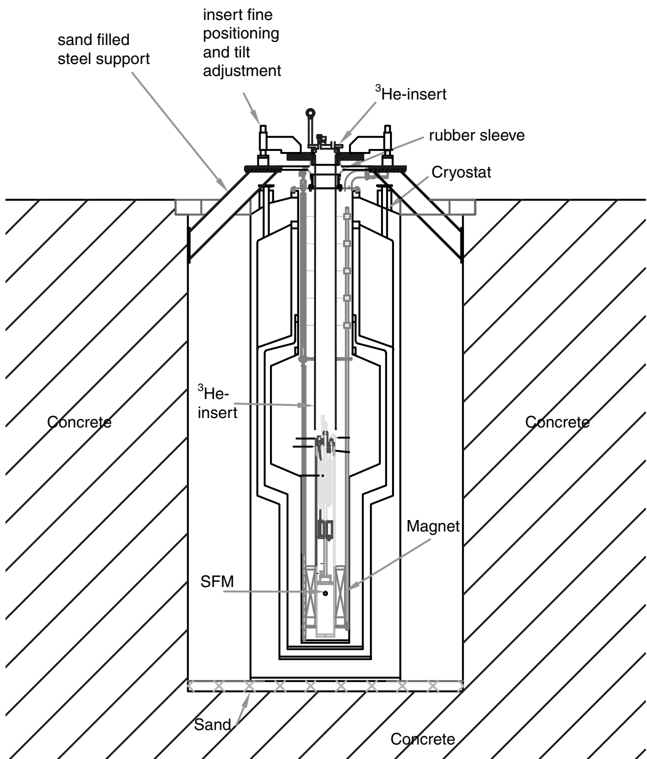

Figure 1. Schematic setup of the whole experimental setup including the cryostat, the ^{3}He insert, the superconducting magnet, and the microscope. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

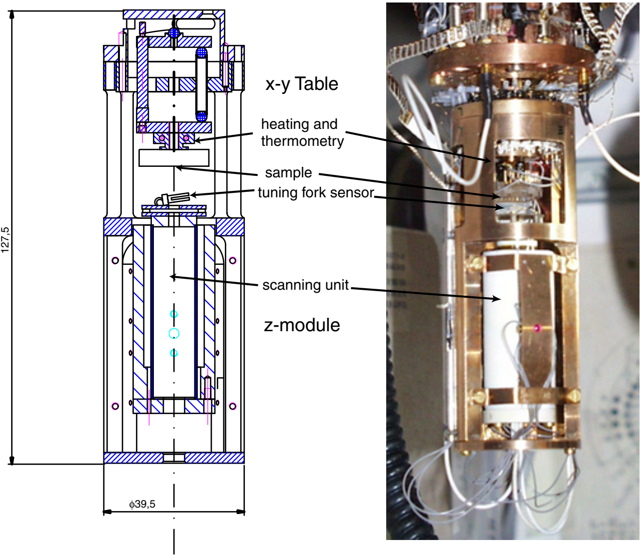

Figure 2. Schematic drawing of the microscope (left) and photography (right). Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

from a special low-vibration platform resting on four sand-filled steel supports into the ^{4}He dewar which also hosts the superconducting magnet. The only mechanical coupling between the dewar and the ^{3}He insert is made via a soft rubber sleeve needed in order to make the cryostat ^{4}He-tight. The ^{3}He insert can be fine positioned parallel to the lab floor and adjusted into exactly vertical position. Pumping lines and the He-recovery lines are plastic pipes laid through a box of sand in order to minimize mechanical coupling between pumps and the system. For the same reason, pumps are not located on the same concrete platform that hosts the cryostat setup. Microphony of the cryostat is reduced using a rubber mat which is tightly tied up to the cryostat body.

Figure 2 shows a schematic drawing of the completely home-built microscope comprising the two main units, the z-module, and the x–y table. This assembly is firmly attached to the ^{3}He pot of the commercial vacuum loading ^{3}He insert. A vacuum beaker that can be pumped down to about 10^{-5} mbar at room temperature surrounds the refrigerator and the microscope (cf. Fig. 1). The microscope can be operated in vacuum at temperatures down to 280 mK. About 50 cables, 6 of which are coaxial lines and 12 are suitable for high voltages up to 1000 V, connect this insert to the electronic setup outside the cryostat. Experiments at base temperature can be performed for about four days before it becomes necessary to recondense ^{3}He.

The z-module of the microscope (cf. Fig. 2) allows coarse tip–sample approach using a slip–stick drive moving the scan-piezo up or down. It hosts the scan-piezo tube at the end of which the tip–sample interaction sensor is mounted.

The outer frame of the z-module is machined out of nonmagnetic CuBe. The slip–stick z-motor has been constructed following the design of [2, 8]. It uses six shear-piezo stacks, which had to be fabricated by ourselves initially but are now available commercially [105]. Each stack consists of six shear-piezo plates and a sapphire endplate. A macor prism is clamped between the six stacks using a CuBe sheet as a spring. AlO plates are glued onto the macor prism in the places where the sapphire endplates of the stacks touch.

The macor prism has a central hole hosting the scan-piezo tube. The latter is made of a lead-zirconate-titanate ceramic [106] with nonmagnetic copper electrodes. The tube scanner has a length of 2 inches and an outer diameter of 0.5 inch. It gives a lateral scan range of 52.2 μm in the x–y direction and a z-range of 5 μm at a temperature of 290 K. At base temperature the lateral range is 8.8 μm and the z-range is 0.85 μm.

A sensor mount is attached to the end of the scan-piezo with tapped through holes for screwing the sensor plate onto it. The screws also provide electrical contact of the sensor plate to six coaxial cables.

The x–y table (cf. Fig. 2) is shown in detail in Figure 3. It consists of three main parts.

An x–y motor allows coarse positioning of the sample. It has a travel range of about 5 mm corresponding to the typical size of a semiconductor chip used in the experiment. The motor is built on a Shapal [107] platform. This ceramic material was used because of its comparably large thermal conductivity of 100 W/(mK) at room temperature, its thermal expansion coefficient of 5.2×10^{-6} K^{-1} at room temperature which is very close to that of piezoceramic materials, and the possibility of machining it. Three thin-walled piezo-tubes [108] with sapphire balls at their ends are fed through holes

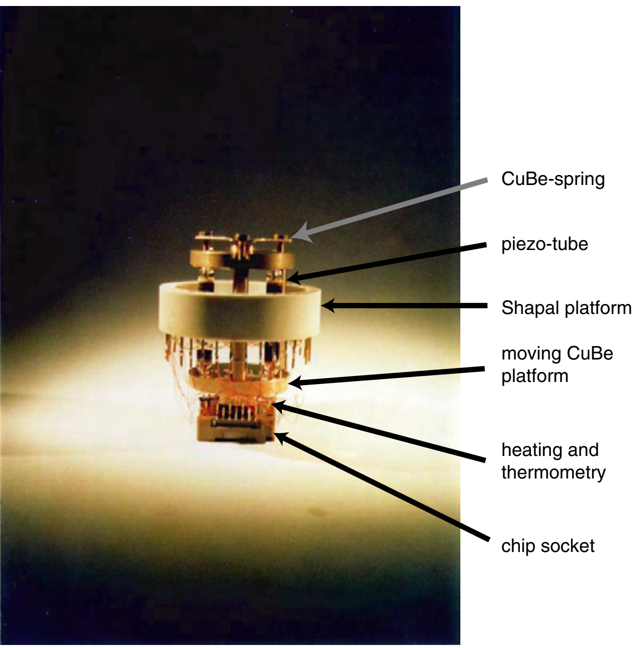

Figure 3. Photography of the x–y table. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

in the Shapal platform and firmly attached with insulating epoxy glue [109]. These tubes stick out above and below the platform. They can bend in x- and in y-direction similar to a conventional scan-piezo due to their four outer electrode segments. The moving x–y platform made of CuBe is clamped with a CuBe spring from top and bottom against the sapphire balls. Suitable sawtooth voltages applied to the electrodes of the piezo-tubes lead to slip–stick motion of the moving platform. At room temperature, about 30 V are sufficient to move the stage; at 100 V a single step amounts to about 1 μm. The motion in the x- and y-direction was found to be orthogonal with high accuracy.

Mounted on this moving CuBe platform there is a Cu block hosting two thermometers and a heating wire used for measuring and controlling the sample temperature. The heater allows us to evaporate the water film from the sample surface before cooldown. It further gives us the possibility to keep the sample warmer than its surroundings during the cooling process in order to avoid freezing contaminations on the sample surface.

On top of the thermometry block we have mounted a commercial 32-pin chip socket for ceramic chip carriers. The pins are connected to pins on the Shapal platform. The samples are prepared in chip carriers which can then simply be plugged into the socket. The sample mount unit can be used for standard magnetotransport measurements independent of the SFM operation.

2.4. Types of Sensors

There are a number of candidates for use as sensors in a scanning probe experiment on nanostructures. The most obvious one is the tip of a scanning tunnelling microscope [10]. Piezoresistive cantilevers have been proposed [11] and applied for low temperature scanning force microscopy [3, 6, 7, 12–18]. However, these cantilevers are expensive and not easily available. Recently, piezoelectric quartz tuning forks have been employed in a scanning near-field optical microscope designed for operation at low temperatures [19]. They have been successfully employed for atomic force microscopy (AFM) [20], scanning near field optical microscopy [19, 21–24], magnetic force microscopy [25], and acoustic near field microscopy [26]. A very involved and specialized sensor is a scanning single-electron transistor [27]. In the following we will briefly introduce the four sensors mentioned.

Probably the simplest sensor allowing capacitive coupling to a buried electronic nanostructure is a metallic tip as conventionally used for scanning tunnelling microscopy (STM). Such tips are commercially available or they can be electrochemically etched from tungsten or platinum/iridium wires. Used in conventional tunnelling mode topographic images can be obtained. However, since in typical semiconductor nanostructures the electronic system is buried underneath an insulating barrier of considerable thickness (typically more than 35 nm), relatively high voltages have to be applied in this imaging mode and irreversible local charging of the structure may result at low temperatures.

STM tips have been successfully employed for the so-called "subsurface charge accumulation imaging" [10] which can be—most simplified—described as a local capacitance measurement. In order to reach a sufficient sensitivity to very small local capacitance changes, stray capacitances have to be minimized by mounting a field-effect transistor (FET) at low temperature in close proximity to the tip. With this FET a low-temperature capacitance bridge can be realized [28] which can measure changes in capacitance as small as about 10 aF. A low-temperature current preamplifier has been employed for the measurement of shot noise in a scanning tunnelling microscope [29].

Piezoresistive cantilevers have been developed at Stanford University [11] in order to avoid more elaborate methods of cantilever deflection measurement, such as laser beam deflection or optical interferometry. This simplifies the design of a cryogenic scanning force microscope considerably. Such cantilevers are now available from Park Scientific Instruments. Piezoresistive cantilevers are fabricated from silicon wafers. The top layer of the cantilever is doped by ion implantation and shows a piezoresistive effect which is used to measure the cantilever deflection. These cantilevers have typical spring constants between 1 and 20 N/m. The resonance frequencies are between 25 and 240 kHz depending also on the cantilever preparation procedure. The total resistance of the piezoresistive layer is of the order of 2 kΩ and voltages of the order of several volts are used for measuring the resistance. This leads to a considerable joule heating of the sensor with a power of the order of a few milliwatts. The relative resistance change $\Delta R/R$ is proportional to the cantilever deflection Δz. That is,

$$\frac{\Delta R}{R} = \alpha \cdot \Delta z$$

where the proportionality constant α depends on the geometry of the lever. Typical values are in the range of

$(1–4) \times 10^{-6}$ nm^{-1}. A Wheatstone bridge is used to measure the resistance change with a resolution at least in the range of 10^{-6}. On-chip fabrication of the bridge is possible and can help to compensate the temperature dependence of the resistance. Vertical resolution of 0.1 Å has been demonstrated at a bandwidth of 1 kHz [11]. Force sensitivities of 8.6 fN/$\sqrt{\text{Hz}}$ have been reported [30].

Piezoresistive cantilevers have found many applications in the field of scanning probe techniques. They were, for example, used for magnetic force microscopy [31], infrared imaging [32], biosensing [33], parallel imaging, and lithography [34, 35] and are still subject of research [30]. An interesting self-sensing cantilever concept with an integrated field-effect transistor has been developed in [36].

For capacitive coupling to a buried electronic system coated [7] and uncoated [3, 6] cantilevers have been used. A metal coating (e.g., made of iridium) makes sure that the tip surface is an equipotential.

Piezoelectric tuning forks are an alternative to the piezoresistive cantilevers. They have initially been developed for the realization of very small and stable oscillators in watches. Due to their use in industry they are cheap and easily available. The forks are fabricated from wafers of α-quartz with the optical axis (c-axis) approximately normal to the wafer plane. Most of them have a (lowest) resonance frequency $f_0 = 2^{15}$Hz and quality factors in vacuum between $Q = 20{,}000$ and 100,000. In scanning force microscopy and related techniques tuning fork sensors offer the possibility of nonoptical detection of the tip oscillation in the dynamic mode via the piezoelectric effect [19–26, 37–39]. It was demonstrated that atomic resolution is possible with these unconventional and very stiff sensors [40]. The fundamental limits to force detection with quartz tuning forks were discussed by Grober and co-workers in [41]. Due to the high oscillator quality of tuning forks the power loss on resonance can be far less than 0.1 μW, which makes them ideal for use in low cooling power cryostats.

For experiments on semiconductor nanostructures a conductive tip is required for coupling capacitively to the buried electron gas. One possible realization of such a sensor is depicted in Figure 4. It is the same type of tuning fork sensor previously discussed and calibrated in [39, 42]. The commercially available tuning fork [110] is first prepared by carefully removing its protecting lid on the lathe. The fork is then soft-soldered onto a small circular piece of printed circuit board at an angle of about 10°. A 15 μm PtIr wire is glued with conducting epoxy [111] to the end face of one tuning fork prong parallel to the direction of its vibrational bending motion and to the copper post which serves as the electrical contact to the tip. The free end of the wire is then etched electrochemically resulting in a sharp tip which serves as a probe for the sample surface. Tip radii of about 30 nm have been confirmed using scanning electron microscopy and transmission electron microscopy techniques. The length of the tip measured from the edge of the tuning fork should not be longer than about 300 μm since the thin wire becomes unstable otherwise due to bending vibrations occurring during scans.

The tip prepared on the tuning fork can be used as a tunnelling tip (STM mode) or as the tip in dynamic SFM

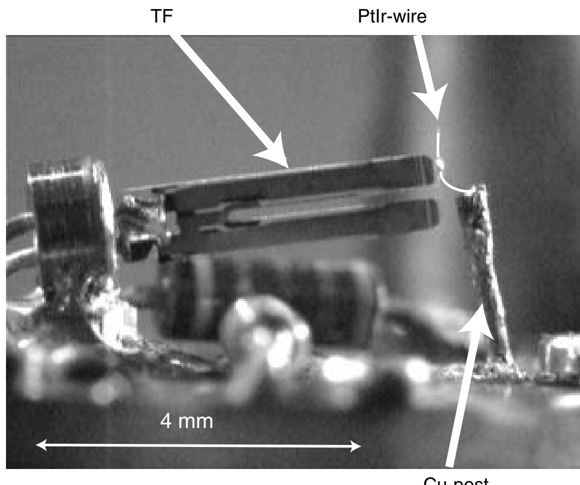

Figure 4. Tuning fork sensor used in our cryo-SFM. The casing of a commercial tuning fork (TF) is soldered on a small circular piece of printed circuit board (PCB). The PtIr wire is glued to the end of one prong of the fork. One end of the wire is connected electrically to the copper post (Cu post); the other end serves as the tip. The PCB can in addition host small electronic components, like the resistor that can be seen in the foreground. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

operation mode without any modifications on the scanning head. This gives simultaneous access to two complementary imaging modes at low temperatures without the need for tip exchange.

Given that the added mass (i.e., the glue and the wire material) is small compared to the mass of a single tuning fork arm and that the relative mechanical coupling of the two prongs is strong compared to the influence of the added mass and the added spring constant (introduced by the wire), tuning fork sensors can be modelled as harmonic oscillators (in complete analogy to conventional cantilevers) with an equation of motion

$$\ddot{x} + \frac{\omega_0}{Q}\dot{x} + \omega_0^2 x = \frac{\alpha_p}{m}U_0 + \frac{1}{m}F_{ts}(x) \tag{1}$$

where x is the deflection of one prong from the equilibrium position, ω_0 is the resonance frequency, and Q is the quality factor of the oscillator. The piezoelectric coupling constant α_p describes the coupling between the mechanical motion and the charges on the tuning fork electrodes, U_0 is the driving voltage, m is the effective mass of the oscillator, and $F_{ts}(x)$ is the tip–sample interaction force. To arrive at this model, the coupling between the center of mass and the relative motion of the prongs which can be estimated to be small has been neglected.

The mechanical oscillation of tuning fork sensors is measured via the piezoelectric effect of the quartz crystal. The induced piezoelectric charge on one tuning fork electrode is given by $q_p = 2\alpha_p x$ and the corresponding piezoelectric current is $I_p = 2\alpha_p \dot{x}$. In addition, a current of magnitude $I_c = C_0 \dot{U}_0$ flows through the capacitance C_0 between the tuning fork contacts. The total current as a function of

frequency $f = \omega/2\pi$ is therefore given by $I(\omega) = i\omega C_0 U_0 + 2i\alpha_p \omega x(\omega)$. If we neglect the tip–sample interaction force we can determine $x(\omega)$ from the harmonic oscillator model [Eq. (1)] and thus the admittance $G(\omega)$ is found to be

$$G(\omega) = \frac{I(\omega)}{U_0} = i\omega\left(C_0 + \frac{2\alpha_p^2/m}{\omega_0^2 - \omega^2 + i\omega\omega_0/Q}\right) \quad (2)$$

This admittance corresponds to the equivalent circuit shown in the inset of Figure 5b. Resonance curves like the one shown in Figure 5b can be excellently fitted with this equation.

In order to determine the mechanical tuning fork oscillation amplitude, the piezoelectric coupling constant α_p has to be determined in a calibration measurement [42]. This can be achieved by measuring the mechanical motion of one prong with a laser interferometer simultaneously with the electrical admittance as shown in Figure 5. From a combination of both measurements an effective mass $m =$ 0.332 mg, a quality factor $Q = 61734$, and a piezoelectric coupling constant $\alpha_p = 4.26$ μC/m were determined. The effective mass calculated from the density of quartz and the dimensions of a tuning fork arm turns out to be 0.36 mg, in good agreement with the measured value. It can be verified with low-temperature force–distance measurements with varying oscillation amplitude that at 300 mK, α_p has within a few percent the same value as that determined at room temperature.

The sensors are completely equivalent to other tuning fork sensors [38] with one prong firmly attached to the support which acts essentially as an extremely stiff piezoelectric cantilever. In other respects there are important differences: for tuning forks as described quality factors Q of up to 250,000 are found under the UHV conditions occurring in the evacuated sample space at a temperature of 300 mK. These values are 1–2 orders of magnitude larger than those reported for the other type of tuning fork sensors [38]. For this reason, such high-Q sensors have to be operated as part of a phase-locked loop. Details can be found in [39].

The idea behind the dynamic mode SFM operation of the tuning fork is the same as for normal cantilevers. The elastic interaction of the tip with the sample surface will shift the resonance frequency via the presence of force gradients. Inelastic tip–sample interactions will alter the Q-value of the oscillator. The sensitivity of the sensor to force gradients can be calibrated experimentally with small amplitude calibration measurements [43]. It is found that the force gradient is related to the frequency shift via

$$\Delta f = \eta\left(\frac{\partial F_z}{\partial z}\right) \quad (3)$$

where $\partial F_z/\partial z$ is the gradient of the tip–sample interaction force and $\eta = 1$ Hz/(N/m) is the proportionality constant. The calibration constant η is independent of the details of the tip shape and depends only on the mechanical properties of the tuning fork.

Recently, a new sensor has been developed based on piezoelectric tuning forks which combines the benefits of soft cantilevers and piezoelectric detection [44]. The microfabricated cantilever is mounted between the two prongs of a tuning fork as shown in Figure 6. The tuning fork simultaneously drives the cantilever and detects its changing oscillation properties when a surface is present. Such sensors may be of future use for scanning probe experiments at very low temperatures.

Perhaps the most sophisticated sensors employed for scanning on shallow electronic semiconductor structures are the scanning single-electron transistors. Single-electron transistors (SETs) are tunnelling devices with a typical size of

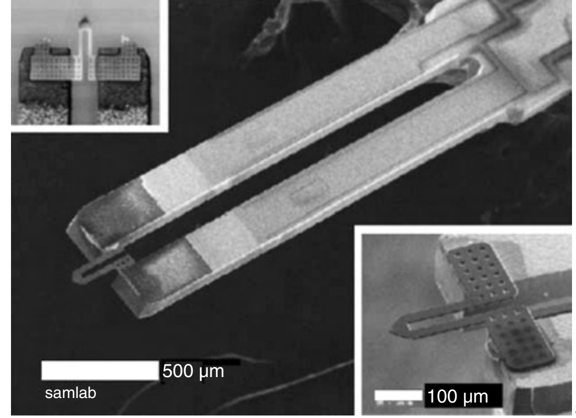

Figure 6. Microfabricated cantilevers mounted between the prongs of a commercial tuning fork. Reprinted with permission from [44], T. Akiyama et al., *Appl. Surf. Sci.* 210, 18 (2003). © 2003, Elsevier.

100 nm. The electrical current through SETs is governed by the Coulomb-blockade effect. The physics behind these devices has been reviewed in [45]. Electrons tunnel from a source electrode onto a small metallic island and subsequently from the island into the drain electrode. The magnitude of the current shows a strong modulation as a function of the electrostatic potential of the island relative to the source and drain electrodes. The period of the oscillation is given by the condition that exactly one elementary charge is additionally induced on the island. SETs can therefore be used as very sensitive electrometers for measuring local electric fields originating from localized charges, or local variations in the electrochemical potential of an electronic system acting as the gate for the island [46, 47].

Scanning SETs have been developed at the Bell Labs in the late 1990s [27, 48–51]. In this approach the SET is fabricated at the end of a glass fiber which has a shallow conical taper terminating at the tip in a flat nearly circular area of about 100 nm diameter [27]. Such a sensor is schematically shown in Figure 7. The preparation of such fibers is the same as that for scanning near field optical microscopy and has been described in [52]. The three metallic electrodes (i.e., source, drain, and island) are fabricated from 10–20 nm thick aluminum. Source and drain electrodes are evaporated onto the fiber from opposite directions onto the side of the fiber. Natural shadowing keeps these electrodes separate. An *in-situ* exposure to oxygen creates the aluminum oxide tunnel barriers of a few nanometer thickness. The island is evaporated in a last step from a direction along the fiber axis. Due to the conical taper of the fiber the aluminum film

forms only at the end face of the tip. At low temperatures these aluminum SETs become superconducting. A magnetic field can be applied to suppress the superconductivity.

In a very simplified model the SET current may be modelled as [27]

$$I_{\text{SET}} = A \cdot \sin \frac{2\pi Q_i(x, y)}{e}$$

where $Q_i(x, y)$ is the total charge induced on the island and A is the amplitude of the current oscillation at a given source–drain bias. When the SET sensor is scanned at constant distance to the surface of a semiconductor nanostructure in the x- and y-direction, the charge induced on the island can be expressed as

$$Q_i(x, y) = Q_i^{(0)}(x, y) + \sum_n C_{ni}(x, y)(\phi_n - \phi_i)$$

where the $C_i(x, y)$ are the capacitance coefficients of the SET island to other metallic electrodes in the system (including, e.g., the electronic nanostructure to be investigated, if it is connected to external leads) and $Q_0(x, y)$ is the induced charge on the island due to the presence of fixed charges in the system (e.g., dopants or other charged impurities). The electrostatic potentials ϕ_i are given related to the applied voltages V_i and the chemical potentials of the electrodes μ_i via

$$-eV_i = \mu_i(x, y) - e\phi_i(x, y)$$

Inserting these relations into the equation for the SET current we obtain

$$I_{\text{SET}} = A \cdot \sin \frac{2\pi\left[Q_i^{(0)}(x, y) + \sum_n C_{ni}(x, y)(V_{ni} + \mu_{ni}(x, y)/e)\right]}{e} \tag{4}$$

with $V_{ni} = V_n - V_i$ being the voltage between electrode n and the island and $\mu_{ni}(x, y) = \mu_n(x, y) - \mu_i$ being the difference in chemical potentials between electrode n and the island (sometimes referred to as the work function difference between the two materials). From this formula it can be seen that the SET current senses local electric charges [via $Q_i^{(0)}(x, y)$], the local chemical potential $\mu_n(x, y)$, and the local capacitance coefficients $C_{ni}(x, y)$. It is clear that in a well defined experiment care must be taken that only one of these quantities depends significantly on position.

Since this sensor is not sensitive to the tip–sample force or force gradient, the height (z-) dependence of the capacitances C_{ni} or the induced charges $Q_i^{(0)}$ can be used for approaching the sensor to the surface [27].

3. KELVIN PROBE FORCE MEASUREMENTS OF TWO-DIMENSIONAL ELECTRON GASES

In this section a method for the local characterization of two-dimensional electron gases will be described. While conventional magnetotransport experiments (i.e., the Hall effect and the measurement of Shubnikov–de Haas oscillations in

the magnetoresistance) allow the determination of an average electron density in the system, the method described here leads to the measurement of a local electron density at the position of the conducting SFM tip.

The sample was a GaAs/AlGaAs heterostructure with a shallow two-dimensional electron gas (2DEG) confined at the heterointerface which is 34 nm below the sample surface. The electrons are supplied by a Si δ-doped plane 17 nm remote from the heterointerface. Four ohmic gold–germanium contacts have been diffused into the samples at the edges of a 5×5 mm^2 piece of wafer giving electrical access to the two-dimensional electron gas.

Experiments were performed at a temperature of 300 mK with a SFM setup employing a tuning fork sensor. A variable DC voltage was applied at the 2DEG contacts while the SFM tip was kept grounded. In this way the electrostatic force acting between the metallic tip and the 2DEG can be controlled. Like in Kelvin-force microscopy [53] this electrostatic force can be measured with the SFM tip. The frequency shift of the tuning fork sensor measures the additional force gradient created by the applied voltage. In contrast to a metallic sample the 2DEG in the heterostructure has a small density of states and a small Fermi energy. Therefore, small voltages applied between the 2DEG and the tip can change the local electron density significantly, leading locally to a total depletion of the electron gas in the extreme case.

Figure 8 shows measured frequency shifts as a function of the applied tip–sample voltage for various tip–sample separations. A clear asymmetry can be observed leading to a weaker (stronger) frequency shift at positive (negative) voltages. For a given voltage, the frequency shift decreases with increasing tip–sample separation.

Qualitatively, we expect a locally enhanced electron density under the tip for negative voltages (in this case the tip is positive relative to the 2DEG) and a reduced density for positive voltages eventually leading to complete local depletion. Therefore we expect an ideal capacitor model with a voltage independent capacitance to work only for negative voltages. For positive voltages depletion of the 2DEG leads to a hole in the capacitor plate which is a change in geometry of the capacitor and must therefore lead to a reduced capacitance. A deviation from the ideally expected parabolic shape of the frequency shift versus voltage is the natural consequence.

Following this qualitative picture we assume a voltage independent capacitance for negative voltages and fit only the left branches of the curves with a parabola according to the equation

$$\Delta f = \eta F_z' = \frac{\eta}{2}\left(\frac{\partial^2 C}{\partial z^2}\right)[U_{ts} + \Delta\mu_{ch}/e]^2 \tag{5}$$

where $F' = \partial F_z/\partial z$ is the gradient of the tip–sample interaction force and $\Delta\mu$ is the work function difference between the tip and the sample. The result is shown in Figure 9 for a tip–sample separation of 15 nm. The information deduced from these fits is twofold. On one hand, we obtain the tip–sample voltage at which the parabola has its maximum. This quantity will be discussed later. On the other hand, we get the curvature of the parabola which is proportional to $\partial^2 C(z)/\partial z^2$. A plot of this quantity as a function of tip–sample separation is shown in Figure 10. It can be seen that the curve can be well characterized by having a z^{-2} dependence. According to a comprehensive comparison of different models for tip–sample arrangements with different tip geometries performed by Belaidi and co-workers [54] such a behavior is consistent with the model of a metallic sphere above a metallic plane. Given that this slope persists up to tip–sample separations of about 700 nm we have to conclude that the tip diameter is at least of the same order of magnitude in this experiment.

We now turn to the discussion of the asymmetry of the Kelvin measurement. The explicit parabolic voltage dependence of the frequency shift can be eliminated from the curves by normalizing Δf_{meas} by Δf_{fit}, (i.e., by plotting the

ratio of the two as a function of voltage). Figure 11 shows the result of the normalization procedure for the curve taken at 15 nm tip–sample separation. By virtue of the normalization procedure and in accordance with our qualitative picture, $\partial^2 C/\partial z^2$ is constant for negative voltages. At a voltage of about −2.5 V, depletion starts under the tip. With increasing voltage the area of the depleted region grows continuously reducing $\partial^2 C/\partial z^2$. We empirically define the onset voltage for depletion U_{depl} in the way indicated in Figure 11. At this voltage a linear fit made in the turning point of the decaying $\partial^2 C/\partial z^2$ curve crosses unity. The same analysis has been applied to all curves in Figure 8 for different tip–sample separations and the result is shown in Figure 12. From these curves we can extract the dependence of U_{depl} on tip–sample separation (see Fig. 13). The series of points can be quite well fitted with a linear function. This finding can be interpreted within a suitable model.

We briefly come back to the second type of information that can be obtained from the parabolic fit shown in Figure 9, namely, the voltage at which the parabola has its maximum. Conventionally this voltage is interpreted as the difference in work functions of the two materials involved. Figure 14 shows this quantity as a function of tip–sample separation. Although the error bars are rather large, a slight trend for an increase at smaller tip–sample separation becomes evident, in contradiction to the notion of a constant material-dependent work function difference $\Delta\mu_{ch}$. The origin of this behavior will be traced back to the presence of

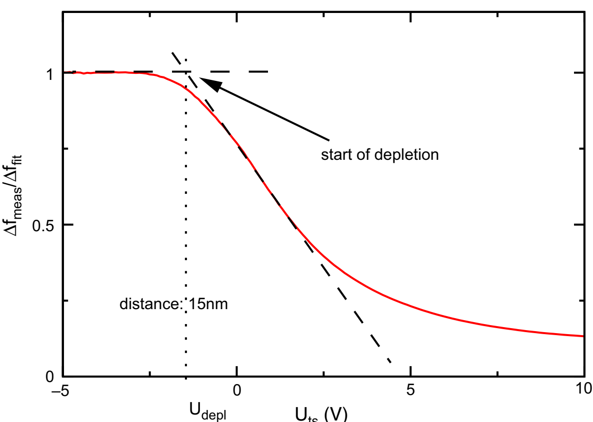

Figure 11. Normalized $\partial^2 C(V)/\partial z^2$. At negative tip–sample voltages this quantity is unity. The reduction at positive voltages is caused by total depletion of the 2DEG under the tip. Such curves allow the definition of a depletion voltage. Reprinted with permission from [9], T. fixed localized charges in the system (surface charges, doping plane).

A general model for the experimental system starts from Poisson's equation

$$\nabla[\epsilon(\vec{r})\epsilon_0\nabla\phi(\vec{r})] = -\rho_{\text{ion}}(\vec{r}) \tag{6}$$

with the spatially varying dielectric function $\epsilon(\vec{r})$, fixed ionic charges $\rho_{\text{ion}}(\vec{r})$ accounting, for example, for ionized donors or surface charges and the electrostatic potential $\phi(\vec{r})$. The two-dimensional electron gas is, for simplicity, considered to be a perfect metal plate and also the tip is regarded as a perfect metal of arbitrary shape. The boundary conditions for the problem are given on the metallic surfaces S_i (i.e., the tip surface and the 2DEG) by

$$\phi(\vec{r})|_{S_i} = \phi_i$$

where the ϕ_i is the electrostatic potential of electrode i. The resulting charge density induced in the two-dimensional electron gas is given by

$$\sigma_{\text{2DEG}}(\vec{r}) = \sigma^{(0)}_{\text{2DEG}}(\vec{r}) + c_{\text{2DEG-tip}}(\vec{r})\phi_{\text{2DEG-tip}} \tag{7}$$

where the surface charge $\sigma^{(0)}_{\text{2DEG}}$ and the coefficient $c_{\text{2DEG-tip}}$ are given by integral expressions involving Green's function of the problem and therefore depend on position $\vec{r}$ on the electrode. Between the electrostatic, the chemical, and the electrochemical potential there is the general relation $\mu_{elch} = \mu_{ch} - e\phi$, such that $\phi = (\mu_{elch} - \mu_{ch})/(-e)$. The applied voltage between two electrodes is the difference of their electrochemical potentials: $V_{ij} = (\mu_{elch,i} - \mu_{elch,j})/(-e)$. Applying these relations to Eq. (7), we obtain

$$\sigma_{\text{2DEG}}(\vec{r}) = \sigma^{(0)}_{\text{2DEG}}(\vec{r}) + c_{\text{2DEG-tip}}(\vec{r})(U_{ts} + \Delta\mu_{ch}/e) \tag{8}$$

where $\Delta\mu_{ch}$ is the work function difference between the tip material and the two-dimensional electron gas and U_{ts} is the applied voltage. At this point we can nicely discuss the influence of the tip on the system. If $U_{ts} + \Delta\mu_{ch}/e = 0$, the electron density is simply given by $\sigma^{(0)}_{\text{2DEG}}(\vec{r})$. This quantity depends, however, on the presence and the exact position of the tip via the boundary conditions of the problem. This means that even if the difference in the work functions between the materials is exactly cancelled by the applied voltage, the presence of the tip can change the local electron density in the 2DEG via the dependence of $\sigma^{(0)}_{\text{2DEG}}(\vec{r})$ on tip position (i.e., via screening).

Application of a suitable voltage U_{ts} at constant tip position will change the local electron density proportional to the differential capacitance function $c_{\text{2DEG-tip}}(\vec{r})$. This function depends on the exact shape of the tip but will for a typical conical tip be similar to a Lorentzian distribution with an extremum below the tip apex [3]. A negative voltage on the tip relative to the (grounded) electron gas will deplete the electrons and the electrostatic model with a voltage independent $c_{\text{tip-2DEG}}(\vec{r})$ will be applicable until complete depletion is reached. Beyond this point $c_{\text{tip-2DEG}}$ will become voltage dependent, since the boundary conditions of the problem change: the 2DEG will behave like a metallic plate with a hole under the tip whose size depends on U_{ts}.

The measured frequency shift in the experiment is proportional to the force gradient in the z-direction felt by the scanning tip. Within our model we find for the force gradient

$$\frac{\partial F_z}{\partial z} = \frac{1}{2}C''(z)\left(U_{ts} + \frac{\Delta\mu_{ch}}{e} + \frac{Q_0^{(0)''}(z)}{C''(z)}\right)^2 - \frac{\left(Q_0^{(0)''}\right)^2}{2C''(z)}$$

where $C''(z) = \partial^2 C_{\text{2DEG-tip}}/\partial z^2$ is the second derivative of the capacitance coefficient between the tip and the 2DEG and $Q_0^{(0)}$ is the charge induced on the tip when the 2DEG is grounded. This induced charge is due to the presence of the fixed ionic charges in the system. The quantity $\Delta\mu_{ch}$ is the difference in the chemical potentials between the tip material and the electron gas (also referred to as the work function difference between the two materials) and U_{ts} is the tip–sample voltage. According to this equation, the force gradient (and thus the measured frequency shift) is parabolic in the voltage and the apex of the parabola is at

$$U_a = -\frac{\Delta\mu_{ch}}{e} - \frac{Q_0^{(0)''}(z)}{C''(z)} \tag{9}$$

This result makes clear that the apparent work function difference given by the apex of the parabola may in fact depend on the z-position of the tip if fixed charges are present in the system, in agreement with the results shown in Figure 14.

In analogy to the remarks made about the depletion of the electron gas, $C(z)$ and also $C''(z)$ will become functions of U_{ts} as soon as the two-dimensional electron gas begins to deplete under the tip.

In order to illustrate the somewhat abstract considerations we demonstrate them with a simple parallel plate capacitor model sketched in Figure 15. It is expected to lead to reasonable results, if the tip radius is large compared to the tip–sample separation. Two planes of fixed charges are present in this model: the doping plane with charge density σ_d is located at a distance d_1 from the two-dimensional electron gas and a surface charge σ_s is located directly at

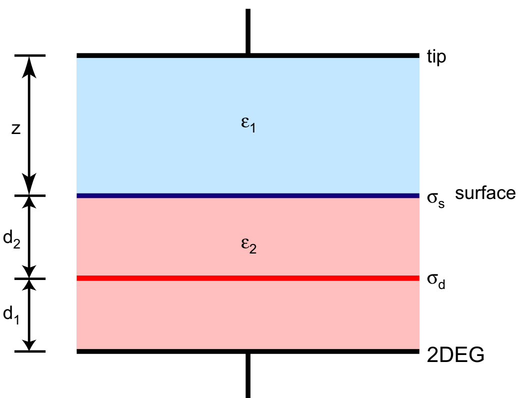

Figure 15. Plate capacitor model for the tip–sample system. Part of the capacitor is filled with the AlGaAs/GaAs dielectric which has a dielectric constant of $\varepsilon_2 = 12.53$ [55]. The other part is the vacuum gap characterized by $\varepsilon_1 = 1$.

the dielectric interface of the sample (ε_2) to vacuum (ε_1). The separation of the tip from the surface is z. In such a system the charge density in the two-dimensional electron gas is given by

$$\sigma_{\text{2DEG}} = -\underbrace{\frac{\varepsilon_1\varepsilon_2\varepsilon_0}{\varepsilon_1(d_1+d_2)+\varepsilon_2 z}}_{C(z)/A}\cdot(U_{ts}+\Delta\mu_{ch}/e) + \underbrace{\frac{\varepsilon_1\sigma_d d_2+\varepsilon_2(\sigma_d+\sigma_s)z}{\varepsilon_1(d_1+d_2)+\varepsilon_2 z}}_{Q^{(0)}_{\text{2DEG}}(z)/A:=-en_s(z)}$$

which has exactly the structure of Eq. (8). We start the discussion assuming $U_{ts} + \Delta\mu_{ch}/e = 0$. For very large tip–sample separation z, the charge density in the two-dimensional electron gas is given by $-en_s^\infty = \sigma_d + \sigma_s$. For very small z it changes to $n_s^0 = \sigma_d d_2/(d_1 + d_2)$. The total voltage that one has to apply across this capacitor in order to deplete an electron density $n_s(z)$ is given by

$$U_{\text{depl}} = -\frac{\Delta\mu_{ch}}{e} + \frac{en_s(z)A}{C(z)} = -\frac{\Delta\mu_{ch}}{e} - \frac{\varepsilon_1\sigma_d d_2 - \varepsilon_2 en_s^\infty z}{\varepsilon_0\varepsilon_1\varepsilon_2} \tag{10}$$

The depletion voltage depends linearly on the tip–sample separation in accordance with the measurement depicted in Figure 13. From the slope $dU_{\text{depl}}/dz = en_s^\infty/(\varepsilon_0\varepsilon_1)$ the local electron density can be determined to be 1.9×10^{11} cm^{-2}. As a comparison we plot curves into Figure 13 which are predicted by Eq. (10) with densities n_s determined from Hall and Shubnikov–de Haas measurements. Given the simplicity of the model, the agreement is reasonable, especially if we take into account that the 2DEG density can be inhomogeneous across a macroscopic sample.

If we evaluate the z-dependence of the apparent work function difference given by Eq. (9) for the plate capacitor model, we find

$$U_a = -\frac{\Delta\mu_{ch}}{e} - \frac{\sigma_s(d_1+d_2)+\sigma_d d_1}{\varepsilon_1\varepsilon_0}$$

independent of z. Inserting our sample parameters, $\varepsilon_1 = 1$, $d_1 + d_2 = 34$ nm, $d_1 = d_2 = 17$ nm, $\sigma_d = 1.6 \times 10^{-3}$ Cm^{-2} (estimated) and $\sigma_s = -1 \times 10^{-3}$ m^{-2} (estimated) we obtain a value of -0.76 V for the second term, indicating that the presence of fixed charges in the sample can have an appreciable influence on the apparent work function difference measured in the experiment. However, given the uncertainties in the estimated values, one should not take the exact value too quantitatively, but rather consider it as an estimate of the order of magnitude of the effect. This z-independent result has to be compared with the experimental results shown in Figure 14 which indicate a small z dependence. Obviously, a more realistic model including the actual tip shape would cure this problem. In fact, the tip shape does influence the geometric capacitance and the dependence of $\partial^2 C/\partial z^2$ on the tip–sample separation. Looking at the order of magnitude of the apparent work function difference in the measurement, we can see that the estimated influence of the fixed charges in the system can be quite significant and is of the same order as typical work function difference s between materials.

More involved models for the tip–sample system would take a more realistic shape of the tip into account, as we mentioned. Further improvement can be gained by taking the screening properties of the two-dimensional electron gas into account self-consistently. This would include density of states contributions to the capacitance which were not taken into account in the presented analysis.

A related experiment has been performed with piezoelectric cantilevers on a two-dimensional electron gas in a magnetic field [7]. In this experiment, the variation of the chemical potential of a two-dimensional electron gas was measured locally as a function of magnetic field B. Oscillations periodic in $1/B$ were detected corresponding exactly to the filling factors determined from transport experiments.

4. SCANNING GATE MEASUREMENTS ON MESOSCOPIC SYSTEMS

4.1. Existing Experiments

Electronic transport in mesoscopic semiconductor structures at low temperatures is nonlocal and phase coherent [56]. In a conventional transport experiment, in which the resistance or conductance of a sample is typically measured as a function of gate voltage or magnetic field, the measured conductance is given by the transmission probabilities between the leads connecting the system to the measurement circuit [57]. In general, it is not possible to reconstruct the scattering potential within the mesoscopic system from the knowledge of the transmission matrix. However, additional information about the quantum states within the device can be obtained from measurements which apply a local perturbation to the system [3, 4, 6, 13–17, 58, 59]. While in [58] the local potential perturbation was fixed and the two-dimensional electron gas in a parabolic quantum well could be displaced, in [3, 4, 6, 13–17, 59] the local electrostatic potential induced by the tip of a scanning force microscope was utilized. In the following, we briefly review the experimental work published in recent years.

In the first paper reporting this "scanning gate technique" Eriksson and co-workers [3] investigated the ballistic electron flow through a quantum point contact at a temperature of 4.2 K. They found that the resistance change caused by the tip-induced potential decays exponentially with distance from the point contact in agreement with elastic scattering by the disorder potential in the collector electron gas. In addition, they measured the angular distribution of the transmitted electrons showing the collimation of the ballistic electron beam close to the point contact. Calculations were presented in this paper indicating that the spatial resolution of the technique is comparable to the electron gas depth below the surface. Similar experiments on a quantum point contact have been reported in [13].

Another measurement on a quantum point contact was performed by Crook and co-workers [16] at 4.2 K where the authors were able to map the transmitted lateral modes with remarkable spatial resolution of about 40 nm although their electron gas was buried 100 nm below the surface. This experiment is the analog of the "wave function mapping " experiment reported in [58]. It exemplifies the ultimate potential of scanning gate techniques to map the states in the interior of a mesoscopic system.

Recently, the electron flow past a quantum point contact was imaged with high spatial resolution achieved at 4.2 K on a GaAs/AlGaAs heterostructure with an only 57 nm thick cap layer above the electron gas [17]. It was shown in the experiment and also modelled theoretically that the classical contribution of the electron flow branches in the two-dimensional collector as shown in Figure 16, a result which had not been anticipated by other experiments. In addition, quantum interference effects were observed in these highly sensitive measurements.

Experiments on two constrictions in series for a "magnetic steering experiment" were reported in [6, 14]. Classical cyclotron orbits of ballistic electrons in a magnetic field with the radius $R_c = \hbar k_F/(eB)$ could be mapped out with a spatial resolution of about 200 nm.

Scanning gate microscopy (SGM) has been applied to the investigation of electron transport in carbon nanotubes [60–62] at room temperature. The authors were able to "directly image individual scattering sites in semiconducting single-wall nanotubes" [61] and metallic single-wall nanotubes [62] or an inhomogeneous potential landscape [60], again in semiconducting single-walled tubes. They showed that the resistance image of a nanotube shows hot spots in locations where the electric field drop was found to be high with electrostatic force microscopy (EFM) [61]. In some cases these hot spots occurred in positions where the nanotube had a kink allowing one to correlate information from three different sources (topography, EFM, and SGM) to extract a unified picture of the system.

A very recent publication by Woodside and McEuen reports low temperature (0.6 K) scanning gate studies of single-walled carbon nanotubes in which one or more quantum dots form leading to the Coulomb blockade effect in the conductance [59]. These authors find Coulomb blockade oscillations as a function of the position of the scanning tip as shown in Figure 17 allowing them to locate the quantum dots along a certain nanotube and to estimate their sizes.

4.2. Measurements on a Quantum Wire

The scanning gate approach has also been employed for the investigation of the transport properties of a semiconductor quantum wire at cryogenic temperatures [63]. We will discuss this experiment in more detail in the following.

The sample is based on a GaAs/AlGaAs heterostructure in which the heterointerface is buried 34 nm below the surface. A Hall-bar geometry, a part of which can be seen in Figure 18, was patterned using photolithography. At the temperature $T = 1.7$ K the bulk electron density measured in this system is $n_S = 4.3 \times 10^{11}$ cm^{-2}, corresponding to a Fermi wavelength of 38 nm. The mobility at $T = 1.7$ K is $\mu = 10^6$ cm^2/V s corresponding to a mean free path of $l_e^{2D} = 10.8$ μm and a diffusion constant of $D = 1.52$ m^2/s.

The quantum wire has been patterned using the so-called AFM lithography [64, 112] directly onto the Hall-bar structure. In Figure 18 the white lines on the Hall bar are the SFM-written oxide lines which deplete the 2DEG below

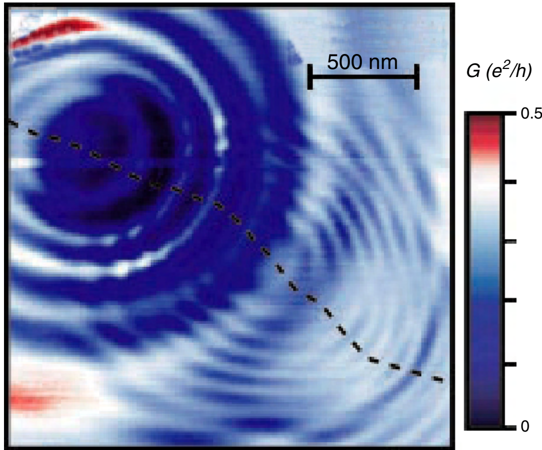

Figure 17. Coulomb oscillations as a function of tip position measured on a carbon nanotube at $T = 6$ K. The dashed line indicates the location of the nanotube. them and thereby form a long quantum wire flanked by two separately contacted regions of the 2DEG which we used as in-plane gates. The wire length is $L = 40$ μm and its lithographic width is $W = 400$ nm. The lateral depletion length is typically 15–20 nms such that the number of modes in the channel can be estimated to be $N = 20$. This number can be confirmed by Shubnikov–de Haas measurements which count the number of modes which become successively depopulated as the magnetic field is increased.

The sample was mounted in the sample holder of a low-temperature scanning force microscope [39]. This microscope utilizes piezoelectric quartz tuning forks with a metallic tip attached to one prong as the force sensor. Operation characteristics at low temperatures and sensor calibration have been described and are reported in [42, 43]. The microscope was cooled to $T = 1.7$ K in the He gas flow of a variable temperature insert. The resistance of the wire was measured at an ac current of 20 nA in a four-probe configuration. The measurement frequency was 421 Hz and a lock-in time constant of 10 ms was used in order to obtain a reasonably large output bandwidth. The tungsten tip of the SFM was kept grounded while it was oscillating with an amplitude of about 1 nm normal to the surface at the tuning fork resonance frequency of about 32 kHz. The basic idea of the measurement is shown in Figure 19. The tip induces a local scattering potential in the electron gas. The wire resistance is changed depending on the position of the tip. Resistance images of 256 × 256 points were taken at scan speeds of 500 nm/s.

Figure 20 shows the resistance image of a 5×5 μm^2 area obtained with a voltage of +200 mV on one of the in-plane gates. The fact that the wire can be electronically imaged indicates that when the tip is above the wire the resistance is enhanced. This resistance contrast is due to the fact that tungsten and the heterostructure have a work function difference of the order of 100 mV which causes the tip to induce a local repulsive electrostatic potential in the 2DEG

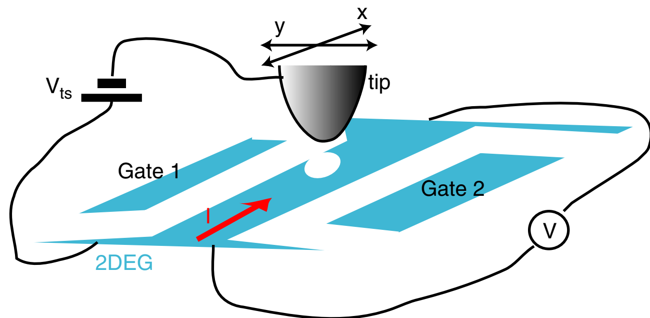

Figure 19. Principle of scanning gate measurements. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

which is scanned along when the tip moves. The stripe of enhanced resistance is not visible in the topmost quarter of the image. From the simultaneously measured topography we know that the wire ends there.

Cross sections through this image as indicated by three horizontal lines in Figure 20 are shown in Figure 21. As the tip moves across the wire the resistance goes from its base value of 3 kΩ through a pronounced peak of 9.4 kΩ. We estimate the number of modes which become locally depleted, ΔN, with a simple model which regards the repulsive tip potential as the cause of an additional resistance ΔR which adds to the background wire resistance R_0. In the simplest case ΔR can be modelled by a short piece of wire with transmission $T = 1$ which is not mode-matched to the rest of the wire. In this case $\Delta R = h/(2e^2)(1/(N_0 - \Delta N) - 1/N_0)$ with $N_0 = 20$ being the number of modes in the wire in the absence of the tip. This gives a substantial depletion of $\Delta N = 18$ modes if the tip is centered above the wire.

From the width of the two lower peaks of about 400 nm which is close to the geometrical width of the wire we estimate that the tip induced potential perturbation cannot be much wider than that.

A very striking feature of the image in Figure 20 is the variation of the resistance along the wire direction. In a perfect wire with no potential fluctuations and perfectly smooth boundaries no such variation would be expected irrespective of the exact geometrical shape of the tip-induced potential. From a comparison of the resistance variations with the surface topography we find no correlation between the two that could explain the former as the result of a varying tip–2DEG separation. We therefore conclude that the variations of the resistance along the wire direction reflect the roughness of the potential landscape in the electron gas.

There are two distinct effects in mesoscopic systems that could cause the observed resistance fluctuations as the perturbation is moved along the wire. The first is the ballistic chaotic motion of *classical* electrons in a spatially varying potential landscape. In order to develop a better understanding of how this mechanism would appear in our measurements we have calculated the classical transmission through wire structures with a given potential landscape as a function of the position of an additional external perturbation. The results which will be discussed in the next section show that the complex electron dynamics does indeed lead to fluctuations in the resistance image.

The second effect which could produce resistance fluctuations along the wire is the *quantum interference* of phase coherent paths which leads to fluctuations in the transmission as a function of tip position. Theories exist that predict conductance fluctuations in a disordered sample when the position of a single impurity is moved [65–68]. Given our sample parameters and the measurement temperature the phase coherence length can be estimated to be $\ell_\varphi \approx 8$ μm but the observability of phase coherence effects is limited by energy averaging through the Fermi-distribution function, [i.e., the thermal length $\ell_T = \sqrt{\hbar D/(kT)} \approx 2$ μm]. Fluctuations will have the order of magnitude $\Delta R = R^2 \Delta G \approx R^2 e^2/h(\ell_T/\ell_\varphi)(\ell_\varphi/L)^{3/2} \approx 100\ \Omega$. The characteristic length scale for these fluctuations is the Fermi wavelength of the electrons.

Figure 22 shows an image of the wire measured in a different measurement configuration, where a dc current was applied and the wire resistance was measured at the resonance frequency of the oscillating tip effectively resulting in a local transconductance measurement. This image taken with increased spatial resolution exhibits amazingly regular stripelike patterns on a length scale of less than 100 nm. Given the considerations about phase coherence the tentative explanation in terms of interference effects seems reasonable. Such quantum interference effects in scanning gate measurements will be further discussed in the next section.

4.3. Theoretical Considerations

Models for conductance fluctuations have been based on different approaches. Among them are the Anderson tight-binding Hamiltonian approach [68, 69], one-dimensional models incorporating randomly spaced delta scatterers [70, 71], and a scattering matrix approach [72].

In order to obtain some insight into the physical processes leading to the observed resistance images different types of theoretical models can be applied. A model aiming at classical effects in the resistance, for example, can be based on a calculation of the classical transmission of a wire within a billiard model following the general approach introduced by Beenakker and van Houten in [73]. If a fully quantum mechanical treatment is desired, a model can be based on the picture of noninteracting electrons in a multimoded wire. It can, for example, be similar to the scattering matrix approach used by Cahay and co-workers [72] for calculating the fluctuations in the resistance of a multimoded wire with randomly placed delta scatterers. In the following, we describe the scanning gate measurement based on such a quantum description.

We consider the Hamiltonian of a two-dimensional quantum wire with confinement-potential $V_c(y)$ and some scattering potential $U(x, y)$. The Schrödinger equation reads

$$\left[-\frac{\hbar^2}{2m^\star}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)+V_c(y)+U(x,y)\right]\psi(x,y)=E\psi(x,y)$$

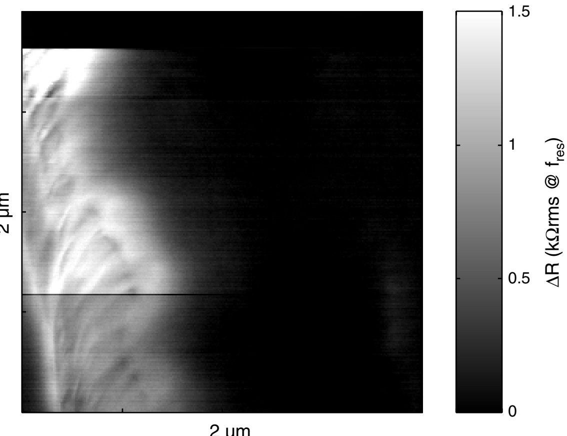

Figure 22. Interference effects in the quantum wire. Reprinted with permission from [63], T. Ihn et al., *Physica E* 12, 691 (2002). © 2002, Elsevier Science.

The tip-induced potential in the scanning gate experiment has a finite extent in the plane large compared to the Fermi wavelength. As a simplified example we consider the scattering potential

$$U(x, y) = \delta(x - x_i) \cdot \frac{\gamma}{b\sqrt{\pi}} e^{-[(y-y_i)/b]^2} \tag{11}$$

which takes into account the finite extent in the y-direction but neglects the extent in the x-direction. This allows us to illustrate some key features of the quantum system without going through the much more elaborate theory for the potential extended in all two directions. The resistance of the wire induced by the scatterer can then be calculated from the conductance formula of Landauer and Büttiker [74–76]:

$$G = \frac{e^2}{h} \mathrm{Tr}(\hat{t}\hat{t}^{\dagger})$$

For specific calculations we have used an infinite square well potential modelling the wire potential. Within this framework we first discuss the influence of the width of the tip-induced potential in the y-direction on cross sections through a resistance image along constant x (c.f. Fig. 21). The two extreme limits are intuitively clear: when the tip-induced potential is much wider than the wire, the wire will act as the probe for the tip induced potential and the cross section will have the width and shape of the tip-induced potential. On the other hand, if the wire width is large compared to the tip-induced potential, details of the internal electronic structure of the wire will become visible. Figure 23 shows the result of a calculation for a wire with width $W = 100$ nm in which four modes are occupied, corresponding to a Fermi energy $E_F = 14$ meV. For $b = 100$ nm the resistance shows a broad unstructured Gaussian peak when the tip crosses the wire. This peak becomes narrower at $b = 50$ nm and develops a flat top at 30 nm (i.e., when the width of the tip-induced potential becomes smaller than the wire width). Reducing b further results in additional fine structure reflecting the mode structure of the wire. With four occupied modes the highest mode has four maxima of the probability amplitude which is reflected in the resistance cross section. The condition for the observability of the mode structure in the wire is that the width of the tip-induced potential has to be smaller than the Fermi wavelength λ_F. Comparing these results to the cross sections through the resistance image shown in Figure 21, we conclude that the width of the tip-induced potential in the experiment was of the order of the wire width, but certainly not much larger.

This model can also be used to illustrate the possibility of imaging individual modes in a quantum wire or quantum point contact. Corresponding experiments on a quantum point contact have been published recently by Crook and co-workers. However, in their experiments, the two-dimensional electron gas with the quantum point contact is buried by 100 nm below the surface and a model for screening by mobile carriers in the remote doping plane had to be invoked in order to understand the experimental resolution of about 40 nm. Figure 24 shows calculated resistance changes due to a Gaussian tip potential ($b = 10$ nm) for a 100 nm wide wire with Fermi energies $E_F = 2.24, 5, 9$ meV corresponding to the occupation of one, two, and three modes. It can be seen that the number of local maxima in the resistance cross sections corresponds to the number of maxima in the probability density of the highest occupied mode, confirming the statement that the mode structure of narrow constrictions can be mapped with scanning gate techniques.

We continue the discussion of quantum effects in scanning gate measurements by a discussion of the case of many scatterers in the quantum wire. For simplicity, we use again δ-shaped potentials in the x-direction with Gaussian shape

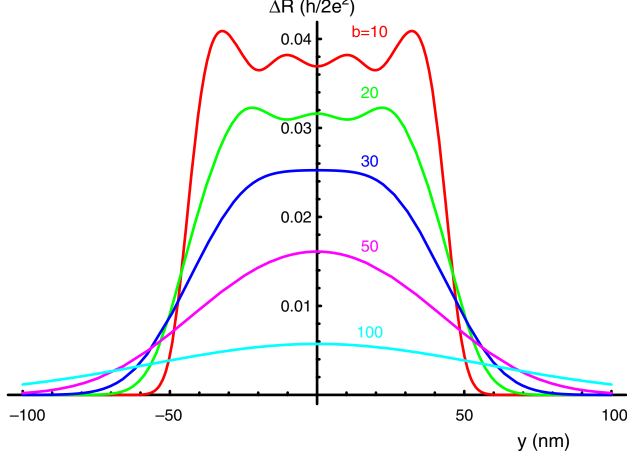

Figure 23. Calculated resistance change in a homogeneous wire due to scatterers with different widths $b = 100, 50, 30, 20, 10$ nm in y-direction and constant strength $\gamma = 4000$ meV nm^2 as a function of the y-position of the scatterer. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

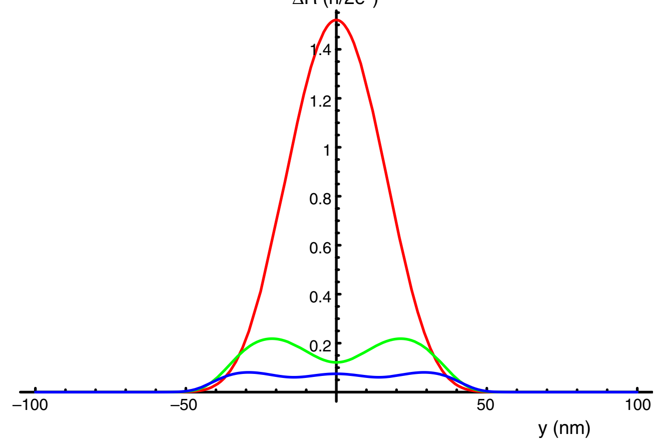

Figure 24. Calculated resistance change in a homogeneous wire with different Fermi energies $E_F = 2.24, 5, 9$ meV and hence different numbers of modes ($N = 1, 2, 3$, respectively). Here the width of the scatterer has been taken to be $b = 10$ nm; its strength is $\gamma = 4000$ meV nm^2. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

in y. In this case the formalism can easily be extended to the case of an arbitrary number of impurities. Qualitatively we now expect interference effects between electron waves to arise due to multiple scattering. Figure 25 shows a grayscale resistance image calculated for two fixed impurities in addition to the moving tip. In some sense, all three "perturbing potentials" form two neighboring cavities with transmission resonances changing when the sizes or shapes of the cavities are changed by moving the tip. Indeed, interference patterns can be seen along the wire axis. In contrast to the expectation for a very wide two-dimensional system, where interference effects have been predicted to occur on the scale of the Fermi wavelength λ_F [65–68], in a wire with a relatively small number of modes more than one frequency contributes to these fluctuations because the individual modes contribute with different Fermi wavelengths. In addition, it can be seen that not all interference stripes are exactly normal to the wire axis. Both findings are also in agreement with the measurement shown in Figure 22 where different frequencies of the fluctuations are observed as well and the stripes' orientation deviates from being normal to the wire axis. All this supports the interpretation of the measurements in terms of interference effects. The quantum interference effects look quite regular (i.e., they come in clearly discernible stripes), and they occur at a smaller length scale.

The aspect of a finite phase coherence length was not taken into account in the model. The obvious question is whether phase coherence is needed over the whole length of the wire to make the observation of interference effects possible. In a conventional transport experiment—where the conductance is measured as a function of magnetic field—the answer would certainly be "yes" because otherwise, the connection of many phase coherent sections in series fluctuating independently would average sufficiently. In *local* scanning gate experiments this argument is no longer true. There is always only *one* fluctuating segment (i.e., the one in which the tip is scanning), and no averaging takes place. Phase coherence effects can therefore be observed even in systems with characteristic lengths $L \gg \min(l_\varphi, l_T)$, provided that temperature is low enough to maintain phase coherence over length scales larger than the mean free path.

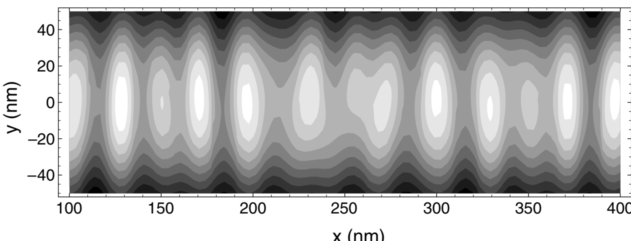

Figure 25. Calculated resistance change ΔR in a homogeneous 100 nm wide wire with four occupied modes ($E_F = 14$ meV). One fixed Gaussian impurity with $b = 50$ nm and strength $\gamma = 500$ meV nm^2 was positioned at $(x = 0, y = 40$ nm). A second Gaussian impurity had the parameters $b = 30$ nm, $\gamma = 500$ meV nm^2, and $(x = 500, y = -20)$. The scanned tip-induced potential was modelled with a second Gaussian potential with $b = 40$ nm and $\gamma = 4000$ meV nm^2. Reprinted with permission from [9], T. Ihn, "Electronic Quantum Transport in Mesoscopic Semiconductor Structures," Springer Tracts in Modern Physics. Springer-Verlag, Berlin, 2003. © 2003, Springer-Verlag.

This argument is also of relevance for the observations in [17], where scanning gate measurement were performed in the vicinity of a quantum point contact. It was observed that interference fringes do not disappear with increasing separation from the point contact. The explanation given in [17] is essentially identical to the argument presented. It implies that the phase coherence length cannot be read from a spatial resistance image obtained from scanning gate measurements. However, interference effects should disappear with increasing temperature. Scanning gate measurements at various temperatures could therefore allow one to determine the phase coherence length and to discriminate between fluctuations of the resistance due to classically chaotic motion and phase coherent effects.

Another aspect neglected in the model is interaction effects. In principle it is conceivable that due to potential inhomogeneities, electrons localize in the wire and form—in the extreme case—quantum dots exhibiting the Coulomb-blockade effect, similar to the situation in carbon nanotubes in the experiments of [59]. However, from the overall conductance of our wires which is smaller than e^2/h and the excellent sample quality we can conclude that interaction effects will play a negligible role in our experiments.

5. SCANNING PROBE EXPERIMENTS IN THE QUANTUM HALL REGIME

5.1. Edge Channels

The importance of the sample edge for the quantum Hall effect was pointed out soon after its discovery [77] on the basis of a model of noninteracting electrons [78]. Later on interactions were considered by using self-consistent descriptions of the sample edge [79–81]. Figure 26 shows the general notion of the self-consistent potential and the electron density at the sample edge in equilibrium. In the bulk of the electron gas (left in the figure) the Landau levels have an

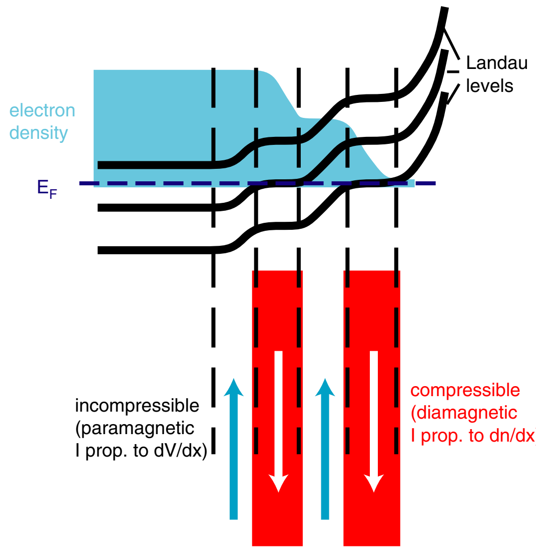

Figure 26. Self-consistent edge channel structure. Reprinted with permission from [82], T. Ihn et al., *Microelectron. Eng.* 63, 81 (2002). © 2002, Elsevier Science.

energetic spacing of $\hbar\omega_c$, where $\omega_c = eB/m$ is the cyclotron frequency, B is the magnetic field normal to the plane of the electron gas, and m is the effective mass of the electrons. The electron density in the bulk is constant. Near the edge the Landau levels have to follow the increasing electrostatic confinement potential and the electron density has to go to zero. Due to the density of states in a magnetic field with peaks in energy at the positions of the ideal Landau levels, the density of states at the Fermi energy oscillates strongly as a function of position leading to oscillating screening properties of the electron gas at the edge. Whenever a Landau level crosses the Fermi energy, screening is good and the potential flattens out. At the same time the electron density shows a strong gradient. These regions are called compressible strips because they have a finite density of states at the Fermi energy. The regions between compressible strips are called incompressible, since the density of states at the Fermi energy vanishes there. In these strips the potential has a strong gradient while the density is flat. Screening in the incompressible strips is poor. Geller and Vignale have calculated the equilibrium currents in the compressible and incompressible strips self-consistently [81]. They found that in the compressible regions the current is proportional to the density gradient and the current flow leads to a diamagnetic magnetic moment. In the incompressible regions the equilibrium current is proportional to the potential gradient and produces a paramagnetic effect. The subtle interplay between these two spatially separated types of current leads naturally to the oscillatory magnetization of a two-dimensional electron gas as a function of magnetic field [83].

Since the theoretical prediction of the existence of self-consistent edge channels and compressible and incompressible strips in the quantum Hall regime there has been a series of experimental attempts to measure local properties at sample edges in high magnetic fields. Electron–phonon interaction was used in first experiments [84]. Optical techniques with a spatial resolution of about 1 μm in the best case also supported the notion of edge channels [85–87]. Later experiments tried to detect the edge currents inductively, but evidence for bulk currents was found [88, 89]. Recently, edge strips were imaged using a metallic single electron transistor fabricated near the edge of a two-dimensional electron gas [90].

5.2. Scanning Probe Experiments

It is obvious to employ scanning probe techniques with their unprecedented potential of spatial resolution for such investigations and several experiments have been reported during the past few years using a scanning single-electron transistor [49], scanned potential microscopy [91], Kelvin probe techniques [12], and subsurface charge accumulation measurements [92–94]. In the following we give a brief overview of these experiments.

5.2.1. Scanning SET Measurements

The scanning single-electron transistor sensors described before have been employed for an investigation of GaAs/AlGaAs heterostructures with a two-dimensional electron gas 100 nm below the surface in [49]. The SET sensor was kept at a distance of 100–200 nm above the sample surface. Spatial resolution is estimated to be a few hundred nanometers.

The scanning SET was operated as part of a feedback loop keeping the SET current [Eq. (4)] and thereby the induced charge on the SET island constant at the operating point by controlling the voltage between the sensor and the 2DEG. This voltage is the measured output signal. Low-frequency (below 100 Hz) lock-in techniques were used in order to extract the small signals from transport through the 2DEG or the capacitance between the SET and the back-gate from the huge unwanted signals of biased surface gates and fluctuating surface dopant charges.

In the sample a back gate 5.4 μm below the 2DEG was used for tuning the electron density which was in the range of 10^{11} cm^{-2} at liquid He temperatures. Mobilities of about 4×10^6 were determined.

In so-called transparency measurements, the local compressibility of the two-dimensional electron gas (i.e., the local density of states at the Fermi level) was measured. This was accomplished by modulating the voltage between the back gate and the SET. The electron gas between these two "metallic" electrodes is kept at constant potential with respect to the sensor and therefore screens the ac field more or less, depending on the (local) filling factor. Compressible strips are found which screen the signal from the back gate well, while incompressible strips do not screen. The inhomogeneous local electron density can be deduced from such measurements by plotting contours of constant filling factors. In some places closed incompressible contours lead to isolated regions in the 2DEG which cannot be charged. Steplike features of the local chemical potential difference between 2DEG and SET could be measured with the sensor at a fixed position while an incompressible strip was made to pass the region below the tip by changing the back gate. Such steps reflect the steplike local self-consistent potential expected in the regions of the strips (see Fig. 26). It was also attempted to measure the Hall-voltage distribution between opposite edges of the sample. Around filling factor $\nu = 2$ a change from a linear to a flat voltage distribution was found. However, the full Hall voltage drop could not be measured due to screening effects by the top gate electrodes defining the edges. It remains to be discussed how far the presence of the metallic SET influences the distribution of potentials and currents, compressible and incompressible strips (e.g., by screening or by an insufficiently compensated work-function difference between 2DEG and SET).

5.2.2. Scanned Potential Microscopy

In another experiment, the quantum Hall effect has been locally investigated using a gold coated piezoresistive cantilever coupling capacitively to the two-dimensional electron system [91]. The 2DEG was again realized in a GaAs/AlGaAs heterostructure, 77 nm below the surface. Measurements were performed at temperatures between 0.7 and 1 K. An ac voltage was applied to the source contact of the Hall bar sample while the drain contact was grounded. This leads to a local electrostatic potential $V_{ac}(x, y)$ in the two-dimensional electron gas. The measured quantity in this

experiment is the force acting on the cantilever. It is dominated by the electrostatic force contribution given by

$$F = \frac{1}{2}C'(x,y)(V_{\text{tip}} - V_{\text{2DEG}} + \Delta\mu_{ch}(x,y)/e)^2 + Q_{\text{tip}}^{(0)'}(x,y)(V_{\text{tip}} - V_{\text{2DEG}} + \Delta\mu_{ch}(x,y)/e) \qquad (12)$$

in a classical capacitive model. Here, $C'(x,y) = \partial C(x,y,z)/\partial z$ is the z-derivative of the position dependent capacitance between tip and 2DEG, $Q_{\text{tip}}^{(0)'}$ is the z-derivative of the charge induced on the tip at zero bias due to fixed charges in the system (e.g., surface charges and ionized dopants), $\Delta\mu_{ch}(x,y)$ is the local work function difference between tip and sample, V_{tip} is the voltage on the tip, and $V_{\text{2DEG}} = -\mu_{elch}(x,y)/e$ is the local voltage in the 2DEG under the tip. In equilibrium the latter quantity is position independent. The idea of the measurement is to apply an ac transport current through the Hall bar sample at frequency ω which induces a position dependent $V_{\text{2DEG}}^{\text{ac, tr}}(x,y)$ reflecting the Hall voltage profile. The resulting ac force is

$$F_{\text{ac}}^{\text{tr}} = -\left[C'(x,y)(V_{\text{tip}} + \Delta\mu_{ch}(x,y)/e) + Q_{\text{tip}}^{(0)'}(x,y)\right]V_{\text{2DEG}}^{\text{ac, tr}}(x,y)$$

used for driving the cantilever at its resonance frequency at 120 kHz. The measured oscillation amplitude is proportional to the driving force (enhanced by the Q-factor of the oscillating cantilever on resonance) and therefore to the local electrochemical potential in the two-dimensional electron gas. At a fixed magnetic field the other quantities (capacitance and induced charge) may also contribute to the position dependence of the measured force, especially in the quantum Hall regime, where localization of electronic charge in the bulk of the Hall bar plays a crucial role and the time constants for establishing an equilibrium electrochemical potential in the bulk can be very long. A suitable reference measurement, in which the ac voltage is applied to all contacts of the Hall bar, implying that no transport current flows and no Hall voltage builds up, can be used for eliminating the undesired prefactor. In this case, the measured ac force, $F_{\text{ac}}^{\text{eq}}$, will be given by the expression for $F_{\text{ac}}^{\text{tr}}$ with the same prefactor, but a position dependent equilibrium voltage $V_{\text{2DEG}}^{\text{ac, eq}}$. Normalizing $F_{\text{ac}}^{\text{tr}}$ by $F_{\text{AC}}^{\text{eq}}$ gives

$$\frac{F_{\text{ac}}^{\text{tr}}}{F_{\text{ac}}^{\text{eq}}} = \frac{V_{\text{2DEG}}^{\text{tr}}(x,y)}{V_{\text{2DEG}}^{\text{eq}}(x,y)}$$

The normalized Hall voltage profile measured in this experiment at a given position along the Hall bar is found to be periodic in the inverse magnetic field $1/B$, in agreement with a general consideration of the effect of B on the voltage $V_{\text{2DEG}}^{\text{ac}}(x,y;B)$. The normalized Hall voltage profile at different filling factors ν around $\nu = 6$ shows a transition between a linear behaviour above and below the plateau in the Hall resistance and a profile with a flat region in the bulk with all the voltage dropping near the edges of the sample. This implies that sample edges and bulk do not equilibrate at these fields implying that the sample edges are effectively decoupled from the bulk. High dc transport currents with creating Hall voltages above the Landau level spacing $\hbar\omega_c$ lead to equilibration of edge channels. No compressible or incompressible strips were observed in this measurement, but the width of the edge state regions is found to increase with the number of edge channels with a width of about 300 nm per channel. In the flat region of the Hall resistance plateau the normalized Hall voltage profile was found to develop significant gradients within the bulk of the sample.

Related experiments for the measurement of Hall voltage profiles were performed by another group using a different technique [7, 12, 18, 95]. In contrast to the previous method not the force [Eq. (12)] is measured in this experiment, but the force gradient

$$F' = \frac{1}{2}C''(x,y)(V_{\text{tip}} - V_{\text{2DEG}} + \Delta\mu_{ch}(x,y)/e)^2 + Q_{\text{tip}}^{(0)''}(x,y)(V_{\text{tip}} - V_{\text{2DEG}} + \Delta\mu_{ch}(x,y)/e)$$

This is accomplished by driving the iridium coated piezoresistive cantilever externally on resonance and measuring the resonance frequency shift caused by the electrostatic force gradient with a feedback loop. Apart from this difference, the technique corresponds to the one presented already: a few Hz ac transport current is applied to the source contact of the 2DEG with the drain contact grounded. This induces a local low frequency variation of the electrochemical potential which in turn leads to a position dependent low frequency modulation of the frequency shift which can be detected using lock-in techniques. The position dependent prefactor of $V_{\text{2DEG}}^{\text{ac, tr}}$ is again eliminated by normalizing to the result of a reference measurements in which the ac voltage is applied to all the contacts of the electron gas. An advantage of not driving the cantilever with the tip–sample voltage lies in the fact that the very low modulation frequency of 3.4 Hz (compared to 100 kHz) can be used which minimizes RC effects in the charging of regions in the 2DEG with localized states.

Three different types of Hall potential profiles are observed in these experiments depending on the value of the filling factor ν (see Fig. 27): linear Hall potential drops are observed up to $\nu = 1.76$ when $\nu = 2$ is approached from lower filling factors. At filling factors around $\nu = 2$ the Hall potential drops rather arbitrarily in the bulk of the Hall bar. At filling factor $\nu = 2.14$ the potential becomes flat in the bulk and all the potential drop occurs near the edges of the sample. Proceeding to lower filling factors the same scenario repeats around filling factor $\nu = 4$. The behavior is consistent with the experimental results discussed before and it is related to the notion of compressible and incompressible regions in [18]. It is shown that the equilibrium center position of the innermost incompressible strip does indeed move with ν according to a theoretical prediction [96].

With this technique the Hall potential distribution was also investigated near potential probe contacts [95]. An incompressible strip is found at filling factors slightly above integer values which is not only present along the mesa edges, but also along the metal contact. It is concluded that the bulk is strongly decoupled from the edge and the ohmic contacts at these filling factors.

5.2.3. Subsurface Charge Accumulation Imaging

The third set of experiments to be discussed here uses the so-called subsurface charge accumulation imaging in the quantum Hall regime at a temperature of 300 mK [10, 92–94, 97, 98]. This technique measures the local accumulation of charge in a two-dimensional electron gas in response to an ac voltage (100 kHz) applied between the conducting tip scanned at constant height above the surface and the 2DEG. The dc perturbation of the tip on the 2DEG is minimized by compensating the work function difference between the tip and the sample with a dc tip voltage of 0.4 V. The tip is connected to a sensitive charge detector which relies on a field-effect transistor mounted at cryogenic temperatures [28]. Signals in-phase and out-of-phase with the ac excitation are detected with lock-in techniques. Since most of the electric field lines between 2DEG and tip terminate far away from the tip apex there is a large background signal adding to the local signal of interest. Detailed fine structure on a length scale of about 100 nm can be resolved on the resulting images acquired in the quantum Hall regime, if the background signal is subtracted employing a bridge circuit [28]. Some of the observed structure in the experimental images can be explained using the idea of compressible and incompressible strips. The suppression of the local charging signal can arise due to two distinct reasons: either the local compressibility of the electron gas below the tip apex is low (low density of states at the electrochemical potential) or the conductivity of the 2DEG surrounding the tip position is too low to allow charging under the tip within half a period of the excitation (RC effect).

Possible models needed for an interpretation of the data are discussed in [98]. The simplest model entirely neglects RC effects and describes the measured capacitive signal as arising from a series connection of a plate capacitor with a geometric capacitance C_g and a quantum capacitance contribution $C_q = e^2\mathcal{D}(B)$ which is proportional to the local magnetic field dependent density of states $\mathcal{D}(x, y; B)$. The most involved model treats the electron gas on a discrete lattice with given local conductances and capacitances between neighboring sites. This conductance and capacitance pattern has to be optimized until the simulation fits the measured image.

The charge sensor is sensitive enough to detect individual charges entering the region under the tip. At suitable filling factors and tip–sample voltage a quantum dot can be formed under the tip which contains only a small number of electrons separated from the surrounding electron gas by a circular incompressible strip. Single electron charging of this dot has been observed [93] and the varying number of electrons in this dot as it is dragged along with the tip has been used for mapping the local potential in the Hall liquid (see Fig. 28).

5.2.4. Local Inter-edge-channel Tunnelling

In this section we discuss another type of local edge state imaging in the quantum Hall regime which is also based on low-temperature scanning probe techniques [82, 99]. In this approach the tunnelling current is measured between edge channels that are separately contacted. The tunnelling current is locally modified using a potential perturbation induced by the conducting tip of a scanning force microscope.

The samples are based on a GaAs/AlGaAs heterostructure with the two-dimensional electron gas residing 34 nm below the sample surface. Figure 29 shows a photograph of the structure which was prepared using photolithographic

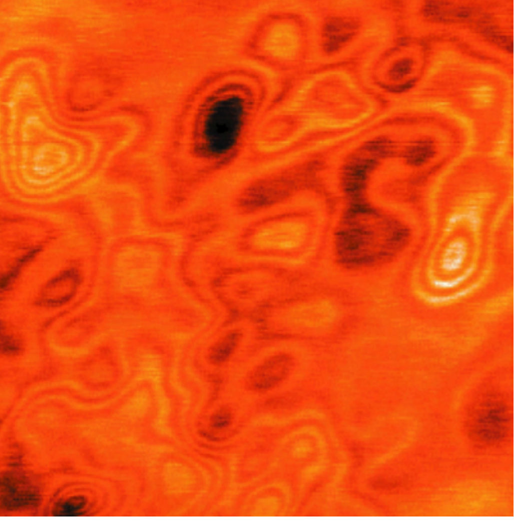

Figure 28. A 2.5×2.5 μm subsurface charge accumulation image taken at a filling factor $\nu \leq 1$. Reprinted with permission from [93], G. Finkelstein et al., *Science* 289, 90 (2000). © 2000, American Association for the Advancement of Science.

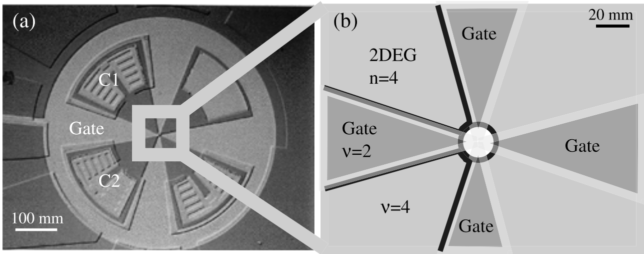

Figure 29. (a) Photograph of the circular mesa structure with the internal contacts C1 and C2. A small circular hole is etched into the center of the structure. (b) Schematic blow-up of the central part of the sample. For appropriate choice of V_G and B the indicated filling factors can be realized leading to the distribution of edge channels as indicated by the black lines. Reprinted with permission from [99], T. Ihn et al., *Physica E* 13, 671 (2002). © 2002, Elsevier Science.

techniques. The structure is essentially a circular mesa with a diameter of about 500 μm with a central hole of 20 μm in diameter. The sample is connected to the measurement setup via the internal ohmic contacts C1 and C2. A star-shaped gate electrode splits the two-dimensional electron gas into four ungated sectors.

The sample is mounted in a home-built low-temperature atomic force microscope utilizing a piezoelectric quartz tuning fork force sensor. The basic principle of the microscope and the characteristics of the tuning fork sensors have been described and can be found in [39, 42, 43]. Experiments were performed in the variable temperature insert of a standard ^{4}He cryostat at a temperature of 1.9 K. A voltage of 10 μV was applied between C1 and C2 and the two-terminal conductance was measured with a current–voltage converter.

Figure 29b shows a schematic magnification of the central part of the structure for illustrating the basic concept of our experiment. Using the appropriate combination of gate voltage, U_G, and magnetic field, B, we are able to set up a situation in which the bulk of the ungated electron gas has a Landau-level filling factor $\nu = 4$ (i.e., two spin-degenerate edge channels exist), while the gated regions have a filling factor of $\nu = 2$ supporting only one spin-degenerate edge channel. The latter will be able to circulate around the central hole, of the structure as shown in the figure. The other edge channel is not allowed under the gate. It will therefore come from C1 (or C2) along the edge of the gate, run in parallel with the $\nu = 2$ edge channel along the edge of the central hole, and then return to contact C1 (or C2) along the other edge of the gate. Since under these conditions the bulk regions of the gated as well as of the ungated 2DEG are insulating, the current from C1 to C2 involves tunnelling processes between the two edge channels. Spatially, tunnelling has to occur in regions where both edge channels run in parallel (i.e., in the vicinity of the edge of the central hole). Conceptually, this tunnelling transport is somewhat related to recent experiments on tunnelling through the edge states around an antidot [100]. However, the quantization of edge states around the central hole (the "antidot") plays no role in our structure. The central idea of the present experiment is that the tunnelling current between the two edge channels can be locally enhanced (or suppressed) by applying a local potential perturbation capacitively induced by the conducting tip.

In order to find the appropriate settings for V_G and B we characterized the structure by measuring the two-terminal conductance between contacts C1 and C2 as a function of these two parameters with the tip withdrawn from the surface of the structure. The result is shown as a grayscale image in Figure 30.

It can be seen that at $V_G < -0.08$ V the regions under the gate are completely pinched off and the conductance vanishes. At $V_G > -0.05$ V the grayscale plot is dominated by the Landau fan given by the 2DEG under the gate. The conductance oscillates as a function of B due to the Shubnikov–de Haas effect. The contribution of the ungated 2DEG can barely be seen in this range of V_G. However, in a very small range of gate voltage around $V_G \approx -0.07$ V vertical cuts through the plot reveal $1/B$-periodic oscillations which are independent of V_G but can hardly be seen on the grayscale plot (i.e., we observe the Shubnikov–de Haas oscillations of the ungated regions). They lead to the bright horizontal lines in the figure where the filling factors for the ungated regions are indicated. It can be seen from the figure that at $B \approx 5$ T and $V_G \approx 0.02$ V we achieve the desired $\nu = 2$ under the gate, while in the ungated regions we have $\nu = 4$.

While keeping the sample under these conditions the tip is now scanned across the sample surface near the edge of the inner hole. The tip was kept at a constant voltage $V_t = 0$ V, but due to the work function difference between the tip material PtIr and the sample there exists an effective electrostatic potential drop between tip and 2DEG which locally depletes the electron gas. Figure 31a shows a 5 μm × 5 μm topographical image of the edge of the central hole of the sample. In Figure 31b the conductance image can be seen measured simultaneously with the topography. The conductance of the sample is enhanced along a stripe of about 700 nm width which follows the curvature of the edge of the 2DEG. The image proves in a direct way that we can indeed enhance the tunnelling coupling between the two parallel edge channels by applying a local potential perturbation.

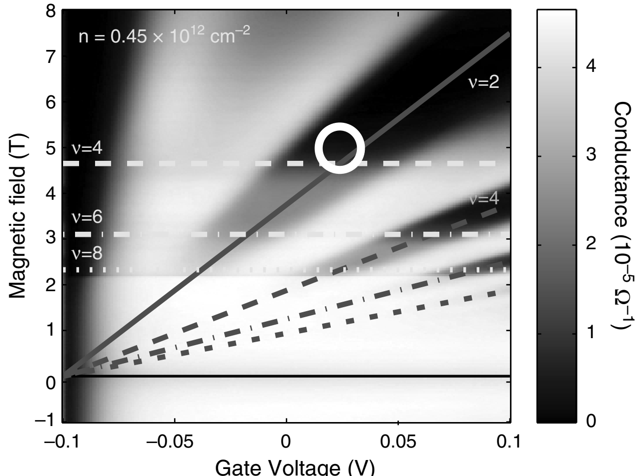

Figure 30. Conductance measured as a function of magnetic field and gate voltage. The bright horizontal lines indicate the filling factors in the ungated regions of the 2DEG. The gray Landau fan indicates filling factors in the gated regions of the 2DEG. Reprinted with permission from [99], T. Ihn et al., *Physica E* 13, 671 (2002). © 2002, Elsevier Science.

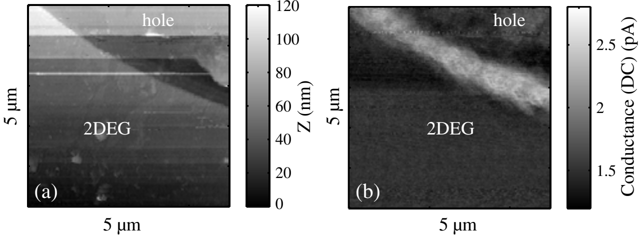

Figure 31. (a) Topographic image of the mesa edge defining the central hole etched into the 2DEG. (b) Conductance as a function of the tip position. The tip induced local potential leads to an enhanced tunnelling coupling of the two parallel edge channels and thereby to an increase in the conductance. Reprinted with permission from [99], T. Ihn et al., *Physica E* 13, 671 (2002). © 2002, Elsevier Science.

It is well established that the conductance or resistance of a sample in the quantum Hall regime is highly nonlocal [101, 102] and the phase-coherence length of electrons in edge channels can be macroscopically large. Therefore it is not *a priori* clear that the local perturbation induced by the presence of the tip will change the tunnelling coupling of the edge channels *locally*. Yet we argue that the self-consistent nature of the edge channel formation may well lead to a local enhancement of the tunnelling coupling. According to the adiabatic edge channel description [74] edge channels will follow equipotential lines along the sample edge. The local perturbing potential will affect the spatial run of the equipotential lines locally (i.e., on the scale of the screening length) and therefore we expect the edge channels to follow this perturbation on a local scale. This scenario is schematically depicted in Figure 32. Edge states form along the mesa edge as well as around the tip-induced anti-dot-like potential. When the tip is sufficiently remote from the edge (Fig. 32a), there is no mutual interaction between the two types of edges. When the tip is close enough to the mesa edge, the edge channel structure will change locally as illustrated in Figure 32b. The tunnelling coupling between the edge channels depends on the exponential overlap of the wave functions and therefore on the width of the incompressible stripe separating them. A spatial rearrangement of the self-consistent stripes will change the inter edge channel coupling. We suggest that the *local* change of the tunnelling coupling creates the observed conductance contrast in Figure 31.

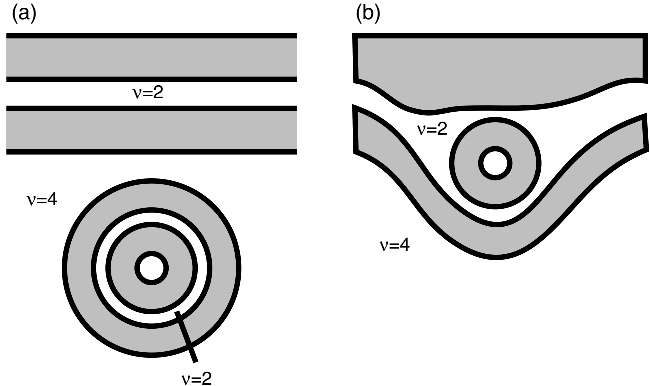

Figure 32. (a) Tip far away from the edge. Two edge states encircle the tip-induced potential hill. States at the sample edge are not affected. (b) Tip close to the edge of the sample. The tip induced potential locally changes the run of the edge currents and thereby modifies the tunnelling coupling between them. Reprinted with permission from [82], T. Ihn et al., *Microelectron. Eng.* 63, 81 (2002). © 2002, Elsevier Science.

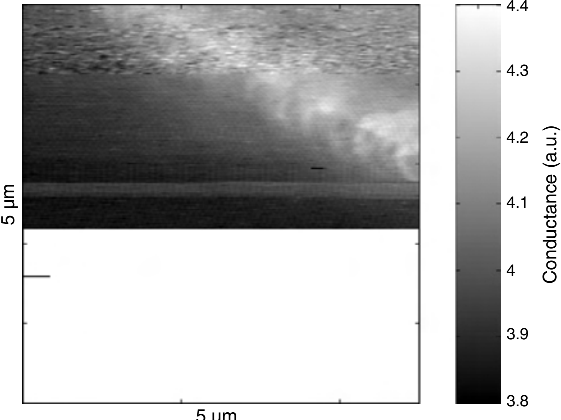

Figure 33. Image of the edge-channel coupling at enhanced spatial resolution. Reprinted with permission from [99], T. Ihn et al., *Physica E* 13, 671 (2002). © 2002, Elsevier Science.

The local nature of the conductance contrast makes the presented imaging method a promising tool for the local investigation of edge channel coupling and inter-edge-channel scattering (see [103] for a review and also [104]). As a matter of fact it can already be observed in Figure 31b that the bright stripe is not homogeneous but exhibits some internal structure. In order to illustrate this further we show in Figure 33 the conductance image obtained in the course of the same cooldown of the sample but with the tip in better condition. Unfortunately the tip shape can change during a cooldown (e.g., due to contaminations picked up from the sample surface). In some fortunate cases, however, the spatial resolution of the images is improved. In Figure 33 it is clearly visible that the extent to which the edge channel coupling can be enhanced depends strongly on the position of the tip even within the stripe of enhanced conductance. The image shows fringes leading away from the center of the stripe reminding one of the fascinating fine structure observed with other methods in the bulk of 2DEGs in the quantum Hall regime [10]. More investigation will help to further establish the presented imaging technique and to deepen our understanding of its interpretation.

GLOSSARY

AFM lithography Lithography technique using the tip of a scanning force microscope for patterning the surface of a sample. For example, with a conducting tip, local anodic oxidation of GaAs or Ti can be achieved when a suitable voltage is applied between the tip and the sample.

Cyclotron frequency Characteristic frequency for the motion of an electron in a magnetic field. If the magnetic field is applied normal to the plane of the electron motion, classical electrons move on circles. If the electron needs a time T for a single roundtrip, the cyclotron frequency is $2\pi/T$.

Landau levels Quantum mechanical energy levels for an electron in a magnetic field. In a two-dimensional system, Landau levels are equidistant in energy, like the states of a harmonic oscillator. However, each Landau level has a large degeneracy, i.e. it can accommodate a large number of electrons.

Mesoscopic system Electronic system in which several relevant length scales, like sample size, the phase coherence length and the mean free path are of the same order of magnitude. If the mean free path is small compared to the other two lengths, the system is called diffusive, otherwise ballistic.

Phase coherence length Characteristic distance over which quantum mechanical particles, e.g., electrons, show interference of their probability amplitudes. The phase coherence length is limited by dephasing processes, such as inelastic scattering.

Quantum Hall effect Arises in a two dimensional electron gas at low temperatures (typically below 4.2 K), when a strong magnetic field (of the order of 10 T) is applied normal to the plane of the electron motion. The Hall resistance is no longer rising linearly with the magnetic field strength, but exhibits plateaus at integer fractions of the fundamental resistance quantum h/e^2. The origin of the effect is the Landau quantization of electronic states (see Landau levels) and the localization of electrons due to potential inhomogeneties and interactions.

Quantum point contact Narrow constriction for electron flow with a conductance close to the conductance quantum $e^{2/h}$. The electron motion normal to the constriction is quantized into modes. Each mode traversing the point contact contributes one conductance quantum to the total point contact conductance. Therefore, the total conductance is quantized, i.e. it is no longer rising linearly with the width of the constriction, but exhibits plateaus at integer multiples of the conductance quantum.

Shubnikov-de Haas effect Oscillatory resistance of an electron gas in a magnetic field. The effect can be observed in metals (it was discovered in Bismuth), but is very pronounced in semiconductors at low temperatures. The effect is due to the Landau quantization of energy levels in a magnetic field (see Landau levels). It allows the determination of the electron density, for example, in two-dimensional electron gases.

Two-dimensional electron gas System in which electrons are free to move in two spatial directions, but quantized in the third. Two dimensional electron gases form, for example, at the interface between the semiconductors GaAs and AlGaAs, or the interface between Si and SiO_2 in a field effect transistor (MOS-FET).

1. INTRODUCTION

Carbon nanotubes are perhaps one of the most exciting members of the family of carbon nanostructures initiated by the discovery of fullerene almost two decades ago [1]. Their very promising properties [2, 3] brought single wall carbon nanotubes (SWCNTs), and multiwall carbon nanotubes (MWCNTs) to the focus of attention of researchers in various fields ranging from nanoelectronics to composite materials. In addition to the straight carbon nanotubes discovered by Iijima in 1991 [4], other more complex but tubular-type structures built of layers of sp^2 hybridized carbon, like Y-junctions, helical coils, and multiple coils, have been predicted theoretically [5–8] and observed experimentally by transmission electron microscopy (TEM) and scanning tunneling microscopy (STM) [9–13].

A SWCNT consists of one atomic layer thick sheet with a graphitelike structure (graphene sheets) seamlessly rolled into a cylinder (Fig. 1), while MWCNTs are built of a set of graphene cylinders with increasing diameter, concentrically placed in each other. The diameter and helicity of a defect-free SWCNT are uniquely characterized by the vector $\boldsymbol{C} = n\boldsymbol{a}_1 + m\boldsymbol{a}_2 \equiv (n, m)$ that connects crystallographically equivalent sites on a two-dimensional graphene sheet, where $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ are the graphene lattice vectors, and n and m are integers (Fig. 2). The interlayer spacing of MWCNTs is consistent with that of turbostratic graphite, 0.34 nm [14]. Typical diameter values for SWCNTs are around 1 nm, while MWCNTs have diameters in the range of a few tens of nanometers. Their structure confers the nanotubes with special properties, very closely determined by the way in which the C–C bonds in the graphene sheet are oriented with respect to the nanotube axis, and by the diameter of the tube [2, 3] (Fig. 2). Depending on the way in which the graphene sheet is wrapped into a cylinder, SWCNTs may be metallic or semiconducting [2]. One-third of all possible SWCNTs exhibit metallic behavior [i.e., their electronic density of state (DOS) at the Fermi energy is different from zero], while two-thirds show semiconducting behavior, with zero DOS around the Fermi energy. MWCNTs are constituted from a random alternation of semiconducting and metallic layers [15]. Due to the strong interdependence between atomic structure and electronic properties, atomic resolution topographic STM images and scanning tunneling spectroscopy (STS) are extremely useful in investigating and understanding the physical properties of carbon nanotubes. STM is the only tool able to give information about both the atomic arrangement and the electronic structure of the very same nanotube.

2. SCANNING TUNNELING MICROSCOPY THEORY

In principle, the concept of the STM is simple (Fig. 3): an atomically sharp, metallic tip is brought within a distance s, of the order of a few tenths of a nanometer, to a conducting surface. Due to their quantum mechanical behavior, electrons may tunnel with equal probability from the tip to the surface and vice versa. If an external bias V is applied between the tip and the surface a preferential tunneling direction is imposed which will yield an average current, I_t. The tip–sample distance s is regulated using a piezoactuator and a feedback loop. The tunneling current measured at a given moment is taken as input signal for the feedback loop.

A comprehensive overview of the theoretical models used to describe the tunneling through a one-dimensional potential barrier—the simplest case of tunneling—is given by Wiesendanger [16]. Two major conclusions arise from the various models:

(1) The transmission T of electrons through a one-dimensional potential barrier depends exponentially on the width s of the barrier:

$$T \propto e^{-2\chi s} \tag{1}$$

(2) The decay rate χ, characterizing the decrease of the probability of the electron to cross over the barrier, is

$$\chi = \frac{2\pi[2m(V_0 - E)]^{1/2}}{h} \tag{2}$$

where V_0 is the average height of the barrier, and E is the energy of the tunneling electron. Independently of the exact shape of the barrier, the strong exponential dependence of T with the barrier width s and the square root of the effective barrier height, $(V_0 - E)^{1/2}$, is typical of tunneling. The exponential dependence makes the tunneling channel be very narrow, thus making possible the atomic resolution.

The tunnel current flowing between the tip and the sample at a bias voltage V will be

$$I(V) \propto \int_0^{eV} \rho_s(E)\rho_t(E - eV)T(E)\,dE \tag{3}$$

where ρ_s is the sample electronic DOS, ρ_t is the DOS of the tip, and T is the transmission coefficient of the barrier. From formula (3) one may observe that the STM offers the opportunity to acquire not only topographic information about the sample but also information regarding the DOS of the sample. If the tip DOS is flat and the transmission coefficient T may be taken as constant, then Eq. (3) reduces to

$$I(V) \propto \int_0^{eV} \rho_s(E)\,dE \tag{4}$$

Then the quantity dI/dV, named differential conductance, will be proportional to $\rho_s(V)$, the sample electronic DOS. However, T may be regarded as constant only in the limit of small voltage variations; it gives deviation from this simple dependence at large bias values.

The real case of an STM measurement is different from the simple case of tunneling through a one-dimensional potential barrier. First of all, in the case of a sharp tip, one has a three-dimensional potential barrier instead of a one-dimensional one. The real potential barriers may strongly differ from the rectangular shape assumed in deducing the formulas (1) and (2). The most frequently used model for the interpretation of STM experiments is the model given by

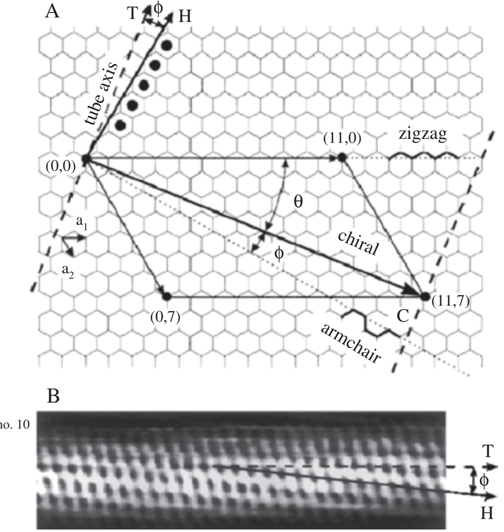

Figure 2. Relation between the rolling of the graphene sheet into a (11, 7) SWCNT (A) and the atomic resolution STM image of a (11, 7) nanotube (B). Reprinted with permission from [45], J. W. G. Wildöer et al., *Nature* 391, 59 (1998). © 1998, Macmillan Magazines Ltd.

Tersoff and Hamann [17]. In this theory the tip is treated as a single *s orbital* with a constant DOS and the tunnel current is proportional to the sample DOS computed at the location of the tip and at the Fermi energy at vanishingly small bias. A more comprehensive and detailed treatment of tunneling is given in the book on STM edited by Wiesendanger and Güntherodt [18].

In practical STM instruments, the positioning and scanning of the STM tip is achieved by piezoelectric actuators. The width of the STM gap is controlled by a feedback loop which keeps the value of the tunneling current at a setpoint value selected by the operator. An STM can operate in several regimes; the two most important ones are as follows:

- Topographic (constant current) imaging: the feedback loop is on, the image is generated from the values of the voltage applied to the piezoactuator to maintain a constant value of the tunneling current. Provided the electronic structure at the sample surface is homogeneous, the topographic profile of the surface will be generated.
- Current–voltage spectroscopy, frequently called scanning tunneling spectroscopy. The scanning and the feedback loop are switched off, the value of the tunneling gap is fixed, the bias voltage is ramped from $-U$ to $+U$, and the corresponding current variations are recorded. The function dI/dV gives information about the local DOS of the sample.

To understand the results of the STM imaging of carbon nanotubes it is useful to keep in mind a few particularities of the tunneling system specific to this case:

- For being imaged in an STM, a nanoscopic object like a carbon nanotube has to be placed on an atomically flat, conducting surface, the support. Highly oriented pyrolitic graphite (HOPG) or Au (111) terraces are the most frequently used substrates [19].
- Opposite from the case of tunneling into a bulk sample, when a carbon nanotube is imaged, the electrons have to cross two tunnel gaps: one between the STM tip and the nanotube, the other between the nanotube and its support [20, 21].
- The electronic structure of the carbon nanotube and its support may be different. As it follows from formula (3), the different values of $\rho_{s(\text{support})}(V)$ and $\rho_{s(\text{nanotube})}(V)$ will yield different values of tunneling current, thus having influence on the height values measured from topographic images [22].
- When the STM tip comes very close to the nanotube, or when switching from pure tunneling to a point contact imaging regime occurs [23], the nanotube may suffer elastic deformation under the STM tip.
- When imaging a nanometer sized object, important convolution effects arise between the object shape and the tip shape. This phenomenon yields the apparent lateral broadening of the imaged tube [24]. The diameter D is related to the apparent height h of the tube by the approximate relation $D = (8Rh)^{1/2}$, where R is the curvature radius of the tip [23]. The height of the topographic profile h is close to the diameter of the tube, and h is often used as a measure of d. But the apparent height depends on the adsorption distance of the nanotube above the substrate and on the difference between the tunneling distances above the tube and over the substrate arising from their different electronic properties. All these distances are not known with precision. Using the apparent height h of the nanotube seems to *underestimate* the actual diameter by as much as 0.2–0.5 nm [25], perhaps due to the radial compression of the nanotube exerted by the tip, or/and due to the second tunneling gap between tube and support the current must go through as already discussed. A fitting procedure of the tunneling current has been proposed [26] for the better determination of the diameter from the measured height.
- Distortion effects may arise from a “floppy” tip. Such a tip may be produced when the rigid STM tip picks up a carbon nanotube from the sample [27]. In this case the attached nanotube will act as the tip generating the image. Such a tip may cause in the topographic STM image reduced apparent height and dips on the sides of the imaged nanotube.

3. SCANNING TUNNELING MICROSCOPY AND SCANNING TUNNELING SPECTROSCOPY OF MULTIWALL CARBON NANOTUBES

Multiwall carbon nanotubes are a variety of nanotubes discovered by Iijima in 1991 [4]. STM was the ideal tool to characterize the topography and the electronic properties of these nano-objects. Topographic and voltage dependent STM imaging of arc grown MWCNTs in a bundle was first reported by Zhang and Lieber [28]. The three-dimensional structure of the bundles was investigated, and it was found that the large bundles consist of closely packed nanotubes with diameters on the order of 10 nm. A switchover from stable imaging when using bias voltages larger than 200 mV to unstable tunneling below this value was found. The observation was interpreted as experimental evidence for the existence of a conduction gap of the nanotube bundle around the Fermi energy. The first STS measurement on individual carbon nanotubes was reported by Olk and Heremans [29]. Their measurements were carried out in air on MWCNTs grown by the electric arc method transferred onto an Au substrate by ultrasonication in ethanol. Both semiconductor and metallic carbon nanotubes were found. The comparison of measured energy gap and experimental diameter values with gap values predicted by theory [30, 31] showed an increasing deviation with decreasing tube diameter. The deviations may originate from the unavoidable error introduced in the measured diameter by tip/sample convolution effects, the more complex structure of the tunneling region than in the well known case of a flat, homogeneous sample [20, 22], and effects arising from the multiple walls of the MWCNTs. On the other hand, it is not known yet to what extent the inner layers of a MWCNT may play a role during tunneling through the nanotube. Theoretical calculations show that the inner layers of a MWCNT may rotate in

the larger diameter outer layer [32]. However, the first STM experiment proving that atomic resolution is possible on a carbon nanotube reported by Ge and Sattler [33] was carried out on MWCNTs. The MWCNTs were produced *in-situ* by the condensation of evaporated carbon on a HOPG substrate. A similar atomic resolution image is reported as in the case of HOPG. The triangular lattice seen on the surface of HOPG is caused by the nonequivalence of the carbon atoms (in the Bernal graphite stacking) produced by interlayer interaction [34, 35]. Thus a similar atomic resolution pattern in the case of a MWCNT like that of HOPG is an indication of interlayer interaction. Additionally Ge and Sattler [33] found a periodicity of 16 nm along the tube axis superimposed on the atomic lattice. This was interpreted as arising from the misorientation of the outer two layers of the MWCNT, analogously with the generation of Moiré patterns known in geometric optics. The STM observation of Moiré patterns on HOPG [36] is well known experimentally; however, no clear theoretical description has been given yet.

Although discovered first, both the experimental and theoretical understanding of MWCNTs is behind that of SWCNTs. Atomic resolution images acquired on MWCNTs grown by chemical vapor deposition [22] were interpreted in a way similar to the work by Ge and Sattler [33]. Hassanien and co-workers [37] interpreted their atomic resolution images taken on MWCNTs like in the case of SWCNTs (i.e., like for a single shell system). In a more recent work Hassanien and co-workers compared atomic resolution images of SWCNTs, MWCNTs, and HOPG, and they concluded that the atomic resolution images on MWCNTs and HOPG are similar. Moreover, the difference between α and β sites (β sites do not have a neighbor in the layer below) was evidenced by STS, too [38].

Topology related changes in the local density of states near the ends of closed MWCNTs were investigated using spatially resolved scanning tunneling spectroscopy and tight binding calculations. Sharp resonant valence band states were found at the tube ends, dominating the valence band edge and filling the bandgap. Calculations show that the strength and position of these states with respect to the Fermi level depend sensitively on the relative positions of pentagons and their degree of confinement at the tube ends [39, 40]. In accordance with theoretical predictions [41], STS measurements on MWCNTs grown directly on the HOPG support for STM measurements showed that for MWCNTs of diameter exceeding 30 nm no differences can be evidenced between the nanotube and the HOPG [42].

STS was successfully used to investigate the effect of mechanical strain on the electronic structure of MWCNTs on a support. The spectroscopic data show that while small deformations do not have a marked effect on the local electronic structure, high strain, like that due to abrupt substrate morphology change, showed a drastic perturbation in the local electronic structure of the tube [43]. This experimental finding is an agreement with theoretical work on the effects of defects produced by strain in the STM image of SWCNTs and alterations in their transport properties [44].

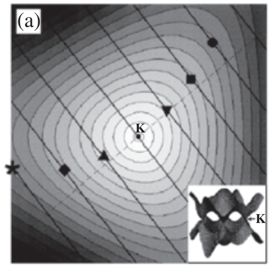
4. SCANNING TUNNELING MICROSCOPY AND SCANNING TUNNELING SPECTROSCOPY OF SINGLE-WALL CARBON NANOTUBES

The first atomic resolution topographic STM images and STS results on SWCNTs were reported simultaneously by two groups [45, 46] on SWCNTs grown by laser ablation, imaged in a low temperature STM on Au substrate. The atomic resolution images allow the determination of the chiral angle Φ between the tube axis and the centers of the closest row of hexagons appearing in the STM image as dark spots (Fig. 2).

The tube diameter and chirality allow the structural identification of the nanotube [2]. The STS results are in good agreement with the calculated densities of states of SWCNTs [2, 30, 47, 48]. Both metallic and semiconductor carbon nanotubes were found. The typical gap values found for semiconductor nanotubes with diameters in the 1.2 to 1.9 nm range were of the order of 0.5 eV, while the metallic carbon nanotubes with diameters in the range of 1.1 to 2.0 nm had subband separations of the order of 1.7 eV [45]. Both groups found that for semiconducting SWCNTs the measured gap values were proportional to $1/d_t$, where d_t is the diameter of the nanotube. Some differences found in the proportionality factors may arise from the differences in taking into account the systematic errors in the determination of the tube diameter due to convolution effects. In first approximation, the distances between van Hove singularities across the gap ΔE_{11} of a semiconducting SWCNT are found to respect the rule $\Delta E_{33} = 4 \times \Delta E_{11}$ and $\Delta E_{22} = 2 \times \Delta E_{11}$, while for metallic nanotubes, the rule is $\Delta E_{33} = 3 \times \Delta E_{11}$ and $\Delta E_{22} = 2 \times \Delta E_{11}$ [49, 50], where ΔE_{11} is the subband separation. This relation may be very useful in experimentally identifying metallic and semiconducting SWCNTs from often noisy STS data.

In the interpretation of the spectroscopic data it has to be taken into account that due to work function differences, the Au substrate may produce the doping of the nanotube by charge transfer [45]. The center of the gap that separates the first two van Hove singularities may be offset toward the valence band by as much as 0.2–0.3 eV. Apparently, there is no systematic difference between metallic and semiconducting tubes [45].

Sharp van Hove singularities found by STS in the DOS of SWCNTs imaged in atomic resolution allowed comparison of these data to tight-binding calculations for specific tube indices (n, m) [51]. The increasing deviation (rounded triangular contours in Fig. 4a) from isotropic dispersion of the π-bands of graphene around the **K** point of the first Brillouin zone (circular contours) with increasing distance from **K** is taken into account. The trigonal anisotropy causes the increase in the splitting of the second and third van Hove singularities as compared with the first one [52]. A remarkably good agreement was obtained between experiment and π-only calculations. Pronounced peaks in the DOS were also found at the end of an atomically resolved metallic SWCNT. Comparison of these data with calculations suggests that the topological arrangement of pentagons is responsible for the localized features in the experiment [51].



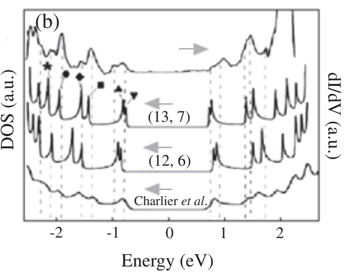


Figure 4. Comparison of measured dI/dV with calculated DOS for a metallic nanotube. (a) Energy dispersion of the π band of a graphene sheet near **K**. The solid lines correspond to the (13, 7) 1D bands obtained by zone folding. Symbols are located at the positions where van Hove singularities occur in these 1D bands. The inset depicts a three-dimensional view of the graphene π/π^* bands. (b) Comparison of the DOS obtained from experiment (upper curve) and a π-only tight-binding calculation for the (13, 7) SWCNT (second curve from top). The broken vertical lines indicate the positions of VHS in the tunneling spectra after consideration of thermal broadening convolution. The symbols correspond to the VHS shown in (a). The calculated DOS for a (12, 6) tube and an independent calculation for a (13, 7) tube [48] are included for comparison. Reprinted with permission from [51], Ph. Kim et al., *Phys. Rev. Lett.* 82, 1225 (1999). © 1999, American Physical Society.

Atomic resolution images of SWCNTs have been also obtained on the top of a rope [53–55]. The achieved resolution made it possible to compare the chiralities of the tubes that belong to the same rope. In some cases it was reported that the nanotubes have different chiralities and some of them may be twisted. In other cases, nearly uniform diameter and chirality were observed. Spectroscopic data taken on bundles show that the I–V curve may vary a lot along the same nanotube, and the spectra may exhibit a pronounced asymmetry [56]. The variation of the noise level of constant current topographic images taken at the same values of positive and negative bias confirm the asymmetric character of the spectra.

The STM tip is not only able to image the nanotube; it can be used as a "tool" to modify the nanotube. SWCNTs were cut to desired size by applying a voltage pulse of the order of 4 V. No polarity dependence was found [57]. After shortening to a length of 30 nm, the STS spectrum of the nanotube piece taken at 4 K showed nonequidistant, steplike features absent before the cutting. The observed effect was interpreted as arising from discrete electron stationary waves observed as periodic oscillations in the differential conductance as a function of the position along the tube axis, with a period that differed from that of the atomic lattice. This technique made it possible to map the square modulus of the electron wave functions that could be observed for several electron states at adjacent discrete energies. The measured wavelengths were found to be in good agreement with the calculated Fermi wavelength for armchair nanotubes [58]. Similar studies were also devoted to chiral metallic and semiconducting nanotubes shortened to a few nanometers [59, 60]. In contrast to the metallic nanotubes, no significant length dependence is observed in finite-sized semiconducting nanotubes down to 5 nm. The STS data obtained from the center of the shortened tubes showed a striking resemblance to the spectra observed before cutting [60].

The STM tip may be used not only to cut the nanotube but as a sliding contact along a nanotube extracted from a nanotube mat [61], too. Abrupt switching from a graphiticlike response to one that is highly nonlinear and asymmetric, including near-perfect rectification, was observed. The observation was interpreted in terms of existence of localized on-tube nanodevices formed by defects.

STS was used to investigate the effects of the ambient atmosphere on SWCNT samples. It was found that some semiconducting samples exhibit metallic behavior on exposure to oxygen, while in the case of other samples the effect of O_2 is restricted to the modification of the apparent density of states at the valence band edge [62]. The investigation of the electrical response of semiconductor SWCNTs to gas molecules showed that while NH_3 produces a sharp decrease in conductance, NO_2 has an opposite effect [63].

Statistical evaluation of nanotube diameters in a SWCNT mat (buckypaper) from the measured gap values and the comparison of these values with statistics obtained form TEM images demonstrated that the evaluation of diameters from gap values has to be done with caution because the gap is not always sharply defined in the STS spectrum [64]. When examined in a large enough bias interval, the positions of the peaks in DOS corresponding to the van Hove singularities form a fingerprint of the wrapping indices n and m of the nanotube, which can be used to better estimate the diameter [52]. Effects arising from interaction with the substrate [65] and possible charge transfer [45, 66] have to be taken carefully into account. These effects may shift the Fermi level, as mentioned, but do not affect too much the local DOS on the topmost part of the nanotube, which is the part that is scanned by the STM tip [65].

Curvature effects in carbon nanotubes studied analytically as a function of chirality show that the π orbitals are found to be significantly rehybridized in all tubes, so that they are never normal to the tubes' surface. This results in a curvature induced gap in the electronic band structure of the metallic tubes. The tilting of the π orbitals should be observable by atomic resolution scanning tunneling microscopy measurements [67]. Indeed, recent STS measurements confirm the existence of the predicted gaps in the case of metallic zigzag nanotubes and the presence of pseudo-gaps produced by tube–tube interaction in bundles [60, 68].

5. COMPUTER MODELING OF SCANNING TUNNELING MICROSCOPY IMAGES

As already emphasized in the previous paragraphs the interpretation of experimental data obtained in a complex tunneling system consisting of a supported nanoobject sandwiched between two tunneling gaps is far from being straightforward. Therefore computer modeling of the expected STM images is of great help in the correct evaluation of the experimental data. Modeling the atomic resolution images has been carried out by Meunier and Lambin. Their method is based on a tight-binding π-electron Hamiltonian for the case of a pointlike tip in combination with a self-supported nanotube [69]. In the calculated images

(see Fig. 5), the depressions (dark features) correspond to the centers of the hexagons of the honeycomb structure. Over these locations the STM tip gets closer to the nanotube to keep the current constant [69]. The light features are produced by the C–C bonds. The calculations confirm the different image symmetries observed experimentally (Fig. 5). In the case of armchair tubes, the honeycomb structure is easily observable; all the bonds look similar [58]. For zigzag tubes a strong anisotropy of the bonds is found. The ones parallel with the tube axis appear much more stronger [25]. For chiral tubes, stripes spiraling around the nanotube are observed [19]. These reverse orientation on bias reversal [70, 71] in the case of semiconducting tubes, as indeed observed experimentally in some occasions [72]. Calculated atomic resolution images of semiconductor SWCNTs show that the angle between the stripes spiraling around the nanotube and the tube axis changes gradually with the changing of the chiral angle (Fig. 6). The two distinct classes of semiconductor tubes $n - m = M(3) + 1$ and $n - m = M(3) - 1$ exhibit complementary behavior. The image acquired with a negative tip in the first case is similar to the image acquired with positive tip bias for the second group of tubes. The complementarity of the two families of tubes is produced by the change in the occupied/unoccupied character of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) when changing from $n - m = M(3) + 1$ to $n - m = M(3) - 1$, due to the phase change imposed by the periodic boundary condition along the circumferential direction [71]. These calculated STM images of SWCNTs may prove to be extremely useful for the quick identification of nanotubes while acquiring experimental data.

The method based on the tight-binding π-electron Hamiltonian is suitable for calculating the expected STM images of 5–7 defects and other defects on carbon nanotubes, too [69]. An overview of the method and of the main results was given recently [73]. In a recent work, Meunier and co-workers used this method to calculate the atomic resolution STM images of a tapered carbon nanotube tip [74]. They found that the STM images of tapers are dominated by a protruding pentagon inherent in the taper structure, which unfortunately does not allow for an easy identification of the atomic structure of the underlying nanotubes, because the electronic structure of the taper is markedly affected by the 5–7 defects.

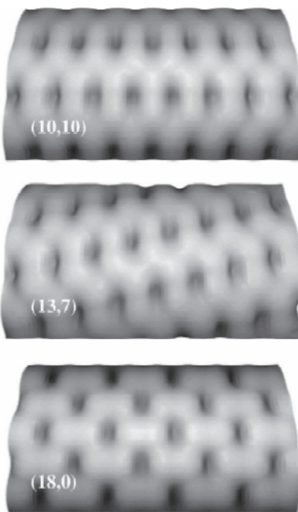

Figure 5. Constant current (topographic) STM images calculated using a tight-binding Hamiltonian and a pointlike tip for: an armchair (10, 10), a chiral (13, 7), and a zigzag (18, 0) nanotube. Reprinted with permission from [70], Ph. Lambin et al., *Carbon* 40, 1635 (2002). © 2002, Elsevier.

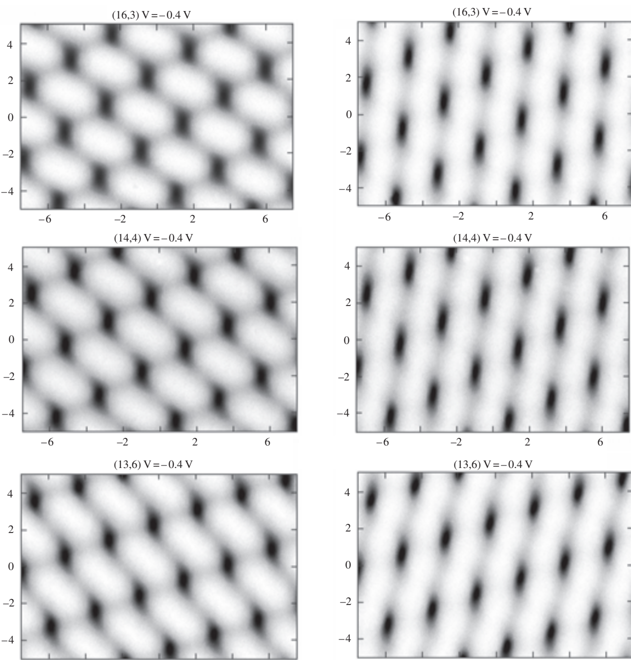

Figure 6. Tight-binding computed atomic resolution STM images of semiconductor nanotubes from the family $n - m = M(3) + 1$, with diameters close to each other: $d_{(16,3)} = 1.38$ nm; $d_{(14,4)} = 1.28$ nm; $d_{(13,6)} = 1.37$ nm, and increasing chirality: $\theta_{(16,3)} = 8.44°$; $\theta_{(14,4)} = 12.21°$; $\theta_{(13,6)} = 18°$, at positive and negative bias values.

A wave-packet dynamical method for the simulation of the geometric and charge spreading effects during tunneling in supported carbon nanostructures was developed and applied successfully for getting insight in the particularities of tunneling in two-dimensional (2D) representations [20] and more recently in full 3D tunneling through carbon nanotubes [75]. In this method the current density flowing through the STM tip–nanotube–support system is calculated based on the scattering of the wave packets incident on the barrier potential. The geometric effects are well described by electrodes and nanotube treated in the jellium-potential approximation (see Fig. 7). The STM topographic profile through a carbon nanotube was calculated which shows that as long as the electronic structure of the supported object and that of the support may be regarded as similar, the major image distortions arise from pure geometric tip-shape convolution [20] already discussed. With increasing differences in the electronic structure of the nanotube and that of the support larger distortions are expected. The incidence angle and energy dependent transmission of wave packets through single and bundled carbon nanotubes were calculated, effects arising from point-contact imaging and tip shape were analyzed, and STS curves were modeled [23]. The calculations show that for tip negative bias

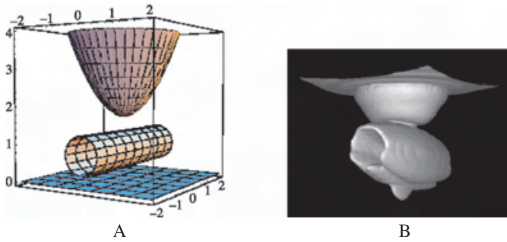

Figure 7. (A) Geometric model of STM tip, nanotube, and support surface. All dimensions are in nm. (B) Snapshot (at $t = 3.5$ fs) of the constant probability density surface of a wave packet tunneling through the tunnel junction shown in (A). Reprinted with permission from [35], G. I. Mark et al., in "Frontiers of Multifunctional Nanosystems" (E. Buzaneva and P. Scharff, Eds.), p. 43. Kluwer Academic, Dordrecht, 2002. © 2002, Kluwer Academic.

the angular dependence of the transmission is determined by the tip shape. The particular tip shape introduces an asymmetry on the negative side of the STS spectrum. For tip positive bias the angular dependence of the transmission depends strongly on the nature of the nanosystem in the STM gap. While the transmission of the STM tunnel junction without nanotubes can be well represented by a one-dimensional model, all other geometries cause a large normal-transverse momentum mixing of the wave packet. Recently an overview and comparison of the tight-binding and wave packet dynamical methods has been given [76].

The usefulness of the wave-packet dynamical method is completely revealed when using it in full 3D simulation [35, 75]. The computer simulation clearly shows that during tunneling the charge spreads along the nanotube. Thus, while the tunnel junction between the STM tip and the nanotube is a zero-dimensional junction, the tunnel junction between the nanotube and the support will be a linear, one-dimensional junction (Fig. 7). The consequences of the spreading will affect the tunneling situations when the nanotube is only partly supported or is placed over a nonhomogeneous substrate [75].

6. STRUCTURAL DEFECTS

As already reveled by early theoretic papers, structural defects, like 5–7 pairs, vacancies, isolated pentagons, and heptagons may have dramatic effects on the structure and electronic properties of carbon nanotubes [77–82]. Irrespective of its nature, a defect in a SWCNT gives rise to backscattering of the electron wave function. Interference of the incoming and backscattered waves leads to a standing wave pattern, which can extend far away from the defect due to the one-dimensionality of the nanotube. The corresponding oscillations of the DOS have been observed experimentally in armchair nanotubes where the Fermi wavelength of 0.73 nm is within the resolution easily achieved in spatially resolved STS experiments [83, 84].

The identification of defects and their detailed investigation by STM could lead to a better understanding of the way in which the defects are formed and how they can be used for the engineering of carbon nanotube devices. As already mentioned in the previous paragraphs, the theoretical models indicate that the defects should have a clear signature in the atomic resolution STM images and in spectroscopy. In a very thorough theoretic study of defects including Stone–Wales defects, which may arise due to tensile stress in SWCNTs, Orlikowski et al. focus on the expected STM images of pentagons, heptagons, and various combinations of 5–7 pairs, too [44]. An approach based on a tight-binding π-electron Hamiltonian for the evaluation of the tunneling current, as proposed by Meunier and Lambin [69], is used. The most prominent features observed in the STM images are a set of bright rings whose positions correlate with the location of the pentagons within the defect. These features are useful, as they enable the ready identification of many of the defects. By contrast, most of the defects have only a relatively modest effect on the transport properties of the nanotubes [44].

Based on the tight-binding approach, Krasheninnikov and co-workers calculated STM images for vacancies occurring on carbon nanotubes [85] and for defects expected after ion bombardment [86]. Vacancies of SWCNTs produce hillock-like features of about 0.1 nm in height and 1 nm in width in the STM images of the nanotubes, which are observable in low bias imaging ($V = 0.1$–0.4 V). Electronic superstructures similar to those in graphite near point defects produced by ion bombardment [87, 88] are evident in the simulated STM images.

Experimental investigation of small diameter kinked MWCNTs [83, 89] confirmed that both in topographic images and in STS measurements, the defects which must be present in the kink region give a detectable signature. In atomic resolution images of SWCNTs the signature of localized defects has been observed on straight SWCNTs [19]. Later, a detailed study by Ouyang and co-workers [90] focusing on atomic structure and electronic properties of intramolecular junctions in SWCNTs showed that about 10% of the SWCNTs grown by laser ablation incorporate defects which could be imaged reproducibly in an ultrahigh vacuum (UHV), low temperature STM. Metal–semiconductor junctions are found to exhibit an electronically sharp interface without localized junction states, whereas a more diffuse interface and low-energy states are found in metal–metal junctions. Tight-binding calculations for junction models based on observed atomic structures show good agreement with spectroscopy and provide insight into the topological defects forming the intramolecular junctions [90].

Two particular cases of "defects" have to be mentioned at the end of this section: (a) the defect concentrations and their STS signature occurring at tube ends, which has been discussed in previous sections [39, 51], and (b) the regular arrangement of defects, which yield novel architectures. This will be discussed subsequently.

7. COMPLEX TUBULAR STRUCTURES

As already pointed out in the Introduction, shortly after the discovery of straight carbon nanotubes, theoretical model calculations showed that with the incorporation of nonhexagonal rings in the hexagonal network, more complex structures can be built from tubular elements. The simplest one is a bent nanotube, a "knee" [7], produced by

incorporating a pentagon and a heptagon in the hexagonal network on opposite sides of a nanotube. Later the atomic structure and the expected electronic structure of more complex intramolecular junctions were explored by theoretical calculations [82, 91–94]. The possible application of these junctions in all-carbon nanoelectronic devices is foreseen. Calculations of the charge on the defect rings reveals an excess of electrons on the pentagon (+0.40 electron) and a deficiency on the heptagon (−0.25 electron) for several joints. This is attributed to the tendency of cyclic π-electron systems to achieve a stable configuration [93]. Quasioscillations of the local DOS with a triple period around the Fermi level were found in the metallic part of the (20,0)/(12,12) metal–semiconductor hybrid [93], very much as in the (10,0)/(6,6) junction [95] reported earlier. The LDOS and transmission coefficient calculations using a tight-binding algorithm suggest that the SWCNT bends can behave as M–S, M–M, or S–S heterojunctions (M = metallic, S = semiconductor) [94]. Electrical transport measurements carried out across the kinked and straight portions of a nanotube showed that while the straight part shows ohmic behavior, a strong rectifying effect is found across the knee [96]. Recent STM measurements on multiwall carbon nanotube knees produced by the arc discharge method indicate that increased electron density corresponding to the pentagon may be observed in topographic images even in the absence of atomic resolution [97], while at the location of the heptagon no such features are found.

Tori and coiled carbon nanotubes constructed by joining several knees head to tail were proposed as possible structures [7, 8, 98]. Scanning tunneling microscopy observation of coiled carbon nanotubes, following the relatively early TEM observation of the coiled carbon nanotubes [9], was first reported by Biró and co-workers [11, 22]. Taking into account that, as already discussed, nanotube junctions may behave like rectifiers, the electrons tunneling from the STM tip on the topmost part of a coil built from a succession of such rectifiers will have a small probability of reaching the substrate if the distance between the junctions is large enough. This may cause the STM tip to come into mechanical and electrical contact (point contact imaging) with the coil built of M–S junctions, while no such contact is expected for the M–M type coils [11]. Recent STS measurements on a coil (grown by the decomposition of fullerene directly on the STM substrate) which did not show any “camel-back” type feature, arising from point contact imaging, confirm the metallic DOS of the coil [99]. A regularly coiled SWCNT is showed in three-dimensional presentation in Figure 8.

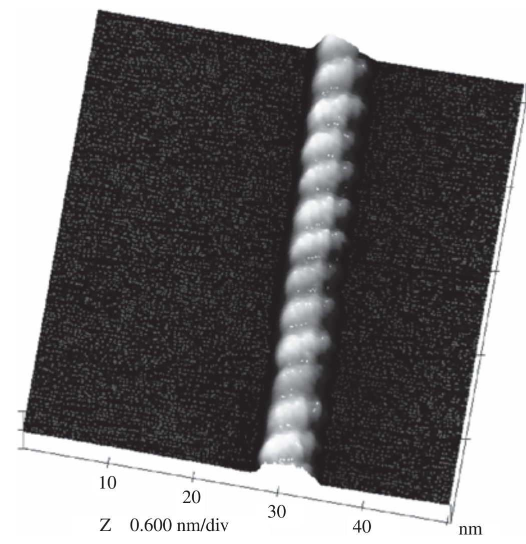

Figure 8. Topographic STM image of a regularly coiled metallic SWCNT in three-dimensional presentation.

With the increase of the number of the defects incorporated in a relatively short region of a tubular structure, branched tubular architectures can be built; the branching can be symmetrical [5, 6] or asymmetrical [100]. Such branched structures have been found by STM in carbon nanotube samples grown by fullerene decomposition (Fig. 9a) and by arc discharge, too (Fig. 9b). The Y-junctions grown by the first method are usually symmetrical [12], while the ones grown using the arc method were found to be less symmetrical, or asymmetrical [101]. In the arc grown tubes, the signatures of point defects, or knees, are observed in STM images preceding the branching point. It is speculated that these defects arise from growth instabilities, which usually are eliminated after the branching [101]. The branching occurs when a specific defect combination is achieved. Recent STS measurements and tunneling conductance maps confirm the existence of both M–M and M–S type joints within such Y-junctions [102]. These Y-junctions could constitute the basic building blocks of large, all-carbon nanocircuitry which needs only a few connection points with the macroscopic world, making it possible in this way to fully exploit the possibilities of carbon nanostructures to achieve new levels of integration. In some occasions one branch of the Y-junction can be a coil [103]. Nanotube networks with complex branching patterns where found after Cr filling. It was observed in the topographic STM images that strong apparent height variations along the tube axis are sensitively dependent on the imaging bias. These results suggest that Cr filling of carbon nanotubes results in strong electronic interactions between tube and filling materials [27].

Recently a new structural model, similar to the Haeckelite structure [104], was proposed for the coiled carbon nanotubes [105]. In contrast to earlier models of coiled tubes this approach allows nonhexagonal to hexagonal ring ratios to be over, or close to, unity. Using this model it

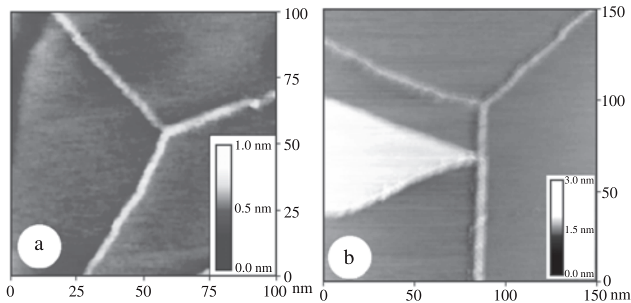

Figure 9. Constant current STM images of two Y branched carbon SWCNTs. (a) Grown by fullerene decomposition [12] and (b) grown by the electric arc method [101].

was possible to construct double helix type structures which were recently observed experimentally by STM [105] and TEM [106]. Figure 10a shows an experimental STM image of a double helix, while in Figure 10b and c two views of a model of double coil type structure generated as described by Biró and co-workers [105] are shown. The STM images in Figure 10d and e were computed for negative and positive tip polarity, using the tight-binding approach of Meunier and Lambin [69]. One can notice that in contrast to straight SWCNTs shown in Figure 5, due to the large number of nonhexagonal rings like in the case of tapers [74], no atomic resolution is possible. The tunneling current maxima show a very weak polarity dependence. The maxima are associated with the two hexagonal rings (highlighted) on the sides of the bonds where the two adjacent pentagons are joined. These rows of hexagons spiral along the tube axis in a double helix. Such structures of larger diameter, for which the calculation is not possible using the available computing facilities, are expected to be seen in the STM like the object in Figure 10a.

A new family of tubular carbon nanostructures was created by filling the inner hollow of SWCNTs with C_{60} balls [107]. These types of carbon nanostructures were named "peapods." STM images of peapods have been published recently [108]. Nothing special could be observed from the topography and the STS spectrum when electrons tunnel from the occupied states of the peapods to the tip. For a reverse bias of 1.5 V, by contrast, there is a large current when tunneling into the unoccupied states of the peapod; the topography shows maxima regularly spaced along the nanotube, which correspond to the fullerene interdistance. This effect was attributed to a large coupling of the LUMO t_{1u} state of the C_{60} with the electronic conduction bands of the nanotube.

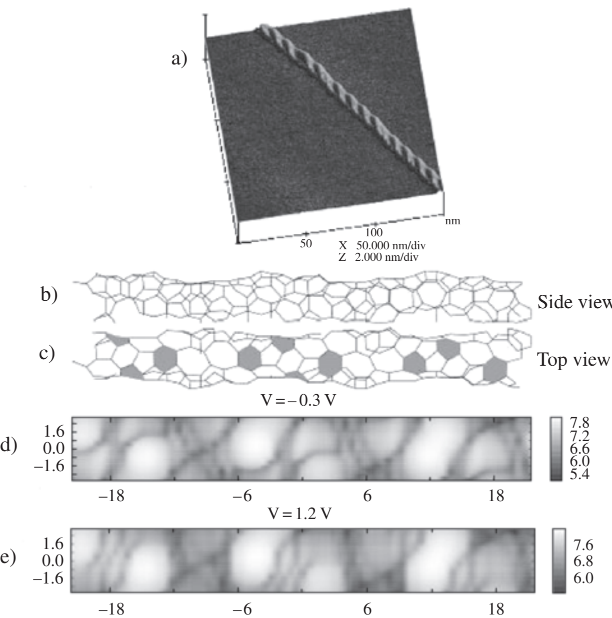

Figure 10. Experimental and calculated STM image of double coil type structures (the experimental image shows an object of much larger diameter than the calculated image). (a) Constant current topographic STM image in 3D presentation of a double coil; (b) structural model of a double coil structure in side view; (c) top view with the rings over which the bright maxima of tunneling current are found highlighted; (d) calculated top view STM image at a tip bias of −0.3 V; (e) calculated top view STM image at a tip bias of 1.2 V.

8. FUNCTIONALIZED NANOTUBES

The demand to functionalize carbon nanotubes (i.e., to attach to their outer wall covalently bonded groups of atoms, which can act as chemical anchoring points) was originally raised in the field of carbon nanotube reinforced composites, because the chemically inert, perfect nanotubes move in the matrix like the sword in the scabbard [109]. Due to its atomic resolution on individual objects, STM is a particularly well suited method for the investigation of the way in which the functional groups are attached to the nanotube. On the other hand, the presence of the functional groups often results in the nanotubes not coming close enough to the support on which they are placed; therefore the van der Waals attraction cannot fix them. This makes the STM imaging of functionalized nanotubes a very challenging task.

The first STM results on functionalized carbon nanotubes were reported by Kelly and co-workers [110]. Fluorination was carried out in a fluorine–helium atmosphere at various temperatures which yielded different degrees of functionalization up to 2C:1F. The fluorinated SWCNTs were imaged under ambient atmosphere using Pt/Rh tips. Fluorination caused the appearance of band shaped functionalized regions transversal to the tube axis, in which the SWCNT appears to have a larger diameter as compared to the nonfluorinated regions. Sharp delimitation of the border from fluorinated to nonfluorinated regions was found. No atomic resolution was possible over the functionalized regions, while atomic details were revealed between these regions. The fluorinated SWCNTs were used as precursors for attaching other chemical moieties, like butyl [110]. In contrast to the fluorinated nanotubes the butylated ones exhibit islandlike arrangement of the functional groups; strong electronic modulation effects are found in the vicinity of the butylated spots. Density-functional theory based calculations showed that depending on the fluorination pattern and tube chirality the fluorinated regions of the SWCNTs may have gaps varying from 2.7 to 0 eV [111]. The differences in the gap may well cause the appearance of the transversal bandlike features in the STM images of fluorinated tubes.

Recently MWCNTs functionalized by ball milling in NH_3 and H_2S atmosphere were investigated by STM and various other techniques [112]. Constant current STM images revealed that the functionalization by $-NH_2$ groups takes place in islands, around which the normal atomic resolution images characteristic for MWCNTs may be acquired. The STS spectra taken over the functional islands as compared to spectra typical for nonfunctionalized parts show and increase of the DOS above the Fermi level [112].

9. CONCLUSIONS

As the overview of the achievements of the first 10 years of STM investigation of carbon nanotubes shows, in this particular case the studied object and the method applied to study

it match in a unique way. Scanning tunneling microscopy and spectroscopy proved to be the most suitable methods for truly revealing the very characteristic electronic properties of carbon nanotubes arising from their one-dimensional character and nanometric size. A remarkable agreement between the theoretically computed results and experiments was achieved. It may be foreseen that in the attempts to achieve carbon nanotube based nanoelectronics for practical applications, STM and STS—probably in combination with atomic force microscopy—will play the role of "quality control tool" and will be a basic element in process monitoring. No doubt that a lot of effort will be needed to find ways in which these tools can be made widely applicable in industrial environments, where the low temperature, UHV scanning tunneling microscopes could be operated only with huge difficulties and high cost.

Many basic level questions concerning the STM investigation of multiwall carbon nanotubes are still open. The advance of this field is expected as suitable techniques emerge for the selective production of few wall carbon nanotubes [113].

The variety of novel carbon nanostructures like coils and multiple coils will pose a new challenge for both theoreticians and experimentalists. In several laboratories the selective synthesis of coiled nanocarbons was achieved already [114, 115]. It is expected that in the near future the coiled forms of carbon nanotube will be available on a regular basis, not only by accident.

A new class of carbon nanomaterials emerges with the discovery of the peapods. The first experimental results already indicate that the STM will be an extremely useful tool in getting deeper insight in the properties of these new materials.

Last, but not least, a very wide field of research opens up with the functionalization of carbon nanotubes. The first results already demonstrate STM and STS are the ideal tools to understand the way in which the chemical moieties are coupled to the nanotubes. A close collaboration between physicists, chemists, and materials scientists will be needed in this field.

Summarizing, one may say that the work done thus far is just the beginning of a quickly broadening path.

GLOSSARY

Branched tubular architectures Carbon nanotube junctions of Y, T, etc. shapes.

Carbon nanotube Allotrope of carbon discovered in 1991 by Iijima, constituted from a single atomic layer thick graphitic plate—called a graphene sheet—wrapped into a seamless tube.

Chiral angle The angle which characterizes the orientation of carbon–carbon bonds with respect to the orientation of the tube axis.

Coiled carbon nanotubes Regularly coiled carbon nanotubes looking like "telephone cables" of nanometer size.

Convolution A particular case of STM imaging when the radius of curvature of the tip is in the range of the radius of curvature of the object to be imaged. The acquired image will be equally influenced by the tip and the sample geometry. Deconvolution is not possible in a straightforward way, only by using dedicated software.

DOS Electronic density of states.

Energy gap The width of the region in which the density of states is zero (semiconductor tube) around the Fermi energy. For a metallic tube the region of finite density of states around the Fermi level is called "plateau region."

Functionalized carbon nanotubes Carbon nanotubes which have attached to their outer walls various chemical groups (functionalities).

Haeckelite structure Graphiticlike sheets or tubes containing a large fraction of regularly arranged nonhexagonal rings.

Helical coils Regularly coiled carbon nanotubes looking like "telephone cables" of nanometer size.

Interlayer spacing of MWCNTs The distance between two consecutive graphene layers.

Metallic carbon nanotube A nanotube which has a finite density of states at the Fermi level.

Multiple coils Carbon nanotubes built from several grown-together coils of identical pitch.

Multiwall carbon nanotube (MWCNT) Carbon nanotube consisting of several concentric SWCNTs with increasing diameter. The interlayer separation is similar to that in turbostratic graphite.

Peapods Carbon nanotubes filled with fullerenes.

Point contact imaging A particular case of STM imaging when due to the nonideality of the potentials and due to the small value of the tunneling gap, the potential barrier between the STM tip and sample is "punctured," so that the conduction mechanism switches from tunneling to ballistic conduction.

Semiconductor carbon nanotube A nanotube which has around the Fermi energy a so-called gap in which the density of states is zero.

Single-wall carbon nanotube (SWCNT) Carbon nanotube constituted from one graphitic cylinder.

STM tunnel junction A narrow channel between the STM tip and sample in which 90% of the tunneling current is flowing.

Stone–Wales defects Defect consisting of fused pentagonal and heptagonal rings.

STS Scanning tunneling spectroscopy, current–voltage spectroscopy acquired scanning the bias and measuring the corresponding tunneling current values, while the feedback loop and the scanning of the STM tip in the plane of the sample are switched off.

Topographic (constant current) imaging STM image acquired in a way that the tunneling current is maintained constant using a feedback loop and a piezoactuator.

Tunnel gap The geometric separation between the STM tip and the sample.

Van Hove singularities Singularities occurring in the density of states of carbon nanotubes.

Y-junctions Carbon nanotubes which have grown together in a Y-like fashion; structurally one the simplest models

implies the incorporation of six heptagons in the junction region.

Self-Assembled Monolayers on Semiconductor Surfaces

D. Zerulla
Heinrich-Heine-Universitaet Duesseldorf, Duesseldorf, Germany

CONTENTS

1. Introduction
2. Organic Self-Assemblies
3. Thiol Monolayers on III–V Semiconductor Surfaces
4. Nanostructuring of SAMs
5. Miscellaneous Self-Assembling Systems
6. Conclusion
Glossary
References

1. INTRODUCTION

Self-assembly is a very general principle in nature, as seen in the formation of for example, membranes from lipid molecules, or probably the most important paradigm, the living cell. Self-assembled monolayers (SAMs) are ordered molecular assemblies that are formed spontaneously by the adsorption of a surfactant. SAMs have recently attracted much attention because of the interesting opportunities for tailoring of solid surfaces. These monolayers exhibit unique chemical and structural properties. The formation of a SAM is initiated by bonding of a specific group of the organic molecule to the surface, followed by a rearrangement of the adsorbate layer with increasing coverage of the surface. This process is driven by intramolecular interactions between the adsorbed organics. Although self-assembly has attracted considerable attention over the last years, the subject has fairly old roots.

Pockels prepared monolayers at the air–water interface in the 19th century [1–4], followed by Rayleigh [5], Hardy [6], Deveaux [7], and others. Later, monolayers of amphiphilic molecules on the water surface were named after Langmuir [8, 9]. The first one to study the deposition of long-chain carboxylic acids on solid substrates was Blodgett [10, 11], who can be seen as the ancestor of our modern self-assembling systems, even if, around that time, amphiphilic monolayers were already used to control the wetting behavior of metal condenser plates in steam engines. Systematic research on self-assembling monolayers was performed later by Zisman [12] and Dewar [13]. For further information regarding the history of organic monolayers, we refer to [14, 15].

In the 1980s, the field of wetting and surface modification underwent a revival, and the great potential of thin organic films was recognized, which led to a very large number of publications in the following years [16–20].

Highly ordered organic films are very promising initial or intermediate states in order to achieve well-characterized tailoring of surfaces. Well-defined chemical modification and control of surfaces and interfaces are also essential for a variety of applications of semiconducting materials, as in photocatalysis, optoelectronic, and photovoltaic devices [21–23]. Recently, alkanethiolate films were also investigated on semiconductors because of their application potential for such purposes. But to date, still much less is known about alkanethiolate films on surfaces of compound semiconductors compared to the extensively studied surfaces of gold, silver, and copper. Passivation of GaAs surfaces using adsorbed thiols has been reported by Lunt et al. [24]. A study on alkanethiols on a chemically prepared InP(100) surface has been published by Gu et al. [25]. We will present very detailed results on the character, structure, passivating properties, and patterning of alkanethiols on III–V semiconductor surfaces in this chapter.

In contrast to the numerous publications in the field "self-assembling systems on coinage metals," the number of papers dealing with self-assembling on semiconductors is by far lower. In this chapter, the very detailed results on metals are sometimes used, to be compared with the results on semiconductors. This comparison allows us to judge if a self-assembling feature is a more general feature or a specific one for semiconductors. However, the main focus of this chapter is self-assembling and nanostructuring on semiconductors. Furthermore, this review is written from a surface-science perspective, with the focus on the fundamental principles governing the growth and structures

of self-assembling monolayers. While this naturally puts the emphasis on chemically simple compounds (e.g., thiols), we also outline the rich opportunities in the areas of lateral patterning, chemical functionalization, chelating compounds, and some technological applications. For the used surface-science techniques, we refer to well-known textbooks.

The chapter is organized as follows. In Section 2, the basic facts about the systems, the sample preparation techniques, and self-assembly are discussed. Section 3 deals with thiols on different III–V semiconductors, the most discussed and, in our opinion, the most fruitful combination. This includes speed of assembly, passivating properties, and a very detailed discussion of the structure of these systems. Section 4 is dedicated to the structuring of self-assembling systems. We present different approaches to structuring, but also discuss in detail the mechanisms behind the different technologies. Section 5 briefly describes systems which have not been discussed in the previous sections in order to give an as complete as possible review on the topic. Section 6 closes this chapter with a general discussion, and we conclude with an outlook and some open issues.

2. ORGANIC SELF-ASSEMBLIES

The most often used organic species in self-assembly is the *n*–alkanethiol molecule. Alkanethiols CH_3–$(CH_2)_{n-1}$–SH (alkyl chain length n) are well known to form SAMs on metals like gold, silver, or copper [16, 26–31]. The self-assembly of the alkanethiols results in a unique arrangement regarding a rather well-defined polar angle of the chains with respect to the surface normal of the metallic substrates. The head group contains a sulphur atom which binds to the substrates by splitting off the hydrogen atom [32–34]. The backbone of the molecule is an alkyl chain which is, in its most simple form, terminated by a methyl end group. Since the bonds in the alkyl chain are only σ (single) bonds, they permit rotation around the bond axis, and therefore the chain has a high degree of freedom apart from the symmetric all-trans conformation. Instead of the terminating methyl group, other groups can be used as a substitute (e.g., –OH, –COOH). Depending on the chemical character of the groups, the assembled monolayer has a hydrophobic or more hydrophilic behavior.

Instead of the saturated alkyl chain, double bonds or even aromatics can be introduced. The head group may also consist of any molecule which binds to the substrate of interest. There have been numerous reports on the properties of such monolayers on metal surfaces, including their structure, chemical properties, and applications for the structuring of surfaces. In contrast to metal surfaces, very few investigations so far have considered the adsorption of alkanethiols on semiconductor surfaces. This lack of knowledge is also in contrast to the large body of investigations which deal with the modification of semiconductor surfaces using inorganic sulphur compounds [33–37]. Reports have been given on the influence of alkanethiols on Schottky barrier heights on metal–semiconductor contacts and on the passivating properties of adsorbed thiols on semiconductor surfaces [35, 37].

Besides thiols in *n*–alkanethiols, often-used head groups are sulphonic and phosphorus acids. Another popular example is organosilicon monolayers (e.g., alkyltrichlorosilane) on hydroxylated surfaces, which are well ordered, but typically do not exhibit the degree of long-range order observed for thiols on coinage metals and III–V semiconductor surfaces [38–41]. A compilation of the most often used SAMs and their structure is shown in Table 1. For more details, we refer to Section 5.

2.1. Substrates

With the advent of the transistor in 1947 (Bardeen and Shockley, Bell Laboratories), semiconductors became more and more important in technological development. Nowadays, practically no modern technological device runs without semiconductors. While silicon (Si) is the basic material for most electronic devices (e.g., processors) [42–49], III–V semiconductors are the materials of choice for optoelectronic devices. Recently, the development of, for example, organic light emitters (OLEDs) and other organic devices demonstrates the necessity of combining and structuring organic–semiconductor systems.

Semiconductor compounds consisting of elements of the third (B, Al, Ga, In, Tl) and fifth row (N, P, As, Sb, Bi) of the periodic system, that is, the so-called III–V semiconductors GaAs, InP, or $Al_xGa_{1-x}As$, are frequently used in

Table 1. Structure of some frequently used SAMs.

Structure	
HS CH_2 CH_2 CH_3 / CH_2 CH_2 CH_2	(a)
HS CH_2 CH_2 CH_2 / CH_2 CH_2 CH_2 OH	(b)
O // HS CH_2 CH_2 C / CH_2 CH_2 CH_2 OH	(c)
HS CH_2 CH_2 CH_2 / CH_2 CH_2 CH_2 SH	(d)

H_3C CH_2 CH_2 S—S CH_2 CH_2 CH_3 / CH_2 CH_2 CH_2 CH_2 CH_2 CH_2	(f)
Cl_3Si CH_2 CH_2 CH_3 / CH_2 CH_2 CH_2	(g)

Note: (a) *n*–alkanethiol, (b) ω–mercaptoalkanol, (c) ω–mercaptoalkane carboxylic acid, (d) α, ω–alkanedithiol, (e) mercaptobenzothiazole, (f) 1,1′–dialkyl–disulfide, (g) alkyltrichlorosilane. For the purpose of illustration, the chain length is set to $n = 6$.

modern optoelectronic devices, such as light-emitting diodes (LEDs), semiconductor lasers, optoelectronic modulators, or light detectors. The reason for using these materials in optics rather than the most widely employed Si is the difference in band structure: many III–V semiconductors have a direct bandgap, resulting in very efficient optical absorption or emission. Silicon is an indirect bandgap semiconductor which, in its crystalline form, has only a few optical applications. The specific optical properties of III–V semiconductors are given by their band-structure characteristics. The wavelength of luminescence (e.g., the color of the LED) is determined by the width of the forbidden gap between the valence and conduction bands. The efficiency of such devices is strongly related to the effective mass or density of states for the carriers in each band.

Because of the above-mentioned optoelectronic properties, the most prominent compound semiconductors are gallium arsenide (GaAs), gallium phosphide (GaP), gallium nitride (GaN), indium arsenide (InAs), and indium phosphide (InP) [50a, 50b]. Heterostructures of alternating thin layers of the above compounds are made in order to tune their optoelectronic properties [50b].

Most semiconductor surfaces used for research are made from high-quality single crystals which are produced by Czochralski or Bridgman techniques. In the case of III–V semiconductors, two surface orientations are of utmost importance. First is the (110) surface, which is the natural cleavage plane. Cleaving a III–V semiconductor along this plane results in surfaces with the highest grade of perfection. For more details, for example, surface relaxation, we refer to [50, 51]. Second is the (001) surface, which is the technologically used plane for etching processes in the electrooptical industry [35–37].

The crystals are typically doped (naturally or artificially) with carrier concentrations of 10^{-15}–10^{-18}/cm^3 in order to make them useful for technical applications. The influence of the carrier concentration on the binding of organic self-assembling monolayers is weak, and thus will be ignored in this review.

2.2. Sample Preparation and Self-Assembly

2.2.1. Sample Preparation and Self-Assembly from Solutions

The alkanethiols (most typically hexadecanethiol or dodecanethiol 95–99.5%) were dissolved in isooctane, ethanol (absolute), or hexadecane. The typical concentrations were in the range of 10^{-3}–10^{-5} M. More polar species (e.g., mercaptobenzothiazole, MBT; see Section 4) were dissolved in an aqueous solution with 5% ethanol. After immersion times of 24–36 h, the samples were rinsed with fresh solvent, dried under a nitrogen stream, and inserted into, for example, the spectrometer immediately. As substrates, either prenotched bars of Czochralski-grown and crystallographically oriented single crystals were used or, for the purpose of comparison, gold films were prepared using a Knudsen cell in UHV (base pressure: 2×10^{-10} mbar), evaporating gold (Goodfellow, 99.999 + %) onto a freshly cleaved slice of muscovite mica. The mechanism behind the self-assembly process on gold was first published by Poirer and Pylant [52]. The corresponding mechanism from dilute solutions on semiconductors will be investigated in Section 3.1, and for vapor deposition in the following paragraph.

2.2.2. Sample Preparation and Self-Assembly in UHV

The alkanethiol (e.g., dodecanethiol Aldrich, 98%) was let into the preparation chamber by means of a sapphire-sealed leak valve (Vacuum Generators VG, U.K.), which is inert to sulphur-containing species. In order to minimize the content of dissolved oxygen in the alkanethiol, the liquid was degassed by several repeated pumping, purging (with N_2, 99.999%, Messer Griesheim, Germany), and freezing cycles, before passing the leak valve. The valve and its surrounding should be slightly heated (35–45 °C) to prevent condensation and physisorption of the alkanethiol molecules on the inner sealing surfaces of the leak valve [53]. Besides spectroscopic techniques, a scanning tunneling microscope (STM) was used to investigate the adsorbed systems in UHV. Because of the active properties of the freshly cleaved InP(110) surface, all experiments (at least with submonolayer coverage) had to take place in UHV. Therefore, the STM head, which was constructed on a CF-100 flange, had to be mounted inside a UHV chamber. The base pressure in the recipient was $2 * 10^{-10}$ mbar using a combination of a turbo molecular and a rotary pump. For the sake of low vibration, this combination could be shut down. In this case, we used a liquid-nitrogen-cooled Titan sublimation pump and an ion getter pump instead. These were able to maintain good vacuum conditions without generating vibrations. When the TSP was cooled with liquid nitrogen, the pressure went down to $5 * 10^{-11}$mbar. The tungsten tips were self-made with the help of a two-step procedure (see [22, 54–58]). Because of additional control of the current direction of the last applied sine wave, the tips are also free from covering oxide layers. Following this procedure, the tips were rinsed with tridest H_2O, and were directly inserted into the vacuum chamber. A self-constructed system allowed not only changing the samples, but also changing up to seven tips at one time, without breaking the vacuum. The supporting X-ray photoelectron diffraction (XPD) and X-ray photoelectron spectroscopy (XPS) measurements were made with an Escalab 220 iXL (Vacuum Generators VG, U.K.) spectrometer, equipped with a monochromatized Al Kα source and a computer-controlled microstage.

The comparative SXPS spectra were recorded at the BESSY synchrotron storage ring in Berlin at the undulator beamline TGM-5, using a VG Baby-Aries spectrometer.

As an example for consecutive adsorption of thiols in UHV, the coverage and order of dodecanethiolate molecules on InP(110) surfaces was investigated by Zerulla et al. [53] and on gold by Widrig et al. [59] and Poirer et al. [60]. In the following paragraph, the coverage and structure of the adsorbed molecules are controlled by spectroscopic means and STM investigations depending on the dodecanethiol dose. Starting from the clean, cleaved semiconductor surface, the STM images show the different states of order in the self-assembling films with molecular/atomic resolution.

Additionally, STS was applied, in order to distinguish covered and uncovered regions with high lateral resolution. Further proof is given by (S)XPS and XPD spectra, obtained from measurements at the synchrotron storage ring BESSY and high-resolution laboratory sources, at all consecutive stages of adsorption. The first straightforward step in the investigation of vacuum-deposited alkanethiols on III–V semiconductors was to monitor the clean, freshly cleaved (UHV conditions) semiconductor surface itself via STM. Depending on the polarity of the tip with respect to the substrate surface, the STM image shows either the positions of the indium or the phosphorus atoms [61–63]. The surface was recorded with a positive tip, therefore showing the filled "dangling bonds" of the phosphorus atoms. The distances of the atoms were analyzed in the [001] and [1–10] directions of the surface. These measured distances of 590 and 420 pm are close to the ideal distances of 587 and 415 pm, respectively, which can be taken from [35–37, 64]. The difference between ideal and measured distances are well in the limit of the temperature-dependent reproducibility of the STM piezocrystals, which were calibrated before with the help of a highly ordered pyrolytic graphite (HOPG) surface. It should be mentioned that surface-relaxation effects have an influence on the height offset of the topmost phosphorus atoms with respect to the indium atoms (I–P), but no effect on the P–P distances within the first layer [35–37, 65].

Further STM investigations on a larger scale show only minor distortions of the surface in the form of small steps (typical height 1–6 atoms). Typically, the surfaces are free from defects for lateral dimensions as large as 1 mm^2. For the typical lateral scale of atomic-resolved STM graphs, this, in fact, allows for the investigation of adsorbates on regions without any substrate defects.

STS measurements of various positions on such freshly cleaved InP(110) surfaces lead to a composite I/U spectrum. The shown spectrum is a result of 256 independent recorded spectra, which have been added to suppress random noise. The main characteristic feature of these spectra is the very good visible bandgap, which is about 1.3 eV at room temperature in the case of InP [53]. In our experiments, the line shape of the spectra was independent of the exact lateral position of the STM tip; therefore, it still represents a more macroscopic feature of the semiconductor, and not an atomic behavior—even if the lateral resolution in the normal image mode achieved atomic resolution. Surface-sensitive (S)XPS studies of these cleaved surfaces, which are proof of their cleanness, are presented in [53, 64–67].

After the characterization of the clean InP(110) surface, a systematic, consecutive, dose-dependent treatment with dodecanethiol molecules was applied to the semiconductor surface. First, a dose of 1 Langmuir dodecanethiol was applied. The result of this treatment was the complete loss of resolution in the STM graphs. The reason for this behavior is probably that dodecanethiol molecules are bounded via the sulphur atoms to the indium atoms [66, 67]. The alkyl chains, on the other hand, only adhere loosely to the surface. Because of the sparse density of the molecules at 1 Langmuir (sticking coefficient <1), sufficient space remains between the molecules. When the STM tip scans across such a molecule, the alkyl chain is moved by the tip. Therefore, a clear STM image could not be obtained.

Nevertheless, the adsorbed molecules can be traced with the help of XP spectroscopy. The spectra show the expected C1*s*/S2*p* intensity ratio of 12:1 (corrected with the respective sensitivity factors and the spectrometer transmission function) for dodecanethiol, while the total signal strength (e.g., C1*s*) of the adsorbed molecules is far below the well-known intensity expected for a typical monolayer (see [32]).

The measured relative and absolute intensities are proof for nonoverlapping molecules with a sparse density at the surface.

This behavior changes if a larger dose of dodecanethiol is applied. It is possible at 100 Langmuir to get a good resolved graph again. The situation is displayed in Figure 1. It shows a dense monolayer of "lying" dodecanethiol molecules. Note that the chains are not randomly distributed, but mostly pointing into a crystallographic main axis (to prevent disturbances by the scanning tip, and therefore misinterpretations, the main axis of the InP crystal was not chosen parallel to the image boundaries, but turned 15° counterclockwise).

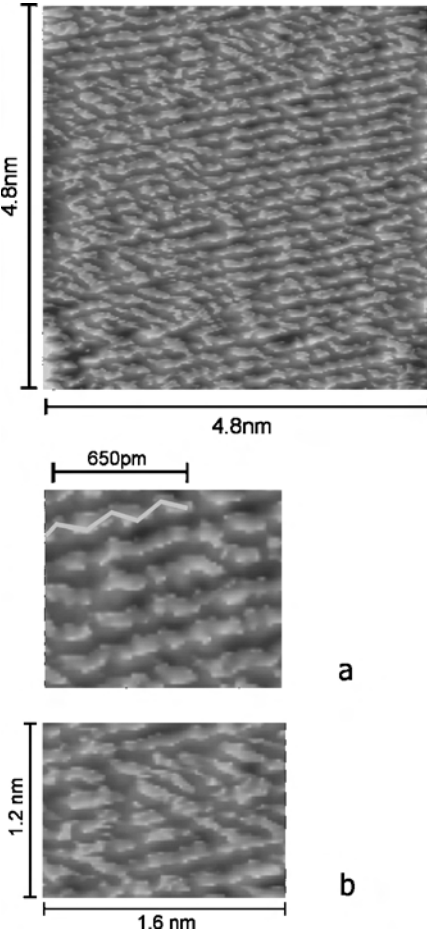

Figure 1. STM picture at 100 Langmuir dodecanethiol ($U_T = 2.4$ V; $I_T = 500$ pA). (a) STM-picture at 100 Langmuir dodecanethiol (enlarged). The all-trans conformation of a single molecule has been graphically emphasized. (b) STM picture at 100 Langmuir dodecanethiol (enlarged). The picture shows a region where some chains are misaligned. Reprinted with permission from [53], D. Zerulla and T. Chassé, *Langmuir* 18, 5392 (2002). © 2002, American Chemical Society.

Figure 1a (enlarged part of Fig. 1) shows the structure of the alkyl chains (all-trans conformation), which can also be resolved in some regions. While most of the chains are pointing into the [001] direction of the substrate, upon closer inspection, it can be seen that some chains point partially into other directions (see Fig. 1b). This can easily be explained by the following fact: because of the σ bondings between the carbon atoms in the alkyl chains, turning of molecular parts around these bonding axes is permitted. While the all-trans conformation is the energetically lowest form, other conformations will occur at room temperature, whose total energies are only slightly higher. Once lying on the surface at high densities, these conformations are also stabilized by the neighboring molecules within the dense package. To confirm the above thesis, it is necessary to investigate all possible geometrical variations which might occur on the surface. Assuming that the orientation of all of the In–S bondings between the substrate and the thiol molecules point into the [001] direction of the substrate due to the InP(110) surface (we will discuss this later), the number of alternate conformations projected onto the surface is limited, at least if the permitted values of the C–C angles are low in number, because of the state of adsorption at the surface. This means that, besides the pure all-trans conformation which is shown in Figure 1a, it should be possible to find a limited number of molecules in slightly differing conformations (e.g., only one turn around one bonding axis, leading to a change in one angle in the carbon backbone in contrast to an all-trans conformation), and therefore a differing orientation of their main axis after the deviating bond. This case is shown in Figure 1b. Further geometric analysis of the STM graphs reveals that the measured bonding angles between the carbon atoms in all-trans conformation molecules are larger then 110° (about 130–140°). First, this is a result of the slightly changed conformation of the molecules, while being physisorbed at the surface. The necessary structure to reach a minimum of total energy for a physisorbed alkyl chain (carbon in sp^3 hybridization) does not have a perfect planar carbon backbone parallel to the semiconductor surface. Second, the STM imaging mode projects this three-dimensional molecule into the two-dimensional space, resulting in images of molecules which seem to deviate from the octahedrally bonded situation.

A further proof that the STM graph displays "lying" molecules is given by angular-resolved XPS measurements. Here, the ratio between the C1*s* and the S2*p* peak intensity does not change while varying the take-off angle. Besides, the pure C1*s* and S2*p* peak intensities at normal take-off angle do not allow for models other than "lying" molecules, especially if models of a higher thickness than a "lying" monolayer can be excluded due to the substrate (e.g., P2*p* or In4*d*) to adsorbate intensity ratio, for example, C1*s* (see adsorption step 3 in Figs. 4 and 5).

If the sulphur atoms were covered significantly by the alkyl chains, the (corrected) intensity ratio (C1*s*/S2*p*) would have to be higher than the measured ratio (12.2), which still displays approximately the stoichiometric ratio.

Increasing the dodecanethiol dose to 1000 Langmuir leads to the conditions shown in Figure 2. Inspection of this STM image reveals two different kinds of regions: the higher ones (brighter gray scales), which we interpret to consist

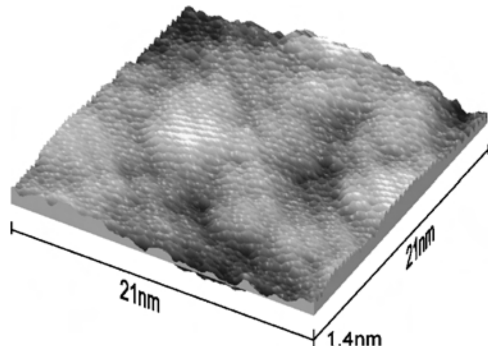

Figure 2. STM picture at 1000 Langmuir dodecanethiol ($U_T = 3.8$ V; $I_T = 250$ pA). Reprinted with permission from [53], D. Zerulla and T. Chassé, *Langmuir* 18, 5392 (2002). © 2002, American Chemical Society.

of "standing" molecules, and the lower ones (darker gray scales), which are still formed by "lying" molecules, as can be seen at lower doses. Note that the STM graph still shows molecular resolution simultaneously in both kinds of regions at room temperature.

To ensure that both the "standing" and the "lying" regions do indeed consist of alkyl chains, both regions have been investigated via STS. The spectra are shown in comparison with an SXPS spectrum (excited at 55 eV with synchrotron radiation), recorded from surface-bonded alkyl chains, prepared from dilute solutions of dodecanethiol (Fig. 3) [32, 66, 68]. Despite the differences in excitation, the energetic positions of the peaks are identical. Both regions can therefore be assumed to be covered with dodecanethiols. The following arguments can be found to support the interpretation.

- From the STS–SXPS comparison, one can conclude that the whole surface is covered by dodecanethiol.
- The average height offset of the bright and dark regions of approximately 1.0–1.4 nm (taken from STM measurements) fits into the model of lying minus standing regions—taking the length of one dodecanethiol molecule (1.84 nm) and the expected angle from the surface normal of 34° into account [66, 67].

- In the following, we will present additional information, derived from detailed XPS studies of the substrate (In3d, P2p) and the adsorbate (C1s, S2p), respectively.

In order to obtain additional reliable information on the surface coverage, we performed highly resolved XPS measurements for all peaks of interest at all stages of adsorption. As an example, we provide the detailed XP spectra for step 3 (1 kLangmuir dose) in Figure 4. The intensity information was extracted from these spectra by calculating the true peak area from an elaborate fitting procedure which uses an iterative background subtraction combined with convoluted Voigt profiles in a multipeak algorithm. The corresponding residuals are also given in each graph. The extracted intensities for all stages of adsorption are given in Figure 5. Note that the data are normalized individually. That is, for example, the ratio between carbon and sulphur is always greater than 12. In Figure 5, the highest point (at step 4) of this ratio is normalized to 1 in order to display all graphs in the same diagram. This allows a detailed comparison between the individual intensities. A measure of the reliability of this method is given by the substrate intensities (In3d, P2p). In principle, both intensities should be identical in pairs at all points. In comparison to the magnitude of changes of the adsorbate intensities, this is true. Now, we focus on the carbon/sulphur ratio. In first-order approximation, the intensity of both elements should rise while more molecules are being adsorbed on the surface. The difference between both intensities in the course of adsorption is due the fact that

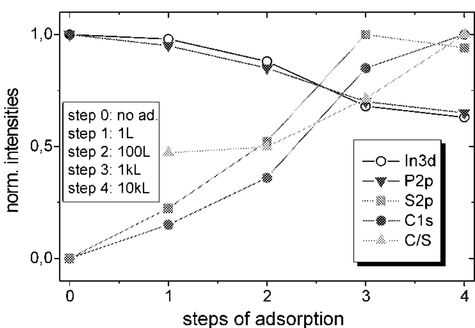

Figure 5. Comparison of the XPS intensities of adsorbate and substrate peaks and the carbon-to-sulphur ratio, derived from background-corrected peak areas at the different adsorption steps. the carbon–alkyl chains are covering the binding sulphur atoms in a standing film, and therefore weaken the XPS intensity of the sulphur signal. This means that the higher the C/S ratio, the more "standing" is the ordered monolayer. Returning to the adsorption step at 1 kLangmuir this means that this film already shows a high degree of standing molecules, but compared to the last step (doses >10 kLangmuir), one finds that the degree of order is not at its maximum. This is exactly how we interpreted the STM graph before. The film is partially well ordered (standing), but has also some regions which have a lower density of adsorbed molecules (lying).

Well-ordered self-assembling monolayers, which can be compared to systems prepared from dilute solutions, are also found. The required minimum dose for a quasifaultless monolayer is between 5000 and 10,000 Langmuir dodecanethiol. An example for such a system is shown in Figure 6. The SAM is prepared at 10,000 Langmuir dodecanethiol on a freshly UHV-cleaved InP(110) surface. The array of "standing" molecules appears faultless, although, on closer inspection, a small deviation in brightness (=height) is detectable. This effect might arise from some residual stress in the SAM, which itself comes from the exceptional three-dimensional tight packing of the alkanethiol molecules

in the well-ordered "van der Waals stabilized" layer (see Section 3.3 and [66, 67]).

Note that neither the gray scale nor the *z*-axis scale of Figure 6 is equivalent to that of Figure 2, but is adjusted for more sensitivity in height display. Figure 7 shows an enlarged section of the former STM graph. Even on this scale, the monolayer appears well ordered. A small distortion of the graph can be found by comparing the resolution in the *X* and *Y* directions. This distortion could be caused by two points. First, the shape of the STM tip could be slightly asymmetric. Second, the tilted structure of the self-assembled monolayer in combination with the impact of the tip into the layer (Fig. 8) could cause such an effect. Because of some further tests with this tip and the knowledge of the inner structure of the monolayer [66, 67], we tend to interpret the distortion to be due to the "tilted" structure of the adsorbate, and not caused by imperfections in the shape of the tip.

The STM analysis of the adsorbate system is completed by a determination of the molecular spacing. For this purpose, not only was an exemplary determination on a "good fitting location" in real space made, but so was a complete two-dimensional fast Fourier transformation (FFT) [53]. The transformation allows us to judge the distances of all investigated molecules simultaneously, and to detect superlattices and repeating distortions in one image. Repeating structures in time (and therefore, due to the scanning, in space) are displayed as bright "spots" (accumulation points). The most prominent spots belong to the rectangular reciprocal surface unit cell of the underlying InP lattice, and are highlighted via white lines for better visibility. As far we can judge from numerous STM graphs, the adsorbed monolayer appears faultless and well ordered. But how can we be sure that the system under investigation is a unique, distortion-free monolayer system on larger scales? From STM measurements alone, it is practically impossible to obtain positive proof of the single-domain structure. If the area under investigation (STM) is successively made larger, there will be a certain point where the necessary molecular resolution will be lost. This is especially true if superlattices, and therefore domain boundaries, are missing, which has to be expected for single-domain structures. Proving the single-domain structure investigations on a macroscopic scale is necessary. For this, we refer to Section 3.3, where two different spectroscopic approaches have been chosen which are able to analyze structural aspects on macroscopic scales [66, 67].

Summarizing the recent results for UHV deposition, four main phases of adsorption on InP(110) were found. First, at doses < 10 Langmuir, the surface is only sparsely covered, still permitting the alkyl chains to move "sideways" on the surface; therefore, no stable STM image was presented. Second, approximately at 10 Langmuir, a dense layer consisting of lying molecules is formed. The contact between the alkyl chains is stabilizing enough to give good resolution, even at room temperature. Third, at doses of 1 kLangmuir, parts of the monolayer start to stand up. This is done neither statistically nor individually, but in well-defined domains, while other regions are still flat on the surface. A comparison between the height of the standing and the lying molecules in the same graph permits us to deduce this difference precisely. From that, we can learn how deep the tip penetrates the organic layer.

From other papers concerned with the behavior of tip–surface interactions on organic films, it is well known that the tip might intrude into the organic layer while scanning [22, 56, 69]. This behavior is also to be expected for the STM parameters used here in connection with the insulating properties of the adsorbate system under investigation (See Section 2). Further proof is given by the height information of the different regions in Figure 2. The average height difference of the "standing" and the "lying" regimes is about 0.8 nm. Note that the given *z* axis in the graph denotes the maximum distance between the highest and lowest point; therefore, the average distance between neighboring regions is significantly lower. If the tip did not intrude into the layer, this distance would be about 1.5 nm (the height of a 34° tilted dodecanethiol monolayer) minus the height of a lying molecule, which should be near 0.2 nm. The result of 1.3 nm is significantly higher than the measured value of 0.8 nm; therefore, the tip intrudes about 0.5 nm into the layer, as is depicted in Figure 8.

In the last stage (dose $>$10 kLangmuir), a macroscopic "single-domain" monolayer covers the semiconductor, which is virtually free from defects. All molecules have the well-defined tilt angle in the [001] direction of the InP (110) surface (see Section 3.3). The chain–chain distances, and therefore the tilt angle, reflect the lattice properties of the underlying semiconductor, which were additionally proved by an FFT analysis of the STM image and locally resolved tunneling spectra.

3. THIOL MONOLAYERS ON III–V SEMICONDUCTOR SURFACES

Thiols on III–V semiconductors are by far the most promising combination, as we will show in the following paragraphs of this section. Their ease of preparation is similar to thiols on gold (with some exceptions; see Section 2), and they form dense and therefore passivating (see Section 3.2) and highly ordered (see Section 3.3) monolayers which can be structured with the methods introduced in Section 3. But first, we will discuss the self-assembly and its speed, depending on the method of sample preparation, in the next paragraph.

3.1. Speed of Self-Assembly

While the adsorption under vacuum conditions is primarily a function of the differential pressure of the molecule species [53, 70], the adsorption from dilute solutions is easily traceable in the time domain [71]. Confining our systems to alkanethiols with lengths between 6 and 20 carbon atoms, the adsorption and self-assembling speeds are very similar. The methods to probe the degree of order or state of assembly can include in-line techniques which can be used without interrupting the self-assembling. This has been done by Grunze and Wöll, using second-harmonic generation (SHG) and sum-frequency generation (SFG) on the adsorption of thiols on gold [72].

The other class of experiments, that is, all surface-science techniques working under UHV conditions, needs an interruption of the assembling process. For gold and silver as substrates, this is not critical because they do not react with the atmospheric oxygen, but for semiconductors, this is not easily done. One method is to prepare as many samples as planned measurements, and to use each sample only one time. Despite the great efforts which are connected with this method, we chose to use it because it opened up the full choice of surface-science techniques [53, 64]. In the following, we present a time-dependent XPS analyzed study on the speed of self-assembly. Our concrete system is 1 mmol concentrated HDT in isooctane on InP (110).

The XPS intensities are presented in Figure 9. In the beginning, all signals, except the substrate-related signals, increase quickly until the alkyl chains start to cover the binding sulphur atoms of the thiol groups. This is the point

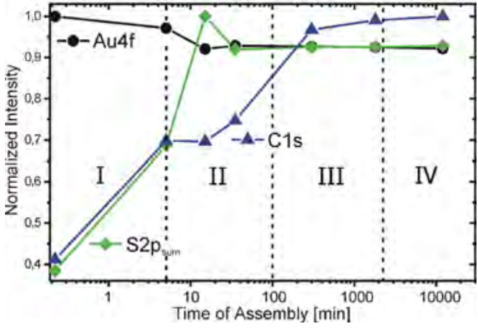

Figure 9. The self-assembling process is monitored via time-dependent XPS spectroscopy of the important substrate and adsorbate elements. Adsorbate: HDT in isooctane [64].

where the ordering starts. After 24–36 h, the system does not change anymore. In order to be on the safe side, we chose assembly times >36 h for our experiments on well-ordered SAMs.

3.2. Passivating Properties

III–V semiconductors are not immune to oxygen. A freshly cleaved (110) surface, and of course other surfaces as well, would oxidize within fractions of a microsecond if not protected against atmosphere. Furthermore, if chemical etching is needed in the production of, for example, nanostructured devices (see Section 4), the monolayer should be able to resist the etching on the time scale of minutes. In the following, we will discuss the passivating properties of self-assembling monolayers on the example of alkanethiols on InP(110). First, we briefly note the preparation procedure which is necessary to make a monolayer free of defects (for more details regarding the preparation, we refer to Section 2). If the self-assembling takes place in a dilute solution, it is necessary to purge the solution first with nitrogen (or Ar) for about 20 min. Otherwise, the residual oxygen in the organic solvent immediately reacts with the substrate surface [32, 64]. But, if the prenotched crystal bars are cleaved in a degassed solvent, which contains μmol · mmol concentrated thiols, oxygen is absent, even in an extremely surface-sensitive SXPS measurement [32, 64]. In order to test the passivating properties of samples with fully assembled monolayers, we exposed the samples to atmosphere and humidity on time scales of hours, days, and even months.

While no changes of the samples were spectroscopically detectable within days, as judged from the SXPS sensitivity scale, on the time scale of a month, slight changes were detectable [64]. But even this slight change proved that at least 90% of the samples were not affected. These results show that readily assembled monolayers can be handled without further precautions in technological processes.

Then, we exposed similar samples to electrochemistry [64, 73]. At the start, a potential which was suitable for etching of the semiconductor was applied and changed to cyclic, while in parallel the current voltage (*CV*) ratio and the capacity were recorded. The results showed that the monolayer protects the semiconductor surface effectively [64, 73]. After some minutes, the monolayer showed the first degradation, but from the current density, it was clear that this is only a minor effect, starting at the edges and at imperfections (e.g., cleavage steps) of the substrate (for more details, refer to [64, 73]).

Summarizing the results, alkanethiol monolayers (for length >6) protect III–V semiconductor (110) surfaces well enough to be used as masks, especially if nanostructured (see Section 4).

3.3. Structure via Spectroscopy

In this section, we will analyze the complete three-dimensional structure of the adsorbate–substrate system from a multitude of spectroscopic approaches. First, we describe investigations of the X-ray absorption near-edge structure (XANES) of adsorbed hexadecanethiol monolayers on InP (110).

We will demonstrate that the self-assembly on III–V semiconductor surfaces results in a unique arrangement of the alkyl chains with a rather well-defined polar angle of the chains with respect to the surface normal. However, on the metal single-crystal surfaces investigated so far, the molecular orientation in the azimuthal direction is not uniform. This is because the surface symmetry permits the formation of several domains of differing azimuthal molecular orientation. Here, we report on self-assembled monolayers, which possess a very high degree of molecular order in both the polar and azimuthal orientation of the organic molecules with respect to the substrate. This unique feature has been observed during investigations of III–V (110) surfaces, which were performed in order to explore the self-assembling properties of compound semiconductor surfaces. These conclusions have been derived from the X-ray absorption near-edge structure XANES measurements taken at the carbon K edge (CK XANES), which have been carried out to determine the main structural features of the alkyl chains on InP (110). First, core-level photoemission XPS studies were performed in order to characterize the adsorbed organic layers of interest, which were prepared by adsorption from millimolar solutions of thiols in isooctane for durations of 24–36 h, according to Section 4.4. InP (110) faces were prepared by cleavage of prenotched bars in solution (see Section 4.4). As we will discuss in more detail in Section 4, essentially only one sulfur species is present on the freshly prepared SAMs in XPS and SXPS experiments. Also, taking into account the complete absence of oxygen-related features, even after contact with the atmosphere, we conclude that alkanethiols form stable and contamination-free monolayers on InP (110). Examples of other investigations on similar semiconductor surfaces can be found in [24, 25]. The XANES measurements in a partial electron yield mode on SAMs of adsorbed alkanethiols on InP 110 were carried out at the beamlines HE-TGM2 and PM5 of the BESSY I storage ring in Berlin. Figure 10 displays angular-resolved CK XANES of a monolayer, prepared by adsorption of hexadecanethiol (HDT). The absorption spectra were recorded at several incidence directions of the soft X-ray photons with respect to the surface normal polar angle (−60 to 80°). Here, the polarization vector of the linearly polarized synchrotron radiation was fixed in the azimuthal orientation to allow only variation parallel to the (110) plane. The spectra exhibit two main absorption peaks. The peak at the higher photon energy is attributed to σ^* C–C related resonance. The strong feature at the lower photon energies near the edge is mainly due to the σ^* C–H orbital [66, 67]. However, the well-resolved splitting that occurs at certain angles suggests a more complicated origin of this feature, which will not be discussed here. Notice the very good matching of the background for all of the spectra at both the lowest and highest photon energies. This is evidence for the reliability of the spectra following the flux-normalization procedure. The spectra show significant angular-dependent changes. In particular, the intensities of these features do not proceed in parallel, but they show pronounced maxima at quite different incidence angles, exhibiting nearly an inverse behavior. However, we will start focusing on the angular dependence of σ^* C–C related absorption, which contains information on the spatial orientation of the carbon backbone of the adsorbed molecules. Therefore, a peak shape analysis has been performed after subtracting an arctan-like step function which emulates the CK edge. In our special case, the exact position and width of this edge are not critical to the fit. The data in Figure 11 display the evolution of the absorption of the σ^* C–C resonance of the CK XANES of HDT (Fig. 10) in dependence on the photon incidence direction as characterized by the polar and azimuth angles. The data have been derived from σ^* C–C intensities obtained from the fits, following flux normalization of the recorded absorption spectra.

The solid line represents a fit curve to the experimental absorption values which will be explained later. The graph shown in Figure 11 reveals a clear minimum, as well as a maximum separated by about 90°. From the angular

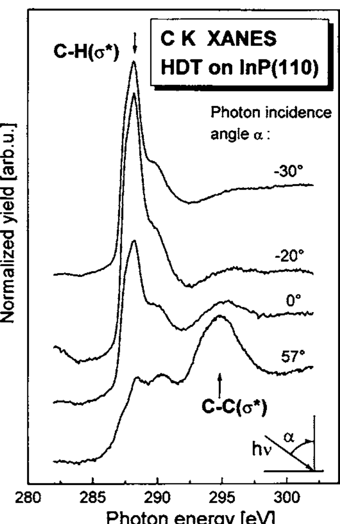

Figure 11. Plot of the absorption strength of the C–C(σ^*) resonances of HDT monolayers on InP and GaP in dependence on the polar angle. Normalization was performed as described in the text, and the maxima were set to 1. Error bars given for 0 and 80°. Reprinted with permission from [67], T. Chassé et al., *Surf. Rev. Lett.* 6, 1179 (1999). © 1999, World Scientific Publishing.

position of these extrema, the tilt angle can be determined to be about 34° from normal. Furthermore, we suggest from the nearly vanishing absorption in the minimum and high absorption in the maximum that a high degree of order has to be present in the layer. Note that the degree of linear polarization of the synchrotron beam itself is near 85%, and therefore not permitting, for example, the complete vanishing of the adsorption in the minimum, even if the order in the layer is perfect. In order to shed light on the azimuthal orientation of the chains, additional intensity data were obtained from a set of measurements taken at normal incidence (polar angle 0°), but varying azimuth angles of the sample 0–360° by rotating the sample with respect to its surface normal. The normalized intensities shown in Figure 12 in this manner also represent different orientations of the polarization vector with respect to the crystallographic directions in the surface plane. The graph clearly shows two striking absorption maxima at azimuth angles close to about 0 and 180°, and low absorption for polarization vector orientations far off these preferred angular directions. This very pronounced preference for strong X-ray absorption at polarization vector orientations about parallel to the (110) plane of InP (110) is rather exceptional. Although the graph of the experimental data is not exactly symmetric, this result provides strong evidence for a preferred tilt of the alkyl chains from normal toward the [001] direction. Because of the high anisotropy of this plot and the number of tested samples, we may essentially rule out averaging effects due to the possible existence of several domains possessing different tilt directions. This is important for the quantitative evaluation of the tilt angle because the data will only reveal the correct tilt angle if the azimuth polarization vector is chosen to correspond to a maximum in Figure 12, as has been done by recording the data displayed in Figure 11. In fact, the solid line in Figure 11 results from a fit to the experimental data following a $\cos^2$ function in dependence on the angle, as suggested by the matrix elements. This fit function has been slightly modified by a low-order polynomial in order to

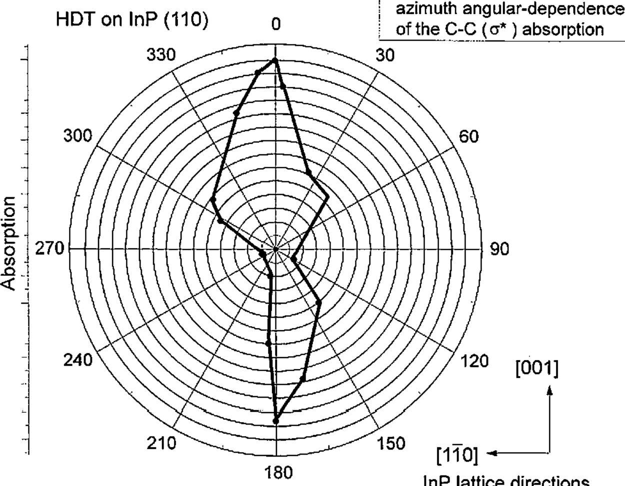

Figure 12. Plot of the changing absorption strength of the σ^* C–C resonance by varying the azimuthal angle while maintaining the polar angle at 0°. Reprinted with permission from [66], D. Zerulla and T. Chassé, *Chem Phys. Lett.* 311, 8 (1999). © 1999, Elsevier Science.

take into account an intensity decrease at highest incidence angles due to limited sample size. From the positions of the maximum and minimum in Figure 11, we can thus directly derive the tilt angle of the alkyl chains to be 34°+/−3°. The error has been estimated by taking into account both the sensitivity to intensity changes near normal incidence (Fig. 11), as determined from the slope of the fit curve, and the difference of the strength of the two opposite absorption maxima in Figure 12. Note, however, that the uncertainty in the azimuth angle of about 10° is much larger, unfortunately.

Thus, we cannot rule out slight deviations from an exact alignment within the (110) plane on this scale. Nevertheless, the experimental data presented above have clearly demonstrated the well-defined orientation of the adsorbed monolayer, resulting in an exceptionally high order of the adsorbed monolayer. To the best of our knowledge, a similarly pronounced preference of molecular orientation and high molecular order of alkanethiols has not been observed before on any other surface so far, including metal surfaces.

This strikingly high perfection of orientation of the adsorbed alkanethiol layers has to be discussed in terms of both adsorbate–substrate bonding and surface structure of the substrate. First, a preferential bonding of sulphur atoms to the surface indium atoms has been observed in several photoemission studies of inorganic sulphur species on InP (110) and InP (001) surfaces [35–37]. In particular, the formation of In–SH and P–H surface bonds has been reported in the case of the dissociative adsorption of H_2S on InP(110) [33, 34]. Second, we have performed synchrotron light-excited SXPS studies with alkanethiols on InP (110). These very surface-sensitive measurements also support the thesis of S–In bonding [73].

The rectangular surface unit cell of this zinc-blende type of substrate is characterized by In–In/P–P spacings along the [001] and [1–10] surface directions of 587 and 415 pm, respectively. The surface indium and phosphorus atom In–P bond lengths, 254 pm, are linked to form In–P zigzag chains within the InP (110) surface plane, which extend along the [1–10] direction. Thus, following structural arguments regarding the space requirements of the alkyl chains and their well-known tendency to form dense structures, a tilt of the alkyl chains toward [001] is indeed much more likely than toward [1–10]. These simple arguments fit very well with our observations regarding the tilt direction, which are schematically summarized in Figure 13. Further, a dependence of the tilt angle on the lateral distance of the sulphur–substrate bonding sites on the surface, and thus on the substrate lattice constant, has to be expected. In fact, we have observed such a trend by investigating thiol adsorption on different semiconductor surfaces, and the results are presented in [67]. Besides this purely geometrical consideration, we have to be aware of the structural inequivalence of the two opposite [001] surface directions due to the asymmetry of the In–P all-trans chains, which exhibit an indium and a phosphorus side. This structural asymmetry is also known to be responsible for the opposite spatial orientations of the empty and filled dangling bond orbitals of the surface indium and phosphorus atoms, respectively. Hence, it is reasonable to suggest that the experimentally observed preference of just one orientation of the alkyl chain has to be attributed to the

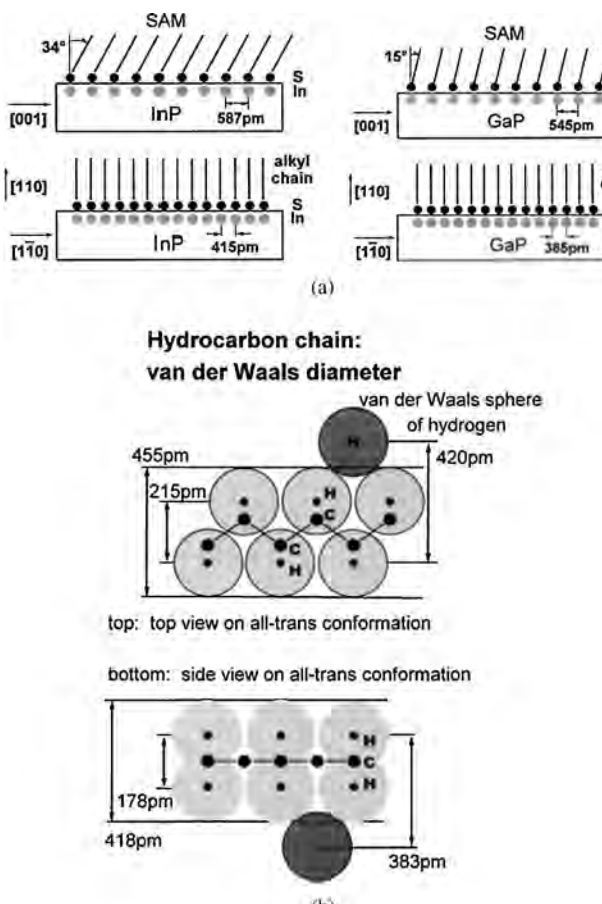

Figure 13. (a) Schematic structural model for the tilt orientation of the alkyl chains of HDT on InP(110) and GaP(110) (side views). Note that details of the local adsorption geometry are not reflected by this drawing. The surface indium and gallium atoms are included in order to emphasize the bonding to the sulphur atoms. The surface phosphorus atoms are not shown. (b) Schematic model of a hydrocarbon chain in an ideal all-trans conformation in combination with the hydrogen van der Waals radii. Space requirements due to the van der Waals interactions are provided by numbers. The reduction of these van der Waals dimensions by approaching an optimum registry is also indicated. orientation of these dangling bonds, most probably to the empty indium dangling bonds. Thus, structure as well as bonding constraints evidently force the adsorbed monolayer to adopt a uniquely well-defined structure, which allows us to propose the existence of single domains of the monolayer on InP (110), only limited by high-cleavage steps or other large defects of the cleaved substrate surface. Summarizing our results, we have observed the formation of a passivating, self-assembling organic monolayer on InP (110) by the adsorption of alkanethiols from the liquid phase. A tilt angle with respect to the sample normal of 34° and an azimuthal orientation parallel to the (110) plane of the InP lattice have been derived from the quantitative analysis of the XANES. The exceptionally well-defined orientation and high order within the adsorbed monolayer, as may be deduced from the strength and anisotropy of the X-ray absorption features, make this interface a candidate for a single-domain monolayer-adsorption system.

We will now extend the XANES measurements and discuss them in more detail. The structure of alkanethiol monolayers on III–V(110) surfaces was studied by analyzing the X-ray absorption near-edge structure (XANES) of the carbon K edge. Pronounced absorption maxima were observed for special orientations of the polarization vector of the radiation as revealed from angular-dependent measurements, suggesting a rather well-defined molecular axis of the alkyl chains. From quantitative evaluations of these angular dependences, the chains were found to be tilted from the normal toward the [001] direction of the (110) surfaces by 34 and 15° in the case of HDT adsorption on InP and GaP, respectively. The similarities as well as the differences in tilt angles between the substrates are discussed in terms of constraints imposed by the surface structure and lattice constants, as well as the space requirements of the van der Waals spheres of the adsorbed thiols. A unique feature observed on these monolayers is the nearly complete alignment of the alkyl chains with respect to the azimuthal orientation. We suggest that this adsorbate system represents the case of a single-domain orientation within the organic monolayer.

The spectra were recorded in a partial electron yield mode at a pressure of $5–8 * 10^{-10}$ mbar. The retard potential of the partial yield detector was typically set to 50 V. All spectra were normalized with respect to the incident photon flux and the independently recorded background curve, which represents influences due to carbon contaminations on the optical elements of the beamline. The intensity calibration was performed by normalizing to the intensity difference between the spectrum background below the edge and at the highest energies, well above the resonances of interest. The orientation of the polarization vector of the soft X-rays was varied systematically by changing the incidence angle of the radiation with respect to the crystallographic orientations of the substrates in order to take advantage of the polarization dependence of the dipole matrix elements, which govern the absorption process.

Recent photoemission studies of the adsorption of alkanethiols (chain lengths $n = 10–18$) on InP(110) have demonstrated that alkanethiols form stable and contamination-free monolayers on this semiconductor surface [32]. This conclusion has been drawn from the complete absence of oxygen-related features in the spectra, even after contact with atmosphere, and the existence of essentially only one distinct sulphur species in freshly prepared thiol layers, which has been attributed to In–S bonds at the interface [32–37, 53, 66, 67]. Note that, from the chemical point of view, based on the experience outlined above as well as from the steric limitations due to the large space requirements of the alkyl chains, which will be discussed below, P–S bonds have been excluded via SXPS measurements, and will not be considered here [64]. In order to derive information on the intramolecular bonding, and most importantly on the structure of the adsorbed monolayer, we have investigated the X-ray absorption near-edge structure of the carbon K edge from alkanethiol SAMs on the cleavage faces of the III–V semiconductors InP and GaP.

Absorption spectra were recorded from SAMs of hexanethiol (HT) up to hexadecanethiol. Most complete datasets were gathered for the longer alkanethiols, which are well known to establish highly ordered SAM domains on metallic substrates like Au(111). In this paragraph, we will focus on the interpretation of these spectra, which were measured on the cleavage faces of InP and GaP. Figure 10 displays a set of CK XANES of a monolayer prepared by adsorption of HDT on InP(110). The absorption spectra in the figure were recorded at several incidence directions of the soft X-ray photons with respect to the surface normal, while keeping the azimuthal orientation of the polarization vector strictly parallel to the [001] surface direction. The spectra exhibit three absorption peaks. The broad peak at the highest photon energy, close to 295 eV, is attributed to the σ^* resonance, which is due to absorption by electron excitation from the C1*s* core level into the antibonding orbitals of the C–C bonds (hereafter called C–C(σ^*) resonance). The sharp peak at the photon energy of about 289 eV, close to the CK edge, mainly corresponds to the C–H(σ^*) resonance [68]. The third peak feature, which may be observed at about 2 eV higher energy compared to the latter, is much smaller in intensity. This peak feature appears much stronger in the absorption spectra for the shorter thiols, suggesting an origin due to the C–S bonds at the end of the alkyl chains. We emphasize the very good matching of the background for all of the spectra at both the lowest and highest photon energies, which is evidence for the reliability of the flux normalization procedure. Both C–C(σ^*) and C–H(σ^*) resonances show significant angular-dependent changes, which are reflected by the evident peak shape changes between the spectra. In particular, the intensity of the C–C(σ^*) resonance decreases when going from positive toward negative polar angles with respect to the surface normal. Note that there is no symmetry of the intensities with respect to the surface normal. Similar spectra of HDT monolayers on GaP(110) are shown in Figure 14. The overall shape of the spectra and the evolution of the intensities exhibit the same general trends as described above for HDT on InP(110). A noteworthy exception to this evident similarity is the smaller energy difference between C–C and C–H related resonances in the case of HDT on GaP. This energy difference is reduced by 0.7 eV (+/−0.3 eV) compared to HDT on an InP substrate. However, this difference calls for further statistical analysis of the whole body of experimental spectra and accompanying theoretical considerations, which will not be provided here. The C–C(σ^*) resonances contain the information on the spatial orientation of the carbon backbones of the adsorbed alkanethiols, which are of particular interest for the structure of the SAM. According to the dipole matrix elements for X-ray absorption, the intensity of the CK absorption resonance will be highest if the *p* contribution to the spatial orientation of the particular molecular orbital is parallel to the polarization of the X-ray light [74, 75]. The significant dependence of the resonance intensities on the polar angle of the photon incidence, and thus also the orientation of the polarization vector, as exhibited by the CK resonances in Figures 10, 11, and 14, indicates a preferential orientation of the carbon bonds of the organic adsorbates on both InP and GaP(110). Quantitative evaluation of the polar and azimuthal angles

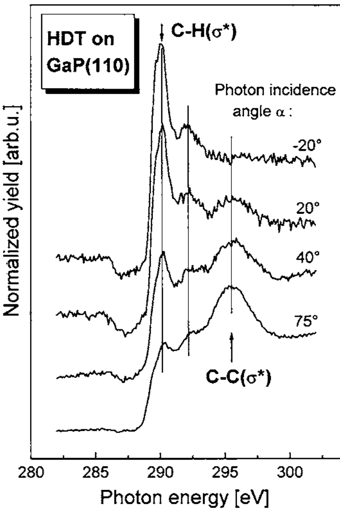

Figure 14. Normalized XANES absorption spectra of an adsorbed HDT monolayer adsorbed on GaP(110) at different polar angles. The retard potential of the partial yield detector was set to 50 V. to be associated with this preferential orientation cannot be derived from the data in Figure 11 alone without detailed knowledge of the corresponding azimuth dependences.

We have recently shown, for HDT monolayers on InP(110), that a very pronounced anisotropy of the C–C(σ^*) resonance can be observed by rotating the azimuthal orientation of the polarization vector around the surface normal at normal photon incidence [66, 67]. In brief, the observed azimuthal dependence of the C–C(σ^*) intensity was strongly peaked along the two opposite [001] surface directions. The intensity nearly vanished far off these surface directions, in particular along [1–10]. Hence, a predominant orientation of the alkyl chains of HDT toward [001] was predicted [53, 66, 67]. In this manner, the anisotropies exhibited in Figures 10, 11, and 14, which were obtained for the particular azimuth with the highest C–C(σ^*) intensity, directly reflect a highly preferred orientation of the C–C bonds with respect to the surface normal, that is, a tilt angle of the alkanethiol chain. A peak shape analysis of the CK spectra has been performed in order to obtain quantitative data. An arctan-like step function was used to emulate the CK edge. In the special case of the C–C (σ^*) resonance and determination of its intensity, the exact position and width of this edge are not critical to the fit because this high-energy peak is already situated well above the threshold. The data in Figure 11 display the evolution of the absorption of the C–C (σ^*) resonance of the CK XANES of HDT (Figs. 10, 14) as a function of the photon incidence direction in terms of the polar and azimuth angles. The experimental data represent the intensities derived from the analysis of the spectral shapes, following appropriate flux normalization of the recorded absorption spectra. Closed and open circles denote data obtained from InP(110) and GaP(110), respectively. The solid lines represent fit curves to the experimental absorption values for SAMs on these two surfaces. The applied model functions for the fits represent the angular

dependence by the term [$\cos^2(90° - (\alpha + \beta))$], essentially, including a single tilt angle $\beta > 0$ of the alkyl chains and the variable photon incidence angle α. The sign of the incidence angle α was arbitrarily chosen to obtain the maximum and minimum for $\alpha > 0$ and $\alpha < 0$, respectively.

The choice of this type of fit function is directly related to the polarization dependence of the absorption matrix elements and Fermi's golden rule [74]. We were able to neglect any effects due to azimuth orientation in the $\cos^2$ function because the experimental data to be analyzed were taken for the favored high-symmetry azimuth orientation, characterized by the polarization vector within the tilt plane, which is determined by the surface normal and the preferred [001] direction. The fit function has been slightly modified by a low-order polynomial in the case of the InP data in order to take into account an intensity decrease at highest incidence angles due to limited sample size. We further emphasize that no angular averaging was included in the fit functions (for example, regarding a range of tilt angles β or several distinct values for α), as might originate from differently oriented domains or from the absence of a preferential orientation. Nevertheless, the fit model matches the experimental data very well over the whole range of investigated incidence angles. We may conclude that a strongly preferred orientation of the alkyl chains exists with respect to the polar angle as well. The pronounced intensity maxima occurring only at certain azimuth and polar angles fix the observed preferential orientation in spherical coordinates by two independent angles, demonstrating the existence of a rather well-defined molecular axis of the hydrocarbon chain of the adsorbed thiol, which extends toward this direction. The data from InP show a clear minimum, as well as a maximum separated by about 90° (Fig. 11). From the angular positions of these extrema, the tilt angle β of this molecular axis of the HDT chain on InP(110) can be determined to be about 34°(+/−3°) from the surface normal toward [001]. In a completely analogous manner, we may determine a tilt angle of 15°(+/−3°) from the normal for HDT on GaP(110). We cannot draw any conclusion on preferred tilts toward the two opposite [001] directions, [001] or [00–1], from the XANES data alone. Although indistinguishable by LEED patterns, these two directions are not equivalent on III–V(110) surfaces because of the existence of the asymmetric In(Ga)P zigzag chains in the surface plane, which extend along [1–10]. This structural asymmetry is also known to be responsible for the opposite spatial orientations of the empty and filled dangling bond orbitals of the surface indium and phosphorus atoms, respectively. Hence, it is reasonable to suggest that the experimentally observed preference of just one orientation of the alkyl chain has to be attributed to the orientation of these dangling bonds, most probably to the empty indium dangling bonds. In fact, by combining analysis of the asymmetric features in the XPD patterns of InP with the XANES data, we have been able to identify the absolute tilt orientation as pointing from the indium side (sulphur-bonding site near indium due to In–S bonds) toward the phosphorus side of the same zigzag chain, as will be discussed in detail elsewhere [53, 64].

An independent check of the orientation of the hydrocarbon chain may be performed by analysis of the intensity evolution of the C–H (σ^*) resonances in the CK XANES. Figure 15 shows a comparison of the angular dependences of C–C (σ^*) and C–H (σ^*) resonances of HDT on InP(110), derived from the same set of spectra. The C–H (σ^*) resonance intensities were obtained by fitting Gaussians to the sharp low-energy peak only, after subtracting the arctan-like threshold function, characterized by a position at 289.5 eV and a full width at half maximum of 0.5 eV, and by excluding the contributions from the second, small resonance. Because of this fitting procedure, the C–H (σ^*) intensity is much more prone to error than the C–C (σ^*) resonance. Evidently, these intensities evolve roughly inversely. This result may also be confirmed for GaP by a glance at the spectra displayed in Figures 10 and 14 for InP and GaP, respectively.

An inverse behavior is in accordance with the above-mentioned proposal of a rather well-defined molecular axis. The individual bond angles C–C–H will be close to the tetrahedral angle due to the ideally adopted sp^3 hybridization of the carbon valence electrons. But in the case of an alkyl chain that extends along an axis, that is, in an ideal all-trans conformation, the C–H bond directions are expected to be 90° off the average C–C orientation, corresponding to the molecular axis. The slight deviation of the minimum/maximum positions of the two curves from a 90° difference may be related to some distortions of the chains. However, we have mentioned the much larger sources of errors for the C–H (σ^*) related resonance, and thus we cannot make any quantitative statements on the significance of this suggestion. Another argument for the presence of a high degree of molecular order in the HDT monolayer may be derived from the high anisotropy of the minimum/maximum intensity ratios of C–C (σ^*) angular dependencies. The absorption curves in Figure 11 were normalized by setting the maxima of the fit curves to 1.0 arbitrarily. Note that the degree of linear polarization of the synchrotron beam itself is near 85%. Therefore, complete vanishing of the absorption may not be expected, even if the order in the layer was perfect. Thus, we can also suggest, from the rather low values of absorption intensity in the minima of Figure 11, that a high degree of order regarding the orientation of the alkyl chain axis should be expected in the organic HDT layers on both investigated

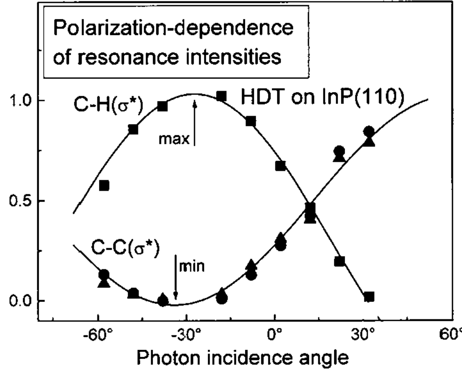

Figure 15. Comparison of the polar angle dependences of the intensities of C–C(σ^*) and C–H(σ^*) resonances for HDT on InP(110). Reprinted with permission from [67], T. Chassé et al., *Surf. Rev. Lett.* 6, 1179 (1999). © 1999, World Scientific Publishing.

substrates. Furthermore, we have performed simulations of the angular dependence in relation to simple models of the intramolecular structure, which are shown in Figure 16. The degree of polarization of the X-rays was assumed to be 100%, and the angular dependence was modeled by a bare $\cos^2$ function of the angle between the possible C–C bond orientations and the polarization vector of the radiation. An ideal all-trans conformation was adopted as a simplified model of a hydrocarbon. The highest absorption and the maximum anisotropy are obtained, as expressed by the minimum/maximum ratio (min = max = 0), for a hypothetical linear carbon atom chain. A tetrahedral C–C–C angle of 109.5° of a carbon zigzag chain within the plane of the variation of the polarization vector reduces and increases the absorption in the maximum and minimum, respectively, resulting in a dramatically reduced anisotropy (min = max = 0.5). The anisotropy would completely vanish (min = max = 1) in the other hypothetical case of a C–C–C angle of 90°, as shown in Figure 16. However, a minimum/maximum intensity ratio of 0.5 and larger would be in strong contrast to the much lower experimental values (min = max $<$ 0.2) which may be taken from Figure 11. Another idealized hypothetical model considers a rotation of the C–C zigzags by 90° with respect to the plane determined by the polarization vector and molecular axis. The total intensity of the maximum is reduced within this model, but interestingly, the anisotropy remains high (min / max = 0). While this behavior would fit the observed high anisotropy in the polar angle dependence, it would be in contrast to the azimuthal anisotropy. Therefore, we may rule out the extreme cases of high-symmetry orientations of all-trans conformations with respect to [001] or [1–10]. In contrast, twisted alkyl chains or, to a certain extent, even some random orientations of individual C–C bonds of the chains fit the experimental observations much better. This result does not at all contradict the generally observed extremely well-defined orientation of the molecular axis. So far, the experimental data and the analysis presented above have clearly demonstrated the well-defined orientation of the adsorbed alkanethiol monolayers (HDT), resulting in an exceptionally high order of the adsorbed monolayers. To our knowledge, a similarly pronounced preference of molecular orientation and high molecular order of alkanethiols has not been observed before on any other surface, including metal surfaces. This strikingly high perfection of orientation of the adsorbed alkanethiol layers has to be discussed in terms of both adsorbate–substrate bonding and surface structure of the substrate. Preferential bonding of sulphur atoms to the surface indium atoms has been observed in several photoemission studies of sulphur species on InP(110) and InP(001) surfaces [35–37], and surface-sensitive core and valence level photoemission measurement of several alkanethiols on III–V(110) also support the thesis of S–In(Ga) bonding [33–37]. Thus, structural constraints by the substrates will be imposed by the different In–In (Ga–Ga) distances in the surface, which provide the links to the adsorbed thiols. The III–V(110) surfaces of zincblende structure possess a rectangular surface unit mesh. The unit mesh dimensions correspond to 587 and 544 pm along the [001], and to 415 and 385 pm along the [1–10] surface directions of InP(110) and GaP(110), respectively. This reflects the 7.9% larger lattice constant of InP. The unit mesh dimensions also correspond to the In–In (Ga–Ga) distances in the surface plane. Following straightforward structural arguments regarding the space requirements of the alkyl chains and their well-known tendency to form dense structures, a tilt of the alkyl chains toward [001] is indeed much more likely than toward [1–10]. These simple arguments fit our observations regarding the tilt direction very well, and are summarized in Figure 13(a) schematically. Further, a dependence of the tilt angle on the lateral distance of the sulphur–substrate bonding sites on the surface, and thus on the substrate lattice constant, has to be expected. This effect is clearly reproduced in our experiments by the smaller tilt angle of 15° on GaP compared to 34° on InP. From these data, we may estimate a vertical distance between the average molecular axes of 487 pm (InP) and 525 pm (GaP), in reasonable agreement with qualitative expectations.

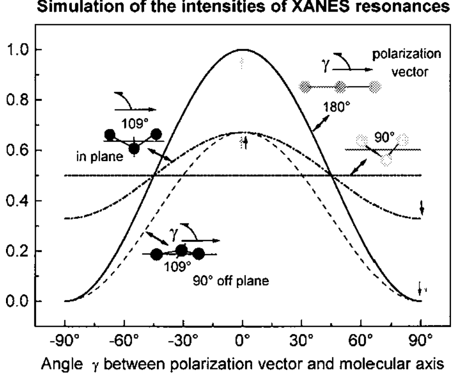

Figure 16. Simulation of the influence of intramolecular arrangement of the carbon atoms and the relative orientation of the C–C plane with respect to the polarization vector during an angular scan for hypothetical orientations of ideal all-trans conformation. So far, this discussion has ignored the actual numbers for the space requirements of the alkyl chains, which essentially originate from the lateral dimensions of the covalently bound alkyl chains and the van der Waals radii of the hydrogen atoms (120 pm) of the organic molecule. The hydrogen atoms are mainly responsible for the intermolecular interactions between the hydrocarbon chains. The relevant data may be obtained from the schematic structures shown in Figure 13(b). It is evident that a problem exists regarding the space requirements of the chains parallel to [1–10], which is most serious for GaP because of the smaller lattice constant. However, by tilting or/and twisting the alkyl chains with respect to the molecular axis, an optimum registry of the van der Waals spheres of hydrogen atoms from neighboring chains may be obtained, which may significantly reduce the minimum van der Waals chain–chain distance from 418 down to 370 pm in the optimum case. Hence, by twisting the chains and adopting the optimum registry of hydrogen atoms between neighboring chains, the structural constraints imposed by the substrates may be essentially fulfilled. We suggest that the actually adopted tilt angles (34 versus 15°), as well as the resulting minor differences in average chain distances (487 versus 525 pm), may be affected by the need

to reach an optimum registry in this direction too. We conclude that structural constraints will not prevent any Ga (In) surface atom from forming covalent bonds to the sulphur heads. This is an important result in terms of passivation of the surface indium (gallium) atoms. Otherwise, missing alkanethiols would permit easy oxidation of the unpassivated In (Ga) in air. Note that passivation of the P-surface sites has to proceed along another route. We further speculate that the need for optimum registry may additionally contribute to the excellent order of the chains in the layers. Summarizing our results, we have demonstrated the formation of a passivating, self-assembling organic monolayers on InP(110) and GaP(110) by adsorption of alkanethiols from the liquid phase. An exceptionally well-defined orientation and high order within the adsorbed monolayers on these semiconductor surfaces has been found by employing the angular dependences of CK XANES resonances. Tilt angles toward the [001] directions of the (110) surfaces with respect to the sample normal of 34 and 15° for InP and GaP, respectively, were obtained from quantitative analysis of the XANES. The considerable difference in lattice constants permitted us to draw some conclusions concerning the substrate influence in the case of these semiconductors. The bonding to the surface and surface structure, as well as intermolecular interactions, impose constraints, which evidently force the adsorbed monolayers to adopt a uniquely well-defined structure. The constraints result in single domains of the monolayers on the investigated III–V (110) surfaces, only limited by high-cleavage steps or other large defects of the cleaved substrate surface.

The sensitivity of XANES to determine the spatial orientation of the bonding axis (especially the C–C and C–H bonds at the CK edge) has been used to construct a model of the complete alkanethiol monolayer with respect to the underlying InP(110) lattice. The angular-dependent (in azimuth and vectorial angle) datasets have been measured, while averaging an area (spot size) of several mm^2, hence representing a truly macroscopic feature. Although the integration of spectral features over large regions has been made, the data reveal sharp angular-dependent changes. In particular, these changes are not symmetric with respect to different surface directions, which has to be expected for an oriented, single-domain system. More precisely, the following conclusions have been drawn from the XANES measurements.

- The angle between the surface normal and the tilted alkyl chains is 34° on InP(110) and 15° on GaP(110) [66, 67].
- The projection of this angle onto the surface lies along the [001] axis of the substrate, which has been confirmed by varying the azimuth angle parallel to the surface from 0 to 360° in 24 steps [66].
- Within the (001) plane, the chains are only tilted to one side of the surface normal, which is confirmed by varying the vectorial angle from −70 to +70° from the normal in more than 30 steps [53, 67].

From SXPS measurements which have been tuned for maximum surface sensitivity, it additionally has been proved that the chemical binding of SAM and the substrate takes place between the thiol sulphur and the indium, while the hydrogen atoms which are deprotonated in the binding process are connected to the phosphorus atoms [65]. The set of XPS intensities also supports the thesis of a well-ordered system. The C/S ratio is at its maximum, while the corresponding substrate intensities are at their minimum. To demonstrate the cleanness of the self-assembled system, we have presented an XPS-survey spectrum [32, 66, 67]. Only peaks which are related to the substrate (In, P) or the adsorbate (C, S) are present. No oxygen or other contaminants are detectable, which is proof of a good surface preparation.

We are now ready to sketch a complete model of the adsorbate–substrate system. However, to eliminate all possible objections to our conclusions, we will further prove the exceptional order of the SAMs by using X-ray photoelectron diffraction on exactly the same UHV-adsorbed alkanethiol film (either prepared in a solution or by vacuum deposition). For that, we made two sets of angular-dependent measurements at room temperature on spot sizes of several mm^2. The first one, with angular variations within the (001) plane, shows no significant deviations in intensity. But the second set (consisting of two independent series), which is made in the (1–10) plane, shows a clear peak at 34°, but not at −34° from normal (see Fig. 17). This peak comes from the so called "channeling" of the photoelectrons along the alkyl chains, and therefore describes the orientation of the chains. Note two important additional pieces of information, which can be derived from these measurements. First, the graph is not symmetric with respect to the surface normal (only one

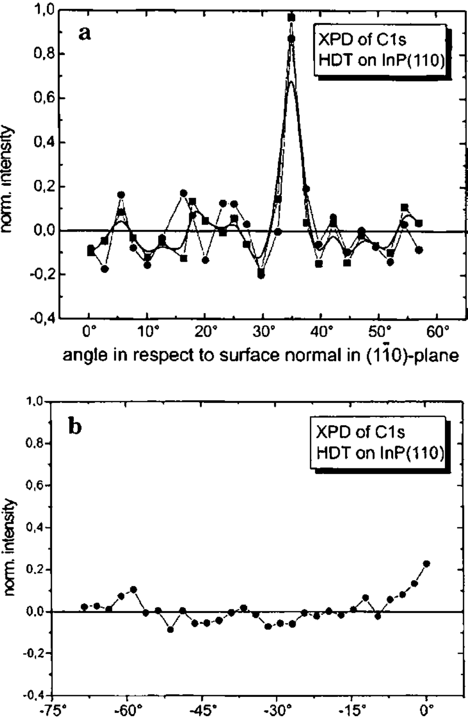

Figure 17. XPD experiment at the energy of the C1*s* peak: (a) along the (1–10) plane, (b) along the (001) plane of the InP lattice. Reprinted with permission from [53], D. Zerulla and T. Chassé, *Langmuir* 18, 5392 (2002). © 2002, American Chemical Society.

peak), and second, the peak is absent in the perpendicular plane. This again allows only one conclusion: the adsorbed monolayer is a single-domain system. Furthermore, from our analysis, one may conclude that fully assembled monolayers, prepared from solutions, and UHV-adsorbed monolayers at high doses (>10 kLangmuir) do form the same kind of structure on InP(110) surfaces. In order to complete the model of the spatial geometry of the adsorbate–substrate system, we are in need of the exact orientation of the substrate lattice with respect to the adsorbate. Having the exact orientation in space of the alkyl chains, the only missing parameter is the orientation of the substrate. From the previously shown XPD measurements on preoriented InP single crystals, it is clear that the alkyl chains lie in the (1–10) plane. The symmetry properties of the semiconductor lattice further allow the determination of "tilt direction" with respect to the sequence and spacing of the nonaxial-symmetric substrate lattice in the denoted plane. Hence, a second set of XPD measurements has been made along the (1–10) plane. In order to investigate the orientation of the substrate and not the adsorbate, the P2*p* peak instead of the C1*s* peak was chosen. The result of this experiment is depicted in Figure 18. Because of the unequivocal result, an interpretation using simple first-order scattering is sufficient. The matching of the first-order scattering model and the XPD peaks is illustrated in Figure 19. Taking all ascertained data from the measurements, we can now complete the structure of the single-domain adsorbate–substrate system. The resulting model, which is additionally confirmed by computer simulations, is shown in Figure 20.

The STM/STS results lead to further insights into the behavior of self-assembling monolayers on III–V(110) surfaces. From the preceding spectroscopic investigations [32, 66, 67], which were carried out with alkanethiols adsorbed from solutions, it was clear that the organic films build up a very highly ordered and dense layer on large scales. The data derived from these spectroscopic measurements include the molecular tilt angle of 34° [InP (110)] and 15° [GaP (110)] from the surface normal into the [001] direction of the substrate. An explanation for this behavior can be given solely by geometrical considerations. The rectangular surface unit cell of this zinc-blende type of substrate is characterized by In–In (P–P) spacing along the [001] and [1–10] surface directions of 587 and 415 pm, respectively. The surface

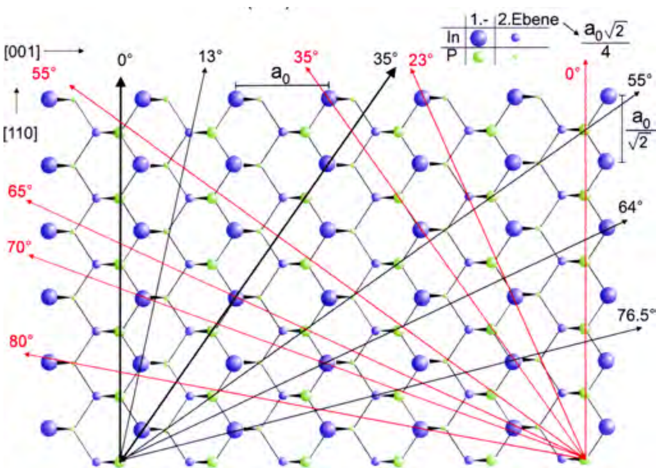

Figure 19. Illustration of the first-order scattering within the (1–10) plane. Reprinted with permission from [53], D. Zerulla and T. Chassé, *Langmuir* 18, 5392 (2002). © 2002, American Chemical Society.

indium and phosphorus atoms (In–P bond length 254 pm) are linked to form In–P zigzag chains within the InP(110) surface plane, which extend along the [1–10] direction. Thus, following structural arguments regarding the space requirements of the alkyl chains and their well-known tendency to form dense structures, a tilt of the alkyl chains toward [001] is indeed much more likely than toward [1–10]. These simple arguments agree very well with our above-mentioned observations regarding the tilt direction.

Furthermore, a dependence of the tilt angle on the lateral distance of the sulphur–substrate bonding sites on the surface, and thus on the substrate lattice constant, had to be expected. In fact, we observed such a trend by investigating thiol adsorption on different semiconductor surfaces [53, 67].

Besides this purely geometrical consideration, we have to be aware of the structural inequivalence of the two opposite [001] surface directions due to the asymmetry of the In–P

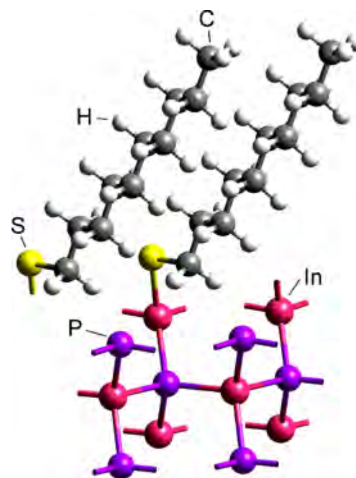

Figure 20. Model of the adsorbate–substrate system. Reprinted with permission from [53], D. Zerulla and T. Chassé, *Langmuir* 18, 5392 (2002). © 2002, American Chemical Society.

zigzag chains, which exhibit an indium and a phosphorus side. This structural asymmetry is also known to be responsible for the opposite spatial orientations of the empty and filled dangling bond orbitals of the surface indium and phosphorus atoms, respectively. Hence, it is reasonable to suggest that the experimentally observed preference of just one orientation of the alkyl chain has to be attributed to the orientation of these dangling bonds, that is, to the empty indium dangling bonds, which was proved by SXPS measurements [53, 67]. Thus, structure as well as bonding constraints evidently force the adsorbed monolayers to adopt a uniquely well-defined structure, which allows us to propose the existence of single domains of the monolayers on InP(110), only limited by high-cleavage steps or other large defects of the cleaved substrate surface.

Summarizing all data, we have proved macroscopically, from pure spectroscopic investigations [32, 66, 67], as well as microscopically from STM/STS measurements, the spatial structure of the complete adsorbate–substrate system. We have shown on self-assembling systems prepared from dilute solutions, as well as on systems prepared in UHV, that the whole layer under investigation is highly ordered and oriented into a specific direction, and therefore is a single-domain system on InP (110) and GaP (110).

Additionally, from the comparison of different preparation techniques (UHV deposition versus dilute solutions), it was possible to shed more light on the role of solvent molecules in the mechanism of self-assembly and the necessary doses. From the measurements with low doses, it is obvious that the preorientation of the alkyl chains, pointing toward the crystallographic [001] axis of the substrate, is induced by the empty (In) dangling bonds on the surface, while the tilt angle itself is a result of the dense package and the three-dimensional space requirements of the alkyl chains at higher doses.

The different stages of adsorption also give an explanation of the comparable high doses needed to obtain a densely packed layer despite the high reactivity, and therefore high sticking coefficient, of the surface. The reason for the requirement of higher doses is that the lying molecules on the semiconductor surface hinder the contact between new incoming molecules and the substrate surface itself. This is also the main reason for the differences in adsorption kinetics in comparison to adsorptions from solutions. There, the alkanethiols are expected to be kept afloat by the surrounding solvent molecules, and that is why they do not block the surface at low coverages. The corresponding results on gold surfaces are quite similar, but do not lead to single-domain systems; see, for example, [76].

4. NANOSTRUCTURING OF SAMs

In principle, self-assembling monolayers are stable against etching, act as lithographic resists, and can be combined with functional groups, to mention only a few examples. Because of the potential technical applications of such organized assemblies in a variety of fields, for example, chemical/optical sensors, these systems have been studied with increased attention for a number of years, and different techniques to structure the monolayers have been developed.

In this section, we will discuss different techniques that enable us to write structures with or into a self-assembled monolayer. Furthermore, we want to shed light on the mechanisms behind the different techniques in terms of changes in the molecular structure. Coarsely, the methods could be divided into techniques which remove parts of the monolayer (Sections 4.1, 4.2) or techniques which add molecules to the surface (Sections 4.3, 4.4).

4.1. X-Ray and *E*-Beam Lithography

Here we will discuss two methods whose origins are quite different. We do this because the final mechanism of the removal of molecules at the surface is the same in both techniques.

First, we discuss the influence of long-term X-ray irradiation on the structure and chemical state of a ready-assembled alkanethiol monolayer on InP (110) and Au (111). For this, we have performed an XPS study in order to investigate these effects. For the general preparation of the monolayer systems, we refer to Section 2. However, because we feel that it is an important point for the interpretation of the experiments, we have checked the surface quality on the gold films and on InP(110) using an ultrahigh-vacuum scanning tunneling microscope. According to these investigations, the gold surfaces are composed of large flat terraces, exhibiting typical dimensions of 200 nm $\times$ 200 nm. The terraces are separated by steps with a height of a few atomic distances. The largest part of the surface belongs to the terraces, which are almost free of defects. On the contrary, only a few single-cleavage steps, typically separated by distances of several micrometers, were found on InP(110), which thus exhibits very large, atomically flat terraces [64].

Thiol monolayers (1–decanethiol (DT), Aldrich, 96%; dodecanethiol (DDT), Fluka, 97%; hexadecanethiol, Fluka, 95%; octadecanethiol (ODT), Fluka, 97%) were prepared in a μM solution in isooctane (Merck, SupraSolv, for organic trace analysis). Before the solvent was used, it was purged with nitrogen for about 30 min to remove the dissolved oxygen. The indium phosphide crystals were cleaved in the above-described solutions. After immersion times of approximately 36 h, the samples were removed, rinsed with fresh solvent, dried under a gentle stream of nitrogen, and inserted into the spectrometer immediately.

The spectra were fitted by a least squares procedure with a model peak shape (Gaussian–Lorentzian convoluted functions) after background subtraction from experimental data using a Shirley-type function (using the software Unifit 2.1 by Hesse et al. [77]).

The samples were characterized by the core-level spectra of the substrates (Au4f, In3d, P2p) and of the organic films (C1s, $S2p$). However, for the purpose of this chapter, we mostly focus on the sulphur core levels of the organic adsorbates. First, we will present the data obtained for the adsorbed alkanethiol monolayers on gold. Figure 21 shows a set of $S2p$ spectra recorded from a DT layer on gold. From bottom to top, the spectra represent increasing accumulated irradiation time by X-rays up to a total of 8.5 h. The bottom spectrum in this figure, which corresponds to the shortest irradiation time, is dominated by a single, well-resolved

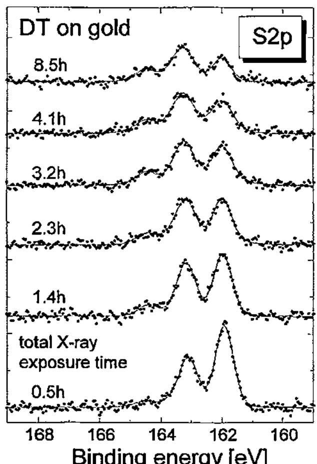

Figure 21. XPS S2p spectra of DT on gold for different X-ray exposure times. The formation of a new chemical species and the loss of sulphur can be seen directly from the spectra as a function of time. Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

$S2p$ doublet structure. There is no signal from oxidized sulphur species observable, which would occur on the highest binding energies (BEs) on the left-hand side in Figure 21. But with an increasing interaction time of the X-rays with the adsorbed organic layer, the typical $2p_{3/2}/2p_{1/2}$ doublet branching ratio for XPS core-level spectra becomes increasingly distorted from this value, and an additional peak structure grows on the high-binding-energy side of the main peak structure. These changes of the spectral shape are evidence for the appearance of another sulphur species. This conclusion is supported by the peak-shape analysis of the spectra. Figure 22 shows two representative experimental spectra, together with the results of a peak-shape analysis using two doublet peaks for the fits of each sulphur spectrum. The corresponding fit components, the background lines, and the fit residuals have also been included in the figure. The fit-sum curves match the experimental data well, and the fit residuals appear to be randomly distributed, in this manner demonstrating the successful description of both experimental datasets by these two doublets. The initially dominating S2p component (Fig. 22, bottom spectrum) at a binding energy ($S2p_{3/2}$ with respect to the Fermi level) of 161.92 eV evidently represents the sulphur head group of the thiolate, which bonds to the gold substrate (hereafter called sulphide component). The second sulphur component at the higher binding energy of 163.36 eV has reached the same relative intensity as the initial one in the top spectrum of Figure 22. It may be related to radiation-induced changes of the chemical bonding of the respective sulphur atoms. We have tested this hypothesis by switching off the X-ray tube for periods up to 12 h. After having resumed the irradiation, we could get about the same intensities from the sample surfaces as before the stop of the irradiation. This test has demonstrated that the chemical transformations that are indicated by the peak-shape changes are, in fact, X-ray induced (including X-ray excited secondary processes), and not solely due to storage of the layers in the UHV environment.

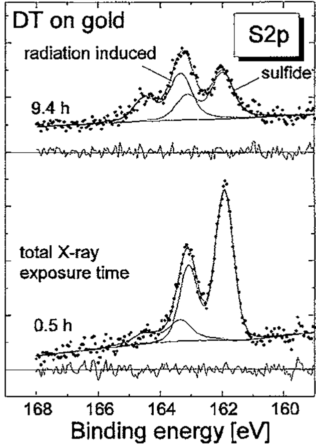

Figure 22. Peak-shape analysis of S2p doublets (representing the sulphide and the radiation-induced species) from DT on gold, including the residuals for exposure times of 0.5 and 9.4 h. Hence, we will call this second sulphur doublet component radiation induced. The evolution of the chemical changes in the thiolate layer while continuously irradiated with X-rays is displayed in a quantitative manner by the sulphur component intensity ratios (radiation induced/sulphide) shown in Figure 23a on a longer exposure time scale. This ratio rises

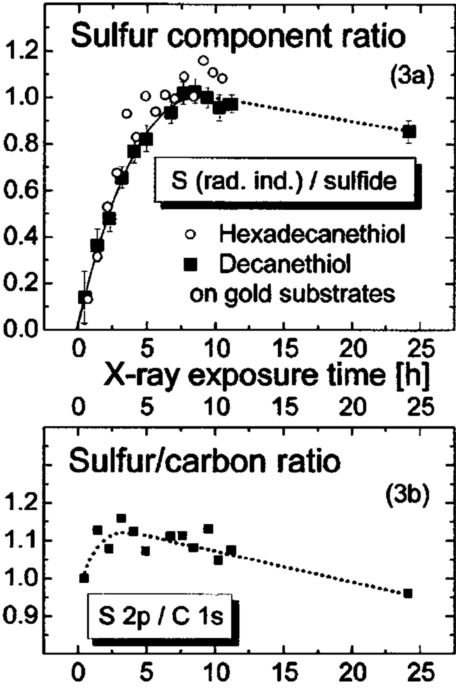

Figure 23. (a) Comparison of the irradiation time dependencies of the relative content of radiation-induced sulphur/sulphide of HDT and DT on gold. Note that extrapolating the data to $t = 0$ suggests a monolayer free of sulphur components other than sulphide from the adsorbed thiol. (b) Comparison of the sulphur/carbon intensity ratios of DT determined on gold. All absolute values have been normalized with respect to the Au4f peak. Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

fast during the initial stages of irradiation. Of course, the individual spectra and their intensities represent an average over the necessary recording time of about 30 min for a single high-quality spectrum, and thus the intensity ratio cannot be given for zero irradiation. However, tracing back the evolution of the data toward lower X-ray exposure gives a component intensity identical to or at least very close to zero for irradiation time $t > 0$. This suggests the absence of the second sulphur species at the initial stage of the XPS investigation. After having reached a maximum level at about 8–10 h of irradiation time by monochromatized X-rays, the intensity ratio exhibits a weak trend to decrease very slowly, in particular at the largest duration of X-ray exposures (24 h). It is important to note that the evolution of the sulphur component intensity ratio proceeds very similarly in the case of HDT and DT adsorption layers on gold (see Fig. 23a). This leads to the conclusion that these moderate differences in chain length are of less importance in the case of these radiation-induced chemical changes. But note that the intensity ratios measured for the HDT film exceed those for the DT film by about 5% typically. Normalized intensities of both the total C1*s* and S2*p* signals, as well as of the sulphide and the radiation-induced S2*p* components, are provided in Figure 24. A significant intensity loss of both the total sulphur and the carbon signal of the thiolate film with increasing X-ray exposure can be clearly observed. The decrease of the sulphur signal intensity proceeds fast during the initial stages of the X-ray exposure, but slows down considerably at later stages. The sulphur intensity decreases much slower beyond irradiation times of about 8–10 h, when it has reached about 60% of its initial value. These pronounced intensity changes cannot be explained by a rearrangement of the organic molecules of the adsorbate layer, but suggest a loss of adsorbate from the surface. Interestingly, the C1*s* intensity decreases at about the same rate (Fig. 24) during the whole investigation. There is only a slight increase of the sulphur/carbon ratio (Fig. 23b) by about 10–15% at intermediate irradiation times, which indicates more complex changes in the layer. This observation may indicate that parts of the alkyl chains have been removed from the adsorbed molecules by radiation-induced bond breaking and desorption or that part of the adsorbed organic molecules are more flat lying on the surface than in the well-ordered SAM. Both effects would increase the sulphur/carbon intensity ratio due to reduced sulphur signal attenuation by carbon. Another minor effect to be recently reported is a slight broadening of the C1*s* spectra toward lower BE after prolonged irradiation that has been attributed to chain damage due to double-bond formation possibly accompanying C–H bond breaking [78, 79]. Nevertheless, the major effect regarding the structural layer damage is the intensity decrease of both thiolate signals (C1*s*, S2*p*), which has to be attributed to a large extent to correlated losses of both sulphur and carbon from the surface. Note that all solid curves in Figure 24 have been drawn to guide the eyes only. In fact, the lines have been obtained by fitting the data with exponential functions. The best results have been found by using two exponential functions with characteristic time constants of about 2–3 h and about 100 h, respectively. We emphasize that similar time constants characterize the intensity loss of the total signals (S2*p*, C1*s*), as well as changes of the two individual sulphur component signals (radiation induced, sulphide). This observation strongly supports the assumption that chemical damage and structural damage are somehow correlated on gold substrates. The behavior of different adsorbed thiol molecules has been investigated in the range of alkyl chain lengths from $n = 10$ to $n = 18$ carbon atoms (only even numbers). All investigated layers exhibited the above-described effects. Small deviations in the data (e.g., shown in Fig. 23a) are visible, but not strong enough to be interpreted as significant influences from the deviating chain–chain interactions due to differences in the alkyl chain lengths. We have been able to visualize the structural damage of the adsorbate layers due to the extended X-ray exposure during our studies in SEM pictures, as shown in Figure 25a for the case of an ODT layer on gold.

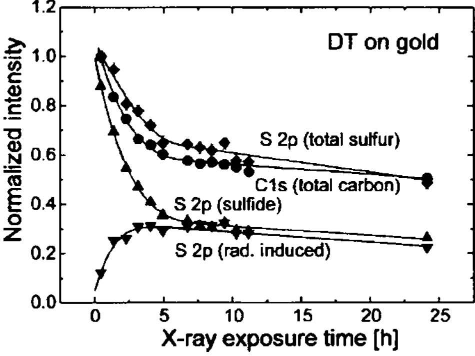

Figure 24. Normalized intensities of the carbon and the sulphur species from DT on gold. The intensities have been calculated from the average peak area of the fitted spectra. Normalizations have been made with respect to the Au4*f* peak of the substrate. This leads to a small overestimation of the loss because the substrate is not covered by the same effective layer thickness at longer exposure times. Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

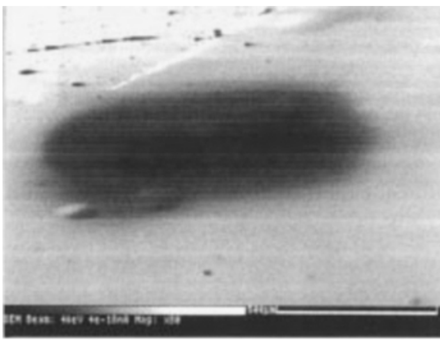
The scanning electron microscopy (SEM) picture of the photoninduced damage of the thiol film was recorded using a VG LEG 1000 electron gun with a primary electron energy of 4 keV and the lowest possible current.

The elliptically shaped dark area represents the spot from the monochromatized X-ray source on the sample. The contrast in the picture is due to different electron reflectivities and secondary electron yields of the irradiated and nonirradiated parts of the thiolate film. The irradiated area can be clearly distinguished from the environment, but within this area, we notice gradual differences in contrast, which may be attributed to an inhomogeneous illumination by X-rays, and thus also inhomogeneous photon density. This renders the application of exact quantitative models for the characterization of the damage evolution difficult.

It should be mentioned that radiation-induced damage proceeds much faster by using nonmonochromatized X-ray sources. This result is quite reasonable, even if the X-ray power is chosen to give equivalent count rates for the photoelectron lines because of the additional photons from the bremsstrahlung and the X-ray satellites, and the much higher background of inelastically scattered and secondary electrons. Radiation-induced damage was also observed



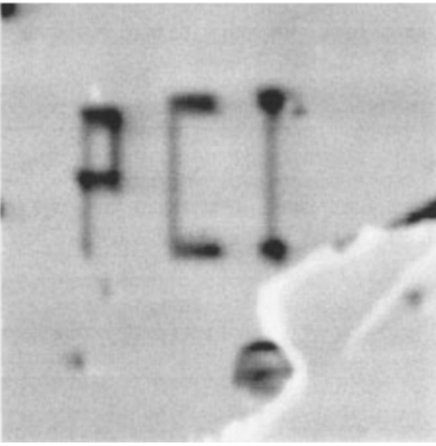


Figure 25. (top) SEM picture of an octadecanethiol monolayer on gold. The dark spot is due to the change of the SE yield by induced damage by the monochromatized X-ray source (1486.6 eV) to the adsorbate. The size of the spot is approximately 1000 μm × 250μm (primary electron energy was 4 keV). (bottom) SEM picture of a dodecanethiol monolayer on InP(110). The pattern "PCI" has been written by electron beam lithography, using a freely programmable electron gun at 10 keV. This picture demonstrates the ease of structuring an alkanethiol layer with electron beams. Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

after applying lower energy synchrotron radiation in the range of $h\nu = 50$–320 eV, as was used for X-ray absorption near-edge structure and soft X-ray photoelectron spectroscopy studies. Moreover, damage of SAMs was also found using electrons in the range of 10–14 eV, supplied by a flood gun, and we have further tested that electron beams <500 eV can damage the layer in the same way. These results ensure that low-energy and secondary electrons contribute to the layer damage. We have applied 4–10 keV electron beams of an Auger electron gun for laterally structuring the SAMs.

For example, the pattern "PCI" has been generated in a dodecanethiol monolayer (Fig. 25b). In fact, electron-induced damage has been reported before [80–82], and it has also been used for patterning purposes. To shed more light on the possible importance of substrate–layer interaction regarding the radiation-induced effects, we have also investigated adsorbed thiol monolayers on InP (110). This surface was chosen for comparison to the metallic gold surface because of the quite different surface structure and bonding of this covalent semiconductor with zinc-blende lattice, and finally because of the available experience in the interpretation of sulphur core-level spectra from several adsorption studies of inorganic sulphur species on InP [35–37, 66]. We have studied the composition and structure of such thiolate layers using XPS and XANES. Very pronounced angular dependencies were observed in the σ^*(C–C) and σ^* (C–H)-related structures in the near-edge region of the X-ray absorption spectra on alkanethiolate layers on InP(110) by varying both the polar and azimuth orientation of the sample with respect to the polarization direction of the synchrotron radiation. The data analysis has clearly shown that self-assembly also takes place on this surface, and it results in an excellently ordered organic monolayer. In contrast to gold substrates, where domains with different azimuth orientations of the alkyl chains exist on the surface, only the tilt orientation of chains parallel to the dangling bond directions of the surface atoms were observed on the cleavage face of indium phosphide. However, for both the XANES data and their detailed discussion, we refer to Section 3.

The adsorbed molecules form a dense monolayer on InP(110), as can be concluded likewise from the observed passivation of the semiconductor surface from oxidation by contact to air. This passivating effect is demonstrated by the complete absence of oxygen-related signals in the XPS core-level spectra (Fig. 26). A survey spectrum only shows photoelectron peaks of both the semiconductor substrate and the organic adsorbate on the background of inelastically scattered and secondary electrons [32]. For the purpose of this chapter, we will focus on the S2p spectra and the corresponding intensities as discussed for the gold substrates above. S2p spectra recorded from an HDT layer on InP(110) are provided in Figure 26. Cursory inspection by eye gives only evidence for a single doublet due to the sulphide component, which is present in all of the individual S2p spectra. But careful peak-shape analysis allows identification of a second sulphur component of low intensity at a higher binding energy. This small component also grows with increasing X-ray exposure, similar to the case of thiolate layers on gold. There have been several studies

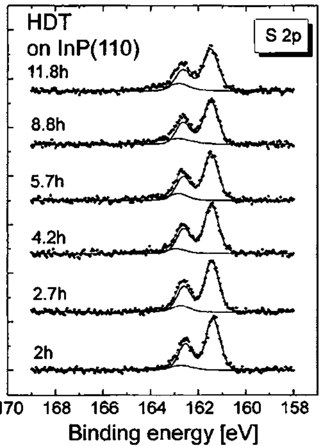

Figure 26. XPS S2p spectra of HDT on InP (110) recorded at different X-ray exposure times. Note the differences compared to alkanethiols on gold. Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

of inorganic sulphur species on both InP(001) and InP(110) surfaces [33–35, 37]. In–S bonds have been observed to dominate mostly, with sulphur components between 161 and 162 eV with respect to the Fermi level, depending on the detailed adsorption geometry and Fermi-level pinning. Polysulfidic sulphur was observed with binding energies near 163 eV. Dissociative adsorption has been verified in the case of H2S on InP (110), with P–H and In–SH surface bonds [33, 34]. The evolutions of both the changes in chemistry and composition of the adsorbed monolayer due to the radiation are displayed in a quantitative manner by normalized intensities and intensity ratios, as shown in Figure 27. Looking at the normalized intensities first, we may observe that both sulphur and carbon intensities decrease with increasing X-ray exposure. But this decrease is limited to less than 15% during the period of investigation (12 h). However, the evolution of sulphur and carbon intensities again proceeds about parallel. Furthermore, a small shift toward lower binding energies and a broadening of the C1*s* peak related to the alkyl chain, as was already mentioned for gold substrates, has also been detected on InP (110) in the very last stage of the irradiation process. Thus, there is again sufficient evidence for structural damage of the adsorbed films on indium phosphide. However, the loss of sulphur-containing molecules is strongly reduced under equivalent excitation conditions compared to the gold substrates discussed above.

Second, the sulphur component intensity ratio (radiation induced/sulphide) also increases with continuing irradiation with X-rays, but it increases much slower than that on the gold surface. At the final stages of the present investigations, this ratio does still increase, and there is no evidence for a reversal of this trend yet. In the case of the dataset presented in Figure 27, we have included periods of excitation by nonmonochromatized X-rays to enhance the radiation-induced effects. We have further extended our comparison of alkanethiol layers on gold films and on indium phosphide to the effects of electron beam patterning. It is very interesting to note that patterned structures were consistently smaller on InP substrates by 30–80% than on gold films under identical excitation conditions in the case of applied electron probes of a few 100 nm lateral size and 4–10 keV primary energy as used here. We explain this observation by a larger number of secondaries in the case of gold, and their larger lateral spread due to the higher electron backscattering in gold. We have been able to confirm these effects of higher backscattering of electrons in gold and the higher number of low-energy electrons at the surface compared to indium phosphide quantitatively in our Monte Carlo simulations, which were performed to support separate studies of patterning by electron beams. The Monte Carlo simulations of the electron trajectories were carried out in consideration of relativistic partial-wave calculations of elastic cross sections by solving the Pauli–Dirac equation, combined with Bethe's continuous slowing-down approximation and the Rao–Sahib–Wittrey approach at low energies.

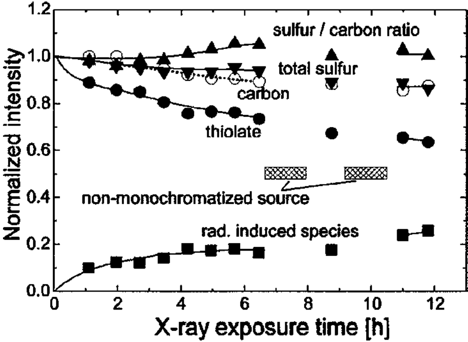

Figure 27. Summary of the carbon and sulphur intensities of HDT on InP (110). All absolute intensities have been normalized with respect to the In3*d* peak of the substrate. The diagonal hatched areas mark the points of time when the nonmonochromatized X-ray source has been used. Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

The higher number of low-energy electrons and the more pronounced backscattering accumulate and generate a high number of low-energy electrons in the surface region, which may introduce damage to the organic films. Thus, both the experimental observation of the substrate-dependent width of patterns in the organic films and the quantitative simulation of electron distribution in the samples provide further supporting evidence for the major importance of secondary electron damage of organic films. It is thus reasonable to suggest that the indirect damage by electrons seems to be very effective compared to direct damage by the X-rays, and thus is likely to dominate the damage, even in the SAMs investigated here. Moreover, care has to be taken in the application of structural probes that use ionizing radiation because of the possibility of damaging the layers by secondaries.

Summarizing this part, we may notice that evidence for both chemical and structural damage of the thiolate layers by extended exposure to X-rays was also observed on InP (110). The striking differences in the quantitative extent of these effects compared to gold substrates provide evidence for the importance of the different substrate–layer interactions and the different substrate properties.

The third part of the data will deal with the analysis of the chemical bonding using core-level spectroscopies. Besides the above-discussed thiolate monolayers on gold and indium phosphide, we have also investigated deposited films of pure dithiol (1,8–octanedithiol) and pure dialkyl or thioether (dioctadecyl–3,3′–thiodipropionate) and HDT as references.

Similar discussions regarding the nature of the adsorbed alkanethiols have been published by Jung et al. on gold [72], and by the author on gold and III–V semiconductors [32]. In the following, we will outline the experiments, main results, and their discussion.

To prepare reference samples for the chemical analysis, the undiluted disulfide DS (poly-octanedithiol, ...–C_8–S–S–C_8–S–S–C_8–..., Aldrich, 97+%; the disulfidic nature was additionally confirmed by Raman spectroscopy) and dialkyl DA (dioctadecyl 3,3′–thiodipropionate, $S[CH_2CH_2CO_2(CH_2)_{17}CH_3]_2$, Aldrich, 99%), as well as HDT were directly applied to a gold surface, and frozen down to liquid nitrogen temperature (LNT) under a protective gas atmosphere to minimize water adsorption. The samples were then inserted into the spectrometer immediately, while they were kept at LNT to prevent degassing of the molecules in UHV. This procedure leads to films which we will call later "thick films." Their thickness is much larger than 100 nm, which is proved

optically and additionally by the fact that the substrate is no longer detectable by XPS measurements. The so-called "thin films" were prepared as follows. The frozen "thick films" were warmed in UHV until they reached room temperature. Thus, most of the film is degassed, and the substrate is detectable by XPS. In the case of long chain reference chemicals, the samples were removed from the UHV environment, and then additionally rinsed with isooctane. After that, the samples were inserted into the spectrometer again. Because of the substrate/adsorbate signal ratio, we estimate the "thin films" to have a thickness approximately up to 5–6 nm. Note that all molecules above the first ML are not supposed to be ordered, but are randomly distributed.

The reference chemicals have been chosen with regard to two aspects: first, because of their sulphur–carbon groups (R–S–S–R or R–S–R, respectively), and second, because of the existence of long alkyl chains which have been used to calibrate the spectra. The X-ray photoelectron spectra were recorded with a VG ESCALAB 220i-XL instrument irradiating the samples with monochromatized Al Kα radiation (22 mA, 10 kV). Spectra were recorded in normal emission, and with an angular averaging mode using an additional magnetic XL lens, if not stated otherwise.

The energy resolution was 0.45 eV (FWHM Ag3d). Binding energies (BE) have been referred to the Fermi energy. The energy scale of the spectrometer was calibrated by adjusting to EB (Au4$f_{7/2}$) 84.00 eV. The spot of the X-ray photons from the monochromatized X-ray source has a size of 1000 μm × 250 μm on the sample, with an approximate elliptic shape. Bremsstrahlung of a nonmonochromatized MgKα source (30 mA, 15 kV) has been used exceptionally to excite the Auger S $KL_{2,3}L_{2,3}$ and S2p spectra, which were used for the chemical state plot. All binding energies in the chemical state plot have been referred to the C1s energy of the alkyl chains, set to 284.60 eV. This allows correct relative adjustment of binding energies from species in highly insulating thick films which exhibit a charging shift of the energy positions.

The deposition of dithiol on gold, in the way described above, leads to the formation of thick films. These are expected to contain sulphur–sulphur bonds such as those in disulphides (DS) mostly, for example, a –C–S–S–C– group, which results in networks of polysulphides. Otherwise, the remarkable stability of these films in an ambient environment can hardly be explained. This assumption has been supported by the detection of specific vibrational modes in Raman spectra, which reveal typical fingerprints of disulphidic species. On the other hand, the dialkyl (DA) films contain –C–S–C– units. In addition to the thick films with, thicknesses in the range of several micrometers, thinner films with thicknesses in the range of only a few nanometers also were prepared by extensive treatment with solvents or partial desorption in UHV. The thickness of the latter films can be crudely estimated from the C1s to Au4f intensity ratios, which were observed roughly in the range of 0.3–3 in these cases. Charging effects were especially observed in the cases of the thick films because of the insulating nature of the adsorbed molecules. The charging-induced shifts in the very thick layers lead to a degeneration of the resolution due to the nonuniformities of the charging. Neither the use of a flood gun nor the change of the X-ray source and the lens modi could completely remove the inhomogeneous charging. However, this does not severely reduce the grade of information obtained. For the comparison of sulphur binding energies from different species and film thicknesses, the energy scales have been calibrated to set the C1s signal of the alkyl carbon of all samples to EB = 284.60 eV to correct any kind of charging-induced shifts. A comparison of sulphur core-level spectra of HDT monolayers on gold and InP (110) and a thick film containing disulphide bonds (DS) is shown in Figure 28. The vertical line indicates the approximate position of the disulphidic S2$p_{3/2}$ components. The faint peak structure at the very high binding energy in the DS spectrum represents some oxidized sulphur. Quick inspection of the spectra by eye reveals that the binding energies of the radiation-induced signals from the monolayer fall quite close to the disulphide signal from the DS. This observation seems to support the hypothesis that the sulphur signal from the monolayers at the higher binding energy may represent disulphidic species, as has been suggested before [78, 79].

Furthermore, we have combined XPS spectra with X-ray-excited Auger electron spectroscopy (XAES) in order to derive Auger parameters, and to apply two-dimensional chemical state plots for chemical analysis of the sulphur bonding. In the "initial state–final state framework," the XPS core-level binding energies and the XAES Auger (kinetic) energies (AE) can be described essentially by the potential energy contribution on the site of the emitting atom due to the electron density distribution in the chemical environment and a relaxation or final state contribution, which characterizes the core-hole screening effects due to the transfer of screening charge or polarization of the environment following the core-hole generation. The Auger parameter α' according to Wagner corresponds to the sum of the BE and the AE [35–37]. The chemical shift $\Delta\alpha'$ of the Auger parameter reflects the changes of the relaxation or core-hole screening due to changes of the chemical bonding situation. Thus, the basic idea of application of Auger parameters and chemical state plots of binding and Auger energies is to use the additional information due to different

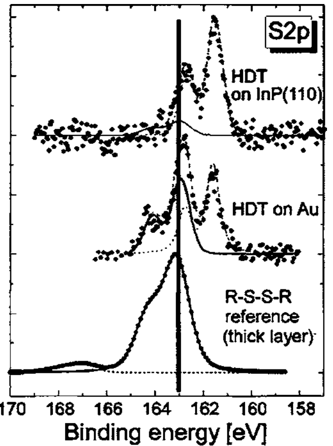

Figure 28. Comparison between the XPS spectra of HDT on InP (110) and gold and a thick layer of a reference disulphide (see text). Reprinted with permission from [32], D. Zerulla and T. Chassé, *Langmuir* 15, 5285 (1999). © 1999, American Chemical Society.

sensitivities to core-hole screening effects. In some cases, this may permit us to distinguish even between species, which have nearly identical binding energies. Figure 29 shows a chemical state plot, which presents the results from repeated measurements of three different adsorbate systems (HDT, DS, DA) and three different layer thicknesses (monolayer, thin film, thick film). The vertical axis represents the kinetic energy of the S $KL_{2,3}L_{2,3}(^1D)$ Auger peak. Binding energies are shown along the horizontal axis. The diagonal lines with slope $= -1.0$ represent identical values of the Auger parameter α', and thus the same relaxation or core-hole screening energy. There is a striking separation into two different groups of data sets in Figure 29. In the upper right corner, that is at the lowest BE and highest KE and thus the highest Auger parameter values, we observe the data points obtained from the sulphide signal of the HDT monolayer and a signal from the thin HDT films that we attribute to those HDT molecules of the thin film at the interface to gold. All other data points from DA, DS, and including the HDT thick film data, as well as the remaining data points from HDT thin films, may be found in the lower left corner of the chemical state plot. The significantly smaller KE and Auger parameter values of the latter data points suggest a much less effective core-hole screening compared to the sulphide in the HDT monolayer. The lowest KE and Auger parameter values were measured for the thick films of DS, DA, and HDT. This is reasonable in terms of the insulating nature of these films and the much reduced ability to screen the core hole compared, for example, to a metallic environment. Slightly higher Auger parameters are observed for thin films of DS, DA, and HDT. All datasets corresponding to DA films are shifted toward lower BE with respect to comparable film signals of other sulphur species. A shift to lower BE for dialkyl samples by 0.4 eV compared to similar disulphidic samples has already been reported in the early data compilations by Siegbahn [83] and Nefedov [84]. The

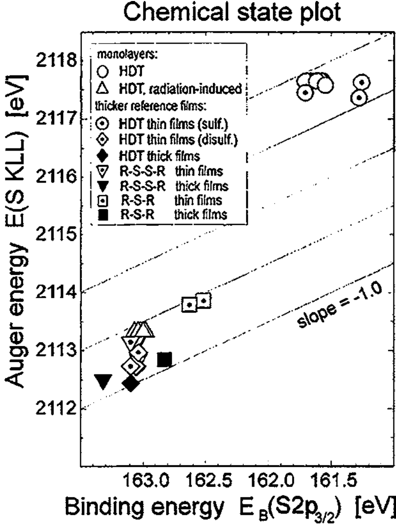

Figure 29. Chemical state plot including binding and Auger energies of three different adsorbates with different layer thicknesses in order to identify the radiation-induced species (see text). relative shifts of about 0.5 eV to disulphides in our investigations are sufficiently large to distinguish DA species from the others. The thin-film HDT results are very similar to the thin-film DS data. We emphasize that the data, which represent the radiation-induced sulphur component of the irradiated SAMs, are very close to the thin DS film data. This observation is another fingerprint pointing to the disulphidic nature of the radiation-induced species in the monolayers. But most importantly, we may conclude from the huge difference in Auger parameters between sulphide and radiation-induced species that the sulphur atoms responsible for the latter signal are not bonded to the gold surface atoms anymore. Otherwise, the metallic substrate should provide a significant contribution to the core-hole screening energy, which is evidently not the case.

In the following, we will discuss the experimental data. The adsorbed monolayers of alkanethiols on metals such as gold are known to exhibit long-term stability. However, it has been shown that extended irradiation by X-rays modifies alkanethiol monolayers on gold films in two ways. First, the chemical bonding of the sulphur atoms at the interface to gold is changed by partial breaking of the sulphur–substrate bonds. Second, the layer is structurally damaged, and loses adsorbate molecules. These results are in good agreement with very recent data by Jäger et al. [79] and Wirde et al. [78], and the appearance of radiation-induced damages of alkanethiolate SAMs on gold films now seems well established.

Besides, we will now focus on the comparison of gold film and InP substrates for the SAMs in order to derive conclusions on the effects contributing to the damage. The experimental observations at hand include the X-ray or radiation-induced changes of the spectra as indicated by the appearance of new spectral components, core-level line broadening and line shifts, total intensity changes, and intensity ratio modifications. These effects have been observed on both investigated substrates, as has been demonstrated in detail in the previous sections. However, there are significant differences regarding the quantitative extent in these effects, and in particular, differences in their evolution with X-ray irradiation time. Most striking is the comparably rapid chemical transformation of the sulphur and the significant loss of material from the SAMs on the gold films in the initial stages of the irradiation (time constant about 2–3 h). This rapid change in the initial stage is not observed on InP. Differences in substrate surface structure and related interface and organic film quality, substrate–layer bonding strength, and substrate-related excitations may contribute to this strikingly different behavior, and call for discussion. Bonding energies of 13.9 and 14 kcal/mol were derived for Au–methanethiol [30] and In–S [85], respectively, suggesting rather similar strengths of sulfur–substrate bonds for the substrates considered here. Note that In–S bonds are, in fact, preferentially formed after the adsorption of sulphur species on indium phosphide [35–37]. In a recent time-of-flight secondary ion mass spectrometry (TOF–SIMS) study of electron-stimulated damage of Langmuir–Blodgett (LB) monolayers and self-assembling monolayers, Rading et al. [86] have concluded that the strength of substrate–film bonding is of less importance for the desorption cross sections by ionizing radiation. Because of these results, we may

reasonably conclude that the quantitative differences of the two substrates considered here should not mainly be related to substrate–film bonding.

The number of surface defects is much larger on evaporated gold films than on the cleavage face of indium phosphide. This was confirmed by STM, as has been mentioned above. Further, due to the existence of several domain types with different azimuthal orientations of the alkyl chains on gold, we may also expect more domains, and thus more adsorbed molecules at domain boundaries, to be present on this substrate. As was mentioned in the brief review of the XANES results, due to the unique azimuthal orientation of the thiolates on InP (110), considerably fewer domains should exist on this surface. But we cannot estimate the relative extent of these effects based on our results. Evidence for reduced order in SAMs on deposited gold films compared to gold single-crystal surfaces has recently been provided in electron energy loss spectroscopy (EELS) studies by Duwez et al. [87]. It has been shown that the stability of SAMs of adsorbed thiols is due to both the sulphur–substrate bonding and the van der Waals interchain interactions to a similar extent for chain lengths of about 10–20 C [28, 29]. Adsorbed molecules near defect sites experience much reduced stabilizing intermolecular interactions compared to those within well-ordered domains on a well-ordered substrate. From defective adsorbate sites, a desorption of rather complete adsorbate molecules after substrate bond breaking seems likely, which may explain that the losses of carbon and sulphur from the surface proceed in a rather correlated fashion. Predominant desorption from defective sites on the gold films may also contribute significantly to the observation of the different time scales that characterize the intensity evolution of the core levels, and thus the loss of organic material from the SAMs on gold in the initial stage (see Fig. 24). The significantly lower rates of material loss, which seem to govern the later stages of the radiation damage on gold films, and evidently the whole range of the irradiation of the SAMs on InP, may then be related to material loss from well-ordered areas. Radiation-induced cross linking of chains is another effect which may stabilize the organic layers against radiation-induced desorption. However, both the observed much faster and larger conversion of sulphur into the radiation-induced sulphur species on gold and the significantly larger increase of the S/C ratio as observed in the initial stage on gold films cannot be sufficiently explained by defect-site-related damage only. The increase of the S/C ratio has indicated partial destruction of the alkyl chains by bond scission, followed by desorption of separated hydrocarbons. Generally, bond breaking is due to vibronic or electronic excitations. In the present case, it is likely to be mostly due to rather localized electronic excitations. In particular, bond breaking in the alkyl chain is an intramolecular process, which is not expected to depend significantly on the substrate. Nevertheless, given the same types of adsorbed alkanethioles and the same photon flux, the larger increase of S/C on gold films indicates an influence of the substrate. We have demonstrated evidence for the importance of the low-energy electrons for the damage of the organic films. Völkel et al. [88] and our group now suggest that the observed difference in the development of S/C ratios may be due to a different number of secondaries originating from the X-ray excitation of the substrate, which may cause severe damage to the organic film. A higher number of secondaries from gold would also be in line with the observed faster chemical transformation of sulphur in the adsorbed alkanethiol layers on gold films, and is expected to contribute to the larger loss of organic material on this type of substrate too. Another important issue is that of the chemical nature and the adsorption geometry of the sulphur atoms of the adsorbed thiols. Our impact on that question remains limited because the XPS method may provide information on the chemical bonding, but it is only indirectly sensitive to structural sites via binding energy shifts. Nevertheless, by focusing on the radiation-induced changes, we have been able to present clear evidence for the disulphidic nature of the radiation-induced sulphur component, as previously suggested by Wirde et al. and Nuzzo et al. [78, 89]. This similarity of the radiation-induced peak to disulphidic or polysulphidic species may also be concluded by comparison to related adsorption studies of thiols and MBT on gold [31], and of several inorganic sulfur molecules on InP too [35–37]. Besides, from the analysis of the Auger data presented here, which included Auger parameters and the chemical state plot (Fig. 29), we have predicted that the radiation-induced sulphur is not strongly bonded to the gold substrate. From our experiments, the interpretation of the radiation-induced sulphur species as a dialkyl seems very unlikely. This problem is, however, linked to the ongoing discussion regarding the chemical nature of the sulphur species at the undamaged interface to gold. In Figure 30, we have sketched a few possible adsorption models, which emphasize the type of adsorbed species, but neglect any details of the local bonding geometries of sulphur on a gold surface. In contrast to the more generally assumed thiolate (RS–Au bonding, Fig. 30a) nature of the adsorbed thiols, there have been papers proposing the disulphidic nature of the adsorbed thiol layers (R–S–S–R bonding to Au via a disulphide group, Fig. 30b,c). These conclusions were derived from analysis of grazing incidence X-ray diffraction (GIXD [90]), X-ray standing wave (XSW [91]), and EELS [87] data

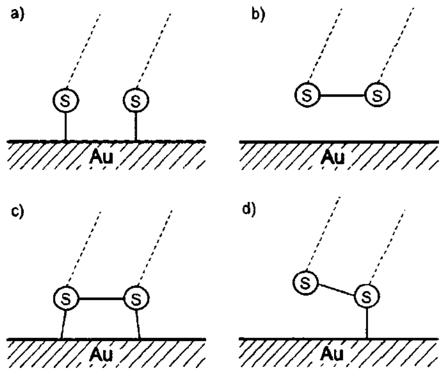

Figure 30. Schematic drawing of different possible bonding configurations of the thiol sulphur head groups: (a) thiolate bonding to the Au surface, (b) disulphide [stabilized above the Au surface by van der Waals forces (not shown)], (c) disulphide with additional dative bondings to the Au surface, (d) disulphide with one single dative bonding to the substrate (note the height offset between the two sulphur atoms). obtained on Au (111) single crystals. Fenter et al. suggested that two inequivalent, but spatially close sulphur adsorption sites exist on Au (111), which led them to the conclusion of disulphides being bound on the gold. It has been proposed that different adsorption sites on transition metal surfaces with different coordination numbers will reflect insignificant BE shifts in core-level photoelectron spectra of the sulphur [92]; similarly, a suggestion has been made that inequivalent sites of the disulphide–sulphur atoms on Au (111) should also manifest in such chemical shifts [90]. However, within the limits of our experimental resolution, we cannot find evidence for another sulphur species different from the initial sulphur species (called sulphide), except the radiation-induced one on our gold films after thiol-solution preparation. Note that disulphides have been detected together with thiolate sulphur in photoemission studies of adsorbed alkanethiols on transition metal surfaces, but these observations were mostly limited to low temperatures and low dosages of alkanethiols from the gas phase [93]. To our knowledge, no photoemission study has reported adsorbed disulphides to appear at the binding energies corresponding to our sulphide species. Thus, there is no direct evidence from photoemission which would support disulphide models, and a characterization of the sulphide at the undamaged surface as a thiolate as shown in Figure 30a is most reasonable. Consequently, the disulphide component appears as a result of the radiation-induced effects in the organic film only. Such a prediction for disulphides contradicts neither the long-term stability of the disulphide species observed in our study nor the well-known much higher adsorption probability of disulphides compared to thiols because the strong intermolecular interactions between the neighboring hydrocarbon chains, possibly accompanied by some bending of chains necessary to allow linking of the sulphur atoms in the covalent bonding, may stabilize the disulphide in the film while suppressing retransformation to thiolates. Upon the continuing influence of radiation, even the S–S bonds may be destroyed, and from the radicals, thiolates can be formed again. In this manner, we may explain the fact that the disulphide contribution to the total sulphur signal does not grow further beyond a maximum value (close to 50% in our investigations), and it only changes to a very minor amount at higher irradiation times.

On the other hand, Fenter et al. have ruled out a significant influence of radiation damage on their GIXD and XSW results, which favor disulphides on the gold surface. They estimated a much smaller damage cross section (about 1/100) for the higher energy X-ray photons used in their study compared to photoemission studies using Al K X-rays, based on the energy dependence of the photoionization cross sections of core levels. We have demonstrated evidence for the importance of electrons generated in the substrate, and thus the X-ray energy dependence of the total quantum yields from the substrates rather than a single core-level photoionization cross section, for example, C1*s* of the film, should much better represent the variation of the damage with energy. According to the photon-energy-dependent electron yields for gold determined by Henke et al. [94], the yield at 8–10 keV (GIXD) is only a factor 2–3 smaller than at 1.5 keV (XPS), while at about 3 keV (XSW), it is even larger by a factor 2 than at the energy of the Al K X-rays. We cannot reasonably judge the second argument raised by Fenter regarding the photon flux because the information on photon flux, and in particular on the irradiated area, is incomplete, and the experimental geometries to be compared are quite different. Nevertheless, we feel that the quantitative estimations by Fenter need some reevaluation.

Significant damage of alkanethiol SAMs by X-rays (10 keV) under vacuum conditions was observed on a time scale of 14 days by GIXD [90], which is actually not too far off the time scale of 4 days determined for the long-term damage of the SAMs of gold (and similarly on InP) in our XPS investigations, keeping in mind the differences in damage cross sections (see above) and the different sensitivity to structural damage of the methods. This discussion has demonstrated that, presently, the effects of radiation damage on the sulfur at the interface may not yet be ruled out completely. Further, Jäger et al. [79] also have posed additional questions regarding the possible effects of adsorption-induced gold surface atom redistribution at the interface to the predicted presence of disulphides. Such thiol-induced reconstructions have, in fact, been reported for Cu (111) [95]. On the contrary, our XPS data may not completely rule out all kind of disulphides on gold. A possible adsorbate of this type has been sketched in Figure 30c. Sulphur is known to form a large variety of bonding configurations with metals, for example, in complexes, including disulphide groups and dative bonds [96]. Upon the damaging influence of radiation, such an adsorbed species as assumed in Figure 30c might transform into disulphides with a complete breaking of bonds to the gold substrate as in Figure 30b or a partial breaking of the sulphur–gold bonding with one sulphur atom remaining closely bound to the gold surface, as assumed in Figure 30d. In the latter case, photoemission spectra would represent the two sulphur components at the energies corresponding to disulphides and to the initial sulphide component, as is, in fact, observed after a few hours of irradiation. This latter bonding situation (Fig. 30d) would also fit the stability of the damaged organic layer and the almost similar intensities of the radiation-induced and sulphide component observed after some hours. Again, there is no direct evidence for such an adsorption from photoemission, and these explanations remain speculative and have to be proven. To allow an appropriate comparison of the existing experimental results and the corresponding adsorption models, both substrates (single crystals versus films) and the preparation methods (vacuum deposition versus deposition from solution) have to be chosen consistently, which has not yet been done. There is evidently a need for methods which offer stronger links between the purely structural and the chemical bonding information than is provided by application of GIXD/XSW or XPS/XAES alone. Investigations on gold complex compounds have demonstrated that XANES might be very promising in this context [97].

Summarizing, we have investigated the damage of alkanethiol SAMs on deposited gold films and InP(110) by X-rays using XPS, XAES, and SEM. Both chemical and structural damage of the adsorbed alkanthioles were observed on either of these substrates. But much stronger and faster development of the damage in the organic monolayers was observed on gold films compared to InP. This has been interpreted in terms of a higher defect density and

larger effects of X-ray-generated electrons from the substrate on the organic layers in the case of gold. The importance of low-energy electrons for the damage and patterning of the layers has been emphasized. A radiation-induced new sulphur component has been clearly attributed to have a disulphide character using both binding and Auger energies. During the discussion, we have found more arguments supporting a thiolate-type SAM compared to disulphide models on gold.

In the preceding, we have focused on the molecular mechanisms of ionizing radiation. In order to use X-rays or electrons for structuring, it is not necessary to understand the underlying reactions. Electrons can be used directly to remove small parts of self-assembled monolayers, as shown before in the pattern "PCI." The drawback of this method is the very time-consuming sequential writing of the pattern which makes this method very highly prized and not suitable for mass production. Using X-rays instead requires a partial opaque mask. This mask needs to be transparent to X-rays, where parts of the SAM need to be removed and vice versa. The production of such a mask needs an additional type of lithography, for example, electron beams. The second drawback of both methods is that the irradiated parts are not completely free from covering molecules. This can be seen from our detailed spectroscopic investigation at the beginning of this paragraph. These remaining molecules can be removed by heating the sample in UHV [69] or electrochemical methods ([98] and Section 3.2).

Further related methods use UV light [99–102], near-UV light [103], visible light [104], and ion beams [105] for the photolithography of alkanethiol monolayers.

4.2. Scanning Probes

In the preceding section, we already demonstrated two different techniques for lateral structuring a molecule-covered surface. One of the most obvious ideas to write small structures into a self-assembled monolayer is to use scanning probe techniques like STM, AFM, or SECM.

An STM allows us to write structures by applying voltage pulses to the conducting tip while scanning. If the voltage is chosen high enough, small parts of the self-assembled monolayer are removed [22, 56–61, 88]. The voltage needs to surpass a certain threshold, which is typically in the range of 5–10 V, depending on the substrate–adsorbate combination. In order to demonstrate these technique, we have applied a voltage of 20 V at high currents (10 nA), and therefore near distances, while scanning a dodecanethiol layer on InP(110). The result is depicted in Figure 31. A 15 nm wide straight groove is shown, which is confined by sharp edges. The advantage of the technique is its very high resolution; its disadvantage is the low speed of writing, which is orders of magnitude slower than even *e*-beam lithography. An AFM can be used to literally scratch grooves into a monolayer [61]. Its advantage is that it allows structuring and scanning of topography of even thick nonconducting organic coatings due to the characteristics of its measurement principle. It should be mentioned that, instead of scratching the structures into the films, it could be used parallel to the STM technique if the AFM tip is coated with a metal and is correspondingly connected to a voltage source.

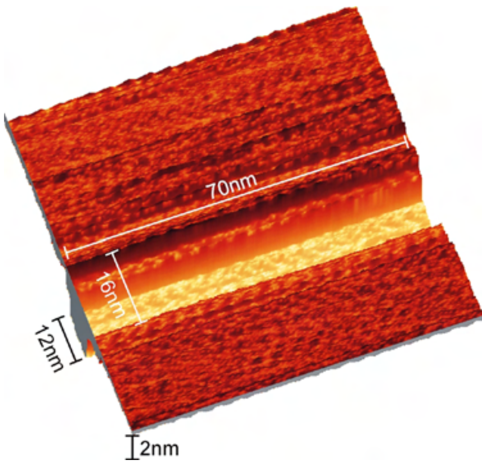

Figure 31. STM-nanostructured dodecanethiol monolayer on InP (110). $U = 20$ V; $I = 10$ nA.

The last microprobe technique which will be mentioned here is the SECM. Contrary to the STM technique, an ultramicroelectrode, a typically on its end flat-polished very thin Au or Pt wire which is coated by a nonconducting glass capillary, poses as a probe. The electrochemical technique is sensitive to redox reactions, and can also be used to deposit organics [98].

4.3. Microcontact Printing and Related Techniques

Microcontact printing (μPC) and related techniques use an old idea which has its roots in the late middle ages. Around the year 1444, Gutenberg invented the idea of using stamps for the purpose of typography. More than 500 years later, Kumar and Whitesides rediscovered this technique (with some changes) in order to transfer microstructured patterns of monolayers on surfaces [106].

The principle of microcontact printing is surprisingly easy. With the help of an elastic stamp of PDMS which is wetted by a self-assembling species, the pattern is transferred to the surface by contact. The technique allows different self-assembling species to be transferred by simply consecutively repeating the procedure with different stamps. Kumar and Whitesides where the first to invent this technique, using the system alkanethiolates on gold [106].

The greatest advantage of this method is its high speed, transferring one whole structure in one single fast stamping.

The time which is needed to obtain a highly ordered SAM from a 10 mM concentrated dodecanethiol in ethanol solution was investigated by Biebuyck et al., and was found to be as short as 0.3 s on Au (111) [21]. The typical time for a 2 mM concentrated HDT solution is between 10–20 s [107–109].

This ability makes the technique especially interesting for industrial applications. Microcontact printing is not the only method of "stamping" the pattern onto a substrate surface. In the following, we will list some further techniques with brief explanations in order to shed some light on the zoo of different techniques.

- Replica molding (REM): This technique deviates from conventional techniques by using a flexible (PDMS) mold. Its elasticity and small surface tension allow for easy removal of the mold after the process is completed The mold itself is produced by high resolving scanning electron lithography [110, 111].
- Microtransfer molding (μTM): The structured surface of a PDMS mold is coated with an appropriate polymer. Afterwards, the excess, which is everything above the mold surface, is removed. The advantage of this method is that nonplane surfaces can be coated, and the consecutive construction of complex three-dimensional structures is possible [112].
- Micromolding in capillaries (MIMIC): Here, the mold comes into contact with the surface first. The polymer (low viscosity) is distributed through the empty channels of the mold via capillary forces [113]. This technique is also very useful for nonplane surfaces, but it cannot produce isolated structures.
- Solvent-assisted micromolding (SAMIM): The last technique briefly described here is SAMIM, which can be seen as a combination of REM and imprinting. A PDMS mold is wetted with a dissolved polymer. After the mold is pressed onto the surface, the solvent dries out, the mold is removed, and the remaining polymer forms the desired structure [114].

This was only a very brief excursion on the topic of stamping. The author has ignored several variations of stamping techniques, as well as other techniques like laser ablation or inkjet printing because the discussion on the topic of lithography is a review of its own. Instead, we refer to the review on soft lithography of Xia and Whitesides [115] and citations therein.

4.4. Consecutive Chemical Reactions

In this last section on structuring, we will investigate the possibilities of creating mixed thiol films, consisting of two structurally and chemically very different thiol species. We will use the aliphatic hexadecanethiol and the aromatic 2–mercaptobenzothiazol (MBT). The competing interaction of both species after successive adsorption on gold is investigated using XPS.

The ability to produce mixed thiol films on surfaces, consisting of molecules with different electronic and chemical properties and combined with structuring in the nanometer scale, however, may lead to additional possibilities of application. Therefore, it is of interest to investigate the behavior of layers of aromatic thiols in comparison to layers formed by alkanethiols. MBT, known to form hydrophobic complexes with many metals, and therefore used as a corrosion inhibitor or a collector for mineral flotation [116, 117], was chosen for the studies presented here. Beside its aromatic character, MBT contains a nitrogen atom, which acts as an additional ligator atom in a chelate-type bonding at the surface, and can be used as tracer atom for identification of the adsorbed species. In connection to the experiments described above, the interaction between alkanethiols and hydrocarbon contamination, produced by sample transfer in air, was investigated. Because of the similarity of the behavior, it seems to be meaningful to discuss them in this context.

The preparation of the samples was described in detail in Section 2. The hexadecanethiol layer (Fluka, 95%) was prepared in a 10^{-3} M solution in isooctane (Merck, Supra-Solv, for organic trace analysis). The adsorption of MBT was carried out in a 10^{-4} M aqueous solution. After an immersion time of 30 min, the samples were rinsed with fresh solvent, dried under a nitrogen stream, and inserted into the spectrometer immediately. The X-ray photoelectron spectra were recorded with a VG ESCALAB 220i XL instrument irradiating the samples with monochromatized AlKa radiation (220 W, 22 mA, 10 kV). Spectra were recorded in normal emission and with angular averaging mode (XL lens), if not stated otherwise. The energy resolution was 0.45 eV. The spectra were fitted by a least squares procedure with a model of the peak shape (Gaussian–Lorentzian convoluted functions) after background subtraction from experimental data using a Shirley-type function. Binding energies are referred to Au4f (84.0 eV).

If a freshly produced gold film is treated with 10^{-4} M MBT solution, an S2p spectrum is recorded, as shown in Figure 32a. Two clearly separated components are found, representing the two differently bound sulphur atoms of the MBT molecule (Fig. 32a). The adsorption of MBT leads to deprotonation of most molecules, confirmed by the main component in the N1s spectrum with the binding energy of 399.0 eV, in comparison to the component of the not deprotonated molecules at 400.6 eV (Fig. 33a). Therefore, the low-energy component in the S2p spectrum (162.3 eV) can be attributed to the exocyclic sulphur of deprotonated and chemisorbed MBT. The second doublet at 163.9 eV is caused by the endocyclic sulphur. A partial oxidation of MBT to products containing sulphur–sulphur bonds like 2,2′–dithiobis(benzothiazole) is responsible for the deviation of the expected intensity ratio of 1:1 [31, 117, 118]. Both types of sulphur atoms in BBTD have nearly the same

ground state potential as the endocyclic sulphur in MBT, and cannot be distinguished by their binding energies [118]. After treatment of the MBT-covered sample in pure isooctane for 30 min, no significant changes in the S2*p* and N1*s* spectra were observed (Figs. 32b and 33b), thus excluding any effects caused by this solvent. Only the C1*s* spectrum (Fig. 34b) shows a decrease of the intensity of the signal assigned to aliphatic C–H bonds against the component caused by the aromatic rest, indicating a displacement of hydrocarbon contamination by isooctane. Next, the samples have been treated in an isooctane/hexadecanethiol solution (see Section 3). The changes in the spectra are remarkable. Figure 33c shows the complete absence of nitrogen on the sample surface. This can only be explained by supposing that MBT has been totally removed by the alkanethiol. This conclusion is supported by the S2*p* and C1*s* spectra in Figures 32c and 34c, respectively. These have changed to the typical signals expected for a monolayer of hexadecanethiol on gold. The C1*s* peak shows only one component, belonging to the alkane chain. The S2*p* reveals the typical two doublets for an alkanethiol. The first component at 162.1 eV belongs to the sulphide, which is responsible for the sulphur–gold bonding. The second and less intensive component (163.8 eV) is from disulphide groups. The generation of disulphide in alkanethiol monolayers may arise from air oxidation, but also from the effect of X-rays or electron irradiation. Extended investigations concerning these effects with different energies and intensities on alkanethiol monolayers have been carried out and will be published next. The data in Figures 32d, 33d, and 34d were obtained by exposing the already established alkanethiol film to an aqueous solution of MBT. In contrast to the reversed procedure described above, the surface remains completely covered with hexadecanethiol. Obviously, the adsorbed alkanethiol molecules are resistant against an MBT-containing solution because of the stabilizing effect of the hydrocarbon chain interaction that predominates with respect to the chelating effect of the MBT structure. Consistent with this phenomenon, the MBT adsorbate is completely removed from the gold surface by the hexadecanethiol-containing solution. A similar process to the replacement of the MBT layer by the hexadecanethiol has also been found for the hydrocarbon contamination mentioned at the beginning of this text. In [31], the removal of contamination from a gold surface after the sample has been dipped into a hexadecanethiol solution is demonstrated. The first spectrum shows carbon contamination (C–H and C–O bonds), which was due to exposing the sample to the atmosphere for several days. After a treatment in hexadecanethiol solution for 30 min, additional features of the alkane–carbon appear. The unchanged intensity of the contamination signal gives rise to the assumption that the removal of the carbon does not start until other adsorption sites have been occupied by the thiols. A further treatment for 90 min (total 2 h) removes the contamination and enhances the alkane signal. The last stage shows that an extended treatment (total 16 h) only slightly raises the intensity of the C1*s* signal, indicating a saturation of thiol adsorption with increasing density of the ordered layer. Summarizing, we have confirmed previous results on the ability of thiols to remove organic molecules from gold. In particular, by comparing the bonding of hexadecanethiol and MBT, we have been able to demonstrate that the specific binding of the thiol layers permits stronger bonding to gold, even in relation to other sulphur-containing molecules. This stabilization of a hexadecanethiol layer on a gold surface is believed to be strongly supported by hydrocarbon chain interaction, which is the well-known reason for the self-assembly. This enables the preparation of mixed films.

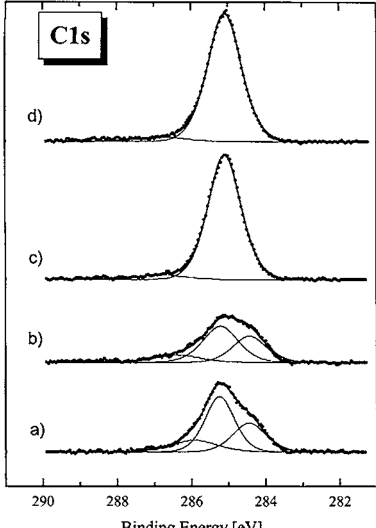

Figure 34. C1*s* spectra after successive treatment of an Au surface with: (a) MBT solution, (b) isooctane, (c) hexadecanethiol solution, and (d) MBT solution. Reprinted with permission from [31], D. Zerulla et al., *Surf. Sci.* 402–404, 604 (1998). © 1998, Elsevier Science.

Starting with a partially covering alkanethiol layer, produced, for example, by stamping the alkanethiol to the surface (see Section 4.3) [21], by different kinds of writing

procedures or with the help of AFM/STM structuring (see Sections 4.1, 4.2) [22, 23], the free parts of the substrate can be covered subsequently with MBT by simply dipping the sample into an MBT solution, leaving the alkanethiol layer structurally undisturbed.

We found that hexadecanethiol displaces the MBT from gold surfaces, similar to the removal of carbon contamination by the alkanethiol. In contrast, MBT cannot replace the adsorbed alkanethiol layer. Therefore, the creation of mixed films has to start with a partial coverage of hexadecanethiol, followed by the MBT, which now can assemble to the uncovered surface without disturbing the alkanethiol.

5. MISCELLANEOUS SELF-ASSEMBLING SYSTEMS

While most of this chapter was focused on alkanethiols as self-assembling species, we will briefly describe further types of molecules which will also self-assemble on semiconductor surfaces.

First, there is the class of functionalized thiols which also consist of a sulphur head group and an alkyl chain, but the terminating group differs from the usual $-CH_3$ group. As long as the terminating group is small in size and does not bind to the semiconductor, we expect the same result as shown in this review. If the terminating group does bind to the substrate, we not only get reversed bounded molecules, but also loops where the head and the terminating group are bounded to the substrate [64]. Instead of exchanging the terminating group, one can change the head group which is responsible for the substrate–molecule binding. Instead of the thiol (–SH) group, sulphonic and phosphorus groups have been used. The choice of the head group should be made with respect to the substrate used. Thiols bind very well on coinage metals (Au, Ag, Cu) and III–V semiconductors, while sulphonic and phosphorus groups bind to oxidized metal surfaces, for example, Al (see Table 1). In the case of the technologically very important Si [42–49], the best choice is to use alkyltricholorosilanes, which give high-quality self-assembled monolayers on this substrate [38–41].

One of the many goals in using SAMs for technological applications is to construct assays for biological and medical sensors. This can be done in two ways. The first is to use well-known self-assembling species as building blocks in the construction of these assays. They may be used as spacers, to specifically bind biomolecules or as a structure-defining substrate themselves [119]. Second, some of the biological species can be used as self-assembling monolayers themselves. One example is the amino acid cysteine, which is able to bind on III–V semiconductor surfaces as well as on coinage metals by its sulphur side group [64]. However, this kind of molecule does not deliver highly ordered monolayers due to two facts. Its chain length is not large enough to have enough van der Waals interactions between neighboring molecules; therefore, one of the most important forces in self-assembly is too weak. Furthermore, it not only can bind with the sulphur, but also with the carboxyl group to most substrates. The result is a nearly unordered monolayer with only weak passivating properties compared to alkanethiols [64].

Table 2. References of semiconductor–SAM combinations in literature.

Substrate	Adsorbate(s)	Author(s)	Ref.
Si(100)	Alkyltrichlorosilane (docosyltrichlorosilane, octyltrichlorosilane)	Nuzzo, Chidsey, Grunze	[38–41, 123]
GaAs	Alkanethiols	Allara	[121–122]
InP(100)	Allkanethiols	Gu Waldeck	[25]
InP(110)	Alkanethiols, mercaptobenzothiazole	Zerulla	[53, 64, 66 67, 75]
GaP(110)	Alkanethiols	Zerulla Chassé	[67]
CdS (1010)	Mercaptobenzothiazole	Mayer Szargan	[75, 124]
PbS, FeS_2	Thiols	Schaufuß, Szargan	[118]

In general, all species that fulfill the following simple rules are likely to form highly ordered self-assembling monolayers:

- a chain length >6 (best: 12–24) [120]
- only one group which binds to the substrate
- the space requirements of the molecules are smaller than the lattice constants of the substrates (more precisely, the distance between binding sites on the substrate).

Of course, these rules ignore complicated molecule–molecule and molecule–substrate interactions, but will suffice in most cases. A compilation of references of semiconductor–SAM combinations in the literature is shown in Table 2. Note that the number of investigations of SAMs on semiconductors is by far lower than on coinage metals. A more detailed treatment, including structure and electronic properties, can be found in Section 4.

6. CONCLUSION

The self-assembly of thiols and related molecules on semiconductors leads to highly ordered systems. Independent of the preparation technique (solution/evaporation), it results in stable, passivating monolayers. For the example of alkanethiols on InP(110), proof is given that the self-assembly leads to single-domain systems with exceptional order. Furthermore, different techniques have been presented which may be used to write structures into the self-assembled monolayers on nanometer scales.

Additionally, even the possibility of constructing monolayers from different self-assembling species was demonstrated. Comparing the results on semiconductor (110) surfaces with those on Au (111), we can conclude that the ease of preparation, passivating properties, and structure are similar. Moreover, it can be stated that the perfection of the adsorbed monolayers is even higher on the semiconductor (110) surfaces than on gold, at least regarding InP (110).

As a future prospect, we suggest using the combination of thiols and a III–V (110) surface in order to construct nanodevices with specifically tailored properties.

GLOSSARY

Chemical vapor deposition (CVD) Technique used to deposit coatings, where chemicals are first vaporized, and then applied using an inert carrier gas such as nitrogen.

Langmuir–Blodgett Name of a nanofabrication technique used to create ultrathin films (monolayers and isolated molecular layers), the end result of which is called a "Langmuir–Blodgett film."

Nanoimprinting Sometimes called soft lithography. A technique that is very simple in concept, and totally analogous to traditional mold- or form-based printing technology, but that uses molds (masters) with nanoscale features. As with the printing press, the potential for mass production is clear. There are two forms of nanoimprinting: one that uses pressure to make indentations in the form of the mold on a surface, and the other, more akin to the printing press, that relies on the application of "ink" applied to the mold to stamp a pattern on a surface. Other techniques such as etching may then follow.

Nanolithography Writing on the nanoscale. From the Greek words nanos—dwarf, lithos—rock, and grapho—to write, this word literally means "small writing on rocks."

OLED or organic LED Not made of semiconductors. It is made from carbon-based molecules. That is the key science factor that leads to potentially eliminating LED's biggest drawback—size. The carbon-based molecules are much smaller.

Self-assembly In chemical solutions, self-assembly (also called Brownian assembly) results from the random motion of molecules and the affinity of their binding sites for one another. Also refers to the joining of complementary surfaces in nanomolecular interaction.

1. INTRODUCTION

Human history has been famously subdivided into distinct ages of materials. Indeed, the progress of scientific sophistication has been tightly linked to the nature of the materials that were predominant in the different eras. The Stone Age, for example, represented the earliest of human ingenuity, when our primitive ancestors created and improved simple tools out of natural rocks. Subsequent Bronze and Iron Ages revealed increased technological savvy as tools and equipments were made from extracted and processed materials. In the "Plastic Age," mankind perfected the science of organic synthesis; and recently, the "Silicon Age" has yielded unprecedented progress in extremely complex electrical devices. In the future, each of these materials will most likely occupy its own niche such that no new material will completely render the previous ones obsolete. However, it can be argued that further progress in particular fields such as regenerative medicine [1], engineering [2, 3], and recently nanotechnology [4] will benefit tremendously from the discovery and development of novel, designed, and integrated materials.

Throughout these ages, scientists have searched for lighter, stronger, more energy-efficient, and in recent times, smaller materials. Materials found in nature in these respects have continued to awe us with their versatility and superiority. The spider silk microfiber, for example, is tougher than steel or Kevlar [5] per unit weight. The male moth antenna can detect a single pheromone molecule secreted by a female over great distances [6], putting current biosensing technology to shame. Breakthroughs in molecular biology and biophysics are starting to give us a glimpse of the molecular basis for these behaviors, and we are starting to learn the basic rules for the organization of biological macromolecules such as proteins, deoxyribonucleic acids (DNA), and ribonucleic acids (RNA) that confer such phenomenal attributes.

Biologists and material scientists are not only interested in the scientific underlying of these natural materials but also in their mimicry and utilization for different applications [7]. Even though spider silk or a moth antenna is currently too difficult to mimic, we have come to realize that biological materials, in general, may have superior qualities over man-made ones for certain applications. Furthermore, any research into biomaterials has benefited from decades of improvements in the chemical synthesis methods of biopolymers, not to mention a wealth of data generated from basic research. Designed peptide molecules, for example, can be synthesized rapidly and analyzed using standard techniques for studying protein structure such as circular dichroism, electron microscopy (EM), and nuclear magnetic resonance (NMR).

A subset of biological materials is the subject of this entry, and all of the members of this set share the same enabling property: they are formed through the self-assembly of particular motifs of biological polymers. Spontaneous associations of diverse molecules into a distinct supramolecular assembly is ubiquitous in biology: for example, the eubacterial ribosome consists of more than 50 proteins and three ribosomal ribonucleic acid molecules that self-organize into a molecular machinery which can perform complex reactions that synthesize proteins [8]. Such nanoscale organizations occur without human instructions or interference, resulting in the formation of structures with little energy expenditure [9].

We will first present the case of self-assembling peptides and describe how researchers have used these systems to create different materials for applications such as mineralization, formation of nanowires, anti-microbial agents, and growth of tissues. We will then focus on DNA molecules that have been utilized as templates for metallization and

Volume 9: Pages (459–471)

engineered to form crystalline structures. Last, we will summarize the use of larger biological entities: bacterial viruses that allow inorganic metal ions to self-assemble on their surfaces. While practically all of these materials are still in their infancy, the promise of biologically inspired materials has galvanized some researchers to study and improve them vigorously. It is our hope that this entry will show the vast promise that biologically inspired materials have on the advancement of many nano-engineering and medical disciplines.

2. PEPTIDE SYSTEMS

2.1. Introduction to Peptides

Peptides and proteins are biopolymers that are the workhorses of the cell. Their functions are as various as their structures, most playing the roles of enzymes that accelerate reaction rates, membrane proteins that act as channels and molecular transporters, while others act as the structural components which enable a cell to hold its shape and to move about. Each is a polymer that is made up of a linear combination of amino acids (Figures 1A and 1B) and can vary in length between a few to tens of amino acids (also called "residues" in the vernacular of biology) in the case of signaling peptides to ten thousand long in a membrane protein of a human cell [10]. This structural versatility of proteins is afforded by the vastness of the amino acid alphabet.

There are 20 naturally occurring amino acids to choose from so that for a 10-amino-acid-long peptide, nature has the option of making 20^{10} (approximately 10 trillion) different species. The peptides and proteins that are found in nature, however, have been selected through billions of years of evolution so that what is left is a miniscule subset of all the possible sequences. These are the proteins whose amino acid sequences give distinct three-dimensional structures or folds so that they can perform tasks in an extremely specific and efficient manner. Indeed, the structure of a protein is the chief reason for its function, and it has been the holy grail of structural biology to predict the three-dimensional structure of a protein from its amino acid sequence.

In essence, biomaterial and nanoscale scientists want to do just the reverse: knowing a desired structure, can he or she design a sequence that can self-assemble to form it? Even though our knowledge of how linear protein molecules fold into higher order structures is still rather rudimentary, the basic principles that we have learned so far have enabled researchers in biological materials to design peptide systems which have already shown considerable promise for a broad range of applications.

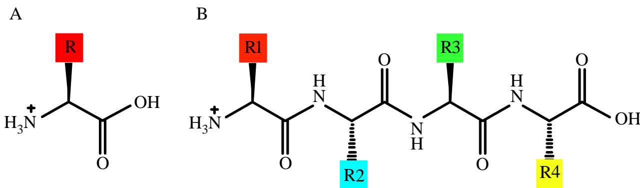

Figure 1. (A) Chemical structure of an amino acid. The side chain, labeled "R" here, can be any one of the 20 naturally occurring amino acids or their derivatives; (B) a four residue (amino acid) peptide. Each peptide is covalently linked to the adjacent one through a peptide amide bond.

2.2. Peptides That Self-Assemble Into Fibers for Biomineralization

Hartgerink et al. reported the rational design [11] and application of a peptide-amphiphilic molecule in a biomineralization process that is akin to the collagen fibers in bone tissue [12]. This lowest structural level in bone is already rather complex, since it involves the integration of an organic protein component with an inorganic, hydroxyapatite (HA) crystal component. Furthermore, the crystals grow in a particular orientation within the collagen fibrils, with their unit cell *c* axis parallel to the long axis of the fibrils [13]. Certainly, any biomaterial that has the potential to replace bone tissue at this level must have similar properties.

Hartgerink et al. synthesized a peptide molecule with a 16-carbon alkyl tail (Figure 2A). The hydrophobicity of the tail and the conical shape of the polymer would drive the self-assembly into cylindrical micelles [14] (Figure 2B). The peptide itself contained amino acids that were deemed to be crucial for particular functions: a string of cysteine residues following the alkyl chain would form intermolecular disulfide bridges, which would confer structural integrity for the self-assembled nanofibers; a linker group made up of glycine residues provided structural flexibility; a phosphoserine residue promoted the nucleation of HA crystals; and an

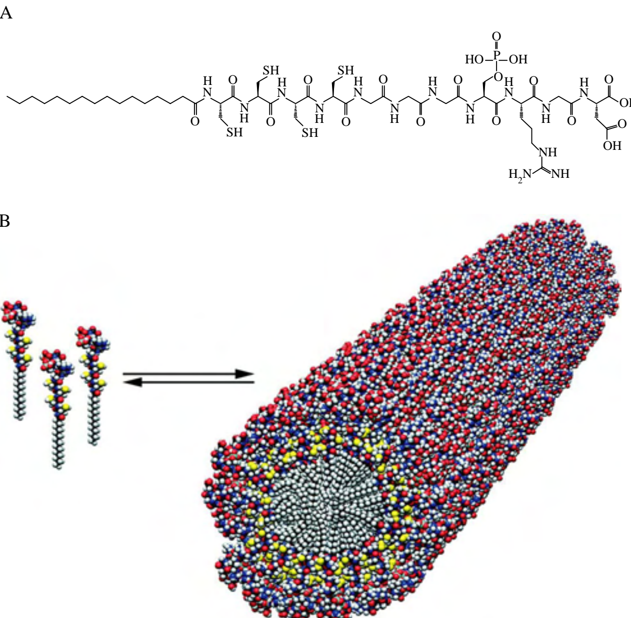

Figure 2. (A) Peptide amphiphile synthesized by Hartgerink et al. for use in biomineralization of hydroxyapatite crystals [11, 12]; (B) the self-assembly of this peptide amphiphile molecule into a cylindrical micelle. The peptide is diagrammed as a van der Waals space-filling model. Reprinted with permission from [12], J. D. Hartgerink et al., *Science* 294, 1684 (2001). (©) 2001, American Association for the Advancement of Science.

RGD sequence motif, which capped the peptide, promoted cell adhesion.

They discovered the assembly of cylindrical micelles under acidic conditions and disassembly in alkaline ones. Cross-linking of the cysteine residues through air oxidation further stabilized the assembled nanostructures. The ability to assemble or disassemble supramolecular assemblies selectively under controlled conditions is beneficial when making new materials since it allows for reversibility of any undesired structures. Further experiments also revealed that the nanofibers have the potential to nucleate HA crystals in the correct orientation. This promising result highlighted the possibility of using biomolecules or their derivatives in making novel materials for medicine and tissue repair and regeneration.

2.3. Peptides That Form Tubes and Vesicles

2.3.1. Short Amphiphilic Peptides

Ideally, the biopolymer constituents used for self-assembly into materials should be rather inexpensive to synthesize in large quantities, easy to handle, and chemically uncomplicated so analysis and modeling can be performed with a reasonable amount of effort. Our laboratory has designed a simple peptide system having those properties [15, 16]. We made short peptides of around six to seven amino acids that had the properties of surfactant molecules in that each monomer contained a polar and a nonpolar region. For example, a peptide called A_6D had six hydrophobic alanine amino acids followed by one polar, negatively charged aspartic acid (Figure 3A). In essence, the molecule looked like a biological phospholipid in that it had a polar head group and a nonpolar tail.

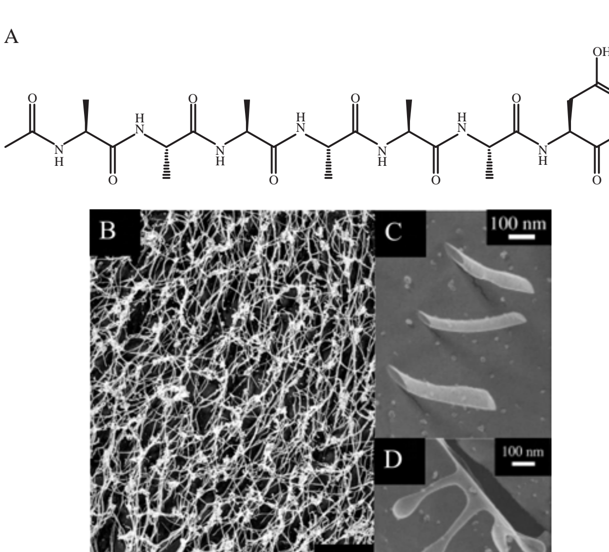

Figure 3. (A) Short surfactant-like peptide A_6D, consisting of six hydrophobic alanine amino acids followed by one negatively charged aspartic acid. (B) The nanotubes formed when this peptide was resuspended in water at pH 7. (C) Picture of V_6D peptide solution showing the presence of tubular structures. (D) V_6D solution showing vesicles budding out.

Dynamic light-scattering experiments on such small peptides in aqueous solution revealed the presence of a uniform assembly that was substantially larger than the size of individual monomers. The homogeneity and size of the supramolecular assembly were sequence-sensitive: peptides of the same length behaved differently when they had different polar head or hydrophobic tail sequences. Such phenomena have been described theoretically and experimentally in other amphiphilic systems. The shape and size of the assemblies are ultimately dependent on the size and geometry of their constituents [14].

In order to visualize the structures in solution, we utilized the transmission electron microscope (TEM). We used the quick-freeze/deep-etch method for sample preparation [17] to preserve the structures that formed in solution for electron microscopy. Each peptide solution was flash-frozen in liquid propane to prevent the formation of ice crystals. One hundred nanometers of vitreous ice were then sublimed, and the sample was coated with a 1-nm-thick platinum layer and a 20-nm-thick carbon coating and visualized using the TEM.

We observed discrete nanotubes and vesicles in the samples that gave homogeneous size distribution in the dynamic light scattering experiment (Figures 3B and 3C). Those samples that were polydispersed tended to give irregular membranous layers. The nanotubes that formed had an average diameter of around 30 nanometers as examined by TEM, consistent with results obtained from the dynamic light scattering. We also observed vesicles budding out of or fusing into a nanotube, suggesting the existence of a dynamic behavior between the different structures in the surfactant peptide system (Figure 3D).

These nanotubes have the potential to act as templates for metallization and formation of nanowires. Furthermore, the nanovesicles may be useful as an encapsulating system for drug delivery. Chemical modification of the peptide monomer may expand the function of these structures: for example, a specific cell-surface ligand can be directly incorporated into a vesicle for targeted delivery of insoluble drugs to particular cells. Current research focuses on these applications, along with more detailed structural studies and modeling of the nanostructures.

2.3.2. Cyclical Peptides with Alternating D- and L-Amino Acids

A prime example of how researchers have applied structural information of biomolecules into designing and characterizing a novel nanobiomaterial is the recent development of nanotube arrays made from cyclic peptides. The concept was first proposed by Hassal in 1972 [18] but has only recently been realized. Through several elegant experiments, Ghadiri et al. have shown that cyclic hexa- and octa-peptides with alternating D- and L-enantiomers of amino acids can regularly stack in an anti-parallel fashion to form very regular nanotube arrays, similar to hollow disks that form long cylinders [19] (Figures 4A and 4B). More importantly, the nanotubes were formed by self-assembly of the peptide disks under particular conditions, which depended on the sequences of the peptides. For example, the initial experiment involved the octa-peptide *cyclo*[-(D-Ala-Glu-D-Ala-Gln)$_2$-], a ring that contained the

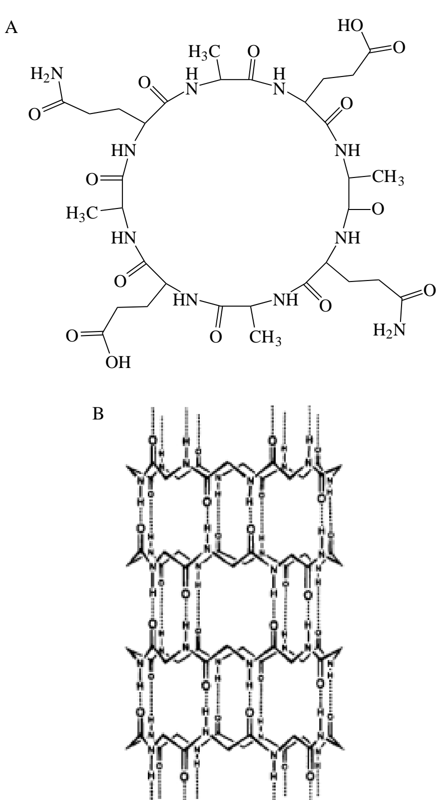

Figure 4. (A) Top-view of a *cyclo*[-(D-Ala-Glu-D-Ala-Gln)$_2$-] monomer, a cyclic peptide with alternating D- and L-amino acids [19]. (B) The structure of the nanotube formed by the antiparallel stacking of the cyclic peptide disks [30]. The dotted lines depict hydrogen bonding between the amide nitrogen of one disk to the amide oxygen of an adjacent disk. Reprinted with permission from [30], M. Engels et al., *J. Am. Chem. Soc.* 117, 9151 (1995). © 1995, American Chemical Society.

hydrophobic D-amino acid alanine (Ala), interspaced with either a negatively charged glutamic acid (Glu) or the polar glutamine (Gln) (Figure 4A). At neutral or alkaline pH, the glutamic acids were effectively deprotonated, and self-assembly was inhibited by electrostatic repulsion of these side chains. At lower pH values, however, the glutamic acids became protonated, the negative charges disappeared, and self-assembly occurred. Such selectivity in initiating assembly adds an important level of control for handling these nanostructures.

This cyclic peptide system has several other important properties: first, the diameter of the pore of the nanotube has the potential to be easily adjustable by changing the diameter of the peptide disk, although eight amino acid-residue peptides may be energetically preferred [20]. Second, due to the geometrical constraints imposed by the alternating amino acid enantiomers, the variable side chains of the amino acids project away from the side of the nanotubes. This is important for added functionality of the system and also for incorporation of the nanotubes into a lipid layer or a hydrophobic self-assembled monolayer (SAM).

One aspect that Ghadiri et al. investigated was the ability of these nanotubes to allow ions [21], small molecules such as glucose [22] and glutamate [23], and metal complexes of various sizes [24] to traverse passively. With an expected pore size of 7.5 angstroms for the eight-residue peptide, ions, small organic molecules, and small metal complexes such as $K_3[Fe(CN)_6]$ and $[Ru(NH_3)_6]Cl_3$ should diffuse through, while the passage of the larger $K_4[Mo(CN)_8]$ should be hindered. For these studies, they incorporated the peptide nanotubes inside a nonpolar lipid environment [25], either in a unilamellar vesicle system or an organosulfur monolayer on gold substrates. The system allowed for a more rapid diffusion of ions than some natural systems such as gramicidin A and amphotericin B. Cyclic voltammogram experiments also revealed the size selectivity of the nanotubes. These results showed that the nanobiomaterial can serve in many applications as synthetic ion channels or as sensors for chemicals of a particular size [26, 27].

By systematically changing the sequence of the residues of the octa-peptide, Fernandez-Lopez et al. have also identified peptides that show antibacterial activity [28]. The peptide nanotube presumably increased the permeability and disrupted the integrity of the bacterial cell membrane. The sequence of the peptide affected the efficiency at which it killed a particular strain of bacteria, most likely because of specific interactions between the peptide side-chains with unique components that exist on the bacterial cell surface. This property is beneficial since inert or useful bacteria inside the body will be spared while pathogenic ones can be specifically targeted. Moreover, the peptides exerted no detrimental effects on mammalian cells, increasing their prospects to serve as antibacterial drugs.

Clark et al., in Ghadiri's laboratory, expanded the system to include nonnatural, β^3-amino acids [29]. Through molecular modeling, the researchers proposed that these cyclic monomers should hydrogen-bond in a parallel manner to form stacked rings similar to the D, L-amino acid system. Furthermore, nanotubes made from cyclical β^3-amino acids are expected to have a dipole moment along their lengths, which may facilitate transport of charged species.

The distinct physical parameters of the nanotubes enabled theorists and computer scientists to perform molecular dynamic studies and *ab initio* calculations of their electronic and molecular structures [30–32]. All calculations have benefited tremendously not only from previous measurements of bond angles and bond lengths of peptide molecules but also from the development of molecular dynamic software for biomacromolecules such as CHARMM [33]. Designing biologically inspired materials is facilitated by these rapid developments in molecular biology and biophysics.

2.3.3. Bolaamphiphilic Peptides

Bolaamphiphiles are amphiphilic molecules that have two hydrophilic ends joined by a hydrophobic segment. Matsui et al. investigated a peptide bolaamphiphile molecule that assembled into a nanotube at acidic pH [34]. The polymer, a bolaamphiphile that contained two glycine residues at each end and a heptane moiety at the center (Figure 5A), self-assembled into a helical ribbon at alkaline pH (Figure 5B), presumably due to the lengthening of hydrogen bonds between the carboxylic acid groups [35].

The nanotube formed was then modified in various ways. Reduction of the nanotube in nickel and copper baths yielded metal-amide complexes that may be used as nanowires in

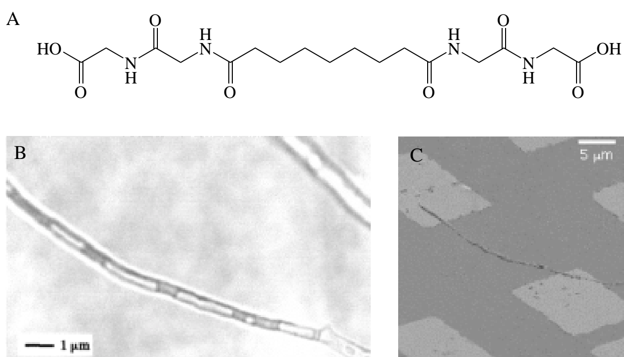

Figure 5. (A) Glycylglycine bolaamphiphile containing two glycine residues at both ends and a hydrophobic heptane group joining them [35]. (B) Tubule formed by the bolaamphiphilic molecule at pH 4. Lett.* 1, 461 (2001). © 2001, American Chemical Society.

electrical circuits [36]. Interestingly, no metal-amide complex formed when the self-assembled structure was in the helical form, where all amide groups were hydrogen-bonded to one another. This suggested that amide hydrogen bonds are required for the formation of the complex, and that metallization will be unique to the nanotube state of this peptide system.

Nanotube immobilization on surfaces had also been achieved under two different conditions. The first condition was via hydrogen bonding to a SAM on gold surfaces [37]. The nanotube was then metallized using the aforementioned technique. The second immobilization was through specific avidin-biotin interactions [38, 39]. The nanotube was initially coated with the protein avidin, and the complex was immobilized on biotinylated SAMs. A scanning electron micrograph showed that the peptide nanotube was immobilized between two gold contacts (Figure 5C).

The experiments mentioned above are preliminary steps toward the use of biological nanotubes as construction scaffolds for nano-electronics. However, many issues remain to be resolved, such as sample heterogeneity and the effective conductivity of the metal-nanotube complex.

2.4. Peptides That Form 3D Scaffold Hydrogels

One of the self-assembling peptide types, also called "molecular Lego," form very stable beta-sheet structures in aqueous solution because they contain two distinct surfaces—one hydrophilic, the other hydrophobic. Like LEGO® bricks that have pegs and holes and can be assembled into particular structures at centimeter and meter scale according to a program, these peptides can do so at the nanoscale level without external instructions. The unique structural feature of these peptides is that they form complementary ionic bonds with regular repeats on the hydrophilic surface (Figure 6A). The complementary ionic sides have been classified into several

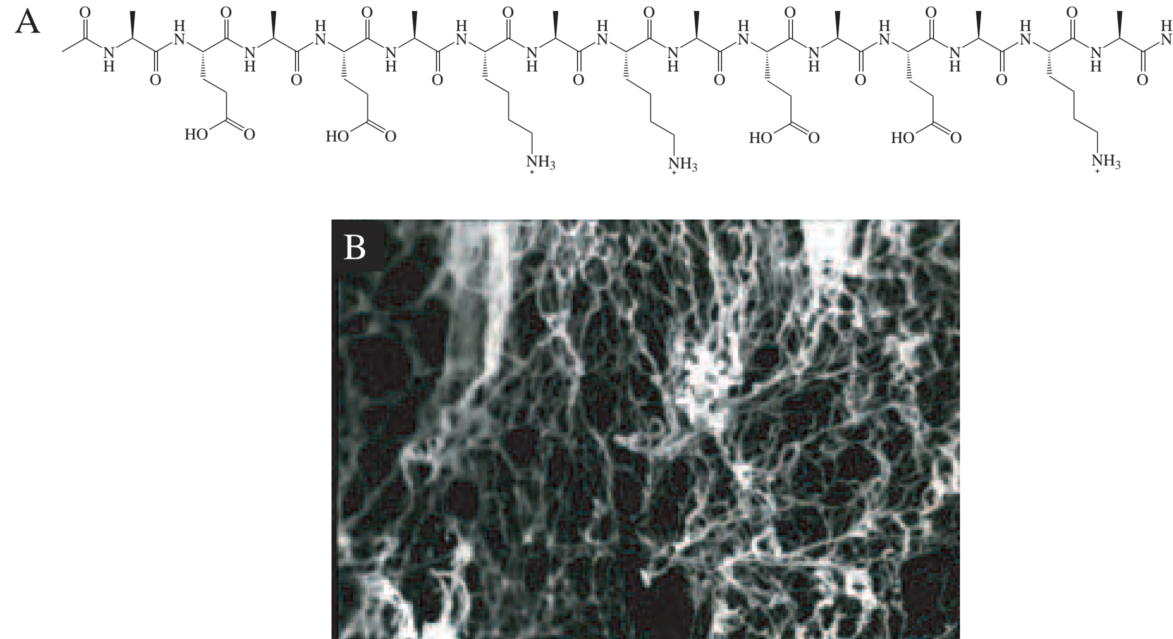

Figure 6. Self-assembling peptide to form scaffold hydrogel. (A) The sequence of the first member of the self-assembling peptides, EAK16, AEAEAKAKAEAEAKAK, serendipitously discovered in a yeast left-handed Z-DNA binding protein [74]. (B) The SEM structure revealed that the peptide self-assemble to form individual interwoven nanofibers with 50–200 nm pores. The diameter of the fiber is about 10–20 nm. Under high resolution by AFM, the filaments are revealed to be a twisted helix with regular helical repeats at early stage of self-assembly. They form scaffold hydrogel with extremely high water content (99.5–99.9%). It is likely that the nanofibers may organize water molecules.

moduli, that is, modulus I, II, III, IV, etc., and mixed moduli. This classification is based on the hydrophilic surface of the molecules that have alternating positively (+) and negatively (−) charged amino acid residues, alternating by 1, 2, 3, 4, and so on. For example, molecules of modulus I have − + − + − + − +, modulus II, − − + + − − + +, modulus IV, − − − − + + + +. These well-defined sequences allow them to undergo ordered self-assembly, resembling situation found in well-studied polymer systems.

Upon the addition of monovalent cations or the introduction of the peptide solutions into physiological media, these peptides spontaneously assemble to form macroscopic structures which can be fabricated into various geometric shapes [40, 41]. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) reveal that the matrices are made of interwoven nanofibers having 10–20 nm in diameter and pores about 50–200 nm in diameter [40–45] (Figure 6B).

Atomic force microscopy and TEM experiments, as well as molecular simulation of the FKFEFKFE peptides, showed that billions of individual peptides self-assemble into nanofibers. Molecular simulation using CHARMM suggests that these individual peptides coalesce together to form a left-handed double helix with hydrophobic phenyalanines on the inside away from water, and lysines and glutamates on the outside to interact with water.

The self-assembly process is a function of time, progressing from mostly short, left-handed helical segments in the first few minutes to long nanofibers after a few hours [45]. This structure represents an example of this class of self-assembling beta-sheet peptides that spontaneously undergo association under water and physiological conditions. If the charged residues are substituted, that is, the positively charged lysines are replaced by positively charged arginines and the negatively charged glutamates are replaced by negatively charged aspartates, there are essentially no drastic effects on the self-assembly process. However, if the positively charged residues, Lys and Arg, are replaced by negatively charged residues, Asp and Glu, the peptide can no longer undergo self-assembly to form macroscopic materials, although they can still form beta-sheet structures in the presence of salt. If the alanines are changed to more hydrophobic residues, such as Leu, Ile, Phe, or Tyr, the molecules have a greater tendency to self-assemble and form peptide matrices with enhanced strength [43–45].

Several peptide materials have been tested for their ability to support cell proliferation and differentiation. A number of mammalian cells have also been tested and all have been found to be able to form stable attachments to the peptide scaffolds [40]. These results suggested that the peptide scaffolds cannot only support various types of cell attachments, but can also allow the attached cells to proliferate and differentiate. For example, once rat PC12 cells on peptide matrices were exposed to neural growth factor (NGF), they underwent differentiation and exhibited extensive neurite outgrowth. In addition, when primary mouse neuron cells were allowed to attach the peptide materials, the neuron cells projected lengthy axons that followed the specific contours of the self-assembled peptide surface and made active and functional connections [41]. Furthermore, when chondrocytes were encapsulated in the scaffolds, the cell exhibited fully functional cartilage properties. These cells not only underwent limited proliferation, but also produced large amounts of type II and XI collagens and glycosaminoglycan, which are typical cartilage cell products [46]. This peptide scaffold is now being developed as a general three-dimensional culture system not only for a broad range of tissue cell cultures but also for tissue repair in regenerative medicine.

2.5. Peptides That Coat Surfaces

One class of peptides has been designed to self-assemble into a monolayer on surfaces and allow cells to adhere to them [47]. These peptides have three general regions along their lengths: a ligand for specific cell recognition and attachment, a linker for physical separation from the surface, and an anchor for covalent attachment to the surface (Figure 7A). The ligand may be of the RGD sequence motif that has been known to promote cell adhesion; the linker is usually a string of hydrophobic amino acids such as alanine or valine; and the anchor can be a cysteine residue for gold surfaces. Zhang et al. have used this technology in conjunction with SAMs prepared through micro-contact printing to place cells into complex patterns (Figures 7B and 7C). This approach may facilitate research into cell-cell communication.

3. NUCLEIC ACID SYSTEMS

3.1. Introduction to Nucleic Acids

Unlike proteins, nucleic acids predominantly play more inert roles in the cell. Deoxyribonucleic acid, for example, is the biopolymer that contains genetic information in its sequence and is processed and replicated by protein machineries. Even though some natural RNAs do perform enzymatic reactions and act as structural scaffolds, they are most renowned as the passive carriers of genetic information that is to be translated into proteins. The simplicity of the roles of DNA and RNA, relative to proteins, is reflected in the limited number of the letters in their alphabet—four as opposed to 20 in the case of proteins. The four letters, called nucleotides, are adenine, thymine or uracil, guanine, and cytosine. Adenine is geometrically compatible with thymine, and guanine with cytosine, such that in solution, one will try to hydrogen bond to the other (Figure 8). This is called complementarity. The most ubiquitous fold that a nucleic acid can form is the complementary right-handed double helix, where two strands of DNA with sequences that complement each other spontaneously form an intertwining double helical structure. For example, a poly-guanine will form a double helix with a poly-cytosine. Unlike most protein folds, this structural body is utterly predictable, as one only needs to know the sequences of the two strands to predict whether a duplex will form. This ease in knowing the conformation of nucleic acids in solution has led to many ingenious experiments that manipulate DNA to perform unnatural functions, the most recent of which are reviewed below.

3.2. Template for Nanowire

The DNA molecule has been suggested as a template for making nanoscale wires for the emergent field of nanoelectronics. This is due to the regularity of the width of the DNA double helix and its robust mechanical properties. Several groups have succeeded in coating DNA molecules with metallic particles and have shown data on the conductive properties of these biotemplated materials.

Braun et al. noncovalently bound a stretch (16 μm) of bacteriophage λ-DNA between two gold electrodes by allowing it to hybridize with short DNA fragments that had been covalently attached to those surfaces [48]. A solution of silver ions was flowed through the self-assembled complex, allowing for the positively charged silver ions to bind to the negatively charged DNA backbone. Reduction of the silver DNA complex resulted in enlarged silver metal particles effectively coating the DNA molecule, which was confirmed using AFM.

Electrical measurements indicated that the wires were nonconducting at low voltage bias, with resistances greater than the experimentally measurable 10^{13} Ω. Furthermore, the shape of the *I-V* curve obtained was dependent on the voltage scan direction. Increasing the silver deposition reduced the severity of some of these issues, implying that modification of certain conditions may yield low-resistance metal wires which have ohmic behavior over a reasonable range of voltages.

Richter et al. employed a similar strategy to produce DNA-templated nanowires that showed relatively low resistances under low-voltage bias [49] (Figures 9A and 9B). They reduced palladium on λ-DNA and immobilized the nanowire on gold electrodes. Electron-beam-induced carbon lines were then formed between the electrodes and the ends of the nanowire, lowering the contact resistances. The resistances obtained were lower than 1 kΩ, with the specific conductivity approximately one order of magnitude lower than bulk palladium.

The resistances of these palladium nanowires were subsequently studied at low temperatures [50]. The study was performed to determine whether the biology of the material affected its behavior as a normal metal system. Theory and experiments on disordered metals showed a trend of increasing resistance with decreasing temperature at sufficiently low temperatures due to weak localization and/or enhanced electron-electron interactions. It was discovered

Figure 8. Chemical structure of the bases in DNA and their complementary partners. Adenine (A) form two hydrogen bonds with thymine (T), and guanine (G) form three hydrogen bonds with cytosine (C). Not pictured is the phosphate backbone of the DNA molecule that connects and arranges these bases in a spiral, ladder-like configuration.

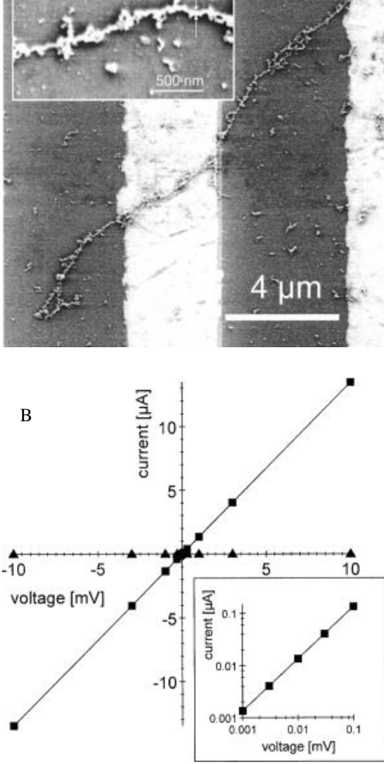

Figure 9. (A) Scanning electron micrograph of a palladium-coated λ-DNA [49]. The templated wire was laid on two gold electrodes over a SiO_2 substrate. (B) *I-V* curve of the wire in figure A. The inset shows the ohmic behavior of the wire down to 1 μV. Reprinted with permission from [49], J. Richter et al., *Appl. Phys. Lett.* 78, 536 (2001). © 2001, American Institute of Physics.

that the palladium metals reduced on a DNA template showed the expected quantum mechanical behavior, with their resistances increasing at low temperatures. This behavior is similar to that of thin palladium films and shows that wires templated with DNA molecules behave normally.

By using first-principle molecular dynamics (FPMD), Mertig et al. discovered conditions in which fine and regular platinum clusters formed on DNA molecules [51]. They hypothesized that the rate of metal formation upon reduction of the DNA-metal ion complex depends on the number of metal nucleation events. Furthermore, this rate-limiting nucleation was controlled by Pt(II)-DNA formation during an activation step when platinum ions bound electrostatically to DNA molecules. Lengthening the activation step resulted in higher occupancy of platinum molecules in the DNA prior to reduction, and ultimately yielded a faster rate of growth and finer metal clusters on the template.

Another metal that has been investigated for surface templating of DNA is gold. Harnack et al. investigated the binding and reduction of tris(hydroxymethyl)phosphine-derivitized gold particles on calf-thymus DNA [52]. The rapidly formed nanowires show electrical conductivities about 1/1000th that of gold, which the authors attributed to the graininess of the material.

Patolsky et al. modified *N*-hydroxysuccinimide-gold nanoparticles with a nucleic-acid intercalating agent, amino psoralen [53]. Addition of this complex with poly-adenine/poly-thymine DNA double-strand resulted in the interacalation of gold nanoparticles to the DNA. Subsequent UV-irradiation covalently cross-linked the two species. Interestingly, deposition of the nanowires onto a mica surface resulted in their structural alignment. Even though electrical studies of these complexes were not performed, the authors showed how they utilized chemical knowledge of a biological system to engineer a desired nanostructure.

3.3. Self-Assembly Into Geometrical Objects

Designing higher-ordered structures such as a polyhedron and other geometrical objects from defined biological building blocks requires the perfect understanding of the behavior of those building blocks. Nucleic acid, in this sense, is the perfect candidate since, as mentioned previously, designing and predicting the complementarity of two nucleic acid strands is trivial. Seeman's group has intelligently designed a quadrilateral [54], a cube [55], a truncated octahedron [56], and Borromean rings [57] made of DNA by using a solid support system [58] (Figures 10A, 10B, and 10C, respectively). Not only did they use the knowledge they have of nucleic acids, but they also employed commonly used nucleic acid modification enzymes to build and analyze the supramolecular objects they designed.

3.4. Formation of DNA Crystal Tiles

Winfree et al. designed a set of Wang tiles made of double-crossover DNA complexes that self-assembled in solution to form macroscopic crystals [59] (Figures 11A, 11B, and 11C). The anti-parallel, double-crossover motif provides structural rigidity and predictability and was inspired by the four-way

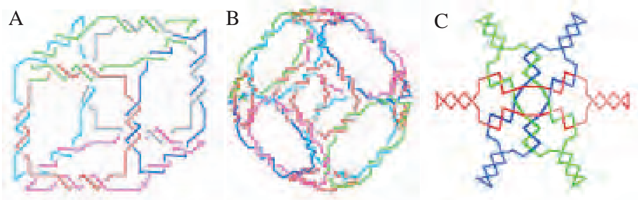

Figure 10. Geometrical objects built with DNA [75]. Pictured are schematics of (A) a cube [55]; (B) a truncated octahedron [56]; (C) a Borromean ring [57]. Reprinted with permission from [75], N. C. Seeman, *Trends in Biotechnology* 17, 437 (1999). © 1999, Elsevier Science.

Holliday junction structure found during meiosis, a biological process that produces the specific chromosome count in eggs and sperm. These mesoscopic tile structures grew to be as large as 2×8 μm in size, with thickness that of a single tile of DNA. Each tile has the approximate size of $2 \times 4 \times 13$ nm and can be associated with one another through "sticky-end" ligation (hybridization and subsequent covalent linkage of complementary sequences between the DNA tiles).

Atomic force microscope images and Fourier analysis showed the presence of two-dimensional sheets with numerous column widths of 13 nm (Figure 11D), consistent with the width of a single DNA tile. Decorating one set of tiles in the two-tile system with two DNA hairpin sequences revealed this columnar structure further in the AFM, since the two hairpins protruded out and provided contrasting height with the rest of the sheet (Figure 11E). The

authors also decorated the sheet with nanogold-streptavidin by incorporating a biotin moiety to the 5' end of one set of the double-crossover DNA tile.

3.5. DNA Molecular Machine

Nanometer-sized molecular "machines" based on DNA, which can cycle through different states, have also been designed. Yurke et al. designed a system, which consisted of three DNA molecules that hybridized to form a complex that could accept an incoming "fuel strand" made of another DNA molecule [60] (Figure 12A). The fluorescent quenching between two dyes on one strand (strand A in the figure) was monitored and served as an indication of the state of the system. Briefly, in an open state the two fluorescent dyes were separated such that quenching was lessened. Upon addition of a fuel strand (strand F), the system became "closed" and the two dyes were located in proximity with one another, causing quenching. Addition of a "removal strand," $\overline{F}$, which was complementary to the fuel strand, reset the system back to the open state and generated a double-stranded DNA waste product. The cycle could then be repeated (Figure 12B).

Another system built by Yan et al. consisted of four-stranded DNA molecules that formed two parallel double helices, joined together by the crossing over of the strands [61]. This complex could adopt two stable conformations—a paranemic crossover and its topoisomer. Each was related to one another by a 180° rotation of one strand end (Figure 13A). In their scheme, Yan et al. broke apart two of the strands to make three strands (Figure 13B), the middle one called the "set" strand, and played a role in the switch between the two conformations. Addition of a "fuel" strand, which is perfectly complementary to the "set" strand, left the complex in an intermediate state. To switch the DNA machine into the other state, a different set of set strands was added which would stabilize the other conformer. Since each of these steps involved only noncovalent, hydrogen

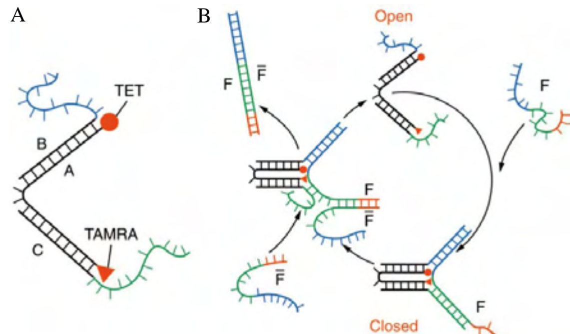

Figure 12. (A) Three strands of DNA that assembled to form the open state of a molecular tweezer [60]. TET and TAMRA are two fluorescent dyes that were attached to the ends of strand A and act as a signal of the state of the system. (B) A schematic showing the operation of the DNA-fueled molecular machine. Addition of fuel strand F closed the system and placed the two fluorescent dyes in promixity to one another, causing fluorescent quenching. The system was reset by adding the release strand, $\overline{F}$, which hybridized to the fuel strand. Reprinted with permission from [60], B. Yurke et al., *Nature* 406, 605 (2000). © 2000, Macmillan Magazines Ltd.

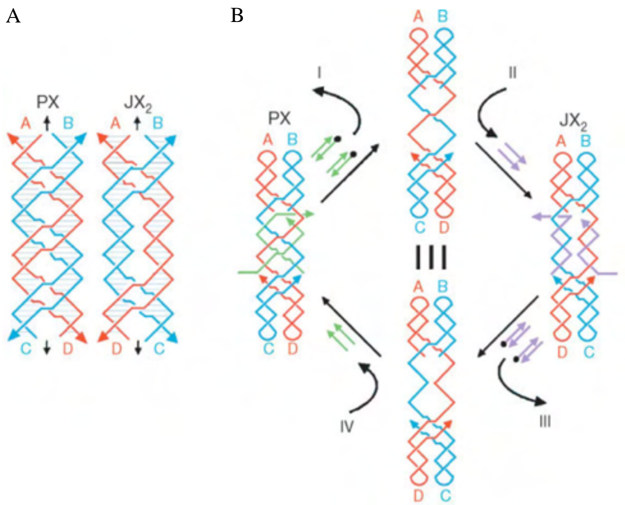

Figure 13. (A) Schematic diagram of the two topological states of a DNA machine designed by Yan et al. [61]. The black arrows indicate a central dyad axis that separates the two helical domains. The arrowheads at the end of the strands indicate the 3'-end of the DNA molecules. (B) Operation of the device. A green set strand in the PX molecule could be removed with the addition of a biotinylated complementary fuel strand, resulting in an unstructured intermediate. The intermediate can be converted into the JX_2 or back to the PX molecule by adding the appropriate set strand. Reprinted with permission from [61], H. Yan et al., *Nature* 415, 62 (2002). © 2002, Macmillan Magazines Ltd.

bonding between the DNA single strands, the cycle could be repeated indefinitely.

4. LIPID SYSTEM

Lipids have long been known to undergo self-assembly to form a variety of structures and colloidal materials. The traditional lipid surfactants that form nano- and micro-structural materials have penetrated into a diversity of applications, from lubricate, detergents, surface-coating to encapsulation for deliveries. The size of individual phospholipid molecules is approximately 2.5 nm in length, but they can self-assemble into millimeter-size lipid tubules with defined helical twists, many million times larger.

Schnur et al. have not only developed an elegant theory to explain the self-assembly of the lipid tubular structures [62], but have also developed a number of applications [63, 64]. They found that the chirality of the monomers plays a key role in the tubular structural formation. Furthermore, they can finely tune the structures at the molecular level both through synthesis of derivatives and using various solvents, especially mixing different types and concentration of alcohols [65]. They coated the metal nanocrystals onto the well-formed, left-handed microhelical tubules. These crystals metal-aligned along the helical ridge on the tubules [66] (Figures 14A and 14B). They also used the metal-coated lipid tubules to coat surfaces so that the properties of the coated surfaces can be completely altered. Their pioneering and innovative research activities have inspired more and more scientists and engineers to conduct multidisciplinary research, namely, to use biological scaffold to construct nanodevices [63].

5. BIOLOGICAL SELECTION OF PEPTIDES

5.1. Phage Display for Generating Peptides with Novel Properties

5.1.1. Peptides that Specifically Bind to Inorganic Surfaces

For particular applications that have no known analog in biology, molecular design may not be an efficient route to pursue. Even though one can potentially test many different biomolecular species to perform a particular function, the sheer number of samples that must be screened makes such an endeavor prohibitive in cost. This has led Belcher's research group to modify an established method called phage display to generate new peptides that can selectively bind to semiconductors.

Whaley et al. started with a random library of 12 amino acid peptides that were fused to the coat protein of M13 bacteriophage (bacterial virus), resulting in one phage displaying one particular sequence of peptide [67]. The DNA that encoded for the peptide was fused with the DNA of the coat protein; sequence determination of the peptide could then be carried out by standard nucleotide sequencing of this stretch of DNA. They proceeded to allow some 10^9 phages bind to different crystalline semiconductor surfaces such as GaAs (100), GaAs (111), InP (100), and Si (100). Any phage that did not bind to the surfaces was washed away, and those that did were eluted, amplified, and rereacted under more stringent binding conditions. The process was repeated five times, yielding an exponential enrichment of those phages that displayed peptides which enabled them to bind to these inorganic surfaces.

For binding to GaAs (100), peptides with a higher number of uncharged polar and Lewis-base side-chains became more predominant with successive rounds of selection. This could be attributed to the interaction of these functional groups to the Lewis-acid sites of the GaAs surface. Furthermore, phages that bound to one particular surface showed poor binding to other surfaces, indicating that the binding was sequence-specific (Figure 15B).

5.1.2. Peptides that Bind to ZnS/Ordering of Quantum Dots

Using a similar selection strategy, Lee et al. identified a bacteriophage that had the propensity to bind to ZnS crystal surfaces (Figure 15A) [68]. These phages were then mixed with ZnS quantum dots, forming a liquid crystalline suspension of the complex. Differential interference contrast imaging and AFM studies of this suspension revealed the ordering of the bacteriophages, most likely due to the geometrical constraints of the phage body, not the attached quantum dot.

Transparent films from a suspension of viral-quantum dot assembly were made and their properties analyzed. It was discovered that the system self-assembled into a smectic-like lamellar layer, with the ZnS quantum dots localized in the region where lamellar layers met (Figures 15C and 15D). Understanding how this self-assembly occurs when the suspension is dried into a film will enable researchers to design various three-dimensional arrangements of inorganic crystals. This will push forward the areas of nano-electronic, optical, and magnetic sciences and engineering.

5.2. Artificial Peptide and Protein Libraries

Artificial peptide and protein libraries have been constructed for selection of novel proteins and peptide motifs that nature never made [69–73]. Many investigators completely designed the peptide and protein libraries *de novo*, without pre-existing protein basis. The idea of constructing protein libraries is for several reasons:

1. to further explore the enormous diversity of protein species,
2. to select for a particular interesting species for a defined purpose,
3. to study protein-folding and interactions,
4. to expand knowledge of biochemistry and life forms,
5. to go beyond biology into materials sciences, molecular engineering, nanotechnology, and uncharted frontiers.

Although nature has selected and evolved many diverse proteins for all sorts of functions that support life, it has not ventured into the functions outside of life. The protein universe is enormous, in comparison with what we know today. There are, undoubtedly, a great number of more proteins that can exist beyond what has been founded in living systems.

Numerous new proteins and peptides with desired and novel properties have been selected for a particular application. This strategy permits us to purposely select and rapidly evolve nonnatural materials, nano-scaffolds, and nano-construction motifs for a growing demand in nanotechnology. The numbers of these biologically based scaffolds are limitless and they will likely play an increasingly important role for design molecular machines, nanodevices, and countless other novel, unanticipated new tools and applications.

6. SUMMARY

In this article, we summarized how different research groups have utilized the self-assembling properties of some biological molecules to form nano-materials for different applications. We categorized the systems into three broad areas, following with the identity of the biopolymer and methodology of the research—designed peptide systems, designed nucleic acid systems, and phage display (*in vivo* evolution). Each system carries distinct advantages over the others. Nucleic acids, for example, exhibit predictability in simple molecular associations. While this increases the ease of designing particular types of structures (such as sheets), it may prohibit the formation of others (such as three-dimensional gels or large nanotubes). Peptides form different nanostructures, but their self-assembling behavior is more complex, has larger degrees of freedom, and is not so well understood. Nevertheless, the different research groups have made headway in assembling different biopolymers into nano- and meso-scale structures and are starting to optimize and make modifications to them.

It is likely that these designed molecular construction motifs and nanoscale materials will become an integral part of future technology for both anticipated applications and even more importantly, unanticipated discoveries.

GLOSSARY

Bacteriophage A virus that infects bacteria.

Dynamic light scattering A scattering technique to determine the hydrodynamic radius and diffusion constant of particles in solution.

Hydrogel A gelatinous substance composed predominantly of water molecules.

Nanobiomaterial Material made from the self-organization of designed biological polymers or their derivatives.

Peptide Short polymers made from amino acids. Peptides are usually shorter than naturally occurring proteins.

Quick-freeze/deep-etch method A method to prepare samples for electron microscopy. Aqueous samples are flash frozen in liquid propane and coated with platinum and carbon. The flash freezing preserves structures in the solution.

Surfactant A compound that reduces the surface tension of water. Usually contains hydrophilic and hydrophobic groups.

1. INTRODUCTION

This article introduces nanofibrillar structures created by self-assembling. The term "self-assembled nanofibers" refers to strands with various shapes such as helices, ribbons, and tubes. Biological organisms are constructed by molecular building blocks and these molecules are assembled spontaneously through various intermolecular interactions [1–6]. Life itself is hierarchically composed of self-assembling molecular building blocks.

There are many kinds of assembled nanofibers in nature. DNA is a double-stranded molecule [7–11]. Each spiraling strand, comprised of a sugar-phosphate backbone and attached bases, is connected to a complementary strand by noncovalent hydrogen bondings between paired bases. Actin forms twisted, rope-like filaments known as F-actins, which are made up of identical building blocks called G-actin subunits [12–14]. Tobacco mosaic virus, for example, forms 300 nm in length × 18 nm in diameter rod-like assemblies composed of 2130 identical protein-armored cylindrical RNAs [15–19]. Each protein subunit contains 158 amino acids.

On the other hand, many artificially self-assembled nanofibers have also been reported in the last two decades [20–32]. Various aggregation morphologies such as helices, tubes, fibers, and ribbon-like and rod-like morphologies have been identified by optical, electron, and probe microscopic observations. Most of their root compounds were serendipitously discovered to form self-assembled nanofibers [33]. The morphologies and properties of these molecular assemblies have attracted the interest of many researchers in a wide range of research fields.

The self-assembled nanofibers themselves can be obtained by simple preparation methods—for instance, by dispersing compounds into media by heat or sonication and then allowing them to stand at a given temperature for a few minutes to several days. These self-assembled nanofibers are interesting due to their numerous potential applications and for understanding biological systems.

Now it is possible to select from a large number of molecular models because many synthetic compounds have been found to form self-assembling nanofibers as well as biomolecules. In this article, the authors would like to introduce self-assembled nanofibrillar aggregates, and specific attention will be paid to aqueous bilayer membrane systems and organogel systems. These self-assemblies show not only unique morphologies but also high molecular orientation toward special functions, for which molecular chirality is an especially important factor. Mirror images of morphologies are formed from enantiomer, and racemates will often destroy developed aggregates [34, 35]. This suggests that chirality is not unrelated with the evolution of life. Well-designed, self-assembled nanofibers can support nanoscopic technologies and their applications.

2. NANOFIBERS FROM COVALENT SYSTEMS

Carbon nanotubes were first discovered in 1991 by S. Iijima et al. as a by-product, while they were examining the generation mechanism of fullerene [36, 37]. These carbon nanotubes form a graphite structure made of a net-like carbon surface in the shape of a cylinder, and both single-wall carbon nanotubes (SWNT) (Fig. 1a) [38, 39], consisting of a single graphitic carbon sheet, and multi-wall carbon nanotubes (MWNT) (Fig. 1b) [37] with a multi-wall structure have been confirmed. The diameter of the single-wall nanotubes is 3 nm and its central cavity is 1–2 nm. On the other hand, the diameter of multi-wall nanotubes ranges from 5–50 nm and the outer diameter of the central cavity can be from 3–10 nm. Characteristically, their lengths exceed 10 μm and both types have a high aspect ratio in every direction. Until now, they were considered expensive solid

carbon compounds as their yield was low. Presently, however, these materials can be created relatively cheap using new industrial methods [40, 41] including discharge, laser evaporation, and catalyst chemical vapor deposition methods, and their application in various fields is being actively explored.

On the other hand, the history of organonanotubes produced from organic matter is much older. In 1984, one of the present authors confirmed that one polypeptide lipid formed aggregates in the shape of a tube with an inner diameter of 4–10 nm and a length of 50–200 nm by self-assembly in an aqueous solution (Fig. 1c) [21]. Since the width of the wall was approximately 5 nm, it is presumed to have been formed as a single-wall bilayer. Nanotubes from longer single-wall bilayers have also been reported in subsequent research [24, 31, 32]. Nakashima et al. discussed microtubes (Fig. 1d) based on bilayer structures [42, 43].

In 2001, *Science* chose carbon nanotubes as one of the top 10 research domains, and growing interest in nanotubes from the field of molecular device physics indicates their application potential in the electronics industry of the future. Especially, SWNTs of approximately 1 nm in diameter have been shown theoretically [44–49] and experimentally [50–53] to become both metal-like and semiconductor-like, and the production and operation of transistors using carbon nanotubes has been reported [54].

Research has already begun on the electronic characteristics of hybrid structures created by inserting different molecules into the space in the center of a nanotube. Iijima and Smith et al. have reported one-dimensional crystallization of C60 molecules by Van der Waals interaction formed by introducing fullerene into nanospace through the deficit part of SWNT and annealing it [55–57]. Further tests have been performed by inserting Ga encapsulated fullerene (Ga@C82) into the SWNT instead of C60, and these results also showed the formation of structures crystallized in one dimension by regular intervals like C60 (Fig. 2a) [57]. On the other hand, similar encapsulation behavior can be attained by organic nanotube systems. Shimizu has excellent photographs of vesicle-encapsulated nanotubes (Fig. 2b) [58].

In contrast to organonanotubes, carbon nanotubes have an essential characteristic property of high electroconductivity, as well as a stable chemistry structure and a morphology that can be kept stable as well. For these reasons, these nanomaterials are certain to be very important in future nanotechnology [54, 59–62]. However, conversely, only limited chemical modification can be performed and addition or conversion of functions is not easy. Self-assembling organotubes, on the other hand, are admittedly unstable both physically and chemically, but the molecules that form them can be exchanged by taking advantage of their aggregate feature, allowing them to take on many different kinds of functions. Moreover, morphologically, they do not necessarily generate tubes alone—various nanofibrillar aggregate morphologies are possible, among which the tube-like aggregate is simply comparatively one of the most stable. This section will end with a brief description of the names of various morphologies that have been produced by self-assembly until now (Fig. 3).

3. NANOFIBERS FROM NONCOVALENT SYSTEMS

3.1. Characterization

Self-assembled nanofibers are generally prepared by dispersing into aqueous or nonaqueous (organic solvents) media with heating and sonication procedures, and then allow to stand the solution at designated temperature for few minutes to several days. Some cases are accompanied by macroscopic transformations through formation of well-developed aggregates. A typical example is a viscosity increase and, thus, the judgment of gelation of organic solvents are conventionally carried out by an inversion fluid method [63].

Microscopic techniques are useful for observation of aggregation morphologies—optical microscopes and scanning and transmission electron microscopes (SEM and TEM). Typical examples will be shown in Figures 1, 2, 5, 8, and 13. Scanning probe microscopes such as atomic force microscope (AFM) have also been used to obtain detailed information on the self-assembled morphologies. Figure 4 shows typical AFM images of the lithosatahine protofibriles [64]. A large number of photographs and images of self-assembled aggregates show various fiber-like morphologies such as rods, tubes, helices, ribbons, tapes, and twisted multiple strands. The freeze-fracture and freeze-drying techniques can be combined with these microscopic observations. Small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) are important techniques to obtain the information of practical quantities such as diameter, thickness, and length of aggregates. Figure 5 shows an example of the powder X-ray diffraction (XRD) spectra of zerogels prepared by freeze-drying of fibrillar aggregate-containing organogels. The authors discussed the molecular packing mode [65]. Thermodynamic properties are, in most cases, performed by differential scanning calorimeter (DSC) [66–73]. Most self-assembled aggregates show phase-transition phenomena such as gel (crystal)-to-liquid crystal and gel (crystal)-to-sol, and thus physicochemical properties of the aggregates drastically change at their transition temperatures. Spectroscopic observations provide information on molecular orientations, packing states, and lateral diffusion behavior. UV-visible [32, 69, 73–76], Fourier transform infrared (FT-IR), circular dichroism (CD) [21, 22, 32, 73, 76–78], fluorescence [79, 80], and nuclear magnetic resonance (NMR) [81] spectrometers have been widely used for investigation and analysis on the molecular orientation. Typical investigations are found in chromophore-containing lipid systems. Shimomura et al. discussed on H- or J-aggregations with λ_{max}-shift of a UV-visible spectra [82]. Ihara et al. discussed chiral-stacking behavior among the sorbyl groups of lipids with both UV-visible and CD spectra [32]. They also discussed the photo-induced polymerization process by following the spectral changes. Hachisako et al. discussed the critical aggregation concentration with visible spectral change induced by the isomerization of the spiropiran-containing lipid [83]. Schnur et al. discussed the relationship between the molecular chirality of lipids and the helicity of aggregation morphology with CD spectra [84]. These suprastructural aggregates often provide specific binding behavior for guest molecules such as dyes. These phenomena can also be detected by UV-visible and CD spectra [76, 85–87]. Fluorescence spectra are helpful for knowing the microenvironment around lipids. Sagawa et al. reported excimer formation when a pyrenyl group-containing lipid forms highly ordered aggregates in organic solvents [80]. These typical spectral data are shown in Figures 6 and 12.

3.2. Nanofibers in Aqueous Systems

Bio-membranes are spontaneously organized from many kinds of molecules such as phospholipids, proteins and polysaccharides. Some phospholipids (**N-1** ~ **N-4**) listed in Figure 7, which are representative of amphiphiles, form bilayer membrane structures spontaneously in water and their hydrophobicity is a major driving force in the aggregation and maintenance of the bilayer structures. These lipids usually form small globules and vesicles in water. A typical example is the vesicular structures observed when soybean-derived phosphatidyl choline is dispersed in water, which was reported in 1965 [88].

In 1977, Kunitake et al. reported in a landmark study that didodecyldimetylammonium bromide, as a totally synthetic lipid, could form bilayer structures in water [33]. Since this turning point, a large number of double-chain alkyl amphiphiles have been synthesized and characterized by many researchers. These findings led to the next step of lipid chemistry. Nobody doubts that the number of alkyl

chains in a hydrophobic part is not directly related whether or not a lipid can form bilayer structures but its molecular shape and intermolecular interaction are rather important.

It has been recognized that bilayer membrane structures can be formed from single chains [20, 89], triple chains [90], and others [29]. Also a hydrophilic part is not within the specified structure. It has been reported forming bilayer membrane structures from amphiphiles with anionic and nonionic groups, as well as twitter ionic and cationic groups.

Through these investigations, in 1984, one of the authors found that special synthetic lipids (**B-1a**) with hydrophilic oligopeptide head groups can form helical or tubular structures in water (Figs. 8a and 8e) [21]. This finding is significant in light of the fact that the thickness of the aggregates corresponds to that of single-walled bilayer structures and that the tubular and helical forms are closely related. At the same time this report on similar tubes through lipid aggregation was published, Nakashima et al. reported that helical ribbon-like aggregates could be produced from L-glutamate-derived lipids but that these were much larger—in microsize rather than nanosize [42, 43]. Further investigation made it clear that the helical form was rather an intermediate to the tubular form and that the formation of fibrillar structures with helices and tubules is deeply related to their chiral properties [22, 24, 31].

Since 1984, many researchers have designed and synthesized chiral lipids that produce nanofibrillar structures in water. They can be roughly classified into two categories: (1) micellar-based aggregates, and (2) bilayer sheet-based aggregates. Figure 7 includes the chemical structures of synthetic lipids that can form nanofibrillar aggregates in water.

3.2.1. Micellar-Based Fibrillar Aggregates

It may be difficult to define a micellar system, but one well-known case of micellar-based aggregates from N-alkyl aldonamides (**B-6**) and a series of diastereomeric and enantiomeric N-octylaldonamides has been studied by Fuhrhop et al. since 1987 [91]. Their TEM microscopic observations indicated that the solubilities and aggregation morphologies of aldonamides depended directly on the stereochemistry of their polyol head groups (Fig. 8g). All antichain head groups, like D-Man for instance, of N-octylaldonamides-induced formation of sheet-like aggregates based on bilayer structures, and highly irregular chain (i.e., twisted chain) conformations, like D-Alt and D-Ido for instance, induced high water solubility with no consequent aggregation. On the contrary, cylindrical micellar aggregates were obtained from N-octylaldonamide with L-Glu, D-Glu, and D-Tal head groups. It was estimated that a moderate molecular bending at the head group induced high curvature in the aggregates. They proposed a model of fibrillar (cylindrical) micelles and then this arrangement was supported by ^{1}H-NMR spectroscopic measurements [92]. Furthermore, it was confirmed by detailed TEM observations and image-processing that micellar fibrils often produced multihelices by twisting themselves. N-Octyl and N-dodecyl-D-gluconamides formed self-organized quadruple helices with magic angles whose pitch is equal to $2\pi\times$ molecular bilayer diameter. Figure 8h shows its TEM image and a contour line diagram obtained by image analysis [93]. Here, each micellar fibril preserved its independence without fusion. A computer model of quadruple micellar fibrils is also shown in Figure 9.

In 1992, Imae et al. [94] reported that N-acyl amino acids formed fibrillar, distorted fibrillar, or twisted ribbon-like aggregates (Fig. 8i), and their aggregation morphologies were dependant upon the types of amino acids and pH of aqueous solutions. Transmission electron microscopic observations showed that N-dodecyl-L-aspartic acid and N-dodecyl-L-alanine formed distorted fibers (pH = 3.6–5.5, temperature < 12 °C) and cylindrical structures without distortion (pH < 6.0, ambient temperature), respectively. Since N-dodecyl-L-glutamic acid formed globular aggregates, it was estimated that the bulkiness of the head group may have influenced the aggregation morphologies. Similar micellar formation was observed in poly(amino acid)s with terminal dialkyl groups. Their aggregation morphology is influenced by the pH-dependant secondary structures of poly(amino acid)s as head groups (**B-1, 2, 3**). [22, 30, 31] The complex **B-9** is known as bolaamphiphiles, which form spherical micelles or vesicles in aqueous solutions as well as amphiphiles. **B-9** is an asymmetric bolaamphiphile with one amino acid head group and one ammonium chloride head group. The diameter of their fibers is 2.5 nm, which corresponds exactly to that of micellar monolayers. (Fig. 8j) [58].

3.2.2. Bilayer Sheet-Based Fibrillar Aggregates

So far, a large number of bilayer-forming lipids have been reported, including some that can form helical and twisted ribbon-like aggregates. Their assemblies are based on distorted sheet-like bilayer membranes with large curvature and are morphologically divided into helical and tubular structures with cylindrical curvature and twisted ribbons with Gaussian, saddle-like curvature.

The first observation was reported in 1984. Didodecyl L-glutamide derivatives with oligo(L-glutamic acid) head groups (**B-1a**) formed helical or tubular aggregates [21]. Transmission electron microscopic observations showed that the **B-1a** formed helical aggregates (Fig. 8a) immediately after dispersion and then grew to tubular aggregates (Fig. 8e). It was confirmed that the tubular aggregates were 5–6 nm thick, which corresponds to the thickness of single-layered bilayer membranes (two molecular lengths) of lipid **B-1a**, and their diameters were 20–25 nm. On the other hand, when the head group is composed of the corresponding DL-glutamic acid, only large sheets without curvature were produced [24].

In addition, when oligo(L-aspartic acid) was used instead of oligo(L-glutamic acid) as the head group of **B-1b**, fibrillar and twisted ribbon-like aggregates were formed (Fig. 8d) [22]. Through these studies, we were also able to reveal the process of morphogenesis of these suprastructural aggregates by TEM observation and light scattering measurement:

1. **B-1b** formed globular aggregates with the largest curvature at the initial step;
2. these globules grew to fibrillar aggregates;
3. double or multiple strands were produced and then fused themselves to make ribbon-like aggregates.

These findings indicate that even a very small difference between L-glutamic and L-aspartic acid in the head group strongly influences the morphology of the aggregates. This

means that aggregation morphology is also very sensitive to temperature and pH factors because these can drastically change the secondary structures of the head groups.

Oda et al. described the difference between helical (and tubular) and ribbon-like aggregates formed from charged gemini surfactants **B-10** with chiral counterions (Figs. 8k and 8m) [95, 96]. In these studies, helical aggregates were formed from long-chain (C_{18}) surfactants, whereas twisted ribbon-like aggregates were formed from short-chain (C_{14} or C_{16}) surfactants. The degree of twist and the pitch of the ribbons could be controlled by the introduction of opposite-handed chiral counterions in various proportions.

In 1985, Helfrich and Harbich [97] attempted to define a theoretical approach for the morphologies of helical and twisted aggregates. An explanation of these phenomena, Oda et al. demonstrated their own theoretical approach using the extended Helfrich model [98–100]. Other researchers have endeavored to solve a riddle of being between geometrical morphologies and chemical structures [101, 102]. So far, no consensus has been established, because supramolecular assembly-forming compounds include many different chemical structures. Several questions still remain; for instance, the nature of the edge of the bilayers has not been clarified. Future work in both experimental and theoretical studies will develop technologies for order-made self-assembling nanofibers.

Two common features necessary for the chemical structure of molecules that form supramolecular assemblies are a chiral carbon atom and moieties feasible for intermolecular interactions. Artificial chiral lipids that can form supramolecular assemblies such as helical, tubular, and ribbon-like aggregates based on bilayer membrane structures are listed in Figure 7. This includes single chain (**B-11**) [74], quadriplex chain (**B-12**) [29], and cholesterol group (**B-13**) [26] as hydrophobic part, and nucleotide group (**B-14**) [28] as a hydrophilic part. Moreover, polymerizable moieties such as diacetyrene group (**B-15**) [25], acrylate group (**B-16, 17**) [103], methacrylate (**B-13**) [26], and sorbate group (**B-18**)-containing lipids [32] have been also reported. Figure 8 includes their typical TEM images.

3.2.3. Non-Lipid Based-Nanofibers

The preceding section discussed special nanofiber structures formed by hydrophobic aggregation and by intermolecular interaction with polar groups. Here, is described the formation of nanofibrillar structures through multiple hydrogen bonding and, consequently, molecular orientation (Figure 10).

On the other hand, the construction and structural analyses of aggregates caused by β-structures are also performed from the viewpoint of protein chemistry [104–108]. For example, prion proteins from patients with Alzheimer's disease or Bovine Spongiform Encephalopathy (BSE) form a different fiber-like aggregate [109–111] than prion proteins from a healthy body, and these proteins include β-structure [112–114].

Although Scrocchi et al. did not aim to produce nanofibers, they chose an arrangement of 6 out of the 37 residues in the human islet amyloid polypeptide (hIAPP) amino acids sequence (**P-1**), and specified the sequence that

makes hIAPP β-formed [109]. Consequently, it was found that the hexapeptides of hIAPP (residues 20–25) promote β-transition of IAPP most strongly, and were seen to produce nanofibers (Fig. 11a). This was especially interesting as it showed that an amino acid sequence of only six residues could serve as a trigger for proteinic β-form induction to

form a nanofiber. However, nanofibers of β-structure origin have extremely low solubility and do not dissolve easily. Therefore, they are not suitable for use as nanostructure materials.

To overcome this hurdle, construction of water-soluble nanofibers from β-structures is now being studied [115]. We have noticed that when sequential oligopeptides with alternating hydrophilic and hydrophobic residues form β-structures, they may also be able to form amphiphilic structures. As an example, a Lys-Leu alternating sequential oligopeptide (**P-2**) was synthesized, and it was confirmed that helical tape-like aggregates were formed in the solution. Transmission electron microscopic images showed that the width of the thinnest portion was approximately 12 nm (Fig. 11b). Moreover, when fluorescence spectra of pyrenyl chromophores at the terminal end of the main chain were investigated, we found excimer formation that demonstrates orientation between the pyrenyl chromophores at the time of nanofiber formation. On the other hand, neither nanofiber formation nor excimer generation was observed in random copolypeptide.

Similar formation of aggregates from β-structures of oligopeptides (**P-3**) was reported by Jayakumar et al., who observed that L-Ileu pentapeptides form aggregates in toluene and DMF (Fig. 11c) [111]. In this case, however, they were insoluble and it was not specified whether nanofiber structure was formed.

3.2.4. Chiral Properties of Suprastructural Bilayer Membranes

Most nanofibrillar assemblies based on micells and bilayer membranes possess chiral centers in their structures. Of course, the chirality of molecules plays an important role in the production of distorted supramolecular assemblies. We have observed that oligo(L-glutamic acid)-containing lipids (**B-1a**) produce nanofibrillar aggregates including helices and tubules but that corresponding DL-derivatives produce only large sheet aggregates [24]. Similar observations have been made for other lipids (**B-6** and **10**): enantiomeric compounds form right-handed and left-handed helical aggregates, and equimolar mixtures (= racemates) often induce drastic morphological change [27, 95]. It is considered that the molecules in the distorted aggregates pack with slight angle with their neighbors, and this feature of molecular orientation produces some unique properties. **B-3** [30], in which dialkyl chains and pyridinium moieties are connected by L-glutamide through three amide groups, formed helical and tubular aggregates. Here, DSC measurement showed two endothermic peaks (with top temperatures of 33 °C (T_1) and 45 °C (T_2), respectively) in the heating process [30]. These aggregates showed extremely strong exciton coupling at wavelengths near the absorption of amide groups and pyridinium groups. The optical activity of amide groups changed from negative to positive around T_1 and optical activities of both groups disappeared above T_2 (Fig. 12a). Neither formation of tubular aggregates nor enhanced CD spectra were obtained from the corresponding ester-type compound at which dialkyl chains were introduced through ester bonds. These results indicate that the three amide bonds around the chiral carbon play an important role in the formation of supramolecular assemblies. The reversal of chirality is probably due to change of the molecular orientation, for instance, from S-chiral to R-chiral. Similar induced CD spectra based on chirally ordered structure have been observed in bilayer aggeregates formed by chromophoric group-containing lipids (**B-11** and **B-18**).

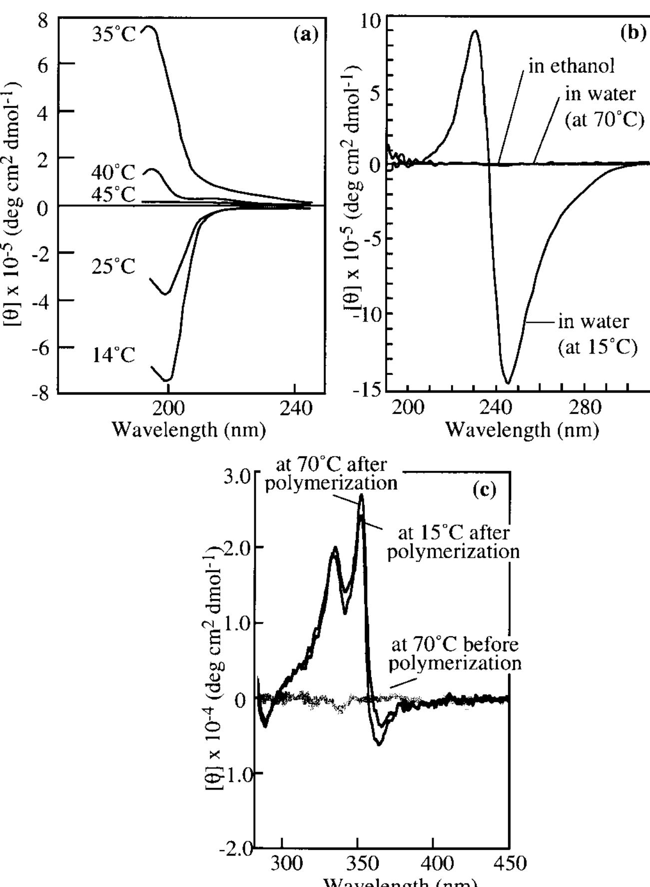

Figure 12. Specific optical activities in (a) **B-3** [30] and (b) **B-18** aggregates in aqueous solutions [32], and (c) **G-11** organogels [163]. (a) The optical activity changes reversibly depending on temperature. (b) The CD pattern indicates that the sorbyl groups as polymerizable moiety are in chirally stacking states among them at a temperature below T_c. (c) Polymerization of methylmethacrylate as a bulk solution promotes stabilization of the highly oriented structure of **G-11** aggregates [163]. Reprinted with permission from [30], H. Ihara et al., *J. Chem. Soc. Jpn.* 1047 (1990). © 1990, The Chemical Society of Japan; and from [32], H. Ihara et al., *Langmuir* 8, 1548 (1992). © 1992, American Chemical Society.

Mirror-image of CD spectrum was obtained in bilayer membrane aggregates from D- and L-form lipids, respectively [84]. Specter et al. [116] reported on the CD spectra and TEM observations of diacetylenic phospholipid in various conditions. The CD spectra of R- and S-enantiomers showed similar patterns but opposite signs and the CD signal of racemic mixture showed approximately nothing. Moreover, TEM observations showed that the R- and S-enantiomers formed tubular aggregates with the same dimensions, and their racemates also formed tubular aggregates without dimensional changes. Since the tubular aggregates of pure enantiomers were grown from

left- and right-handed helical aggregates, respectively, it was anticipated that racemic mixture almost phase-separated.

It is well known that achiral dye molecules bound to chiral poly(α-amino acid) show CD spectra (induced circular dichroism (ICD)) around their absorption bands [117–119]. Similar phenomena have been observed on chiral bilayer assemblies. When an achiral dye molecule, such as methyl orange, was added to **B-4** aggregates in an aqueous solution, it combined with the cationic membranes to give three dispersion species, belonging to S-chirally oriented dimmers on the surface, monomers on the surface, and monomers incorporated into the bilayers, respectively [76]. Many chiral lipids possess similar functions through formation of highly oriented structures [85–87].

3.2.5. Stabilization of Fibrillar Assemblies

Compared with nano assemblies from lipids, carbon nanotubes are useful in light of their physical and chemical stability, but this stability causes limitations on modification. The assembling systems, however, provide unlimited opportunities for modification. For example, the mixing of L- and D-isomers of **B-1a** causes their racemates to show absolutely different morphologies from their original forms. **B-1b** ($n = 4$) can form only fragmented fibrillar aggregates spontaneously, but this morphology can be transformed to well-developed twisted ribbon-like aggregates by mixing with a triple chain-alkylated, lipid-forming tubular aggregates [32]. However, these morphological transformations mean to be so weak for their industrial use. Therefore, it must be valuable to stabilize their aggregates. This attempt has been carried out by physical and chemical methods. The chemical methods are roughly classified into three types as summarized in Figure 13. However, most of these methods include polymerization, and, thus, the resulting bilayer membranes lose some functions such as molecular fluidity instead of obtaining stability. Of course, stabilization is required in some cases to expand their applications.

Polymerizable lecithins (**B-15**) with diacetylenic alkyl chains such as 1,2-bis(10,12-tricosadi-ynoyl)-sn-glycero-3-phosphocholine ($DC_{8,9}PC$) are known to form tubular microstructures when their liposomes are cooled below the chain-melting transition [25]. Tubular and helical structures from **B-15** measured from 0.3 to 3 μm in diameter and from

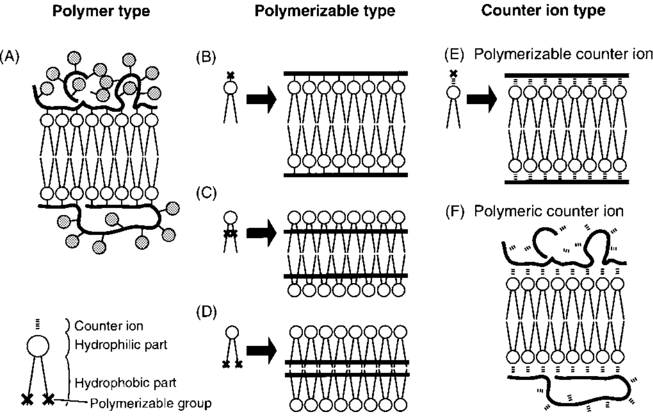

Figure 13. Stabilization of bilayer aggregates by polymerization.

5 to over 1000 μm in length. Both dimensions depended on the solvent system (ratio of water-to-alcohol). Irradiation with UV rays or γ-rays induced photopolymerization of diacetylenic units, but the helical or tubular structures were lost. A series of monoacryl and diacryl double-chain ammonium amphiphiles (**B-16** and **17**) were synthesized for investigation of their dispersion characteristics before and after photopolymerization [103]. **B-16** formed vesicular aggregates after dispersion into water and transformed into helices when allowed to stand at room temperature for 1 month. Polymerization of acryloyl groups leads to destruction of aggregation morphologies.

On the other hand, we reported the dispersion states and effect of polymerization on the aggregation morphology from polymerizable lipid (**B-18**) [32]. The introduction of polymerizable sorbyl groups at the end of the hydrophobic alkyl chains is far enough from the chiral carbon in order to prevent obstruction of the chiral interactions between lipids. **B-18** formed single-wall helical bilayer structures (Fig. 8u) with large chirality (Fig. 12b) in aqueous solutions below T_c (= 51 °C). Ultraviolet irradiation of the **B-18** aggregates caused photoreaction of the sorbyl groups at a rate 25 times faster in the stacked species (below T_c) than in the nonstacked species. This photoreaction was accompanied by morphological transitions from helical aggregates to tubular aggregates below T_c and to twisted fibrillar aggregates above T_c. Almost no morphological change was observed as a result of this polymerization over a wide range of temperatures.

3.3. Nanofibers in Organic Media

Hydrogels can often be formed from aqueous solutions of hydrophilic polymers, biomolecules such as proteins, and inorganic materials such as silicates. They have been studied in detail, and related books [120, 121] and reviews [122] have been published by many researchers. Some of these gels and gelators are widely used in industries, food science, and cosmetic science. Recently, it has been found that some specia, low molecular weight compounds formed gels in organic media [123]. These can be referred to as organogels (organic gels). Organogels are very unique, not only in that the gelation is induced by three-dimensional network formation with well-developed fibrous aggregates, but also in that these aggregates are on the basis of highly oriented structures like aqueous lipid bilayer membranes. Therefore, they attract our interest in spite of their instability, and we further label them "self-assembled organogels" to distinguish them from conventional gels. Self-assembled organogels include various fibrillar aggregates such as rods, helices, and sheets, and the challenge to stabilize their morphologies and molecular orientation to widen their applications is now being met. In this section, we focus on nanofibrillar aggregates formed in organic solvents.

Low molecular weight compounds that can produce gels from organic solvents have been known for 50 years. However, the gelation of organic solvents and oils as macroscopic phenomena has been a main subject of interest for several decades thereafter. From the late 1980's to the early 1990's, several kinds of organogels were discovered simultaneously. In this period, many researchers joined the research field

of nano-sized molecular architectures to develop molecular devices for supersensitive sensors, high-density memory storage, and so on. It appears that a point-of-view toward organogels has been shifted into explication and control of molecular buildings formed from low molecular weight organogelators, spontaneously. The original root compounds of organogelators (Fig. 14) have been discovered serendipitously by researchers who were working in various research fields [70, 124–127]. Therefore, the chemical structures of most organogelators are derived from intermediate molecules designed for specific functions.

3.3.1. On Driving Forces and Chemical Structures

A hydrophobic effect is the most essential driving force for molecular aggregates in aqueous solution systems but almost disappears in organic media. More positive intermolecular interactions play an important role in molecular aggregation in organic media. Hydrogen-bonding interaction is especially effective and many organogelators are classified into this category. 12-Hydroxystearic acid (12HSA, **G-6**) and its related salts were early examples of organogelators [128–130] and the first report of 12HSA was brought by Tachibana et al.

Figure 14. Root organogelators developed in the late 1980's to the early 1990's **G-1** [124], **G-2** [125], **G-3** [126], **G-4** [70], **G-5** [127].

in 1965. Lithium 12HSA forms twisted fibrous aggregates, whose direction of the twist depends on the optical isomerization of lithium 12HSA. Transmission electron microscopic observations show that the direction of the twist is left-handed for the L-form, but right-handed for the D-form, and that no twisted fibers are obtained for the DL-form. Furthermore, the helical structures formed from 12HSA are sensitive to counter metal ions. 12HSA forms developed ribbon-like aggregates with diameters of 10 to 100 nm in soybean oil. However, the number of cross-sections is relatively few according to SEM observations. Addition of sodium salt of 12HSA to these organogels contributes to improvement of gelation ability with metamorphoses from flexible ribbon-like aggregates to bundled rigid fibers with equal diameters. Terech et al. elucidated the oriented structure of 12HSA organogels at the molecular level by a combination of several techniques [131]. Small-angle neutron scattering (SANS), small-angle X-ray scattering (SAXS), and wide-angle X-ray scattering (WAXS) investigations revealed the structural model of the 12HSA fibrous or twisted, strand-like aggregates in organic media. The 12HSA molecules form head-to-head aggregates in fibrous networks and the growth of fibrous aggregate in the fiber axis direction is promoted by hydrogen bonds between the hydroxyl groups of 12HSA. A polarity of solvents influences the diameter of fibrous aggregates since the laminating of fibrous aggregates in the vertical direction is brought by dipole-dipole interactions between carbonyl groups of 12HSA. Microscopic morphological arrangements of fibrous aggregates inevitably lead to structural changes of cross-section and/or junction zones, and finally exterior transformations such as transparency (turbidity) and other physical properties will appear.

Peptide-based derivatives will be useful as organogelators because their amide bonds work as a stronger driving force for molecular aggregation. Peptide-based organogelators have a plural number of hydrogen bondable moieties. **G-4** [70, 73] as a typical example, possesses three amide bonds around an L-glutamic moiety, which works as a good organogelator. Transmission electron microscopic and SEM observations showed a three-dimensional network with fibrillar aggregates in its organogel and xerogel (Figs. 15a and 15b, respectively). The minimum diameter of the aggregates in the picture is 20 nm, which is 2–3 times larger than the molecular length estimated by SAXS [73]. However, if two of the three amide bonds are replaced by the ester bonds, no gelation is observed even when their concentration is 10 times higher than the former. It was also confirmed that addition of trifluoroacetic acid as an inhibitor for hydrogen bonding causes gel-to-sol transition. MOPAC calculation indicated that the three amide bonds around the L-glutamic acid moiety provided a proper conformation for intermolecular interaction.

K. Hanabusa et al. investigated the gelation abilities of single-chain alkylated mono- or dipeptides toward general organic solvents [132–134]. Peptides containing L-isoleucine and L-valine (**G-7**) work as distinguished gelators for various organic solvents such as alcohols, ketones, esters, dimethyl formamide (DMF), dimethyl sulfoxide (DMSO), and aromatic compounds. Both the length of the alkyl chain and the side chain structure of amino acids are important in the

Figure 15. Chemical structures of various low-molecular mass organogelators (Ref.: **G-6** [128], **G-7** [134], **G-8** [157], **G-9** [169], **G-10** [213], **G-11** [80], **G-12** [172], **G-13** [83], **G-14** [135], **G-15a** [63], **G-15b** [63], **G-16** [138], **G-17**[215], **G-18** [78], **G-19** [147], **G-20** [123], **G-21a** [216], **G-21b** [176], **G-21c** [173], **G-22a** [177], **G-22b** [166], **G-22c** [166], **G-23** [214], **G-24** [151], **G-25** [158], **G-26** [159]).

production of fibrous aggregates. If a hexyl chain is introduced instead of an octadecyl chain, the compound neither produces organogels in solvent nor forms fibrous aggregates. The possible structure for the long chain-alkylated dipeptides was proposed to be an antiparallel β-sheet through intermolecular hydrogen bonds between the amide and urethane groups.

Cyclohexane diamide derivatives have hydrogen bonding sources [135, 136]. Although the two isomers of *trans*-1,2-cyclohexane diamide derivatives (**G-14**), which are (1R, 2R) and (1S, 2S), can produce a gel for many organic solvents, *cis*-isomer derivatives have no gelation ability. Furthermore, dialkylated 1,3- and 1,4-cyclohexane diamide derivatives did not produce organogel. It was considered from their aggregation morphologies that one-dimensional growth of molecular assemblies through intermolecular interactions was indispensable to the formation of fibrous aggregates. The alkyl chains connected to the *cis*-isomer are spread spatially since they are located at axial and equatrial positions, respectively. The molecular packing formation in the aggregates is also important for one-dimensional growth and this can also apply to 1,3-isomers and 1,4-isomers.

A two-component gelation system revealed essential information about the gelation mechanism. A pair of compounds, **G-15a** and **G-15b**, was designed as a two-component system because a dumbbell-type cocrystal was produced from a barbiturate derivative and triaminopirimidine through the intermolecular hydrogen bonds [63]. The heating process normally carried out to dissolve an organogelator into the solvents is unnecessary to produce organogels in chloroform with the combination system of **G-15a** and **G-15b**. Molecular orientation of the two-component system was supported by FT-IR and SAXS measurements. Transmission electron microscopic observations show the twisted fibrous aggregates in organic solvents. Since each molecule cannot form an organogel individually, it is understandable that the arrangement of the hydrogen bond-forming moiety and bulkiness of the molecule are important in inducing self-assembled organogels. This argument is supported by the results of dendritic two-component gels. Dendrimetric peptides with carboxylic acid form organogels with a linear aliphatic diamine in nonhydrogen bonding solvents [137].

Saccharide-based lipophilic derivatives (**G-5** and **G-16**) can be organogelators. Hafkamp et al. reported that gluconamide derivatives (**G-16**) form stable organogels in a number of solvents such as *o*-xylene, chloroform, and ethyl acetate [138]. Transmission electron microscopic observations showed that **G-16** formed fibers or bundled fibers. Studies of gluconamide derivatives were carried out to explicate gelation mechanisms. **G-16**, whose free hydroxyl groups were protected by bismethylene, was synthesized to confirm the effects of free hydroxy groups on the formation of organogels. Since these compounds did not form organogels in any solvents, it was clarified that the hydroxyl groups played an important role in the gelation.

Since saccharides have many hydrogen-bonding sources, they are, like amino acids, invaluable materials for design of organogelator molecules. Friggeri and Gronwald et al. have reported 11 methyl 4,6-benzylidene derivatives of the monosaccharides D-glucose, D-mannose, D-allose, D-altrose, D-galactose, and a-D-isose (**G-18**) [139–141]. The driving force of aggregation was estimated as intermolecular hydrogen bondings by FT-IR and ^{1}H-NMR spectroscopies. Gelation ability was evaluated in a large number of organic solvents, and it was found that insignificant differences among the chemical structures are effective decisively on their gelation ability. Furthermore, a remarkable change in molecular mobility around T_{gel} was observed by the line-broadening effect of ^{1}H-NMR. Structural details in fiber network in the solid state and gel state were deduced by ^{1}H-NMR, FT-IR, and SAXS. The series of these sugar-based derivatives is useful to construct architectures of molecular assemblies as base compounds.

There are some derivatives that can produce organogels without intermolecular hydrogen-bonding interaction. A typical example is the steroid derivative with polyaromatic group (**G-1**), first reported in 1987 by Weiss et al., who investigated the gelation ability of the isoandrosterone derivatives [124, 142–144]. The kinetics were investigated in detail by using electron paramagnetic resonance (EPR), SANS, infrared (IR), and CD spectroscopies. After this finding, more than 40 derivatives, including steroid and aromatic groups, have been reported. They are sometimes classified by the abbreviations ALS, where A, L, and S correspond to aromatic (A), linking (L), and steroid (S) groups, respectively. Effects of chemical structures of each part on the gelation were investigated in detail; for instance

1. stereo-chemistry at C-3 and the nature of the chain at C-17 of the steroidal part,
2. various aromatic groups such as 9,10-anthraquinones, cinnamate, 2-naphtyl, 1-pyrenyl, phenyl, and their substituted compounds,
3. the length and functionality of the linking groups.

Several important considerations for organogelators from aromatic compound-linked steroid were concluded as follows [145]:

1. H-bonding, even when possible, may be absent in low molecular-mass organic gelator (LMOG) assemblies when other packing contributions (e.g., π-π interaction and London dispersion forces) dominate [146].
2. Charge-transfer interactions within gelator strands can stabilize gels [147].
3. Thixotropy can be induced by adding a small concentration of a second (nongelling) ALS molecule whose size and shape are similar to those of a good ALS gelator.
4. The fraction of ALS gelator within the solid network is dependant on temperature and on the solubility of the gelator in the liquid component [143, 144].
5. The bulk properties of a liquid mixture, rather than the properties of the individual components, determine the dimensions and shape of the gelator assemblies [142], as well as the relative ordering of T_{gel} values within a series of ALS gelators.
6. Subtle changes in molecular shape can alter profoundly the ability of an ALS to gel organic liquids.

Inductions of functional groups such as crown ether and azo-benzene into cholesterol were performed by Shinkai et al. [175–177]. Application of these organogelators are described in Section 3.3.4.

We estimate that a steroid group will give limited solubility to organic solvents compared to a long chain alkyl group and thus may work as a sorbophobic moiety. Positive interaction can probably be induced by polyaromatic groups. Supporting this, anthryl derivatives connected to dialkyl chains have been studied as organogelators [125, 148–150] 2,3-Bis-*n*-decyloxyanthracene, **G-23**, produced organogels in many organic solvents [125]. Since 2,3-dialkoxynaphthalene showed no ability of gelation for any organic solvents, increasing aromaticity promoted gelation ability. Even if the anthracene moiety was replaced by anthrax quinone and phenazine, effective gelation was observed. The number and length of alkyl chains were also sensitive to gelation abilities. Freeze-fracture electron micrographs of **G-23**-propanol gels indicated a three-dimensional network of fibrous rigid bundles with 60–70 nm diameters.

Some organometallic compounds can also be organogelators, in which case the essential interaction source is surely derived from the chelation behavior. Terech et al. reported that mononuclear copper β-diketonate derivatives **G-24** formed both organogels [151] and thermotropic disc-like mesophases in cyclohexane [152, 153]. Some binuclear copper tetracarboxylates [154–156] form neat thermotropic columnar mesophases and organogels at less than 1 wt% concentrations in hydrocarbons. These organogels form disc-like molecules including semi-rigid, rod-like threads whose diameter was 1.7 nm, which corresponds to the diameter of disc-like molecules.

At the end of this section, chemical structures and aggregation forms of low-molecular organogelators are summarized in Fig. 16 and Table 1.

3.3.2. Chemical Stabilization of Organogels

Some lipophilic peptides have been investigated not only as organogelators but also with respect to their self-assembling behaviors. This latter property gives them distinct advantages compared with conventional gel systems. The fibrillar aggregates are based on highly ordered structures, and thus show aqueous lipid membrane-like behaviors such as phase transition, phase separation, and chirality enhancement through molecular orientation. Although these features are advantageous for extended applications, it is also clear that their thermal and mechanical instabilities are a disadvantage in some application fields.

Some approaches have been proposed for stabilization of organogels. Introducing polymerizable group into a gelator is a reasonable method for this purpose. The first example of polymerizable organogelator was a sorbyl group-introduced peptide (**G-8**) in 1995. In this case, significant stabilization was not observed by photo-induced cross-linking among the peptides because oligomerization was a predominant reaction in the process [157]. On the other hand, de Loos et al. reported a bis(ureido)cyclohexane derivative containing a methacrylate moiety as a polymerizable organogelator (**G-25**) [158]. This compound produces organogels with developed fibrous aggregates in various organic solvents. Gel formation was maintained after polymerization by UV irradiation in the presence of a photo-initiator and the resultant gel showed highly thermal stability up to temperatures above the boiling point of the solvents. Polymerization of photo-induced polymerizable groups containing organogelators (**G-26**) was demonstrated by Masuda et al [159, 160]. Diacetylene containing organogelator (bolaamphiphile) was used for the purpose of stabilizing. Polymerization could be monitored by UV spectroscopic observations, and was induced by photo or γ-ray irradiation. In each case, stability of the organogel preserving fibrous aggregates rose in several samples after polymerization. However, reversibility of sol-to-gel transition and most properties based on molecular fluidity disappeared.

Sometimes, metal ions increase the mechanical strength of organogels. 1-O-(p-Aminophenyl)-4,6-O-benzylidene-α-D-glucopyranoside (**G-18**) behaves as a good gelator for various organic solvents [78, 139]. The T_{gel} values for ethanol gel were markedly improved by addition of $AgNO_3$, $CoCl_2$, or $CdCl_2$. The T_{gel}s for 1 wt/vol% of organogel in ethanol are -10 °C and 71 °C, respectively, in the absence and presence of equimolar $CoCl_2$. This remarkable change is due to cross-linking of **G-18** molecules by Co(II)-amino group interaction. It seems that hydrogen bonds and coordination bonds work cooperatively for reinforcement of organogels. Similar observations were obtained using a diketonate ligand-containing organogelator [161]. Maitra et al. reported that the donor-acceptor interaction promoted

organogels (**G-19**) [147]. Pyrene-containing bile acid derivatives formed highly stable organogels with needle-like aggregates in various solvents even with less than 1% of the gelator. The T_{gel} increased with increasing amounts of trinitrofluorenone as an electron acceptor that could not form a gel in solvents. In an organogel system, several intermolecular interactions participate to maintain the gel formation. Control of these interactions is useful not only for understanding the gelation mechanism but also for developing functional organogels.

3.3.3. Approach for Nanostructured Materials

Organogel systems can be applied as a liquid organic media. Gu et al. [162] and Hafkamp et al. [138] described morphological imprinting of fibrous aggregates using tetraoctadecylammonium bromide and gluconamide derivatives coordinated with metal ion, respectively. Each organogelator can produce organogels with fibrous aggregates in styrene and methyl methacrylate. Polymerization of the solvents was carried out with UV light in the presence of a photoinitiator. Fibrous aggregates with similar diameter were observed before and after photo-polymerization, and the gelator molecules could be removed from the resultant polymer matrix by the solvent extraction method (Fig. 17) [138]. According to optical and electron microscopic measurements, the diameters of the strand-like pores were bigger than those of the original fibrous aggregates. It was expected that the monomers that exist near the surface of fibrous aggregates could not react since their mobility and fluidity were restricted. Similar observations were obtained with organogels from a pyrenyl group-containing peptide lipid (**G-11**) in styrene and methylmethacrylate. In this study, we obtained significant information on the molecular orientation states before and after polymerization of the bulk solution. Enhanced CD spectra around the pyrenyl group was observed after polymerization and maintained even at 70 °C, a temperature was even higher than its T_{gel}. These results indicate that highly oriented structures can be stabilized by polymerization of a bulk solution [163].

Ono et al. have reported that hollow, fibered silicas are prepared by transcription of various suprastructures formed in organogels [164, 165]. Three cholesterol-based gelators with monobenzo-18-crown-6 (**G-22a**), monoaza-18-crown-6 (**G-22b**), and 1,10-diaza-18-crown-6 (**G-22c**), respectively, were synthesized. These compounds produced organogels. Scanning electron microscopic observations of the xerogels showed that their organogelators assemble into a fibrous network structure, a curved lamellar structure, and a cylindrical tubular structure, respectively, in cyclohexane. Sol–gel polymerization of tetraethoxysilane was carried out in each of the gel systems. The silica obtained from **G-22a** showed a granular structure and a hollow fiber structure featuring the rough surface and the thick tube wall, respectively, in the absence and the presence of metal. This structure was created by adsorption of the anion-charged silica particles onto the cation-charged organogel fibers. On the other hand, the silica obtained from **G-22b** and **G-22c** had a hollow fiber structure featuring a smooth surface and thin tube wall both in the absence and the presence of metal salt. In the absence of metal salt, it was considered that the cationic charge generated by protonation of azacrown ethers plays a crucial role in the creation of such hollow fiber structures. In the presence of $KClO_4$, sol–gel polymerization resulted in tubular silica with a multilayered structure like a roll of paper (Fig. 18) [166]. The findings suggested that sol–gel polymerization proceeded along the surface of the curved lamellar stucture of **G-22b** or **G-22c** and the silica eventually grew

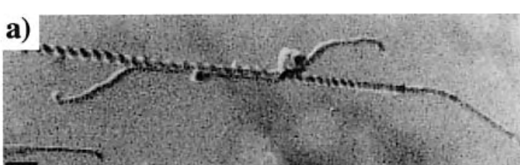

Figure 17. TEM images (Pt shadowing, bar 110 nm) of a dried gel (a) of **G-16** [138] in ethyl acetate and imprinted pores (b) of **G-16** [138] (bar 1.35 μm). Reprinted with permission from [138], R. J. H. Hafkamp et al., *Chem. Commun.* 545 (1997). © 1997, Royal Society of Chemistry.

into a tubular structure. Vesicular and helical silica structures with several tens to several hundreds nm in diameter were obtained by using similar methods [166–168]. Future studies will certainly realize the production of more complicated and uniform nano-transcribed materials with desired fashion.

3.3.4. Control of Highly Ordered States

Some organogelators form highly ordered structures like those in aqueous bilayer membranes. Therefore, it is a convenient method to arrange the functional groups in the molecular assemblies. The arrangement and control of functional groups will certainly be an invaluable technique in many application fields such as sensors, molecular devices, and nano fabrication.

Lipophilic peptide-derived organogelators such as **G-10** and **G-11** show specific chirality, which is detectable by CD spectroscopic measurement around the chromophore groups. We have made some examinations to confirm whether or not specific properties observed in aqueous bilayer membranes can be reproduced in organic solvents. Phase separation behavior was observed in a mixture of **G-4** and an azobenzene-attached **B-4** derivative in benzene. Distinct CD spectra based on the azobenzene moiety were observed below T_{gel} [69]. The cotton effect of this mixture disappeared above T_{gel} and thermal reversibility was observed. On the other hand, a carboxylic acid-containing L-glutamate derivative (**G-9**) produced organogel with developed fibrous aggregates in several organic solvents [169].

These specific chiral properties stimulated us to implement optical resolution with chiral organogels. We reported the first example in 1995. When danoyl phenylalanine as a chiral guest molecule was dissolved in organogels from **G-4** and **B-3**, distinct enantioselective elution to an alkaline solution was observed. Interestingly, CD and DSC measurements showed that the best result was obtained through **B-3** domain formation phase separated from G-4 aggregates [170].

This finding encouraged us to control the chirality of organogels. For this purpose, we synthesized a double-chain alkyl L-glutamide derivative with an isoquinoline-head group (**G-12**) [171, 172]. This behaves as an organogelator with developed twisted fibers. It was confirmed that chelation with metal chloride in cyclohexane-ethanol (100:1) solution remarkably perturbed the chirality and morphology of the aggregates. Addition of copper ion ($CuCl_2$), which can form a square planar coordination, induced the chirality enhancement with morphological change from twisted fibrous aggregates to ribbon-like aggregates. On the contrary, cobalt ion ($CoCl_2$) and zinc ion ($ZnCl_2$), which can form an octahedral coordination state, caused serious morphological change with remarkable decrease of the chirality [171, 172].

On the other hand, Ishi-i et al. reported that a Zn(II)-porphyrin appended-cholesterol organogelator (**G-21c**) interacts with [60]fullerene to form a 2:1 Zn(II) porphyrin/[60]fullerene sandwich complex [173, 174]. The distinct bathochromic shift of the soret absorption band, which was found in the organogel with [60]fullerene in toluene, indicates that intermolecular electronic interaction exists between the Zn(II) porphyrin moiety and the [60]fullerene in the gel phase. Circular dichroism measurements suggested that the Zn(II) porphyrin moieties are strengthened to orient chirally in the gel phase by the interaction with [60]fullerene. The formation of a Zn(II) porphyrin/[60]fullerene sandwich complex would induce a morphological change-in-pitch length of twisted fibrous aggregates.

Light and metal ion-responsive organogelators were demonstrated by Murata and Shinkai et al. [175–177]. These gelators appended a crown ether moiety (**G-22a**), azacrown ether moiety (**G-22b** and **22c**), and azobenzenyl moiety (**G-21b** and **G-22**) to cholesterol, respectively. The azobenzenyl appended-cholesterol derivatives with a natural (S)-configuration at C-3 and those with an inverted (R)-configuration at C-3 formed organogels, but their solubilities and gelation abilities toward each solvent were quite different. LD, CD, and UV spectroscopic measurements showed that the azobenzene moiety was oriented in clockwise (in (R) chirality) or anticlockwise (in (S) chirality) direction when they interacted in the excited state. Furthermore, a sol–gel phase transition was induced by photoresponsive *cis*-trans isomerism of the azobenzene moiety. The molecular arrangement of crown ether appended-cholesterol derivatives was altered by the addition of metal ions and ammonium ion. The T_{gel} of this organogelator in methylcyclohexane/benzene (4:1) increased with increasing concentration of Li^+, Na^+, K^+, Rb^+, and NH_4^+, but decreased with increasing concentration of Cs^+. It was presumed that the 1:2 metal/crown complex with Cs^+ resulted in a disordered structure of organogels, but contrarily that 1:2 metal/crown complex with other metal ion and ammonium ion promoted their stability.

3.4. Nanofibrillar Structures from Polymers

3.4.1. Phase Separation Method

It is well known that block copolymers consisting of two or more compositions will form cube-like, rod-like, vesicle-like, and even lamella-like shaped microphase separation structures depending on the membrane casting conditions [178–185]. Therefore, it is also possible to produce a nanofibrillous microphase separation structure by choosing the chemical composition and varying the membrane casting conditions [186–193].

Liu et al. and Yang et al., for example, succeeded in producing a nanofibrillar-like microphase separation structure from A-B-C block polymers resulting from the combination of polystyrene (A), poly(2-cinnamoylethyl methacrylate) (B), and poly(tert-butyl acrylate) (C) (**P-4**) (Fig. 19a) [190]. To briefly introduce the method of production, a toluene solution of polymer was put into a polyethylene capsule, and a solid was obtained by evaporation and annealing. Transmission electron microscopic observation of the section of this solid showed a very beautiful nanofibrillar-like microphase separation structure with a diameter of about 25 nm as seen in Figure 19b [192].

On the other hand, Fujiwara and Kimura succeeded in producing a nanofiber from A-B or A-B-A block copolymer by the cast method from solution [191]. Specifically, it was obtained from a 0.2 wt% solution of block copolymer from poly(L-lactide) (A) and poly(oxyethylene) (B) which

Yang et al., *Angew. Chem. Int. Ed.* 40, 3593 (2001). © 2001, Wiley-VCH; from [191], T. Fujiwara and Y. Kimura, *Macromol. Biosci.* 2, 11 (2002). © 2002, Wiley-VCH; from [187], K. de Moel et al., *Chem. Mater.* 13, 4580 (2001). © 2001, American Chemical Society; from [199], L. Feng et al., *Angew. Chem. Int. Ed.* 41, 1221 (2002). © 2002, Wiley-VCH; from [198], B. Yu and H. Li, *Mater. Science Eng.* A325, 215 (2001); © 2001, Elsevier; and from [197], A. G. MacDiarmid et al., *Synthetic Metals* 119, 27 (2001). © 2001, Elsevier Science.

was prepared (**P-5**), cast on mica, and afterwards annealed for 2 hs at 60 °C. From TEM observation, the diameter of the nanofiber formed from the A-B block copolymer was about 20 nm (Fig. 19c) [191], and that from the A-B-A block copolymer was about 6 nm (Fig. 19d) [191]. The authors hypothesize that the core is made from lactide (A) and that this part has a crystal structure.

de Moel et al. have proposed the crew-cut method as a new technique of attaining nanofibrillar microphase separation structures from block polymers like polystyrene (A) and poly(4-vinylpyridine) (B) (**P-6**) which are difficult to separate [187]. Specifically, a 1:1 complex was produced by adding equimolar amounts of pyradine and 3-pentadecylphenol (PDP) to a chloroform solution of A-B block polymer. This was then evaporated very slowly by drying at 50 °C for at least 12 hs. Next, a 0.5 g sample was put into a dialysis tube filled with ethanol, and most of the PDP(s) were removed by dialyzing for 2 weeks. Decompression dryness was carried out at 50 °C after washing by ethanol overnight, and a sample was obtained. Transmission electron microscopic observation showed that a nanofiber with a diameter of about 30 nm was formed from (A) in the core part (Fig. 19e) [187].

3.4.2. Injection Molding Method

When using a high polymer, it is possible to produce nanofibers by adapting an injection molding method. Although production of the nanofiber from a high polymer is somewhat forced, two techniques may be used: either injecting high polymer solution into nanosize pores [194–197] or polymerization and pushing out from nanofiber-like capillaries [198].

Feng et al. reported the production of nanofibers using the former technique by injecting poly(acrylonitrile) as a template into porous anodic aluminum oxide (Fig. 19f) [199]. Yu and Li adapted the latter technique with porous metal using poly(*p*-phenylene) (**P-7**) as a template to produce nanofibers (Fig. 19g) [198]. Features such as super-hydrophobicity [200–203] and erection luminescence [204–206] were obtained using both injection methods, but the nanofibers produced also had disadvantages such as low diameter uniformity and a tendency to become condensed.

In order to solve these problems, a technique called the electrospinning method has come into practical use. This technique was patented in 1934 by Formhals [207] and was little known at first, but it has been attracting attention for the past several decades as a nanomanipulation technique [208–211]. The electrospinning method is the technique of putting polymer solution and metal electrodes into a poor solvent such as water, and blowing off the polymer solution by applying high voltage between it and the metal electrodes, and producing nanofibers. In this case, the diameter and length of fibers formed depends on the concentration of polymer solution, the distance between the polymer solution and metal electrodes, and the voltage applied. MacDiarmid et al. have reported nanofibers formed using this technique with an average diameter of about 50 nm, by injection using a 2 wt% poly(aniline) chloroform solution and applying a voltage of 25,000 V from a distance of 25 cm [197]. Polystyrene nanofibers of about 30 nm in diameter were also prepared using the same technique, meaning that micron-order fibers can be prepared from nanofibers cheaply and easily (Fig. 19h).

4. SUMMARY

"Self-assembled nanofibers" are formed from miscellaneous synthetic compounds and show various charming shapes as described herein. Although it is hard to completely understand the relationships between their morphologies and chemical structures, experimental and theoretical

approaches indicate several important factors such as:

a) moderate solubility into media,
b) intermolecular interaction moieties and their sterical position,
c) molecular shapes for highly ordered molecular packing,
d) molecular chirality.

Many reports also indicate a wide range of possible applications for these self-assembled nanofibers, from morphological applications such as preparation and utilization of replica of them to molecular level applications of specific molecular orientation. In this article, we introduced self-assembled nanofibers constructed mainly of relatively simple compounds, but oligomers and polymers such as cyclic polypeptide, cyclodextrin, and cyclic polysaccharide are also known to form self-assembled nanofibers [212].

It is prospected that self-assembling nano architectures including fibrillar aggregates have many potential applications because nature, especially human, is an excellent example of a hierarchical product of self-assembling molecules—there are so many excellent examples of hierarchical products of self-assembling molecules in nature itself, not the least of which is the human body. We sincerely hope that research on self-assembled nano architectures will be helpful in the development of molecularly precise materials and devices. The diversity of self-assembled nanofiber systems, including a large number of molecules, provides much opportunity to modify the chemical structures of self-assembling molecules. With the present rapid progress and expansion of this field, we feel a premonition that many applications will be found for nanofibers in the near future, including using combinations of morphologies and functions to provide suggestions for the origin of life.

GLOSSARY

α-helix One of the secondary structures of peptides, rod-like shape caused by intermolecular hydrogen bonding.

Amiloid fiber Fiber-like aggregate structures formed β-structure protein. These structures cause prion protein structure such as Alzheimer's disease or Bovine Spongiform Encephalopathy (BSE).

Atomic force microscope (AFM) Provide pictures of atoms on or in surfaces to measure the forces (at the atomic level) between a sharp probing tip (which is attached to a cantilever spring) and a sample surface.

β-sheet One of the secondary structures of peptides, its formed sheet-like shape is caused by intramolecular hydrogen bonding (antiparallel and parallel structure).

Bilayer membranes Amphiphiles self-organize in water to form molecular bilayers which assume the shape of globule, vesicle, lamella, fiber, and so on.

Carbon nanotube Fullerene-related structures that consist of graphene cylinders closed at either end with caps containing pentagonal rings.

Chiral/chirality Nonsuperimposable upon their mirror images and chirality is particularly important for molecules interacting within a biological environment, where many of the native molecules are chiral.

Circular dichroism (CD) The difference in absorption between left- and right-handed circulary polarized light.

Differencial scanning calorimetry (DSC) DSC measures the amount of energy (heat) absorbed or released by a sample as it is heated, cooled, or held at constant temperature. DSC also performs precise temperature measurements.

Hydrogen bonding Occurs where the partially positively charged hydrogen atom lies between partially negatively charged oxygen and nitrogen atoms.

Organogel Self-assembly of low molecular weight gelators to fiber-like structures, which entangle to form a three-dimensional network, immobilize organic fluids.

Peptide Two or more amino acids can be linked together by a dehydration synthesis to form a peptide. The characteristic chemical bond is called a peptide bond.

Supramolecular assemblies Infinite repeating structure comprised of several chemical species held together by intermolecular interactions and showing transcendent properties which are not observed in its constituent molecule alone.

Transmission electron microscopy (TEM) TEM allows to determine the internal structure of materials, either or biological or nonbiological origin used by a beam of electrons, to illuminate the sample.

ACKNOWLEDGMENTS

The authors deeply thank Ms. Yu Hamasaki, Mr. Tomohiro Shirosaki, and Mr. Takao Satoh for their capable assistance.

1. INTRODUCTION

1.1. Self-Assembly—A Key Aspect of Nanotechnology

In recent years the field of nanotechnology has experienced a veritable explosion of ideas, which resulted in many potential applications for nanostructured materials. In fact, nanostructures are seen as the key that will enable practical devices in the future of information storage and processing, communications, and biotechnology [1–3]. Since these are part of the nano-, bio-, and information technology triad [4] that is expected to power a multi-prong industrial revolution of the 21st century [5–9], the importance of nanostructures would be difficult to overestimate.

The key feature that nanostructures offer for such a diverse range of potential applications is the ability to tailor the electronic [10–21], optical [10, 12, 17, 19, 21–23], and magnetic [14, 17, 24–26] structure and properties of materials. Coincidentally for a variety of properties, this ability emerges at essentially the same length scale in the single-digit nm range [18, 27]. If devices are required to operate at room temperature, the presence of thermal fluctuations on the order of $kT = 25$ meV sets the energy scale. Transport and confinement of electrons determine most of the properties of interest, so the appropriate scales of nanostructures can be estimated for a single electron with mass m and charge e.

Quantum confinement. The quantum-mechanical energy difference between the lowest two quantum well states for an infinite potential well of width l is

$$E_{QM} = \frac{3h^2}{8ml^2} \tag{1}$$

If we require $E_{QM} \geq kT$ to prevent thermal excitations, the width of the well must be $l \leq 7$ nm.

Single-electron "electrostatics." The Coulomb energy for a single electron on a sphere of radius r surrounded by medium with a dielectric constant ε is

$$E_C = \frac{e^2}{\varepsilon \cdot r} \tag{2}$$

Using ε of silicon and $E_C \geq kT$ requirement again, we obtain a limit for the diameter of that sphere (nanoparticle) $2r \leq 9$ nm.

The superparamagnetic limit. The minimum size of a particle used in magnetic data storage is determined from the requirement that its magnetization cannot be changed by thermal fluctuations. The estimate in that case involves a model more complicated than the above ones, but the result is about 3 nm [25, 27].

Another aspect common to most potential applications of nanostructures is that typically more than one such structure is required; ordered nanoscale assemblies [17, 23] of

size-controlled structures are usually preferred for optimal performance. Perhaps the most stringent requirements for relative and absolute positioning are inherent for devices based on just a few nanostructures, for example, single-electron transistors or collections of qubits for quantum computing [15, 28–30], because interactions between the nanostructures need to be precisely controlled [29] and registration with the next level of the device (e.g., contacts) has to be maintained. On the other hand, for some optical and electronics applications no coherence is required, and thus the high packing density and size uniformity of nanostructures become more significant than their ordering [19, 31]. For the ultimate data storage media [14, 16, 25] or for materials with novel properties [10, 17, 23, 32, 33], one needs both high density and precise positioning over macroscopic areas and/or volumes. Overall, whether for manipulating the interactions or for increasing the packing density, the positioning of the nanostructures needs to be controlled on the scale comparable to or smaller than the size of the structures themselves.

Both defining and positioning structures with sub-10 nm accuracy is beyond the limits of traditional photolithography, so accordingly a large number of alternative lithography techniques [1, 3] are being currently developed. There is also a considerable effort in increasing the throughput [34, 35] of electron beam lithography, a serial method used to prepare masks for a large number of alternative lithography approaches [1, 3]. Increased availability and quality of scanning probe microscopy (SPM) instruments in recent years propelled the development of a number of SPM-based lithography approaches [1, 3] that allow to produce complex surface architectures from constituents as small as individual atoms [36]. Notably, the dip-pen nanolithography (DPN) [37, 38] routinely allows to achieve sub-100 nm resolution [38, 39]. The inherent advantage of using an SPM-based approach is that the structures can be made, imaged, and corrected by the same instrument. Current SPM instruments, however, use a single probe tip to define the structures, so the writing speed limits the applications to making small arrays of nanostructures for research, or perhaps using SPM instead of a costlier electron beam writer for mask definition. But the progress in development of probe-tip arrays [40] suggests that some of the speed limitations can be overcome by writing with multiple tips in parallel [38].

Even with the impressive advances in sub-100 nm fabrication techniques [3], it is evident that all their inherent limitations become more difficult to negotiate when the size of the nanostructures falls below 10 nm—the range that holds the most potential for achieving the novel phenomena important for both basic research and practical applications. This is one of the primary reasons why a self-assembly approach becomes a more attractive alternative for creating and controlling nanostructures.

In self-assembly, natural interactions between atoms, nanostructures, and their environment produce kinetically or thermodynamically preferred structures and patterns, so the method is inherently parallel and thus should be able to produce macroscopic amounts of materials. An important distinction needs to be made between self-assembly and self-organization [41]. Hereafter, the spontaneous formation of structures with sizes on the order of 10 nm and a well-defined size distribution will be referred to as self-assembly (SA) of nanostructures. A natural tendency to form ordered assemblies will be referred to as self-organization (SO). In general, SA is required to produce large numbers of individual particles with unique and/or tailored properties, while SO provides a pathway for combining nanostructures into novel materials, or for establishing connections between nanostructures and the macroscopic world. Thus in general, systems that possess both self-assembly and self-organization properties are desirable to realize the full potential of nanotechnology.

1.2. Self-Assembly on Surfaces

There are several compelling reasons why surfaces became and will remain an important part of the nanotechnology "playground" [2]. Surfaces offer a quasi-two-dimensional (2D) environment ("quasi-2D" because usually more than one atomic layer is involved even in surface processes) and thus represent macroscopic objects with somewhat reduced complexity. Since the overwhelming majority of nanofabrication techniques [1, 3] are surface-based, there is a natural synergy between basic and applied research into nanoscale surface processes. Most lithography-based approaches [1, 3], as well as molecular beam epitaxy (MBE) and its variants [42], allow to create 3D structures by stacking multiple layers [10, 17], but even in those cases, the surface processes on the topmost layer play the key role during growth.

The practical importance of surface processes is partly responsible for the development within the last few decades of a large number of surface characterization techniques [43]. Numerous microelectronics applications and wide availability of high-quality single-crystal substrates made semiconductor surfaces, especially those of silicon, perhaps the most studied and the best understood surface systems. Scanning tunneling microscopy studies [44, 45] coupled with advanced theoretical modeling [46] have been particularly fruitful in elucidating details of silicon surface structures [47–50] with real-space atomic resolution, and recent instrumentation developments may soon allow surface electronic transport measurements on the same scale [51, 52].

Surface atomistic processes ultimately define the dynamics [53] and thermodynamics [54–56] of nanostructures on surfaces and thus their self-assembly. On a slightly larger scale, surface stress [53, 54] is another factor crucial in both self-assembly and self-organization of nanostructures on surfaces. Surface defects, in particular atomic steps [57], extend self-organization up to macroscopic scales [10, 27, 41, 58]. This availability of multiple scales of physical processes and interactions is extremely important for achieving directed self-assembly and self-organization, since different parameters during the growth and post-processing of nanostructures can be independently controlled to selectively enable particular mechanism(s) to be dominant at appropriate stages. On the other hand, the interplay between several mechanisms is often more beneficial than each one of them acting separately. In the following we provide a number of examples of self-assembly and self-organization on silicon surfaces, with a particular focus on the role of the multiscale phenomena as means of controlling the evolution of these systems.

1.3. Outline

This review proceeds by considering the processes and methods on a continuously decreasing scale, to reflect the multi-scale nature of the self-assembly and self-organization phenomena. In Section 2 the idea of using templates to guide SA and SO is introduced at a relatively coarse (macroscopic) scale. The templates themselves can be either artificially patterned (Section 2.2), for example, by photolithography, or a product of a SO process, for example, atomic step arrays (Section 4.1), or a combination of both approaches (Section 2.2.3). Thus, the formation and applications of such templates are important issues in their own right. Section 3 considers nanoscale processes associated with SA of nanostructures, and role of surface strain in forming nanostructures and interactions between them. Sections 4.2–4.4 demonstrate how nanoscale self-assembly can be combined with self-organized templates to produce ordered arrays of uniform nanowires and nanodots. In Section 5 molecular and atomic structures are considered, with surface reconstructions as SO atomic templates with well-defined chemical and structural properties. These can be used to guide SA of elemental and molecular adsorbates (Section 5.1), to produce low-dimensional structures with novel properties (Section 5.2), and to test concepts of devices on atomic scale (Section 5.3). In addition to their many potential device applications in electronics, macroscopic templates with nanoscale features also represent structures that are both relevant for interfaces with biomolecules and can benefit from bio-inspired assembly strategies. Since such biointerfaces are the cornerstone of the emerging synergy between the nano- and biotechnology, their discussion in Section 6 offers a fitting outlook into one of the most important future pathways opened by surface-based self-assembly.

2. MACROSCOPIC TEMPLATES

The templates considered in this section are (at least conceptually) macroscopic in size—a feature important for handling and integration with existing devices, and for ability to produce macroscopic amounts of SA and SO nanostructures. The lateral periodicity of these templates is in the $\approx$0.5–1.0 μm range, a size range that has several important implications. First, a wide variety of patterning methods can be used to define such templates. Second, there is the possibility of interfacing with microelectronics both in terms of matching scales and common processing methods. And third, one is able to produce nanostructures from "coarse" sub-micron scale templates through size-reduction, SA, and SO.

Surface templates are briefly introduced in Section 2.1, followed by an in-depth discussion of a large class of prepatterned surface templates in Section 2.2. Subsection 2.2.1 outlines the direct patterning and size-reduction approaches that can be used to form SA and SO nanostructures based on micron-scale templates. Subsections 2.2.2 and 2.2.3 describe the use of common processing techniques, such as etching and heating, in conjunction with prepatterned templates, and the types of SA and SO nanostructures that can be achieved by these approaches.

2.1. Templates and Interfaces

The template-based self-organization approaches are likely to be necessary in conjunction with almost any of the self-assembly methodologies under development today. From the practical perspective, the output of solid-state devices is based on macroscopic circuitry, and thus connections and alignment between the nanoscale elements and the appropriate "leads" must be provided; similar "bridging" of the gap in scales is needed in many other applications [3, 59]. To obtain arbitrary and complex patterns, the self-organization driven by properties of individual self-assembled particles may be aided by the top-to-bottom "instructions" provided by the template. Incidentally, the alternative view of such a process is that of a template as a basis for bottom-up assembly of simple structural elements, for example, by ensuring appropriate anchoring of molecular electronic components.

Conceptually, the templates used for surface patterning can be subdivided into two types: external and surface templates. The *external templates* are those prepared independently of the surface being patterned. The vast variety of noncontact masks for light and e-beam lithography [1, 3] fall into this category, and their discussion in any detail is beyond the scope of this article. External templates used as masks for directed atomic or molecular deposition are typically directly patterned, rather than SO or SA.

There are some examples of self-organized external masks, however. Atomic deposition through a standing light wave pattern [60–62] can be used to create arrays of uniformly spaced lines (e.g., for use as metrology standards [63]) and potentially more complex patterns [64]. Similar light wave patterns can also be created by mixing the incident laser beam with light scattered off the surface, for example, during pulsed-laser irradiation of silicon substrates [65]. These laser pulses create silicon nanoparticles, which under appropriate conditions adopt increasingly more ordered configuration and thus result in more ordered standing wave patterns. Therefore, even though a nominally external light wave template is used, because of the interactions between the template and the surface structures, SO arrays of SA nanoparticles can be created [65].

The rest of this section is focused on *surface templates* with macroscopic features. As the name implies, surface templates are typically formed by surface processes and thus are themselves subject to self-assembly, self-organization, as well as the more traditional direct patterning approaches, or any combination thereof.

2.2. Prepatterned Surface Templates

Perhaps the simplest way to prepare a surface template is to define the desired pattern using one's method of choice and then selectively add or subtract material(s) to form the structures. The deposited material may be in form of preassembled nanostructures (e.g., clusters), but, strictly speaking, deposition onto a prepatterned surface involves only rudimentary self-organization, that is, via direct selectivity of the deposition process to the predefined areas in the pattern. The caveat of this straightforward approach is that the chosen pattern definition method must be capable to produce structures at the required resolution [1, 3].

E-beam lithography allows direct patterning of submicron features, for example, to selectively grow InAs quantum dots within 100–200 nm wide lines [66], or to form laterally ordered arrays of $Si_{1-x}Ge_x$ nanostructures with similar spacing [67]. E-beam patterning of 2D arrays, however, is a time-consuming process for resolution below 100 nm, so alternative patterning techniques are being explored. Nanoimprinting [1, 3, 68, 69] has been used to define a 2D array of Si mesas with 250 nm pitch and 10–60 nm dimensions for ordered growth of Ge nanodots [70]. In this case, remnants of the mesas (after annealing to clean the sample surface) acted as nucleation centers for growing Ge nanodots. Since no mask, for example, oxide or resist, was used to ensure the selective deposition, the growth and nucleation of the Ge dots was in this case largely controlled by Ge surface diffusion. Thus to obtain an array with dots nucleated on each mesa and only on the mesas, a higher density array would be necessary [70]—a requirement difficult to fulfill using the direct patterning approaches.

"Size reduction" methods [3] can be used to extend the patterning resolution. Two of the most common reduction approaches are described in Section 2.2.1: shadow deposition and edge-selectivity. Although only relatively simple patterns and structures can be produced by direct patterning, their complexity (but generally not the surface number density) can be increased by postprocessing, for example, etching (Section 2.2.2) or heating (Section 2.2.3).

2.2.1. Size Reduction

Shadow deposition is an approach that achieves size reduction through the use of geometric factors, and thus allows deposition of periodic patterns of structures with sizes down to 10–100 nm size using micron-scale masks. *Nanosphere lithography* (NSL) is an example of a shadow deposition (or "natural lithography") technique [71, 72] that provides an excellent illustration of the main principles of the method (Fig. 1a). The small commercially available "nanospheres" that form the basis of NSL are typically about 500 nm in diameter, since their primary applications in biotechnology require optical observation and handling. These nanospheres can be suspended in solvents, and, while in suspension, spin or drop-coated on essentially arbitrary surfaces. As the solvent evaporates, the spheres are drawn together by capillary forces to form hexagonally close-packed arrays (Fig. 1a) with 10–100 μm^2 defect-free domains, which can be used as masks for deposition or etching of dots or triangles on 10–100 nm scale [72]. There are three modifications of NSL that push the size limit down into the 1–10 nm range: masks of smaller (<100 nm) nanospheres, double-layer (DL) masks, and angle-resolved (AR) NSL. Monodisperse smaller nanospheres are not as readily available and their assembly is harder to control, but both DL masks and AR NSL not only produce the smaller structures, but also allow variations on the simple hexagonal array motif [72]. In particular, AR NSL [72, 73], which uses deposition at off-normal angles (Fig. 1a), can produce nano-overlap and nanogap structures, as well as nanoparticle chains, because the size and position of the shadowed area continuously vary with the angle [72].

Another type of a template that can be used for size reduction via off-normal shadow deposition is a V-groove

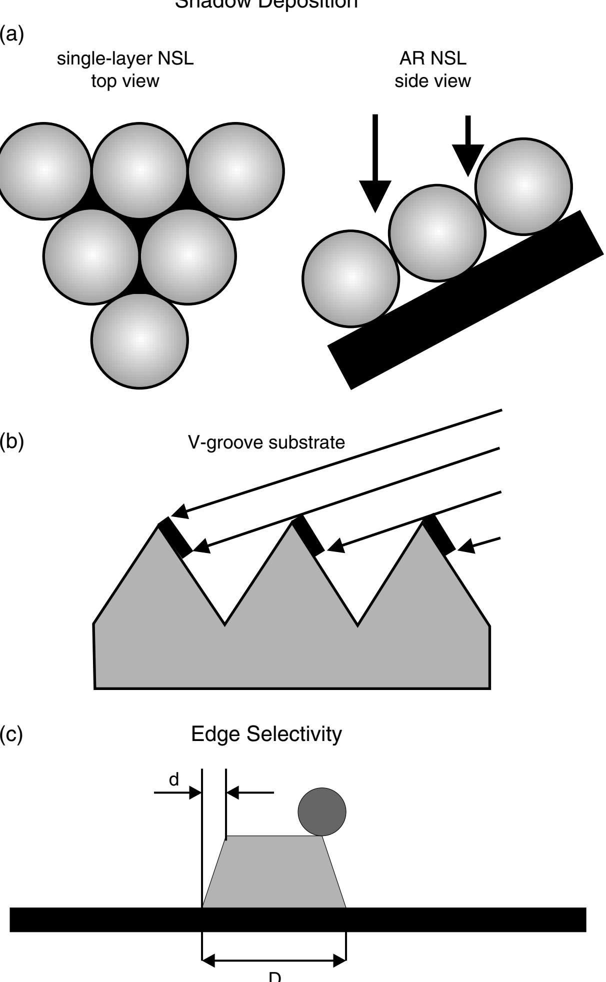

Figure 1. Common methods of size reduction. In shadow deposition, a specific geometry is used to produce features smaller than the original template, e.g., (a) an array of nanospheres [72], (b) a V-groove substrate [74]. Edge selectivity (c) of deposition or diffusion can also be used to confine nanostructures to edges of a pattern [75–77], which effectively achieves higher lateral resolution than the original patterning method.

pattern (Fig. 1b), for example, produced by combination of laser interference and anisotropic etching [74]. The steep ≈60° angle of the V-groove facets means that during a grazing angle evaporation neighboring ridges shadow all but the topmost area on each facet (Fig. 1b). Metal wires with 20 nm width have been thus achieved—a factor of 10 reduction from the original ≈200 nm V-groove periodicity [74].

A second commonly used method of size reduction is based on the fact that for any structure (Fig. 1c) the width of its edges d is always smaller than the size of the structure itself D; thus size reduction by a corresponding factor of D/d can be achieved via *edge-selectivity* of the deposition (or postprocessing). For example, Cu deposited on Si surface, patterned by conventional microlithography with lines of photoresist (2–5 μm width), selectively nucleated into sub-micron Cu clusters on the edges of the photoresist lines [75]. Because the Cu clusters were confined to edges of the pattern, the effective resolution (≈150 nm) in this case was better than the (≈1 μm) resolution of the patterning

technique [75]. In a similar manner, silicon mesa structures on Si(001) have been used as templates for growing linear arrays of self-assembled Ge islands. Because the islands aligned either along the edges of the top facet [76], or along the side facets of the mesas [77], the effective resolution of the patterning was beyond that of the conventional lithography used to define the mesa structures.

2.2.2. Etching of Patterned Surfaces

The resolution and speed limitations of direct patterning suggest that the patterning can be faster if only unstructured nucleation or anchoring points are patterned instead of the full structure. The nucleation points can then be transformed into more complex structures and patterns via postprocessing. Because some form of etching is always used in conjunction with patterning, a combination of an ordered 2D pattern and anisotropic etching is one of the most straightforward applications of this approach.

Nanopits, with facets determined by the etch anisotropy for different crystal orientations, can be formed by an anisotropic etch through windows opened by e-beam exposure of a protective oxide layer (Fig. 2a) [78]. Arrays of such "concave nanopyramids" have been demonstrated with densities up to 1.5 Terapits/in^2 (8 nm pit size, 20 nm pitch), but for the smallest pits uniformity was rather poor (determined by variation of the protective oxide thickness) [78]. One of the benefits of this approach is that the action of the e-beam was only required to open the windows in the oxide, and thus if an alternative means (e.g., DPN [37, 38] or nanoimprinting [68, 69]) can be employed, the bottleneck in speed associated with e-beam writing may be avoided. The anisotropic etch has also been used to produce nanopyramids (Fig. 2b) and grids [79, 80], but in this case the effect was due to a decrease in the etch rate with increasing ion-beam exposure, and thus the rate and the possibilities for scaling up were limited by the required minimum exposure per point. One can envision, however, using such an approach to define masters for soft lithography [1, 3], for example, nanoimprinting [68, 69].

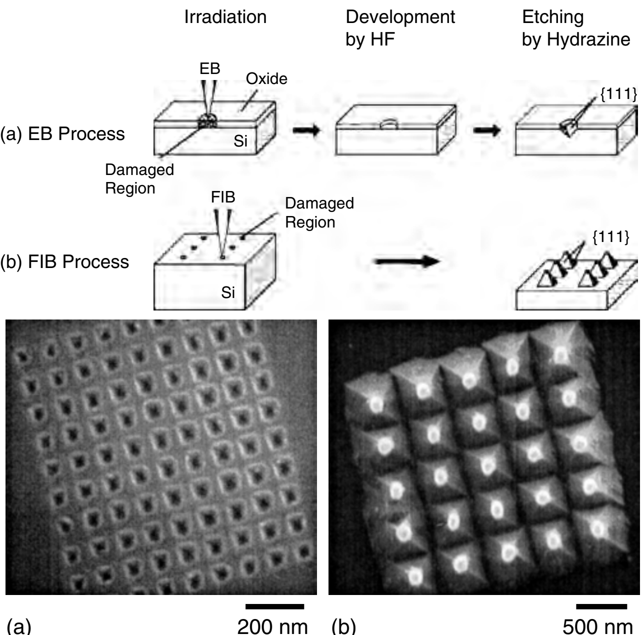

Figure 2. Nanopyramid arrays formed in Si(001) by (a) hydrazine etch through e-beam patterned oxide and (b) using focused-ion beam exposure to retard Si etch rate. Both the concave (a) and convex (b) nanopyramids are formed by ⟨111⟩ facets because anisotropic etch rate in hydrazine is lower for (111) than for (001) plane. Adapted with permission from [80], M. Koh et al., *Appl. Surf. Sci.* 162, 599 (2000). © 2000, Elsevier Science.

2.2.3. Heating of Patterned Surfaces

High-temperature annealing is often applied to semiconductor surfaces before processing, typically for surface cleaning. The requirement for an ultra-high vacuum (UHV) environment limits possible applications of any patterning method involving such a step; it is possible, however, to provide uniform heating across a whole Si wafer, so the limitation is essentially that of a batch mode processing. The transformation of Si surfaces during heating is one of the most in-depth-studied aspects of Si processing and the associated processes are, in general, well understood [57, 58, 81–84]. This understanding results in the ability to control the evolution of Si surface structures extremely well. For example, with properly adjusted surface temperature and Si deposition rate, arrays of atomically flat Si mesas tens of microns across can be created on lithographically patterned surfaces [85]. Similarly, a combination of MBE growth and heating has been used to produce nanostructures on patterned GaAs surfaces via preferential migration of material onto selected facets of micron-size holes or mesas [86].

When a silicon surface is heated in UHV to a high enough temperature, some silicon atoms can evaporate. Because of their weaker bonding, atoms at low coordination sites, such as edges of surface steps and islands, begin to evaporate at lower temperature than atoms incorporated in defect-free surface planes, for example, (111) or (001). When a surface is heated just enough to enable evaporation of the atoms with low coordination, this leads to the retreating motion of all atomic steps on that surface. On top of a mesa a few microns in size, this motion can eventually eliminate all the steps and achieve an atomically flat surface [85]. Conversely, steps at a bottom of a deep micron-size hole will retreat to form an atomically flat plane at its bottom [81]. In both cases, once the flat surface has formed, the evaporation rate from that area dramatically decreases [81, 85, 87] because all the remaining atoms have higher coordination than those at defect sites.

Step motion due to the selective evaporation of material from step edge offers many possibilities for self-organization of templates. For example, an array of holes patterned into a vicinal surface (Fig. 3a) stays put during step evaporation, but the multiple steps around the holes keep moving until they get pinned by the edges of the holes, and thus an ordered array of holes is transformed into an ordered array of bunched steps [81, 87, 88]. The benefit of combining the self-organization of the steps with a simple initial pattern is the possibility to produce intricate step bunch

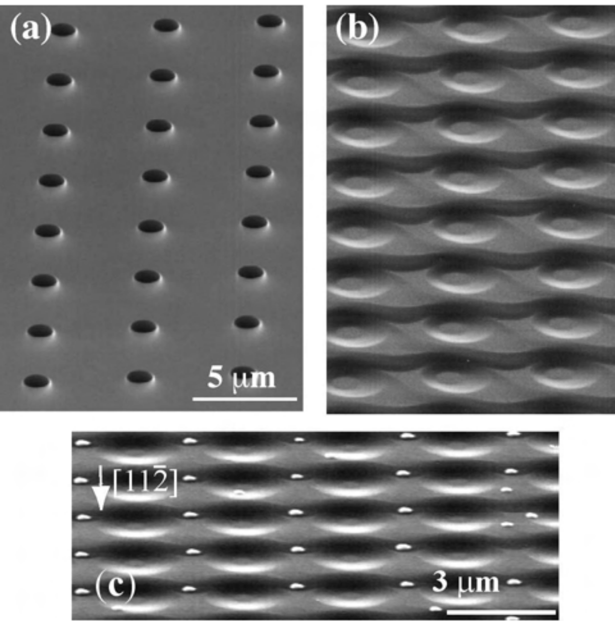

Figure 3. Step-band networks on Si(111) as templates for controlled Au island formation. The templates of ordered step bunches can be prepared from an initial hole pattern (a) by heating in UHV for 1–2 min at 1200–1300 °C (b). Examples of 0.8-μm holes patterned on 1.5° miscut Si(111) with the hole pattern rotated 7° azimuthally from the miscut direction are shown in (a)–(b). Deposition of a few ML of Au on the step-band templates, followed by annealing for 20–30 min at 400–600 °C, results in an ordered array of Au particles (c). The example shown in (c) started with a pattern of 0.6-μm holes. Adapted with permission from [90], Y. Homma et al., *J. Appl. Phys.* 86, 3083 (1999). © 1999, American Institute of Physics.

patterns (Fig. 3b) [88]. Such step bunch patterns can then be used as templates for selective deposition, for example, growth of GaAs on Si(111) vicinal surfaces, where site selectivity can be obtained via desorption or diffusion depending on the substrate temperature [88]. More features can be introduced into this type of a template if the surface is not heated long enough for the holes to completely disappear (fill-in). The resulting regular arrays of step bunches and holes can be used for selective deposition of metals (e.g., Au and Ga) and semiconductors (e.g., GaAs and Ge), which after appropriate annealing form ordered arrays of islands (Fig. 3c) [89–91]. A similar method has been also used to form device-quality arrays of quantum wires and dots on patterned high-index GaAs substrates [92–94].

The approach of combining lithography-defined patterns with self-organization on vicinal surfaces is thus particularly attractive, because it potentially offers a way to integrate self-assembled and self-organized nanostructures with micron-scale patterns and structures for device applications [92, 95]. This is also one of the few methods that produces ordered arrays of metal nanoclusters on Si surfaces (Fig. 3c), which can be used to define Si nanopillars through vapor-liquid-solid growth [90] (see also Section 3.2.1) or reactive-ion etching [96–98]. Conversely, because lithography is used for patterning, the inherent limitation of this process is the relatively low density (spacing on the order of 500 nm and above) of nanostructures in the resulting arrays (Fig. 3c).

3. SELF-ASSEMBLY AND HETEROEPITAXY ON SILICON

Heteroepitaxy is one of the main routes to growth of self-assembled nanostructures on silicon surfaces. Specifically, molecular beam epitaxy (MBE) [42] is the primary deposition technique used in research under UHV conditions. The two parameters that determine the thermodynamically favored growth modes are considered in Section 3.1: surface and interface energies, and surface strain. Section 3.2 provides examples of application of these general principles to heteroepitaxy of metals and semiconductors on silicon. The effects of the nonequilibrium kinetics and other deposition techniques are also discussed where applicable.

3.1. Growth Modes during Heteroepitaxy

The morphology of the surface formed during heteroepitaxy of lattice-matched materials is determined in the thermodynamic limit by the free surface energies γ of the two materials and the interface [17, 41, 99, 100]. Namely, high surface energy adsorbate will form random disjointed three-dimensional islands and leave the substrate exposed (also called *Volmer–Weber* (VW) growth, Fig. 4). More precisely, the corresponding condition is

$$\gamma_{\text{substrate}} < \gamma_{\text{adsorbate}} + \gamma_{\text{interface}} \tag{3}$$

A low energy adsorbate that satisfies the condition

$$\gamma_{\text{substrate}} > \gamma_{\text{adsorbate}} + \gamma_{\text{interface}} \tag{4}$$

will wet the substrate and thus form a continuous film (also called *Frank–van der Merwe* (FM) growth, Fig. 4). In ideal layer-by-layer growth, the nucleation of higher layers is strongly suppressed until the lower layer is completed. However, for subsequent layers the effective $\gamma_{\text{substrate}}$ is reduced

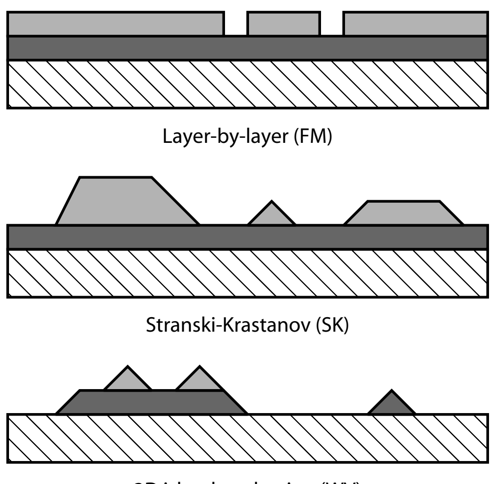

Figure 4. Equilibrium thin-film growth modes. In the layer-by-layer mode, a low surface energy adsorbate wets the substrate with a continuous film. In the SK mode, the first (or the first few) adsorbate layer reduces the substrate surface energy enough to stop the wetting behavior and proceed with nucleation of 3D islands. For an adsorbate with high surface energy, random 3D islands form directly on the substrate.

by the first layer, so instead of continuing in the layer-by-layer fashion the growth mode commonly changes to formation of islands on top of the first layer, resulting in *Stranski–Krastanov* (SK) mode (Fig. 4).

This relatively simple scheme, however, makes two important assumptions that often are not satisfied. First is the assumption of lattice-matched materials, which is in general not true, in particular in cases of technologically relevant material combinations (e.g., Ge/Si). Second is the assumption of a thermodynamically controlled process, which is not always satisfied even approximately (and never exactly, since all experimental processes are of finite duration).

In heteroepitaxy, if the lattice constant of the substrate is larger than that of the film, the resulting strain is tensile. In the opposite case, for example, for Ge/Si, the strain is compressive. In general, the difference in lattice constants results in SK-like growth mode, even if the surface energies favor the layer-by-layer growth, because roughening of the growth front allows to relax the elastic strain that otherwise would build up in the film [10, 17, 41, 99]. If this relaxation is not sufficient, plastic strain relief sets in, for example, creation of misfit dislocations and other defects in the film.

The dominance of kinetic effects versus thermodynamic stability is largely determined by the deposition flux and substrate temperature during growth. If the diffusion of the deposited atoms allows them to sample multiple bonding configurations, the energetically favored sites become populated with higher probability, and the resulting distribution tends towards the thermodynamically stable structures. If, however, either diffusion rate or diffusion length is limited, the deposited atoms are likely to be incorporated into the nearest site (typically an island edge) and thus kinetically preferred structures are formed.

While the variability of the growth modes that occurs in real heteroepitaxy was initially seen as an impediment to the smooth film growth required for device-quality materials, it soon became evident that these effects can be used to either enhance the film quality, or to produce self-assembled nanostructures [17, 41]. For example, if the flux and substrate temperature during the deposition are adjusted to allow the adsorbate atoms to diffuse to reach the nearest substrate step, the so-called step-flow growth mode is realized, which results in very smooth films; for example, homoepitaxy of Si under such conditions is routinely used to grow high-quality Si buffer layers. Additional examples of equilibrium and nonequilibrium driven SA in heteroepitaxy on Si are presented throughout Section 3.2.

3.2. Self-Assembly in Strained Heteroepitaxy

Formation of nanoscale islands via SK or VW heteroepitaxial growth is one of the most widely studied forms of self-assembly on a variety of substrates [17]. On silicon, the substrate of choice for microelectronics applications, the deposition of metals (Section 3.2.1) and semiconductors (Sections 3.2.2 and 3.2.3) has been examined for possible SA island formation. For metals, alloys, and semiconductors, both equilibrium and nonequilibrium processes can lead to SA.

3.2.1. Metal and Metal-Semiconductor Heteroepitaxy on Silicon

Metals tend not to form SA nanostructures when deposited directly on silicon, because of silicide formation and surface energy differences [48]. Thus formation of metallic nanostructures on silicon has to be guided by preferential deposition or diffusion on nanostructured and/or passivated surface templates [17, 27, 101–103], but not by heteroepitaxy-induced strain alone. One notable exception is the growth of several (primarily rare-earth) metal silicide nanowires on Si(001) (Fig. 5), which is driven by the asymmetric mismatch of the respective silicides with the Si lattice constant along orthogonal directions [102, 104–106]. The wires are formed in this case, because the growth proceeds uninterrupted along the direction where the constants match, but is limited in the perpendicular direction. An intriguing property of these wires is that they appear to be stable against atomic step motion during annealing; that is, moving steps get pinned around the wires, but the wires remain uninterrupted (Fig. 5) [102, 106]. While certainly very useful for creating individual long uninterrupted wires, this property, however, limits the possibilities of using stepped surface templates (Section 4.1) to control self-organization of many of such wires (Section 4.3).

Oxidation of metal films on silicon can result in SA metal-oxide nanostructures; in this case the volume change during the oxidation, rather than the lattice mismatch, is believed to be responsible for the SA process [107, 108]. One of the reasons metal oxides have attracted attention is that such SA structures can be magnetic [108] and thus offer a way to combine the benefits of silicon substrates and magnetic devices. SA 3D islands of ferromagnetic metal compounds that are used in semiconductor-based spintronics, for example, MnAs [109, 110], have also been demonstrated on Si(111) with SA achieved via the combination of the lattice mismatch and growth kinetics [110]. More complicated SA schemes are possible, for example, by metal deposition onto SA structures formed by the Ge/Si heteroepitaxy (Sections 3.2.2–3.2.3) which produces metal-semiconductor compound nanocrystals [111].

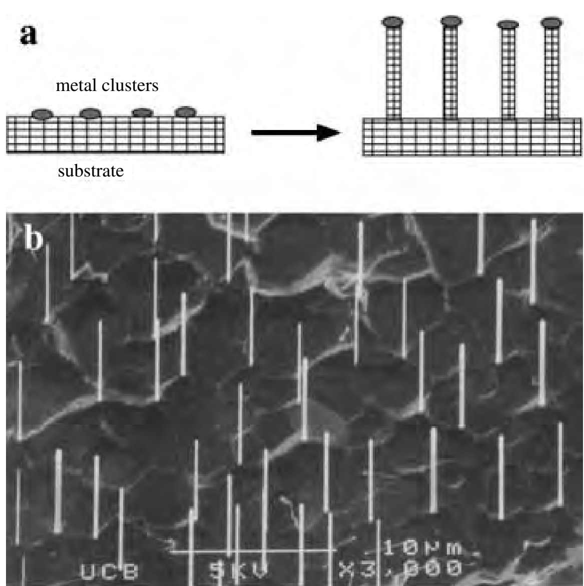
ZnO is a metal oxide that has attracted attention for optical device applications, because of the exciton binding energy of 60 meV, that is, larger than that of wide-bandgap semiconductors. ZnO SA quantum dots form in VW-like growth mode on silicon surfaces with intermediate layers, for example, silicon oxide [112] and GaSe bilayer [113]. For potential applications, for example, room-temperature short-wavelength nanolaser arrays, the main interest is in large island densities [114], which have been achieved by the vapor-liquid-solid (VLS) growth [115].

VLS [116] is a general method of growing semiconductor nanostructures [117] and nanowires [115, 118, 119] using metal nanoparticles as catalysts (Fig. 6a). VLS has been successfully used to grow bulk unsupported Si nanowires [119, 120] and oriented Si nanowires on Si surfaces (Fig. 6) [115, 121, 122]. Free-standing single-crystal nanowires in general do not form during semiconductor heteroepitaxy (Section 3.2.2), because such anisotropic crystals are thermodynamically unstable relative to bulk structures. The primary role of the metal particles is then to kinetically promote the growth of nanowires [115]. Their secondary role is to determine the diameter of the growing nanowires, which can thus be controlled if size-selected metal nanoparticles are used [115, 119]. The third possible function of the metal clusters is controlling the position of the resulting nanowires, which becomes meaningful if the clusters themselves can be positioned on a surface. During the VLS growth of Si, the metal (e.g., Au) particles partially melt and form a liquid alloy with the Si substrate. During the subsequent Si deposition, the liquid becomes a preferential adsorption site and the alloy quickly supersaturates with Si, which leads to Si precipitation and nanowire growth [115]. Silicon nanowires preferentially grow along the ⟨111⟩ direction, which produces *epitaxial* nanowires with unique orientation on Si(111) (Fig. 6b) and nanowires along the three equivalent ⟨111⟩ directions growing on Si(001) (Fig. 6c) [115].



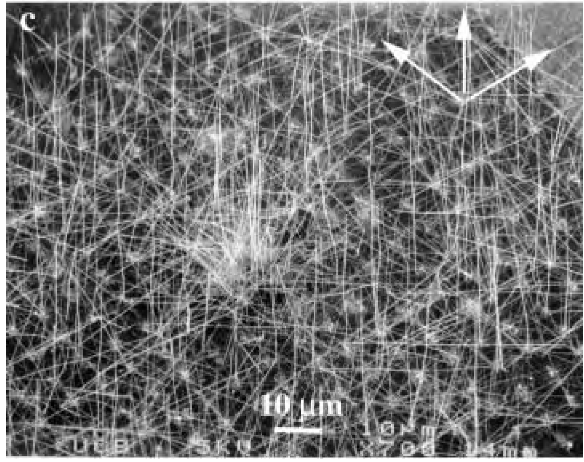


Figure 6. Silicon nanowire growth by vapor-liquid-solid epitaxy (VLSE). (a) VLSE schematic. (b) Vertical Si nanowires grown on Si(111) wafer. (c) Three sets of Si nanowires (preferred orientations indicated by arrows) grown on Si(001). Reprinted with permission from [115], Y. Y. Wu et al., *Chem. Eur. J.* 8, 1261 (2002). © 2002, Wiley-VCH.

VLS is thus a technique of choice for growing densely packed arrays of oriented single-crystal self-assembled Si nanowires. The seed metal particles, which terminate the wires, may be beneficial for some applications (e.g., for chemical selectivity), but also result in essentially unavoidable residual metal content—potential disadvantage for applications where high-purity Si is required (e.g., electronics). The self-assembled nanowires produced by VLS are not inherently self-organized (apart from the preferential orientation on epitaxial substrates), but because of its flexibility in terms of materials and conditions, VLS can potentially be combined with other approaches to produce self-organized structures.

3.2.2. Semiconductor Heteroepitaxy on Silicon: III-Vs and Ge

Semiconductor heteroepitaxy includes the three "canonical" material systems in which SA nanostructures with well-defined shapes and size distributions form under a variety of growth and postdeposition treatments: Ge/Si (≈4% mismatch), InAs/GaAs (≈7% mismatch), and InP/GaAs (≈3.8% mismatch) [17]. In addition to the widely studied elemental semiconductor heteroepitaxy of Ge/Si discussed below, SA of *compound semiconductors* on Si surfaces has been attempted as well, with the idea that the large lattice mismatches [123] that prevent smooth film growth in such combinations can result in SA of 3D islands. MBE of GaAs on Si(001) results in formation of SA islands with nucleation and evolution of shapes and sizes similar to those observed in the Ge/Si system, which suggests that a similar mechanism is responsible for SA [124]. High-quality SA GaAs quantum dots can be also produced by "droplet epitaxy" on GaSe-terminated Si(111) surface [125] or As-terminated Si(001) [126], whereby initially nanometer-size Ga droplets are formed under Ga flux and then they are transformed into GaAs by annealing under As flux [125, 126]. InAs is another III-V semiconductor for which the direct MBE growth on Si(001) results in SA quantum dots [127], but a more common method for growing quantum dots of InAs [128, 129] and other compound semiconductors [130] is to use H-terminated Si(001) substrates.

As already mentioned, Ge/Si is a *prototype for elemental semiconductor heteroepitaxy* that exhibits self-assembly and self-organization. The system is currently seen as one of the most promising for a variety of device applications; for example, see [21, 33, 131–133]. The extensive body of experimental and theoretical work on Ge/Si epitaxy and nanostructures is covered in several recent reviews [10, 21, 41, 54, 134]. In part because they are so widely studied, the mechanisms of SA nanostructures formation and evolution have been very controversial in this system and the debate offers an instructive example of development of the general understanding of the SA process.

Si and Ge have the same crystal structure, but Ge lattice constant is 4.2% larger, which results in compressive strain when Ge films grow pseudomorphically on Si. First, several uniformly strained full atomic layers of Ge form a wetting layer (Fig. 7a). The thickness of this wetting layer is largely determined by the ability of tetragonal distortion in vertical direction to relieve the strain. Since the lateral compressive strain still accumulates with increasing film thickness, the film becomes unstable against long-wavelength corrugation of the surface, a process particularly pronounced during growth on vicinal substrates (Fig. 7c), whereby ripples with more than 10 times the periodicity of substrate steps develop [41, 135]. Note that these structures, because of their large periodicity, can only contain very shallow facets. When such roughness is not sufficient for strain relief, steeper (higher-index) step bunches are introduced, leading to formation of 3D islands (Fig. 7b) with well-defined facets [10, 41].

3.2.3. Ge/Si Island Shapes and Evolution: Kinetics vs. Equilibrium

Similar to the surface roughening with increasing film thickness discussed previously, for classification purposes, the shapes of Ge islands on Si(001) (Fig. 8) can be described within the same framework of introducing progressively higher-index (steeper) facets with increasing island size [41, 54]. For the smallest islands, {105} facets with 11.3°

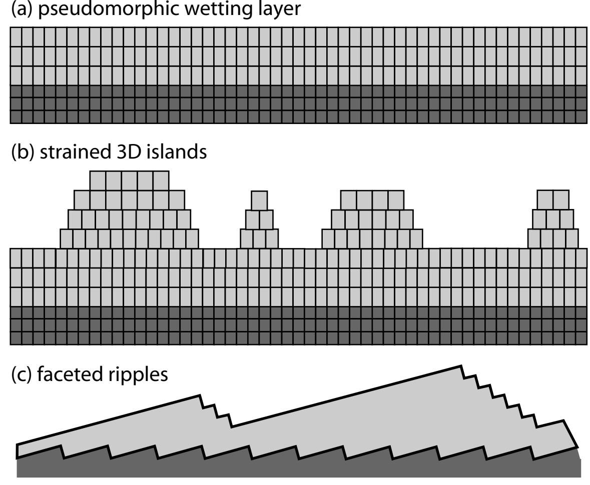

Figure 7. Strain relief in the Stranski–Krastanov growth mode. (a) Pseudomorphic wetting layer with tetragonal distortion. (b) Coherently strained 3D islands with steep facets. (c) On a vicinal substrate, faceting of the film through step bunching.

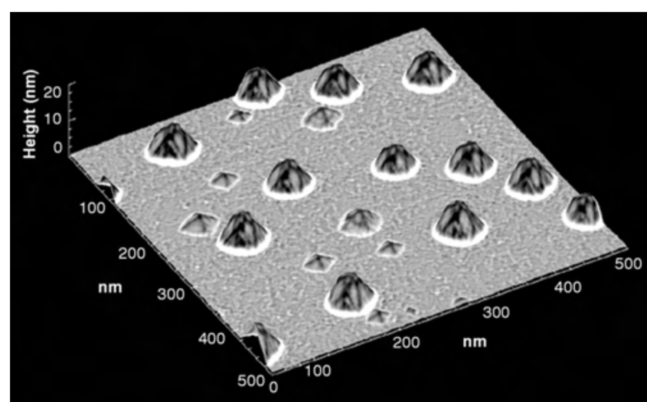

Figure 8. STM topograph of strained Ge nanocrystals on Si(001), showing both pyramids and domes. The gray scale is proportional to the local surface curvature as determined by the Laplacian $\nabla^2 h(x, y)$: positive curvature is white, flat areas are gray, and negative curvature is black. tilt relative to (001) plane appear. These islands come in two shapes: square-based *pyramids*, and elongated (in either ⟨100⟩ or ⟨010⟩ direction) "*huts*" with two trapezoidal and two triangular sides [41, 136]. For larger islands two more facets appear: {113} with 25.2° tilt relative to (001) plane and {518}. The latter was reassigned as {15 3 23} with 33.6° tilt [137] through comparison to a stable Ge surface [138]. Multifaceted islands with roughly symmetric bases are referred to as "*domes*" [54, 139] and consist mainly of {113} and {15 3 23} facets, but also contain small {105} and (001) facets. Finally, the largest islands are called "*superdomes*" [54, 140]; they are similar in shape to domes, but contain {111} and other steeper facets near edges.

Explaining the different island shapes (Fig. 8) and their relative stabilities, in an attempt to derive rational methods of growing SA nanostructures, became one of the most controversial problems in the field of SA systems. The huts were the first Ge/Si island type to be discovered [136], but now they are considered to be only metastable, because in annealing experiments huts transform into pyramids [141]. Pyramids and domes, on the other hand, co-exist (Fig. 8) over a wide range of coverage, temperature, growth, and annealing conditions, and thus the growth and shape transition mechanisms of these two island types have been extensively studied and debated for over a decade [10, 41, 54].

The main issue is whether the observed changes in island shapes are the result of a *kinetic roughening process* (e.g., Ostwald ripening [142]) or simply an *equilibrium distribution*, determined by the appropriate island energies. For practical purposes the equilibrium structures are preferred: they inherently evolve towards controlled uniform sizes, potentially can be grown by any deposition method, and are more likely to remain stable over the lifetime of devices (which may be orders of magnitude longer than the duration of the deposition process). If, on the other hand, the island types are determined by growth kinetics, then good understanding of the relative rates of the various processes is indispensable for controlling the appropriate growth parameters and stabilizing the structures (e.g., through surfactants or encapsulation).

Observable distinctions between kinetic and equilibrium processes are readily predicted by simple models. Classic Ostwald ripening, for example, leads to strictly unimodal, albeit not very narrow, particle size distribution and the average particle size growing monotonically with time [142]. For equilibrium models, in a system with several competing interactions, the existence of an optimal particle size (and shape) can be expected. Unfortunately, the actual experimental observations for the Ge/Si system are inconsistent with predictions from simple kinetic or equilibrium models. The problem then becomes that of choosing the appropriate model extensions and including additional surface processes, which in general tends to obscure the differences between model predictions. The development of the complex equilibrium models for this system has been extensively covered recently [54, 143, 144]; the somewhat more illustrative example of the kinetics models is briefly discussed in what follows.

The classic Ostwald ripening model and its extensions to 3D crystals on surfaces [53, 142, 145–148] predict that the chemical potential of an island decreases continuously with size because of the decreasing radius of curvature and surface/volume ratio. The atoms then have a higher probability to *detach* from smaller islands and to *attach* to larger ones; thus the larger islands grow at the expense of the smaller ones, which means that the average island size increases with time and the surface number density of islands decreases. The island size distribution on Ge/Si samples with co-existing pyramids and domes remains bimodal during growth and annealing [54, 141], so it clearly does not correspond to a simple Ostwald ripening. It has been suggested that a discontinuous change in the chemical potential of an island during its shape transformation could modify Ostwald ripening kinetics to produce a bimodal distribution [149, 150]. Quantitatively, the experimental size distribution [149] shows indications of size-limited behavior for both pyramids and domes, and thus narrower than expected width of these distributions. Therefore, an additional island size-dependent term in the adatom attachment rate is required in a kinetic model. Multiple such mechanisms have been suggested [54], for example, the increased strain for large islands at their edges and in surrounding substrates which favor detachment and flow away from these islands respectively [143].

Realistic equilibrium models [54] also have to include multiple energy terms: bulk strain, facet, interface, and edge energies for individual islands [151, 152], as well as interisland elastic interactions and ensemble thermodynamics [54]. As a result of the multiple terms in both kinetic and equilibrium models, their predictions depend on a number of unknown parameters and thus are difficult to compare to each other and experimental data. Other practical aspects of this system further increase the complexity; to name just two: above 650 °C all Ge islands are only metastable with respect to SiGe alloying [153], and transition shapes exist during growth but disappear upon cooling [137].

The general difficulty in assigning exclusively kinetic or equilibrium character to SA island formation has been noted in comparing growth behavior of Ge/Si, Co/Si, and Co/Ge/Si, where "in spite of the marked differences in surface thermodynamics and kinetic pathways... remarkably similar nanocrystal arrays" have been formed on the surface [111]. The main conclusion from the extensive research on the prototypical Ge/Si heteroepitaxy is that while the structures themselves appear to be thermodynamically stable, their growth is determined as much by kinetic pathways towards the equilibrium, as by the equilibrium configuration itself [54, 143, 154]. In other words, partially annealed configurations may exhibit strong nonequilibrium features, but with sufficient annealing distributions consistent with equilibrium theories emerge. One possible "general" scenario was suggested in [143]. Initial island nucleation and 2D–3D transitions are strongly kinetics-dependent. With increasing coverage, strain effects become relevant and island sizes and densities approach equilibrium values, but size-dependent kinetic terms are still significant. As the deposition flux is decreased and stopped, further annealing brings the system close to the equilibrium configuration, including saturated values of island sizes and density.

3.2.4. Ge/Si Multilayers

The ability to form *ordered multilayer* structures during the Ge/Si heteroepitaxy arises from interlayer interactions, which are discussed in detail in several excellent specialized reviews [10, 41, 134]. Here we focus on the importance of the multilayer ordering as a unique self-organization mechanism for self-assembled surface structures. Briefly, during the multilayer Ge/Si heteroepitaxy, nanostructures formed in the preceding layer affect the strain in the subsequent overlayer, which leads to self-alignment of nanostructures between the layers [10, 41, 135, 155]. In fact, these interactions can lead to improved size-uniformity and lateral ordering of the nanodots in the topmost layer even when the first layer was randomly nucleated [10, 41]. Almost perfect uniformity and lateral ordering is achieved when the first layer is prepatterned either artificially [133] or by self-organized template on the substrate [10, 41]. The latter cases offer some of the best practical realizations of truly self-organized arrays of self-assembled nanostructures (Section 4.4.2).

4. SELF-ASSEMBLED NANOSTRUCTURES ON VICINAL SURFACES

Vicinal surfaces and atomic steps are intimately related to self-assembly and self-organization on silicon surfaces. First, the vicinal surfaces themselves are subject to SO. Various aspects of these SO processes are described in Section 4.1: vicinal Si(111) and Si(001) used as substrates, formation of regular arrays of single atomic steps, step bunches, and domain boundaries. The traditional 3D heteroepitaxial growth modes are modified by the presence of multiple substrate steps, because in addition to the respective surface energies γ, substrate and adsorbate step energies σ have to be taken into account (Section 4.2). One of these growth modes, step decoration, based on the preferential adsorbate attachment at steps, provides the most intuitive way of using steps to guide SO (Section 4.3). But additional ordering, in particular in direction along the steps, can be obtained by combining vicinal templates and strained heteroepitaxy, as demonstrated in Section 4.4.

4.1. Vicinal Surfaces as Self-Organized Templates

Atomic steps are always present on macroscopic surfaces, so it is natural to develop self-organization schemes that benefit from their presence, rather than attempt to eliminate them. For example, step flow growth techniques take advantage of stepped surfaces for smooth film growth. Because atomistic processes in step dynamics can be controlled by macroscopic surface parameters, for example, wafer miscut angle, temperature, deposition and annealing rate, etc., there are many approaches that lead to self-organized step arrays. Such SO arrays of steps and step bunches represent surface templates macroscopic in one direction (along the steps) and nanoscale in two other directions (step-step separations and step heights).

Single-crystal silicon wafers with (001) and, to a lesser extent, (111) orientations are widely available for device fabrication and research purposes. Because of the increasingly stringent requirements of the semiconductor industry, production of these wafers is extremely well-controlled in terms of their composition, number of defects, and orientation. Since it is impossible to produce an atomically flat surface across a whole wafer, often it is beneficial to introduce a controlled miscut to produce a more ordered structure. The miscut orientation is usually defined in terms of its azimuthal ϕ (in-plane) and polar θ (out-of-plane) angle with respect to a low-index plane orientation, for example, [001] or [111]. Nominally (001) and (111) substrates are often randomly misoriented by about 0.5° in both ϕ and θ; accuracy in both angles of 0.1° and better is possible for customized substrates. Perhaps some of the best evidence for the ultimate wafer-scale control of the miscut and wafer orientation comes from recent advances in pattern formation by twisted wafer bonding (Fig. 9), with regular nanoscale patterns demonstrated over macroscopic areas [156, 157].

Steps are inherently linear objects, and thus the obvious goal for SO stepped templates is creation of uniform arrays of straight steps. While control of lateral ordering of SA nanostructures is possible even with straight steps (as discussed in Section 4.4.1), templates with 2D patterns are the most direct way to achieve lateral ordering. Similarly to the wafer bonding example (Fig. 9), by choosing a miscut rotated by ≥10° in both ϕ and θ angles from a low-index orientation, 2D patterns of atomic terraces or facets 10–100 nm in size are produced upon annealing. The large miscut in ϕ ensures that two equivalent step orientations act as boundaries of atomic terraces for each of the pattern elements, and determines whether the pattern is symmetric by the relative alignment of the miscut direction with respect to these two step orientations [41, 158]. The misorientation in ϕ in this case is an ordering parameter analogous to the misorientation between the hole pattern and the step direction in case of patterned templates [87, 95] discussed in Section 2.2.3 (Fig. 3). The large miscut in θ is mainly used to induce formation of steep (i.e., with tilt angles comparable to θ) facets [41, 158] which for miscut $\theta < 5°$ can be formed only by additional patterning on a larger scale (e.g., [88, 90]).

For silicon surfaces that have been prepared via a high-temperature anneal in UHV, the structure of the atomic steps and facets is intimately related to surface reconstructions [159]. For Si(001) vicinal surfaces with a small polar miscut, this leads to formation of two types of steps: S_A and S_B, with the 2 × 1 reconstruction dimer rows in the upper terrace parallel and perpendicular to the steps, respectively [160–164]. This limits the applicability of Si(001) vicinal surfaces as stepped templates, because the S_B steps are always rough [164, 165]. Moreover, for polar miscut above 2° an increasing fraction of the steps is converted into double-height D_B steps with dimer rows perpendicular to step edges [160, 161]. For 4–5° miscut, full conversion to double-height steps is achieved and the D_B step edges become relatively straight because of step-step interactions, but they are never atomically straight over many lattice sites. Because of the structure of Si dimers, such surfaces have found applications for molecular self-assembly discussed in Section 5.1.2.

The 7 × 7 surface reconstruction, characteristic for Si(111) after a high-temperature anneal, is three-fold symmetric (Fig. 10a), so naïvely one may expect that straight steps would be even harder to form on this surface. However, atomic steps formed on slowly cooled vicinal Si(111) surfaces adopt a preferred displacement of the 7 × 7 reconstruction across the steps, and the terrace widths are quantized in units of the 7 × 7 unit cell (or rather 1/2 of it, as seen in Fig. 10a) [166]. The origin of this effect is in the large size and extreme energetic stability of a 7 × 7 unit cell, which strongly favor steps that preserve its structure [167, 168]. And while kinks on the Si(001) steps can be formed by thermal fluctuations [165], these fluctuations are insufficient to add or remove 1/2 of a 7 × 7 unit cell, leading to essentially atomically straight steps on well-annealed surfaces (Fig. 10a). As shown in Figure 10b, an improper miscut can force kink formation and rough steps on a Si(111) surface. Another potential source of defects on terraces and steps, also seen in Figure 10b, are the 7 × 7 domain boundaries [169, 170], but those can be avoided over micron-size areas by appropriate cooling sequence [171, 172] or otherwise controlled [87, 95]. In fact, because the relevant atomistic processes for Si(111) surfaces are well-understood [57, 58, 168, 173–176], several approaches for creating self-organized templates based on atomic steps on vicinal Si(111) surfaces have been developed, all of them achieved by a

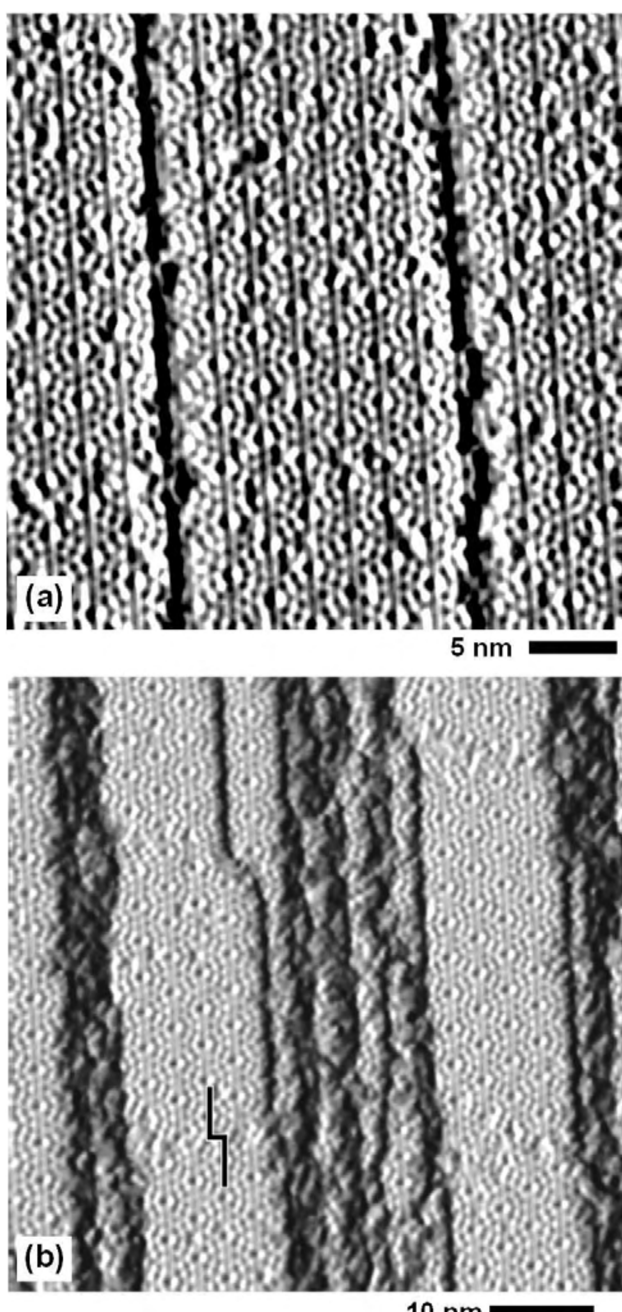

Figure 10. Atomic steps and 7×7 reconstruction on Si(111). (a) Atomically straight step edges (thick dark lines) incorporate rows of 7×7 corner holes. The faint lines parallel to the step edges emphasize the terrace width quantization in units of half a 7×7 unit cell (2.3 nm). (b) Three types of defects for a step array on Si(111): irregular step bunches, kinks along single steps, and 7×7 domain boundaries (jog in the black line). Downhill is to the right. The derivative of the STM topography is used to emphasize the reconstruction and steps in (a) and (b). Adapted in part with permission from [171], J. Viernow et al., *Appl. Phys. Lett.* 72, 948 (1998). © 1998, American Institute of Physics.

combination of controlled heating, annealing, or deposition: uniform arrays of straight atomic steps (Section 4.1.1), arrays of step bunches (Section 4.1.2), and arrays of steps and domain boundaries (Section 4.1.3).

4.1.1. Arrays of Single Steps and Step Interactions

The most stable step orientation on Si(111)7×7 surface is $[\bar{1}\ 1\ 0]$ direction, that is, the one that contains a row of corner holes on the upper terrace (Fig. 10a) [173, 176–183]. Such step edges are possible for two orientations of the surface normal: tilted from [111] towards $[1\ 1\ \bar{2}]$ or $[\bar{1}\ \bar{1}\ 2]$. The steps with the $[\bar{1}\ \bar{1}\ 2]$ tilt are taken as the most stable configuration since they are found to occur during Si/Si(111) homoepitaxy [178]. Atomic step templates with the kink densities as low as one 2.3-nm kink in 2×10^4 atom spacings ($\approx 8\ \mu$m) have been achieved [171] for vicinal surfaces cut 1.1° towards $[\bar{1}\ \bar{1}\ 2]$ (Fig. 11a). In addition to the exceptionally straight steps, another feature of these templates is the single-domain 7×7 reconstruction, which spans entire terraces over micron-sized areas, as evidenced by the lack of fractional kinks (i.e., those smaller than the 2.3 nm

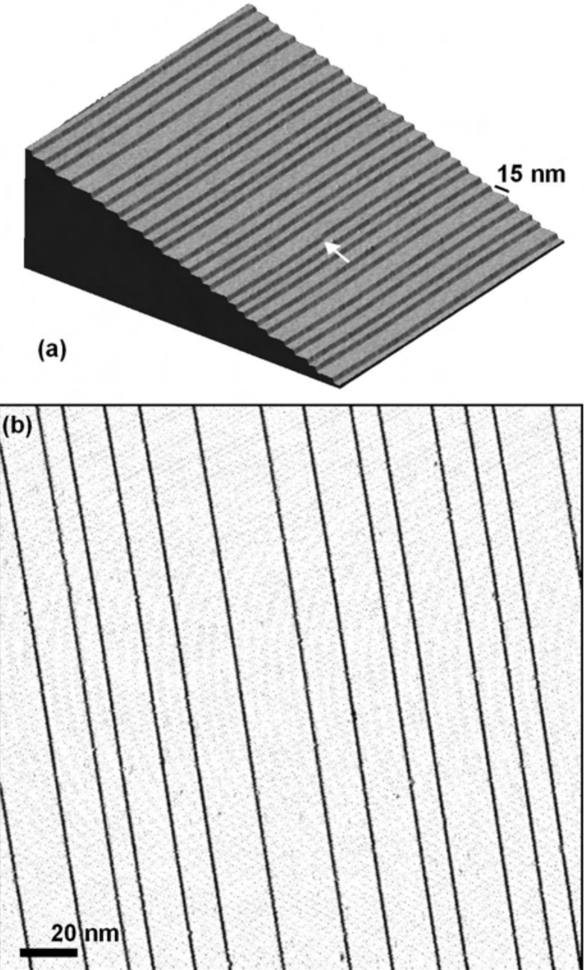

Figure 11. Arrays of single steps on Si(111). (a) Three-dimensional view of a high-quality array of single steps (0.3 nm height) prepared on Si(111) miscut by 1.1° towards the $[\bar{1}\ \bar{1}\ 2]$ direction. There is only one kink (arrow) in the 340×340 nm^2 area; the rest of the steps are atomically straight [171]. The vertical scale is enhanced by a factor of 20. (b) Faint traces of the 7×7 reconstruction pattern and the absence of kinks in this STM topography derivative image indicate that the 7×7 reconstruction is single-domain over the entire image.

1/2 of the 7 × 7 unit cell) [171, 184], direct STM observations of large areas without domain boundaries [171, 184] (Fig. 11b), and high-quality photoemission spectra achieved from such surfaces [172]. The presence of such large areas of single-domain reconstruction reflects the interplay between the 7 × 7 reconstruction helping to stabilize the straight step edges and step edges serving as nucleation sites for the single-domain reconstruction. By appropriately adjusting the preparation conditions, it is thus possible to either create single-domain templates for large-scale anisotropic surface reconstructions (Section 5.2), or SO templates with quasi-2D-periodicity (Section 5.1.3).

The uniformity of the terrace width distributions on the low-miscut surfaces does not match the perfection achieved along the step edges, because several of the possible 7 × 7 = 49 registrations occur between the 7 × 7 domains on adjacent terraces [166, 171, 182, 185]. Among the seven registrations parallel to the step edge, those that preserve the (1 $\bar{1}$ 0) mirror plane symmetry (i.e., those where the rows of corner holes perpendicular to the step edges continue from one terrace to the next) are prevalent (Fig. 10a), and the overall terrace width distribution exhibits a standard deviation of 3–4 nm (≈1–2 quanta). The average single-step separation is determined by the polar miscut angle and 0.31-nm step height; for example, the spacing is approximately 15 nm for 1.1° miscut (Fig. 11a) [171]. The equilibrium terrace width fluctuation is determined by a balance between the entropy cost of straight steps and the elastic energy cost of narrow terraces (i.e., small step separation) [186–188].

Elastic interactions between steps can be generalized according to their symmetry into monopole and dipole character. The monopole term originates from the presence of elastic-stress domains on reconstructed surfaces; on vicinal surfaces atomic steps act as domain walls and the corresponding domain-wall energy has a logarithmic dependence on their separation l [189]. The elastic-dipole interaction between steps arises to compensate for the nonzero moment of the surface capillary forces acting on upper and lower terraces (Fig. 12). The dipole interaction thus can have components perpendicular or parallel to the substrate (Fig. 12) and its energy has l^{-2} dependence [190, 191]. The dipole interaction is repulsive for steps of the same sign (i.e., the same downhill direction), so it helps stabilize step arrays on vicinal surfaces. The terrace width distribution on vicinal Si(111) surfaces is predominantly determined by the dipole interactions between steps [186]. Note that the dipole

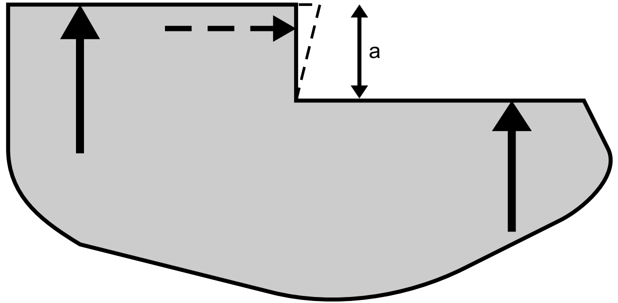

Figure 12. Surface capillary forces acting on the upper and lower terraces produce nonzero moment acting on the step, with components perpendicular and parallel to the surface.

interaction can be attractive in cases where materials with different elastic constants are involved; for example, adsorbate islands can be either attracted or repelled by the steps. When both the monopole and dipole interactions are included, one has to add to the total energy an attractive cross-term with a l^{-1} dependence [192, 193]. The combination of these elastic interactions is responsible, for example, for the minority terrace width distribution on vicinal Si(001) surfaces [194].

For polar miscut of 1–2°, long-range dipole repulsion stabilizes arrays of individual steps on both Si(001) and Si(111). The equilibrium terrace width fluctuations are determined for Si(001) and Si(111) primarily by the monopole and dipole terms, respectively, with fluctuations proportional correspondingly to $l^{1/2}$ and l [187, 188]. Smaller step separation l is thus expected to produce increasingly straight steps, but the resulting larger miscut angles often produce step bunching. On Si(001), as discussed earlier, step doubling produces the D_B steps with dimer rows perpendicular to step edges [160, 161] and in this configuration formation of individual kinks is difficult to suppress over multiple dimer sites. Si(111) steps become unstable against formation of triple steps [176] for polar miscut angles larger than about 2°. An isolated triple-height step is energetically unfavorable compared to three single steps, but with decreasing step spacing the elastic-dipole repulsion increases, and the total energy cost can be lowered by forming the triple steps (with correspondingly larger spacing) [186].

4.1.2. Step Bunches and Facets

Just as for single steps, vicinal surfaces with miscut towards [1 1 $\bar{2}$] or [$\bar{1}$ $\bar{1}$ 2] directions produce better ordered step bunches [184, 195] than other vicinal surfaces [58, 196–198]. In particular, on surfaces with polar miscut towards [1 1 $\bar{2}$], periodic arrays of (111) terraces and high-density facets are formed [184, 195]. Periodicity of these step arrays is independent of the miscut angle up to 6°, but the width of the stepped facets increases with the miscut [184, 195], which in principle should allow to create arbitrary ratios of the flat and stepped regions by adjusting the miscut angle (Fig. 13). Both the perfection and constant periodicity are attributed to the exceptionally stable structure of the facet that forms, which is characterized by an average facet angle of 12.7° [195] and is composed of narrow ledges with reconstructions similar to the 5 × 5 analog of the 7 × 7 reconstruction [184, 195]. It is important to note that because of the large width of the flat terraces and thus significantly reduced step interactions, formation of the regular arrays of bunched steps is much slower than that of the single steps [184].

The bunched step facets are energetically stable, but the step edge perfection of the single steps is lost during their formation. In the range of miscut angles between the (111) and (001), the evolution of stable structures is characterized by several stable planes: (5 5 12), (113), (114), (118), (331), and mixtures of various facets in between [158, 159, 196, 199–201]. Thus, in general, the local structural perfection is recovered at large miscut angles, but not the long-range periodicity of the steps.

There is, however, a number of vicinal Si(111) and Si(001) surfaces that lend themselves for use as self-organized templates (Fig. 14). Particularly with Au as an adsorbate [58],

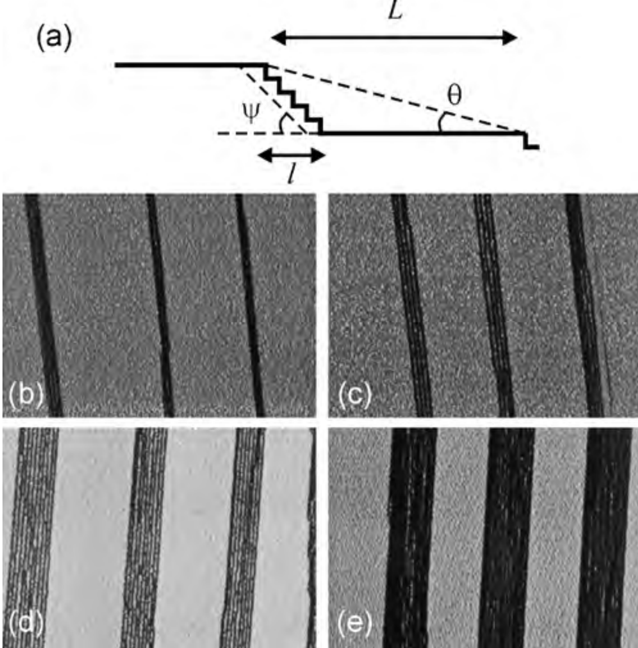

Figure 13. Arrays of step bunches on vicinal Si(111). (a) There are two parameters for uniform arrays of step bunches: the periodicity L defined by the polar miscut angle θ, and the terrace width (L–l) defined by the facet angle ψ of the bunches. For Si(111) miscut towards the $[\bar{2}\ 1\ 1]$ direction, the periodicity and the stable facet angle remain constant for $\theta < 6°$; therefore the terrace width systematically decreases in the miscut series of 1°, 2°, 4°, and 6° (b–e). The derivative of the STM topography is shown to emphasize the stepped regions. Downhill is to the right. Adapted in part with permission from [195], F. K. Men et al., *Phys. Rev. Lett.* 88, 096105 (2002). © 2002, American Physical Society.

a large fraction of the possible orientations has actually produced well-ordered structures, and many other possible crystallographic orientations have yet to be explored. Electronic properties of these surfaces are described in Section 5.2. In terms of its structure, perhaps the simplest is the case of a vicinal surface with 9.45° miscut towards $[\bar{1}\ \bar{1}\ 2]$ direction. It is composed of steps separated by (111) terraces

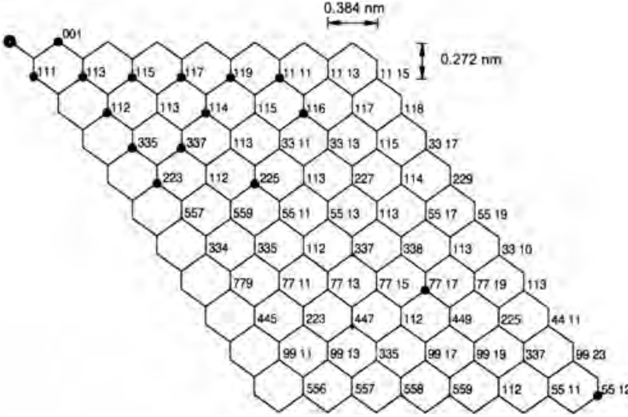

Figure 14. Silicon crystal lattice between (001) and (111) orientations. Single unit cells of bulk-terminated orientations are marked with solid circles. After [159], A. A. Baski et al., *Surf. Sci.* 392, 69 (1997). © 1997, Elsevier Science.

that accommodate a single row of the 7 × 7 reconstruction and one additional string of Si adatoms (Fig. 15) [202]. This is an example of a self-assembled atomically precise grating with the largest corrugation and unit cell achieved on Si surfaces [202]. The periodicity of this structure is expressed in terms of the Si lattice constant—one of the best-known lattice parameters, which suggests possible applications for nanoscale metrology [203, 204]. Atomically precise nature of this template also allows to create ordered atomic structures over at least hundreds of nanometers (Section 5.2.2).

4.1.3. Steps and Domain Boundaries

Stepped templates, discussed in the previous two subsections, took advantage of the near-equilibrium step structures, achieved through high-temperature annealing and stabilized by the 7 × 7 reconstruction or its analogs. Another well-studied process on silicon surfaces is the behavior and structure of steps and 7 × 7 domains during homoepitaxial growth [205–209], which is generally a nonequilibrium process, but can also result in ordered structures. Similarly to the annealing case, the ordering can be guided either by prepatterning the surface, or by controlling the deposition conditions.

On lithographically patterned elongated mesas oriented parallel to $[1\ \bar{1}\ \bar{2}]$ direction, step-flow growth results in terraces with stable steps along the two symmetric $\langle 211 \rangle$ directions, and under appropriate conditions dense and rather regular step arrays are formed (Fig. 16) [59, 210].

As discussed in Section 4.1.1, to produce atomically straight single steps, it was important to achieve equilibrated *single-domain* 7 × 7 reconstruction over entire terraces (Figs. 10, 11) [171, 184]. An alternative approach to step ordering is to allow random nucleation and growth of the 7 × 7 domains at multiple sites near the step edges. Because of the large unit cell, registration between random domains is unlikely, so when such domains collide, out-of-phase boundaries (OPBs) are formed [87]. Thus a 2D quasi-periodic network of atomic steps and OPBs is formed [87, 95], with the periodicities determined by step separation and 7 × 7 domain nucleation conditions. The uniformity of these networks can be dramatically improved by depositing additional Si. During Si homoepitaxy, atoms preferentially are

incorporated at cross-points of OPBs and steps, and combined with fluctuations of the growth rate this results in wavy growth fronts, with the periodicity of the waviness determined by the growth conditions. During such growth, the area of smaller domains tends to diminish, until they merge with larger neighbors, and thus a considerably more uniform network of steps and OPBs is formed [87, 95].

4.2. Heteroepitaxy in Two Dimensions

The step-flow growth is an example of a 2D equivalent of the layer-by-layer growth in three dimensions. The other 3D growth processes can also be generalized for cases of submonolayer deposition on stepped surfaces, where essentially 2D growth occurs [17, 41]. Instead of the surface free energies γ, however, one has to consider a set of respective step energies σ: substrate steps ($\sigma_{\text{substrate}}$), adsorbate island edges ($\sigma_{\text{adsorbate}}$), and the interface between a substrate step and an island attached to it ($\sigma_{\text{interface}}$). Replacing γ's with σ's in Eq. (3) for 3D growth, we get a set of conditions for the adsorbate to form disjointed islands along steps:

$$\sigma_{\text{substrate}} < \sigma_{\text{adsorbate}} + \sigma_{\text{interface}} \tag{5}$$

For continuous adsorbate stripes attached to substrate steps:

$$\sigma_{\text{substrate}} > \sigma_{\text{adsorbate}} + \sigma_{\text{interface}} \tag{6}$$

The familiar equilibrium growth modes that reappear in a 2D world can be classified as row-by-row, Stranski–Krastanov, and island growth in analogy with the 3D equivalents (Fig. 17). A new possibility arises if the following condition is satisfied:

$$\sigma_{\text{interface}} > \sigma_{\text{adsorbate}} + \sigma_{\text{substrate}} \tag{7}$$

in which case adsorbate islands will form, but avoid the step (Fig. 17). This is a uniquely 2D phenomenon, since in 3D growth this would correspond to adsorbate islands floating above the substrate.

In 2D growth just like in the 3D case, the general rule is to use low deposition flux and sufficiently high substrate temperature to approach the equilibrium distributions in experimentally observed growth modes. The next two sections discuss examples of the use of the different 3D and 2D growth phenomena in self-assembly and self-organization of nanostructures on Si surfaces.

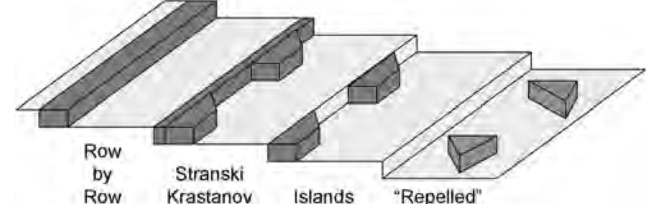

Figure 17. Equilibrium growth modes at steps. The first three regimes (left-to-right) are essentially 2D equivalents of the classic equilibrium growth modes—compare to Figure 4. The step energy rather than the surface free energy is the parameter responsible for the different growth modes in the 2D case. The last regime, with islands not attached to steps, is a uniquely 2D phenomenon (3D equivalent would be islands *floating above* the substrate surface).

4.3. Step Decoration and Self-Assembled Nanowires

Step decoration takes advantage of preferential attachment and/or growth of the deposited material at the atomic steps. The technique was pioneered almost half a century ago when it was used to visualize atomic-height steps on cleavage surfaces of sodium chloride by decorating them with gold [211]. Step selectivity of various surface processes can be utilized to produce step decoration; for example, for silver on graphite, step decoration can be achieved through: selective nanocluster growth [212], diffusion [212–214], and nanowire growth by electrochemistry [215, 216]. For epitaxial systems, step-flow growth results in nanowires of the adsorbate material attached to lower step edges of the substrate (Fig. 17). This growth mode has been first realized for the GaAs/GaAlAs system [217, 218], aided by the almost perfect chemical and structural match between these materials.

The step-flow growth of self-assembled nanowires can also be achieved for metal-on-metal combinations, if a substrate with high surface energy (e.g., W, Mo) and an adsorbate with low surface energy (e.g., Cu) that does not alloy with the substrate are used [219–225]. STM imaging with elemental contrast through spectroscopic states [222, 224, 226] allowed observation of the structure of these metal nanowires with atomic resolution and study of the corresponding growth modes [103]. Quantitative analysis of thus obtained nanowire width distributions produced two results important for rational size-control of SA nanowires: equilibrium structures exhibit the narrowest size distribution and the lower limit on such distribution is imposed by the roughness of substrate steps [103, 227].

Step arrays of vicinal Si(111) [171, 184] discussed in Section 4.1.1 thus represent an ideal substrate for self-assembly by step decoration because they provide atomically straight steps and essentially single-domain Si(111)7 × 7 terraces (Fig. 11)—both factors beneficial for producing self-assembled nanowires with narrow width distribution. Two material combinations have been primarily explored for step decoration on vicinal silicon surfaces: insulator-on-semiconductor CaF_2/Si [27, 103] and semiconductor-on-semiconductor Ge/Si [10, 41]. CaF_2/Si(111) is an excellent model system for studies of submonolayer growth and exploring structures and interactions in the <10-nm range, because of the combination of the high-quality vicinal

templates and atomically sharp interfaces. Ge/Si combination produces superior multilayer systems on a larger (>100 nm) lateral scale and, because inherently conducting SiGe structures are created in the process, it is better suited for characterization by optical and conductivity measurements, including looking for signatures of electron confinement at low temperatures.

4.3.1. CaF_2 Nanostripes on Vicinal Silicon Surfaces

CaF_2/Si(111) is a material combination that has been studied for nearly two decades both as a model heteroepitaxial system and as a possible device platform. For devices, it offers a possibility of epitaxial semiconductor-insulator-semiconductor and metal-insulator-semiconductor structures [228–230]. Model studies of growth modes in 2D heteroepitaxy [103, 231–236] also benefit from the nearly lattice-matched CaF_2/Si(111) combination that forms high-quality epitaxial films and atomically sharp interfaces [228]. CaF_2/Si(001) combination has not been as widely studied [237–240], but step decoration has been recently reported for this system as well [240].

Two types of CaF_2/Si(111) interfaces exist: a F-terminated interface at temperatures below 700 °C, and a Ca-terminated interface from 700 °C to the desorption of CaF_2 at 800 °C (for a monolayer (ML) coverage). A significant fraction of the interface remains F-terminated on a stepped surface, even at high annealing temperatures [241–243]. The F-terminated interface preserves the orientation of the Si(111) substrate (type A epitaxy) while the Ca-terminated interface rotates the structure azimuthally by 180° (type B epitaxy) [244–249]. The differences in bandgaps and band alignment between the clean Si substrate and the two types of interfaces [250, 251] allow to positively identify the different types of structures, even on surfaces with complex topography, via the chemical imaging STM mode [234, 252].

In general, one would expect a transition from island nucleation to step-flow growth with decreasing supersaturation, that is, increasing temperature, decreasing deposition rate, and decreasing step spacing. The results presented in Figure 18 are consistent with such transition: low temperature (550 °C) and low coverage result in randomly distributed small islands (Fig. 18a), higher temperature (600 °C) and coverage result in apparent step-flow growth (Fig. 18b). The distribution of the small CaF_2 islands across terraces in Figure 18a indicates that there is preferential attachment of CaF_2 islands at lower step edges, and a weak repulsion from upper steps edges [234], both factors beneficial for step-flow growth. The presence of residual islands on wider terraces in Figure 18b suggests that the higher deposition temperature corresponds to CaF_2 diffusion length of about 8–9 nm. The CaF_2 stripes in Figure 18b then are far from equilibrium even at 600 °C, which explains the substantial edge roughness. Interface conversion and Ca/Si(111) 3×1 formation [228, 253] prevent deposition at temperatures above 650 °C for step-flow-like growth, so smooth CaF_2 stripes cannot be achieved on Si(111) via a standard step-decoration approach. Moreover, as explained in the next section, the initial stages of growth in this system on vicinal surfaces with step separation <15 nm are strongly affected by the presence of the steps.

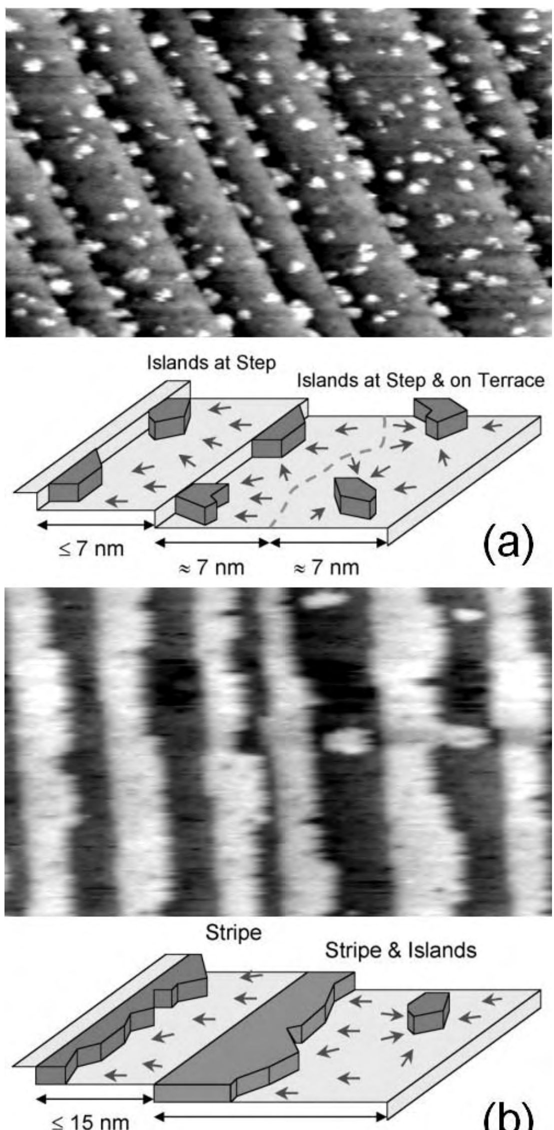

Figure 18. Nonequilibrium CaF_2 growth modes at Si(111) steps. (a) At 550 °C the diffusion length is ≈7 nm, that is, less than half the average terrace width, resulting in diffusion-limited growth. Small islands preferentially attach to steps, but also randomly nucleate on terraces. (b) At 600 °C the diffusion length of 8–9 nm allows step-flow growth on most terraces, except the widest ones where not all the CaF_2 molecules can reach the step. STM images 100 × 60 nm^2, downhill is to the right, CaF_2 appears bright, Si—dark. Adapted in part with permission from [234], D. Y. Petrovykh et al., *J. Vac. Sci. Technol. A* 17, 1415 (1999). © 1999, Elsevier Science.

Smooth CaF_2 stripes can, however, be grown via a process that takes advantage of the interface conversion. Deposition of 1.5 ML of CaF_2 followed by a post-anneal at 830 °C establishes a complete layer of Ca-terminated structure with CaF_2 stripes on top (Fig. 19) [27, 103, 234, 254]. Note that the stripes are located at upper rather than lower step edges; in fact, they avoid the lower edge to such an extent, that even for coverage very close to 2 ML an uninterrupted gap is maintained [234, 254]. This apparent repulsion is due to the 180° azimuthal rotation introduced into the CaF_2 film

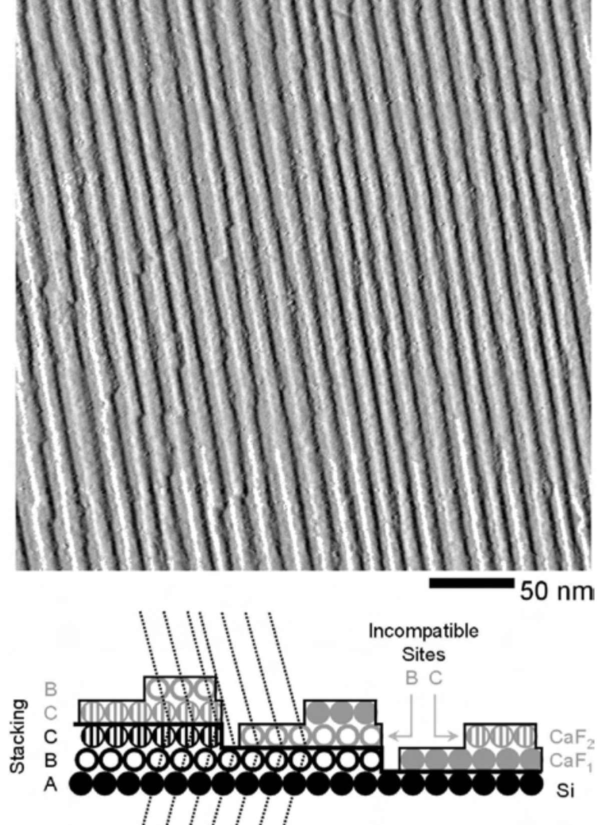

Figure 19. Reverse step-flow growth for CaF_2 on Si(111) at high temperature (830 °C post-anneal). Continuous CaF_2 stripes ≈7 nm wide start at the upper step edge and propagate in the uphill direction. This unusual growth mode is caused by a reversal in stacking at the interface, which causes a lateral incompatibility in the structure across a step. This prevents step flow and ensures that adjacent stripes strictly avoid each other. The derivative of the STM topography is shown to emphasize the steps and stripe edges. Downhill is to the right. at the Ca-terminated interface [246] and the resulting mismatch in the orientation of Si steps and CaF_2 in the second layer (see diagram in Fig. 19) [234, 236, 254].

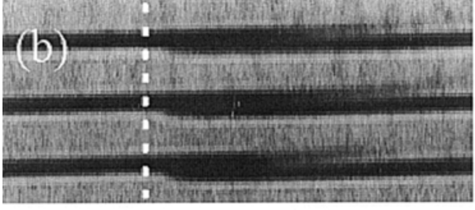
The stripe-and-trench CaF_2/Si(111) structure in Figure 19 is in fact very advantageous as a template for selective deposition, because the periodicity and the width of the trenches can be independently controlled by adjusting the miscut and the coverage, respectively. The stripes and trenches are too narrow for selective decoration by metals via direct deposition [255] or electron-stimulated desorption [256] that have been used for CaF_2 surfaces. Organic molecules [257] including chemical vapor deposition (CVD) precursors [258] can, however, be selectively deposited into the trenches due to their higher reactivity (Section 5), and thus Fe nanowires have been successfully grown on such templates via selective CVD [259]. The combination of the well-controlled self-assembled template and the widely applicable selective CVD deposition makes this approach promising for growing other types of self-assembled metal nanowires with width and periodicity <20 nm [14, 27, 103].

4.3.2. Step Decoration in Ge/Si Heteroepitaxy

In Ge/Si heteroepitaxy, most of the step-decoration research has been focused on growth using vicinal Si(001) substrates and primarily on multilayer structures [10, 41]. For submonolayer deposition of Ge, agglomeration at atomic steps has been demonstrated [260] and attributed to step-flow growth, lower step energy for Ge, and enhanced relaxation of Ge-Si lattice mismatch at steps [10]. Deposition of SiGe/Si multilayers on vicinal Si(001) results in *self-organized arrays of self-assembled SiGe nanowires* [261], the process driven by local strain relaxation [135, 262–264]. The nanowire-like structures within each SiGe layer are formed by thickness undulations within the ≈5-nm-thick layer with about 100 nm periodicity (Fig. 20) [261]. The facets of these wires are defined by Si and SiGe step bunches; thus the structural confinement of the individual wires can be improved by using templates with stronger bunching, such as Si(113) [261, 265]. The width and periodicity of these structures (intrinsic characteristics of the bunched Si(001) and Si(113) templates) are larger than those achievable for the CaF_2/Si(111) system discussed earlier. The larger size and the multilayer nature of the samples make conductivity measurements possible for this system, and the resistivity exhibits strong anisotropy (perpendicular vs. parallel to the wires) for these samples at temperature <100 K [10].

For Ge/Si(111) material combination, nanowires have been demonstrated on a Si(111) substrate miscut 0.5° towards [$\bar{1}$ 1 0], that is, direction perpendicular to that discussed in Section 4.1.1. The template thus consisted of atomic steps with ≈110 nm periodicity, and the nanowires with 4.5 nm average height and 43.4 nm average width formed on upper step edges [266, 267]. The material distribution in these wires appeared to be nonuniform, which together with the upper step position rules out step flow as the possible growth mode. The suggested mechanism included initial formation of SA Ge dots on top of a wetting



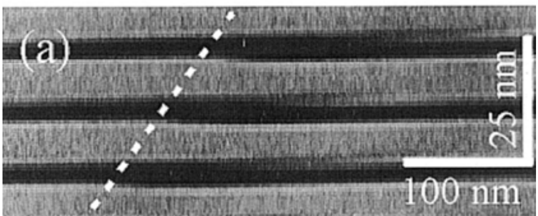


Figure 20. Self-organized arrays of self-assembled SiGe nanowires. A cross-sectional TEM image of SiGe faceted nanowires grown on vicinal Si(113) is shown. The wire stacking changes within the SiGe/Si multilayer between the central (a) and top (b) regions. Reprinted with permission from [261], K. Brunner et al., *Physica E* 7, 881 (2000). © 2000, Elsevier Science.

layer (i.e., SK growth mode), with the dots migrating towards upper step edges for strain relaxation. The wires were then completed by additional Ge migration into the gaps between the dots during the subsequent deposition [266, 267].

4.4. Strain and Steps—Two-Dimensional Control of Self-Assembly

To the extent that the two can be separated, the effects of surface strain and steps on heteroepitaxial growth modes have been separately considered in Sections 3.2 and 4.3, respectively. In general, strain provides a very useful mechanism for self-assembly of nanostructures with uniform size and shape distributions, while stepped templates are very effective in ordering structures over macroscopic areas. Here we demonstrate how the combination of the two approaches can result in systems of self-assembled nanostructures that also exhibit 2D self-organized ordering, using examples from the two systems introduced in the previous section: CaF_2/Si and Ge/Si. The 2D growth phenomena described for these prototype systems are quite general, as similar growth patterns are also observed in strained heteroepitaxy of III-V semiconductors [268–270].

4.4.1. CaF_2/Si(111) Quantum Platelets and Novel 2D Growth Mode

For the CaF_2/Si system, the possibility of unusual 2D growth modes is indicated by growth patterns such as shown in Figure 21. The equilibrium growth modes determined by the step energies alone (Section 4.2) would predict that the adsorbate must preferentially either wet the steps or form a broken interface, but not both simultaneously! Specifically for CaF_2/Si(111) combination, complete wetting (e.g., Fig. 21 left) is expected, because the surface energy of Si is almost three times higher than that of CaF_2 [228]. Clearly, some additional factor plays a significant role during heteroepitaxial growth on a vicinal surface.

As discussed in Section 3.2, strain often determines shapes and sizes of self-assembled nanostructures in heteroepitaxial systems; the elastic energy should then be also considered for an array of SA islands at steps [271]. Two model parameters describe strained islands on a vicinal surface and set the scales of interactions: terrace width W and optimal island size L_0. The terrace width is determined by the miscut of a sample and can be controlled in practice within a wide range of values (Section 4.1.1). The optimal size L_0 for an isolated strained island is determined by the balance of decreasing edge/area ratio and increasing strain energy with increasing island size; in practice L_0 is related to the lattice mismatch during heteroepitaxy [271, 272]. An accurate, albeit simple, estimate of L_0 is given by the size of a structure over which a mismatch of more than one lattice constant is accrued. For example, for a 2% mismatch typical under CaF_2/Si growth conditions [228], it is about 50 atoms $\approx$15 nm, in good agreement with the size of isolated islands observed in the CaF_2/Si(111) system. Other elastic interactions in the system, for example, edge/step repulsion, also would typically have a characteristic scale on the order of L_0, since the scales are related to the same set of substrate and adsorbate elastic parameters. The L_0/W ratio determines the growth mode for systems where strain energy dominates over step energies [271].

For the CaF_2/Si(111) system in Figures 21 and 22, the optimal island size L_0 is on the order of the terrace width W; that is, the interactions of island edges with substrate steps are strong even for low coverage. Islands attached to steps then initially grow to reach the width of $\approx 1/2W$, to minimize the repulsion between their free edges and both neighboring steps, and near-optimal length $\approx L_0$ along steps (Fig. 22a).

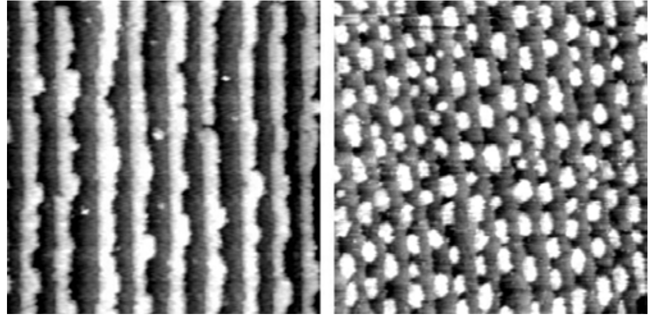

Figure 21. Step wetting and de-wetting behavior for Si(111) + CaF_2. Equilibrium growth predicts either wetting or de-wetting growth at steps, depending on the step and interface energies (Fig. 17). Elastic interactions in the CaF_2/Si(111) system, however, are strong enough to modify the equilibrium behavior, and realize both wetting and de-wetting growth depending on the coverage and step spacing [234, 254, 271].

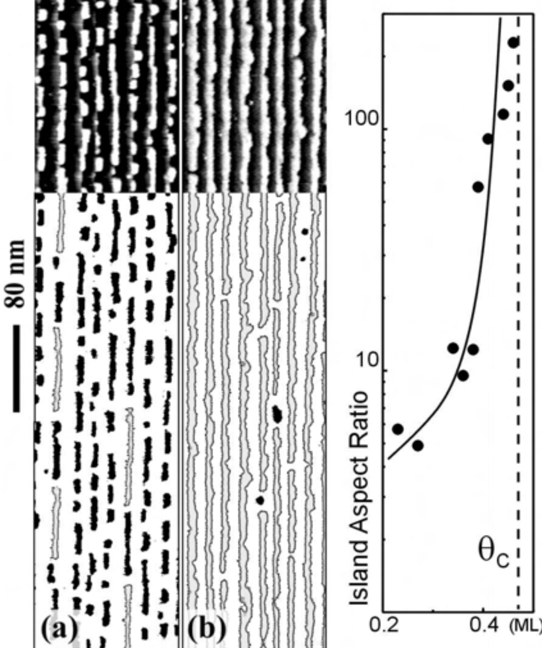

Figure 22. Island-to-stripe transition at a critical coverage. A drastic change in the CaF_2 growth mode is observed for 1.1° miscut Si(111) between 0.23 and 0.40 ML coverage. The growth front morphology changes from short islands (black) to long stripes (gray). The observed rough-to-smooth growth front transition is a feature unique to 2D growth. Such a critical coverage θ_C is predicted by a model that considers the effect of elastic interactions and step energies on the growth front morphology [271].

This apparent nonwetting behavior is the result of strain, rather than high step energy of the islands. With increasing coverage, islands grow along the steps but maintain near-constant width, because the edge-step repulsion dominates over intra- and interisland elastic energy gain. Only when a complete stripe is formed at a step, the free edge begins to advance towards the upper step edge, and the growth appears to be in step-flow mode with increasing coverage (Fig. 22b).

The rough-to-continuous interface transition is remarkably sharp in this system: there is less than 0.2 ML difference in coverage between the broken and continuous stripe configurations (Fig. 22). The "reverse SK mode" is also a strictly 2D growth phenomenon, since in three dimensions initially rough growth interfaces do not subsequently become smoother. The qualitative difference between the 2D and 3D growth modes that produces the novel behavior is the fact that in two dimensions the growth proceeds at multiple growth fronts *simultaneously*, whereas in three dimensions multilayers are grown sequentially. Both of the growth regimes can be potentially useful for forming continuous stripes (Figs. 21 left and 22b) and nanodots (Fig. 21 right), respectively. In the latter case, by properly adjusting the deposition parameters, arrays of CaF_2 nanodots can be produced with density on the order of 3×10^{11} cm^{-2} = 2 Teradots/in^2 and fairly uniform size distribution (Fig. 21 right) [234, 254].

4.4.2. Self-Organized Lateral Ordering of Ge/Si Nanostructures

Finding the right substrate was the major part of fulfilling the quest for self-organized 2D-ordered arrays of uniform Ge quantum dots. The search began with direct deposition of Ge on vicinal Si substrates with orientations previously used to grow SA Ge islands. On vicinal Si(113) this resulted in Ge dots aligned primarily at large (>12 ML) step bunches [261, 265]. The island formation was attributed to enhanced island nucleation at large Si step bunches, and higher strain produced Ge islands, rather than wires seen in partially relaxed SiGe growth (Section 4.3.2) [261]. Adjacent islands remained separated by narrow gaps in all cases, although there appeared to be a small amount of Ge accumulated in these gaps [265]. There was no correlation of island nucleation across terraces, most likely because the island size (80 nm) was much smaller than the terrace size (>300 nm) [261].

Similar results have been obtained for Ge growth on Si(001) miscut 4° towards [110], where Ge islands ≈100 nm in diameter formed at step bunches separating ≈360 nm (001) terraces [273]. In this case islands also showed no correlation across terraces and maintained separation along the steps, but whereas on the vicinal Si(113) islands appeared to be nucleating on the bunched steps [261], for vicinal Si(001) the islands were not as well aligned along the bunches, and upper side of (001) facets was determined to be the preferential nucleation site [273]. The same Si(001) 4° miscut surface prepared under conditions that avoid bunching consists of double-steps separated by about 4 nm [200]. Ge islands grown on this vicinal substrate were smaller (only ≈30 nm) but were not confined to individual terraces, and thus while the dense steps enhanced the nucleation, they did not affect ordering of the Ge islands [10].

The immediate conclusion from the above examples of Ge/Si heteroepitaxy is that the substrate steps and step bunches can control the positioning of Ge nanostructures, but for best results the substrates with the appropriate periodicity (typically <100 nm) would be required. SiGe alloy formation can be helpful for self-organization of nanostructures during Ge/Si heteroepitaxy, including their two-dimensional ordering, because co-deposition of Ge and Si on vicinal Si surfaces allows to control the strain and surface morphology as the growth proceeds, by adjusting the Ge/Si ratio, and by changing between continuous and interrupted growth.

Deposition of a single 2.5-nm $Si_{0.55}Ge_{0.45}$ layer on Si(001) substrate with $\theta = 4°$ polar miscut results in a surface covered with oriented triangular structures [41]. The structures are actually composed of three facets reminiscent of SA Ge pyramids on Si(001): a (001) square bound by $\langle 100 \rangle$ steps, and two {105} parallelograms (Fig. 23a) [41]. This pattern of SiGe surface faceting with three facet types is reported to be unique for a semiconductor surface [41]. The faceting mechanism has been attributed to a strain-driven transition from straight step bunches into energetically favored {105} facets. Specifically, for the polar miscut $\theta \approx 4°$ the step bunch tilt of ≈8° corresponds almost exactly to a $(\bar{1}\ \bar{1}\ 10)$ plane which is unstable with respect to breaking up into a zig-zag pattern of {105} facets and $\langle 100 \rangle$ steps [41]. Another important factor that favors the faceting for this particular type of step bunches is that, even though step length and surface area increase after faceting, no new steps have to be created. Substrates with $\theta \approx 2°$ miscut towards the same or 45° rotated azimuth ϕ do not show similar regular faceting,

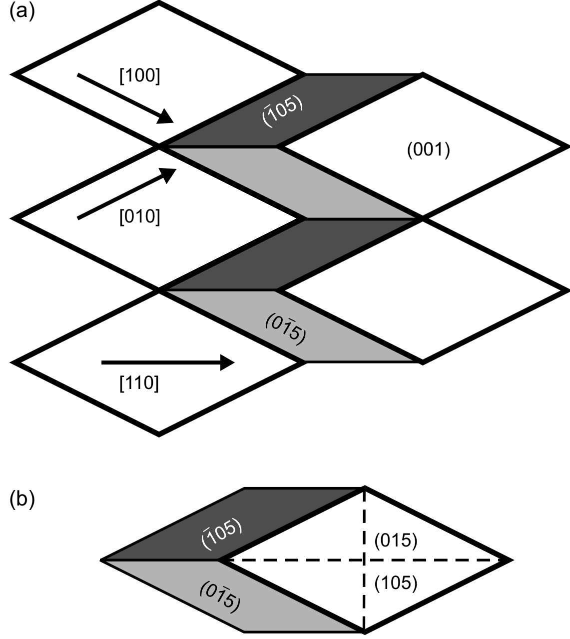

Figure 23. Faceting and island ordering for SiGe films on vicinal Si(001). (a) Ideal facet arrangement for $Si_{0.55}Ge_{0.45}$ film on Si(001) with 4° miscut. (b) $Si_{0.25}Ge_{0.75}$ islands form on the same substrate. Their shape can be obtained from the above pattern by adding a square {105} faceted pyramid on each (001) terrace. Adapted with permission from [41], C. Teichert, *Phys. Rep.* 365, 335 (2002). © 2002, Elsevier Science.

even though individual {105} facets do form [41]. {105} is not the only facet common to both SA Ge islands on Si(001) and vicinal Ge/Si. For higher miscut $\theta = 10°$, three types of steeper {113} facets form structures for $Si_{0.7}Ge_{0.3}$ grown and annealed on Si(118) [274].

On the same as above Si(001) substrate with $\theta = 4°$ polar miscut, deposition of a single 2.5-nm layer of a film with increased Ge concentration ($Si_{0.25}Ge_{0.75}$) results in formation of Ge-rich islands. The (001) facet of the $Si_{0.55}Ge_{0.45}$ morphology is replaced with two more triangular {105} facets, so the islands have hegaxonal base elongated in [110] direction, and four {105} facets: two trapezoidal and two triangular, and form a close-packed quasi-periodic array (Fig. 23b) [41]. Both the average size of the islands (about 50 nm) and their orientation are very similar to the above pattern of facets of the $Si_{0.55}Ge_{0.45}$ film, suggesting that one rational way to search for ordered SA Ge-rich islands is to look in Si-rich films for pattern formation on the same scale and with ⟨100⟩ preferred directions.

Another example of the correlation between the Si-rich film faceting and Ge-rich island ordering occurs for Si(001) substrate with $\theta = 2°$ and $\phi = 45°$ miscut. For 2.5-nm $Si_{0.55}Ge_{0.45}$ film, ripples along [010] direction with 70 nm separation are observed [275]. For Ge-rich $Si_{0.25}Ge_{0.75}$ film of the same nominal thickness, {105} faceted 3D islands arranged in chains parallel to the [010] form (Fig. 24) [275, 276]. In this case, island width of ≈35 nm has a narrow distribution and, compared to the 70-nm period of the above faceted $Si_{0.55}Ge_{0.45}$ surface, suggests island nucleation on both (001) terraces and step bunches [41]. The lengths of the islands, however, are more broadly distributed, reflecting little ordering of the rippled substrates along this direction.

As expected, in both of the above cases for islands grown on vicinal substrates, both the lateral ordering and the island size distribution were superior to those obtained on flat Si(001) substrates under the same conditions. However, even in case of the more uniform islands on the 4° miscut substrate, the width of the size distribution was still about 25%, and the lateral ordering was rather short-range. The structure uniformity was much better in terms of the orientation, which coupled with their statistical ordering allowed measurements of magnetic roughness and anisotropy for Cu/Co sandwiches [277] and arrays of nanomagnets [278] deposited on these nanostructured substrates.

It turns out that for the best ordering of Ge/Si structures, self-assembly of Ge islands on stepped substrates, discussed in the beginning of this section, had to be combined with uniformly faceted SiGe multilayers, discussed as templates for SiGe nanowire growth in the previous section. The multilayer $Si_{0.55}Ge_{0.45}$ wire arrays (Fig. 20) can provide a self-organized rippled substrate with 120 nm periodicity (1.5 nm modulation) [279] comparable to the size of Ge islands grown on vicinal Si. When Ge was deposited on top of a 10 nm buffer Si layer, the Ge islands exhibited remarkable 2D ordering (Fig. 25) [10, 279]. The islands were {105} faceted and truncated pyramids with approximately square bases; the absence of elongation similar to that in Figures 23 and 24 was attributed in part to the absence of [100] and [010] steps on these substrates [279]. Two substrate orientations corresponded to SiGe nanowire multilayers grown on Si(001) miscut 2° towards [100] and 1.5° towards [1 $\bar{1}$ 0], resulting in wires along [010] and [110], respectively [279]. On these two types of substrates, Ge islands formed close-packed arrays with simple-cubic and face-centered lattice, respectively, and size uniformity on the order of 10% (Fig. 25) [279]. Minimization of the strain energy of the whole system, taking into account the orientation of the

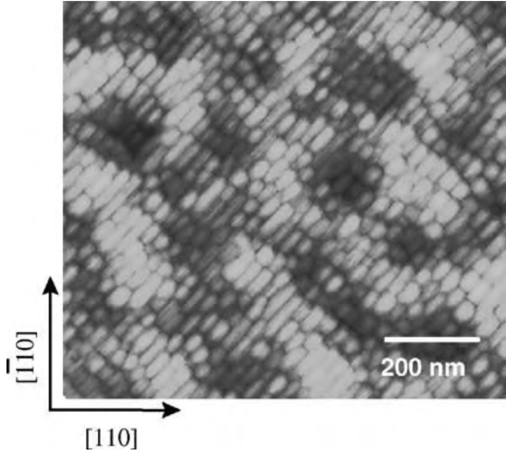

Figure 24. Lateral island ordering by matching substrate periodicity. The surface of a 2.5-nm $Si_{0.25}Ge_{0.75}$ film on Si(001) with 2° polar and 45° azimuthal miscut exhibits chains of mainly prism-like islands with the long axes exclusively aligned along [010]. Figure 25. Self-organized uniform arrays of self-assembled Ge islands. When a self-organized periodic array of SiGe nanowires (Fig. 20) is used as a template for Ge deposition, uniform close-packed arrays of {105} faceted Ge islands form on the top layer. Depending on the substrate orientation, the wires in the template are oriented along [010] and [110] directions, which results in simple-cubic and face-centered lattice of the Ge island array, respectively. vicinal substrate and elastic dipole repulsion of neighboring islands, is believed to be responsible for the lateral ordering [10, 151, 279]. To date, this system represents perhaps the best example of an island array with uniform 2D ordering achieved through self-assembly on a self-organized substrate—a major milestone on the way towards practical SA and SO.

4.4.3. Ordering by Strain and Dislocation Networks

When elastic strain-relief mechanisms cannot accommodate lattice mismatch during heteroepitaxy, plastic dislocations set in [280]. The critical thickness for $Si_{1-x}Ge_x$ heteroepitaxy on Si(001) depends on the Ge concentration, and ranges between 1 and 100 nm, although theoretical and experimental values often disagree [41, 281, 282]. For $Si_{1-x}Ge_x$/Si(001) growth, the misfit dislocations propagate from the interface and manifest themselves on the surface as ridges and troughs along [110] and [$\bar{1}$ 1 0] directions [283, 284]. Variations in alloy compositions and growth temperature regimes produce networks of such intersecting dislocation lines (up to tens of microns in length) with different density [285–287], as described in detail in [41].

Deposition of Ge or SiGe on these dislocation networks results in nucleation of {105} faceted pyramid-like islands along the two orthogonal directions defined by the troughs and ridges. For low coverage, the islands are exclusively nucleated along the dislocations; with increasing coverage, close-packed chains of islands form along the dislocations, and the rest of the surface is filled with {105} faceted hut- and pyramid-like islands [41]. The range of elastic interactions within a dislocation network is comparable to the width of individual lines; thus, much like for islands on vicinal substrates from the previous section, to improve the lateral ordering the density of dislocations in the network has to be increased to the point where the individual lines touch each other. This has been demonstrated for $Si_{0.7}Ge_{0.3}$ growth combined with 1 keV Si^+ ion bombardment, where a checkerboard pattern of {105} faceted pyramids and pits with ≈190 nm periodicity formed on the surface [41]. Such patterned surfaces are potentially useful for applications, because the dislocation networks are inherently macroscopic objects, but currently it is still difficult to ensure the formation of close-packed arrays of dislocation lines over the scale comparable to the length of individual lines.

5. MOLECULAR AND ATOMIC SELF-ASSEMBLY

Self-assembly and self-organization on the scale of molecules and atoms is both the most ambitious and the most ambiguous goal of nanotechnology. The ability to manipulate elements and compounds on the level of their smallest structural units potentially opens up unlimited possibilities. On the other hand, for processes such as organic synthesis or surface reactions, for example, during growth of nanoclusters in solutions [19], the distinction between "self-assembly" and "traditional" chemistry is not easy to define. The following sections focus on SA and SO on surfaces with atomic-scale templates, in particular those with self-organized templates.

Several general approaches can push the controlled self-assembly to the limit of individual molecules and atoms. For example, self-assembled templates of CaF_2 stripes on vicinal Si(111) (Section 4.3.1) can be prepared with trenches between the stripes as narrow as 3–4 nm. Through chemical selectivity of such a template, individual molecules can then be adsorbed within the trenches, thus forming quasi-one-dimensional structures (Fig. 26) [257]. In another example, strain-relief patterns similar to those discussed in the previous section, but on nanometer rather than micron scale, can serve as templates for self-assembly of atomic clusters 1–10 nm in size for metals [288] or semiconductors [289]. Even though atomic-scale SO templates were used in both of the above examples, the resulting SA structures in general did not exhibit atomic or molecular precision in their sizes or ordering. Such precision is possible, however, if *atomically precise* self-organized templates are used.

5.1. Surface Reconstructions as Templates for Self-Assembly

Surface reconstructions are ideal candidates as templates for self-assembly. First, by definition they exhibit atomically precise periodic pattern over large areas. Second, the two major factors responsible for surface reconstructions [47, 49, 50, 55, 56, 99, 290], surface strain and broken bonds, are also the key factors in controlling self-assembly and positioning of nanostructures.

The key driving force towards atomic precision as self-assembled structures become smaller is the increasing interactions between building blocks. For example, step arrays on Si(111) have a step width that is quantized in units of 1/2 of the 7 × 7 unit cell (7 atomic rows or 2.3 nm, see Fig. 10a)

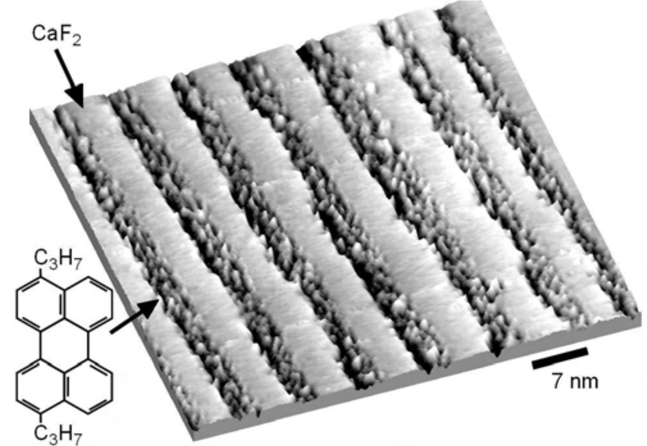

Figure 26. Quasi-one-dimensional confinement of organic molecules. Molecules of 3,10-di(propyl)perylene selectively adsorb between CaF_2 nanostripes on a self-organized CaF_2/CaF_1 template on vicinal Si(111) (Fig. 19). By adjusting the width of the CaF_2 nanostripes, the molecules can be confined in trenches as narrow as 3–4 nm (7–8 nm shown). Adapted with permission from [257], H. Rauscher et al., *Chem. Phys. Lett.* 303, 363 (1999). © 1999, Elsevier Science.

[166, 171]. At larger step spacings there is not enough interaction between adjacent steps to force a sharp width distribution (Section 4.1.1). For a $\approx 1°$ miscut angle with 15 nm average step spacing, one observes a coexistence of terraces with 5, 6, and 7 unit cells (Fig. 11) [171]. However, with a miscut of 10° the surface arranges itself into a regular pattern with a period of exactly 17 atom rows (5.73 nm) and a single 7×7 unit cell per terrace (Fig. 15) [202]. In fact, the existence of large unit cells, such as 7×7, points towards the possibility of creating both two- and one-dimensional structures with perfect periodicity. Such patterns can be used to form devices close to the atomic limit, such as a memory where bits is stored by the presence or absence of individual silicon atoms in 5×4 unit cells precisely lined along tracks 5 atom rows wide. Other examples of controlling self-assembly on the atomic scale include molecular adsorption and formation of "magic" clusters on reconstructed silicon surfaces.

5.1.1. Silicon Surface Chemistry and Functionalization

The combination of the versatility of silicon surfaces with essentially unlimited supply of custom-designed molecules and reactions provided by organic chemistry is an important pathway towards surface functionalization [291]. The sheer number of the different aspects of the silicon surface chemistry explored to date means that here they can only be enumerated; fortunately, a number of excellent recent reviews cover these topics in detail. Interaction of silicon surfaces with hydrogen and reactivity of hydrogen-terminated silicon surfaces under UHV conditions are reviewed in [292]. The technologically important silane chemistry is described in [293]. Reactions of small organic molecules with Si(001) are reviewed in [294, 295]. Si(111)7×7 and Si(001)2×1 surface reconstructions play a major role in determining chemistry of the silicon surfaces in model UHV studies. Reviews [291, 296] provide extensive descriptions of general principles of organic chemistry on silicon surfaces including: $[2+2]$ and $[4+2]$ (Diels Alder) cycloaddition in UHV, creation and reactivity of hydrogen- and halogen-terminated silicon surfaces, dry and wet hydrosilylation, and reactivity of various terminal functional groups.

Some of the major goals of surface functionalization are: surface passivation and protection, patterning surface chemistry or topography, surface-based sensing, molecular recognition, and molecular electronics. In general, the first three types of surface functionalization take advantage of the silicon surface reconstructions only in using the attachment chemistry that matches the reactivity of broken and double bonds available on reconstructed surfaces. The most advanced research goals in terms of molecular recognition and electronics intend to rely on the specific atomic arrangements on reconstructed surfaces much more closely, as briefly described in the next subsection.

Surface passivation typically involves covering the surface with a complete molecular layer and thus in general does not involve nanostructuring or self-assembly. However, similarly to self-assembled monolayers (SAMs) on gold [297, 298], layers of molecules covalently attached to silicon and presenting various terminal functionalities can be produced on silicon through gas-phase [293, 296] or wet chemistry [296, 299, 300]. In addition to providing chemical resistance or functionality, these layers are also being explored for applications as masks in nanolithography [1, 3] and for photopatterning [291, 296].

Using bare silicon surfaces for sensing is not practical, because they quickly oxidize or otherwise react in the ambient environment. Practical sensing applications typically rely on surfaces protected from the ambient environment by a functionalized molecular layer that has also been modified to selectively react with the sensing target; some of the relevant approaches are presented in Section 6.

5.1.2. Self-Assembly with Molecular Precision

A good example of a patterning approach that makes use of molecular self-assembly involves using block copolymers [301, 302], that is, polymers that consist of two or more chemically distinct fragments (blocks). If the constituents are immiscible, phase separation occurs [301, 302] on the scale determined by size of the fragments (typically 10–100 nm), which for block copolymer films on surfaces results in pattern formation [303]. With a proper choice of the components, these patterns can be used as self-assembled lithography or etch masks to produce nanoscale features on surfaces over macroscopic areas [304–307]. Alternatively, selective adsorption or reactivity of the copolymer components can be used as templates for self-assembly of nanostructures [308, 309]. Phase separation mechanism produces block copolymer patterns with inherent short-range (10–100 nm) ordering. Long-range ordering of the patterns can be achieved by using surface templates with periodicity comparable to the size of the copolymer components. The ordering can be induced by either topography [310, 311] or chemical heterogeneity [307, 312, 313] of the surface templates. Self-organized arrays of step bunches (Fig. 13, Section 4.1.2) have been particularly useful as templates for both of the above approaches [310–313].

The direct use of surface reconstructions as patterns for molecular adsorption is inherently restricted to model studies in UHV [294]. One potentially useful aspect of the reactivity of clean silicon surfaces is the selectivity in terms of chirality of small organic molecules [314, 315], which is intimately related to the atomic arrangement on reconstructed surfaces.

Si(001) surface offers compelling properties as a model substrate for molecular electronics: interfacing with conventional devices [316, 317], and a convenient target for attachment of organic molecules through double bonds in silicon dimers [294, 295]. In addition, on vicinal Si(001) surfaces with 4° miscut toward the [110] direction, arrays of (001) terraces with all the dimers oriented in the same direction can be prepared [162] (Section 4.1.1). The uniform orientation of the dimers on these templates has been used to produce organic layers with anisotropic electronic properties [295]. The atomic structures of Si(111)7×7 and Si(001)2×1 surfaces allow self-directed surface chain reactions to occur on these surfaces [318–320], in which reactions propagate along directions defined by the symmetry of respective surfaces creating lines of molecular adsorbates—suggesting a potential pathway towards surface-based molecular circuits.

5.1.3. Atomic Clusters Self-Assembly and Self-Organization in Two Dimensions

A variety of adsorbates form two-dimensional structures on silicon surfaces with unit cells up to a few nanometers in size, most of them based on the respective surface reconstructions [48]. Recently the Si(111)7×7 surface has been used as a template for adsorbing metal atoms on specific sites within the cell, which leads to atomically precise self-assembled monodispersed nanostructures, also referred to as surface magic clusters [321]. Both Si and Ge form such clusters on Si(111)7×7 [321–323]. For metal adsorbates, initial work used transition metals. Particularly regular patterns are observed with Group III metals, such as Ga [324], Tl [325, 326], Al [327], and In [328]. Figure 27 shows a spectacular example: the bright spots are small clusters of six Al atoms adsorbed at the centers of both halves of the 7×7 unit cell [327].

5.2. Electronic Properties of Low-Dimensional Surfaces

Because they are assembled with atomic precision, low-dimensional surface structures are some of the best model systems for examining the properties of low-dimensional electronic states. In addition to serving as atomic templates for these structures, silicon substrates also provide the convenience of a bandgap, which helps to decouple metallic surface states from bulk three-dimensional bands. The scanning probe tools that potentially would allow direct conductivity measurements on surface nanostructures are still only being developed [51], so macroscopic techniques such as surface conductivity measurements [52, 329], photoemission [330–332] and inverse-photoemission spectroscopies [333] are usually used to investigate properties of low-dimensional surface states.

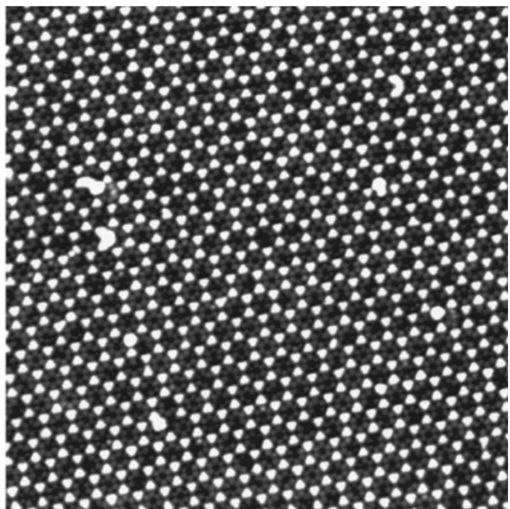

Figure 27. Atomically perfect Al nanocluster array on Si(111)7×7. The Al clusters are located at the centers of both faulted and unfaulted halves of the 7×7 unit cells and appear as bright dots on this STM image (50×50 nm^2). Each cluster contains six Al atoms. Both the structure and the positioning of the nanoclusters in this case are thus atomically precise. Reprinted with permission from [327], J. Jia et al., *Appl. Phys. Lett.* 80, 3186 (2002). © 2002, American Institute of Physics.

5.2.1. Two-Dimensional Patterns

A whole hierarchy of superlattices can be built up by noble metals on Si(111) [52, 329]. The starting point is the $\sqrt{3} \times \sqrt{3}$ structure of Ag and Au, which consists of honeycomb trimers [334, 335]. Adding additional Ag or Au atoms on top of a selected subgroup of trimers gives rise to structures, such as $\sqrt{21} \times \sqrt{21}$, and 6×6 [336, 337]. The $\sqrt{21} \times \sqrt{21}$ structure of Au on top of the $\sqrt{3} \times \sqrt{3}$-Ag structure is shown in Figure 28. These surfaces have the special property of being metallic, which is rather unusual for silicon surfaces [336, 338]. Although the stoichiometric $\sqrt{3} \times \sqrt{3}$ HCT structure with 1 ML of Ag is semiconducting [336], the addition of just a few percent of Ag or Au atoms provides enough electrons to fill a steep surface conduction band inside the bulk bandgap. Surface conductivity measurements, including four-point probes with independent STM tips, have been used to investigate the conductivity of the two-dimensional electron gas at a surface [52, 329]. The full complement of quantum numbers (energy E and momentum $\mathbf{p} = \hbar\mathbf{k}$) has been obtained by angle-resolved photoemission experiments [339]. Particularly important is the Fermi surface, which shows the location of the states at the Fermi level in $\mathbf{k}$-space. These states are responsible for conductivity and many other electronic properties, while electrons below the Fermi level cannot move due to Pauli's exclusion principle. Photoemission has revealed delicate patterns that are formed by the Fermi surfaces of these structures, as shown in Figure 29. A surface doping of a few percent produces small electron pockets, which give rise to small Fermi circles in two dimensions (Fig. 29a). The addition of Au in a $\sqrt{21} \times \sqrt{21}$ superlattice on top of the $\sqrt{3} \times \sqrt{3}$-Ag superlattice enlarges these Fermi circles by adding extra electrons to the band (Fig. 29b). In addition, the extra $\sqrt{21} \times \sqrt{21}$ reciprocal lattice vectors translate this Fermi circle to other parts of $\mathbf{k}$-space and form an intricate pattern of replicas. It can

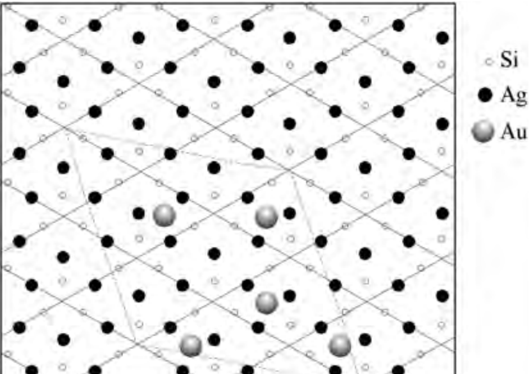

Figure 28. Superlattices formed by Ag and Au on Si(111). A monolayer of Ag forms a $\sqrt{3} \times \sqrt{3}$ superlattice (black dots), and an additional $5/21 = 0.24$ monolayer Au forms $\sqrt{21} \times \sqrt{21}$ superlattice on top of the $\sqrt{3} \times \sqrt{3}$ lattice (see the dotted unit cell containing 5 Au atoms). The corresponding Fermi surfaces are shown in Figure 29a and b. Adapted with permission from [339], J. N. Crain et al., *Phys. Rev. B* 66, 205302 (2002). © 2002, American Physical Society.

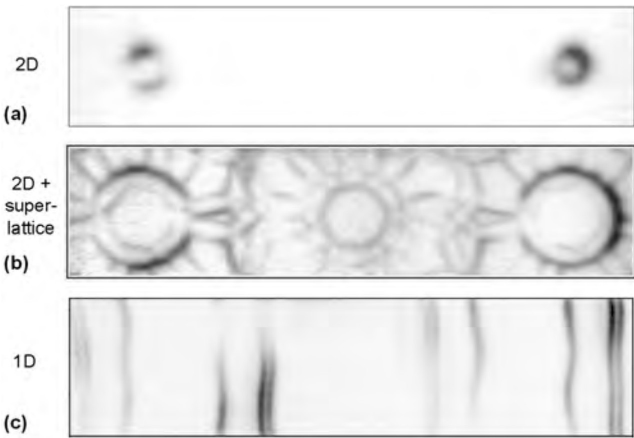

Figure 29. Fermi surfaces of two- and one-dimensional surface states on silicon, obtained by angle-resolved photoemission with energy and angle multidetection. The x- and y-axes are the **k**-vector components parallel to the surface, with $\mathbf{k} = 0$ at the center. A truly one-dimensional Fermi surface would consist of vertical lines since the energy does not depend on the wave vector perpendicular to the chains (vertical). (a) Si(111)$\sqrt{3} \times \sqrt{3}$-Ag (see Fig. 28) with a few percent excess Ag forming small electron pockets. (b) Si(111)$\sqrt{21} \times \sqrt{21}$-(Ag+Au) with a superlattice of Au atoms on top of the $\sqrt{3} \times \sqrt{3}$-Ag lattice forming large Fermi circles. The $\sqrt{21} \times \sqrt{21}$ superlattice causes faint replicas of the Fermi circles. (c) Si(553)-Au, a nearly one-dimensional structure containing a single Au chain per unit cell. be viewed as an electron diffraction pattern of the strong, primary Fermi circles that are located at the two $\sqrt{3} \times \sqrt{3}$ lattice points.

Metallic surface states on silicon offer the possibility of studying electrons in low dimensions, where exotic new phenomena have been observed and predicted [340–349]. Already in two dimension there are effects, such as the integer and fractional quantum Hall effect [345, 346]. In one dimension the predictions are even more exotic. The very existence of individual electrons is in question. Basically, electrons moving along a line in space cannot help penetrating each other and thereby forming many-body excitations. Furthermore, these excitations are predicted to separate in collective excitations of spins without charge (spinons) and charges without spin (holons) in a one-dimensional metal [344, 348]. A key for observing such effects is that the electrons are completely decoupled from the three-dimensional substrate. Since the Fermi level is located in the bandgap of silicon, metallic surface states cannot interact with states from the silicon substrate and thus their reduced dimensionality is preserved.

5.2.2. One-Dimensional Chains

One-dimensional structures can be formed by self-assembly on stepped surfaces, as reviewed in detail by Ortega and Speller [225]. Here we focus on chains of atoms adsorbed at silicon surface. They serve as the ideal quantum wires for testing the theoretical predictions of exotic phenomena in one dimension. One might think that the ultimate quantum wire would be a single string of atoms suspended freely in space. However, according to early arguments by Peierls, the atoms in such strings form pairs and lose their metallicity. It has become possible to produce metallic chains of metal atoms by self-assembly at stepped silicon surfaces [13, 27], where they line up parallel to the step edges. X-ray diffraction from the Si(557)-Au structure shows that gold atoms are incorporated rigidly into silicon lattice positions [350] without detectable Peierls distortion.

On Si(111), chain structures can be formed either by using stepped surfaces as templates or by spontaneous breaking of the three-fold symmetry of flat Si(111) into three domains of chain structures. A collection of four such structures is shown in Figure 30 [13]. Alkali metals [351], alkaline earths [253], noble metals [329], indium [22, 352, 353], and even magnetic rare earths, such as Gd [354], form single-domain chain structures on vicinal Si(111), as long as the coverage is well below 1 ML (typically 0.4 ML or 1–2 chains per unit cell). For a detailed overview of these chain structures see [13, 331]. The stability of these chain structures might be related to the stability of the honeycomb chain (HCC) [355], which is a structural element in many of them. This chain consists of a strip of graphitic, π-bonded Si. At a coverage approaching 1 ML the surfaces become two-dimensional and restore their three-fold symmetry, as shown in Section 5.2.1.

The Si(001) exhibits a native surface anisotropy that gives rise to dimer rows. The difficulty is selecting one of the two 90° rotated domains which are separated by a single surface step. A miscut angle of about 4° leads to the formation of double steps and has been used successfully for producing Si(001) with a dominant domain [162]. Other approaches include using rather flat surfaces and sophisticated growth methods [356, 357] or electromigration [358]. Substituting Si dimer rows by metals, such as In, creates dimer rows of adsorbates [359, 360]. Long chain structures of Si dimers

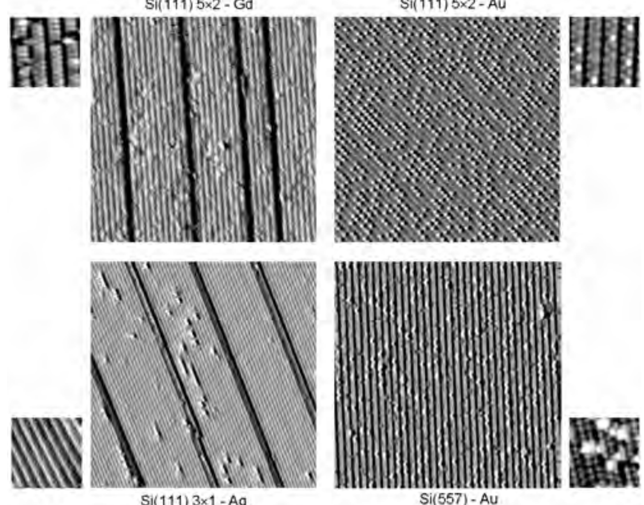

Figure 30. Chain structures formed by sub-monolayer deposition of metals on Si(111). The overview panels (60×60 nm^2) show the x-derivative of the STM topography, which produces dark lines at step edges (downhill to the right). The close-up panels (7×7 nm^2) show the topography itself. Adapted with permission from [13], F. J. Himpsel et al., *J. Phys.: Condens. Matter* 13, 11097 (2001). © 2001, Institute of Physics.

have been also observed on cubic SiC(001) [361]. So far, all row structures on Si(001) have been semiconducting and therefore less suitable for low-dimensional electron physics.

A number of vicinal Si(111) and Si(001) surfaces lend themselves as templates to the formation of one-dimensional chain structures, as shown in Figure 14 (Section 4.1.2) [159]. Particularly for Au as an adsorbate, a large fraction of the possible orientations has actually produced well-ordered structures with uninterrupted chains [362–369]. Only one of these structures (Si(557)-Au) has been analyzed structurally by X-ray diffraction [350] and total energy minimization [370, 371]. Surprisingly, the Au chain lies at the center of the Si(111) terrace, not at the step edge where one would expect higher coordination for adsorbates. Apparently, the simple idea of step decoration fails here. A more sophisticated strain-relief mechanism might be at work, which is not necessary at the step edge because atoms at the top of a step can relax laterally. The Au atoms substitute for a row of Si surface atoms and are thus locked in by three back-bonds, which explains their resilience against a Peierls distortion.

The coupling between the chains can be varied in a systematic way by changing the miscut angle. The transition between two- and one-dimensional chains happens at a chain spacing of about 5–6 atomic rows ($\approx$2 nm), judging from the vanishing of the two-dimensional band dispersion observed in photoemission [362]. For example, the Si(553)-Au surface with a chain spacing of 4-1/3 rows has a ratio of 10–40 for the intra- to interchain coupling, whereas the Si(557)-Au surface with 5-2/3 rows step spacing has a ratio $>$70 [362]. One-dimensional Fermi surfaces consist of straight lines perpendicular to the chain direction (Fig. 29c), as opposed to the two-dimensional circles in Figure 29a and b. The energy is independent of the **k**-component perpendicular to the chains. A slight waviness in Figure 29c indicates a residual two-dimensional character. A tight binding fit to the Fermi surface provides the ratio of the electron coupling parallel and perpendicular to the chains ($\approx$40:1 for the doublet and 12:1 for the singlet). Since wave functions decay exponentially, there is a wide range of couplings that can be covered by a narrow range of step spacings.

5.3. Atomic-Scale Memory

One of the first goals of nanotechnology, set by Richard Feynman in his pioneering 1959 talk at CalTech, is an atomic-scale memory. Using a cube 5 atoms wide to store one bit, Feynman estimates that "all of the information... accumulated in all the books in the world can be written... in a cube of material 1/200 inch wide." The tools are in place now to make an attempt at realizing this dream. Assembling atoms with the STM at low temperature has been possible for some time. Recently, we have been able to demonstrate an atomic memory operating at room temperature (Fig. 31 and [372]). Such a device is useful for finding the fundamental limits of data storage, irrespective of practicality. A chain structure induced by Au on flat Si(111) forms self-formatted "tracks" (dark horizontal stripes in Fig. 31). White dots on top of the tracks give the surface the appearance of a CD-ROM, except that the scale is in nanometers, not microns. The resulting storage density is a million times higher. It has been demonstrated that the white dots correspond to single Si atoms, by filling the vacant sites by Si deposition [372]. The extra Si atoms reside on a 5×4 lattice and can be used to store data if the presence of an atom is assigned to a one and its absence to a zero. Each bit thus occupies a territory of $5 \times 4 = 20$ atomic sites. A reduction of the area/bit is not possible for this particular system, as shown from the correlation function between adjacent bits and their analysis in terms of nearest-neighbor interactions [373]. The occupancy of the closest 5×2 site is highly suppressed, as shown in Figure 32.

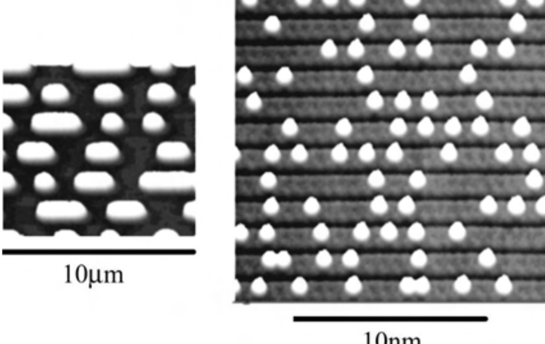

Figure 31. Atomic memory obtained by self-organization on a Si(111) surface with 0.4 monolayer of gold. Extra Si atoms (bright dots) occupy lattice sites on top of tracks that are five atoms wide (1.7 nm). Compared to a conventional CD-ROM (left), the scale is reduced from microns to nanometers, which leads to a 10^6 times higher density. Adapted with permission from [372], R. Bennewitz et al., *Nanotechnology* 13, 499 (2002). © 2002, Institute of Physics.

Such an atomic-scale device is useful for a deeper understanding of the limiting factors in data storage. In [372] the limits on storage density, retention, signal-to-noise, and readout speed were explored. The readout error rate is still uncharted, although the raw signal-to-noise figure is better than in hard disks. However, an optimum code for filtering and error correction needs to be worked out, analogous to

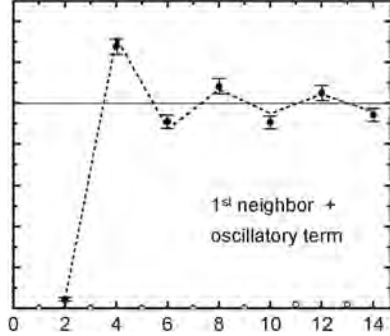

Figure 32. Correlations in a one-dimensional lattice fluid of Si atoms on top of the Si(111)5×2-Au chain structure (points). Theoretical modeling (dashed line) shows that a nearest-neighbor repulsion suppresses the occupancy at site 2 and causes a pile-up at site 4 (top). An extra oscillatory interaction is required to explain the subsequent oscillations beyond site 6. Such interactions between neighboring atoms limit the ultimate storage density achievable by an atomic-scale memory in Figure 31. Adapted with permission from [373], A. Kirakosian et al., *Phys. Rev. B* (submitted).

the partial response maximum likelihood (PRML) method that has been so successful for hard disks (see [372] and references therein). Such extremely selective filtering methods rely on a well-known signal shape, which allows all other waveforms to be filtered out. The signal from the STM readout of the model atomic memory is highly reproducible, but is different from that of a hard drive: it is unipolar in nature, whereas on a hard disk readout pulses alternate in sign and are less than a pulse width apart. These important distinctions indicate that a different noise reduction model will have to be used for the atomic memory, perhaps one similar to those used in long-distance communications through optical fibers.

Another useful information storage benchmark is the DNA molecule, which uses 32 atoms to store one bit. This compares well with the 20 atoms per bit in the Si-based atomic memory. Moreover, the current readout rate of the atomic memory by STM is roughly the same as that estimated from the DNA transcription rate—on the order of 100 bits/s [372]. The biological molecular machinery probably has not been optimized to simply maximize the transcription rate, and thus even the simplistic STM readout can potentially be several orders of magnitude faster [372]. However, the general trend of the drastic drop in readout rate with increasing storage density holds for both DNA and the atomic memory in comparison with current magnetic storage [372]. Such trends clearly have important implications for any future development of practical storage devices.

6. NANOSTRUCTURES AND BIOLOGY

The information storage density and readout rate comparison from the previous section is only one illustration of the fact that biology provides perhaps the best examples of systems that self-assemble and self-organize on scales from nanometers to meters. It is therefore not surprising that recently many biological processes are scrutinized in search for elements and methods that potentially can be duplicated in artificial systems [374–376]. At the same time, it is clear that nanotechnology will provide some of the most powerful tools and methods for studying and perhaps controlling the biology on a cellular and subcellular level. Accordingly, the studies of interfaces between various biological and bio-inspired structures and semiconductors have attracted much interest in both the life and physical science communities [376–378]. Higher-order biological systems, for example, proteins or cells, typically possess a three-dimensional structure with nanoscale features [375, 376, 379] and thus are affected by nanostructured surfaces [380–383]. Proper interfacing with biological structures then requires macroscopic templates with nanoscale features, that is, just the types of templates discussed in Sections 2 and 4.1, functionalized with appropriate surface chemistry (Sections 5.1.1–5.1.2).

6.1. Making Silicon Surfaces Bio-Compatible

Attaching nanometer-scale molecules to silicon surfaces opens up a whole new field, where a hierarchy of organic molecules is built up on top of a silicon template, as discussed in Sections 5.1.1–5.1.2. However, the chemistry of attaching biomolecules to silicon surfaces without denaturing them is still in its infancy. Short snippets of DNA have been successfully attached to Si(111) [384] and Si(001) [385, 386] surfaces via intermediary molecular layers, but if the development of the other types of DNA chips and sensors [387–390] is any indication, many additional opportunities are waiting to be explored.

While direct attachment of organic molecules to the silicon surface bonds is the most precise way to combine silicon with biotechnology, there are standard methods for creating bio-compatible surfaces via buffer layers. The most common method uses a Au buffer layer which makes a strong bond to thiol derivatives of organic molecules [388]. The method builds on the vast expertise in creating self-assembled monolayers (SAMs) on Au surfaces [297, 298]. At Si surfaces, Au forms large islands due to its low surface energy, and a Ti or Cr wetting layer is required between the Au and the Si to flatten it out [312, 391, 392]. It has been demonstrated that bunched step structures can be replicated with a fidelity of a few nanometers in this fashion [391]. There is a minimum Au coverage of 3 nm (about 12 monolayers) to reach the full coverage of alkane thiol SAMs, which is necessary for obtaining oriented SAMs [392]. Short snippets of DNA thiols have been attached in this fashion, and their orientation has been determined by near-edge X-ray absorption fine structure spectroscopy (NEXAFS) [392]. Another method for attaching organic molecules to silicon is the use of siloxane chemistry, which works on the native oxide surface [393].

Silicon surfaces can be used to induce self-organization in a number of biomimetic materials: block copolymers (as discussed in Section 5.1.2), biopolymers [394], and mushroom-shaped supramolecular nanostructures [395]. Recently it has also been demonstrated that the self-organized templates based on vicinal silicon surfaces (Section 4.1.2) can potentially be used in a biosensor. The biosensor platform in question is based on the preferential alignment of liquid crystals by surfaces that have submicron oriented structure [396, 397]. The approach has been originally developed based on statistically oriented obliquely deposited gold films [398–400]. The stepped silicon templates have an additional benefit of deterministic orientation (defined by the wafer miscut) and silicon surfaces prepared in UHV after proper passivation have been shown to induce alignment of liquid crystals [401]. Moreover, the nanostructured topography of silicon masters can be replicated in polymers through micromolding [402], which opens the possibilities for producing cheap disposable well-oriented substrates for research and applications.

6.2. Bio-Inspired Self-Assembly and Beyond

The area of nanostructured macroscopic templates is where the interplay between the biological world and that of artificial self-organized systems is possibly the most prominent. Biologically derived templates have been used to pattern surfaces [379, 403]. Biological molecules, in particular DNA, can be also used to add tailored and specific functionality to nanostructures and surfaces in order to guide self-organization [404–406]. Biological molecules

themselves can also be used as self-assembled scaffolding for inorganic nanostructures; particularly fruitful in that regard are quasi-one-dimensional molecules [407, 408] and organic nanotubes [409] which can be formed via a number of non-covalent interactions: metal coordination, hydrogen bonding, π-π stacking, hydrophobic effect, etc. While synthesis and self-assembly of these supramolecular structures has been very successful, their self-organization on a large scale (i.e., mats or arrays of 100–1000 fibers or nanotubes) is a more difficult task to achieve via only the short-range intermolecular interactions; therefore some of the properly functionalized silicon substrates can potentially be used to guide the self-organization on a larger scale.

More complicated pieces of the biological molecular machinery can be harnessed for self-assembly and self-organization as well. A very recent example is offered by the use of genetically engineered bacteriophages to create a composite film with self-assembled semiconductor nanodots self-organized within domains spanning from nanometer to centimeter scale [410]. The same type of a bacteriophage can be also engineered to selectively bind a number of semiconductors and oxides and even distinguish between crystal orientations [375, 411]. The recognition mechanism remains under investigation, but this development opens possibilities for creation of very specific customized biomimetic molecules that would serve as markers, as well as assembly and delivery vehicles for self-assembly and self-organization of nanostructures.

GLOSSARY

Epitaxy A growth process of a solid film on a crystalline substrate in which the atoms of the film replicate the arrangement of the atoms of the substrate. Homo- and heteroepitaxy respectively refer to the growth of a layer with chemical (and structural) parameters identical to and different from those of the substrate.

Miller indices Means of indexing crystal orientations and directions, for atomic planes and rows Miller indices are equal to reciprocals of the fractional intercepts with the crystallographic axes.

Self-assembly Spontaneous formation of structures with a well-defined size and shape distribution typically determined by thermodynamic stability of the structures and/or growth kinetics.

Self-organization Natural tendency of structures to form ordered arrays or assemblies.

Step decoration Nucleation of adsorbate structures at surface steps due to migration of adsorbed atoms across a terrace and preferential attachment at a step.

Surface energy The modification of the total energy of a solid due to the presence of its surface, that is, the difference between the energy of a truncated solid and the same number of atoms in the bulk. The term surface energy is often used for the surface free energy.

Surface reconstruction Rearrangement of the surface atoms driven by reduction of the surface energy. Reconstruction causes changes of the symmetry, periodicity, and ordering of the surface structure.

Surface states Modified electronic states at the surface, for example due to a rearrangement of broken bonds at semiconductor surfaces or due to the step in the inner potential at metal surfaces (see Section 5.2).

Vicinal surface A high Miller index surface, typically with low atomic density and high surface energy and thus unstable with respect to faceting. In practice, a vicinal surface is created by a controlled miscut with respect to a low-index surface.

1. INTRODUCTION

Composite materials are a very common part of everyday life. Examples of macroscale composites include plywood (composed of layered wood and glue), fiberglass (composed of glass fibers surrounded by an epoxy glue), reinforced concrete (composed of steel wires surrounded by concrete), socks (composed of interwoven elastic rubber and cotton fibers), and paint (inorganic pigment particles suspended in an organic mixture). Simply put, a nanocomposite is a material composed of two or more discrete, nanometer-sized (1 to 100 nm) components. Self-assembled organic/inorganic nanocomposites are composed of discrete nanoscale organic and inorganic components that have been spontaneously organized based on noncovalent interactions. These organic/inorganic nanocomposites often demonstrate interesting properties because of the nanoscale size effects in constituent phases, high interfacial area, and synergic properties of these components.

1.1. Size Effects

Material properties depend on the nature and sizes of the constituent components. For example, metal [1, 2], inorganic ceramic [3], semiconductor [3, 4], and other electrically and/or optically conductive material [5, 6] properties change from bulk toward quantum-derived as critical size dimensions are decreased toward the nanoscale. Metal nanoparticles, have overall properties between those of an individual molecule and bulk [7]. A decrease in particle size also decreases the number of neighboring metal atoms that facilitate metal–metal bonding due to an increase in the number of surface atoms [8, 9]. Because individual atoms do not hold core elections as strongly, metal properties such as the work function are altered. Inorganic nanoparticles with smaller particle sizes may show increased bandgap, and semiconductor nanoparticles may demonstrate quantum well effects that are useful for the control and storage of electrons [3]. For solids composed of arrays of nanoparticles, properties such as conduction of light and electricity depend heavily on the size and size distribution of the original particles [10]. For example, photonic crystals, based on ordered nanoparticle arrays, control the propagation of photons due to periodic variation in dielectric constant in an analogous fashion to semiconductor control of electrons [5, 6]. Natural opal is iridescent because the ordered, periodic array of nanoparticles with similar size as visible light wavelengths (400 to 700 nm) diffracts visible light [5]. Metallic arrays experience changes in electrical properties such as capacitance and conductivity, while magnetic materials experience magnetostatic interactions that change bulk magnetic properties [6].

As the components decrease in size, the interfacial or surface area increases dramatically. This can have a profound effect on the final system properties. For example, the melting point of a collection of nanoparticles is lower than bulk material because of the high surface area [11]. Higher pressure is also required to induce solid-state phase transitions in many nanoparticles due to a kinetic barrier for breaking surface bonds as opposed to those in the bulk [11]. In general, placing two materials with different properties in close, ordered proximity produces new controllable structures and properties because of beneficial interactions between the phases [12, 13].

1.2. Property Synergies

Organic/inorganic nanocomposites are attractive because properties of inorganics (e.g., rigidity, high surface area, thermal and mechanical stability) are combined with those

of organics (e.g., optical, electrical, and magnetic functionality, porosity, and hydrophobicity). Optical materials, magnetic materials [14], electrical materials such as low k thin films, solid electrolytes, structural materials, improved plastics, coatings, chemical sensors [14], catalysts, separation membranes [12, 13], and other advanced applications are possible as a result of these unique and often superior properties.

In many cases, optical nanocomposites have improved optical efficiency, mechanical strength, and sensing functionality [15] while maintaining optical transparency [16]. Materials with optical anisotropy have aligned organic molecules that are stabilized by an inorganic structural framework [17]. Addition of organic components such as monomers and photosensitive or fluorescent dyes to a transparent ceramic strengthens the material and introduces new functionality [17]. Finally, robust mechanical sensors composed of color-changing, sensing polymers encapsulated within a rigid framework have been constructed [18].

Normally, electrical components are composed of inorganic materials because of controllable conduction, magnetism, and dielectric transitions inherent to these materials [17]. However, a reduction of dielectric constant and brittleness may be possible through a combination of organic and inorganic components. As a result, nanocomposites would allow a decrease in microchip component size. High computing speeds may be possible due to the quantum control and storage of electrons in organic/inorganic structures [3]. Also, nanocomposite solid electrolytes with better ion transport properties due to changes in crystalline structure can be synthesized [19, 20].

Mechanical properties of structural components are improved by utilizing nanocomposites. These composites benefit from the combination of inorganic phase thermal stability and mechanical hardness with organic phase plasticity and synthetic flexibility. Nanocomposite materials may experience an increase in strength and a reduction of brittleness due to decreased crack propagation. For example, composite coatings that mimic the alternating biopolymer/$CaCO_3$ layers in nacre seashell have shown improved indention hardness [21]. Polymers containing nanoparticles typically have improved mechanical and thermal properties due to altered polymer chain [22] and nanoparticle mobility [23].

Other applications for nanocomposites include sensors, catalysts, and separation membranes. Sensors utilize high surface area mesoporous ceramics functionalized with organic sensing layers or constituents [24, 25]. For catalysts, nanocomposites composed of organometallic active centers on high surface area inorganic supports are more thermally stable than those on polymeric supports [26]. These catalytic materials often have greater selectivity, reactivity, and durability as a result [4]. Organic/inorganic separation membranes have better selectivity and performance because of the functionality, site specificity, and high surface areas [27–31].

1.3. Synthesis Methods

Effective nanocomposite synthesis depends on the ability to manipulate the dimension, composition, structure, and cooperative interactions of individual components [12]. In general, nanostructured materials are synthesized by breaking apart bulk materials through ball milling, lithography, or other techniques or by assembling nanoscale building blocks or scaffolds together. The former technique is used extensively in the semiconductor and electronics industries through electron beam lithography, reactive ion etching, and other techniques. Ball milling, in which mechanical abrasion physically breaks a bulk material apart, is often used to create nanoscale building blocks that can be subsequently assembled together [32]. Although nanocomposites have been synthesized for decades by both routes, the recent development of self-assembly has broadly expanded the interest and synthetic flexibility in the latter "bottom up" approach. In fact, self-assembly has emerged as one of the most promising techniques for the efficient fabrication of nanostructured materials.

The method of self-assembly spontaneously assembles and organizes various building blocks into periodic, hierarchical structures via noncovalent intramolecular or intraparticulate interactions [33]. The basic synthesis strategy has been outlined by Ozin et. al. [34]:

1. Building blocks such as molecules or particles are selected, localized, and concentrated into specific areas of the system.
2. Structure directing agents assemble, create defined spaces and architectures, and partition the building blocks into specified regions.
3. Reactions or assembly within the defined spatial regions under the influence of interfacial forces results in formation of self-assembled composites.

The advantage of self-assembly is that it starts from components in almost every conceivable ratio and uses mild, flexible synthetic steps that are versatile enough to form nanocomposites with a wide variety of material properties and property enhancements. Because self-assembly is a spontaneous process involving a balance of multiple noncovalent interactions between components, the final materials are often robust, stable, and possibly self-healing [35].

This chapter addresses organic/inorganic nanocomposites synthesized via direct self-assembling synthetic procedures or via postsynthetic procedures involving modification and incorporation of organic components into preformed, self-assembled structures. In the scope of this work, self-assembly does not refer to synthesis procedures that employ electric or magnetic fields to induce system organization. Langmuir–Blodgett, self-assembled monolayers, and other two-dimensional (2D) array materials are not included because of their inability to form consolidated engineering materials. The field of supramolecular chemistry also forms a wide variety of structures containing both organic and inorganic components. However, these materials will only be addressed briefly.

2. BACKGROUND OF SELF-ASSEMBLY

Self-assembly occurs with molecules (nanometer sized or less), colloidal particles (1–2000 nm) [36], or macroscale objects (mm) [37, 38]. The building blocks used in self-assembly are important because they carry information such as shape, topology, and surface properties that will define

material characteristics [5]. Controlling these building blocks will allow for materials with improved overall properties.

Biological processes that involve molecular recognition, self-assembly, and replication such as protein synthesis or DNA helix structures inspired much of the early work toward self-assembly and molecular templating of inorganic crystals [34]. In the formation of bone and shell, biological systems utilize self-assembly via calcium carbonate deposition and biomineralization around preformed, biologically controlled vesicle arrays [39]. Examples of other naturally occurring materials formed in this way are packed silica spheres in opal, diatom silica skeletons, and layered inorganic/biopolymer in nacre (abalone shell), as shown in Figure 1. The advantage of these biological materials is that they are organized on multiple length scales in a hierarchical fashion [40]. Today, a field called biomimetics [40] uses ideas that are inspired by observing natural solutions to materials science problems and extracting the essential operational features for use in novel synthesis procedures. For example, cystein and lysine amino acids, which are frequently used in sponges to direct inorganic growth, have been used to synthesize spherical and columnar silica [41].

Self-assembly has synthesized many useful materials over the past 40 years. For example, in the 1960s, zeolites, with 0.4 to 1.5 nm micropores, were synthesized via self-assembly of crystalline inorganic structures around organic structure directing agents such as alkylammonium ions [36, 43]. Zeolites have been used extensively in industry for catalysis and separations and several reviews are available [43–46]. However, many catalytic and separation applications require materials with larger pore channels. In 1992, MCM-41 became the first mesoporous material with large pore sizes to be synthesized by supramolecular self-assembly (also called supramolecular templating) [39, 47]. This mesoporous silicate contains a hexagonal array of pores templated by self-assembled surfactant liquid crystalline structures [48, 49]. The discovery of this approach greatly motivated research in this field. A series of ceramics such as silicates, aluminosilicates [50], titanium oxide [51], niobium oxide [51], tantalum oxide [51], tin oxide [51], tungsten oxide [51], alumina [52], or various mixed oxides such as aluminosilicates can be synthesized by this method. The pore sizes of these materials can be up to 50 nm and the pore channels can be arranged in hexagonal, cubic, lamellar, or other mesophases. However, unlike zeolites that contain crystalline walls, these mesoporous materials often have amorphous pore walls.

2.1. Forces in Self-Assembly

Self-assembly is based on weak interactions such as hydrogen bonding (3–5 kcal/mol), electrostatic interactions, van der Waals forces (1 kcal/mol), π–π interactions, solvophobic (such as hydrophobic) interactions, and capillary forces. Hydrogen bonding, the most frequently used interaction in self-assembly [36], involves the strong attraction that occurs between an electronegative atom like nitrogen (N) or oxygen (O) and a hydrogen (H) that is bonded to another electronegative atom. Electrostatic forces attract oppositely charged species. Van der Waals attractive forces result from instantaneous, nonuniform distributions of electrons that are manifested as temporary and induced dipoles in adjacent molecules. Extended delocalized *p* systems like benzene rings or conjugated polymers experience attractive forces that encourage molecular stacking based on the favorable overlap of *p* orbitals. Because of unfavorable entropic ordering of polar molecules in a hydration sheath around hydrocarbons, solvophobic interactions arise that encourage hydrocarbon agglomeration and possible phase separation. Capillary forces are based on unequal pressure across curved liquid–vapor interfaces between nanoparticles and within pores. Because intermolecular forces such as van der Waals, hydrogen bonding, and π–π interactions usually are inversely proportional to higher powers of molecular distance, they are only relevant at very short distances. With the exception of hydrogen bonding and electrostatic interactions, all of these bonds have a similar energy to thermal oscillation at room temperature [35]. The self-assembly process usually requires several of these weak interactions to work in concert.

2.2. Self-Assembly of Surfactants

Amphiphiles self-organize into a wide variety of structures (also called association colloids) [53] such as micelles, emulsions, or liquid crystal aggregates [1]. This unique capability enables self-assembled amphiphiles to act as structure directing agents in the synthesis of organic/inorganic nanocomposites and other self-assembled materials.

2.2.1. Surfactants

Surfactants, a specific class of the amphiphiles that are often used as detergents and soaps, can be categorized based on their anionic, cationic, or nonionic hydrophilic headgroups. Anionic groups include sulfate, sulfonate, phosphate, and carboxylate while cationic surfactants often have pyridinium or quaternary ammonium headgroups. Nonionic surfactants usually contain hydrophilic poly(ethylene oxide) headgroups. Table 1 shows examples from each of these surfactant classes.

Table 1. Common surfactants used in self-assembly.

Surfactant	Name/class	Hydrophobic–hydrophillic
O—SO_3Na	sodium dodecyl sulfate	dodecane-sulfate
$N^+(CH_3)_2H_3C$ Br^-	cetyltrimethyl-ammonium bromide (CTAB)	alkyl chain-ammonium bromide
$HO-[CH_2CH_2O]_x-[CH_2CH(CH_3)O]_y-[OCH_2CH_2]_z-OH$	pluoronic	poly(oxypropylene)–poly(oxyethylene)
$[\ ]_x[O\ ]_y$OH	brij	polyethylene–poly(oxyethylene)
$H_3C-[CH_2]_x-C{\equiv}C-C{\equiv}C-[CH_2]_y-C(=O)OH$	diacetylene	alkyl chain-carboxylic acid

2.2.2. Micelles

Surfactant molecules have a tendency to aggregate at surfaces (hence the name surfactant from surface active). They can also self-organize into micelles and other structures when a critical concentration (termed the critical micelle concentration or CMC) is reached. The theory describing the formation of micelles was first proposed by McBrain and Salmon in 1920 [54]. As Figure 2 shows, micelles in an aqueous system are roughly spherical pseudophases that consist of 50 to 100 surfactant molecules. Surfactant molecules are arranged so that their hydrophilic heads are exposed at the micelle aqueous media interface. Surfactant hydrophobic tails are clustered and intertwined [53, 55] to form an internal environment that very closely resembles a hydrocarbon liquid such as decane but with higher viscosity [56, 57]. The hydrocarbon tails in micelles or liquid crystals are not arranged like radial spokes in a wheel; they are in fact jumbled and often bent so that interaction between tails and the aqueous phase is minimized [58]. These structures are deformable and they readily change size, shape, and morphology due to new environmental conditions such as temperature and salt or surfactant concentration [58]. As Figure 3 demonstrates, micelles are in a state of dynamic equilibrium in which surfactant molecules are added and removed from the micelle ($t_1 \approx$ microseconds) and entire micelles can be destroyed and recreated ($t_2 \approx$ milliseconds to seconds) [58]. Note that if a hydrophobic solvent is used instead of water, reverse micelles that project their tail outward can be formed.

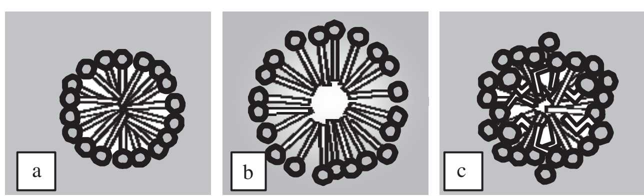

Figure 2. A schematic representation of micelle structure. Three possible tail arrangements are illustrated: (a) tails overlap at the center; (b) water penetrates the core; and (c) chain protrusion and bending correct deficiencies of (a) and (b). Panel (c) most closely resembles the actual physical structure of a micelle [53].

An equation [59] has been used to determine the number of surfactant molecules per micelle or aggregation number, Z, for many block copolymers and ionic or nonionic surfactants,

$$Z = Z_0 N_A^2 N_B^{-0.8} \tag{1}$$

where N_A and N_B are the chain lengths of the insoluble and soluble portions of the molecule respectively, and Z_0 is related to molecular interactions and volume (refer to [59] for list of values for common surfactants) [4]. The number of surfactant molecules per micelle (Z) increases as the surfactant hydrophobic chain length (N_A) increases [53].

Micellization is a spontaneous process with a negative change in Gibbs free energy (ΔG) given by $\Delta G = \Delta H - T\Delta S$, where ΔH refers to the change in enthalpy and ΔS refers to change in entropy. Example values for these thermodynamic quantities at 25 °C are: $\Delta H = -10$ to 20 kJ/mol, $\Delta S = 50$ to 150 kJ/mol K, and $\Delta G = -20$ to -30 kJ/mol [60]. As a result of a balance between hydrophobic attraction and headgroup repulsions (see Fig. 5), ΔH can be either positive or negative. The favorable replacement of surfactant–water interactions by surfactant tail–surfactant tail and water–water interactions during the micellization process contributes to a negative ΔH [53, 61, 62]. Experimental evidence has shown that only the first 2 methylene groups (out of 12 or more) of hydrophobic tails are exposed

$\bullet_1$

$\bullet_2$

Figure 3. Relaxation times $\bullet_1$ and $\bullet_2$ for surfactant removal from micelle and for micelle destruction respectively [58].

to an aqueous environment while the rest are effectively shielded [63]. However, micellization also creates unfavorable (positive ΔH), repulsive forces between neighboring headgroups such as the electrostatic repulsion between ionic headgroups with the same charge and the hydration sheath overlap around each head group [64]. The driving force for micellization is a large positive entropy change ($\Delta S > 0$). The micellization process decreases the entropy of the surfactant molecules by ordering them into precise arrangements. However, important changes also occur to the water molecules during this process. Strong hydrogen bonding between water molecules must be distorted to accommodate a hydrophobic solute molecule (or hydrophobic tail) into solution [61]. Water will preferentially orient and align with a certain degree of order around this solute in a hydration layer so that interwater hydrogen bonds are maintained [53]. The formation of micelles allows more of the water to return to its less ordered state, thereby contributing a large increase in entropy. Each micelle possesses approximately two layers of water in its hydration sheath, which is far less than the number of water molecules in the combined hydration sheaths of 50 surfactant tails [63].

2.2.3. Surfactant Liquid Crystalline Phases

A small increase in concentration above the CMC causes the number of micelles to increase but it does not change the surfactant aggregation number [65]. As the total number of micelles increases and the distance between micelles decreases, interactions like Coulombic repulsion between micelle counterion clouds [58] and the unfavorable interaction between layers of hydration surrounding each micelle create a driving force for spherical micelles to transform into liquid crystalline phases.

A liquid crystal is composed of aligned molecular arrays that can flow and deform like a liquid. Typically, molecules that form liquid crystals have length to diameter ratios or aspect ratios of 10–20 [62]. Liquid crystals can be composed of molecules that are aligned in layers (cholesteric and smectic) or in a random arrangement (nematic). A lyotropic liquid crystal is one that contains multiple components such as an amphiphile in solvent (soap and water) [66]. Since the molecules that form a liquid crystal have long-range order based on weak intermolecular interactions, they can undergo liquid deformation and at the same time exhibit crystalline optical properties such as the diffraction of light and optical anisotropy (direction dependant properties) [66]. The following discussion will deal exclusively with surfactant lyotropic liquid crystals because they can spatially organize a system into hydrophobic and hydrophilic regions [58] that are useful for the synthesis of hierarchically ordered organic or inorganic materials [67].

Lyotropic surfactant liquid crystals are based on the close packing of surfactant molecules. While micelles are spherical and monodispersed near or slightly above the CMC, an increase in surfactant concentration to 10 times the CMC [68] causes the micelle cores to grow and organize into cylindrical rods or lamellar disks with a wide range of surfactant aggregation numbers [53, 58]. These organized structures pack into periodic arrays in such a way as to expose hydrophilic head groups toward the hydrophilic solvent. Lamellar, hexagonal, or cubic structures with increasing 1- to 3D periodicity are based on the packing of layers, cylinders, or spheres respectively (Fig. 4) [66]. These structures maintain a disordered liquid-like arrangement of surfactant tails within a confined environment [69]. The lamellar structure consists of parallel alternating surfactant double-layer sheets and hydrophilic solvent in which the tails dissolve each other thus exposing the heads to the solvent. Hexagonal phases are built up from a number of long, parallel cylinders of surfactant that are packed together with the heads exposed outward. Uniform surfactant spheres pack together in a way that also exposes head groups outward to form an isotropic cubic arrangement. The cubic mesophase is bicontinuous in that the surfactant tail phase forms a continuous grid in three dimensions surrounded by a continuous grid of water. Hexagonal and cubic structures can be inverted to expose their hydrophobic tails outward if the solvent is hydrophobic instead of hydrophilic. Each mesophase has an interface curvature that depends on a balance of repulsive forces between headgroups and van der Waals interactions between tails (Fig. 5) [70].

Effect of Surfactant Molecule Structure on Liquid Crystalline Phases The shape of a surfactant molecule in the self-assembling system can be geometrically depicted using its cross-sectional head group area (a_0), tail volume (v), and length of hydrophobic tail (l_c) as shown in Figure 5 [53]. The head group area and tail volume are determined by dividing surfactant surface area and internal hydrophobic volume by the micelle aggregation number (number of surfactant molecules per micelle), respectively. The head group area depends on the hydrophilic chain length for nonionic surfactants. The length of the hydrophobic tail is determined empirically by the surfactant chain length in a hydrophobic media. A packing parameter, P, that describes the shape of micellular and liquid crystalline aggregates, is given by [53]

$$P = v/(a_0 l_c) \tag{2}$$

Figure 6 illustrates the relation between the packing parameter P and packing shapes of different surfactants and lipids [65]. Changes in pH, salt concentration, and temperature may affect the headgroup area and therefore the packing

parameter [53]. For example, a counterion salt in solution will act as a buffer between oppositely charged surfactant headgroups and reduce the effective headgroup area thereby changing the surfactant packing parameter [64]. An increase in temperature often reduces the repulsion between headgroups due to a smaller hydration sheath and this can result in a shift from a hexagonal to a lamellar structure [71]. Each liquid crystalline phase has a different mode of hydrocarbon tail packing. The volume fraction occupied by the surfactant in a lyotropic liquid crystalline system is also important in determining the liquid crystalline phase [3].

The use of a packing parameter provides an empirical route to understanding the self-assembling system; however, the packing parameter alone does not fully describe the complexity of surfactant packing. Surfactant concentration [62], system temperature, solvents, external fields [67], and specific surfactant interactions or morphologies may dramatically affect the final assembled structures. For example, an increase in temperature or surfactant concentration can cause a system to shift through the following sequence: spherical micelles, elongated micelles, lamellar liquid crystalline phase, and finally bicontinuous liquid crystalline phase [58]. The structure of the surfactant molecule plays an important role in determining the final structure formed [58]. Surfactants with special interactions and morphologies may form supramolecular assembly with rod or disk morphologies [67] or other complicated structures like gyroid, modulated lamellar and packed spheres [3].

Lipid	Critical packing parameter	Critical packing shape	Structures formed
Single-chained lipids (surfactants) with large head group areas: SDS in low salt	<1/3	Cone	Spherical micelles
Single-chained lipids with small head group areas: SDS and CTAB in high salt, nonionic lipids	1/3–1/2	Truncated cone	Cylindrical micelles
Double-chained lipids with large head group areas, fluid chains: phosphatidyl choline (lecithin), phosphatidyl serine, phosphatidyl glycerol, phosphatidyl inositol, phosphatidic acid, sphingomyelin, DGDG,[a] dihexadecyl phosphate, dialkyl dimethyl ammonium salts	1/2–1	Truncated cone	Flexible bilayers, vesicles
Double-chained lipids with small head group areas, anionic lipids in high salt, saturated frozen chains: phosphatidyl ethanolamine phosphatidyl serine + Ca^{2+}	~1	Cylinder	Planar bilayers
Double-chained lipids with small head group areas, nonionic lipids, poly (cis) unsaturated chains, high T: unsaturated phosphatidyl ethanolamine, cardiolipin + Ca^{2+} phosphatidic acid + Ca^{2+} cholesterol, MGDG[b]	>1	Inverted truncated cone or wedge	Inverted micelles

3. SYNTHESIS OF ORGANIC/INORGANIC NANOCOMPOSITES VIA LIQUID CRYSTALLINE TEMPLATES

A large variety of nanocomposites can be synthesized by a self-assembly process that spontaneously organizes and arranges different building blocks into ordered self-assembled structures. Often, materials can be synthesized that have order, functionality, and periodicity on multiple scales using surfactants (refer to Fig. 7). On the molecular scale, chemical design or modification of structural parts determines overall molecular architecture. On the nanometer scale, synthesis conditions determine liquid crystalline conformation, size, and periodicity. On the micrometer

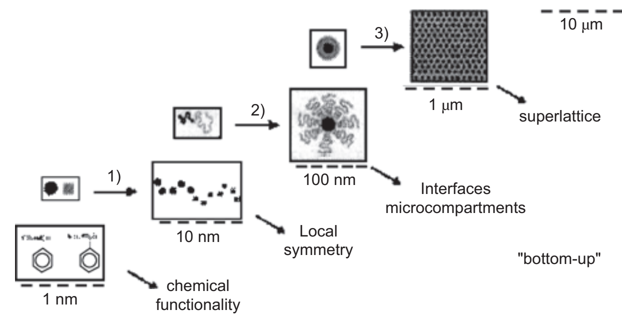

Figure 7. (1) Chemical functional groups and molecules on the atomic scale for (2) self-assembly into larger nanometer sized aggregates based on shape and interactions. These aggregates (3) template micrometer-sized periodic arrays for the formation functional devices. Modified with permission from [3], S. Forster and T. plantenberg, *Angew. Chem. Int. Ed.* 41, 688 (2002). © 2002, Wiley–VCH.

scale, external electrical, magnetic, and mechanical (flow) fields influence the formation of extended superlattices [3].

A crucial step in the formation of hierarchical materials with order on multiple scales involves the liquid–crystalline template synthesis procedure. A commonly used organic/inorganic nanocomposite synthesis process involves the simultaneous co-assembly of surfactants and other building blocks like inorganic silicate species. This co-assembly technique often involves the sol–gel formation of inorganic clusters [18, 21].

3.1. Sol–Gel Process

The sol–gel process utilizes low-cost, commercially available precursors to synthesize inorganic materials and organic/inorganic hybrid materials at low temperature and mild reaction conditions [73]. In general, a sol is a solution containing metal oxide colloidal particles formed by hydrolysis and condensation of the appropriate metal alkoxide or metal halide precursors [74]. A gel contains clusters that span the entire container or clusters that are intertwined so that the viscosity is greatly increased. Commonly used metal alkoxides, $M(OR)_n$, contain metal atoms (M) such as Si, Ti, Al, Zr, and La connected to alkoxide groups (OR) (e.g., CH_3O and CH_3CH_2O). Metal halides MX_n employ the same metal atoms connected to halides (X) such as Cl or Br. The sol–gel process provides a versatile way to synthesize various materials such as optical coatings, low-density aerogels, inorganic membranes, membrane reactors, and colloidal powders with controlled sizes and morphologies.

3.1.1. Sol–Gel Chemistry

Hydrolysis and condensation reactions convert discrete precursors in solution into extended clusters capable of forming engineering materials. Although the sol–gel reaction mechanism depends on which metal precursor is utilized, silica based sol–gel reactions are described as an example because silica materials are most common.

The silica-based sol–gel process involves the following reactions (1) to (3). Reaction (1) involves the hydrolysis of a tetraalkoxysilane with water to generate silanol groups. Alcohol condensation reactions (2) between a tetraalkoxysilane and a silanol group release an alcohol molecule while water condensation reactions (3) between two silanol groups release a water molecule. Reaction (4) shows a hydrolysis reaction of an organosilane that contains a nonhydrolyzable ligand R′. These hydrolyzed organosilane molecules can undergo alcohol or water condensation reactions similar to those shown in reactions (2) and (3). Also, copolymerization of organosilanes $[R'_xSi(OR)_{4-x}]$ with tetraalkoxysilanes $[Si(OR)_4]$ via cross-condensation reactions may lead to a hybrid silica framework containing molecular level mixing of the organic ligands. The reaction kinetics are controlled by the choice of solvent, choice of alkoxide groups, system pH, and the ratio of water to inorganic precursor [33, 73, 75]. Larger alkoxide groups such as butoxide usually result in a slower reaction rate because of steric hindrance.

Reaction Scheme 1. Silica hydrolysis and condensation reactions.

$$\equiv Si(OR) + (HO)Si\equiv \longleftrightarrow \equiv Si{-}O{-}Si\equiv + ROH \text{ Condensation} \quad (2)$$

$$\equiv Si(OH) + (HO)Si\equiv \longleftrightarrow \equiv Si{-}O{-}Si\equiv + H_2O \text{ Condensation} \quad (3)$$

$$= Si\mathbf{R}'(OR) + H_2O \longleftrightarrow = Si\mathbf{R}'(OH) + ROH \text{ Hydrolysis} \quad (4)$$

Symbols "≡" and "=" represent three and two siloxane bonds that connect to the Si atoms.

3.1.2. Sol–Gel Dip Coating

These sol–gel reactions usually occur in solution and result in silicate colloidal solutions that can prepare various inorganic and hybrid thin films, membranes, powders, particles and fibers through conventional processing techniques such as spin-coating, dip-coating, spraying, aerosol processing, and fiber extrusion.

Sol–gel dip-coating techniques offer a convenient method to form thin films on either planar or nonplanar substrates. The process can be divided into five steps: immersion, start-up, deposition, drainage, and evaporation, as shown in Figure 8. Formation of silica thin films by the dip-coating process has been well developed [76]. Beginning with a silicate sol containing weakly branched silicate species, solvent (e.g., ethanol and water) evaporation during the coating process enriches silicate species within the sol trapped on the substrate surface. This enrichment promotes silicate aggregation, gelation, and formation of thin films on the substrate.

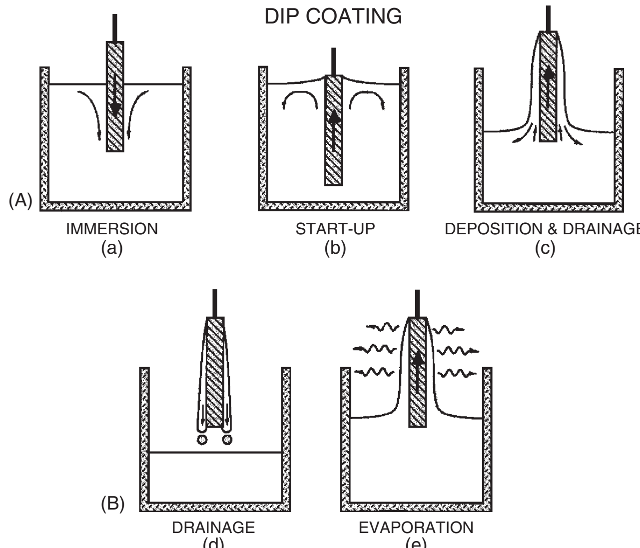

Figure 8. Schematic illustration of a sol–gel dip-coating process. Reprinted with permission from [76], C. J. Brinker and G. W. Scherer, "Sol–Gel Science: The Physics and Chemistry of Sol–Gel Processing," p. 789. Academic Press, San Diego, 1990. © 1990, Academic Press.

A balance between capillary pressure and silica network modulus determines pore sizes of the thin films. Higher capillary pressure and lower network modulus usually result in denser thin films. The thickness of the deposited films can be determined using Eq. (3), where U is the substrate speed, ρ is the density of the sol, η is the viscosity, and γ_{LV} is the liquid vapor interfacial energy [76]:

$$h = c_1(\eta U/\rho g)^{1/2} \tag{5}$$

When the liquid viscosity and coating speed are high enough to lower the curvature of the meniscus, Eq. (4) is used to express the thickness. Usually, a higher coating speed and sol viscosity lead to a thicker film [76]:

$$h = 0.94(\eta U)^{2/3}/\gamma_{LV}^{1/6}(\rho g)^{1/2} \tag{6}$$

3.1.3. Co-Assembly of Surfactant and Silica

As discussed, surfactants self-assemble into micelles and liquid crystalline mesophases in aqueous media at high concentrations. In 1992, Mobil scientists demonstrated that surfactant and silicate can co-assemble and form nanocomposites containing ordered surfactant lyotropic liquid crystalline phases via van der Waals and electrostatic interactions. Surfactant removal results in mesoporous silica (MCM-41) replicas of the liquid crystalline surfactant assembly (see Fig. 9). This co-assembling synthesis approach has been extended to create a large variety of mesoporous and nanocomposites through van der Waals, electrostatic, hydrogen bonding, or other noncovalent interactions. Examples of these mesoporous materials include mesoporous SiO_2 [77–80], SiO_2 containing interstitial Ti [81] or Al [82], aluminosilicates [83], $AlPO_4$ [84–88], Al_2O_3 [89], TiO_2 [90], Nb_2O_5 [91], SnO_2 [92, 93], ZrO_2 [94], mixed oxides [95], and metal Pt [96].

The synthesis procedures usually start with a solution containing surfactant, inorganic precursors, and solvent. There has been debate about whether micelles or liquid crystalline phase formation and inorganic precursor association with the surfactant molecules are sequential or simultaneous processes [48]. One possible self-assembly mechanism involves the initial formation of a liquid crystalline phase. This mechanism assumes that the concentration of the surfactant is sufficiently high to not only form micelles but, in some cases, ordered mesophases. Subsequent association and reaction of inorganic clusters solidifies the mesostructure. This route involves mineralization around already formed liquid crystalline arrays at higher surfactant concentrations and diffusion of inorganic precursors into preformed liquid crystals [97].

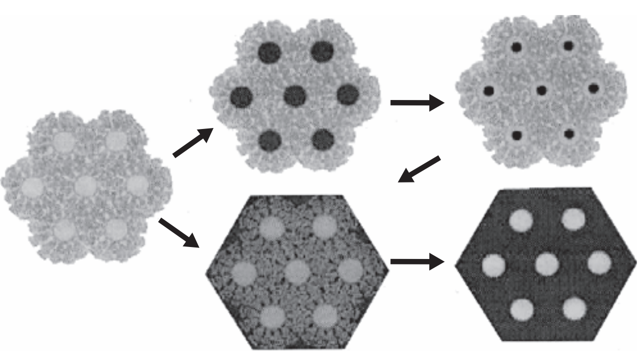

Figure 9. Overview of liquid crystalline templating routes to nanoparticle and mesoporous material formation: (1) Swelling liquid crystal interior with hydrophobic reactants for (2) nanoparticle formation and (3) reaction of hydrophilic reactants followed by (4) surfactant removal to form a mesoporous material. Reprinted with permission from [3], S. Forster and T. plantenberg, *Angew. Chem. Int. Ed.* 41, 688 (2002). © 2002, Wiley–VCH.

Although this synthesis route may hold true in some instances, a growing amount of evidence implies the simultaneous formation mechanism is more likely. During the formation of inorganic clusters in solution, alcohol byproducts increase surfactant CMC and reduce the long-range order of the system [98]. Also, nuclear magnetic resonance (NMR) evidence does not support the sequential mechanism for many commonly used silica systems [49]. Since some synthesis techniques such as evaporation induced self-assembly start to assemble well below the CMC, it is believed that surfactant–inorganic interactions play an important role in the simultaneous formation of a periodic structure [6].

A widely accepted mechanism for many surfactant/sol–gel syntheses of inorganic materials is shown in Figure 10. This theory states that the liquid crystalline phase is created based on cooperative self-assembly of the clusters and surfactant before substantial solid formation has occurred. As the inorganic clusters form, they begin interacting via electrostatic or hydrogen bonding, or other noncovalent interactions with surfactant head groups present in solution. These charged clusters grow and encourage the packing of liquid crystalline structures into arrays such as rods with short-range order and with weak framework walls [52]. Interactions between phases transmit the liquid crystalline structural information to the inorganic clusters [49]. The inorganic/organic arrays then combine to form extended composite structures. In thin films, the cooperative assembly of inorganic associated micellular complexes occurs first at a microscopic gas–liquid or liquid–solid interface [97].

The self-assembly of organic and inorganic components occurs because of favorable interactions [70] and entropic gain that result from inorganic components replacing the water hydration sheath surrounding the surfactant [49]. Synthesis conditions must be optimized to allow for favorable interaction between the liquid crystal surface and inorganic clusters and to allow a lowering of the interfacial energy [99, 100]. This occurs by matching the density of electrostatic charge or hydrogen bonding sites present at the interface between organic and inorganic phases [101, 102]. Metal oxide surfaces typically consist of metal hydroxy groups MOH. Charge matching between this growing surface and the surfactant interface depends on the pH of the system, the valence and content of the metal oxides, the pKa of the surfactant, and the ratio between silica and surfactant. Initially [39, 99], cationic surfactants were used so that the negatively charged inorganic clusters would be charge matched by positively charged surfactant headgroups [22, 48]. It is also possible to use anionic surfactants with positively charged clusters, surfactants, and clusters with

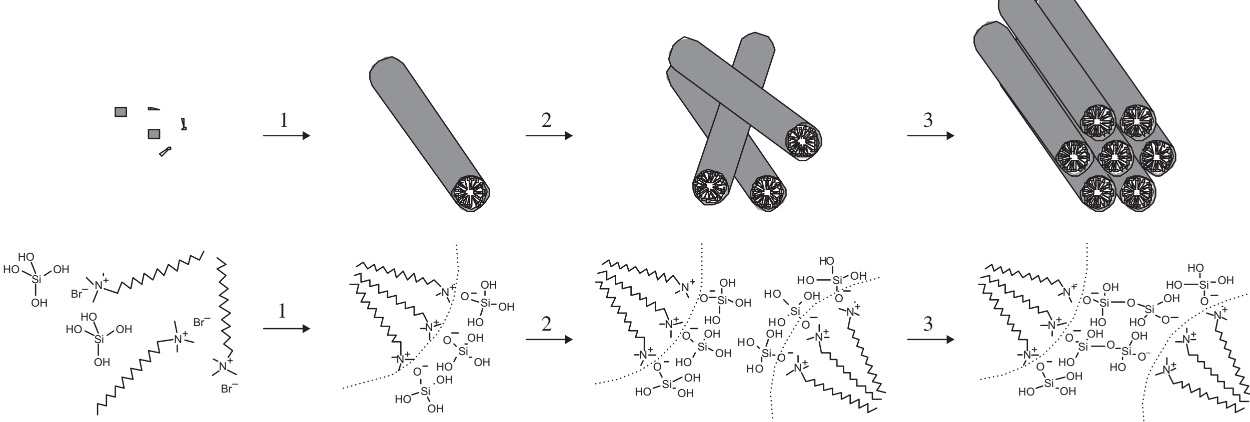

Figure 10. Templated mesostructured inorganic synthesis via (1) co-assembly of surfactant and inorganic precursors into cylindrical micelles that are (2) forced into close proximity based on solvent removal or precipitation allowing interactions and condensation reactions between growing inorganic clusters to finally form a (4) hexagonally arrayed surfactant/inorganic network containing cross-linked inorganic [49].

the same charge brought together by counterions, or nonionic surfactants with neutral inorganic precursors brought together by hydrogen bonds [52]. Changing the pH above or below the isoelectric point of the inorganic clusters can vary the inorganic cluster charge. Nonionic surfactants utilize hydrogen bonding from metal oxide surface hydroxyl groups to the surfactant headgroups as opposed to electrostatic interactions. The forces between phases transmit self-assembled surfactant information to the growing inorganic matrix and control the morphology of the composites [6, 103].

3.1.4. Synthesis Methods

Two major synthesis methods have been developed to synthesize mesoporous materials and nanocomposites: solution precipitation and evaporation induced self-assembly (EISA).

Solution Precipitation The solution precipitation method involves precipitation of co-assembled products in the form of particles, powders, or thin films from solutions that were prepared using inorganic precursor and surfactant [90, 97, 102, 104–107]. The precipitation mechanism [1, 47], which mimics natural biomineralization, involves interactions between the inorganic clusters and surfactant molecules and deposition of the inorganic clusters based on the liquid crystalline scaffolds [33, 47, 108]. Important aspects of this synthesis include concentration of surfactant and inorganic precursors, temperature, and solution pH, which may determine the rate of inorganic cluster formation and the electrostatic charge of the cluster surface [1]. The liquid crystalline array constrains crystal growth by a sterically imposed template mechanism, controls mass transport of inorganic precursors [109, 110], and serves as sites for crystal nucleation based on locally high precursor concentrations at the surfactant interface. Once nucleation has occurred, the growing crystal, which sometimes orients itself based on interfacial forces, increases in size by the addition of adjacent ions [64]. As shown in Figure 11, this method typically results in the formation of small, micrometer sized particles that are difficult to use for membrane applications [33].

Evaporation Induced Self-Assembly EISA combines the simplicity, readiness, flexibility, and affordability of sol–gel processing technology with the efficiency and spontaneity

of silica/surfactant cooperative assembly. EISA simultaneously and spatially organizes organic and inorganic components into two- or three-dimensional nanostructures during conventional processes like dip-coating, spin-coating, aerosol processing, fiber extruding, and microwriting. Mesostructured thin films, particles, and patterns (or arrays) containing different mesophases can be achieved readily and rapidly by controlling the various parameters such as initial surfactant concentration. Figure 12 shows representative transmission electron microscopy (TEM) images of a thin film prepared by a dip-coating process, lamellar particles by an aerosol process, and micropatterns by microwriting and inkjet printing techniques, respectively.

Dip-Coating The formation of nanostructured thin films through EISA and a sol–gel dip-coating process begins with a homogenous solution of soluble silica and surfactant in ethanol/water solvent. Solvent evaporation during the coating process enriches silica and surfactant and induces their co-assembly into liquid crystalline mesophases. During the drying process, polymerization of silica freezes the mesophase and results in nanostructured thin films exhibiting hexagonal, cubic, or lamellar mesostructures. A similar EISA process involves spin-coating solutions onto substrates to form mesostructured thin films. The advantages and unique features of these processes include:

(1) Mesostructured thin films can be readily fabricated within a time scale of seconds. Research conducted using *in-situ* small angle X-ray scattering and ellipsometry techniques suggests that this coating process involves the formation of many intermediate structures [76]. The rapid formation process kinetically freezes these intermediate structures, resulting in thin films containing metastable structures. Control of sol–gel reaction kinetics, inorganic cluster sizes, pH, and solvent evaporation rate is necessary in order to achieve a highly ordered mesostructured thin film [76]. Mesostructure is determined based on the choice of surfactant and surfactant concentration.

(2) This is a continuous process that allows synthesis of defect-free thin films for membranes, sensors, low-dielectric constant (low-K) materials, and other applications. In fact, low-K mesoporous thin films prepared by EISA have been used in the current semiconductor industry for next generation microelectronic applications.

Fan et al., *Nature* 405, 57 (2000) © 2000, Macmillan Magazines Ltd.

Aerosol Process Aerosol techniques have been widely used to generate different sizes of droplets for drug delivery, humidification, particle syntheses, and other applications. Figure 13 schematically depicts the formation of nanostructured particles by an aerosol EISA process. Using the surfactant containing sol as precursor solution, an aerosol apparatus generates droplets that pass through the drying and heating zones. The solidified particles are then collected using a filter. During this process, solvent evaporation from the droplet air–liquid interface enriches surfactant and silicate, resulting in their co-assembly and the formation of mesostructures growing from the interface toward the interior. Further drying and solidification processes result in the formation of various mesostructured particles.

Micro-Writing and Printing Microwriting and printing techniques use the surfactant containing sols as ink to write or inkjet print various EISA mesostructured patterns and arrays. The micropen or printing cartridge injects surfactant containing sol droplets on the substrates (e.g., paper, transparency, and glass slides). Co-assembly of silicate and surfactant induced by solvent evaporation and coalescing of these enriched droplets create various hierarchical patterns and arrays on the substrates.

3.2. Design of Nanocomposites

The EISA approach has been extended to synthesize various nanocomposites. An example phase diagram for a surfactant/hydrophobic component/hydrophilic component system at a given temperature and pressure is shown in Figure 14. This phase diagram demonstrates the utility of the self-assembly methodology for incorporating a variety of components such as monomers or inorganic precursors (silica) into different mesophases. Using the surfactant phase diagram as a conceptual guide, one can consider oil as a wide variety of hydrophobic additives (e.g., monomers, hydrophobic colloidal particles, or functional polymers.) that are incorporated within the hydrophobic micellar cores. In a process similar to that of dishwashing, micelle formations spatially separate and organize inorganic silicates and the additives. Further self-organization of silicate and the micelles into hexagonal, cubic, or lamellar mesophases simultaneously positions the silica, surfactant and additives into precise three-dimensional arrangements. A wide variety of additives (e.g., metal ions, organic functional ligands and molecules, pigments, monomers, oligmers, polymers, metal colloidal particles, catalyst particles, biomolecules, and cells) can be readily introduced to the surfactant/silicate solutions.

As an alternative approach, also shown in Figure 14, direct co-assembly of silicate and functional surfactant micelles can also lead to the formation of nanocomposites with spatially defined functionality. For example, polymerizable groups on a surfactant can react so that the liquid crystal structure is retained after self-assembly has taken place [114, 115]. When used in tandem with the sol–gel process, polymerizable surfactants can easily form nanocomposites with a variety of architectures. Organization of these molecules into arrays is beneficial because of the alignment and condensation of reactive groups on the surfactant tails. Studies have shown that this association increases the rate of polymerization because of the more effective intermolecular collisions [64]. This process can form polymers with controlled mesostructure such as spheres. Sometimes it is difficult to maintain the mesostructure of lyotropic liquid crystals during the polymerization process [64, 114].

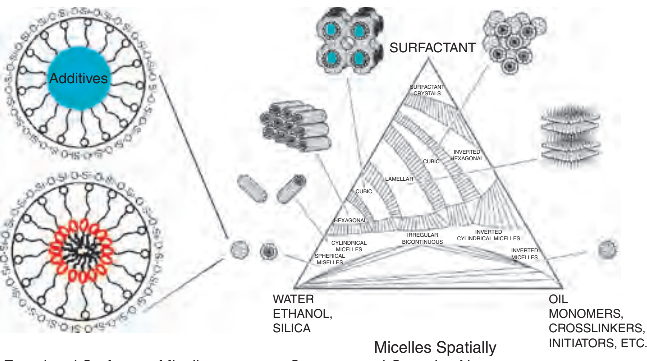

Figure 14. Generic detergent (surfactant–oil–water) phase diagram showing common surfactant mesophases and the ability of surfactants or functional surfactants to spatially separate organic additives and functional groups. Reprinted with permission from [33], C. J. Brinker et al., *Adv. Mater.* 11, 582 (1999). © 1999, Wiley–VCH.

The lamellar phase is the easiest to maintain during polymerization. Other research has been able to synthesize polymers that retain the original hexagonal, cubic [114], and inverted hexagonal mesophase [115].

3.3. Mesoporous Inorganic Nanocomposites

3.3.1. Functional Mesoporous Inorganic

Since the discovery of templated mesoporous silica synthesis, great efforts have been made to functionalize the surface of these materials. Organic functionalities often provide the mesoporous materials with better hydrophilicity and stability to compression [116], better compatibility and more favorable interactions with other components like polymers, improved hydrothermal stability [117], decreased water adsorption [118, 119], less agglomeration between particles [22], and the capability to graft new reactive complexes such as organometallic catalysts to the surface [119–122]. Organic groups such as methyl [116, 123–125] alkyl chains [126], vinyl [14, 127], methacrylate [128], amino [129], thiol [130–132], sulfonic [129], phenyl [133, 134], and metal/ligand complexes [120, 135] are just some examples of moieties that have been functionalized onto the surface of mesoporous silica. In general, either surface grafting or direct synthesis techniques functionalize mesoporous silica.

Surface Grafting Techniques Surface grafting techniques attach organic molecules to the pore surface of preformed mesoporous silica by silylation of surface SiOH groups. Most commonly, the surface modification reaction involves an organosilane molecule R-SiX_3, where X represents an alkoxide or halide group and R is a nonhydrolyzable ligand such as an alkane [130]. Also, molecules can be adsorbed onto the internal surface of the mesoporous material to change the surface properties [136]. This modification coats the internal surface in a similar fashion to self-assembled monolayer formation on flat surfaces [130]. Bourgeat-Lami [22] has compiled an extensive list of references covering the surface modification procedure including: coupling agent chemistry [137] inorganic surface reactivity [138–140], and modified surface properties [141–143] such as stability toward various solvents [144]. Table 2 lists several MCM-41 type materials that have been functionalized by surface grafting.

Direct Synthesis Techniques The direct synthesis approach involves co-condensation of organosilanes that contain nonhydrolyzable functional ligands with a silica precursor like tetraethoxysilane (TEOS) in the presence of the templating surfactant. Hydrolyzed organosilanes containing hydrophobic ligands often serve as co-surfactants by inserting their ligands into the hydrophobic micellar cores through hydrophobic interactions. In this way, organosilane molecules preferentially concentrate at the inorganic/surfactant interface. Surfactant removal leads to the formation of a mesoporous material with organic ligands covalently bonded on the surface. Table 3 lists more examples of organically modified mesoporous silica and their applications.

Another class of mesoporous organic/inorganic materials contains organic moieties integrated within the pore wall.

Table 2. Surface grafted organic functionalization in MCM-41 type materials.

Grafted organic group	Technique	Characteristics	Ref.
Methyl ($—CH_3$)	react silica with trimethylchlorosilane, hexamethyldisilazane, and tetramethyldisilazane	pore surfaces become hydrophobic and more stable; ambient dried silica aerogels can be synthesized	[116, 123–125]
Vinyl ($—CH{=}CH_2$)	react silica with vinyltrichlorosilane or hydrolysis and condensation of vinyltriethoxysilane	deduce intra-channel functionalization by studying kinetics of alkene bromination	[14, 127]
2,4,6-triphenylpyrylium cation	cation formed inside MCM-41 by reaction of chalcone and acetophenone or by ion exchange of 2,4,6-triphenylpyrylium tetrafluoroborate	photoinduced electron transfer reagent for isomerization of *cis*-stilbene to *trans*-stilbene	[145]
Substituted triarylmethylium	zeolite and MCM-41 exposed to benzaldehyde and *N*,*N*-dimethylaniline or anisole to create large interstitial methylium cations	heterogeneous photosensitizers for 1,3-cyclohexadiene dimerization	[146]
Thiol ($—(CH_2)_3SH$)	tris(methoxy)mercaptopropylsilane modified the silica pore surface; Thiol end groups self-assembled into monoloayers	thiol binds heavy metals or other functional molecules; extremely efficient in removing heavy metals such as mercury from both aqueous and organic waste streams	[130, 131]
Manganese (Mn) and 1,4,7-triazacyclononane (TACN) complexes	(3-glycidyloxypropyl)trimethoxysilane TACN ligands, and then Mn dopants used to sequentially modify silica	catalytically active, nonaromatic Mn complex on silica pore surface	[135]
Ferrocenyl ($—(C_5H_4)_2Fe$)	treated MCM-41 with a pentane (1,1′-ferrocenediyl) dimethylsilane	NMR and EXAFS spectroscopy indicate structure is tethered to the silicate wall via Si–O linkages	[120]
Ethylenediamine, diethylenetriamine, and ethylenediaminetriacetic acid salt	grafted to surface using ($RSi[OMe]_3$) type synthetic reagent	readily binds metals such as cobalt	[147]
Amine and cyanide	3-aminopropyl, 2-cyanoethyl organosilanes grafted to silica surface	demonstration of organic modification by adsorption, IR, and TGA	[148, 149]
Amine ($—NH_2$ or $—NR_2$)	surface modification using either 3-aminopropyltriethoxysilane or 3-chloropropyltriethoxysilane; surface chloro groups further modified to produce surface piperidine groups	highly active and regioselective catalyst for the epoxide ring-opening of glycidol by fatty acid addition	[150]
Globular enzymes: cytochrome *c* (bovine heart), papain (papaya latex) and trypsin (bovine pancreas)	immobilization of enzyme onto solid support in aqueous solution	improve chemical sensing and biocatalysts	[151]
Anthracene, naphthalene, and thianthrene	silica modified using polynuclear aromatic compound in iso-octane and tert-butyl alcohol	catalyst	[152]
Thianthrene	chemical vapor deposition of thianthrene under argon; radical cations formed	methodology developed for control of chemical reactivity in constrained environment	[153]
Alkyl halides, alkanes, and water	liquid-phase adsorption at room temperature	study of the variation in intensity of the observed X-ray diffraction peaks as a function of sorbate scattering power	[136]

Table 3. Direct organic functionalization in MCM-41 type materials.

Organic guest	Technique	Characteristics	Ref.
Fluorinated alkane-, mecapto-, and amino-functionalized organosilanes	organosilane added to surfactant rich silica sols made from TEOS; these sols were then used as inks in three rapid EISA printing processes	patterened, highly ordered, functionalized three-dimensional structures were formed within second	[113]
Thiol($-(CH_2)_3-SH$)	mixture of (3-mercaptopropyl) triethoxysilane (MPTS) and tetramethoxysilane (TMOS) were hydrolyzed and condensed in the presence of CTAB and organic waste streams	thiol binds heavy metals or other functional molecules; extremely efficient in removing heavy metals such as mercury from both aqueous	[132]
Sulfonic surface groups ($-SO_3H$)	MPTS and TEOS hydrolyzed and condensed in the presence of surfactant, SH then converted to sulfonic acid by mild oxidation with H_2O_2 followed by acidification	polyol esterification catalyst	[129]
Straight chain alkanes ($-CH_n$)	organic–inorganic thin films were prepared by co-condensation of alkyltriethoxysilanes (alkyl chain = 8–18) and TEOS using an EISA dip-coat process	highly ordered, multilayered structure depended on the length of the alkyl chain and the solution temperature	[126]
Phenyl and *n*-octyl	co-condensation using organosilane	catalyst	[133, 134]
Methacrylate ($CH_2{=}C(CH_3)CO_2-$)	co-condensation of TMOS and 3-(trimethoxysilyl)propyl methacrylate in the presence of CTAB; additional monomer incorporation and reaction forms silica/poly (methyl methacrylate) nanocomposite	grafted methacrylate groups accessible to bromination and polymerization	[128]

Bridged silsesquioxanes (Fig. 15) and other silica precursors hydrolyze, co-condense, and co-assemble with surfactant to form functionalized mesostructured materials. Each of these silsesquioxane precursors contains a nonhydrolysizable organic ligand that covalently bridges two alkoxysilane groups. Co-assembly organizes surfactants and these organic moieties into spatially defined arrays. Surfactant removal leads to the formation of a mesoporous material with organic moieties integrated within the pore walls. Bridging organic groups such as aromatic rings [13], alkyne [155], alkene [156], and alkane chains [157] have been incorporated within a silicate matrix. After removal of the surfactant, silicates with highly ordered pore structure, crystal-like wall structures, and/or high internal surface area have been synthesized by this method [158]. For example, mesoporous silica containing ethane or ethylene incorporated within the silica network demonstrated a high >1200 m^2/g surface area [156]. Not only could these materials absorb organic compounds unlike unmodified MCM-41, but incorporated ethylene groups could also be brominated with little or no damage to the pore structures. Ethane molecules incorporated uniformly within a silica matrix have also been used to produce a variety of highly ordered mesophases that can be used as catalysts, adsorbents, and hosts for other nanocomposites [157]. mesoporous silsesquioxanes have many applications including the production of low dielectric constant materials, catalysts, sensors, adsorbents, and as host for other nanocomposites. Table 4 describes many of the procedures used to create ordered structures from these silsesquioxanes.

These modification techniques can be combined with solvent EISA techniques (see Section 3.1.4) to produce organic functional thin films, particles, and patterned arrays using conventional dip-coating or spin-coating, aerosol processing, and microwriting or inkjet printing techniques, respectively [13].

Applications of Organic Modified Mesoporous Silica in the Microelectronics Industry Organic modified mesoporous silica has a broad range of applications ranging from catalysts, adsorbent, separation, sensors, to molecular host materials. However, because of the emerging importance of these materials to the microelectronics industry, this section will focus on low dielectric constant materials based on organic modified mesoporous silica.

Continuous miniaturization of devices and circuits has driven rapid growth in the semiconductor industry, resulting in better device performance and lower cost per bit. The decrease of feature sizes and the increase of metal level result in an increase of interconnect resistance (R) and the associated total capacitance (C). As the device dimensions shrink toward 0.1 μm, the interconnect delay, defined as the RC delay, becomes a dominant factor in determining device performance [160, 161]. Reducing the RC delay by lowering the ratio of total resistance or capacitance to device delay has become a challenge for both materials development and interconnect architecture design. Although optimization

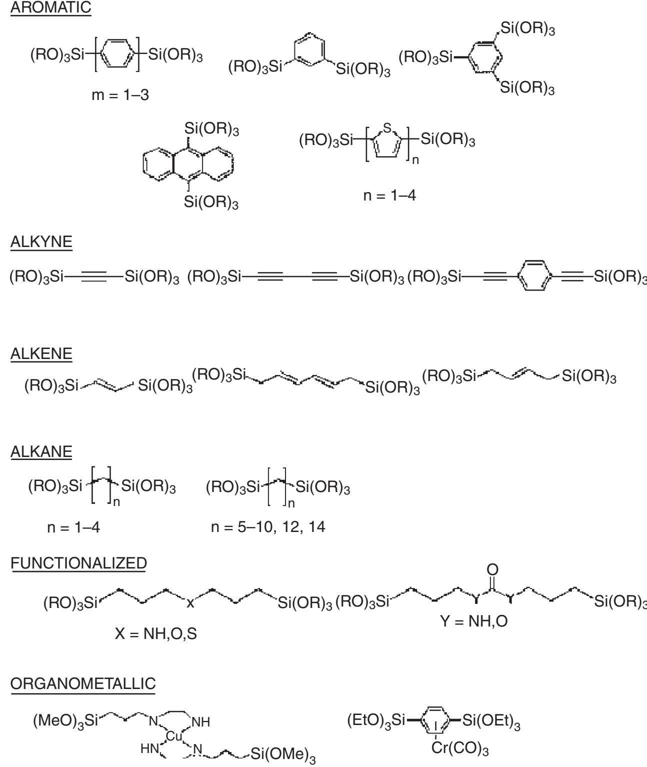

Figure 15. Representative bridged polysilsesquioxanes used in direct internal pore wall functionalization. Reprinted with permission from [159], K. J. Shea and D. A. Loy, *Chem. Mater*. 13, 3306 (2001). © 2001, American Chemical Society.

of the interconnect design can lower a large fraction of this delay, viable solutions have not yet been found. Thus, efforts have been concentrated on replacing the current interlayer dielectrics (ILDs) ($K \sim 4$) with lower-K ILDs, and on changing interconnects composed of Al/W to Cu-based interconnects [162].

The dielectric constant can be described using a basic capacitor made of two conducting parallel plates separated by an insulator, also known as the dielectric (refer to Fig. 16) [163].

The electrical charge (Q) stored on either plate can be found from the equation

$$Q = C * V \tag{7}$$

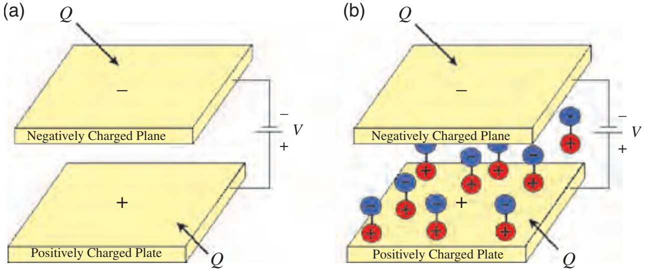

Figure 16. Schematic of a basic capacitor: (a) the dielectric between the two parallel plates is air or a vacuum, and (b) the dielectric is a material that is capable of being polarized.

where V is the applied voltage between the two plates and C is a proportionality constant defined as capacitance. The capacitance can be determined from the expression

$$C = \varepsilon(A/d) \tag{8}$$

where ε is the permittivity of the dielectric material, A is the area of one plate, and d is the distance between the two plates. The permittivity of a material describes the ability of a material to become polarized by an electric field. In Figure 16, there are two capacitors, one with air as the dielectric and the other with a material capable of being polarized as the dielectric. The polarized material has a permittivity that can be found from the relationship

$$\varepsilon = \varepsilon_0 + (P/\xi) \tag{9}$$

where ε_0 is the permittivity of a vacuum (8.85×10^{-12} F/m), P is the polarization (vector sum of all dipoles per unit volume), and ξ is the electric field strength. The relative permittivity ($\varepsilon/\varepsilon_0$) is defined as the dielectric constant (κ). Interlayer materials with lower dielectric constants allow smaller device dimensions due to the less interconnect delay and faster on/off component switching.

Low-K materials are typically designed by the addition of fluorine to the material or by the introduction of pores to lower the density. To date, various new low-k dielectrics have been extensively studied, including fluorine-doped SiO_2 ($K \sim 3.4$), hydrogen silsesquiosxane (e.g., XLK^{TM}) ($K \sim 3.0$–3.2), spin-on organic polymer (e.g., Silk^{TM}), spin-on inorganic dielectrics (e.g., Nanoglass^{TM}) ($K \sim 2.5$–3.0), chemical vapor deposition carbon-doped SiO_2 (e.g., Black Diamond^{TM}) (K$\sim$ 2.5–3.0), fluropolymer, and surfactant templated SiO_2 ($K \sim 1.8$–2.3). Among these materials, spin-on SiO_2-based dielectrics are among the most promising candidates because they are easily manufactured and integrated into circuits. However, traditional SiO_2-based spin-on low-K films (e.g., Nanoglass^{TM}) usually contain a highly disordered, often fractal, gel network with large pores (over 10 nm) and a broad pore size distribution. These network characteristics dramatically deteriorate the dielectric and mechanical performance. In contrast, surfactant templated SiO_2 dielectrics are much better candidates for low-K applications because of unimodal 2–10 nm pore size distribution, controllable porosity, a complete connectivity of the silica framework, absence of drying stress, and controllable pore surface chemistry.

Mesoporous methylsilsesquioxane (MSSQ) (Fig. 17) and methyl modified mesoporous silica are currently being examined by the semiconductor industry as low-K interlayers. These materials are prepared using TEOS and the appropriate methyl precursors through the surfactant templating approach described earlier. The incorporation of methyl groups provides thin film hydrophobicity, prevents water adsorption, and thus decreases the dielectric constant (water has a dielectric constant of 80). Controlled porosity and pore surface chemistry of MSSQ systems provide low dielectric constants between 2.1 and 2.8 [164, 165]. Table 4 describes many of the procedures used to create ordered structures from these silsesquioxanes.

Figure 17. Ideal structure of methlysilsesquioxane [165].

3.3.2. Incorporation of Organics during Co-assembly Process

Surfactants are such useful tools for the synthesis of nanocomposites because they partition hydrophobic molecules inside micelles or liquid crystal assemblies, resulting in spatially ordered arrangements of these components [167]. Organic components can be added to the initial solution during the sol–gel co-assembly process so that they are incorporated within the newly formed inorganic structure. This incorporation technique can form mesoporous materials with larger pore sizes or nanocomposites based on the addition of swelling agents or monomers.

Swelling Agents The original work used liquid crystal templates swollen by 1,3,5-trimethylbenzene to increase the mesoporous silica pore size from 2 to 10 nm [39, 47, 168]. Organic compounds such as alkanes [169] or alkylamines [170, 171] partition into the liquid crystal template during sol–gel co-assembly to enlarge the final mesoporous material pore size. In fact, it is possible to synthesize an inorganic matrix with pores on the order of 10 to 25 nm instead of the typical 3 nm pore size [172, 173]. Even preformed silica can have its pore size expanded with swelling agents such as amines [170]. The pore structures in these expanded materials generally become less ordered as the pore size is increased [170]. These systems are useful for the production of high surface area catalysts with large pore sizes as well as drug delivery devices for the controlled release of incorporated organic components. Current research is creating materials with larger pores and ordered structures so that catalysts can be synthesized to react with larger organic chemicals [169, 172, 174].

Functional Component Incorporation Because functional components like dyes have different properties based on the specific surfactant microenvironment, these materials can be used for optical applications or to probe and gain fundamental understanding of the self-assembly process, solute partitioning [175, 176], solute reactivity [177], surfactant packing [178], and internal inorganic structure [179, 180]. Solute molecules can either associate near the inorganic interface, within the mostly hydrophilic chain sections, or be solubilized inside the hydrophobic cores [175]. Small amounts of chlorophyll demonstrate a similar ultraviolet (UV) adsorption pattern to that of chlorophyll in solution, indicating solubilization within the cores for this particular solute [176]. Reactive molecules incorporated within mesoporous materials demonstrate that the reactivity

Table 4. Mesoporous materials synthesized with bridged silisesquioxanes.

Bridging group	Technique	Characteristics	Ref.
Methyl	co-assemble MSSQ with star-shaped hydroxy-terminated poly(ϵ-caprolactone), star PMMA, and triblock copolymer poly(ethylene oxide-b-propylene oxide-b-ethylene oxide) respectively; surfactant removed by heating to 400 °C	dielectric constants of 2.1, 2.2, and 1.5 respectively	[164–166]
Benzene, ferrocene, acetylene, thiophene, and bithiophene	bridged silisesquioxane precursors synthesized and hydrolyzed in the presence of surfactant to produce periodic mesoporous materials	benzene and thiophene materials had highest degree order	[155]
Alkyl, vinyl, and benzene	evaporation-induced self-assembly produced thin films and particles	highly ordered materials had increased mechanical properties and decreased dielectric constant	[13]
Ethane and ethylene	bridged silisesquioxane precursors synthesized and hydrolyzed in the presence of CTAB to produce periodic mesoporous materials with uniform organic bridge incorporation	produced highly ordered mesophases with a wormlike morphology and surface areas as high as 1200 m^2/g; no damage to pore structure during bromination or organic compound adsorption	[156, 157]
Benzene	precipitation in basic aqueous solutions containing alkyltrimethylammonium surfactant	material had hexagonal mesopores with crystal-like pore walls that were composed of alternating benzene and silica layers	[158]

and transport of organic guest into the surrounding media depends on the surfactant and salt concentrations [177]. As shown in Figure 18, amphiphilic fluorescent metal complexes inside an inorganic framework provide information on the surfactant microenvironment [178]. Specific binding of the dye to inorganic structural sites with different coordination numbers allows inorganic material information to be obtained [179].

Monomer and Polymer Incorporation Simultaneous polymer/inorganic nanocomposite formation utilizes the same principles mentioned for mesoporous materials with expanded pore sizes. Hydrophobic components like monomers and certain catalytic complexes can be incorporated into the hydrophobic cores of micelles or liquid crystalline structures, resulting in spatially ordered arrangements of hydrophobic and hydrophilic sol–gel components. Surfactant and inorganic components co-assemble and form organic/inorganic nanocomposites containing ordered surfactant lyotropic liquid crystalline phases (see Fig. 14). Subsequent polymerization of the incorporated monomer such as methacrylate [21, 181] with incorporated catalyst or by thermal or photoinitiation results in an interpenetrating polymer/inorganic nanocomposite that still contains the structure directing surfactant. For example, Sellinger et al. spatially positioned hydrophobic monomers within micellar cores during EISA and subsequently polymerized these monomers to synthesize lamellar silica/polymer nanocomposite thin films that mimic the structure of nacre (see Fig. 19) [21]. These synthetic nacre films exhibit increased indentation hardness and resistance to wear [21, 182]. Thus, the monomer incorporation method utilizes surfactant-assisted co-assembly of inorganic clusters, surfactants, and organic monomers to spatially separate and organize these components into hexagonal, cubic, lamellar, or other precise arrangements.

Co-assembly using liquid crystal arrays swollen with preformed polymers such as styrene [184] or polyaniline [185] allows improved material properties. For example, conductive polyaniline incorporated into mesoporous metal oxides has increased conductivity at higher temperatures because of increased thermal stability and favorable interactions with the structural matrix [185].

3.3.3. Surfactant/Inorganic Nanocomposites

After sol–gel co-assembly synthesis of mesostructured materials such as MCM-41, the surfactant is often removed to allow for incorporation of more robust materials. However, these inorganic/surfactant composites have several beneficial properties and uses in their own right such as the study of the self-assembly process and of the internal environment after material formation, improvement in material properties such as stability [186], novel catalysts with good selectivity, isolation of magnetic components, improved separation membranes, and improved optical characteristics for optical applications. The synthesis of inorganic/surfactant nanocomposites involves the same synthetic methods used for mesoporous inorganic materials except that there is no surfactant removal step [187–189].

Normal Surfactants Although surfactants are typically not mechanically robust, their incorporation within a mesoporous material allows synergistic improvement of properties. In terms of structure, a silica framework creates a protected environment for the surfactant molecules allowing them to become fully rigid at high pressures [178].

The surfactant can actually improve silica properties allowing structural elasticity, reduction of cracks [190], reversible deformations, and bulk moduli similar to solid silica [178]. Also, further improvement in material properties should be possible when stronger interactions between surfactant and the inorganic surface are employed. However, these materials are still not stable enough for structural applications.

Other interesting inorganic/surfactant materials with interesting magnetic, catalytic, separation, and optical properties have been synthesized. Magnetic materials such as iron oxide separated by layers of surfactant demonstrate novel properties such as superantiferromagnetic domain structures [191]. Silica/surfactant nanocomposites also have high catalytic activity due to active surface sites such as $=SiO^-$ on the silica [192] or electrostatically bonded surfactant [176]. Surfactants can coat specially designed inorganic solids via adsorption allowing effective interactions with components from different solvents. In this way, a membrane composed of a hydrophobic conductive backbone surrounded by surfactant can filter water-soluble, electroactive compounds [193]. Also, the surfactant can improve optical properties based on controlled nanophase separations [175, 194]. In fact, optically transparent films are possible by leaving the surfactant inside the composite [194].

Functional Surfactant Functional surfactants are molecules that combine the amphiphilic properties of surfactants with specially designed functional groups such as polymerizable groups or optically active centers. Since these surfactants are synthesized prior to the self-assembly process, there is a high degree of synthetic freedom concerning both the choice of functional center and its location on the amphiphile. Polymerizable surfactants lock in the mesostructure after the co-assembly process by cross-linking between amphiphiles. These surfactants contain reactive groups such as diacetylene [18], methacrylate [195], or ethylene [196]. Advantages of polymerizable surfactants in the synthesis of nanocomposites are that:

1. By changing the amphiphile structure, the extent of polymerization reaction can be varied and the mesostructure can be altered between cubic, hexagonal, and lamellar [18].
2. A simple one-pot synthesis allows the inorganic and organic phases to cross-link and polymerize simultaneously or sequentially.
3. Mesostructure is often maintained during amphiphile polymerization [115, 197].
4. The synthesis can proceed without additional monomers that may change the packing efficiency and structure of the liquid crystal.
5. There is no need for postsynthesis surfactant removal that may damage or alter the structure and interactions between phases.
6. The combination of inorganic structure and cross-linking between amphiphiles strengthens and improves the overall material properties such as material strength and optical transparency [18, 21].
7. Functional and conjugate polymers such as poly(diacetylene) are aligned and protected within the inorganic framework allowing for the possibility of controlled electrical conduction and chromatic reversibility [18].

Optically active centers can be placed in different locations on a synthesized co-polymer surfactant to control the fluorescent properties based on its specific chemical environment [198]. As Figure 20 shows, an amphiphile containing a photoelectronic endgroup produces an interesting inorganic/surfactant composite in an economically more efficient way than pore wall modification or surfactant adhesion [176]. Applications for this type of material include nonlinear optical switching materials and photoconversion materials [176]. A limitation of this technique is that the active center must have specific interactions with itself and with the solvent system in order to self-assemble.

Another interesting example is the formation of mesostructured chromatic organic/inorganic nanocomposites using functional nonionic surfactants that contain diacetylene moieties within the hydrophobic portion of the molecules and hydrophilic oligmeric ethylene oxide headgroups [18]. As shown in Figure 21, co-assembly of silica and the surfactants leads to the formation of nanocomposites with lamellar, cubic, or hexagonal mesostructures. Topochemical polymerization of the diacetylene groups by UV irradiation results in conjugated nanocomposites that show responsive color changes to the external stimuli (e.g., temperature, chemical, or mechanical stimuli). Figure 21 shows the chromatic transformation of the conjugated polydiacetylene/silica nanocomposite thin films due to the temperature stimuli. While as coated nanocomposite thin films are transparent and colorless, UV irradiation through a mask polymerizes the diacetylene moieties within the irradiated area and creates a blue thin film containing a colorless pattern. The

Lu et al., *Nature*, 410, 913 (2001). © 2001, Nature.

blue color is due to adsorption of the red portion of visible light by the conjugated diacetylene. When subject to a high temperature (e.g., 60 °C) for seconds, the blue film transforms its color to red due to the configuration change of the polymer and other factors. Such chromatic transformation may be reversible. Further polymerization leads to the red film with a blue color pattern. These chromatic properties are useful for sensing applications [18].

4. OTHER ASSEMBLY TECHNIQUES

Other nanocomposite synthesis methods include infiltration [199, 200], surface modification, layer-by-layer assembly [201], intercalation, and nanoparticle array approaches. The infiltration approach incorporates and polymerizes monomers within a preformed inorganic mesoporous template that has been prepared by a surfactant templating technique or by self-assembly of colloidal silica particles [200, 202, 203]. The layer-by-layer method utilizes electrostatic interactions of positive and negative components to fabricate layer structures one layer at a time. Intercalation involves the filling of voids between swollen layers of material. Finally, nanoparticles can be assembled into periodic arrays with a variety of methods such as precipitation or particle confinement.

4.1. Infiltration Methods

Infiltration involves introduction and subsequent polymerization of organic monomers within the pore channels of a preformed inorganic matrix such as mesoporous silica or microporous zeolites. Typically, monomers are introduced via liquid infiltration, vapor adsorption and condensation, or sublimation methods. After reaction, polymers are confined within the rigid inorganic environment. An alternate method involves the infiltration of preformed polymers into the mesopores [204].

Polymerization mechanisms such as free radical polymerization, addition reaction, metal catalytic reaction, and ring-opening polymerization react incorporated monomers and synthesize a large variety of nanocomposites. Reaction within the mesoporous material dramatically affects kinetics and the final polymer structures (e.g., molecular weight and molecular weight distribution). However, free radical polymerization may be initiated with UV irradiation or conventional initiators [205–210]. Because of constrained molecular motions and isolation of the active species in the confined pore channel environment, the propagation reaction may be accelerated at elevated temperatures while the termination reaction may slow down, resulting in higher molecular weight polymers. For example, Ng and co-workers utilized radical polymerization of methyl methacrylate within mesoporous silica using benzoyl peroxide as initiator to obtain poly(methyl methacrylate) (PMMA) with a much higher molecular weight than formed under identical solution conditions [210]. However, polyaniline and polyacrylonitrile formed within the nanocomposites through an oxidation and free-radical polymerization mechanism respectively demonstrate considerably lower molecular weights than those of bulk material. The limited growth may be due to the constrained diffusion of monomers into the pore channels [205–208].

4.1.1. Infiltration of Mesoporous Silica

Silica is the most commonly used host material because of its ease of synthesis and the wide variety of possible pore morphologies, sizes, and surface functionalization. Early work, which infiltrated aniline into mesoporous silica via vapor phase condensation followed by polymerization, formed silica/polyaniline nanocomposites [205]. Other silica based nanocomposites contain polymers such as poly(2-methoxy-5-(2'-ethyl-hexyloxy)-1,4-phenylene vinylene) (MEH-PPV), acrylonitrile, polystyrene, PMMA, poly(phenol-formaldehyde), polyethylene, and ferrocenlysilanes. Poly(phenol-formaldehyde)/silica nanocomposites have been prepared by addition reaction of phenol and formaldehyde within the mesostructured pore channels (see Fig. 22) [211]. Silica/polyethylene nanocomposites were prepared by a metal-catalyzed atom transfer radical polymerization (see Fig. 23) [212]. Ring-opening polymerization of silicaferrocenophane inside MCM-41 was reported to form poly(ferrocenylsilane)/silica nanocomposites (see Fig. 24) [120, 213]. Table 5 summarizes polymer/mesoporous silica nanocomposites prepared by the infiltration methods. The unique features and application of these nanocomposites are also included in Table 5.

4.1.2. Infiltration of Zeolites

Zeolites have also been used as hosts for inorganic/polymer nanocomposite synthesis. Historically, the most extensively studied system involves radical polymerization of polar vinyl monomers within zeolites [214]. Other conducting polymer systems include poly(methylacetylene) [215], polypyrrole [216] and polyaniline [217]. A problem with zeolite infiltration is that the host pore sizes are often too small for effective and continuous polymerization.

4.2. Layer-by-Layer Sequential Assembly

Layer-by-layer sequential assembly utilizes electrostatic interactions between anionic and cationic components to fabricate heterostructure ultrathin films. This is conducted

by sequentially dipping a substrate into a polyanion and polycation solution (see Fig. 25) [218]. The initial step involves cleaning and charging the underlying substrate in preparation for the initial layer. This substrate is then

dipped into a solution containing soluble but oppositely charged components such as polyelectrolytes or charged quantum dots [22] that attach themselves to the substrate based on Coulombic attraction [219]. The newly formed layer is then exposed to an oppositely charged electrolyte that adsorbs based on favorable interactions. The relative rates of component adsorption and desorption must be controlled to obtain a homogeneous film with the correct thickness [220]. Film thickness depends mostly on the number of deposited layers (each layer is approximately 1.5 nm thick) [221]. The synthetic freedom inherent in this method allows a wide variety of surfaces to be used as the original substrate, and an extensive list of possible materials for incorporation includes metal or ceramic nanoparticles, polyelectrolytes, conjugated polymers, supramolecules, dyes, fullerenes, biological molecules such as proteins, and electrostatically active components such as chromophores [201, 218, 222–226].

Precise control of material properties is possible through variation of the sequence and composition of the deposited layers. For instance, anionic polymer and ceramic nanoparticles can be layered with polycations in a variety of patterns such as ABAB, ABAC, and other patterns. The possibility of incorporating different layers allows precise tuning of the index of refraction at different depths. Also, electrostatic interactions from the underlying molecules may align dipoles or polymers and result in polarized components and material anisotropy without the use of electric fields [218]. Such unique multilayer films are used for microelectronics, X-ray optics, chemical and biological sensors, and light emitting devices [201, 221–223].

Table 5. Polymer/silicate nanocomposites formed by infiltration.

Guest	Host	Technique	Characteristics	Ref.
Polyaniline	aluminosilicate MCM-41	aniline vapor adsorption in pores followed by oxidative peroxydisulfate initiation	confined, conductive polymer filaments confined in MCM-41	[205–207]
Acrylonitrile, graphite	MCM-41	acrylonitrile vapor adsorption in pores; polymerization initiated by aqueous addition of $K_2S_2O_8$ and $NaHSO_3$ radical initiators; polymer pyrolysis yields graphite filaments	confined graphite has microwave conductivity 10 times higher than bulk pyrolyzed polyacrylonitrile	[208]
Polyethylene	titanocene-mounted mesoporous silica	extrusion polymerization of ethylene on titanocene/methyl-alumoxane active centers	crystalline linear polyethylene nanofibers obtained	[212]
Polymethyl-methacrylate, polystyrene, or polyvinylacetate	MCM-41	monomer vapor adsorption in pores followed by benzoyl peroxide and UV light initiation	Pore size depends on the glass transition temperature of polyvinylacetate in MCM-41	[209, 210]
MEH-PPV	surface modified, hexagonal mesoporous silica	hydrophobic silica pores infiltrated with MEH-PPV polymer by thermal cycling	control of energy transfer in semiconducting polymers	[204]
Poly(phenol-formaldehyde)	MCM-41	phenol and formaldehyde vapor adsorption in pores followed by acid-catalyzed polymerization; removal of mesoporous host yielded polymer fibers	20–30 Å polymer fibers possible	[211]
Poly(ferrocenlysilane), Fe clusters	MCM-41	sublimation of ferrocenophane $Fe(C_5H_4)_2SiMe_2$ into pores followed by pyrolysis	forms magnetic composite	[120, 213]

The greatest disadvantage in the electrostatic self-assembly method is that a great number of time-consuming steps are required to form a material with any considerable thickness. However, this method has an advantage over Langmuir–Blodgett film formation in that the layer-by-layer technique forms films that are held together with electrostatic attraction as opposed to van der Waals forces [221].

4.3. Intercalation

A slight variation of electostatic self-assembly involves intercalation. The galleries (voids) between lamella (sheets) of material such as clay, graphite, transition metal chalcogenide, or mica can easily be intercalated (filled) with a wide variety of organic guest molecules based on interactions between sheet and filler, as shown in Figure 26 [35, 109]. Because each sheet of host material is weakly bound to neighboring sheets, the sheets are swollen by the addition of reactive chemicals, change in pH, or introduction of polar chemicals. Ionic clays are often used because of the ease and flexibility in forming ion pairs [227]. Before modification or swelling, most layered host materials are negatively charged and they are balanced with removable cations like Na^+ or Ca^{2+} [228]. For instance, potassium, which balances the overall negative charge in mica, can be replaced with other cations or polycations in an ion exchange reaction [35]. This involves exposing a cleaned suspension of clay or graphite to a suitable chemical that swells and replaces the ions [229]. Often, large cations such as tetraalkylammonium ions form pillars between the sheets, thereby creating high surface area materials for catalytic applications [230]. Also, monomers often adsorb onto the surface and react to

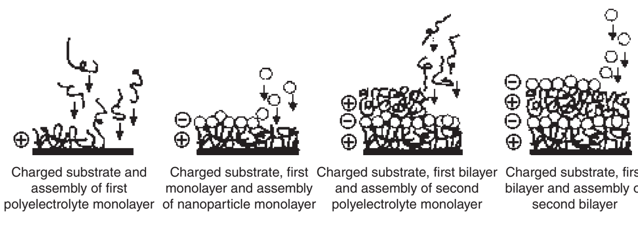

Figure 25. Layer by layer self-assembly of cationic poylelectrolyte and anionic nanoparticles. Reprinted with permission from [218], K. C. Cooper et al., *Proc SPIE*, 4512, 93 (2001). © 2001, SPIE—The International Society for Optical Engineering.

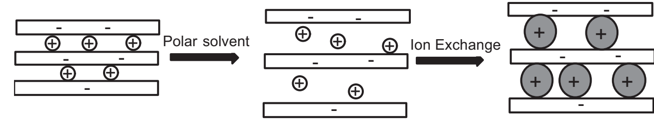

Figure 26. Intercalation of negatively charged lamellar structure by polar swelling and ion exchange of interstitial cations with new cationic species such as polymers.

form a nanocomposite [22]. For example, the incorporation of conducting polymers produces materials with interesting anisotropic conductivity [231, 232].

The advantage of intercalation is that atoms, ions, or particles are reversibly included and sometimes aligned within a structurally preserved microreactor at room temperature [228, 233]. Once again, interactions between phases such as electrostatic and hydrogen bonding self-assemble the material together [227]. Large surface area allows a high degree of interaction between phases thereby strengthening the material to avoid disintegration [228].

4.4. Nanoparticle Self-Assembly

Nanoparticles or colloids self-assemble into arrays with different properties based on interparticle interactions and particle shape, size, and size distribution [10, 109]. A colloid refers any particle with a size from 10 Å to 1 μm and a colloidal solution refers to a stable suspension of these particles [22, 53]. When packed together to form an array, spherical nanoparticles can fill a 3D space in a myriad of different conformations. However, if there is a driving force (such as pressure) for the spheres to occupy as much of the space as possible and become close-packed [234], there are only two acceptable configurations: cubic-close-packed (ccp) and hexagonally close-packed (hcp) (Fig. 27) [235]. Often ccp is preferentially formed instead of hcp because of the inherent entropic difference between the two structures [236]. In this way, 74% of the space is filled by spheres that each touch 12 nearest neighbors and leave void spaces that form a sphere-void interpenetrating network (meaning each phase continuously extends across the system in all directions). For other shapes, such as surfactant-coated nanoparticles that contain facets or flat edges, specific binding of like-sized faces preferentially occurs because of the favorable formation of a

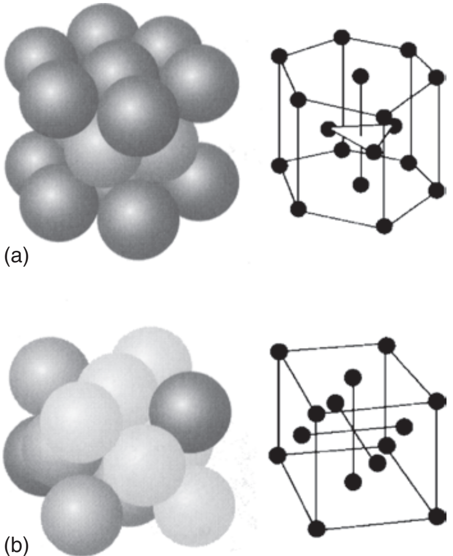

Figure 27. Schematic showing (a) hexagonally closed packed and (b) cubic close packed arrays. Reprinted with permission from [239], D. F. Shriver et al., "Inorganic Chemistry." Freeman, New York, 1999. © 1999, Freeman.

surfactant bilayer between particles [237]. It is also possible to use cubic particles to form cubic superlattices [238].

Colloidal particles can be used to form ordered, 3D arrays of nanoparticles by gravity- or centrifuge-induced particle sedimentation, filtration, solvent evaporation, confinement within membranes or gels, use of high pressures, and application of electrical or magnetic fields [5, 6, 22, 240–248]. The best routes for assembling colloids into these colloidal crystals involve particle sedimentation, intraparticle electrostatic interactions, or physical confinement to control stacking and periodicity [5].

Sedimentation usually involves ordering spherical colloids into 3D arrays by controlling particle density, size, and rate of sedimentation [5]. The sedimentation velocity, which normally depends on particle size and density, controls the order of the colloidal crystal based on kinetics and the ability of particles to find energy minima. Larger and denser particles such as amorphous silica (density = 2.19 g/cm^3) naturally have a greater tendency to precipitate but do not always form ordered matrices because the sedimentation velocity is too high. Particles must be larger than approximately 0.7 μm so that gravity forces them into minimum energy sites. Otherwise these objects would take extended periods of time to settle because the particles remain in solution [245]. Using sedimentation, silica has been produced in ccp lattices that mimic natural, iridescent opal [249]. Although this process can form lattices as large as 1 cm^3, sedimentation is problematic because the process can take months or years to complete for submicrometer particles and there is a lack of control over crystallinity, morphology, and the number of layers produced [5]. Techniques such as simultaneous solvent evaporation [250] and applied electric field [251] have attempted to compensate for the shortcomings inherent in sedimentation. Solvent evaporation forms ordered arrays of nanoparticles as long as the evaporation rate is slow enough [6, 22]. Slow evaporation allows particle diffusion into the proper crystalline position while fast evaporation produces disordered arrangements. Electrophoretic assisted particle settling involves the application of an electric field to control the settling velocity of the spheres [245, 251]. Variation of the electric field on charged particles alters the settling velocity and forms ordered arrays in reasonable time frames. Often, colloids are ordered into periodic arrays due to physical confinement within mircofluidic flow, overlapping sound waves (sonication), or a structural scaffold [5, 235].

After the ordered array has been formed, the interstitial regions of the nanoparticle array can be infiltrated with inorganic or organic precursors to form a nanocomposite [234, 248] (also see the infiltration section). Sometimes, the simple introduction of a precursor solution to the dried solid will allow sufficient infiltration. However, it is often necessary use several freezing, evacuation, and then heating (or freeze–pump–thaw) cycles to remove gasses in the solid and those dissolved in the monomer [234]. Nanoparticle thin films and membranes are used for filtration, solar cells, batteries, photoconductive material, photo- or electroluminescent materials, liquid and gaseous chemical sensors, electrodes, and absorbents [11].

5. INORGANIC PARTICLE/POLYMER NANOCOMPOSITES

Inorganic particle/polymer nanocomposites often utilize ceramic or metallic colloids with diameters in the 1–100 nm range that are coated or associated with a polymer layer or continuous polymer phase. A layer of polymeric material surrounding inorganic nanoparticles creates interesting aggregates, allows new packing morphologies, and introduces novel confinement properties to the system. This incorporation can result from covalent attachment of the polymers to the particle, encapsulation of the particles by polymerization or melting, or by simultaneous reaction of the organic and inorganic precursors to form the nanocomposite [224]. Nanoparticles within a polymer matrix allow the nanocomposites to have many advantageous properties such as increased toughness due to the mobility of the nanoparticles [23]. Another attractive characteristic of these nanocomposites is transparency of the composite material [252]. Synthesizing nanoparticles with defined particle size and morphology is an important first synthetic step in the creation of these nanocomposites.

5.1. Synthesis of Nanoparticles

5.1.1. Background

Many methods have been developed to synthesize a large variety of monodispersed nanoparticles [4, 253] by high-energy ball milling [32], chemical, or other approaches. The chemical approach usually involves reacting organic or inorganic precursors inside confined environments created by dendrimers [254], membrane pores [5, 199, 255], close-packed lattices of spherical colloids [241, 256], carbon arrays [257], gels [1], zeolites [258], lipid vesicles [259], Langmuir–Blodgett films, colloids [260], microemulsions [261–265], liquid crystals [3], and polymers [22, 266]. Other synthesis approaches like combustion flame [267, 268], plasma [269, 270], laser abilation, chemical vapor deposition [271], spray pyrolysis [272], electrospray [273], plasma spray [274, 275], aerosol [112, 276–278], and sonolysis [11, 279] have also been used to produce various nanoparticles.

Nanoparticles are commonly composed of calcium carbonate [280]; Ag [281], Fe/Cu alloys [282], and other metals [266, 283]; SiO_2 [78, 142, 284], TiO_2 [285, 286], ZnO [264, 278], WO_3, Nb_2O_5, and other metal oxides [287]; II–VI chalcogenides such as CdS, CdSe [11], CdZnS [288], and CdMnS [289]; and AgCl [290], Ag_2Se [291], and other metal salts. A current trend in nanoparticle synthesis is toward polymers [5, 292], such as monodispersed latex nanoparticles [293], and nanocomposites [261, 262, 294, 295]. These nanocomposites are often layered particles containing a core of one material surrounded by a shell of another. For example, it is possible to polymerize monomers around metal or inorganic particle exteriors to form a core–shell morphology [293, 294, 296, 297]. Besides spherical particles, other shapes such as cubes [238], rectangular prisms [298], nanotubes [32], nanofibers [199], cylinders [299], disks, discoids, and toroids [111] have been synthesized [299].

5.1.2. Nanoparticle Synthesized Using Self-Assembled Surfactants

Microemulsions, formed by thermodynamically stable oil in water micelles or reverse micelles of water droplets stabilized in oil with surfactant, have been used as nanoreactors with controlled size and chemical environment for the formation of nanoparticles (Fig. 28) [58, 299]. Because microemulsions may consist of monodispersed spherical, cylindrical, or sponge-like structures with features on the order of 10 nm [58], they can template the synthesis of a wide variety of particle shapes [1, 4, 10, 293, 299]. However, it is often crucial to synthesize nanoparticles with a narrow size distribution as well as controlled interfacial properties, morphology, shape, and composition [32]. These factors greatly affect the final material properties because they exert a great influence over the ability of particles to form periodic arrays. Particle size is generally several times larger than the original micelle size, and it is controlled by the concentrations of surfactant and aqueous reactants and the ratio between them [299]. Morphology of the nanoparticle can be tailored using specially designed surfactants [1].

The basic particle formation steps include particle nucleation either inside the micelle [220] or in the bulk solution; particle growth which involves continuous surfactant stabilization, micellular growth, and surfactant and reactant diffusion though the reaction media; and termination of particle growth. For either inorganic or organic nanoparticles, a short burst of particle nucleation is achieved by the sudden mixing of inorganic precursors [299] or by the introduction of an initiator [5]. The high interfacial surfactant surface areas (100 m^2/ml) form favorable sites for particle nucleation [220] and exert control over the growth [58, 300], internal structure, and surface properties of the nanoparticles [10]. After particle nucleation has occurred, particles grow via precursor addition to the particle surface or by agglomeration of adjacent particles. Reaction kinetics and particle size depend on the type and amount of surfactant used, temperature, particle environment, precursor concentration and transport limitations [301]. As this reaction progresses, surfactant diffuses to and stabilizes [301] particle-containing micelles at the expense of surfactant in solution and empty micelles. Because agglomeration yields particle polydispersity and unstability in the colloid system toward premature precipitation [32, 218], this growth mechanism is usually suppressed by control of overall particle concentration in solution and by the proper choice of surfactant stabilization agents. Particle growth is terminated by depletion of reactant, surface attachment, steric influences, or precipitation. Naturally, a limited amount of reactant

Table 6. Silica particle/polymer nanocomposites.

Polymer	Technique	Characteristics	Ref.
Polyaniline (PANI)	aqueous phase polymerization in the presence of 35 nm diameter colloidal silica particles	electrical conductivity of 37.8 wt% PANI /silica nanocomposite (6.1×10^{-2} S cm^{-1}) higher than pure PANI (10^{-1} S cm^{-1})	[306]
Polypyrrole	polymerization in the presence of ultrafine silica sols	precipitating polymer coats and attaches particles together in a 100 to 300 nm raspberry morphology	[295]
4-vinylpyridine (4VP), acrylates, and styrene	interaction between basic 4VP and acidic silica or methacrylate-capped poly(ethylene glycol) produced favorable interactions between phases; composite formed by co-polymerization of 4VP with methyl methacrylate, butyl acrylate, or styrene	functional surfactant and co-polymers stabilize colloidal particles and allows a higher silica content; highly transparent, free-standing nanocomposite films were synthesized; nanocomposite particles and films have a "currant-bun" morphology	[307–310]
Poly(methyl methacrylate)	graft or adsorb initiator onto the silica surface followed by polymerization of the MMA monomer	core-shell silica/PMMA latex nanocomposites have raspberry-like morphology	[261, 262, 311, 312]
Polystyrene	polymer nanoparticles and modified silica colloids aggregate due to specific chemical (amine-aldehyde) or biological (avidin-biotin) interactions	core-shell nanocomposite materials consist of a silica core and a polystyrene shell	[296]
	silica particles are functionalized with DPE initiator and activated using *n*-BuLi; styrene anionic polymerization initiated by particle surface in benzene solution	living polymerization of styrene	[316]
Poly(methyl acrylate)	graft 3-(trimethoxysilyl)propyl methacrylate groups onto the surface of the silica colloids; system self-assembles into hexagonally ordered when more monomer added; monomer and surface groups polymerize	aggregated arrangements have significantly improved mechanical properties	[313–315]

present will stop particle growth [293]. Attachment of polymers on the nanoparticle surface caps the growing particle and prevents further growth by steric and electrostatic repulsions [220]. Sometimes specific binding agents like thiols are added to the solution to terminate cluster growth by attaching to the growing particle surface [220]. Steric termination occurs when there is no more surfactant in solution available to diffuse to the micelle and increase its size further [299]. It is important to note material density for colloidal synthesis techniques because gravity is a driving force for particle precipitation. Typical inorganic densities range from 2 to 4 g/cm^3 for materials such as silica (2 g/cm^3), cadmium sulfide (2.5 g/cm^3), calcite (2.6 g/cm^3), zinc oxide (4 g/cm^3), zinc sulfide (4 g/cm^3), and titanium oxide (4 g/cm^3) [22].

5.2. Nanoparticle Composite Synthesis Techniques

For nanoparticles, the sequential composite synthesis approach creates a second phase in a system of either preformed nanoparticles or polymer. Preformed nanoparticles form inorganic/polymer nanocomposites by either (1) directly polymerizing monomers in the presence of an inorganic sol or (2) modifying the surface of the silica particles with functional groups followed by polymerization of the monomers. Sometimes, polymerization preferentially forms a precipitated polymer shell on the individual particles based on specific interactions between the silica surface

Table 7. Metal particle/polymer nanocomposites

Metal/polymer	Technique	Characteristics	Ref.
Platinum/polystyrene	polymerize styrene in a system containing dispersed, 1–2 nm platinum nanoparticles, dialkyldithiophosphates, and octadecanethiol	platinum colloids self-assemble within the polystyrene matrix into structures such as hollow shell; morphology depends mainly0n on the chain lengths of the dialkyldithiophosphates	[317]
Silver/block copolymer PS-PVP	Silver nanoparticles initially adsorb onto PVP domains exposed on a preformed block copolymer film surface; after annealing of the films, nanoparticles migrate to the PS block of the polymer due to the lower surface energy of PS over PVP	Nanoparticles incorporate into the polymer film	[319]
Silver/HDPE	add HDPE to films of dodecanethiol modified silver nanoparticles in ρ-xylene; heated, homogeneous mixture drawn on a hot shoe at 120 °C	pearl-necklace-type arrays of spherical particles aligned in the drawing direction	[318]
Gold/ultrahigh molecular-weight polyethylene	mix ultrahigh-molecular-weight polyethylene with hot solution of dodecanethiol-modified gold nanoparticles; solid state drawing forms nanocomposite.	uniaxially oriented arrays of gold nanoparticles	[320]
Gold or copper/ poly(amidoamine) dendrimers	*in-situ* reduction of $HAuCl_4$ or copper precursor in the presence of poly(amidoamine) dendrimers	synthesize 2–3 nm gold or copper colloids encapsulated and stabilized by dendrimers	[321, 323]
Gold/poly(4-vinylpyridine) and poly(acrylic acid)	modify gold nanoparticles with pyridine, carboxyl, and flavin functional groups; poly(4-vinylpyridine) and poly(acrylic acid) then added in a layer by layer approach based on hydrogen bond interactions	core/shell gold nanoparticles containing organic multilayer shells	[322]

and the new shell [10]. In other cases, functional or reactive surface groups are required to increase the adhesion between phases or form a covalent link between polymer and particles. Hydrogen bonding, electrostatic interactions, and covalent bonds are required for close association of the phases.

Preformed polymer acts as a structure-directing agent during the formation of organic/inorganic nanocomposites. Often, reduction of a metal salt or metal alkoxide precursor in the presence of a self-assembled polymer system forms particles inside the swollen polymer matrices [22, 266, 302]. Initially, an inorganic precursor solution diffuses and swells a cross-linked polymer. Subsequent sol–gel [95, 303] or ion exchange [220] reactions form metal oxide or metal particles within the polymer matrix. The properties of the polymer and particle interfaces are important because they will determine the amount of adhesion between phases. Polymer/particle interactions can be increased by covalently linking the two phases or by using hybrid polymers with metal containing units [304]. This technique is very useful for mechanical reinforcement of elastic polymer because the nanoparticles act as cross-linking points in the polymer [266]. Also, if metal nanoparticles are combined with conducting polymer, an increase in conductivity is experienced [305].

Other methods for the formation of an organic/inorganic nanoparticle system include infiltration and adsorption of the metal nanoparticles into the polymer system, layer-by-layer self-assembly of nanoparticles and polyelectrolytes, melting of the polymer around the metal nanoparticles, and simultaneous polymer and inorganic particle formation. In the last case, inorganic precursors, monomer, and coupling agents can be combined and reacted simultaneously to give an interpenetrating network [22]. Different morphologies are obtained depending on relative speeds of either formative reaction.

5.2.1. Silica Nanoparticle/Polymer

Silica is one of the most commonly used colloids for the syntheses of inorganic particle/organic nanocomposites. Polymer systems such as polyaniline [306], polypyrrole [295], 4-vinylpyridine [307–310], PMMA [261, 262, 311, 312], poly(methacrylate) [313–315], and polystyrene [296, 316] have all been combined with silica nanoparticles to create a wide variety of nanocomposites. Table 6 summarizes several different silica particle/polymer nanocomposites, the experimental methods that synthesized them, and novel characteristics.

These techniques create composites with different morphologies such as core–shell, raspberry, and currant-bun. As shown in Figure 29, hexagonally ordered arrays of silica

Table 8. Other particle/polymer nanocomposites

Particle/polymer	Technique	Characteristics	Ref.
Titanium dioxide/PSS	layer-by layer self-assembly of cationic titania nanoparticles and anionic PSS polymers on *N*-2(2-aminoethyl)-3-aminopropane modified substrate	nanocomposite film of multiple alternating titania and PSS layers	[244]
Iron oxyhydroxide/κ-carrageenan and cellulose sulfate	κ-carrageenan and cellulose sulfate polysaccharides stabilize surface of 10 nm iron oxyhydroxide nanoparticles	core/shell iron oxyhydroxide nanoparticles with tight crosslinked polysaccharide layer	[324]
Iron oxide/PMMA	thin layer of silica coats magnetic iron oxide rods as small as 70 nm; addition of nanoparticles to PMMA solution and subsequent solvent evaporation results in solid film	nanoparticle agglomeration avoided by magnetizing iron oxide; final nanocomposite thin film composed of iron oxide/PMMA	[325]
Cadmium sulfide (CdS)/PMMA	CdS nanoparticles coated with silica and modified with initiator, polymerize methyl methacrylate around nanoparticles or disperse them in a PMMA matrix; cast nanocomposites into films	nanocomposite films retain the photoluminescence of the CdS quantum dots and show homogeneous nanoparticle dispersal	[297]
CdS/MMA and DDAMA	CdS nanoparticles synthesized inside didecyldimethylammonium methacrylate (DDAMA) reverse micelles in MMA organic phase; after nanoparticle formation, MMA and DDAMA were polymerized	transparent solid polymer matrix containing nonaggregated 20–80 nm CdS nanoparticles was formed	[326]
CdS or ferrite/AOT and isooctane organogel	CdS or ferrite nanoparticles stabilized in sodium bis(2-ethylhexyl) sulfosuccinate (AOT)/isooctane reverse micelle system; addition of ρ-chlorophenol formed organogel	phenols self-assemble into stacked fibers encapsulate CdS or superparamagnetic ferrite nanopaticles	[327]
Clay/styrene	Silica gel and clay nanoparticles functionalized with 1,1-diphenylethylene (DPE) initiator; modified surfaces initiate styrene polymerization; other monomers such as isoprene added later	living anion polymerization demonstrated by formation of styrene-isoprene block copolymer/nanoparticle composite material; bound polymer has low molecular weight and high molecular weight distribution	[294]

particles in polymer have also been demonstrated. Possible applications of these silica particle/polymer nanocomposites include biological assays, abrasive-resistant coatings, and catalyst supports.

5.2.2. Metal Nanoparticle/Polymer

Metal nanoparticles have many unique properties due to quantum size effects and a large number of unsaturated surface atoms. Dispersing these metal nanoparticles into a polymeric matrix provides processability, solubility, and stability [266]. Platinum [317], silver [318, 319], gold [320–322], and copper(323) nanoparticles have been incorporated into polystyrene, poly(2-vinylpyridine), poly(styrene-*b*-2-vinyl pyridine) (PS-PVP), high density polyethylene (HDPE), ultra-high-molecular-weight polyethylene, polypyrrole, poly(amidoamine) dendrimer, and poly(acrylic acid) polymer systems. Table 7 summarizes experimental methods and characteristics of several different metal particle/polymer nanocomposites.

5.2.3. Other Inorganic Nanoparticles/Polymer

Besides silica and metal colloids, nanoparticles such as titanium dioxide [244], iron oxide [324, 325], cadmium sulfide [297, 326, 327], and clay [294] have all been incorporated into polymer systems such as poly(sodium 4-styrenesolfonate), polysaccharides such as κ-carrageenan and cellulose sulfate, PMMA, polystyrene, and sodium bis(2-ethylhexyl) sulfosuccinate (AOT)/isooctane organogels.

The applications of these nanocomposites range from photovoltaics, catalysts, sensors, and reverse osmosis membranes [286]. One of the major applications of semiconductor nanoparticle/polymer composites is in the field of photovoltaics. Akimov et al. first demonstrated synthesis of conductive polymer nanocomposites containing 2 to 50 nm CdS nanocrystals, which were prepared in poly(vinyl alcohol), poly(vinylpyridine), and photographic gelatin. The composites exhibited good photosensitivity and photoconductivity. Also, nonlinear optical properties of quantum confined semiconductors are enhanced in polymer systems. Table 8 summarizes experimental methods and characteristics of these particle/polymer nanocomposites.

GLOSSARY

Amphiphile Molecule containing hydrophilic and hydrophobic regions.

Association colloid Micelle, emulsion, or liquid crystalline aggregation of amphiphiles based on weak interactions such as solvophobic interactions.

Biomimetic Observing natural solutions, extracting the essential operational features, and applying them to new engineered systems.

Bridged silsesquioxane Organometallic compound composed of two alkoxysilance groups covalently bound together by an organic ligand.

Capillary pressure Pressure differential inside a partially filled pore with a narrow diameter due to a curved interface. This pressure difference causes structural collapse in some mesoporous materials during solvent removal.

Critical micelle concentration (CMC) Minimum surfactant concentration for the formation of micelles.

Cubic mesostructure Bicontinuous two phase system that can be formed from the close packing of spheres into a periodic array.

Dip coating Immersion and controlled removal of a solid from a solution to cover the surface with a uniform layer.

Evaporation induced self-assembly (EISA) Evaporation of a solution containing inorganic precursors and surfactant allows co-assembly of inorganic clusters with liquid crystalline phases in the synthesis of a mesostructured inorganic material.

Gel A solution containing a solute that has formed a large, entangled network so that the system viscosity is greatly increased.

Hexagonal mesostructure A two phase system that consists of long parallel cylinders packed together in an array so that each cylinder is surrounded by six neighboring cylinders with the other phase in the voids.

Intercalation The infiltration and filling of a lamellar material with a guest species.

Lamellar mesostructure Consists of parallel alternating layers of two phases.

Layer-by-layer sequential assembly Alternating layers of anionic and cationic species are deposited on a substrate by a cycle of dip-coats in the corresponding solvents.

Liquid crystal Aligned molecular array that can flow and deform like a liquid.

Lyotropic liquid crystal An aligned molecular array that contains multiple components such as aligned surfactant in water.

Mesopore Pore with a 1 to 50 nm pore size.

Mesoscale Size scale of 1 to 50 nm.

Mesostructure Arrangement of material parts on the 1 to 50 nm size scale.

Micelle Roughly spherical pseudophase in an aqueous solution consisting of an aggregation of amphiphilic molecules that align to expose hydrophobic tails inward and hydrophilic heads outward.

Microemulsion Two phase system composed of small, 100 nm or less, droplets stabilized in a solvent by a surfactant.

Nanocomposite Material composed of two or more components that have at least one dimension between 1 to 100 nm.

Reverse micelle Roughly spherical pseudophase in an organic solution consisting of an aggregation of amphiphilic molecules that align to expose hydrophilic heads inward and hydrophobic tails outward.

Self-assembly Spontaneous organization of components into periodic or hierarchical structures based on noncovalent interactions.

Sol A solution containing dissolved metal oxide clusters such as colloidal particles.

Sol–gel process Useful synthesis route for metal oxide solids reacting soluble metal alkoxide or metal halide precursors to form metal oxide sol clusters in solution. Cluster size increases until a gel is created.

Solution precipitation For sol–gel systems, particles are formed from a solution of inorganic precursors and surfactant that interact and self-assemble together.

Supramolecule Atoms or molecules that aggregate together based on a series of noncovalent interactions to create a specific structure.

Surfactant A specific class of amphiphile often used as detergents and soaps. Usually a surfactant contains a hydrophobic head and a dydrophilic tail.

1. INTRODUCTION

Porphyrin [1–3] is a macrocyclic molecule consisting of four pyrrolic rings bridged by four methine groups. The pyrrolic and methine CH groups are usually called as β- and *meso*-positions, respectively, as shown in Figure 1A, and various substituents can be introduced into these positions in place of hydrogen atoms. Porphyrin is a highly conjugated 18π-electron system, which causes decrease of the HOMO-LUMO bandgap energy, and therefore it is interesting in view of visible-light absorbing and emitting materials as desirable for electronic and photonic applications as well as artificial photosynthetic building units. Another characteristic feature is that porphyrin can incorporate various metal ions in the central core surrounded by four pyrrolic nitrogen atoms to provide metalloporphyrins (Fig. 1A). In many cases, the central metal ion such as zinc, magnesium, iron, cobalt, and so on, can accept fifth or sixth ligation (denoted as L_n in Fig. 1B) at axial position(s) to allow construction of desirable supramolecular porphyrin architectures. The porphyrin skeleton is found in biological systems [4–15] such as chlorophylls or hemes, which play important roles such as light-harvesting, energy and electron transfer to convert the light energy to chemical energy in photosynthesis [4–12], transport and activation of molecular oxygen, and catalysis of oxidation-reduction reactions [13–15].

Supramolecular chemistry [16–20] has developed rapidly since the 1980s. Even complicated structures aiming novel functions have been successfully assembled from simple molecular units by the use of noncovalent interactions such as hydrogen bonding, ligand-to-metal coordination, hydrophobic, van der Waals interactions, and π-π interaction between aromatic molecules as well. These organization processes involving thermodynamic equilibria between simple units are called "self-assembly" or "self-organization." The most important feature of the supramolecular approach is that small and simple subunits, which can be easily synthesized and do not show any significant functions by themselves, are automatically assembled to produce macromolecular systems exhibiting desirable functions. The self-assembly plays important roles especially in biological systems and finds so many relevant examples. Most typically, complementary hydrogen bond formation is the source of gene replication operating in DNA/RNA molecular recognitions [13–15]. Three-dimensional structure formation of polypeptides is based on their hydrogen-bonded α-helices and β-sheets [13–15]. Hydrophobic interactions are the fundamental driving force of substrate binding to the active site of many enzymes. Nature also uses coordination bonds as the strongest among intermolecular forces. In the photosynthesis system, chlorophylls are fixed to membrane proteins by coordination of histidine-imidazole to their central metal to construct the light-harvesting antenna complex [4–6] and the special pair of chlorophylls [7–12].

Self-assembly allows the construction of complicated large molecular system even in the porphyrin chemistry, in which sometimes it may be difficult to synthesize such a complex system by using covalent linking. In the 1990s, many ideas of self-assembled porphyrins [20] have been proposed to construct mostly the light-harvesting antenna complex and the special pair models of photosynthesis and to reveal the relationship between their structures and biological roles. Although supramolecular approaches to synthesize such porphyrin systems contain noncovalent interactions as described, most systems have employed the idea of

ligand coordination to the outer metal or central metal of porphyrin. Hydrogen-bonded porphyrin assemblies have also been reported. Since porphyrins are usually dissolved in nonpolar solvent such as chloroform, benzene, toluene, and so on, linking of porphyrins by hydrogen bond is more effective and stable in such nonpolar media. Other interactions such as hydrophobic, van der Waals, and π-π interactions cannot be main driving forces, but may be used secondarily or cooperatively to stabilize the porphyrin assembly.

Recent attentions are also directed to nanometer-scale molecular fabrication to push forward the idea of molecular electronic and photonic devices [21–25]. Since miniaturization of LSI built by metal-oxide-semiconductor (MOS) is close to its absolute limit [24], a molecular-scale device, which may provide high-performance computers [25], is now definitely required. One of the important characteristics required for the material to build up such a device may be highly conductive organic molecules such as carbon nanotube [26, 27] and multi-porphyrin array [28]. Since the size of porphyrin molecule is around 1 nm square with a 0.34-nm height, nanometer-scaled architecture of technological requirements can be built up by assembling less than 100 porphyrin building blocks.

At the same time, third-order nonlinear optical (NLO) materials have also attracted attention because of potential utilities for photonic applications such as ultrafast optical switching and modulations [29–31]. Various types of organic compounds have so far been designed and synthesized to obtain materials with large third-order susceptibilities $\chi^{(3)}$ [32–34]. Porphyrins are one of the most promising candidates for such NLO materials in the view not only of the largest class of the values attained hitherto, but of allowance of versatile structural modifications and variations of central metal ions to design ideal properties [28, 35–43].

As mentioned earlier, porphyrin has great potential to demonstrate excellent properties as optical and electronic materials toward the goal of single-molecular electronics. Efficient conversion of light energy to chemical or electric energy is certainly the most fascinating scientific challenge to be met in this century. Porphyrin as a functional mimic of chlorophyll should play central roles in elucidating the mechanism of photosynthesis as well. In order to achieve these targets, large numbers of chemists have been trying to obtain multi-porphyrin systems based on covalent and supramolecular approaches. In this review, we will introduce methodologies and recent advances of self-assembled multi-porphyrin systems by the use of noncovalent interactions, especially focused on the self-assembly by introducing unique substituents to the central porphyrin matrix in the past few years.

2. SELF-ORGANIZATION VIA COORDINATION TO OUTER METAL IONS

Coordination of *meso*-substituted ligand, such as pyridyl, 2,2′-bipyridyl, phenanthroline, terpyridyl, crown ethers, and 8-hydroxyquinoline (oxine) as shown in Figure 2, to outer metal ion(s), other than the central metal ion of porphyrin, has been employed in many literatures to construct supramolecular architectures. Geometries of porphyrins in the resulting supramolecule are determined by the coordination structure around the outer metal ion and can be controlled by adjusting the coordination direction of ligand to the metal ion. In general, the ligand used in constructing a supramolecular porphyrin array contains electron-donating atom such as oxygen, nitrogen, and sometimes sulfur, whose affinity to the metal ion is determined by the rule of hard soft acid base relation. In this section, self-assembly by complexation of the ligand of porphyrin substituent with outer metal ions will be introduced.

2.1. Coordination of Pyridyl Ligand to Outer Metal Ion

Supramolecular formation by pyridyl coordination to Pd(II) or Pt(II) has been extensively developed by Fujita [44–46] to varieties of macrocyclic compounds. Porphyrin-containing pyridines behaved similarly and multi-porphyrin macrocycles were reported along the line. One of the examples using *meso*-substituted 4-pyridyl porphyrin is shown in Figure 3 [47]. When porphyrin **1** having two 4-pyridyl substituents at 5,10-positions reacted with one equivalent of *cis*-$Pd(NCPh)_2Cl_2$, the pyridyl ligand coordinated to Pd ion by exchanging PhNC to form dimer **2**. On the other hand, reaction with *trans*-$Pd(NCPh)_2Cl_2$ provided tetrameric square **3** with four porphyrins at the corners of the square. Since Pd(II) or Pt(II) prefers square planar arrangement with four ligands and PhNC is more labile than chloride

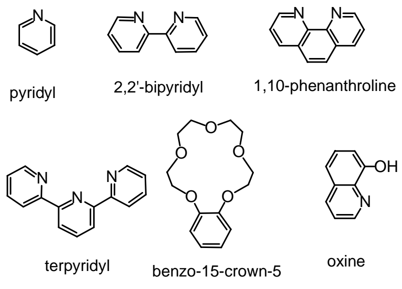

Figure 2. Structures of ligand for coordination to outer metal ion.

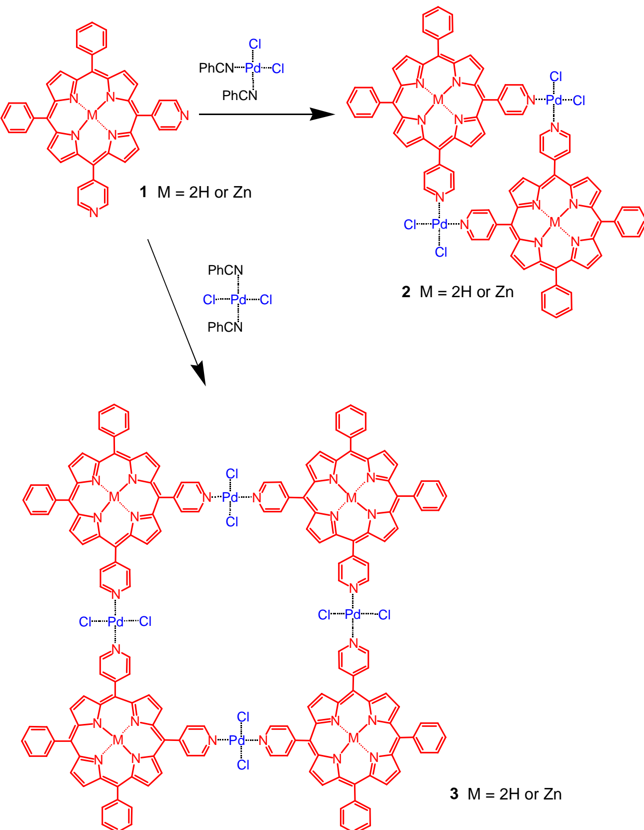

Figure 3. Formation of porphyrin dimer **2** and tetramer **3** from 5,10-bis(4-pyridyl)porphyrin **1** with *cis*-$Pd(NCPh)_2Cl_2$ and *trans*-$Pd(NCPh)_2Cl_2$, respectively [47].

or pyridyl, *cis*- and *trans*-$Pd(NCPh)_2Cl_2$ afford two respective supramolecules, **2** and **3**. Contrary to **3**, 5,15-bis(4-pyridyl)porphyrin **4**, in which two pyridyls are placed at two facing *meso*-positions, gave different square organization **5**, as shown in Figure 4 [47]. In this case, porphyrins and *cis*-$PdCl_2$ parts occupy the edges and the corners, respectively.

The square made by 5,15-bis(4-pyridyl)porphyrinatozinc and $Re(CO)_3Cl$ incorporated a 5,10,15,20-tetrakis(4-pyridyl)porphyrin (H_2TPyP) by axial coordinations of four pyridyl groups to central zinc ions (Fig. 5) [48]. Formation of pentamer **6** was confirmed by fluorescence measurement with an association constant of 4×10^7 M^{-1} in CH_2Cl_2. The fluorescence quenching of zincporphyrin moiety (~90%) and the growth of H_2TPyP fluorescence with the corresponding time scale were observed, indicating the occurrence of energy transfer from zinc moiety to H_2TPyP within the complex **6**.

The square porphyrin nonamer **7** (Fig. 6) was synthesized from a mixture of *trans*-$[PdCl_2(NCPh)_2]$ and three different porphyrins: one central X-shaped unit (TPyP), four T-shaped units on the edges (tris(4-pyridyl)porphyrin), and four L-shaped units at the corners (5,10-bis(4-pyridyl)porphyrin) [49]. The nonameric array was formed in 90% yield at room temperature in a dilute chloroform solution (total concentration below 10 mM). The nonameric structure was supported by ^1H NMR titration, light-scattering measurement with a radius of 5 ± 7 nm,

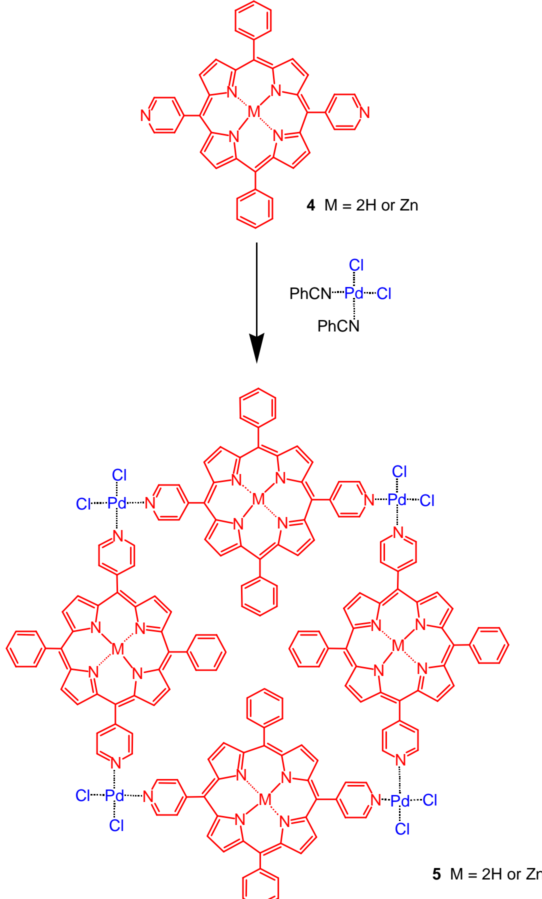

Figure 4. Formation of porphyrin tetramer **5** from 5,15-bis(4-pyridyl)-porphyrin **4** with *cis*-$Pd(NCPh)_2Cl_2$ [47].

size-exclusion chromatography, vapor phase osmometry (VPO), and electrospray mass (ESI-MS) spectra with tricationic and tetracationic molecular ions. The fluorescence of a stoichiometric mixture of porphyrins without Pd(II) was quenched over 90% by titration of Pd(II) salt to form the nonamer **7**. The fluorescence lifetime measurements also showed that the average lifetime of a mixture of porphyrins without Pd(II) in toluene was 12 ns and that of the array was less than 1 ns due to the heavy-atom effect. Porphyrin tapes **8** and **9** (Fig. 7) were also synthesized in a similar manner to that of **7**. Addition of two equivalents of O-shaped mono(4-pyridyl)porphyrin to one equivalent of I-shaped 5,15-bis(4-pyridyl)porphyrin two equivalents of *trans*-[$PdCl_2(NCPh)_2$] gave Pa(II)-assisted tape **8** as a mixture of dimer, trimer, and tetramer. Tape **9** was made by mixing X-, L-shaped porphyrins, and *trans*-[$PtCl_2(NCPh)_2$] (2:2:6) for 4–5 days at 40 °C as a mixture of trimer, tetramer, and pentamer. These formations were confirmed by ESI-MS measurement. There have been some reports on supramolecular porphyrins with similar dimeric or tetrameric structure by using 4-pyridyl ligand and different metal sources, such as Pd(dppp), Pt(dppp), Ru(II), and so on, where dppp denotes diphenylphosphine [50–58].

Recently, Fujita et al. reported porphyrin trimer **11** constructed by complexation of 5,10,15,20-tetrakis(3-pyridyl)porphyrin **10** with Pd(II) ion (Fig. 8) [59]. The reaction of porphyrin **10** with two equivalents of [$Pd(en)(ONO_2)_2$] in H_2O/MeCN at 80 °C for one day allowed a purple solution of **11**, which was isolated in a 96% yield by adding acetone to the solution. The trimeric structure maintained in a MeCN/H_2O (1:1) solution as

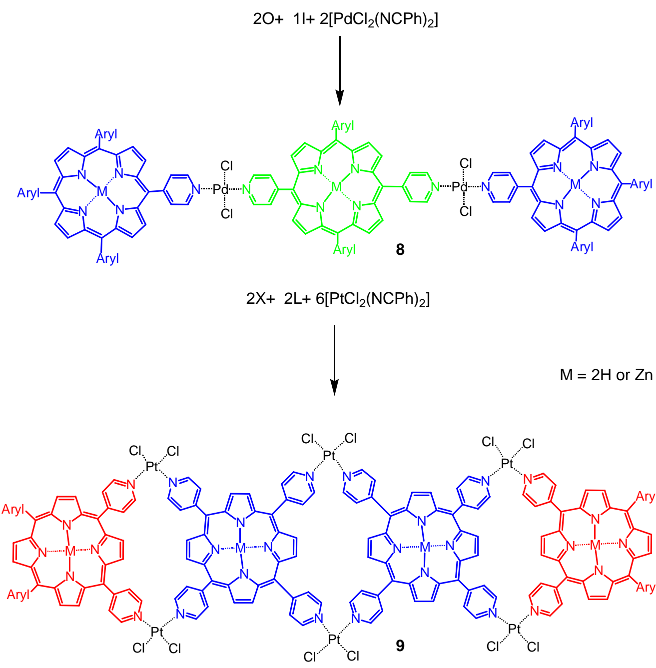

Figure 7. Self-assembled porphyrin tapes **8** and **9** [49].

supported by the evidences of ^{1}H NMR and cold spray-ionization mass (CSI-MS) spectroscopic analyses. One NO_3^- ion could not be exchanged by PF_6^- ion even with a large excess of NH_4PF_6 and was trapped by the trimer supported by mass spectroscopic data. X-ray crystallography revealed the prism structure of **11**, in which six Pd(II) ions were located at apical positions of the prism. The axial-to-equatorial flipping of two Py-Pd-Py sites at a diagonal position allowed the formation of a cavity, which would be expected to incorporate a small organic guest such as pyrene in an aqueous solution.

2.2. Chelate Formation to Give Stable Assembly

Chelating complexations of 2,2′-bipyridyl, 1,10-phenanthrolinyl, and terpyridyl with specific metal ions provide a method to fix the porphyrin geometry with large stability constants. The orientation of the porphyrins directly linked by the chelating substituent should also depend on the geometry around the chelated metal ion. Porphyrin dimer **12**, in which two porphyrin units were connected directly to symmetrical 4,4′-positions of the bipyridyl group, was designed and synthesized (Fig. 9) [60].

Figure 8. Porphyrin trimer **11** given from 5,10,15,20-tris(3-pyridyl)porphyrin **10** and *cis*-$Pd(en)(ONO_2)_2$ (en = ethylenediamine) [59].

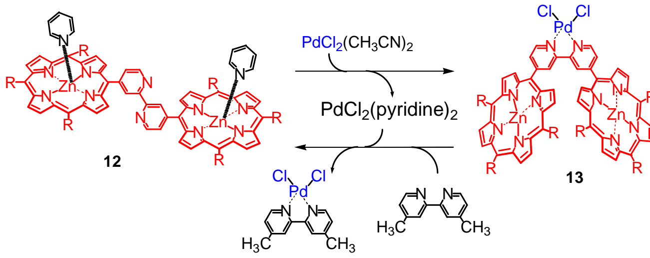

Figure 9. Reversible conversion between **12** and **13** by Pd(II) ion and 2,2′-bipyridyl [60].

Addition of 2.2 eq. of $PdCl_2$ to **12** converted the freely rotating bipyridyl conformation to the cofacial one giving rise to the formation of bisporphyrin **13** with a dihedral angle of 60°. The subsequent addition of 4,4′-dimethyl-2,2′-bipyridine regenerated back the initial bisporphyrin **12**. Spatial geometries of two porphyrins could be regulated by reversible complexation of the bipyridyl part with $PdCl_2$.

Porphyrin dimer bridged by 1,10-phenanthroline moiety has been synthesized and reacted with Cu(I) ion to afford self-assembled porphyrin tetramer **14** with a tetrahedral geometry (Fig. 10) [61]. Different metal ions Zn(II) and Au(III) were inserted into two porphyrin centers of the dimer to modulate the electron transfer rate, where, first, one Au(III) ion was inserted to synthesize mono-metalated complex and then Zn(II) ion was inserted. The electron transfer reaction was investigated by transient absorption measurement by using 30-ps pulse laser in dimethylformamide (DMF). The rate of forward electron transfer reaction from Zn(II) porphyrin to Au(III) porphyrin in tetrameric complex **14** was accelerated by 18 times relative to the uncomplexed dimer due to the operation of superexchange mechanism of the intervening Cu(I) phenanthroline complex.

2,9-Diphenyl-1,10-phenanthroline derivatives have also been used to synthesize catenanes and rotaxanes [16–19]. Compound **19**, the first report of porphyrin-containing catenane, is represented in Figure 11 [62]. The first ring **17**

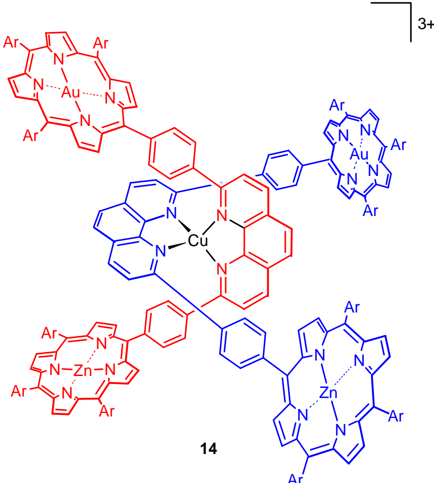

Figure 10. Porphyrin tetramer **14** by coordination of 1,10-phenanthroline, which bridges Zn(II)-porphyrinyl and Au(III)-porphyrinyl to Cu(I) ion [61].

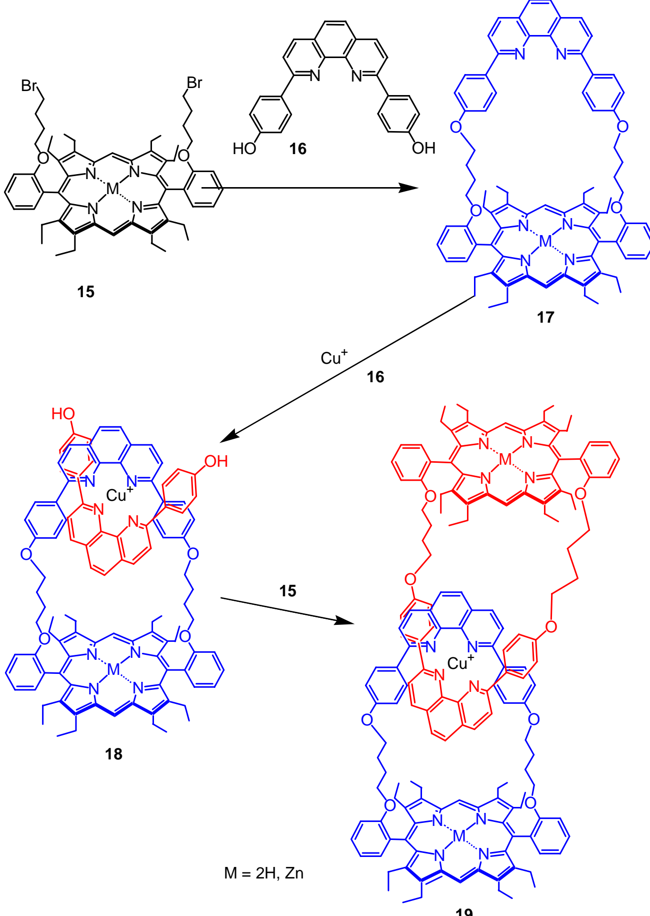

Figure 11. Synthetic route of catenane **19** [62].

was incorporated with the second open chain component **16** through the coordination interaction with Cu(I) ion to give a precursor **18**. Further coupling of compounds **18** with **15** gave rise to the formation of catenane **19** in a 33% yield, in which two porphyrin units were interlocked by complexation of two phenanthroline moieties with Cu(I) ion. The absorption spectra of **19** resembled those of monomeric species and indicated the absence of electronic interactions between two porphyrins of a large spatial separation distance.

Sauvage has reported several asymmetric catenanes and rotaxanes containing a Zn(II) porphyrin unit as an electron donor and an Au(III) porphyrin unit as an electron acceptor to investigate long-range electron transfer reactions. Catenane **24**, which consisted of Au(III) porphyrin and Zn(II) porphyrin units, was synthesized according to a strategy similar to the case of **19** with modified connection units, as shown in Figure 12 [63]. In this case, too, no significant interaction between two porphyrins was observed in the absorption spectrum, but highly efficient fluorescence quenching of Zn(II) porphyrin was observed. This quenching may be responsible for the electron transfer from Zn(II) porphyrin to Au(III) porphyrin, although the detailed mechanism has not been reported yet.

The construction of rotaxane-like threaded porphyrin assembly **26** was reported by the same author and co-workers (Fig. 13) [64]. Reaction of an equimolar mixture of

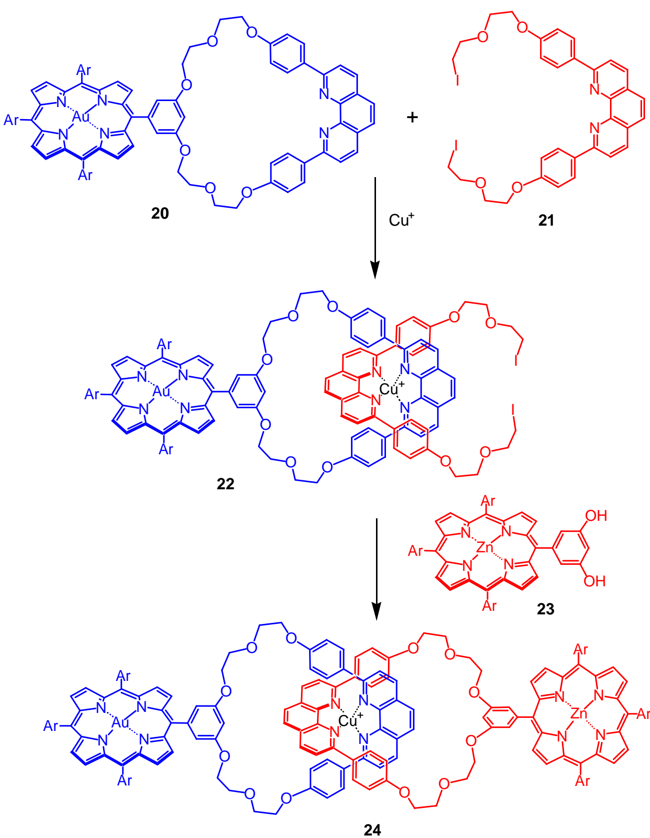

Figure 12. Synthetic route of catenane **24** [63].

Zn(II) and Au(III) porphyrins each bearing phenanthroline moiety in a closed ring, and string component **25** gave a mixture of three porphyrin species: Zn(II)-Zn(II), Au(III)-Au(III), and Zn(II)-Au(III) in the ratio of 2:1:1. The desirable hetero-complex Zn(II)-Au(III) **26** was separated by chromatography and no scrambling was observed in a solution at room temperature. When threading was undertaken for Zn(II) porphyrins, the isolated yields of Zn(II)-Zn(II) complex depended much on the structure of the connecting group L of **25**, being 6, 60, and 95% for trimethylene, 1,2-phenylene, and 4,4′-diphenylene ether, respectively.

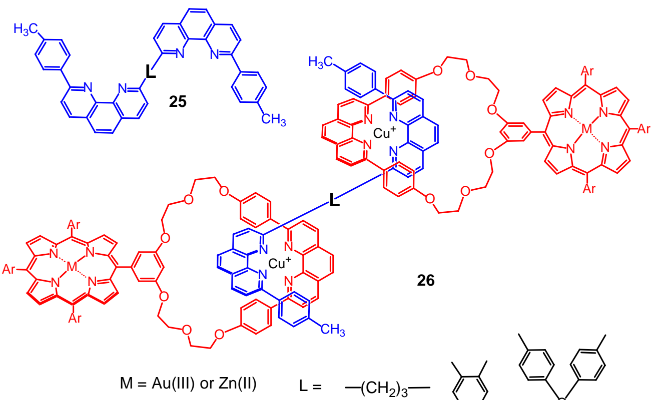

Figure 13. Structure of threaded self-assembly **26** [64].

The same author and co-workers have reported a real rotaxane **29** without fixation by metal coordination [65]. Two terminals of the string were connected to Zn(II) porphyrins, and a ring part, which was threaded by the string, had a Au(III) porphyrin, as shown in Figure 14. Reaction of precursor **27** having two formyl groups with benzaldehyde and dipyrromethane followed by zinc insertion gave **28**. Finally, **29** was obtained by the removal of Cu(I) ion from **28** by treatment with KCN. Steady-state fluorescence measurement showed strong fluorescence quenching of the Zn(II) porphyrin units by 87% indicating electron transfer from the Zn(II) porphyrin to the Au(III) porphyrin. The electron transfer rate was estimated roughly as 3.5×10^9 s^{-1}, which was slower than that of the covalently linked Au(III) and Zn(II) bisporphyrin by 2,9-diphenyl-1,10-phenanthroline [66] due to the lack of covalent bonds between porphyrins in **29**. In the case of rotaxane **30**, the distance between donor porphyrins and acceptor porphyrins was controlled by reversible complexation and decomplexation reactions at the phenanthroline units to generate long distance and close proximity orientations, as shown in Figure 15 [67]. The conformation of **30** was confirmed by observation of NOE between H5,6 and Hpy showing a proximity between the rear part of the 1,10-phenanthroline moiety bridging two zinc porphyrin units and the gold porphyrin

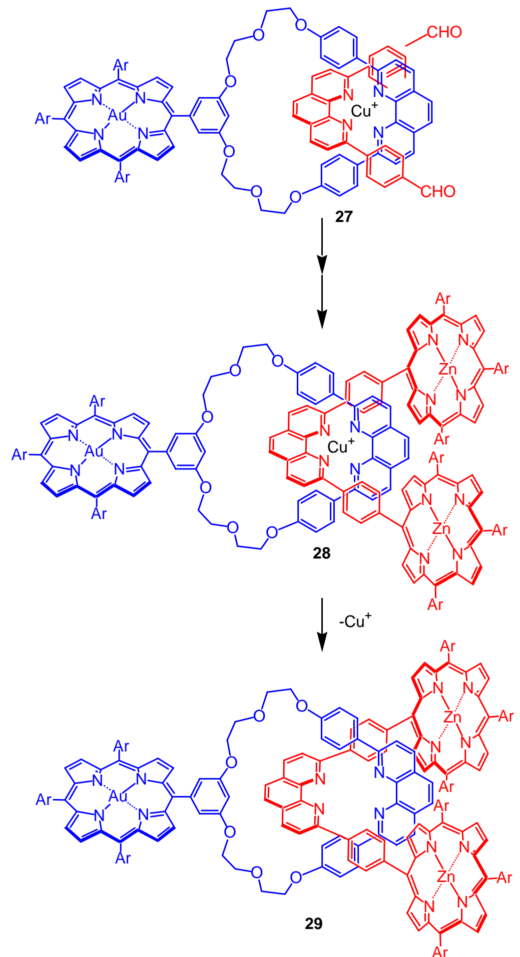

Figure 14. Synthetic route of rotaxane **29** [65].

Figure 16. Linear porphyrin dimers assembled by chelate complexation of 1,10-phenanthrolines (**32** [68] and **33** [69]) and terpyridyl (**34** [70–72]) to outer metal ions.

part. On the other hand, NOE measurement of the decomplexed form **31** demonstrated the close proximity between Hm and Ho as well as Hpy and Ho′, as drawn schematically in Figure 15. The estimated center-to-center (Au-Zn) separations from space-filling model are 19 and 7 Å for **30** and **31,** respectively. Interesting photochemical properties are expected, but not examined.

Another example of self-assembly via chelate formation of 1,10-phenanthroline with tetrahedral Cu(I) or Zn(II) ion to form porphyrin dimers (**32, 33**) is shown in Figure 16. [68, 69]. In the case of **33** [69], different metal ions such as Ni(II), Cu(I/II), Zn(II), and Li(I) were employed for the complexation of the phenanthroline moiety and the changes in the absorption spectra were measured. The binding of all metal ions at the phenanthrolinic moiety perturbed the porphyrin π-system to give red-shifts of all peaks. The Soret and Q bands[1] of Zn(II) and Cu(II) porphyrins were much more sensitive to the variation of external metal ion bindings than those of free base porphyrin.

Terpyridyl is a tridentate ligand with three pyridyl nitrogens and is known to form very stable complexes with hexacoordinating metal ions such as Ru(II). Sauvage has reported three chromophore complexes containing free base or Zn(II) porphyrin, bis(terpyridine)Ru(II), and Au(III) porphyrin parts [70–72]. For example, triad **34** was synthesized to investigate the energy transfer reaction between them, as shown in Figure 16 [72]. Terpyridyl substituted Au(III) porphyrin, por(Au), was reacted with $RuCl_3$ followed by $AgBF_4$ to form a por(Au)-Ru(terpyridyl)Cl_2 complex, which was then converted to **34** by the reaction with terpyridyl substituted free base porphyrin. Photoinduced energy transfer from the triplet state of Au(III) porphyrin moiety to the free base porphyrin site (center-to-center distance of 2.1 nm) occurred in glassy media at low temperature with a rate constant of 2.5×10^7 s^{-1}. The energy transfer process was mediated by the central bis(terpyridine)Ru(II) moiety and was explained by an electron exchange mechanism [72].

Oxine is known to form extremely stable, neutral, and rigid complexes with metal ions such as Al(III) and Ga(III) by assembling three oxine units [73, 74]. *Meso*-oxinyl substituted porphyrin **35** afforded rigid gallium-tris(oxinyl) complex **37**, where three porphyrins were arranged like a pinwheel, as shown in Figure 17 [75, 76]. This minimum unit was extended to a dendritic structure **38** by introducing another oxinyl group at the facing *meso*-position. Molecular mechanics calculation (with MM+ force field) deduced the most stable configuration and the center-to-center separation distances between two porphyrin units were estimated as 15, 17 and 18.5 Å for *a-b*, *b-c*, and *c-a*, respectively. Interestingly, the fluorescence intensities of both Ga complexes **37** and **38** were increased significantly compared with each monomeric component **35** and **36**. At the same time, [efficient excitation energy transfer was found to occur between component porphyrins through the analysis of fluorescence anisotropy decay]. A rapid component of ~10 ps appearing in the complex was assigned to the energy transfer time constant between the nearest porphyrin units in the complex according to the Förster model. The excitation energy was stored in the complex by repeating energy transfer roughly

[1] Porphyrin has electronic transitions absorbing the visible light. The relatively weak transition from ground state (S_0) to first excited state (S_1), which corresponds to the HOMO-LUMO bandgap, and the strong one from S_0 to second excited state (S_2), are called Q band and Soret band (or B band), respectively (see Fig. 20).

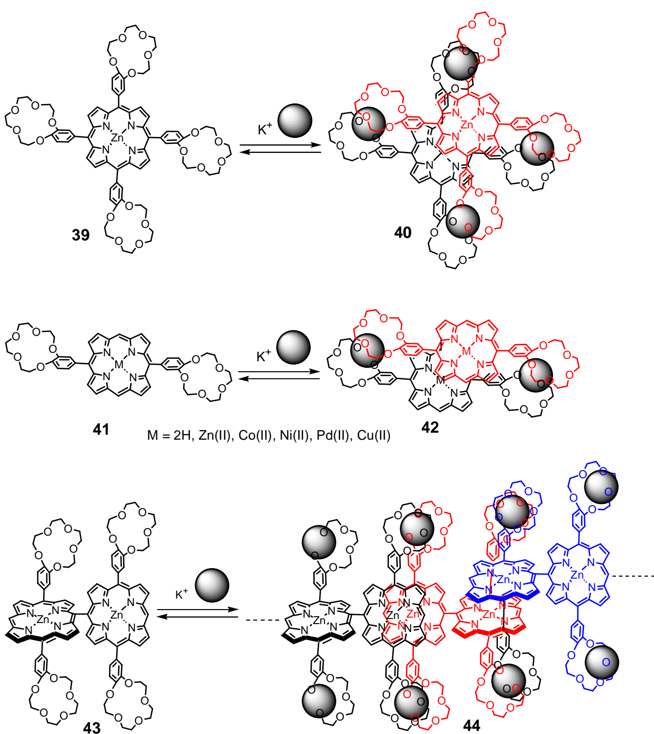

Figure 18. Self-assembled face-to-face porphyrin dimers (**40** [77] and **42** [80]) and polymer (**44** [80, 81]) by complexation of benzo-15-crown-5 substituents with potassium ion.

~800 times within its lifetime of 8.6 ns among three porphyrins in the complex **37** behaving like a photosynthetic light-harvesting complex [75].

2.3. Self-Assembly by Metal Ions with Crown Ether

5,10,15,20-Tetrakis(benzo-15-crown-5)porphyrinatozinc **39** forms face-to-face porphyrin dimer **40** by sandwich-type complexation of eight benzo-15-crown-5 substituents with four metal ions such as sodium, potassium, magnesium, calcium, and barium, as shown in Figure 18 [77–79]. Particularly, reaction with potassium ion gave the most stable face-to-face dimeric complex with a stability constant of 10^{23} M^{-5} in $CHCl_3$-MeOH (1:1) and the interplanar distance between two porphyrin rings was estimated as 4.2 Å. The complexation of 5,10,15-tris(benzo-15-crown-5)porphyrinatozinc with potassium ion exhibited much lower stability constant of ~10^{16} M^{-4}. Recently, the stability constants of 5,15-bis(benzo-15-crown-5)porphyrins **41** with potassium ion in $CHCl_3$/MeCN (2:1) have been determined as follows: 1.9, 2.2, 3.3, 3.5, 1.7, and 18.0 × 10^{18} M^{-3} for M = 2H, Zn(II), Co(II), Ni(II), Pd(II), and Cu(II), respectively [80]. Further, this dimerization induced by potassium ion has been applied to *meso-meso* linked bis(porphyrinatozinc) **43**, each porphyrin bearing two benzo-15-crown-5 substituents [80, 81]. Bisporphyrin **43** was linked by complexation with potassium ion to form polymer **44** in a mixed solvent of $CHCl_3$ and MeCN (2:1). The mean molecular weight and aggregation number were determined as ca. 10^5 Da and 50, respectively, by light-scattering measurement.

3. SELF-ASSEMBLED PORPHYRINS BY AXIAL COORDINATION

Porphyrin can incorporate many elements into the center as shown in Figure 1A [82]. In many cases, the central metal or nonmetal atom can accept one or two axial coordination(s) from outer ligand(s) (L_n, in Fig. 1B). The stability constant K_n and dynamic behavior of complexation between porphyrin center and axial ligand depends much on the nature of the central atom and electron-donating properties of the ligand. There are many possible combinations between central metal and ligand, and the nanostructure with most desirable optical/electronic functions can be obtained by careful choice of the best combination among these. Further, it is interesting that axial coordination of the outer ligand to the central element changes the spectroscopic and electrochemical properties of porphyrin. Such spectroscopic change in the visible light region varies the color of porphyrin and may be applicable for chemical sensors [83]. Chlorophylls both in the antenna complex [4–6] and in the special pair [7–12] are also fixed by membrane proteins through axial coordination of histidine-imidazole to their central Mg ions. These arrangements successfully drive the important photosynthetic functions. In this section, several examples of supramolecular architecture formation by axial coordination to porphyrin center will be presented.

3.1. Self-Assembled Porphyrin Dimer

Self-assembled porphyrin dimers by coordination of *meso*-substituted ligand to another porphyrin center are summarized with schematical drawing, as shown in Figure 19. In these cases, coordination directions of *meso*-substituted ligands such as 1-methyl-2-imidazolyl [84], 2-pyridyl [85, 86], 2-hydroxyphenyl [87, 88], and pyridyl groups connecting through arylamide spacer [89, 90], are orientated to almost perpendicular with respect to the porphyrin plane. As for central metal ions, it should be commented here that most transition-metal ions quench the excitation energy by the presence of odd spin or facilitate effective singlet-triplet intersystem crossing and no fluorescence is generally observable. Zn(II) ion is almost a sole exception and behaves similarly as Mg(II) in chlorophylls. Zn(II) is easily inserted into the porphyrin framework and the product is stable toward heat and acid. These facts cover almost completely the drawbacks of a little less efficiency in energy/electron transfer reactions since Mg(II) is difficult to incorporate and labile toward the action of heat and acid. Therefore, varieties of photosynthetic models have been constructed based on porphyrin Zn(II) complexes. In 1996, Zn(II) analogs of bacteriochlorophylls were found to be a main component of photosynthetic reaction center in the *acidiphilium bacteria* living under acidic conditions (pH 2.5–6.0) [91]. The principal nature of chlorophylls maintained in these Zn(II) analogs. Although interest in supramolecular structure formation sometimes introduces hexacoordinating metal ions such as Ru, Co, Mn, Fe, and others, these metalloporphyrins cannot act as functional mimics of photosynthetic energy/electron transfer reactions, but these metal ions may play important roles in electric conducting materials by using oxidation-reduction activities.

In the case of 1-methyl-2-imidazolyl substituent, porphyrin dimer **45** showed a large stability constant of over 10^{10} M^{-1} in chloroform [84]. ^1H NMR showed that a half of the porphyrin ring was affected by the strong ring current effect of the facing porphyrin, and the UV/visible absorption spectrum gave split Soret bands with splitting energy of 1035 cm^{-1} arising from exciton interactions of slipped cofacial arrangement of two porphyrin units in a solution (Fig. 20) [84, 92]. The large splitting comes from blue and red shifts by exciton interactions of face-to-face and head-to-tail transition dipoles, respectively (see Section 5). Since zinc ion embedded in porphyrin framework accepts only one

Figure 19. Dimerization of porphyrins by coordination of *meso*-substituted ligand to another porphyrin center [84–90]. Substituents of porphyrins have been omitted for clarity.

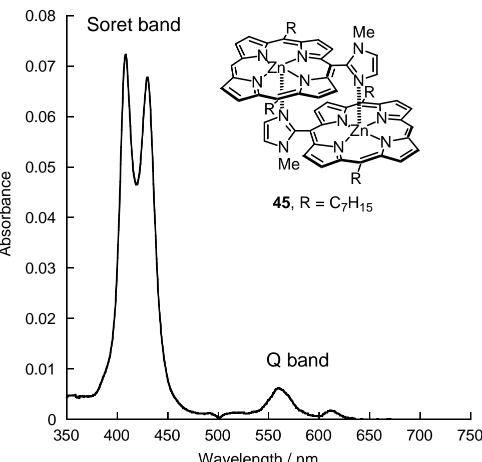

Figure 20. UV/visible absorption spectrum of complementary coordination dimer **45** in $CHCl_3$, where substituent R is *n*-heptyl group.

axial coordination, further organization cannot proceed and its chemistry becomes simplified to a great deal. From X-ray crystallographic study [93], the interplanar distance and the metal-to-metal distance were determined as 3.23 and 6.13 Å, respectively, which resembled those of dimeric structure of the native special pair in the bacterial photosynthetic reaction center [7–12]. These data suggested strong interactions between two chromophores which might have caused changes in optical and electrochemical properties. Similar distances were also found in 2-pyridyl-substituted porphyrinatozinc dimer **46** as 3.30 (3.31) and 5.955 (5.859) Å, respectively, determined by the X-ray study [85]. In this case, the split of Soret bands with splitting energy of ca. 1040 cm^{-1} was observed too.

[Since Ru(II) ion is inert for ligand exchange reaction compared with Zn(II) ion] and can accept hexacoordination with high stability, 2-pyridyl-Ru(II)-porphyrin dimer **47** with sixth ligation of CO or pyridyl was synthesized and their spectroscopic and electrochemical properties were reported [86]. Cyclic voltammogram measurements showed stepwise oxidations for the first oxidation potential of porphyrin rings, and for the Ru(II/III) ions of **47** due to strong interactions between two porphyrins. Absorption spectrum showed one broadened Soret band due to exciton interactions, but did not split in contrast to the zinc dimer complexes **45** and **46**.

2-Phenolate substituent in basic media could coordinate to trivalent central metal ions, Fe(III) and Mn(III), to afford neutral dimer complexes **48** [87] and **49** [88]. However, the crystal structure of Fe(III) complex **48** showed that two porphyrin planes of the dimer were not parallel but inclined with a dihedral angle of 13.5° and the average separation between the two porphyrin rings was 4.09 Å, indicating modest π-π interaction between two chromophores. Hunter and co-workers have reported several self-assembled porphyrins by using pyridyl pendant groups and reported also two types of dimer **50–52** exhibiting the stability constants K in the range 10^6–10^8 M^{-1} in chloroform [89, 90]. Self-assembled dimers by using pyridyl substituted porphyrin at β-position have been reported (Fig. 21) [85, 94]. ^1H NMR spectrum of dimer **53** [85] in $CDCl_3$ was broadened suggesting the exchange reaction with monomeric species at

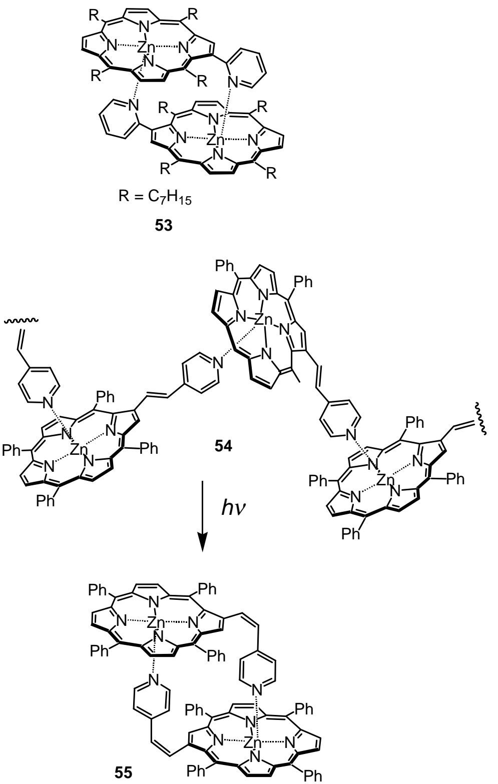

Figure 21. Self-assembled porphyrin dimers **53** [85] and **55** [94] by coordination of β-substituted ligand to another porphyrin center.

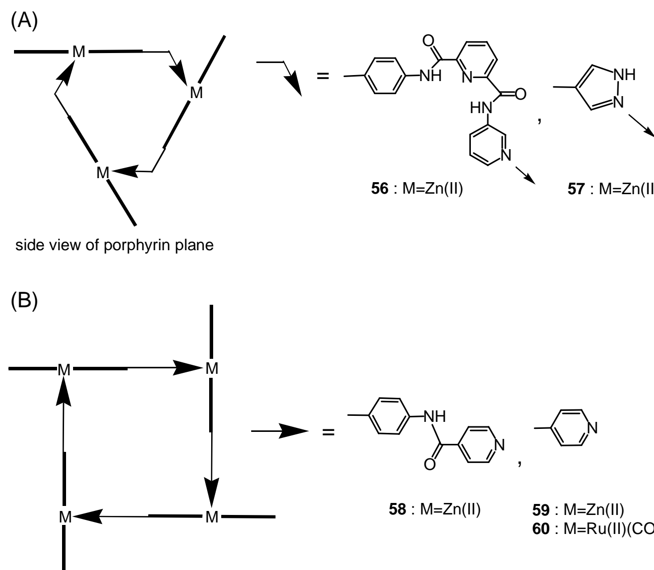

Figure 22. Cyclic trimer (A) [95–97] and tetramer (B) [95, 98–100] of porphyrins by coordination of *meso*-substituted ligand to another porphyrin center. The bold bar represents the side view of porphyrin plane.

room temperature. The spectrum was sharpened at −35 °C with a single set of dimer signals. The complexation reaction was certainly concentration dependent and measurements of absorption spectra undertaken in dilute CH_2Cl_2 solution (∼10^{-4} M) required lowering the temperature to approximately −40 °C to observe the complete formation of dimer **53**. 5,10,15,20-Tetraphenyl porphyrin (TPP) derivative instead of alkyl substituent did not give dimeric species due to significant intermolecular phenyl-phenyl contact. Burrell and co-workers [94] synthesized β-substituted 4-pyridyl-vinyl-TPP with *trans* (62%) and *cis* (20%) alkene linkages. Two isomers were different in the coordination direction of pyridyl nitrogen. Therefore, these zinc complexes gave polymeric species **54** and dimer **55** for *trans* and *cis* isomers, respectively. Both assembled structures were determined by single-crystal X-ray analyses. Two porphyrin planes of dimer **55** were not parallel with a dihedral angle of 32° due to geometrical requirements of the *cis* alkene linkage. The polymer **54** was converted into dimer **55** by irradiation with UV light.

3.2. Cyclic Porphyrin Oligomer

When 3-pyridyl group was introduced into the side arm instead of 4-pyridyl in **50**, the angle between coordination direction and porphyrin plane changed from 90° to near 150° to give porphyrin trimer **56**, as shown in Figure 22A [95, 96]. The ^{1}H NMR spectrum of **56** in $CDCl_3$ was concentration independent. The pyridyl protons were shifted upfield to a great deal at around −6.4 to −0.9 ppm due to the porphyrin ring current. The molecular weight corresponding to trimer was obtained from VPO measurements in $CHCl_3$ at the concentrations from 3 to 20 mM. The absorption spectrum of **56** in CH_2Cl_2 depended on the concentration; at lower concentration of 10^{-7} M, the spectrum corresponding to monomeric species was obtained, but a split of the Soret band by 9 nm in same intensity was observed at higher concentration of 10^{-4} M. The split of the Soret band at higher concentrations indicated the exciton coupling interaction [92] among three porphyrins. The stability constant of trimer **56** was determined as 5×10^{12} M^{-2}. A split of the Soret band of self-assembled porphyrin trimer **57** by coordination of *meso*-substituted pyrazolyl ligand was also reported [97]. In this case, the trimeric structure was cooperatively stabilized by coordinations of pyrazolyl to central metal ion and hydrogen bonds between pyrazolyl NH and carbonyl oxygen of another *meso*-substituent, as shown in Figure 23,

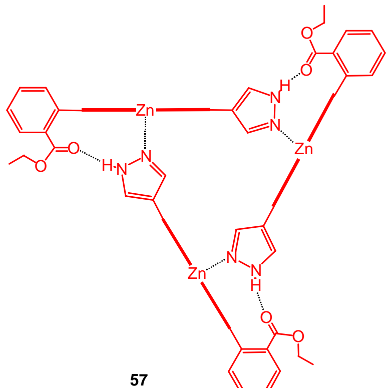

Figure 23. Cooperative stabilization of porphyrin trimer **57** by coordinations of pyrazolyl to central zinc and hydrogen bonds [97].

exhibiting the stability constant of 6×10^{13} M^{-2} at 22 °C. The trimeric structure was supported by ^1H NMR, ESI-MS, and VPO measurements.

Further, in order to obtain a square tetramer **58**, the angle was turned to 180° by changing the *meso*-substituent to 4-(isonicotinamide)phenyl, as shown in Figure 22B [95, 96]. The stability constant of tetramer **58** was determined as ca. 10^{13} M^{-3}. The tetrameric structure was also characterized by ^1H NMR, VPO, and absorption spectrum measurements. An attempt for construction of cyclic tetramer by *meso*-4-pyridyl porphyrinatozinc **59** was unsuccessful by the evidence of X-ray crystallographic study, which revealed the polymeric structure of $(\text{4-pyridyl-porphyrinatozinc})_n$ [98]. However, by using inert Ru(II) ion instead of labile Zn(II) as the central metal ion, the formation of tetramer **60** in solution was confirmed by NMR and FAB-mass spectrometries [99]. Variable temperature NMR study revealed that 4-pyridylporphyrinatozinc produced the polymeric species at room temperature. The result may be compatible with this X-ray study. However, cyclic tetramer **59** could form as a major product only by lowering the temperature to −40 °C [99]. Finally, the crystal structure of cyclic tetramer **59**, which was obtained from a benzene solution, was reported [100].

The natural light-harvesting antenna complexes in photosynthetic bacteria [4–6] have a higher-ordered macrocyclic ring structure composed of many chlorophyll molecules. In the first step of the photosynthesis reaction, the antenna complexes play important roles to absorb light and to transfer the absorbed light energy into the reaction center. Therefore, many chemists have desired to construct the porphyrin macromolecule as artificial antenna complexes by covalent as well as noncovalent approaches. Hunter and co-workers have synthesized monomeric cobalt-porphyrin having two side arms different in coordination direction and length, which may facilitate the coordination with a bend angle of about 30° between two porphyrin planes, to afford a large cyclic complex with approximately 12 porphyrin units, as shown in Figure 24 [101]. Here, the mass spectrometric study (FAB, ES, and MALDI) to detect the oligomeric species **61** was unsuccessful and only monomer peak was observed. The structural estimation was obtained from GPC (gel permeation chromatography) data, which were calibrated by using Co-porphyrin compounds as the reference, and estimated the number of monomer units to be 11.5.

Recently, a large macrocyclic antenna mimic by connecting imidazolyl-zinc coordination units, as explained in dimer **45**, and *m*-phenylene bridging parts has been successfully synthesized [102]. As shown in Figure 25, zinc insertion into free base gable porphyrin **62** gave a mixture of polymeric species **63**, macrocyclic pentamer **64**, and hexamer **65** by the evidence of GPC analysis (Fig. 26, thin line). Although polymeric mixture **63** with broad distributions of relatively higher molecular weight was observed, two separate peaks were detected at longer retention times corresponding to macrorings **64** and **65**. After the reorganization experiment, where the mixture was diluted in $CHCl_3$:MeOH = 7:3 to 1:1 mixture (down to 3.5 μM) to dissociate the coordinate bond and then the solvent was slowly evaporated at 25 ± 1 °C, the higher-molecular-weight part disappeared and converged to the two peaks (Fig. 26, bold line). Atomic force microscope (AFM) observation of the converged sample confirmed the presence of round-shaped particles with uniform height of ca. 1.5 nm, as shown in Figure 27. Small-angle X-ray scattering measurements were undertaken to determine the molecular size of **65**, which was isolated from the converged mixture by preparative GPC separation. The Guinier analysis of the scattering data gave diameters of 42.36 and 40.26 Å for sphere and cylinder approximations, respectively, according well with the outer diameter of cyclic hexamer ca. 41 Å estimated from molecular mechanics calculation. The fluorescence quantum yield of **65** was determined as 0.51 relative to that of the monomeric bis-zinc gable-porphyrin. Similar relations have been observed between the natural light-harvesting complex and its dimeric subunit [103]. This porphyrin macroring is regarded as the first successful antenna mimic to investigate the light-harvesting in photosynthesis.

3.3. One-Dimensionally Self-Assembled Porphyrin Polymer

One-dimensional multi-porphyrin array is one of the candidates for single-molecular electric wire. Therefore, several interesting researches on construction of such a molecular wire by noncovalent as well as covalent approaches have

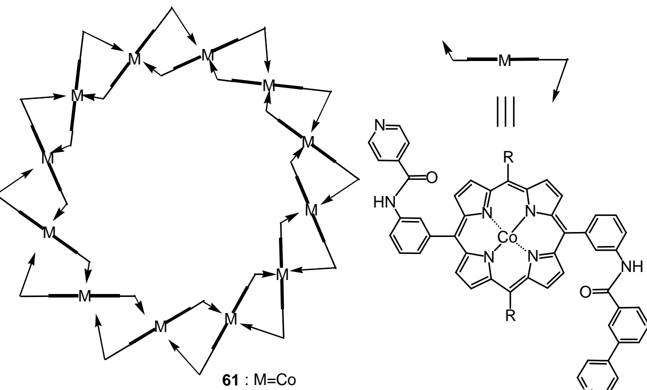

Figure 24. Cyclic porphyrin oligomer assembled by two different substituents inducing a bend angle of 30° between porphyrin planes [101].

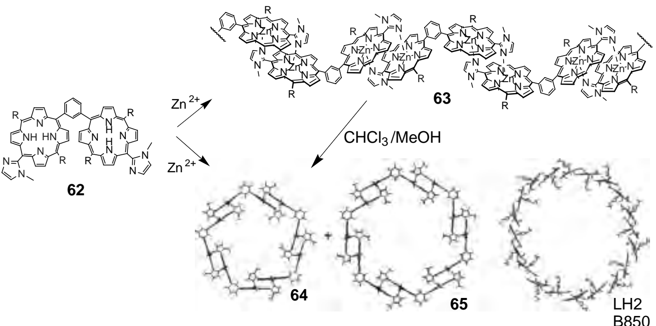

Figure 25. Formation of porphyrin macrorings **64** and **65** as light-harvesting antenna mimic [102].

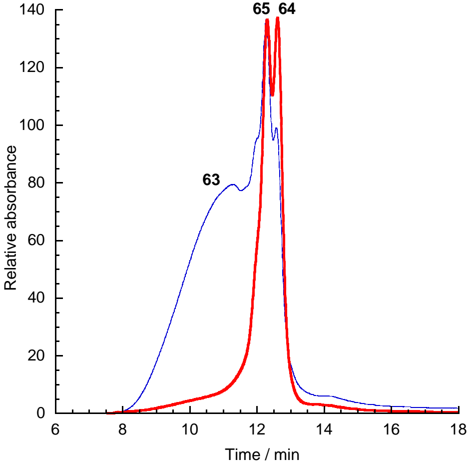

Figure 26. GPC charts of polymeric mixture **63** (thin line) and a converged mixture of **64** and **65** (bold line). Exclusion limit of column was 7×10^4 Daltons and eluent was chloroform.

been reported in recent years. In this section, one-dimensional multi-porphyrin arrays by coordination of *meso*-substituted ligand to another porphyrin center will be reviewed.

One of the examples is porphyrin aggregate by the complementary coordination of imidazolyl to Mg ion (**66**) with strong interaction between porphyrin rings (Fig. 28) [104–106]. As described in Section 3.2, zinc ion accepts only one axial coordination to provide dimer **45** and further organization of *trans*-bis(1-methyl-2-imidazolyl)porphyrinatoZn could not proceed. Therefore, Mg(II), which could accept the hexacoordination, was introduced into *trans*-bis(1-methyl-2-imidazolyl)porphyrin. NMR study of the self-organized complex of Mg porphyrin **66** in $CDCl_3$ showed a growth of the coordination structure by the continuous

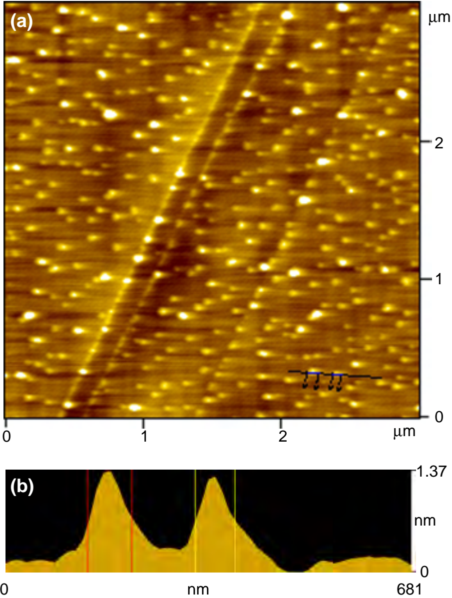

Figure 27. (a) AFM image of self-assembled porphyrin macroring spin-coated on a mica plate. (b) Cross section along the line in (a).

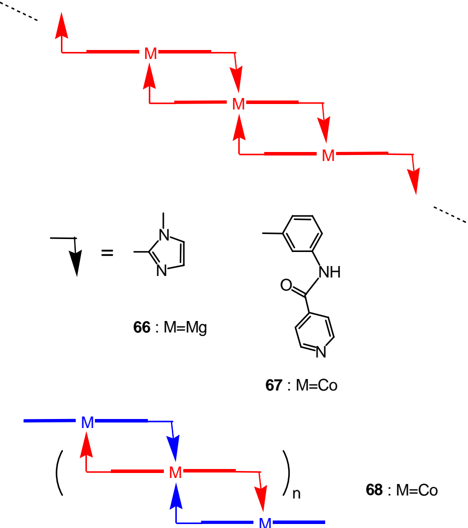

Figure 28. Linear porphyrin polymers **66** [104–106] and **67** [90] by coordination of *meso*-substituted ligand to other porphyrin centers, and oligomer **68** [90] terminated by mono-substituted chain stopper.

repetition of hexacoordination and was suggested by significant up-field shifts of protons due to the strong ring current effect and split Soret bands as well. The evidence of the elongation of organized structure could be obtained from electrospray ionization mass spectrum, which showed the existence of the assembly up to heptameric species [106].

Hydroquinone was introduced into a *meso*-position to obtain another type of one-dimensionally propagated array of Mg porphyrins, as shown in Figure 29 [107]. Figure 30 shows ^{1}H NMR spectra of free base **69** (A) and Mg complex **70** (B). The spectrum of **70** showed larger splits of β-pyrrole protons and tolyl protons than **69** due to increasing asymmetry by complexation. The protons assigned to the hydroquinone part shifted more characteristically from 7.21–7.45 to 6.58–6.38 ppm. Temperature-dependent NMR study down to −40 °C elucidated considerable upfield shifts for all protons in the following order:

$$\mathrm{Ha} \approx \mathrm{Hc} > \mathrm{Hb} \approx \mathrm{H}\beta' > \mathrm{H}\beta'' \approx \mathrm{Hi}$$
$$\approx \mathrm{Ho} > \mathrm{Hi}' > \mathrm{Ho}' > \mathrm{H}\beta$$

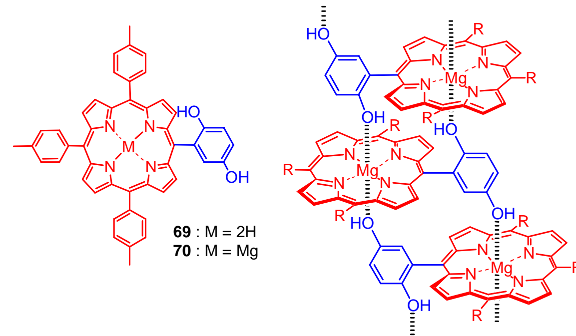

Figure 29. A proposed structure of mono(hydroquinonyl)-porphyrin Mg complex **70** (R = *p*-tolyl) [107].

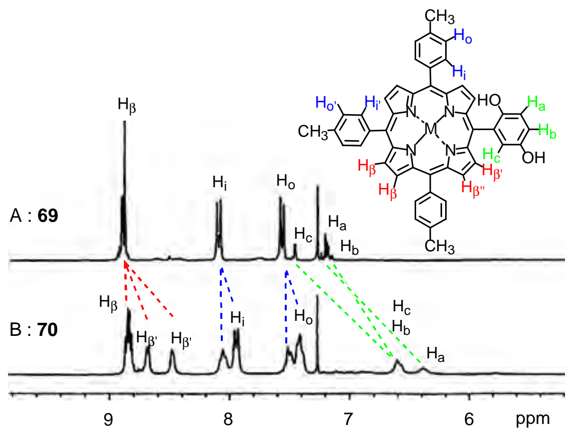

Figure 30. ^{1}H NMR spectra of free base **69** (A) and Mg complex **70** (B) in $CDCl_3$ (8 mM, 20 °C) [107].

The largest shifts were observed for hydroquinonyl peaks Hc and Ha suggesting the molecular organization of Mg porphyrin in a slipped cofacial arrangement.

Bis(*m*-(isonicotinamide)phenyl)-porphyrinatoCo allowed the formation of polymer **67** by coordination of pyridyl ligand to the central cobalt ion (Fig. 28) [90]. Cobalt ion can also accept the sixth coordination to afford the construction of a linear array in a way similar to the case of **66**. The pulse-gradient spin-echo NMR diffusion experiments, which give the information of relative molecular sizes, showed that the diffusion coefficient of **67** was much smaller than that of monomeric Co porphyrins, suggesting a large polymer. GPC analyses of **67** revealed the degree of polymerization of 95 at 7 mM concentration. A mixture of **67** and mono-substituted porphyrinatoCo **52** (Fig. 19), which acted as a chain stopper, gave oligomeric mixture **68** in solution. The length of the oligomer **68** decreased with the use of increasing amounts of the chain stopper **52**.

We succeeded in constructing one-dimensionally self-assembled giant porphyrin array **72** (Fig. 31) by coupling of the complementary coordination unit of imidazolyl to central zinc ion like **45** [108]. Here, the functional target was photosynthetic energy/electron transfer reactions and the central metal ion was limited to Zn(II) due to the reason already discussed. Molecular weight of **72** was determined by GPC analysis. Figure 32 illustrates chromatograms of **72** along with those of polystyrene standard mixtures. The distribution peak maximum appeared at around 1×10^5 Da corresponding to 160 porphyrin units of **71** and molecular length of 110 nm. Since elution of **72** started even before the exclusion limit of MW 5×10^5, the largest molecular weight was at least 5×10^5 Da corresponding to 800 porphyrin units and a 550 nm molecular length. AFM image of **72** dispersed on a mica plate from a chloroform solution in 2.5×2.5 μm range revealed that wirelike structures propagated as a single molecule several hundreds nanometers in length and around 1.3 nm in thickness, corresponding to the single-molecular chain of polyporphyrin (Fig. 33). Even such a stable structure forming polyporphyrin **72** could be dissociated into bisporphyrin unit **71** by the addition of MeOH or pyridine (see Section 5). A mixture of $(\mathbf{73})_2$ and **72** dissolved in a 1:5 molar ratio in chloroform was analyzed by GPC with the column having an exclusion limit of MW 7×10^4 (Fig. 34, line (a)). Two isolated peaks at 8 min (exclusion limit) and 14 min were detected indicating no scrambling between these components. The same mixture was dissolved in chloroform-methanol (1:1), followed by evaporation to reorganize. Then, a series of oligomers **74** marked by 1, 2, 3, and more (Fig. 34, line (b)) was observed. This reorganization process becomes important in the systems such as photocurrent generation [109, 110] and nonlinear optics [43, 110], where specific functional group R′ of **73** is required for facilitating electron transfer and molecular polarization, as well as the construction of large macrocyclic porphyrin arrays **64** and **65** as light-harvesting antenna complex model as discussed in Section 3.2. The photocurrent generation and NLO property will be discussed in Section 6.

3.4. Other Porphyrin Assemblies by Axial Coordination

4,4′-Bipyridyl, 1,4-diazabicyclo[2.2.2]octane (DABCO), and mono- to tetra-pyridyl-appended porphyrins have been employed widely to construct a variety of unique porphyrin

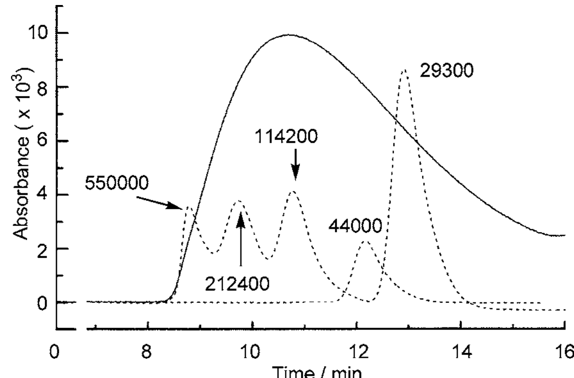

Figure 32. GPC chart of **72** (bold line) and mixtures of polystyrene standard (dotted line, the numbers indicate molecular weight) with a column of exclusion limit 5×10^5. The eluent was EtOH-free $CHCl_3$.

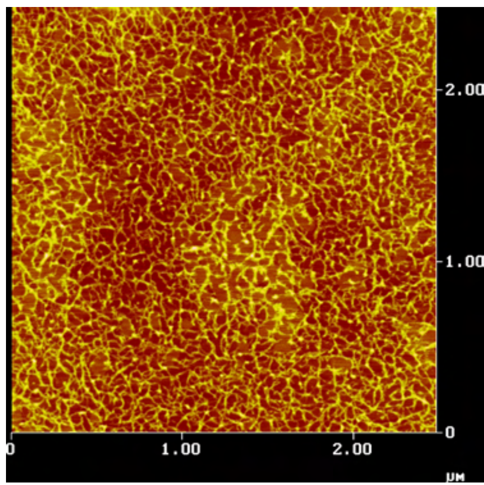

Figure 33. AFM image of linear multi-porphyrin array 72 dispersed on a mica plate.

architectures by axial coordination to other porphyrin centers. In many cases, Zn(II) was selected as the central metal ion to accept the axial coordination. Its relatively strong affinity constants especially to pyridyl gave various examples. Simple coordination chemistry by the acceptance of only one axial ligand, and its light-emitting property, are their characteristics. Many examples have been reported to push forward such noncovalent chemistry for controlling nanostructures and will be introduced in this section (some of these are already introduced in the discussion as seen in Fig. 5 and Sections 3.1–3.3).

One of the early examples conducted by Anderson et al. is shown in Figure 35 [111, 112]. Two zinc porphyrins connected by flexible alkoxycarbonylalkyl chains containing pyromellitdiimide, which is a strong electron acceptor, were synthesized to incorporate some guest molecules in the cavity. 5,15-Bis(4-pyridyl)porphyrin was bound by axial coordination of 4-pyridyl group to two zinc porphyrins as well as by π-π interactions between free base porphyrin and pyromellitdiimide units to give relatively large association constant

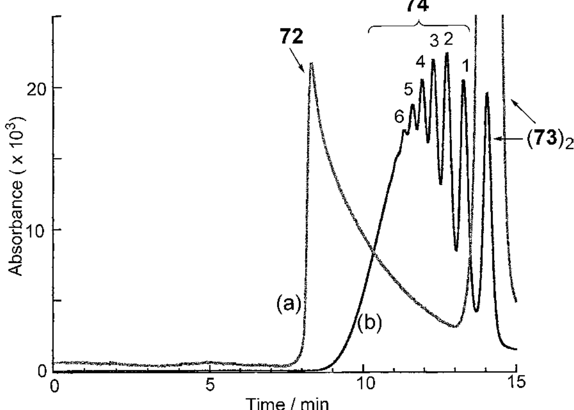

Figure 34. GPC chart of a mixture of 72 and $(73)_2$ in a 5:1 molar ratio (a) and the same sample mixture once dissolved in $CHCl_3$-MeOH (1:1), then evaporated, and redissolved in $CHCl_3$ (b). The exclusion limit of the column employed was 7×10^4.

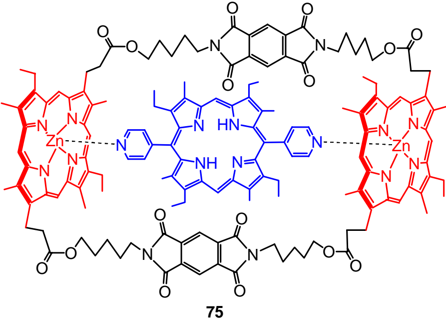

Figure 35. Self-assembled porphyrin trimer 75 stabilized by two axial coordinations and π-π interactions between free base porphyrin and pyromellitdiimide [111, 112].

of 2.6×10^5 M^{-1}. The fluorescence of free base porphyrin in 75 was quenched due to electron transfer to the pyromellitdiimide part. Chernook et al. synthesized self-assembled porphyrin systems 76 and 77 (Fig. 36), in which *trans*-bis(3-pyridyl)- and *cis*-bis(4-pyridyl)-substituted free base porphyrins bound to coplanar bis(porphyrinatozinc) by 2-fold coordination, respectively [113]. The complexation constants of both systems were in the range 10^6 to 10^7 M^{-1} in CH_2Cl_2 determined by absorption and fluorescence titration experiments. The emission from zinc porphyrin units within the complex was quenched and that from the free base increased, indicating the occurrence of singlet-singlet energy transfer between the components.

Hunter reported a self-assembled porphyrin trimer containing a naphthalenediimide bridging group as the electron acceptor 78 and its reference compound without a diimide grouping 79 [114]. Free base porphyrin was loaded onto bis(porphyrinatozinc) by two pyridyl arms (Fig. 37). These structures were confirmed by VPO, ^1H NMR , and absorption spectra showing a discrete and stable 1:1 complex at the concentration range of 10^{-2} to 10^{-7} M. The stability constant of 78 was determined as 3×10^8 M^{-1} in CH_2Cl_2 by using fluorescence titration technique. Photoinduced electron transfer to diimide quenched 70% fluorescence of free base porphyrin. The weak fluorescence from uncomplexed zinc porphyrin parts was not changed by the acceptance of a

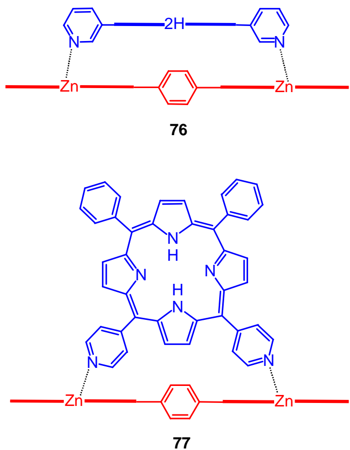

Figure 36. Self-assembled porphyrin trimers 76 and 77 [113].

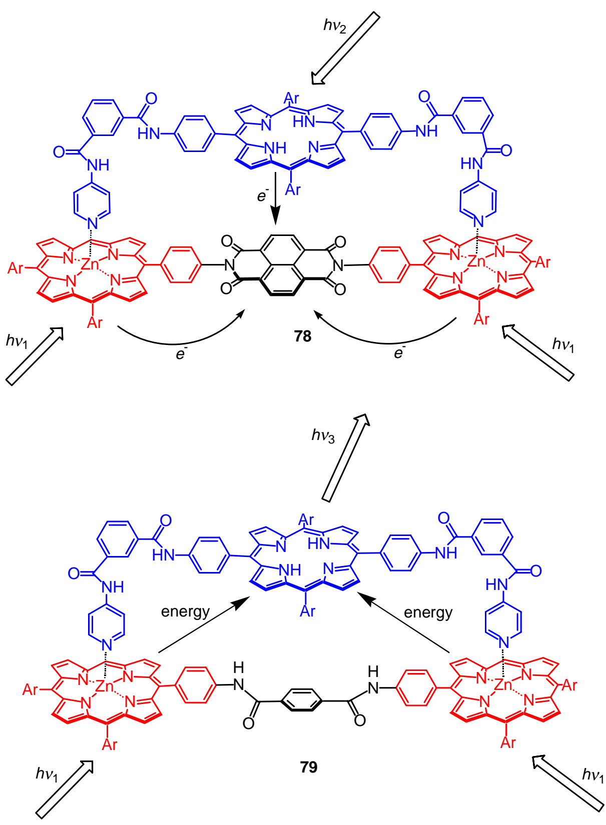

Figure 37. Self-assembled porphyrin trimer containing naphthalenediimide as an electron acceptor **78** and no acceptor **79** to control electron and energy transfer processes [114].

free base porphyrin as a guest. This indicated that fast electron transfer from zinc porphyrin to diimide units occurred concurrently in **78**. On the other hand, complex **79**, having no acceptor, showed energy transfer from zinc porphyrin to free base porphyrin. The electron and energy transfer processes are summarized schematically in Figure 37 [114].

Anderson has reported double-strand [42, 115, 116] and triple-strand [117] porphyrin ladders (**80** and **81**), as shown in Figure 38. The linear porphyrin arrays are conjugated by diacetylene linkages. Bridging reagents employed were 4,4′-bipyridyl and DABCO for **80**, and diacetylene linked free base 5,5′,15,15′-tetrakis(4-pyridyl)-bisporphyrin for **81**. In all cases, ^{1}H NMR spectra showed that all the protons of the bridging ligand were shielded by porphyrin ring current effect to give large up-field shifts. In the case of conjugated dimer **80** ($n = 2$) with DABCO, aggregation became much stronger with an equilibrium constant of 1.2×10^{7} M^{-1} for the formation of bimolecular porphyrin aggregate relative to that of monomer (3.8×10^{2} M^{-1}) in CH_2Cl_2 [115]. The stability constant for 2:2 complex was determined as 4×10^{21} M^{-3} in CH_2Cl_2. The double-strand conjugated polymer with 4,4′-bipyridyl exhibited nine times larger third-order optical nonlinearity than the single-strand one by holding the π-conjugation in a coplanar form [42]. The absorption spectrum of triple-strand **81** was not a simple sum of those of the components and the stability

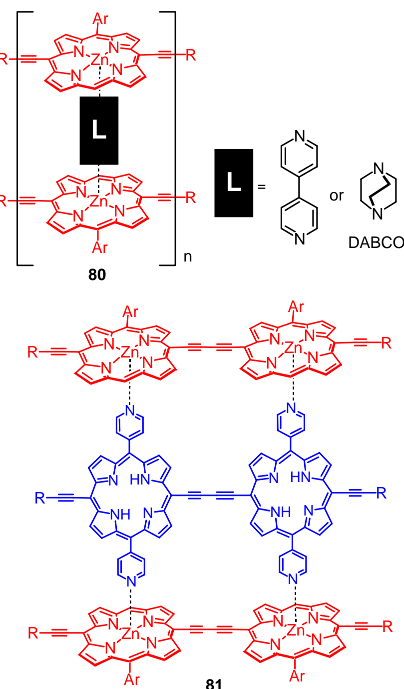

Figure 38. Double-strand conjugated porphyrin ladders **80** [42, 115, 116] and triple-strand **81** [117].

constant could not be determined accurately in CH_2Cl_2 (10^{16}–10^{19} M^{-2}) [117]. The spectral changes by the formation of **80** and **81** will be discussed in Section 5.

Alessio and co-workers synthesized a dimeric zinc porphyrin building block possessing the structure similar to compound **2** shown in Figure 3 by using Ru(II) instead of Pd(II) ion. Higher-order assemblies **82** and **83** were constructed from this building block by axial coordination of bridging ligand 4,4'-bipyridyl and 5,15-bis(4-pyridyl)porphyrin, respectively, as shown in Figure 39 [54]. One-dimensional, two-dimensional, and

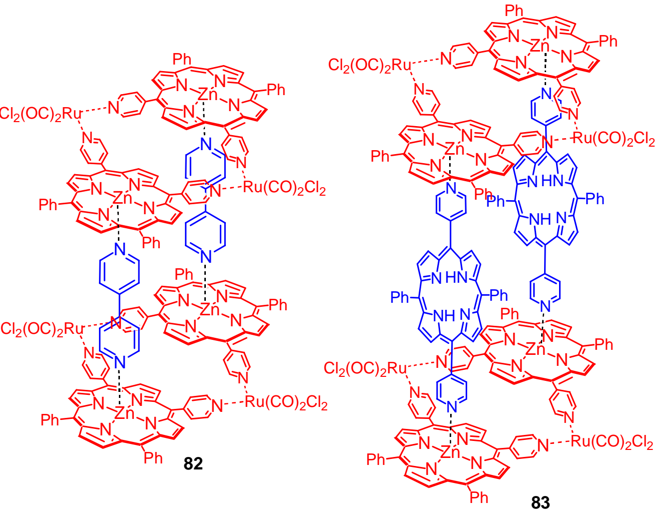

Figure 39. Molecular sandwiches **82** and **83** constructed by axial coordination of bridging ligand to Ru(II)-assisted dimeric porphyrin building block [54].

variable-temperature NMR investigations indicated assembly formation of sandwich-like 2:2 complex quantitatively in a $CDCl_3$ solution. Single-crystal X-ray analyses showed that **83** was a discrete assembly of two dimers connected by bridging free base porphyrins. The two bridging porphyrins oriented in a coplanar arrangement with a distance of ca. 11.4 Å.

The same authors have reported a discrete porphyrin tetramer **85** constructed by two-point self-coordinations of Ru(II)-assisted bis[5,10-bis(4-pyridyl)porphyrinatozinc(II)] (Fig. 40) [118]. Free base bisporphyrin **84**, which was complexed by $Ru(CO_2)Cl_2$ at each 4-pyridyl substituent and had one unbound 4-pyridyl residue on each porphyrin, as a building block was expected to form the tetramer **85** by insertion of Zn(II) ion into two porphyrins. ^{1}H NMR spectrum of the crude product showed sharp signals corresponding to discrete self-assembly as a main species and minor broad peaks attributed to oligomer. The pure **85** was isolated by silica gel chromatography and crystallized by slow diffusion of *n*-hexane into $CHCl_3$ solution. The single-crystal X-ray analysis revealed a propeller-like arrangement consisting of four porphyrins with a S4 symmetry along the rotation axis passing through two Ru(II) ions. The cooperative interaction of four axial coordinations of pyridyl substituent, which was arranged in a *cis* form (substituted at 5 and 10 positions of porphyrin), gave a discrete assembly by recognizing the building block.

At the same time, *meso-meso* linked bis(5-(4-pyridyl)porphyrinatozinc) **86** and its cyclic tetramer **87** have been reported (Fig. 41) [100]. The boxlike assembly **87** has a cavity of ca. $10 \times 10 \times 8$ Å^3. ^{1}H NMR spectrum gave sharp peaks and pyridyl protons were upfield-shifted by the effect of porphyrin ring current, suggesting the existence of a self-assembled cyclic tetramer **87** from **86** in $CDCl_3$. A GPC analysis of **87** showed a sharp elution peak with

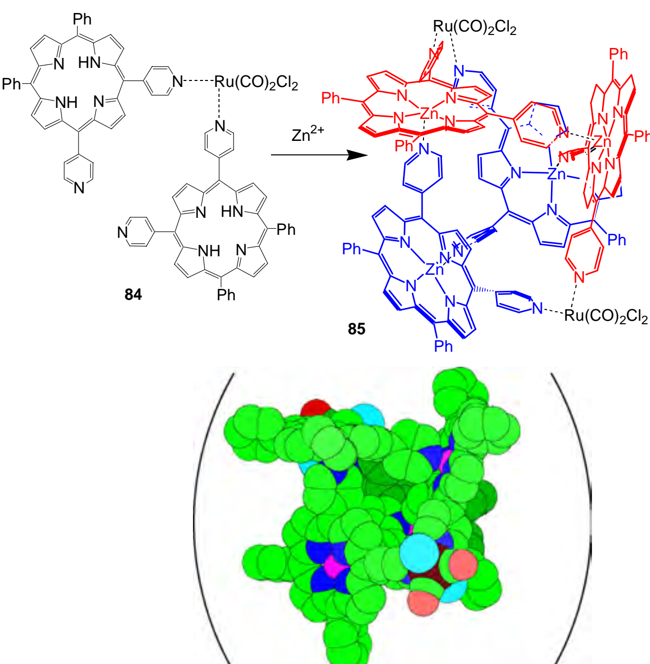

Figure 40. Dimer **84** and cyclic tetramer **85** [118].

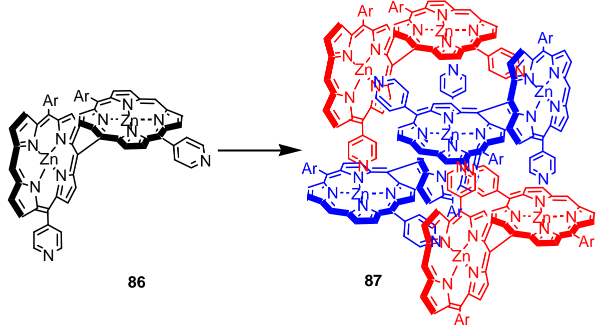

Figure 41. *Meso-meso* linked bis(5-(4-pyridyl)porphyrinatozinc) **86** and its cyclic tetramer **87** [100].

a shorter retention time than that of monomer indicating discrete cyclic assembly. The CSI-MS measurement in a THF solution observed the parent ion of tetramer **87** as the major peak with a much smaller peak corresponding to monomer. The association constant was estimated as at least 10^{25} M^{-3} in $CHCl_3$ from fluorescence spectrum, which did not depend on the concentration down to 1.6×10^{-8} M.

Imamura and Alessio and co-workers have developed a self-assembled porphyrin system by using Ru(II) or Os(II) ion as the central metal ion to construct kinetically stable architectures. Figure 42 represents a series of

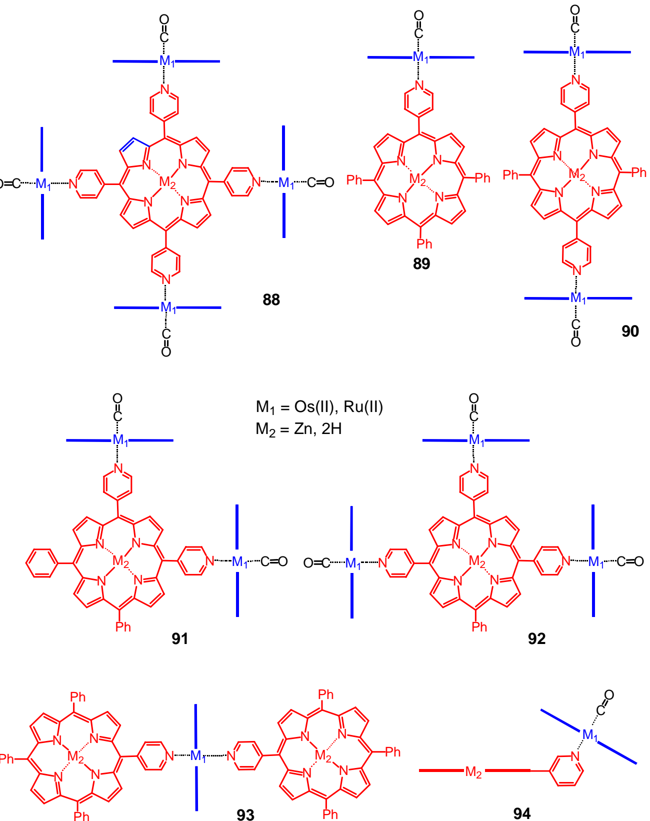

Figure 42. Schematical representation of systematic porphyrin assemblies by using coordination of *meso*-substituted pyridyl to Ru(II) or Os(II) center [119–124].

porphyrin arrays constructed by using coordination of *meso*-substituted pyridyls to central Ru(II) or Os(II) [119–124]. Alessio et al. prepared pentamer **88** by combination of four Ru(CO)-TPP walls with one central free base or zinc tetrapyridyl porphyrin as a bridging ligand [119]. Reaction of Ru(CO)(EtOH)-TPP with tetrakis(4-pyridyl)porphyrin was carried out in chloroform at room temperature to afford **88** rapidly and quantitatively as confirmed by ^{1}H NMR measurement. Imamura and co-workers reported a series of porphyrin assemblies **88–93** by using Os(CO)- or Ru(CO)-porphyrins as walls [120–122]. In these cases, Os(CO)(EtOH)- or Ru(CO)(MeOH)-porphyrins were used as the precursor of the wall and reacted with pyridyl porphyrin in toluene under Ar atmosphere and reflux conditions. The organizations were also confirmed by ^{1}H NMR measurement. The cyclic voltammogram and electronic spectral measurements of the oligomers indicated that there was no distinct interaction within the macrocycles. Two authors also reported porphyrin assemblies **94** by using an axial coordination of *meso*-substituted 3-pyridyl-porphyrin to Os(II) or Ru(II) center [123, 124].

Imamura and co-workers have reported porphyrin tetramers **95**, **96** [86], and octamer **97** [125], as shown in Figures 43 and 44, respectively. The substitution of axial CO ligands in dimer **47** (Fig. 19 in Section 3.1) and tetramer **60** (Fig. 22 in Section 3.2) with free base 4-pyridyl- or 3-pyridyl-porphyrin by the photolysis of CO by medium-pressure mercury lamp in toluene followed by pyridine coordination gave the desirable higher-ordered assemblies, whose structures were analyzed by elemental analyses and FAB- or ESI-MS measurements. ^{1}H NMR spectra also revealed the tetrameric and octameric structures. Integral intensities of NMR signals agreed with the 1:1 composition of Ru(II) and free base porphyrins (2:2 for tetramers **95**, **96** and 4:4 for octamer **97**). The pyridyl and β-pyrrolic protons of the newly introduced axial porphyrin unit were shifted to up-field due to the ring current effect of the ruthenium porphyrin part.

Sanders and co-workers have also reported self-assembled porphyrin systems by using axial coordination to Ru(II) and other metal ions. Figure 45 illustrates dendritic multi-porphyrin arrays **98** and **99** [126]. Compound **98** was synthesized in two steps, in which monomeric Ru(II) porphyrin Ru(CO)(solvent)-por and 1 eq. of free base trimer $(por)_3$ were reacted in benzene at room temperature to form $[Ru(CO)\text{-}por\cdot(por)_3]$ and then $[Ru(CO)\text{-}por\cdot(por)_3]$ and $(por)_3$ were coupled by photoirradiation to give $[(por)_3Ru\text{-}por\cdot(por)_3]$ **98**. Free base trimer having three 4-bipyridyl substituents was treated with monomeric Ru(CO)(solvent)-por in chloroform to give rise to the formation of **99**. The NMR measurements supported these structures. Crystals of **99** suitable for single-crystal X-ray analysis were not obtained, but tripyridyltriazine(Py_3T)-assisted trimer **100** could be crystallized by slow diffusion of methanol into a

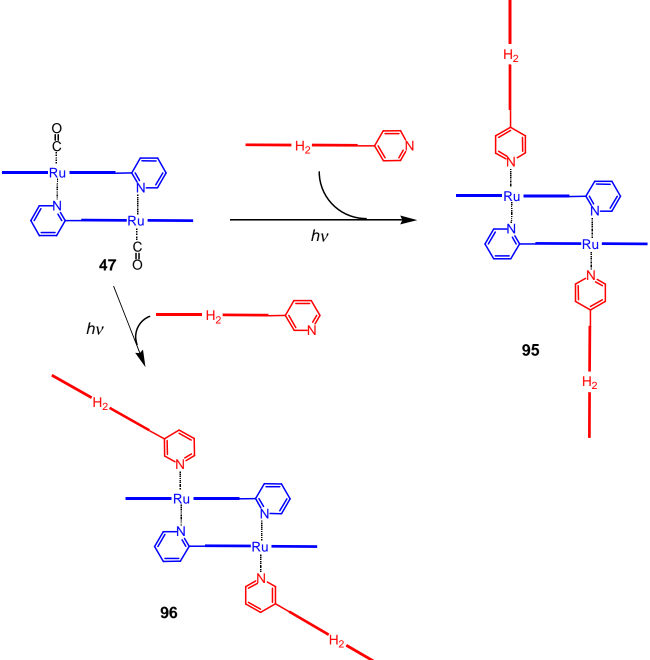

Figure 43. Formation of higher-ordered organization from dimer **47** by photoirradiation [86].

Figure 44. Formation of porphyrin octamer from tetramer by photoirradiation [125].

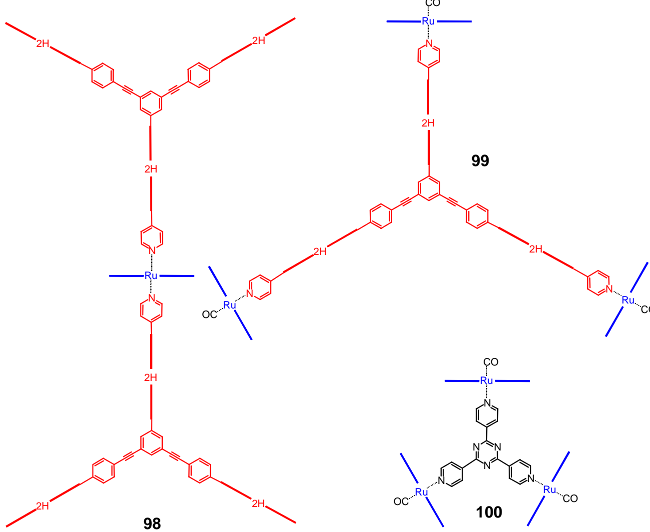

Figure 45. Dendric multi-porphyrin arrays based on Ru(II) [126].

toluene solution. The X-ray structure of **100** showed that the angles of Py_3T nitrogens and porphyrin plane were ranged from 85° to 90° and the distances between Ru(II) and nitrogens of Py_3T were 2.15 to 2.22 Å.

Self-assembled heterometallic oligoporphyrins **101** and **102** constructed by cooperative Zn(II) —N, Ru(II) —N, and Sn—O coordination bonds have been reported by the same group, as shown in Figure 46 [127]. The heterometallic porphyrin oligomers were designed to exhibit complementary geometries and cooperative binding properties by using different affinities toward ligand species. Here again, Ru(II) ion forms inert complexes with nitrogen ligands with hexacoordination, while Zn(II) porphyrin prefers nitrogen atoms with kinetically labile pentacoordination. On the other hand, Sn(IV) porphyrin prefers oxygen atoms with a hexacoordinate octahedral geometry and exhibits relatively slow ligand exchange rates. Therefore, carboxylate groups extended from a *meso*-phenylene position of Zn(II) or Ru(II) porphyrin bound to the Sn(IV) center of bis(4-pyridyl)porphyrin and at the same time two pyridyls of the Sn(IV) porphyrin coordinated to Zn(II) or Ru(II) centers in a cooperative fashion. These structures were determined by 1D and 2D (COSY and NOESY) NMR techniques.

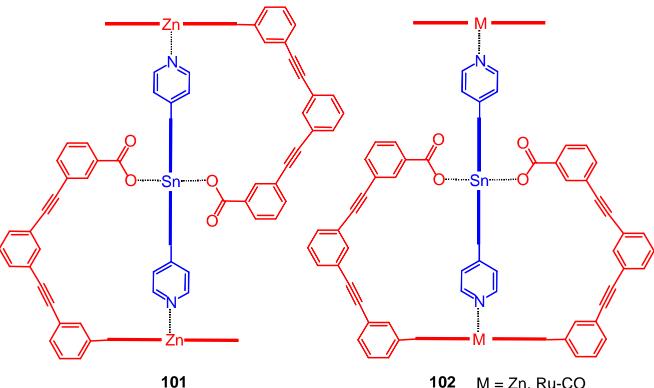

Figure 46. Self-assembled heterometallic oligoporphyrins constructed by cooperative Zn(II)—N, Ru(II)—N, and Sn—O coordination bonds [127].

Recently, Rh(III) porphyrin has been employed for building blocks of nanoarchitectures [128, 129]. Reaction of Rh(III) porphyrin monomer, whose axial positions were coordinated first by an iodide ion and a MeOH molecule, with 4,4′-bipyridine, DABCO, 4,4′-bipyrimidine, 2,7-diazapyrene, and 5,5′-dicyano-2,2′-bipyridine could give dimeric species **103** with these bridging diaza ligands by substitution of MeOH (Fig. 47). X-ray crystal structures of dimeric complexes with DABCO, 2,7-diazapyrene, and 5,5′-dicyano-2,2′-bipyridine were analyzed successfully. Porphyrin trimer **104** and pentamer **105** were synthesized by using a combination of carboxylate coordination to Sn(IV) and pyridine coordination to Rh(III) porphyrins. The ligands bridging Sn(IV) and Rh(III) porphyrins were isonicotinate and free base 5-(4-pyridyl)-15-(4-benzoate)porphyrin for **104** and **105**, respectively. X-ray crystal analysis of **104** showed that two Rh porphyrins

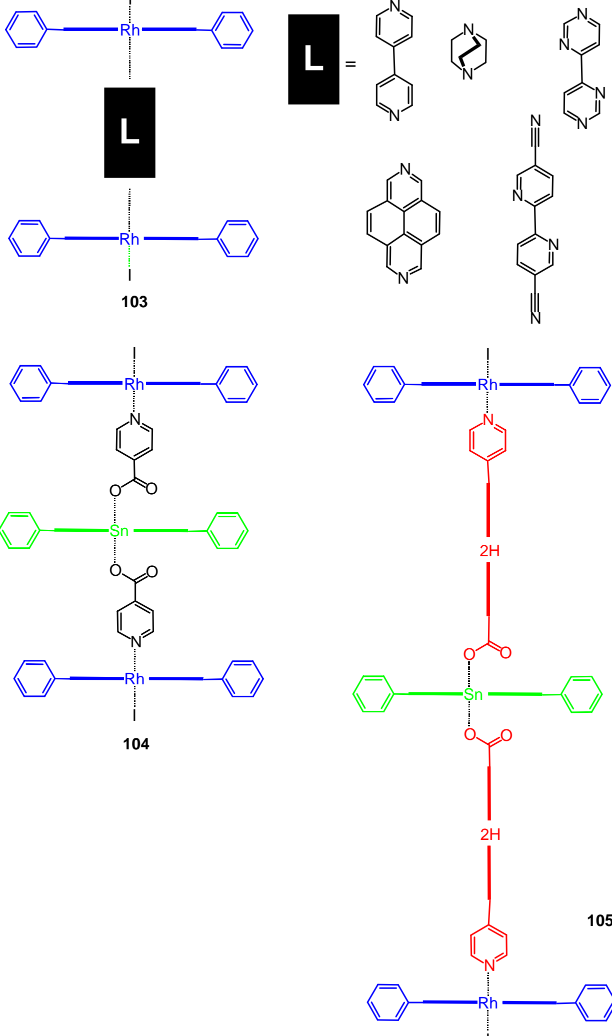

Figure 47. Supermolecules from Rh(III) and Sn(IV) porphyrins by using axial coordinations [128].

were equivalent through an inversion center of Sn atom and almost planar. The isonicotinate molecules were also planar and directed perpendicularly to the Rh porphyrin. An eleven-porphyrin array **106** was constructed by using three different metalloporphyrins: Sn(IV), Rh(III), Ni(II), and free base (Fig. 48) [128]. A Sn(IV) porphyrin acted as a core which was coordinated by two carboxylate substituted porphyrin trimers. Four Rh(III) porphyrins were bound to pyridyl groups at the four terminals of this array. The porphyrin array **106** was analyzed by 2D NMR techniques (COSY, NOESY, and TOCSY) to obtain spatial information. A cyclic porphyrin tetramer **107**, consisting of two bis(diphenylphosphine)-substituted zinc(II) porphyrins and two Rh(III)TPP units, was also constructed (Fig. 49) [129]. When Rh(III)-TPP was mixed with a same equivalent of bis(diphenylphosphine)-substituted Zn(II) porphyrin in $CDCl_3$, ^{1}H and ^{31}P NMR spectra suggested the formation of mixtures of several different species. When 0.5 equivalent of 4,4′-bipyridyl was added to the solution, cyclic porphyrin tetramer **107** was formed quantitatively. This process was monitored by ^{1}H NMR and all the information from ^{1}H, COSY, NOESY, and ^{31}P NMR spectra proved the existence of **107** as a single species.

Anderson et al. have developed a template-directed synthesis of cyclic porphyrin oligomers [130–132]. The synthesis of cyclic porphyrins by the use of appropriate templates

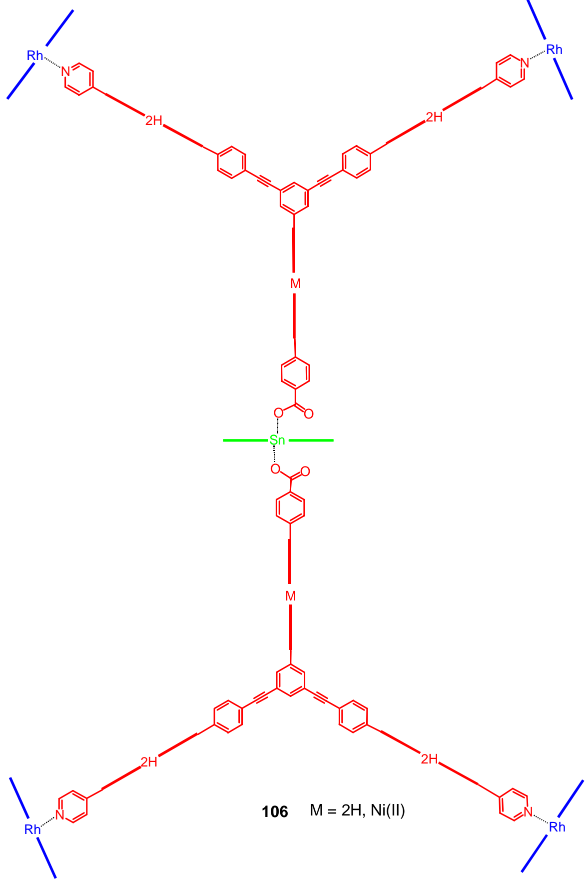

Figure 48. Self-assembled porphyrin 11-mer constructed from Rh(III) and Sn(IV) porphyrin building blocks [128].

Figure 49. Self-assembled cyclic porphyrin tetramer **107** by coordination of phosphine to Rh(III) center and bipyridyl bridging [129].

enabled to increase the yield significantly. The key step was the first process to self-assemble the substrates in a juxtaposition for the reaction, and then the desirable porphyrin macromolecule was produced by intramolecular covalent bond formation. As shown in Figure 50, 4,4′-bipyridyl was added to two zinc porphyrins to facilitate the closed conformation. The Glaser coupling reaction at two terminal acetylene groups of linear porphyrin dimer **108** produced cyclic dimer **109** in a 83% yield. The untemplated reaction gave only 21% of **109** with large amounts of other higher cyclic oligomers. On the other hand, a larger template reagent, tetrapyridyl-porphyrin, effectively promoted the formation of cyclic tetramer **110** containing one free base porphyrin with a high yield of 77%. In a similar way, the coupling reaction of monomer **111** in the presence of tridentate ligand Py_3T as the template gave a symmetric cyclic porphyrin trimer **112** in a 55% yield (Fig. 51).

4. SELF-ASSEMBLED PORPHYRINS BY HYDROGEN BONDS

Hydrogen bond formed between hydrogen atom adjacent to electronegative element and lone pair electron of mainly oxygen, nitrogen, and sulfur atoms is relatively weak interaction of 20 kJ/mol at most. However, stable aggregations can be formed through cooperative hydrogen bonds at multiple sites as seen in biological systems. For example, a double helix of DNA is built up by a lot of hydrogen bonds between nucleic acid base (nucleobase) pairings [13–15]. Sessler and co-workers have introduced cytosine and guanine derivatives, which can form a stable nucleobase pair of C-G by

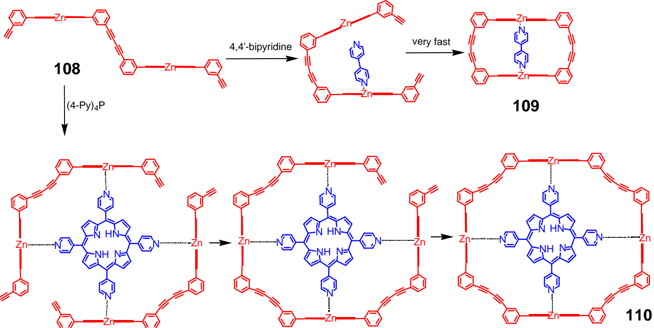

Figure 50. Template syntheses of cyclic dimer **109** and tetramer **110** assisted by 4,4′bipyridyl and tetrapyridyl-porphyrin.

Figure 51. Template synthesis of cyclic trimer **112** by using Py_3T [130–132].

triple hydrogen bonds, into each *meso*-position of respective porphyrins, as shown in Figure 52 [133]. Association constant of dimer **113·114** was determined to be 210 ± 40 $M^{-1}$by fluorescence lifetime measurement in a $CHCl_3$ solution. However, the photoinduced singlet-singlet energy transfer reaction within the hydrogen-bonded complex was not observed because of intracomplex diffusional encounter quenching between donor **113** and acceptor **114**. In order to suppress the flexibility, more rigid supramolecules have been developed by the combination of **115–117** [134]. In these systems, the donor and acceptor molecules were connected through *para*-phenylene linkages to hydrogen bonding units of guanosine (G) and cytidine (C), respectively.

Figure 52. Self-assembled porphyrins by triple hydrogen bonds in a nucleobase pairing [133, 134].

Association constant of dimer **115·116**, which was arranged side-by-side with an interplanar angle of ca. 90° and with the center-to-center distance of ca. 22.5 Å, was determined as 22,000 ± 2000 M^{-1} by ^{1}H NMR study in a CD_2Cl_2 solution. The photoinduced singlet-singlet energy transfer occurred within both dimer **115·116** and trimer **116·117·116**, and quantum yields were determined as 0.57–0.64.

Uracil derivatives have also been used in the construction of a triply hydrogen bonded self-assembly. Two 5,15-bis(5-uracil)porphyrinatoZn, in which two uracil substituents orientated in the *cis* arrangement as shown in Figure 53, formed a face-to-face dimer **118** by cumulative 12 hydrogen bonds bridged by two triaminopyrimidine molecules [135]. The interplanar distance between two porphyrins was estimated to be 10 Å providing a cage cavity to incorporate a host molecule such as 4,4′-bipyridine. Recently, five 2,6-diacetamido-4-pyridyl and four 6-uracil *meso*-substituted porphyrins have been synthesized for building up various types of multi-porphyrin supramolecules by triple hydrogen bonds between 2,6-diacetamido-4-pyridyl and uracil [136]. Two equivalents each of 5,10-bis(2,6-diacetamido-4-pyridyl)porphyrin and 5,10-bis(6-uracil)porphyrin in THF gave square tetramer **119** (Fig. 53). Formation of the tetramer was confirmed by ^{1}H NMR, dynamic light-scattering, ESI MS, and VPO measurements. ^{1}H NMR study showed the association constant of 6×10^{12} M^{-3} in THF-d_8.

Supramolecular multi-porphyrin macrocycle **120** by alternating disposition of three 1,3,5-triazine-bridged bis-porphyrin units and three barbituric acid units by eighteen

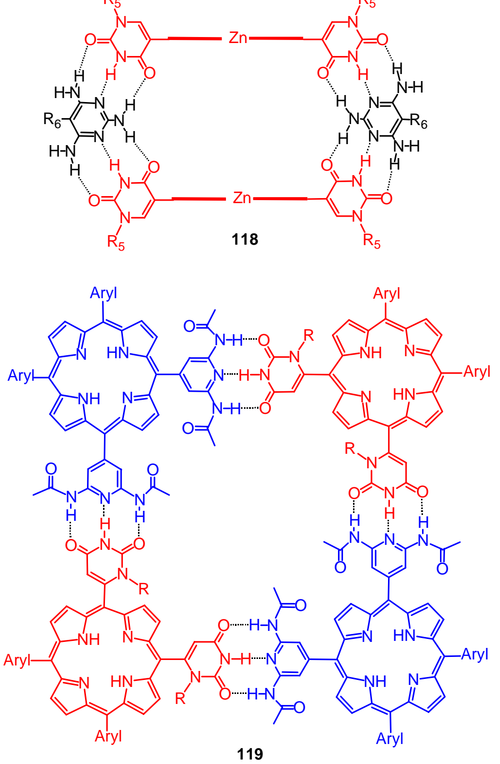

Figure 53. Self-assembled porphyrins of uracil derivatives **118** [135] and **119** [136] by triple hydrogen bonds formation.

N—H···N and N—H···O hydrogen bonds was synthesized (Fig. 54) [137]. ESI-MS measurement of a 1:1 mixture of bisporphyrin and barbituric acid in CH_2Cl_2 afforded the dicationic parent peak of **120** and VPO measurement suggested the molecular weight consistent with the assembly of three bisporphyrin and three barbituric units. ^1H NMR and NOE experiments indicated the formation of a discrete supramolecular structure rather than polymeric species and diffusion-ordered 2D NMR, which displays 1D chemical shift spectrum with a diffusion spectrum in the other dimension and gives information on the molecular radius [138], showed that over 90% of the two components were assembled to form assemblies of an approximately 2.5 nm size.

Two porphyrins bearing 4-pyrazolyl and 3,5-dimethyl-4-pyrazolyl substituent have been synthesized [139]. 3,5-Dimethyl-4-pyrazolyl-substituted porphyrin provided cyclic tetramer **122** as shown in Figure 55 with an association constant of 9.3×10^3 M^{-3} in $CDCl_3$. On the other hand, 4-pyrazolyl derivative without a methyl group favored the formation of dimeric species **121** and association constant was determined as 39 M^{-1}. The structural characterizations in both cases were performed by ^1H NMR, IR, and ESI-MS measurements. In the case of **121** without the methyl group in the pyrazolyl group, the rotational barrier between pyrazolyl and porphyrin plane was relatively low, and therefore steric hindrance between methyl groups at other *meso*-substituted tolyl groups might have prevented the formation of higher-ordered oligomer.

Self-assembled porphyrin dimer **123** through hydrogen bonds between two carboxyl groups with an association constant of 10^7 M^{-1} has been reported (Fig. 56) [140]. This dimer fabricated a cavity to incorporate a pyrazine molecule by coordination to two facing porphyrin centers of **123**. This molecular recognition has been applied to construct a multi-porphyrin system [141]. Thus, the free base porphyrin bearing four pyrazine arms **124** and dimer **123** allowed the formation of nonameric porphyrin assembly **128** with each

Figure 55. Two modes of intermolecular hydrogen bondings between pyrazolyl substituents with and without methyl groups giving porphyrin dimer **121** and tetramer **122**, respectively [139].

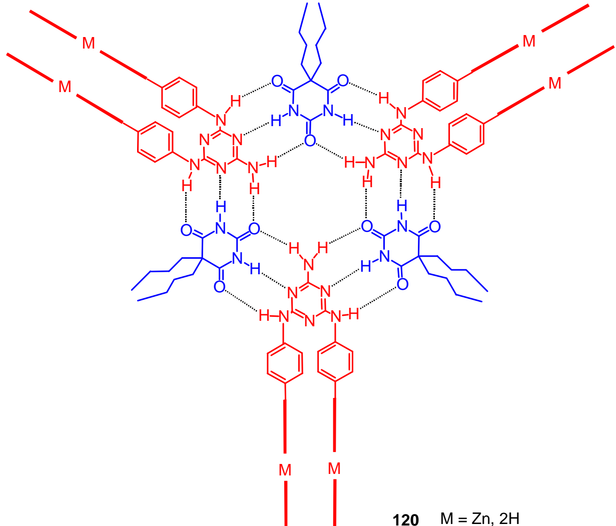

Figure 54. Supramolecular multi-porphyrin macrocycle **120** consisting of three triazine-bridged bisporphyrin units and three barbituric acid units [137].

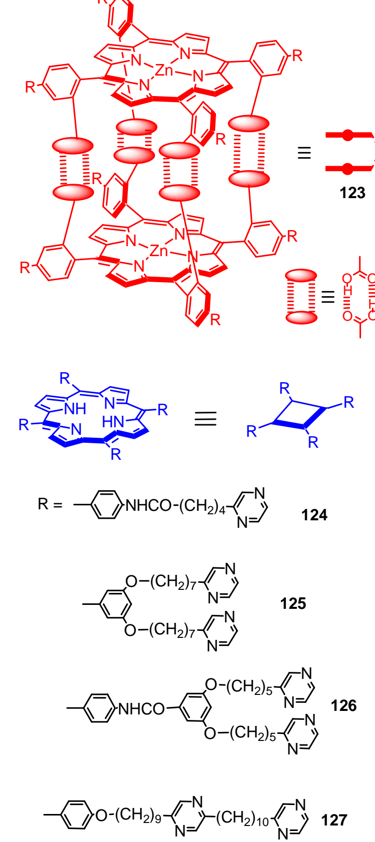

Figure 56. Schematic structure of dimer **123** organized by hydrogen bonds between carboxyl groups and free base porphyrin **124–127** bearing pyrazine pendants at *meso*-positions [140–142].

binding constant of 4×10^7 M^{-1}, as shown in Figure 57. Within the resulting complex, photoinduced energy transfer from zinc porphyrin moiety to free base porphyrin was observed with the energy transfer efficiency of 82%. The same authors synthesized three multi-porphyrin arrays assembling 16 porphyrin units **129–131** from three types of free base porphyrin having eight pyrazine substituents **125–127** by the same methodology [142]. The assemblies **129** and **130** were in a parallel configuration, while **131** was in a serial arrangement. All titration experiments for the formation of these assemblies showed similar complexation behavior and the binding constants of the inner and the outer pyrazine could not be separated. The existence of free **123** in solution was estimated to be less than 8% considering the binding constant. The energy transfer efficiencies were calculated from the fluorescence quenching of zinc porphyrin moieties in the complex as 61, 80, and 55% for **129**, **130**, and **131**, respectively. The reasons for the lowest efficiency observed in **131** having a serial arrangement of antenna units were considered as (i) the single-strand orientation of a side chain by two bulky antenna units constrained the farthest antenna units far from the central free base porphyrin, (ii) the energy transfer between inner and outer antenna units interfered with that from the antenna to the central porphyrin.

Two monomeric Cu(II) porphyrin units of **132** bearing four ammonium cations were tied by four bis-*p*-phenylene-[34]crown-10 molecules to give cofacially arranged supramolecular Cu(II) porphyrin dimer **133**, as shown in Figure 58 [143]. The X-ray analysis of single crystals of **133** with eight PF_6^- from an acetonitrile solution revealed a dimeric structure. The mean interplanar separations between two porphyrins and Cu-Cu separation were 3.65 Å and 4.76 Å, respectively, showing π-π stacking in a slipped cofacial orientation. In addition to the π-π interaction between porphyrins, the supramolecular assembly was stabilized by [N^+—H···O] and [C—H···O] hydrogen bonds between the dibenzylammonium sites of porphyrinsubstituent and the oxygen atoms of macrocyclic polyether linkages.

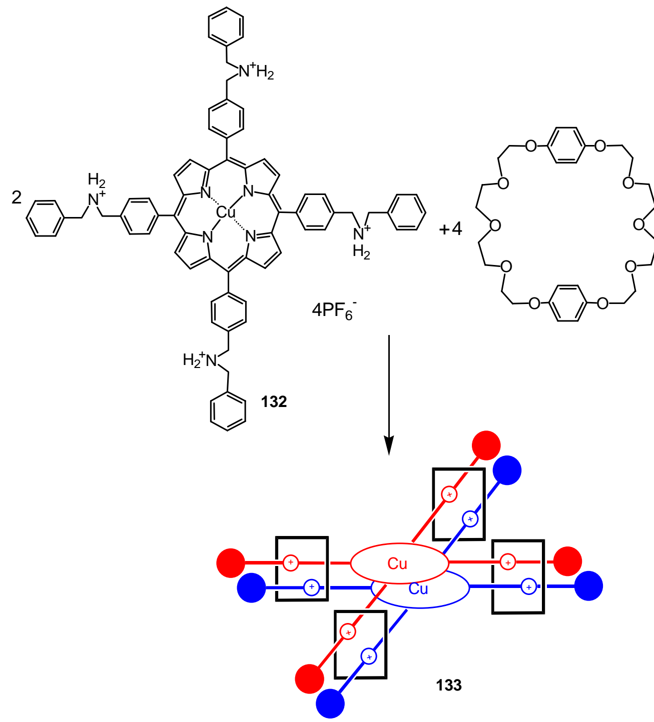

Figure 58. Formation of porphyrin dimer **133** tied by four bis-*p*-phenylene-[34]crown-10 molecules [143].

Supramolecular assembly by imidazolyl-imidazolyl hydrogen bonds afforded stacks of porphyrins [144, 145]. Bis(4(5)-imidazolyl)porphyrin **134** was synthesized to investigate the formation of cooperatively hydrogen-bonded aggregation (Fig. 59A) [144]. Porphyrin-porphyrin interaction in

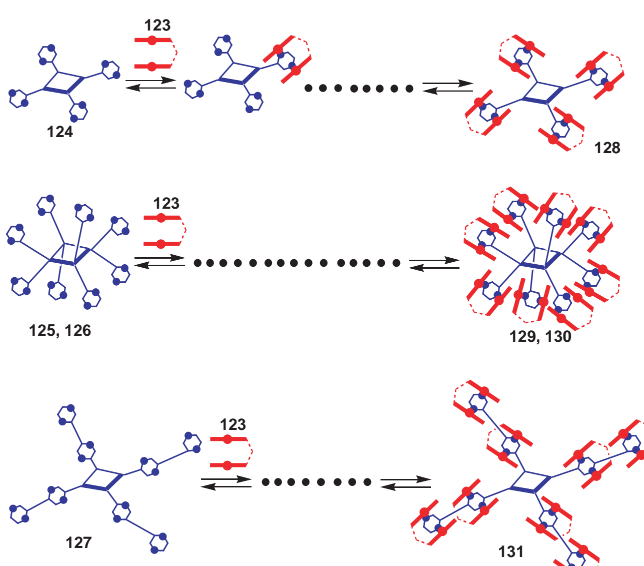

Figure 57. Formation of a porphyrin nonamer and 17-mers by stepwise complexation of **123** with **124–127** [141, 142].

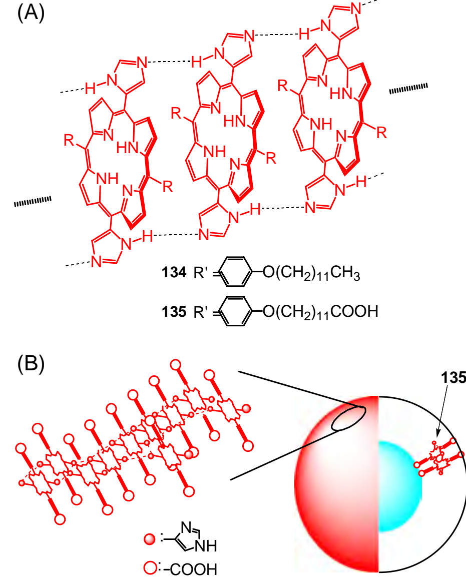

Figure 59. Schematic drawings of one-dimensional aggregation by imidazolyl-imidazolyl hydrogen bonds (A) [144], and of the liposome structure consisted of **135** in an aqueous solution (B) [145].

the resulting assembly of **134** reflected sensitively in their UV spectra. In nonpolar solvent such as toluene and cyclohexane, significant broadening of the Soret band was observed. This observation can be explained by the exciton coupling theory for two porphyrin chromophores. Since mono- and non-imidazolyl substituted porphyrins did not show such peak broadenings, cooperative hydrogen bonds and π-stacking interactions were necessary to form this supramolecular structure. ^{1}H NMR spectrum of **134** in $CDCl_3$ gave broad peaks, which were sharpened gradually by the addition of MeOD. Figure 60 shows the titration behavior of chemical shifts of imidazolyl, pyrrolic, and aromatic protons. The down-field shift with increasing CD_3OD amount was observed indicating gradual breakage of hydrogen bonds between imidazolyl groups. Energy and/or electron transfer reactions were examined from the supramolecule to the externally added acceptor, such as benzoquinone or Mn(III)porphyrin. The increased efficiency by a fact observed for the supramolecule compared with monomeric species was ascribed to delocalization of excitation energy over the whole space of the supramolecule.

This idea of supramolecular organization by imidazolyl-imidazolyl hydrogen bonds has been applied to form liposome by their own intermolecular interactions alone without assistance of any other lipid components [145]. Therefore, amphiphilic bis(imidazolyl)porphyrin **135** having two *meso*-ω-carboxyalkoxyphenyl substituents as hydrophilic head groups was synthesized. Compound **135** was dispersed in water by sonication and subjected to a gel filtration column separation to isolate the fraction corresponding to small unilamellar vesicles (Fig. 59B). The formation of liposome with a mean diameter of 27 ± 8 nm was supported by dynamic light-scattering (DLS) measurements. Figure 61a shows a top view of the AFM image and Figure 61b the side view along the line in Figure 61a. The observed width at the baseline level was 26 nm. A TEM image of the liposome dispersions showed many particles of diameters in the range 20–30 nm corresponding to the size distribution obtained by the DLS measurement, as shown in Figure 61c. The liposome possessed a cavity containing an interior aqueous phase and could keep polar solutes inside the liposome.

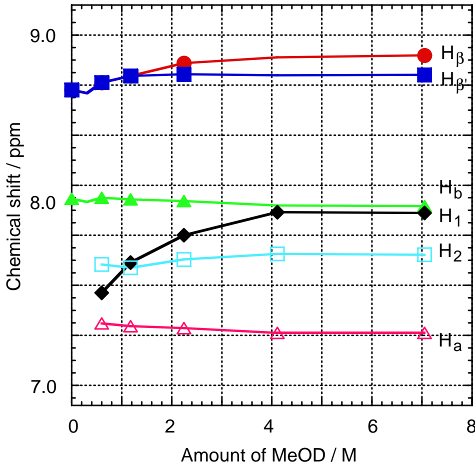

Figure 60. NMR titration of **134** in $CDCl_3$ with CD_3OD.

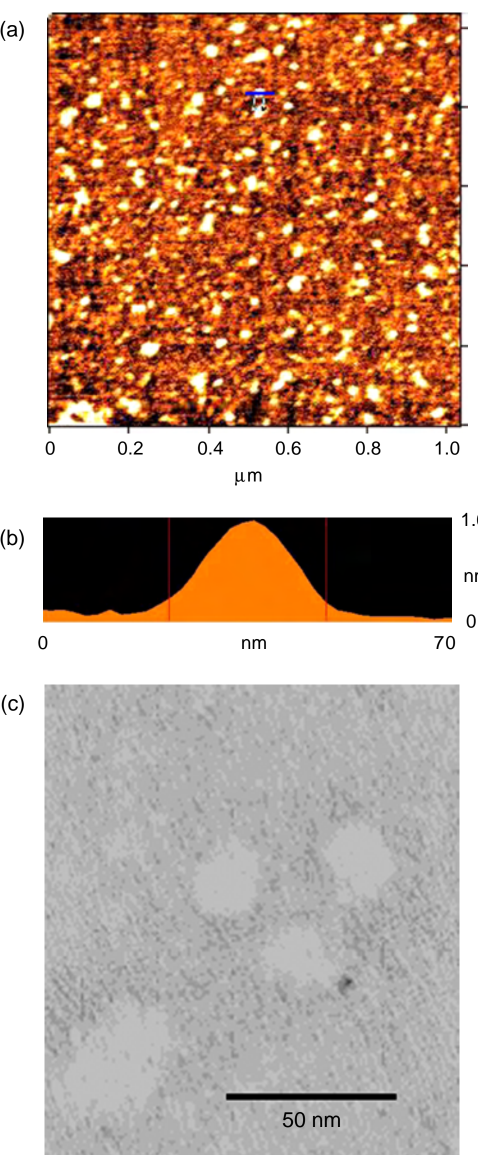

Figure 61. AFM image of dispersion prepared from **135** developed on mica. (a) A top view and (b) a cross section along the line in (a), (c) TEM image of negatively stained samples of dispersion from **135** with uranyl acetate.

The liposome obtained solely from porphyrin amphiphiles is regarded as a huge light-harvesting antenna, which could be regulated in a nanometer-scaled structure.

5. SPECTROSCOPIC CHARACTERIZATION OF SELF-ASSEMBLED PORPHYRIN ARRAYS

If the interaction between porphyrin chromophores in the resulting multi-porphyrin array is strong enough to induce the exiton couplings [92], its absorption spectrum is changed from that of a monomer or subunit, depending on the distance and orientation between porphyrin chromophores. In the self-assembled systems, porphyrins in the array are

arranged in various orientations to each other and investigation on spectral changes allows structural information of the assembly. Furthermore, the absorption and fluorescence spectra shift to longer wavelengths by fifth and sixth axial ligation to metalloporphyrin [146]. Here, we introduce two examples of our self-assembled porphyrin arrays to explain the exciton interaction between porphyrin chromophores.

Figure 62 shows absorption spectra of slipped cofacial dimer **45** (solid line) and its free base monomeric porphyrin **136** (dashed line) in $CHCl_3$ with a schematic representation of two perpendicular transition dipoles, M_x and M_y. In the case of monomeric porphyrin, these transitions are almost degenerated and therefore a single Soret band appears at 414 nm. On the other hand, the Soret band of dimer **45** split into two peaks to appear at 408 and 430 nm, as a result of blue- and red-shifts from the degenerated band, respectively. This splitting behavior can be explained by the exciton theory [92]. As shown in Figure 63, the interaction between two dipoles of M_x orienting along the head-to-tail direction induces two exciton states and the in-phase transition (in the same direction) is allowed, but the out-of-phase transition (in the opposite direction) is forbidden, resulting in the red-shift. In a similar way, the interaction between two M_y components in a face-to-face arrangement causes a blue-shift of the Soret band. These explanations accord with the observed spectrum and may apply to other self-assembled systems arranged in face-to-face or head-to-tail geometry.

In Section 3.3, we discussed the multi-porphyrin array **72** prepared by coupling of the complementary coordination unit of imidazolyl to central zinc **45**. The one-dimensional polymer **72** has a huge molecular weight in chloroform and exhibits large split of the Soret band appearing at around 410 and 490 nm; splitting width was approximately 80 nm, as shown in Figure 64. The splitting behavior of **72** can be explained again by using the exciton interactions caused by *meso-meso* coupling and coordination. Covalently linked porphyrin array at *meso*-positions has been developed first by Osuka and co-workers and its splitting behavior of the Soret band was explained by exciton interaction between

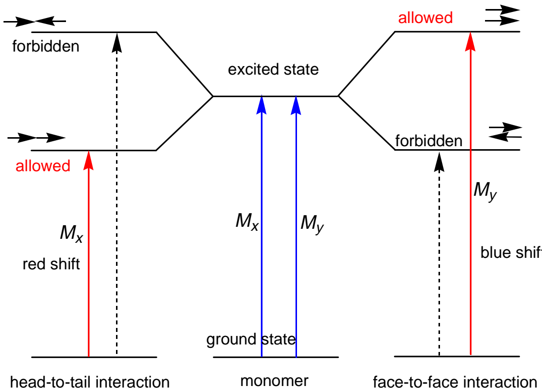

Figure 63. Energy level diagram for splitting behavior of the Soret band of dimer **45** in Figure 62.

M_x components inducing a large red-shift, with no interaction for M_y and M_z due to the orthogonality [147–149]. For example, the Soret band of *meso-meso* coupled free base porphyrin dimer (demetallated **71**) was split into 415 nm for M_y and M_z components and 453 nm for the M_z component; splitting width was 38 nm [108]. The complementary coordination in **72** induces another exciton interaction in a slipped cofacial arrangement. As mentioned earlier, the interaction of M_y's or M_z's components in a face-to-face orientation gives a blue-shift of the transition to 410 nm. On the other hand, M_x's components are shifted to a longer wavelength up to 490 nm by interaction with those of the neighboring porphyrin units. The shift at longer wavelength should depend on the degree of coordination. Therefore, the effect of addition of MeOH, which is a competing ligand to break the zinc-imidazolyl coordination bond, to a $CHCl_3$ solution of **72** was examined by monitoring the absorption spectrum (Fig. 64). The splitting width of the Soret band decreased with the addition of MeOH, resulting in an obvious blue-shift of the longer Soret band passing through a

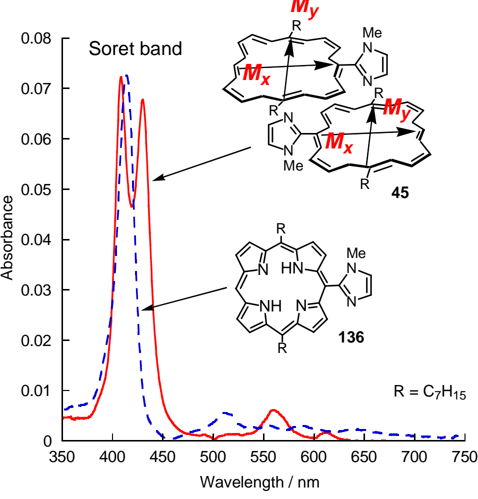

Figure 62. Absorption spectra of complementary coordination dimer of **45** (solid line) and its free base monomer **136** (dashed line) in $CHCl_3$.

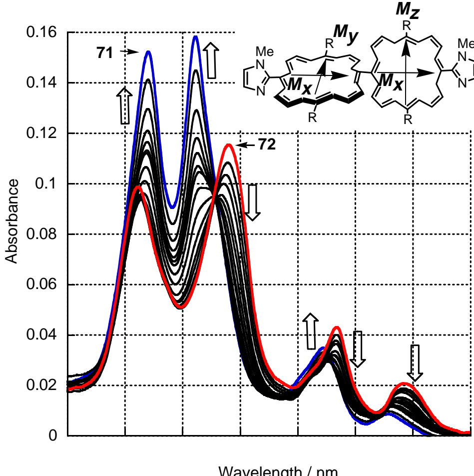

Figure 64. Change of absorption spectra by the addition of MeOH to a $CHCl_3$ solution of **72**. Each spectrum was measured after the addition of MeOH in the amounts 0, 1, 2, 3, 4, 5, 7, 9, 10, 12, 14, 16, 20, 25, and 30 volumes to 100 volume of the $CHCl_3$ according to the order of the arrow indicated.

clear isosbestic point at 478 nm and a smaller red-shift of the shorter Soret band. On the addition up to 30% MeOH, the shift reached almost the saturation point with the splitting of 41 nm corresponding to that of isolated **71**. These results clearly show that the addition of competing ligand such as MeOH can simply and reversibly control the length of self-assembled porphyrin array.

Conjugation of diacetylene linked porphyrin array conducted by Anderson could be controlled by the axial ligand and to construct and to break ladder complexes **80** and **81** (see Fig. 38) [42, 115–117]. The ladder formation was expected to force coplanar arrangement in neighboring porphyrin units, and might increase the conjugation between porphyrins inducing red-shift in absorption spectrum due to the decrease of HOMO-LUMO bandgap energy. As shown in Figure 65, the ladder complex **80** (n = 6 and L = DABCO) exhibited red-shifted Q-band at around 840 nm and Soret bands of a larger split width [116]. The spectral features were changed by the addition of excess DABCO breaking the ladder complex. The blue-shifted Soret band due to weak face-to-face interaction in the ladder complex shifted to longer wavelengths indicating the dissociation of the stack. At the same time, the longest Q band in the ladder shifted to shorter wavelengths because of the lack of conjugation by free rotation about the diacetylene bonds. When 4,4′-bipyridyl was chosen as the bridging ligand L, Q band became sharper and was red-shifted by 16 nm relative to that of the complex with DABCO, indicating more planar arrangement due to the elimination of the steric hindrance between the interstrand aryl groups. Figure 66 compares the absorption spectrum of free base dimer **138** (a), zinc dimer-pyridine complex **137** · (pyridine)$_2$ (b), and triple-strand **81** (c) in CH_2Cl_2. The spectrum (c) was not represented by the simple sum of spectra (a) and (b) indicating that the conformations of **137** and **138** were changed by the formation of the triple-strand **81**. The splitting width of the Soret band increased and the Q band shifted to longer wavelength showing expansion of conjugation due to increase of the planarity too.

6. PROPERTIES OF SELF-ASSEMBLED PORPHYRIN ARRAYS

One of the goals of research on self-assembled porphyrin array is to develop practically useful materials in the molecular electronic and photonic devices as well as artificial photosynthetic system to convert light energy to electric power. Various types of self-assembled porphyrin arrays fabricated in nanometer-scale have been reported and introduced in this chapter. However, the technology to realize the molecular-sized electronic devices has not been achieved yet by using the multi-porphyrin array as well as other conductive organic molecules. On the other hand, NLO property and photocurrent generation by using multi-porphyrin arrays have been studied extensively in recent years. In this section, we will introduce the importance of noncovalent assembly of porphyrins to develop the NLO materials and highly efficient photocurrent generation system.

Third-order NLO materials with a large real part of susceptibility $\chi^{(3)}_{real}$ are useful for ultrafast optical switching and light modulation device to realize the all-optical networking [29–31]. Furthermore, two-photon absorption (TPA) is one of the third-order NLO phenomena corresponding to the imaginary part $\chi^{(3)}_{im}$ and is a nonlinear absorption process depending on an incident light intensity [150]. TPA materials could find useful applications for 3D optical memory, photodynamic therapy, optical power limiting, 3D microfabrication, and fluorescence microscopy. The strong optical nonlinearities are given in principle by large π-conjugated molecules. Additionally, introduction of donor/acceptor groups at the molecular terminals increases

its polarizability and induces much larger NLO response. As mentioned in Sections 3.4 and 5, the third-order NLO properties of π-conjugated multi-porphyrin arrays of diacetylene linkage have been studied [40–42]. Double-strand polymer **80** (L = 4, 4′-bipyridyl) exhibiting larger conjugation due to planarity between porphyrin units than that of single-strand polymer **139** (Fig. 67) was used for the NLO study to test the effect of increased conjugation on the optical nonlinearity by degenerate four-wave mixing measurement with 50-ps pulse laser at 1064 nm [42]. The number average molecular weights (M_n) of **139** and **80** were determined as 2.1×10^4 and 5.6×10^4 Da, respectively, by GPC analysis. The real part of molecular polarizability per porphyrin unit $|\gamma_{xyyx}|$/N of **80** was determined as 7.6×10^{-45} m^5 V^{-2}, which was nine times amplified relative to that of **139** (0.84×10^{-45} m^5 V^{-2}) by the formation of ladder structure, where SI units of m^5 V^{-2} may be converted to esu unit by multiplying $(4\pi/9) \times 10^{-8}$ [41]. Further, a large two-photon absorption cross section was observed at 1064 nm for **80** as 5×10^4 GM, which was also seven times enhanced by ladder structure formation. These observations were explained by a reasonable assumption of three-level model [40–42] and showed that the self-assembly of double-strand formation might be useful for nonlinear optics.

In addition to expansion of π-conjugation, introduction of donor/acceptor substituents into the array structure to induce higher polarizability is another important factor to increase the NLO property. The self-assembled linear porphyrin array **72** (Fig. 31) can scramble with a specific terminator porphyrin **73** in $CHCl_3$/MeOH or pyridine to afford oligomers **74**. Since the molecular polarizability of the oligomer is expected to increase by choosing the acceptor groups at both molecular ends, two series of porphyrin oligomers were simply synthesized by the reorganization process. One of the series had no acceptor (R′ = n-heptyl) **140–142** and the other was terminated with porphyrins as an acceptor **143–145** (Fig. 68) [43]. Table 1 summarizes results of optical Kerr effect (OKE) measurement with 150-fs pulse laser at an off-resonant wavelength of 800 nm. The $|\gamma_{yyyy}|$

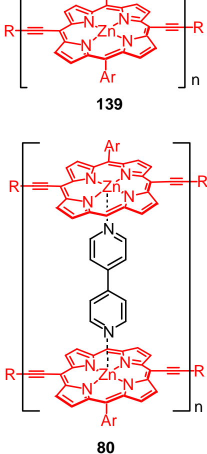

Figure 67. Structures of conjugated porphyrin polymer **139** and double-strand ladder **80** for NLO measurements by DFWM with 50-ps pulse laser [42].

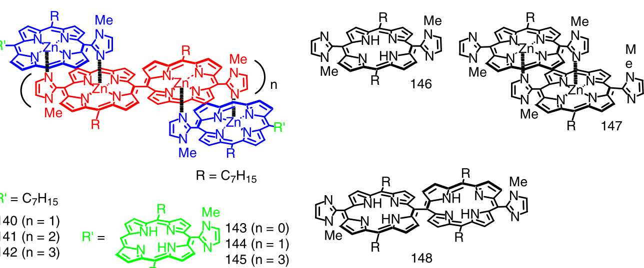

Figure 68. Structures of porphyrins for optical Kerr effect measurements with 150-fs laser [43].

values of oligomers **140–142** were in the range from 10^{-31} to 10^{-30} esu, while the $|\gamma_{yyyy}|$ of the series of compounds **143–145** were extremely large, ranging from 10^{-30} to 10^{-29} esu, 10 times larger than those of **140–142**. The large enhancements of the $|\gamma_{yyyy}|$ values were observed when free base porphyrins were attached at the terminal positions of core zinc porphyrin arrays. The terminal free base should have acted as an acceptor with respect to inner zinc porphyrin. The complementary coordination structure must also have contributed to such a large increment of nonlinear response. There are several reports on NLO materials, but the values are difficult to compare, because methods and conditions are different in each experiment. Here, NLO properties of organic molecules measured under similar conditions to the above, that is, employing an OKE technique with femtosecond pulse laser at off-resonant wave length, will be compared [151, 152]. The γ values, corresponding to $|\gamma_{yyyy}|$, of C_{60} derivative with electron donor, -$(NH_2)_2$CNCN, was determined to be 3.5×10^{-32} esu as the largest among C_{60} derivatives [151]. A donor-acceptor conjugated copolymer consisting of 2,7-diethynylfluorene as the acceptor unit and tetraphenyldiaminobiphenyl as the donor site with average molecular weight (M_w) of 17,600 (M_w/M_n = 2.8) showed the γ value of 450×10^{-32} esu [152]. These values may be comparable to those of the porphyrin system summarized in Table 1. There is a possibility to obtain large nonlinearities by covalent approach to connect donor/acceptor substituents to porphyrin, but it means a difficult synthetic target to develop such systems. The methodology of simple

reorganization process in the self-assembled system presented here may afford a facile structural modification to gain even further large nonlinearities. This optical nonlinearity observed in a femtosecond time scale is a candidate for the application to ultrafast optical switching.

The self-assembled porphyrin system by complementary zinc-imidazolyl coordination has been applied to photocurrent generation [109]. Thiol group, –SH, is well known to be attached to gold surface to produce stable —S—Au bonds. Terminal monomeric porphyrin **73** bearing an ω-mercaptoalkyl substituent (R′ = -$OC_6H_{12}SH$) was attached onto gold electrodes to obtain a self-assembled monolayer, SAM (Fig. 69). Multi-porphyrin array **72** then propagated on this SAM simply by accumulating bisporphyrin **71** as follows: an aliquot of **72** dissolved in a 1:1 mixture of pyridine/nitrobenzene in order to dissociate the array structure into monomeric **71** was applied dropwise to the electrode and pyridine was evaporated to develop the complementary coordination of imidazolyl to the central zinc. Another aliquot of porphyrin was applied again and the accumulation procedure was repeated. Absorption spectrum of this multilayered electrode showed an increase of light absorption depending on the repeated number of the deposition cycles

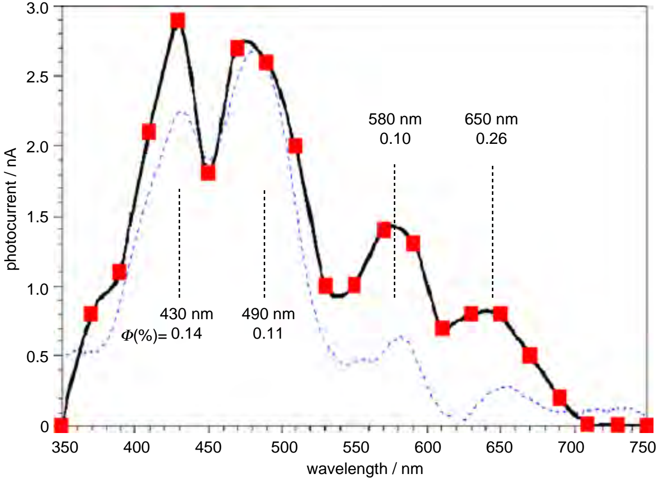

Figure 71. The action spectrum (square plot) with absorption spectrum (dotted line) of multilayered electrode.

in the range of 350 to 750 nm [109, 110]. AFM measurement confirmed long porphyrin assemblies extending from the surface of the electrode (Fig. 70). The heights were not homogeneous with a broad distribution and some assemblies reached a scale of a few hundred nanometers. Irradiation of the multilayered electrode generated photocurrent more efficiently compared with simple SAM. The action spectrum, which was obtained by plotting photocurrent as a function of the irradiating wavelength, resembled the absorption spectra of porphyrin-assembled electrodes in the whole range of 350 to 750 nm (Fig. 71). Photocurrent quantum efficiencies [153] at the respective absorption peaks were estimated as 0.14% (430 nm), 0.11% (490 nm), 0.10% (580 nm), and 0.26% (650 nm). Photocurrent values of SAM and multilayered electrodes (a)–(d) are plotted as a function of the absorption area ($A\lambda$) integrated over the range of 350 to 750 nm in Figure 72. The photocurrent density linearly increased with

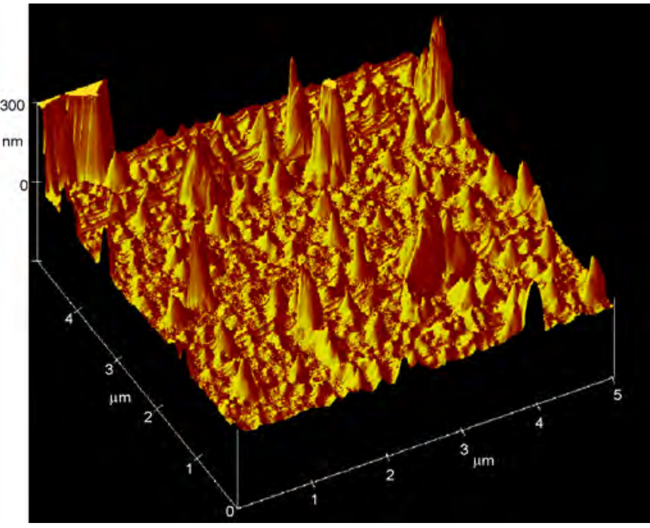

Figure 70. AFM image of multi-porphyrin array propagated from SAM on gold electrode.

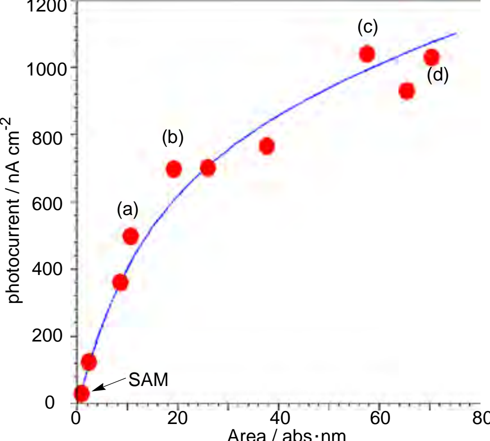

Figure 72. Plot of photocurrent density of SAM and other electrodes as a function of the absorption area integrated over the range 350–750 nm. Concentration and repetition cycles are (a) 1 mM and once (n = 2), (b) 0.1 mM and three times (n = 4), (c) 1 mM and three times (n = 13), and (d) 1 mM and four times (n = 16), respectively.

the increase of the absorption area especially in the range 0–20 $A\lambda$. This increase came from the improved efficiency in absorbing light energy and the excitation energy transfer by perpendicularly accumulated porphyrins from the surface. Further, effective charge separation and electron/hole transfer along the multi-porphyrin chains may be contributing to the photocurrent generation. Although the SAM technique has opened an excellent way to lead realistic materials, the single-molecular layer on the surface is limited by the low efficiency of light absorption. The process by self-assembly accumulating the chromophore to multiply light absorption may propose a strategy for solving the problem.

7. SUMMARY

In the past few years, much attention has been focused on nanostructure generation and nanotechnology, and large bodies of porphyrin architectures have been constructed by using covalent and noncovalent linking methodologies. In this review, we have presented self-assembled porphyrin systems toward photosynthetic mimics and single molecular devices constructed by noncovalent interactions of hydrogen bond, π-π interaction, coordinations of *meso*-substituted ligand to outer metal and other porphyrin centers. In order to build desirable nanostructures with specific function for the practical use, there are several important points on designing porphyrin assemblies: (1) Direction to connect porphyrins is determined by the coordination direction of the *meso*-substituted ligand and coordination geometry around the metal ion. The same is true for multiple hydrogen bonding interactions. (2) Stability of the porphyrin-porphyrin connection depends on the number of interactions, that is, cooperatively multiple bindings are more effective than single binding. (3) If transition metal ions with unoccupied d-orbitals are chosen as the porphyrin center, singlet excitation energy is quenched and therefore fluorescence and photocurrent generation will not be expected. Instead, variable oxidation states of the transition metal are thought to be advantageous for electric conduction and switching of the coordination properties. (4) Strength of the interaction between neighboring porphyrins increases with decrease of the interplanar distance, and then strong interaction causes change in their spectroscopic features and reduction-oxidation properties.

Synthesis and purification of porphyrins are not easy tasks considering their preparative methods associated with low yields and large amounts of by-products. Even so, the porphyrin building block fascinates researchers because of its high π-conjugation system assembled in one nanometer-sized building block. Porphyrins accommodate various metal ions into the center acting as molecular recognition site and allow the introduction of various functional groups at *meso*- and β-positions to construct wonderful nanoarchitectures.

GLOSSARY

Atomic force microscopy (AFM) One of the scanning probe microscopies by detecting the local force operating between sample surface and probe tip. The spatial resolution is usually a few nm.

Association constant Equilibrium constant of forward complexation reaction; $L + M = LM$, $K = [LM]/([L] \times [M])$. Synonymous with stability constant. Reciprocal of dissociation constant.

Chelate Metal complexation by multidentate ligand. The word "chelate" came from craw of crab in Greek.

Chemical shift In the NMR spectroscopy, the resonant frequency depends on the effective magnetic field around the nuclei, which are affected by induced magnetic field by electron. The shielding effect increases with an electron density. The chemical shift is proportional to strength of the magnetic field and represented as the ratio of frequency with that of reference in ppm.

Cyclic voltammetry Electrochemical method to determine the oxidation/reduction potential.

Dendrimer Well-regulated highly branched polymer.

Dynamic light scattering (DLS) Characterization of particle size from diffusion coefficient given by the light scattering measurement.

Fluorescence Emission of light from excited singlet state after the absorption of light energy.

Fluorescence anisotropy decay The measurement of anisotropy as a function of time by laser pulses provides the rate of the excited energy transfer or migration.

Fluorescence quantum yield A ration of the number of emitted photons to the number of absorbed photons.

Förster model Energy transfer theory explained as dipole-dipole interaction between donor and acceptor. In this model, the emission band of donor must overlap with the absorption wavelength of acceptor.

Gel permeation chromatography (GPC) Analytical or preparative method to separate a mixture based on difference in molecular size or shape. GPC analysis gives an information on molecular weight by comparison with appropriate standard samples.

Hard-soft-acid-base rule (HSAB rule) One of the measures for relative strengths of acids and bases. An acid, usually a metal ion, prefers the bases having similar softness or hardness.

Heavy-atom effect See the singlet-triplet intersystem crossing.

Highest occupied molecular orbital and lowest unoccupied molecular orbital (Homo-Lumo) Usually, HOMO and LUMO correspond to the ground state (S_0) and the lowest excited state (S_1), respectively.

Hydrophobic interaction Hydrophobic solutes strongly interact with each other in hydrophilic media such as in water.

Liposome Spherical bilayer membrane structure entrapping inner aqueous phase with a size of around a few nm to a few μm.

Mass spectroscopy Determination of molecular weight by detecting the positively or negatively charged molecular ion. There are several ionization methods such as FAB (fast-atom-bombardment), ESI (electrospray ionization), MALDI (matrix-assisted-laser-desorption-ionization), and so on.

Molecular mechanics calculation A calculation method giving optimized-structure and energy for conformations of

molecules based on the empirical bond lengths and angles, strain, torsion, steric repulsion, van der Waals interaction, and electrostatic interaction.

Nuclear magnetic resonance spectroscopy (NMR) NMR gives information on the chemical environment around nuclei. The nuclei having no spin such as ^{12}C exhibits no magnetic resonance, but if net spin is not zero as seen in ^{1}H and ^{13}C, we can observe NMR signals allowing information about chemical structure such as chemical shift, spin coupling, and integration.

Optical kerr effect (OKE) Refractive index of molecule or media is proportional to the incident light intensity.

π-π interaction π-Stacking interaction due to overlapping of π-electron cloud between aromatic groups.

Peptide Amide bond, -NH-CO-, formed from amino group of an amino acid and carboxy group of another amino acid.

Ring current effect The shielding effect, which comes from the magnetic field generated by π-electron system. Effective magnetic field of nuclei is shielded by this effect to reduce the chemical shift.

Singlet-triplet intersystem crossing Transition from single/triplet state to triplet/single state. In principle, single-triplet transition can not occur due to spin-forbidden. However, we can observe the triplet state transition from the singlet state mostly by the presence of spin-orbit coupling. Facile intersystem crossing can be expected when a molecule contains a heavy atom because of large spin-orbit coupling (heavy atom effect).

Small-angle X-ray scattering measurements (SAXS) SAXS provides information on the size and shape of macromolecule or colloid in the spatial range from 1 to 300 nm.

Space-filling model Same with CPK model developed by Corey-Pauling-Koltun. The tool for molecular graphics and modeling based on van der Waals radii.

Superexchange mechanism Electron transfer reaction, which occurred through chemical bond allowing long-range electron transfer even at low temperature. Molecular orbital of bridging or spacer group might be used as the electron path from donor to acceptor.

TEM (transmission electron microscopy) TEM works like a optical microscope by using electrons instead of light. The shade of transmitted electrons through the sample was detected by fluorescence screen attaining a possible spatial resolution higher than 1 nm.

Transient absorption measurement Time resolved absorption spectrum measurements providing information on an excited state of a molecule and a lifetime of excited state or charge separated state by using laser pulses as the excitation light.

van der Waals interactions Interactions between instantaneous electrical polarization induced by electron movement in the molecule, called van der Waals dispersion forces.

Vapor phase osmometry (VPO) Determination of a mean molecular weight by vapor-pressure and osmometric measurements of a sample solution.

X-ray crystallography Powerful tool for determination of three-dimensional structure of molecule by measuring X-ray diffraction of a single crystal. Precision atomic coordinates, thermal parameters, and symmetric properties can be obtained.

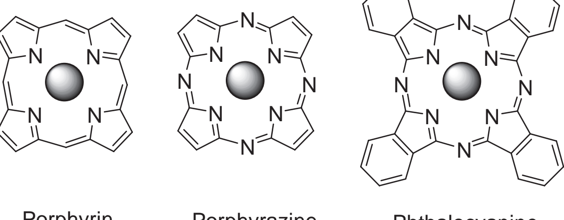
CONTENTS

1. Introduction
2. Self-Assembled and Self-Organized Porphyrinic Materials—Nomenclature and Descriptors
3. Assemblies Mediated by Coordination Chemistry
4. Assemblies Mediated by Hydrogen Bonding
5. Assemblies Mediated by Electrostatics
6. Porphyrins on Surfaces
7. Miscellaneous Multi-Porphyrin Assemblies and Aggregates
8. Summary
Glossary
References

1. INTRODUCTION

The manifold applications of porphyrins, porphyrazines, and phthalocyanines derive from their photophysical and electrochemical properties, their remarkable stability, as well as their predictable and rigid structure. These applications range from oxidative catalysts, to photonic materials, to therapeutics. The properties of all three pigments are modulated by appending various chemical moieties onto the macrocycles, by choice of metallo derivative, and by the choice of environment. In materials containing multichromophoric



systems, furthermore, the relative orientation of the chromophores, the nature of the linker, and the size of the system also dictate the properties and functions. Nanoscaled assemblies, aggregates, or crystals composed of these dyes display photonic properties unobtainable either by single molecules or by bulk materials. With these concepts in mind, there has been considerable effort in the design and synthesis of chromophores that self-assemble or self-aggregate into predictable, precisely positioned structures. Although this chapter focuses on porphyrinic systems, many of the same concepts and methodologies are applicable for the latter two pigments.

1.1. Porphyrinoids

Porphyrins are tetrapyrrole macrocycles that are found in nature in systems such as hemoglobin and various photosynthetic systems [1], but a very large number of derivatives have been synthesized in the laboratory. Historically, the phthalocyanines were discovered early on in synthetic dye industry, and the porphyrazines came later. Though all three types of

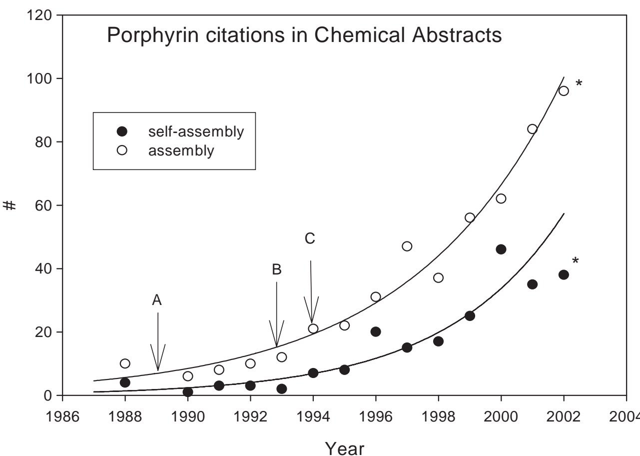
macrocycle have related photophysical properties, the porphyrins have been the primary focus of research because of synthetic accessibility and greater solubility in organic solvents. While much of the research in the past decades on multiporphyrin systems has been directed toward understanding electron/energy transfer processes in biology [2–8] and to a lesser extent in polymers [9–14], more recently, some of the focus has shifted toward other applications such as components of molecular electronic and photonic materials [3, 15–19]. Other applications exploit both the photophysical properties and the rigid structure of porphyrins to make materials such as molecular sieves [20–22], catalysts [23], sensors [24], actuators [25], and nonlinear optics [26]. Much elegant organic synthetic work has yielded discrete multiporphyrinic systems held together by covalent bonds, especially with acetylene and phenyl acetylene linkers [13, 27–46], and by direct bonding or fusion of the porphyrin macrocycles [29, 47–52]. The physical characterization of these types of molecules has provided insights into the complexities of electron/energy transfer processes [28, 32, 33, 53]. The Achilles' heel of most discrete molecular systems containing more than a few porphyrins is that the overall yield is too low to be commercially viable. Similarly, the synthesis of porphyrin polymers, either by themselves or grafted onto/into a variety of well-established polymeric systems, has also yielded interesting materials that have a distribution of properties due to polydispersity [9–12]. In most cases, the precise positions of the photoactive moieties in polymers are neither predictable nor precise. Both the relative positions of the macrocycles and the nanoscaled size of the system are necessary for the function of many photonic materials [54]. Thus, many labs have exploited supramolecular chemistry to self-assemble and self-organize porphyrins into a large variety of nanoscaled arrays, aggregates, or crystals that serve as the active components of materials with diverse functions [19, 35, 55–58]. Since the supramolecular chemistry of porphyrins is by far the most developed, the focus of this chapter is on the recent developments in functional, supramolecular, porphyrinic materials. However, studies on the assemblies of porphyrazines and phthalocyanines have yielded interesting results [59].

The opportunity to provide a perspective on self-assembling and self-organizing porphyrinic materials is both exciting because of the tremendous progress in the field (Graph 1), and daunting because of the limited time and space to accomplish the task. Thus, boundaries must be set. The primary focus of this chapter will be on the developments of the last few years since there are several reviews and chapters that cover the large body of work on the chemistry, the properties, and application of porphyrins up to early 2000 [35, 56–61]. There are also a variety of reviews on both self-assembly and multiporphyrin systems [55, 56, 61–68]. Unfortunately, the excellent work on covalently bound multiporphyrin arrays, dendrimers [33, 69–72], and polymers such as phenylacetylene linked arrays of Lindsey [27, 28, 31–34, 37, 38], the directly linked and fused systems of Osuka and others [29, 47–51, 73], the acetylene linked arrays of Therien [39–46] and Anderson [74, 75] or the polymeric materials of Jones [9–12, 76, 77], and the multichromophoric photosynthetic mimics of Gust [78, 79] among others, is



Graph 1. The number of papers cited in chemical abstracts on self-assembling porphyrins is increasing exponentially. Key papers include the electrostatic assembly of an ion-conducting chain (A) [257], a discrete dimer by H-bonding (B) [237], and discrete arrays by metal ion coordination (C) [140]. * = Projected.

also beyond the scope of the present review.[1] There are also numerous reports on the incorporation/encapsulation of porphyrins into gels and other matrices [80]. All of these covalent or aggregated systems have provided a wealth of knowledge on the chemistry, photophysics, and potential applications of porphyrins to modern materials. The design and synthesis of supramolecular porphyrinic materials build upon our understanding of the biological and covalent analogues, in the hope of understanding or mimicking the former, and improving or finding new properties compared to the latter.

1.2. Biological Inspiration and Current Uses

Any discussion of porphyrins must acknowledge that the initial inspiration for research in the field arises from the diverse functions of these molecules in various biological processes. Photosynthesis is the source of most of the free energy that makes life on earth possible—both in terms of stored energy and in the production of dioxygen. Porphyrins [1] are the chief arbitrator of solar energy in photosynthesis; therefore life depends on these molecules. A variety of diverse organisms exploit porphyrins in extraordinarily different ways because of their stability, their photo- and electrochemical properties, and the ability to fine-tune these functions by modifications of either the tetrapyrrole macrocycle or environmental factors. These functions include: (1) chlorophylls are used in the collection and conversion of solar energy into chemical potential in photosynthesis [6], (2) iron porphyrins are used as oxidation catalysts such as in cytochromes P450 [81], (3) iron porphyrins serve as electrical conduits or shuttles such as in cytochromes C, (4) nickel porphyrinoids are used as reducing agents such as in methyl-coenzyme-M reductase [82], (5) iron porphyrins act as the transporter of small molecules such as in hemoglobin and myoglobin. It is not surprising, then, that the chemistry,

[1] Our aim is to derive general themes from the "mis-shapen chaos of well-seeming forms!" (W. Shakespeare, *Romeo and Juliet I*, 1, 184).

structure, and function of porphyrins continue to be of interest even after over 150 years of research [1].

Porphyrins also form the basis of many commercial products that serve, among other things, as catalysts, sensors, and therapeutics. The synthesis and application of porphyrins and porphyrinic materials to *circa* 2000 has been extensively reviewed [60]. At present the porphyrins in these products are either monomers or short conformationally dynamic oligomers, and the function arises from the aforementioned diverse photo- and electrochemical properties of the macrocycle as well as their robustness. In contrast to the commercial products, the function of biological photosynthetic systems relies on arrays of several to hundreds of porphyrins in a precise structural arrangement [2, 6, 83–86]. These nanoscaled solar energy converters are nearly quantum efficient! Inspired partly by biology and partly by the need for technological innovation to make materials with new functions, there has been substantial effort to synthesize multiporphyrinic systems by both covalent, *vide supra*, and non-covalent bonds. For reviews to 2000, see [35, 55, 56, 58, 60, 61, 65, 67, 87–93]. Both routes have advantages and disadvantages. Covalently linked multichromophore arrays (see, e.g., [19, 28, 29, 37, 49, 50, 61, 94, 95]) are discrete molecules and can be purified, thus facilitating characterization of both structure and function. These covalent systems have been pivotal in our understanding of the photo and electronic (photonic) properties of large dye-containing molecules. Most large, complex multiporphyrinic structures are difficult to make in appreciable quantities and yields via synthetic organic chemistry, and this is a major impediment to their use in commercially viable products.

1.3. Self-Assembly and Self-Organization

Supramolecular chemistry uses designed intermolecular interactions (non-covalent bonds) and shape complementarities to self-assemble or self-organize simpler molecules into more complex structures that are often unobtainable by synthetic organic chemistry (see, e.g., [89, 96, 97]). Intermolecular forces are heuristically divided into several sometimes-overlapping types, but all arise from the distribution of electrons on the molecule or atom. The self-assembly and self-organization of molecules into ever more complex structures relies on the molecular information programmed into the component molecules in terms of specific and nonspecific intermolecular interactions [97]. Conceptually, specific intermolecular interactions (such as metal ion coordination and hydrogen bonding) tend to be directional and more predictable than nonspecific intermolecular interactions (such as van der Waals and other electrostatic forces) which tend to be nondirectional and have a broader range of interaction energies and distances [54]. In general, self-assembly refers to the synthesis of discrete or highly ordered systems wherein there is little tolerance for error. In contrast, self-organization tends to entail the organization of many copies of molecular or supramolecular subunits, and is more tolerant of error [98]. Both self-processes are stochastic and dynamic in the sense that the molecules search conformational, dynamic, and associative space as they evolve into a structure or structures that represent a thermodynamic minimum. Intermediate kinetic products with different structures may sometimes be observed and isolated. An elegant essay by Lehn [97] further discusses molecular informatics. Since supramolecular entities are usually thermodynamic products formed from equilibrating solutions, the problem with this approach is that the structure often changes as conditions vary. However, the photonic properties of several robust supramolecular porphyrinic systems have been reported (see, e.g., [54, 77, 99–103]).

Supramolecular materials and devices have hierarchical structure, and in analogy to the terms used in structural biology, these can be classified as the primary, secondary, tertiary, and quaternary structure of a system (Fig. 1) [98, 100, 104]. The primary structure is the individual molecular components. The secondary structure is the designed, supramolecular entity formed by self-assembly processes. Though there is much to be discovered, synthetic chemistry and synthetic supramolecular chemistry are well-developed fields. The tertiary structure then describes the structural relationship of the supermolecule to its immediate environment, as in crystal packing and aggregation where the supermolecules self-associate, or in another modality, how the supramolecular system positions into/onto substrates. Though there has been notable progress especially with porphyrin tectons for crystal engineering [20, 21, 105–110], there is much to be learned in this arena, as we are unable to *a priori* predict the packing of unit cells into crystals [111–113] or to control aggregation such that the product is monodispersed. Finally, the quaternary structure describes how the self-assembled or self-organized material is incorporated into a device via another self-process (as opposed to, e.g., manipulation of individual structures with a scanning probe microscope tip). The interconnections to the macroscopic world may also be a part of the quaternary structure. This last structural descriptor is especially important for molecular electronics and nanoscaled devices, and is perhaps the least understood and developed.

In many ways the self-assembly of supramolecular porphyrinic materials has the opposite benefits and deficiencies as those made by synthetic methods—ease of synthesis from smaller components in greater yields, but added difficulties in characterization of both structure and function. Since

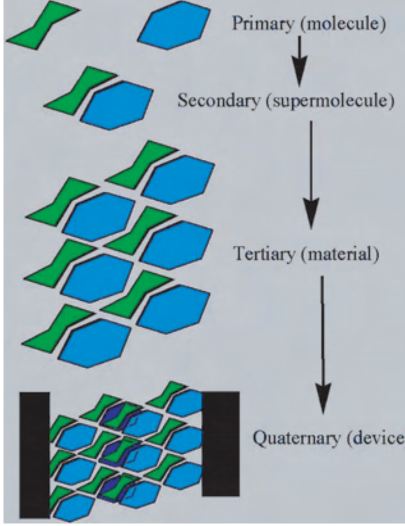


Figure 1. Levels of organization of functional materials.

supramolecular entities are usually thermodynamic products resulting from oftentimes-complex equilibria, characterization of self-assembled and self-organized systems can be difficult. Structural characterization of many supramolecular systems relies heavily on crystallography [20, 21, 105–113], but the structure in the crystal may or may not be relevant to the structure in solution. Several mass spectral techniques have been particularly useful in solution-phase characterization of self-assembled structures [114]. However, since most noncatalytic applications require solid-state porphyrinic materials such as crystals, colloids, or solids on surfaces, the solid state is of greatest concern. Recent developments in supramolecular porphyrin chemistry have begun to address this issue by correlating the structures in both liquid and solid phases [20, 99, 100]. Though generally not specifically addressed by practitioners of supramolecular chemistry, if the material must be crystalline in order to function as designed, the yield of crystals should also be considered. An approach used by many researchers is to design, synthesize, and study smaller supramolecular systems and use these results as a guide to form more complex structures with the same or similar molecular building blocks.

The practical applications of any nanoscaled photonic material based on organic substituents must thoroughly address three major stability issues: thermal fluctuations, oxidation/reduction reactions, and sensitivity to dioxygen. The structural fidelity of self-assembled and/or self-organized materials both in terms of deposition onto surfaces and in terms of thermal fluctuations is a major design criterion that has only recently begun to be addressed [115]. Porphyrins, phthalocyanines, and porphyrazines can be exploited to address all of these issues [60]. More recently, there has been a shift from synthetic supramolecular chemistry towards the design of nanoscaled systems that perform functions that rely on supramolecular structure [54, 55, 116]. For porphyrins [104], these applications include molecular electronics [16, 18, 19, 79, 117, 118], sensors [119–121] or sieves [20, 68, 106, 108, 122], receptors [123, 124], magnets [125–127], and molecular capsules for systems such as fullerenes [128–130].

1.4. Nanoscaled Photonic Materials

It is well established that the function of many materials depends on the geometric order of the component molecules and/or atoms as well as the molecular dynamics [54, 55, 97, 115, 116]. This is especially true of materials—biological or man-made—that are used to conduct electrons and/or photons (photonic materials), since these functions exquisitely depend on the relative alignment and relative energies of the molecular orbitals of the component molecules. Beyond the choice of molecule and the solid-state structure, the photonic properties of a system can be fine-tuned by making components that are on the scale of tens to hundreds of nanometers. Indeed, for the case of photonic materials, nanoscaled devices have properties that can be obtained neither by the component molecule nor by the "bulk" material. The unique properties of nanoscaled photonic materials arise from the confinement of the electrons to a volume with dimensions much less than the wavelength of light. There are numerous reviews on this topic, for example, for systems assembled by coordination chemistry [65, 101, 104]. The applications of porphyrin-based nanoparticles, assemblies, and layers may make inroads first as component devices for highly specialized applications, but as the field of nanoscaled photonics matures they will find further applications that disrupt the current technologies [131]. There are two fundamentally different approaches to self-organization: one uses designed interactions between molecules/ions to build up a three-dimensional structure, and the other uses an external mold such as aerogels to dictate the aggregation of the building blocks, which potentially can synthesize materials over "all length scales" [132]. The second method has been used mostly for inorganic materials, but these new methods are incorporating more complex organic molecules. This latter method also affords geometries not possible by simple self-assembly processes.

2. SELF-ASSEMBLED AND SELF-ORGANIZED PORPHYRINIC MATERIALS—NOMENCLATURE AND DESCRIPTORS

Given the above, the goal of much of the research on supramolecular chromophoric materials is to design materials with functions and properties that are beyond the range of covalent arrays and polymers. The formation of nonlinear optical (NLO) materials is often cited as a goal because of the need for non-centrosymmetric crystals (see, e.g., [26, 74] for recent porphyrin-based examples). Other applications include shape-selective catalysts, molecular sieves, sensors, actuators, and molecular electronics. The focus of this perspective is to provide insights into the formation and utilization of self-assembled and self-organized porphyrinic materials with special emphasis on the relationship between structure and function. Furthermore, we have generally limited the scope to papers published in the last three years since there are several excellent reviews up to *circa* 2000 *vide supra*. The perspective is divided by the mode of assembly/organization (e.g., metal ion coordination, hydrogen bond, electrostatic) and into discrete, open, and polymeric systems.

We have attempted to group the structures found in the literature into several broad, and occasionally overlapping, topological categories in order to discern trends in synthetic methodologies, structure, and function. "Discrete" means that the self-assembling building blocks are designed to result in only one supramolecular product albeit with varying yields. "Closed" describes a system that encompasses an area or volume wherein each molecule is at least ditopic, and is a subset of discrete systems. Conversely, "open" indicates a linear or branched system with obvious ends that in principle can be polymeric or discrete. Generally, at least one component of topologically open systems is monotopic. Discrete systems tend to be assembled from specific intermolecular interactions and tend to be topologically saturated, but this is not a requirement. The mode of self-assembly via directed or specific (H-bond, metal coordination) and nonspecific (electrostatic, van der Waals, etc.) intermolecular interactions is also an essential feature not only of the structure

but of the material's function, *vide infra*. The stylized representation of the multiporphyrin systems in the figures will aid in the discussion, and the key is presented in Figure 2. There have been several attempts to develop a systematic nomenclature for self-assembled supermolecules—especially those assembled by coordination chemistry [63, 133], but simple schematic representations better serve the purposes of structural identification and this review. The choice of assembly method, metalloporphyrin, the directionality of the linkers or recognition moieties, and the exocyclic and/or auxiliary ligands are all used to design porphyrin arrays of varying degrees of complexity. Some supramolecular entities are constructed in more than one step or reaction, but in general this is not a hierarchical assembly process. The hierarchical organization of supramolecular arrays—tertiary structure—can be accomplished either in a second step by the addition of auxiliary chemical entities designed to stitch the supermolecules into some higher-order structure, by imbedding them in a matrix that organizes them into an aggregated structure, or *in-situ* by secondary self-processes. The packing of supramolecular entities into a crystal can belong to more than one of these overlapping categories depending on the design and nature of intermolecular interactions. In some cases, the hierarchical organization of porphyrinic arrays is concomitant with their incorporation into a device—quaternary structure.

The chemical and photophysical properties of porphyrins and metalloporphyrins can be adjusted to perform a variety of functions that can be fine-tuned in several ways. Substitutions on the macrocycle (such as *meso-tert*-butyl and *meso*-adamantyl) that distort the otherwise planar structure can modulate the ground-state absorption spectra as well as the spectral dynamics of the excited state by six orders of magnitude [134, 135]. Supramolecular assemblies of porphyrins with various quenchers have been used to study intermolecular electron transfer [8]. Transition metals with appropriate redox potentials can also modulate the porphyrin excited-state lifetime [28, 33] by transient intramolecular electron transfer reactions such that the complete quenching of luminescence is observed for Ni(II) porphyrins [134, 135]. Nonluminescent species are of interest for optical limiting devices [26, 52, 74]. Halogenation of the macrocycle and/or its substituents can modulate both spectral properties and the redox potential of ligated metals [60]. The desired properties of porphyrinic materials can thus be modified as well.

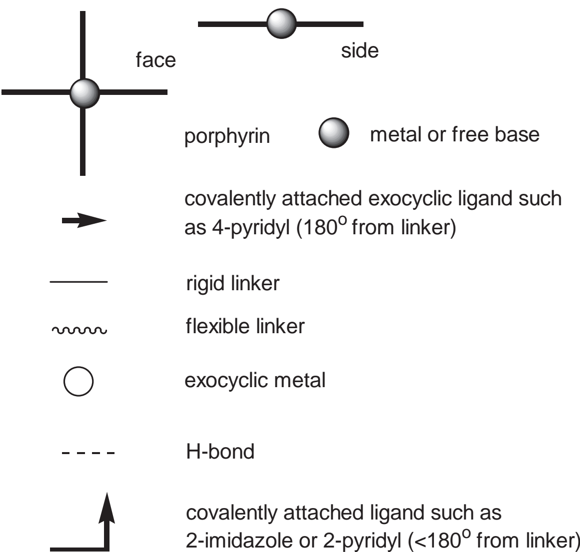

Figure 2. Key to symbols used in figures.

3. ASSEMBLIES MEDIATED BY COORDINATION CHEMISTRY

The well-understood coordination geometries of transition metals (e.g., [136]), coupled with multitopic ligands designed with complementary geometries, have yielded a very large number of discrete, cyclic nanostructures [88, 137]. Coordination chemistry is by far the most used method to assemble porphyrins into various structures—discrete and polymeric—and porphyrins bearing pyridyl groups are the basis of much of these [19, 25, 56, 61, 63, 65, 67, 87, 92, 93, 133, 138]. The square planar geometry of the macrocycle, plus the axial positions of metalloporphyrins, plus the coordination chemistry of the various transition metals that can serve as linkers, allow for the design of a very large number of self-assembled species. There are many variations on this general theme in the formation of crystalline solids wherein at least the unit cell is designed [20, 21, 106, 108, 110]. It should be noted that coordination polymers and materials have a long, rich history. Virtually all porphyrinic materials assembled by transition metals have different photophysical properties than the individual porphyrinic building blocks because of the heavy-atom effect [99, 115, 139]. Additionally, the metal ion linkers may have redox potentials that are appropriate to accept or donate electrons from the excited-state porphyrin. The potential applications of both porphyrin-based and other transition-metal assembled systems for optoelectronics have been well established [101].

3.1. Closed Multiporphryin Arrays

The formation, characterization, and exploitation of closed multiporphyrin systems mediated by metal ion coordination has been the central theme of several research groups for the last few years as these are generally quite easy to make and are the thermodynamically favored product. As initially reported, porphyrinic squares can be formed in two ways [140]: (1) when the porphyrins serve as the corners and metal ions as the sides (Fig. 3A), and (2) when the porphyrins constitute the sides and the metal ions the corners (Fig. 3B). One of the obvious applications of these closed systems is that they can serve as tailor-made hosts for a variety of guests. The size of the cavity can be tuned by a variety of ways, and the use of metalloporphyrins further diversifies the potential uses as sieves, sensors, and catalysts. The metal ion linkers have included Pt, Pd, Ru, and Re, but many others can also be used depending on their coordination geometry, ligand substitution patterns, and desired functional properties [23, 102, 104, 122, 139–151]. These structures are quite predictable and are almost unavoidable as long as labile *cis* or equatorial metal ion positions are

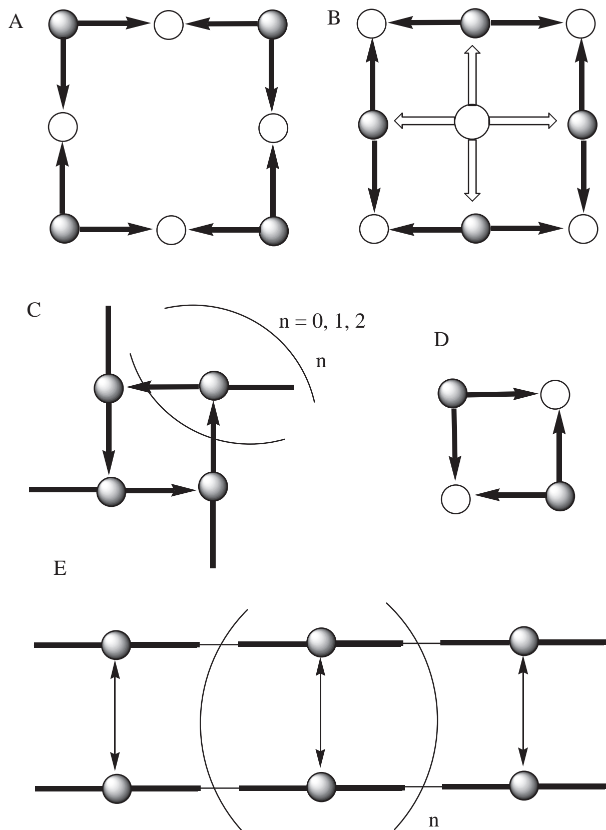

Figure 3. Closed arrays.

available for Figure 3B, and labile *trans* or axial metal ion positions are available for Figure 3A. The porphyrins in supramolecular arrays such as Figure 3A are less conformationally dynamic and are on average co-planar because of the 90° coordination topology of the macrocycle. These features make Figure 3A-type metalloporphyrin squares ideal candidates for secondary self-assembly steps mediated by 180° ditopic ligands such as 4,4'-bipyridine, DABCO, etc. to form layered structures wherein each layer is in register (exactly aligned) [140]. Alternatively, secondary self-organizational processes, such as pi-stacking, can result in nanoscaled aggregates [115]. Self-organization of 3A-type or 3B-type assemblies is also possible by appending long-chain hydrocarbons to the periphery, which allows thin films of these materials to be deposited onto surfaces (see Section 6.2.3).

The porphyrins in squares of the type found in Figure 3B can rotate to some extent, presenting a face toward the inside of the array, and thus enclose a greater volume which can be exploited to bind guests for molecular recognition or catalysis [23, 102, 104, 122, 145–151]. These reports have shown that 3B-type assemblies can be incorporated into devices or perform a function. Microporous films containing 3B assemblies serve as a chemical sensor, the assumption being that the analyte resides in the host, and the signal transduction mechanism relies on the diffraction of visible light because of refractive index changes. Porphyrinic squares such as Figure 3B have been incorporated into other films and devices that demonstrate that they can act as molecular sieves. When the sides of Figure 3B are metalloporphyrins, di- tri- and tetratopic guests of appropriate size (such as other porphyrins shown in outline in Fig. 3B) are readily incorporated [122] as would be expected from crystal structures of similarly arranged lattices of porphyrins. Tetra- and tritopic porphyrin guests will be perpendicular to the sides and will enhance the structural integrity of the square and curtail the conformational dynamics. Since the guest porphyrin can have a redox active metal, this arrangement could be used as an oxidation catalyst that would lessen the self-oxidation reactions that hamper the applications of catalysts based on single porphyrin molecules. The large $\sim 2.5\text{-nm}^2$ area on each face precludes regio-specific reactions. Conversely, 180° ditopic guests can rotate such that the porphyrin square host affords two smaller cavities and regio-specific reactions are favored. This approach to the design of new catalysts is facile because each of the building blocks can be systematically altered to optimize the activity or selectivity.

Figure 3B-type squares assembled using transition metals bearing chiral BINAP ligands afford a means to modulate the function of the array [88, 92, 93, 152–154]. Even though the chiral moieties are outside the central cavity, substantial circular dichroism effects in the porphyrin region are observed, indicating that the photonic properties are substantially different than the nonchiral nanoscaled material. The added feature of this approach is that the supramolecular species is more soluble in organic solvents. A variant of the Figure 3A motif that extends the cavity size utilizes the organometallic 1,4-di-platinate of benzene [152]. The luminescent transition metals used as linking ions afford yet another way to modulate the functionality. The co-crystallization of C_{60} with Figure 3B-type arrays has yielded pillared systems [130].

Figure 3C-type squares represent a simple square self-assembled from one building block linked by axial coordination of exocyclic ligand [155, 156]. These and similar systems are self-complementary because of their shape and ligand direction. For rigid, exocyclic 90° ditopic ligands, squares are the major product (given the usual caveats of self-assembly thermodynamics), but with more flexible external ligands, oftentimes there are significant amounts of the open polymer or supramolecular macrocycles with different numbers of subunits $n \neq 1$, depending on the thermodynamics of the intermolecular bonds, rotation energetics, etc. [157–159]. A 3C square using ruthenium metalloporphyrins leaves the sixth axial site open for further derivatization, and when four equivalents of a free base monopyridylporphyrin are added, which bind the four available axial sites, an assembly containing eight porphyrins is obtained [160]. A variant of this mode of assembly uses ~90° covalently linked metalloporphyrin dimers with axial coordinating ligands at the corner of the link such that self-dimerization results in a closed capsule with four porphyrins [161].

Simple dimers composed of two porphyrins and two metal ions (such as in Fig. 3D) can be considered closed in that they enclose a space [140], but these types of self-assembled porphyrinic systems can also be considered the first generation of linear polymers (see Section 3.2). These dimers are useful as a basis for characterization of larger structures and as building blocks to form hierarchical structures

[141–143, 152, 153, 162]. The exocyclic metal ions need not be only structural, but can add to the functionality of the system such as the modulation of redox properties [141]. Assemblies containing emissive rhenium linkers [150] also modulate the photophysics [139]. The linkers may also serve as a means to dictate the packing of unit cells in a crystal lattice [20, 106, 108]. Another capsule is formed by the dimerization of porphyrins bearing ligands 120° from the porphyrin plane and by four linking metal ions to give a structure with cofacial porphyrins [163]. As an example of guest-assisted assembly, a porphyrin trimer that encapsulates a prism-shaped space has been reported [164]. When two metalloporphyrins are covalently linked with an appropriate spacer, they can be coordinated by a porphyrin bearing two exocyclic ligands [118,165].

The initial report on the self-assembled dimers and squares of types 3A, 3B, and 3D [140] also described a secondary self-assembly step. Two 180°-linked-type dimers with zinc metalloporphyrins were assembled into a square structure (or a two-rung ladder) by the addition of 4,4’-bipyridine (Fig. 4A). Similarly, two 3B-type supramolecular squares were assembled into a cubic structure (Fig. 4B) by the addition of the same ditopic ligand [140] to make a supramolecular species with eight porphyrins—each in an exactly defined geometry. Other later examples of this strategy include ruthenium linked dimers [162].

Another mode of forming porphyrinic squares is to rigidly bond two metalloporphyrins via a variety of organic moieties and then link two of these molecules by a variety of 180° ditopic ligands ($n = 0$ in Fig. 3E) [166]. The ditopic ligands can be chosen for their binding strength to the metal center of the porphyrin, and include 4,4′-bipyridine, DABCO, pyrazine, and terephthalic acid. When n is greater than 0, porphyrin ladders are formed where the binding of the sides increases as the number of rungs increases [74, 75]. Two zinc porphyrins covalently attached by diacetylene can form a square 3E-type where $n = 0$ upon addition of two equivalents of a rigid 180° ditopic bipyridyl acetylene derivative, or form open oligomers when the bipyridyl linkers are flexible [167].

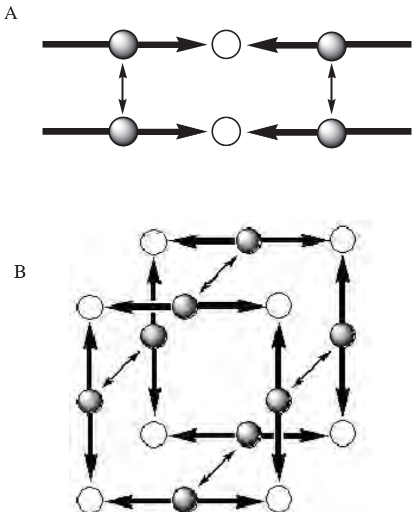

Figure 4. 180° ditopic ligands can can be used in secondary self-assembly steps to link two one-dimensional arrays to form a ladder (A), and two two-dimensional arrays to form a cube.

It is well established that the synthetic yield of large cyclic molecules increases dramatically by incorporation of a template into the reaction mixture. This can be considered an assembly process because the guest directs the synthesis of the host. The methodology has been employed to make macrocycles containing two to six porphyrins (Fig. 5A, B, C) [13, 168–170].

By taking advantage of well-known differences in the ligand affinities of different metals, it is possible to generate more complex closed nanostructures such as Figure 5D in a combinatorial [171] process, wherein the differences between zinc and rhenium metalloporphyrins for pyridyl and phosphine ligands preferentially form a symmetric cyclic structure. This differential metal coordination strategy has been used to form open arrays as well (see Section 3.2).

A 21-component porphyrin nonamer (Scheme 1) can be assembled from three types of porphyrins (4 corners, 4 sides, 1 center) and 12 $PdCl_2$in good yields [99, 115]. This is the next generation up from the squares, but it may represent the ultimate discrete, closed array that can be made by this method because many attempts to form the next generation array have resulted in poor yields of what is likely the discrete array of 16 porphyrins (4 corners, 8 sides, 4 centers). In the same secondary self-assembly method used for the dimers and squares, 4,4’-bipyridine can be used to assemble two nonamers to yield a sandwich of 18 porphyrins—all in a precise location in the supramolecular architecture. Without the bipyridine, these nonamers can self-organize into aggregates that have properties unique to this scale (see Section 7.2).

3.2. Open Multiporphyrin Arrays

Discrete open systems generally contain one or two types of porphyrin building block, but occasionally higher-order oligomers are formed. The latter case is usually accomplished by capping the open ligands of a central porphyrin or by a multistep supramolecular synthesis, which combines dimers and/or trimers with different metal ligand affinity

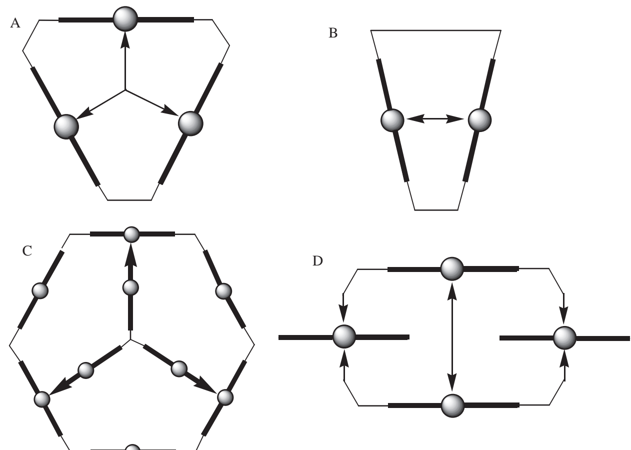

Figure 5. Template-assisted formation of multiporphyrin macrocycles.

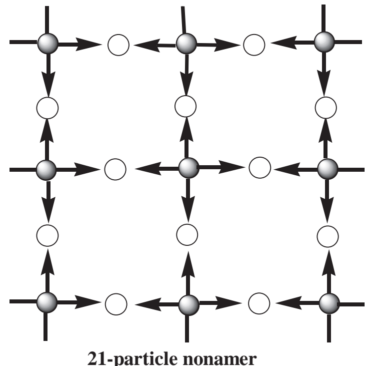

Scheme 1.

strategies [56, 63, 88, 133]. Supermolecules with more than one type of porphyrin and/or metal ion linker can exhibit a broader range of functions [8, 101]. Some of the solid-state structures fall in this category [20, 108, 109]. This limited range of discrete open self-assembled systems results from the fact that merely adding "stopping" units still results in statistical mixtures where the average length is dictated by the thermodynamics of the intermolecular interactions. Most of these systems are conformationally dynamic because of one or more monotopic interactions (Fig. 6).

Conceptually, the discrete open arrays that assemble more than one porphyrin around a central metal ion (Fig. 6A) are similar to the simple dimers using the same strategy using Pt(II) or Pd(II) metal ions [140]. In addition to other reports using these square planar metals [92, 152, 173], ruthenium has been widely exploited (see, e.g., [139, 144, 174]) to form dimers with porphyrins at 90° or 180° angles. These three metals have also been used to form tetrameric 6A-type arrays (e.g., [173]). There are a variety of ligands other than pyridine that can be appended to the porphyrin macrocycle

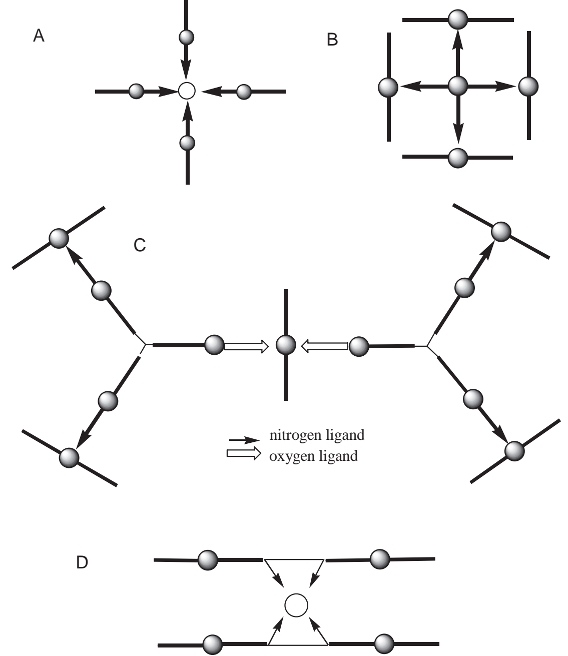

Figure 6. Open arrays.

that facilitate self-assembly mediated by metal ion coordination, and one of the most common is the terpyridyl moiety. Thus, two porphyrins bearing a single terpyridyl group can be dimerized by addition of a wide variety of metals [175–178].

In a similar approach, coordinating metalloporphyrins around a central chemical entity that bears more than one ligand capable of coordinating in the axial position can make discrete open multimers of porphyrins. If the central multitopic ligand is tetra-4-pyridylporphyrin (TPyP), then four ruthenium porphyrins can coordinate to make a pentamer (Fig. 6B) [139, 144, 179, 180]. The pyridyl groups can also be in the 3-position to give a pentamer with two porphyrins on each side of the central macrocycle [181]. Covalently linked metalloporphyrin dimers can be assembled with a free base porphyrin bearing flexible amine ligands [182]. The advantage of this strategy is that the free base porphyrin can act as an electron/energy trap and the peripheral porphyrins as antennae. Other multitopic central ligands have included 4,4′-bipyridine, DABCO [179, 183], and recently several cross-conjugated macrocycles bearing pyridyl moieties at a 180° angle [184] have been reported. These latter ligands are much larger supramolecular building blocks than the former. 2,2′-Bipyridines bearing porphyrins can be used to assemble arrays when the bipyridine binds a metal ion. Thus, when each half of the bipyridine is linked to a porphyrin via vinyl groups [185], or each half is directly attached to either the 4 and 4′ [186, 187] or the 5 and 5′ positions [187] (Fig. 6D), arrays of four porphyrins are formed upon the 2,2′-bipyridyl subunit binding to tetracoordinate metals. When the porphyrins are on the 4,4′-positions and a hexacoordinate metal is used, in principle a trimer bearing six porphyrins would be formed. Terpyridines bearing a 4′-pyridyl moiety have been used; in this case, when the terpyridyl unit binds a metal ion and the pyridyl units bind ruthenium porphyrins, a dimer is formed [188], and the same type of strategy works with bipyridyl linkers [189].

Figure 6B-type arrays are the parent structures for both lattices and linear polymers in which the metalloporphyrin is hexacoordinate and/or only the TPyP is used, *vide infra*. Several metalloporphyrins are hexacoordinate (e.g., Fe, Cr) and in principle the Ru porphyrins in the cited examples can be made hexacoordinate by photolytic removal of the CO ligand. These discrete systems have been used to examine the effects of heavy atoms and the assembly conformation on the photophysical properties [139, 141, 144, 162, 180] of ruthenium porphyrin oligomers. Other examples of this mode of assembly include a tripyridylphosphine [190] that is itself a ligand for a rhodium carbonyl catalyst.

Another route to discrete but open porphyrin architectures uses essentially three supramolecular synthetic steps and knowledge of the concept of hard-soft ligand-metal binding interactions. The propensity of tin porphyrins to be hexacoordinate and their preference for hard ligands such as oxygen, can be used in conjunction with metalloporphyrins with metals (such as ruthenium, zinc, or rhodium) that prefer softer ligands (such as pyridyl), to build complex multiporphyrinic structures. An elegant example can be found in Figure 6C, wherein two building blocks bearing three covalently bound porphyrins (two with a pyridyl group and one with a benzoic acid group) are dimerized by the coordination of benzoate to a tin porphyrin, and the four terminal pyridyl

groups on this dimer then axially coordinate to four metalloporphyrins [183]. Complex multiporphyrin arrays, such as shown in Figure 6C, can be built in reverse order as well by capping the two exocyclic pyridyl groups on a covalently bound trimer with Ru porphyrins to form an intermediate with a carboxyphenyl group free. In a second step, stitching two of these together via coordination of both axial sites on a Sn(IV) porphyrin results in a system with 11 porphyrins of four different types. 4-Carboxypyridine can be used with one tin porphyrin and two rhodium porphyrins to form a linear trimer [183, 191–193].

3.3. Porphyrin Polymers and Aggregates

What distinguishes the simple open multimers from the polymers discussed in this section is largely the fact that two or more of the components of the self-assembling system are at least ditopic. Though they have a long, rich history, coordination polymers are of renewed interest in nanoscaled materials (see, e.g., [194]). The simplest cases, (Fig. 7A, B, C) are merely polymeric forms of the dimers discussed earlier, but more complex polymers can be formed (such as in Fig. 7D and E). Again, since the photonic properties of multiporphyrinic systems depend exquisitely on the relative size, orientation, and mode of assembly, each of the linear polymers is expected—and observed—to have different properties. It is well known, for example, that face-to-face aggregates have different optical properties than the side-to-side aggregates. The parent dimers to 7A and C were reported along with the porphyrin squares [140], and subsequent papers described tape 7C [99]. Tapes such as 7D (e.g., [195]) and 7E have been found to have large third-order nonlinear optical properties [26, 196]. These latter modes of self-assembly may be somewhat related to the autocatalyzed self-aggregation of certain bacteriochlorophylls in nonpolar solvents where a secondary alcohol on a pyrrole axially coordinates the magnesium (e.g., [197]). Many of the structures of these types of systems (Fig. 7A–E) have been characterized by single crystal X-ray analysis and other solid-state methods [21, 109, 198–200]. A 7C-type polymer that forms a two-dimensional network of hexacoordinated zinc porphyrins was recently reported [201]. Many of the earliest publications on porphyrin crystal engineering relied on metallotetrapyridylporphyrin self-coordination or on free base tetrapyridylporphyrin coordination to external metal ion linkers [20, 21, 106, 108, 110]. Hexacoordinate metallotetraphenylporphyrin derivatives with flexible pyridyl ligands at the 3-position of the 5, 15 phenyl groups can self-organize into 7D-type linear polymers, which under the right conditions can close to form a ring [202]. More rigid 5,15-bis(imidazolyl)-10,20-(4-dodecyloxyphenyl)-porphyrinato zinc molecules self-assemble into rigid 7D-type polymers [4]. The self-complementary coordination of 2-aminophenyl-porphyrinato zinc subunits to form a 7D-type n=0 dimer is in equilibrium with the open oligomers [203]. Hydrothermal processing continues to provide crystals with more rigid structures, likely the thermodynamic products, of porphyrins with a variety of metal ions. A recent example uses tetracarboxyphenyl groups and Ca(II) to make an interpenetrating network which is further organized by strong hydrogen bonds [22]. This illustrates the fact that even in solid-state crystals there may be many different polymorphic structures using the same or similar supramolecular design principles.

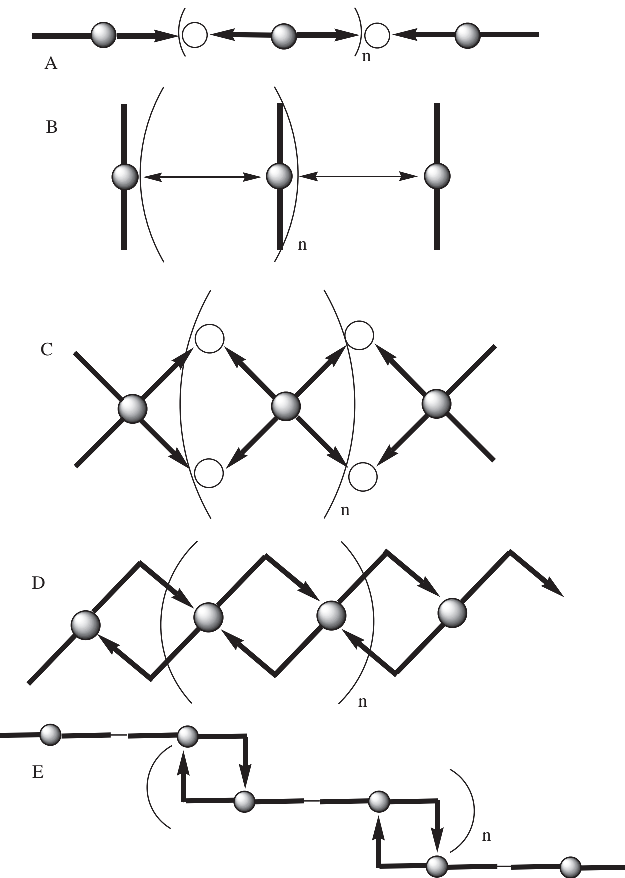

Figure 7. Polymeric arrays.

One interesting method to make polymeric multiporphyrin arrays combines both the synthesis of covalently bound polymers of tin metalloporphyrins, and the axial coordination of these subunits by porphyrins bearing a single benzoate group (Fig. 8A) [193]. The hybrid approach of combining second types of synthetic porphyrin oligomers followed by coordination of these oligomers by other porphyrins [179, 204] or other chromophores promises to greatly expand the repertoire of porphyrin self-assembly, as it bridges several levels of self-assembly and self-organization [97, 98]. Polymers of type 8B and 8C are readily accessible as well. Recently reported is a method for making porphyrin derivatives with the coordinating exocyclic ligand built directly on (a part of) the macrocycle [205–208]. This allows for the formation of coplanar dimers and multimers where the macrocycles are "conjugated" via the metal ion coordinating bonds (Fig. 8C). These dimers, for example, have photonic and electrochemical properties not seen by other means of self-assembly. This approach, combined with other modes of self-assembly, may afford interesting materials with complementary photonic properties. An 8C-type structure is an intermediate in the synthetic pathway to [2]porphyracene (a fused porphyrin dimer) [52, 209].

Mesogenic systems formed from self-assembled porphyrin dimers (Fig. 7A, $n = 0$) appended with long-chain

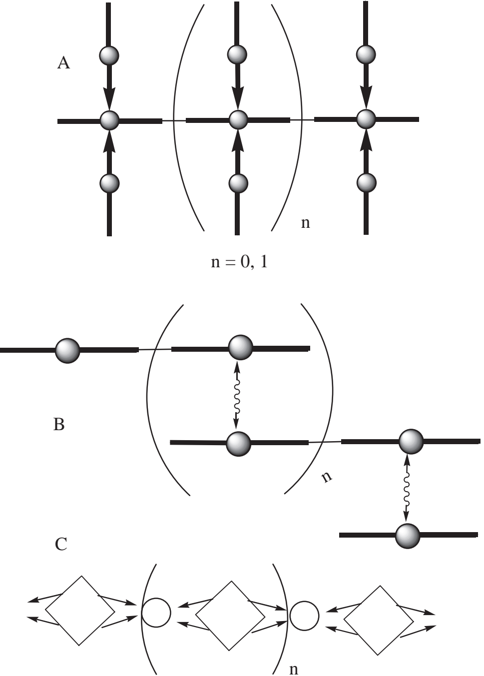

Figure 8. Other polymers.

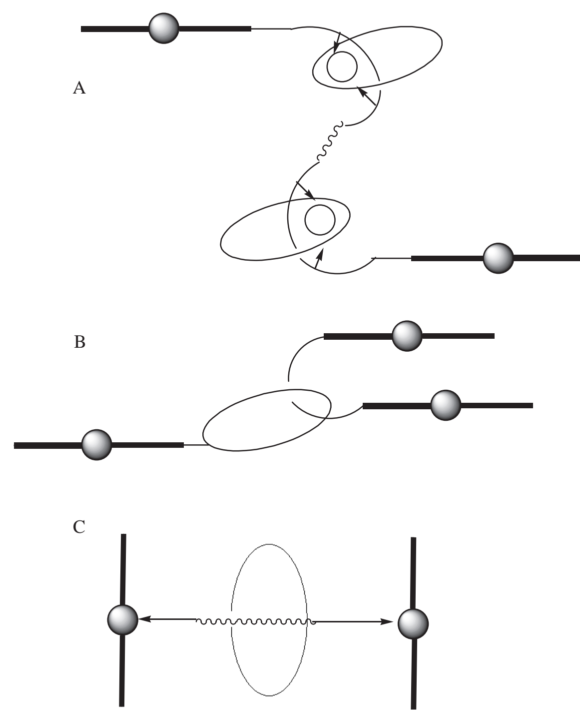

Figure 9. Arrays made with mechanical bonds.

hydrocarbons have been found to form ringlike domains of greatly varying size, thickness, and height [210–212]. A variety of mesogenic systems have been reviewed [66, 67, 213–215], and a few will be discussed in Section 6.2.3.

3.4. Porphyrins Linked by Mechanical Bonds

Rotaxanes and catenanes are chemical entities where a mechanical bond joins two different molecules; minimally, the former involves a linear guest and a ring-shaped host (Fig. 9), while the latter links two rings as in a chain [216]. Most of the self-assembled multiporphyrinic systems to date are rotaxanes, and coordination chemistry is generally the method to string the linear guest molecule through the host macrocycle to result in systems like Figure 9A and B [159, 175, 217–221]. Alternatively the ring may be formed around a template. In addition to examining electron/energy transfer in systems held together by mechanical bonds, the porphyrins act as a probe of the molecular and mechanical dynamics of these systems [87, 217, 222]. The rearrangement of these molecules represents prototypical molecular machines in that they can serve as nanoscaled “ball and socket” joints, “universal” joints, and wheel and axles [216]. Rotaxane systems have been widely proclaimed to be part of the initial foray into molecular based nanoscaled electronic devices [15, 16, 55, 223, 224], but much remains to be solved—especially the interconnections between devices. Another mode of rotaxane formation is to use coordination chemistry to stopper the rotaxanes (Fig. 9C) [225, 226]. The 9C-type rotaxanes afford an avenue toward the synthesis of more complex multiporphyrinic arrays by exploiting the differential metal ion coordination strategy, or the stoppers themselves may be arrays of porphyrins.

3.5. Themes and Trends

These structures rely on the coordination chemistry of the metalloporphyrin and the coordination of external metal ions by exocyclic ligands as separate but designable building blocks that assemble in essentially one step. For the closed multiporphyrin arrays, one of the most common themes is that these types of structures are excellent hosts to a variety of guests. The size of the internal cavity can be fine-tuned by many means, including the size (length) of the exocyclic ligand, secondary self-assembly steps, and the formation of structures that are larger than the most common square tetramer. Metal mediated self-assembly of porphyrin arrays yields structures that are more robust, and the design of specific structures for a given function is more predictable than for other means of self-assembly or self-organization. Fullerenes are an example of large, chromophoric guests for which self-assembled arrays and dimers (Fig. 10) have been tailor-made [128–130] or incorporated into self-assembled structures [227]. Therefore, it is likely that this mode of assembly will continue to dominate the organization of molecules by both selfprocesses. In addition to tailoring the cavity to the size and shape of target guests, the various photonic properties of these nanoscaled materials can be exploited for redox catalysts, sensors, and sieves.

4. ASSEMBLIES MEDIATED BY HYDROGEN BONDING

One of the overarching themes in nature is the organization of matter into ever more complex structures that, when properly arranged, function as viruses, cells, and organisms. One of the underlying principles of this organization is

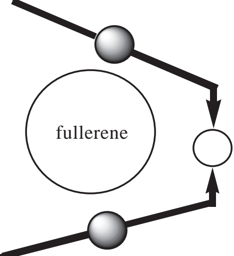

Figure 10. Self-assembled host binding a guest.

shape and intermolecular bond complementarity—the information contained in the molecule is ultimately sufficient for molecular self-assembly. Though more complex structures often require enzymes or templates, the fundamental building blocks do not. Of the specific intermolecular interactions, hydrogen bonding is by far the most exploited for both defining structure and storing information. The role of hydrogen bonds in these functions arises from their number, energetics, and their directionality. For example, the complex topological structure and function of proteins rely heavily on hydrogen bonds, as do the base pairs in nucleic acids DNA and RNA. These structures form and are stabilized via the cooperative interactions of many complementary hydrogen bonds (see, e.g., [228]). Nature relies on the fact that these interactions are reversible so that mistakes in structure can be reversed and corrected. It is from biology that scientists take their initial inspiration in the design and exploitation of complementary hydrogen-bonding entities to self-assemble molecules into various nanoscaled materials. The structure and function of these materials arise from the molecular and supramolecular structure as well as the mode of assembly. The design, strength, and uses of hydrogen bonds in supramolecular chemistry have been well reviewed [111, 229–234].

The rigid structure of the porphyrins make them ideal scaffolds to append hydrogen-bonding groups that allow self-assembly upon addition of the complementary hydrogen bonding motif. Functional biomimetics continues to drive much of the research on porphyrin materials and receptors (see, e.g., [235, 236]). The nanoscaled structures resulting from the self-assembly and/or self-organization of multiporphyrinic arrays and materials mediated by complementary hydrogen-bonding groups, like the metal ion mediated counterparts, can be closed, discrete, open, or polymeric. There are many fewer reports on self-assembling porphyrin arrays mediated by H-bonds because these intermolecular interactions are much weaker, which hampers characterization in solution. Also, the solid-state structures may be different than those in solution. (Thus many of the reports of porphyrin assembly via hydrogen bonds are solid-state structures [20, 21, 107, 108] because of the difficulties in characterization.) Hydrogen-bonding motifs are directional, but they may also be ditopic in that more than one complementary group can bond to the same moiety. When the complementary molecule is a porphyrin, multiporphyrin arrays result.

4.1. Closed Multiporphyrin Arrays

H-bonds are directional and the cooperative formation of closed self-assembled arrays can result in sometimes surprisingly stable materials (Fig. 11). These relatively weak intermolecular interactions can be exploited in materials wherein responses to thermal or solvent polarity are desired. Other than temperature and solvent as factors in the assembly, the concentration range for the closed structures is limited. As is well known in biology, open polymeric structures are favored at high concentrations, and of course at low concentrations monomers or partially assembled species are present. Another feature of many hydrogen-bonding groups is that there are specific sequences of hydrogen bond donors (D) and acceptors (A); for example the DAD triple H-bonding potential of a triaminotriazine is complementary to that of the ADA motif of barbituric acids. But because of the reversibility of H-bonding interactions, slipping these two complementary groups by two hydrogen bonds results in a system whereby the two entities remain bound, but with only hydrogen bond. The consequence of this is that even the closed arrays are still dynamic in solution under the best of circumstances. Limited interporphyrin charge and energy transfer has been observed in squares assembled by H-bonds (Fig. 11A), but in general the porphyrin photophysics is more similar to the monomers than is found for the coordination arrays. The early examples of these

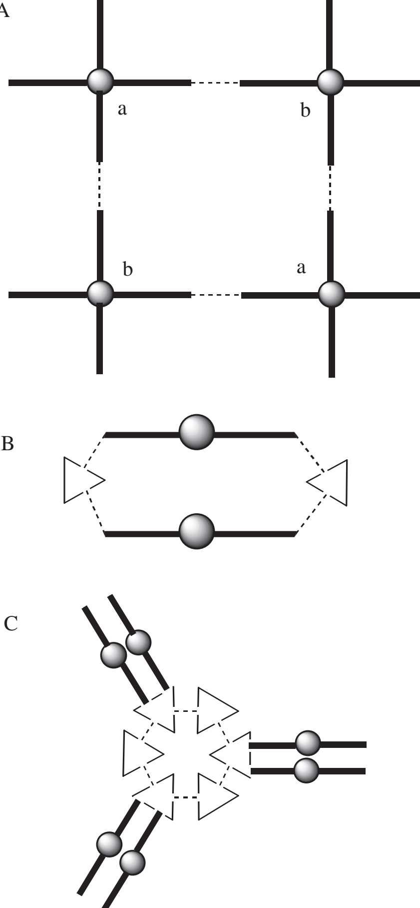

Figure 11. Closed arrays.

closed arrays used uracylic and triazine moieties along with a nonporphyrin complementary hydrogen-bonding group (triangles) to form a supramolecular cage (Fig. 11B) [237]. A rosette with three co-facial porphyrin pairs (Fig. 11C) [238] is formed from a bisporphyrintriazine and a variety of barbituric acid derivatives. It is possible to design closed square arrays of porphyrins (Fig. 11A) by placing two copies of one type of a monotopic hydrogen-bonding moiety at 90° on one porphyrin (a in Fig. 11A) and two copies of the complementary monotopic hydrogen-bonding group at 90° on another porphyrin (b in Fig. 11A) [239]. Since the hydrogen-bonding groups in 11B and C are ditopic, several possible structures can result, but conditions are chosen so that the predominant form of the supermolecule is closed. It is also possible to exploit the aforementioned dynamics of complementary hydrogen-bonding systems to design and synthesize squares that are formed via self-complementary interactions (Fig. 11A, where $a = b$) [172]. In this particular case the intermolecular forces are about an order of magnitude weaker than the square made via heterocomplementary H-bond groups [239]. Comparing the thermodynamics of forming the closed arrays (90° ditopic porphyrin) with the thermodynamics of forming the open arrays (180° ditopic porphyrin) mediated by the same complementary H-bonding groups allows the assessment of the role of cooperativity in the formation of closed structures without changing recognition motifs or molecular dynamics. There are other reports of closed 11C-type structures [240]. More robust 11B-type cage structures are formed by the α^4 rotamer (all directed towards the same face) of tetra-(2-carboxyphenyl)porphyrins wherein the carboxy moieties bind the two porphyrins with four sets of self-complementary double H-bonds [241, 242]. When four equivalents of these metalloporphyrin cages are combined with a porphyrin bearing four pyrazines flexibly attached to four meso phenyl groups, a secondary self-assembly step occurs wherein each pyrazine group coordinates both of the zinc centers of the cage. Encapsulation of all four meso-appended pyrazine derivatives results in a nonameric array [243], and the antenna effect on energy transfer for these nonameric arrays was studied. The porphyrins used for 11B-type cages generally have two or more rotameric conformations (atropimers), but the supramolecular cage traps the conformation with the hydrogen-bonding groups on the same face [237]. While closed structures 11A and 11C are relevant to electron/energy transfer across hydrogen bonds, 11B-type cages may be exploited for guest recognition or catalysis. H-bonds and ion-pairing can be used to make structures with porphyrins and iron terpyridine [244, 245]. A square can be formed from two 180° covalently linked zinc porphyrins when 4(3-H)pyrimidone is added, where the nitrogen on the heterocycle binds axially to the zincs and the amido positions serve as self-complementary H-bond units. This is an H-bond version of a 3E-type square ($n = 0$) [246].

4.2. Open Multiporphyrin Arrays

As mentioned earlier, the same set of porphyrins assembled by hydrogen bonding can be monomeric, polymeric, or closed depending on conditions. Other than simple dimers [239, 240], there are few examples of open multiporphyrinic systems that are discrete. The problem with forming open multiporphyrinic systems via hydrogen bonding is that the intermolecular interactions are so weak, that tapes such as a trimer (Fig. 12A, $n = 1$) are formed in low yields and are only one of several supramolecular entities in the solution. In the solid state, X-ray studies reveal that a variety of other nonspecific intermolecular forces (pi stacking, van der Waals, etc.) reinforce the structure mediated by hydrogen bonds (see, e.g., [22, 68, 107, 229, 233, 239, 247–249]).

4.3. Porphyrin Polymers and Aggregates

Because sugars have a variety of recognition functions in living systems, porphyrins appended with a variety of sugars have been the focus of several research groups. The multiple hydroxy groups on sugars make them ideal candidates for the formation of porphyrin aggregates and polymers (e.g., [250]). Several reports on the formation of gels and fibers from porphyrins bearing sugar groups (Fig. 12B) have appeared [251, 252]. Imidazole-imidazole hydrogen bonding has been used to make 12C-type polymers [196, 253, 254].

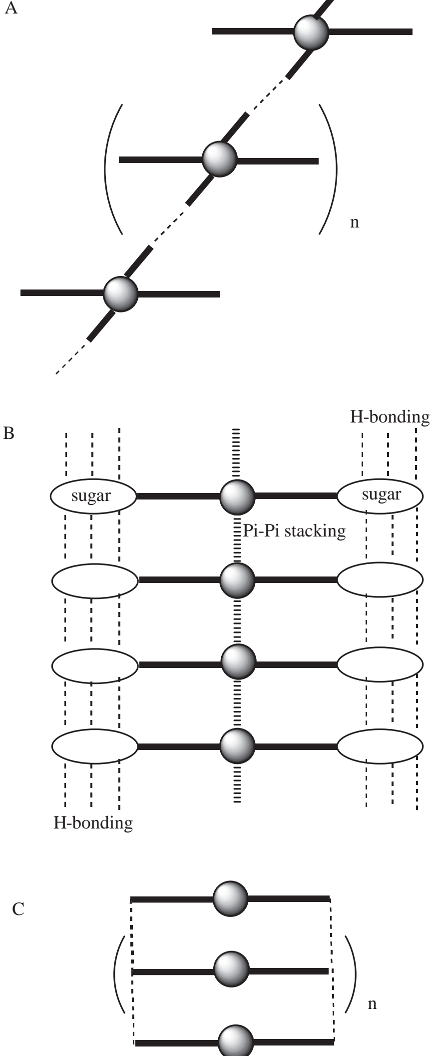

Figure 12. Polymers by H-bonds.

There are many solid-state examples of porphyrins assembled by hydrogen bonding. Though the crystals are not nanoscopic, the specific intermolecular interactions that are exploited to place the porphyrins in a designed geometry and order often result in nanoscaled channels, or cavities that can be used to recognize guests (sensors), act as molecular sieves, or as shape and size selective catalysts [20, 67, 68, 105–108, 249]. In addition to the one-dimensional structures in Figure 12, there are a variety of structures with designed two- and three-dimensional interactions such as those in Figure 13 [105, 106]. The crystal structure of 12C-type columnar aggregates reveals remarkably stable channels [249].

4.4. Themes and Trends

Though each individual hydrogen bond is only worth a few kcal/mol, there are many complementary organic groups that are capable of more than three H-bonding interactions (e.g., [255]). The >8-kcal/mol total interaction energy between these latter groups in nonpolar solvents is more than sufficient to make robust self-assembled materials, though complementary groups with more than three H-bonding sites have not been generally applied to porphyrin materials chemistry. The weak intermolecular interactions can be exploited as structural sensors to environmental factors such as temperature and solvent, wherein the resultant modulation of interchromophore distances alters the photonic properties which report on the status of the assembly. The aggregates of porphyrins are also relevant to the formation and activities of photosynthetic antenna complexes, which may or may not use a protein scaffold to maintain structural integrity of the chlorophyll arrays.

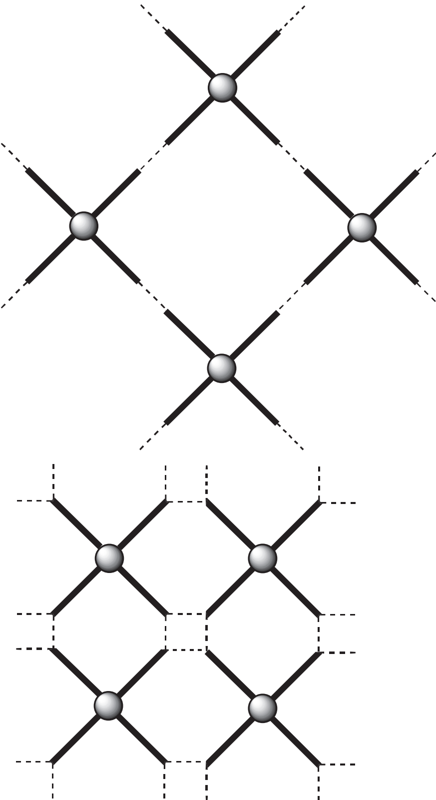

Figure 13. Lattices and arrays by H-bonds.

5. ASSEMBLIES MEDIATED BY ELECTROSTATICS

For the purpose of discussion in this review, electrostatic assembly is defined as arising from the interactions of full or partial charges (ions and dipoles) on the component molecules, though other intermolecular forces such as hydrogen bonding and metal ion coordination certainly have electrostatic contributions. Charge-charge interactions are usually neither specific nor directional, but dipolar interactions are directional. The specific placement of charged groups in proteins, lipids, and other biological molecules or biopolymers is an important aspect of both tertiary and quaternary structure, as well as of function. Phosphatidylcholine lipid bilayers, for example, are formed by a variety of nonspecific intermolecular electrostatic interactions [256]: (1) electrostatic interactions in the charged head groups, (2) dipolar interactions in the ester region, (3) and van der Waals interactions amongst the hydrocarbon tails. These nonspecific interactions are necessary in membranes to assure that they are structurally dynamic, that is, fluid.

5.1. Porphyrin Polymers and Aggregates

There have been numerous papers on the mixing of positively charged porphyrins with those bearing negative charges, or with other molecules with complementary charge. One of the first examples of porphyrin self-organization (as opposed to uncontrolled aggregation or crystallization) by any means used transiently formed porphyrin cations with lipophilic anions such as tetraphenylborate to create “linear” chains that conducted ions across a lipid bilayer [257, 258]. This was an early example of a working molecular electronic device, and it performed as a photogated ion-conducting transistor (see Section 7.1) [259]. Charged porphyrins include the anionic forms tetra-carboxyphenylporphyrins (TCPP), tetra-phosphonatophenylporphyrins (TPPP), and tetra-sulfonatophenylporphyrins (TSPP), the cationic tetra-N-methyl-pyridiniumporphyrins (TMePyP), and the tetrakis-tri-alkylanalyniumporphyrins (TAAPP). Mixing solutions of TSPP and TMePyP along with a surfactant results in specific types of aggregates [260], where the size depends on surfactant, solvent, temperature, and concentration, just as it does for other self-assembled aggregates such as those made by hydrogen bonding. Without the surfactant, these species aggregate as well to form what are likely more ordered structures in solution [261, 262]. TSPP has been found to interact with phthalocyanine dyes [263]. The addition of an amino acid such as phenylalanine to a mixture of cationic and anionic porphyrins induces them to form chiral aggregates [264]. The anion-controlled assembly of porphyrin-bicyclic guanidine conjugates, which are much less symmetric than the porphyrins described earlier, results in chiral aggregates [265]. This latter system is noteworthy because there is more information designed into the molecule, so more structural information is read out and expressed in the aggregate structure. Also reported, is the formation of chiral aggregates

of less symmetric charged porphyrins by vortex mixing [266, 267], where the vortex is somewhat akin to a chiral mold or template such as porphyrin-DNA assemblies [268, 269]. Sulfonated C_{60} has been mixed with TMePyP to form electrostatic assemblies on chitosan films [270]. Several solid-state materials have been reported where the structures of the system arise at least in part by electrostatic interactions, for example, between porphyrins with carboxylate anions and potassium anions [20]. Irregular, polydispersed aggregates are also formed from TSPP in solution [261, 262], and even from neutral porphyrins such as TPP and TPyP [271–273]. In addition to porphyrins bearing charges on the peripheral groups, the protonated diacids of some porphyrins in solution [274] undergo structural changes that result in the meso aryl groups possessing a smaller dihedral angle with the macrocycle, which allows aggregation of zwitterionic derivatives. The electrostatic association of TSPP with cationic polyamines forms pH-dependent species at lower pH values [275], and the charged polymer has been used to adsorb this porphyrin onto glass substrates (see Section 6.2.4).

5.2. Themes and Trends

The electrostatic association of porphyrins to other dye molecules, to polymers, and to charged particles continues to be a fruitful strategy to make nanoscaled materials. However, the relative orientation of the chromophores, the size of the particles/aggregates, and the polydispersity of these systems are difficult to control and make them difficult to incorporate into nanoscaled devices. A related method is the layer-by-layer deposition of charged porphyrins, metalloporphyrins, and charged polymers. These systems are remarkably robust and afford a greater degree of control of molecular position (see Section 6.2.4).

6. PORPHYRINS ON SURFACES

Despite the advantages of using the processes of self-assembly and self-organization to construct materials that can serve as components of nanoscaled devices, several significant obstacles must be overcome. The advantages include efficient use of chemicals, and the ability to organize molecules in a precise architecture. But because of the reversibility of the intermolecular interactions that allow self-assembly and self-organization to result in thermodynamic products in high yields, the major obstacles to employing such materials are issues of stability. Device stability to thermal fluctuations, to redox chemistry, to environmental changes such as humidity, and to dioxygen is crucial. But, all of these factors can affect the equilibrium of self-assembled systems, thus the structure and function. Another issue is that most structures formed by self-processes take place in solution, and the deposition of these structures onto surfaces with high structural fidelity is not necessarily straightforward. Most applications require the removal of the solvent, and the inherent concentration changes often perturb the equilibrium, which results in structural rearrangements of the supramolecular system. Scanning probe microscopies, such as atomic force microscopy (AFM) and scanning tunneling microscopy (STM), are some of the best methods to evaluate structures on surfaces [276]. There are a few examples of self-assembled (discrete, monodispersed) systems that can be deposited onto surfaces with high structural fidelity and are stable at room temperature. As one might expect, these successful systems are largely assembled via metal ion coordination, as hydrogen bonding is generally too weak. There is a large body of work on forming self-organizing systems on surfaces, including monolayers, liquid crystals, layer-by-layer electrostatically formed films, and chemisorbed materials. The synthesis and characterization of electropolymerized thin films of tetra(4-aminophenyl)porphyrin from an aqueous solution onto electrodes to form an emeraldine-type polymer was reported [277] though the morphology of the film was not well defined.

6.1. Self-Assembled Structures

One of the first examples of self-assembled porphyrin arrays that address the above issues is a self-assembled nonamer. The 3×3 tessellation of nine porphyrins of three topologies (+, T, and L-shaped) is mediated by the *trans* coordination geometry of Pd(II) in a variety of organic solvents (Scheme 1). These nonamers (the next generation of a 3A square) can then self-organize into columnar stacks of 1 to ~ 20 layers to form 6.5 nm $\times$ 0.5 nm to 10 nm nanoscaled aggregates [99]. The length of the columnar stack can be fine-tuned by choice of appended alkane, by choice of solvent, by choice of metal, and by kinetics [100, 115]. These stacks can be deposited onto glass surfaces without any observable change in structure or function because of the weak interactions between the aggregate and the substrate and the strength of the intermolecular forces holding the nonamer and the stack together. The individual (nonaggregated) nonamer can be deposited on a Au 111 surface—an example of a purely self-assembled structure deposited on a surface (a 14G-type of arrangement). Most importantly for applications, all of these constructs, and their photonic functions, are stable in air at room temperature for years [100, 104, 115]! The next step will be to self-organize the self-assembled nonamers into two-dimensional arrays on surfaces. An elegant use of electrochemical potential of an electrode surface that modulates the surface mobility of adsorbed molecules allows for the self-assembly porphyrin arrays has been reported [278].

6.2. Self-Organized Structures

Because self-organized systems are generally less ordered and more tolerant of defects than self-assembled systems, both in solution and on surfaces, these types of systems are generally easier to make and characterize. Most of these systems can be divided into three general categories: (1) the macrocycles can be chemically bound to the surface, such as porphyrins bearing hydrocarbons terminated with thiols; (2) the macrocycles can be bound to the surface by coordination chemistry, such as when ligands are attached to the surface either chemically or by adsorption; and (3) self-assembly by direct adsorption on the surface under controlled conditions or by using moieties that impart liquid-crystal properties to the molecules. Some of the applications for these types of layered films are to modify electrodes to make them selective for various analytes, and to modify fibers for detection of analytes by optical absorption or emission. The placement

of long-chain hydrocarbons allows for the two-dimensional organization of porphyrins [279] and phthalocyanines [103, 280, 281] on surfaces that can be characterized by scanning probe microscopy [276, 282].

6.2.1. Chemically Bound

Though commonly referred to as self-assembled monolayers (SAMs), these materials are more accurately described as self-organizing systems (Fig. 14A, B, E, F, where 'x' = S or other reactive group). There has been considerable research on SAMs and there are numerous reports on porphyrin containing monolayers. One of the most common avenues into these materials is to chemically bind (Fig. 14A) a hydrocarbon-bearing thiol group to a gold surface [95, 283–288]. Other substrates such as indium-tin oxide (ITO) [287] and polypyrrole [289] have been used. The nature of the hydrocarbon linker modulates the physical and photonic activity of the monolayer. More complex (structurally, redox, and optically) photonic triple-decker molecules containing porphyrins, phthalocyanines, and both porphyrins and phthalocyanines have been used to form monolayers with more complex redox and optical properties [36, 95, 290–295]. The increased physicochemical complexity affords an opportunity to design and characterize devices that act as multistate counters for molecular electronics applications. Thiol bound monolayers terminating with a porphyrin bearing an imidazole facing away from the surface can serve as a template to construct 7E-type multilayers, but as with other multilayers, the length of the self-coordinating polymer varies, the dispersity increasing as each layer is added [296].

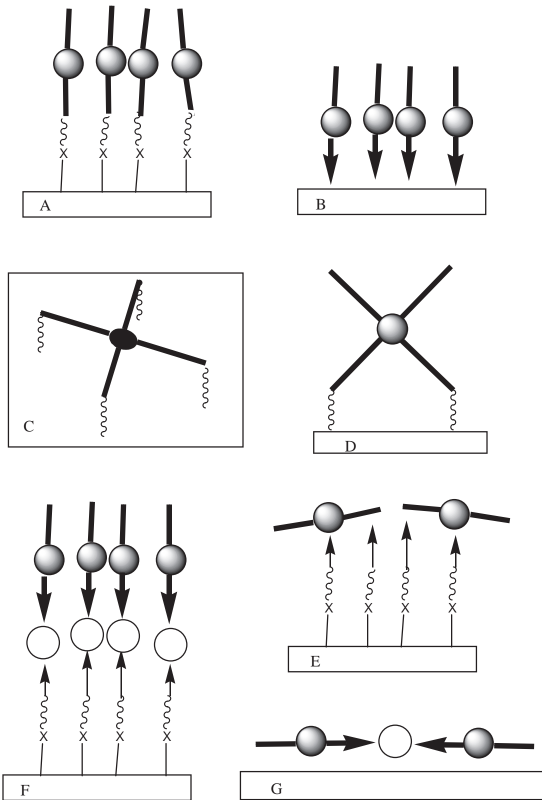

Figure 14. Self-assembled porphyrinic structures on surfaces.

The interaction of carboxylate moieties with surfaces (Fig. 14B, C, D) has also been used to form monolayers on gold [200, 279, 297, 298], mica [299], and at the air-water interface [300]. The weaker substrate-molecule interactions of these systems allow more facile modification of the surface. When porphyrins bear reactive groups (poised to form supramolecular or covalent bonds) on the side or edge facing away from the surface, more layers may be added with varying degrees of structural fidelity to the initial layer. Characterization of multilayer systems is often more difficult. A hybrid system with octacarboxlyate porphyrins adsorbed face-down onto a gold surface surrounded by a bolaamphophile or other monolayers has been reported [301–303]. The motivation behind this work is to make nanoscaled test tubes on the surface for further reaction or sensing applications.

6.2.2. Coordination

There are several examples of 14E-type monolayers where a ligand is covalently attached to the substrate and this binds to an axial position of a metalloporphyrin [304–310]. This method to make monolayers on surfaces generally orients the plane of the porphyrin parallel to the plane of the surface, but there is a lot of room for the macrocycle to tilt so that there is a range of orientations. This method allows for studies by surface plasmon resonance, surface-enhanced Raman scattering, and surface-enhanced infrared absorption. Again, one of the potential applications of these systems is the use of surface-modified electrodes for analytical chemistry.

As mentioned earlier, the relative orientation of the porphyrin rings with respect to each other and with respect to the surface is of paramount importance to the photonic properties of the system. An elegant way to use coordination chemistry to orient metalloporphyrins perpendicular to the surface is to make monolayers with flexible linkers and ligands that generally are poised to bind 6-coordinate metalloporphyrins in both axial positions, resulting in layers with the plane of the macrocycle perpendicular to the surface [311, 312].

6.2.3. Thin Films Using Liquid-Crystal-Type Interactions

One of the early successes in the self-organization of a porphyrin-based device utilized liquid-crystal-type interactions to form thin films of a photoconducting zinc porphyrin with eight dodecyloxy groups on the pyrroles [117, 313, 314]. Electron-hole pairs are generated upon irradiation of a section of a device that has this porphyrin derivative placed between two optically transparent electrodes with an applied electric field. The device then performs as a high-density nanosecond charge trap that can be used as an optical memory device. Similar porphyrins were used to make liquid-crystal thin films between ITO coated glass slides, which displayed electric-field modulated near-field photoluminescence [315]. These studies show that there is a correlation between the device's physical properties and the morphology of the self-organized, photoactive, organic layer. Other liquid-crystal-forming porphyrins with properties dependent on the nature and position of the hydrocarbon have also

been reported [316–318]. There are several examples of discrete multiporphyrin arrays (such as 3A-type, 3B-type without the guest, and 6A-type) that have long-chain hydrocarbons appended on the periphery that form monolayers by the Langmuir–Blodgett method (e.g., [319]), which then can be transferred to surfaces such as glass with reasonable structural integrity [320]. These films are an early example of using a secondary procedure to self-organize self-assembled supermolecules. A good example of an alternating-current light-emitting device based on Langmuir–Blodgett films of porphyrins was reported [321], where the transient character of electroluminescence is explained in terms of a space-charge assisted electron injection.

Solid vesicle membranes made of bixin-porphyrin derivatives have been reported to form stable colloidal solutions, which can be photopolymerized to yield 30- to 120-nm spheres [322] which can then be cast onto surfaces. Self-assembled fibrillar networks are formed from porphyrins bearing two lipid groups on the same side [323].

6.2.4. Layer-by-Layer Deposited Films

Only a few examples of films containing porphyrins made by the layer-by-layer technique are cited, because to date the degree of organization after the first layer is somewhat limited. Briefly, the process involves dipping a charged substrate into a solution containing an organic molecule or polymer of the opposite charge. After annealing and rinsing, it is dipped into a second solution that has molecules or polymers with the opposite charge as the first. This can be repeated, but the structural fidelity generally decreases with increasing number of layers. The density of defects in each layer is a major issue for most layer-by-layer systems, but is not generally reported. For porphyrins, an early example used TSPP (tetra anionic) and TPyP appended with four cationic $RuBiPy_2$ units [324]. Two-dimensional arrays formed from TPyP and cadmium ions made by Langmuir–Blodgett methods and deposited on surfaces [325], or the equivalent palladium ion linked array made with the layer-by-layer method [326], are two of the best examples of self-organized two-dimensional layers using specific intermolecular interactions. The stepwise self-organization of a bis-bipyridinium–porphyrin dyad and gold nanoparticles on a conductive ITO surface results in a system where the redox properties are significantly different than the component molecules [327]. A cationic polyamine adsorbed onto glass promotes adsorption of anionic TSPP [275] and similar systems [328]. The association of tetrapyridyl cobalt porphyrin coordinated to four $Ru(BiPy)_2$ associates with anionic Zn(II)TSPP in layer-by-layer films on electrodes has been used to examine nitrite oxidation as an analytical application [329]. ITO electrodes modified with porphyrin-fullerene dyads as the active layer gives rise to improved light-harvesting properties in the visible region [330].

6.3. Themes and Trends

The ability to deposit specifically designed self-assembled (discrete) supramolecular structures onto surfaces without change in structure or function remains a significant challenge for the exploitation of this methodology in real-world applications and devices. Self-organized monolayer systems, on the other hand, are more accessible because of the tolerance for local defects, but the horizontal dimensions of these are generally quite large. The layer-by-layer method has both advantages (ease of preparation) and disadvantages (greater defect density than SAMs), but may find numerous applications as sensors, and other systems requiring surface modification. The adsorption of a $La(III)(TPyP)_2^-$ sandwich compound onto a liquid Hg surface can provide access to two-dimensional arrays on this and other surfaces when they are chemically cross-linked with a dibromo hydrocarbon [331, 332]. The overall structure of these systems is likely a grid, but since the cross-linking step results in kinetic rather than thermodynamic products, the degree or order is likely not comparable to self-assembled/organized systems. This work is notable since it is an attempt to organize porphyrin sandwich compounds on surfaces with greater structural stability and arrangement unobtainable by self-assembled monolayers of similar compounds (see Section 6.2.1).

7. MISCELLANEOUS MULTIPORPHYRIN ASSEMBLIES AND AGGREGATES

There are several applications for nanoscaled porphyrin aggregates where the architectural order of the macrocycles is of little consequence or indeed undesirable. For example, nanoparticles are used for drug delivery, or as nonspecific sensor elements in cross-reactive or stochastic sensor arrays. A recent report describes the formation of 10- to 75-nm radius porphyrin nanoparticles using methods similar to those used to make inorganic nanoparticles [333], specifically, by injecting an organic solution containing the porphyrin and a small percentage of a short polyethylene glycol (PEG) into water (Scheme 3B). The solvent ratio, the specific PEG, and the rate of mixing, all affect the particle size. Dynamic light scattering and the optical spectra in solution characterized the particles. But more importantly for device applications, many of the particles can be deposited on glass surfaces without agglomeration, and without disrupting the nanoparticles. It was shown that iron porphyrin nanoparticles catalyze the oxidation of cyclohexene with about 1000 times the turnover of the individual porphyrin (normalized to the same number of porphyrins). The product ratios were close to those of the individual porphyrin, but it remains to be seen if the nanoparticle catalysts exhibit regioselectivity on more complex substrates.

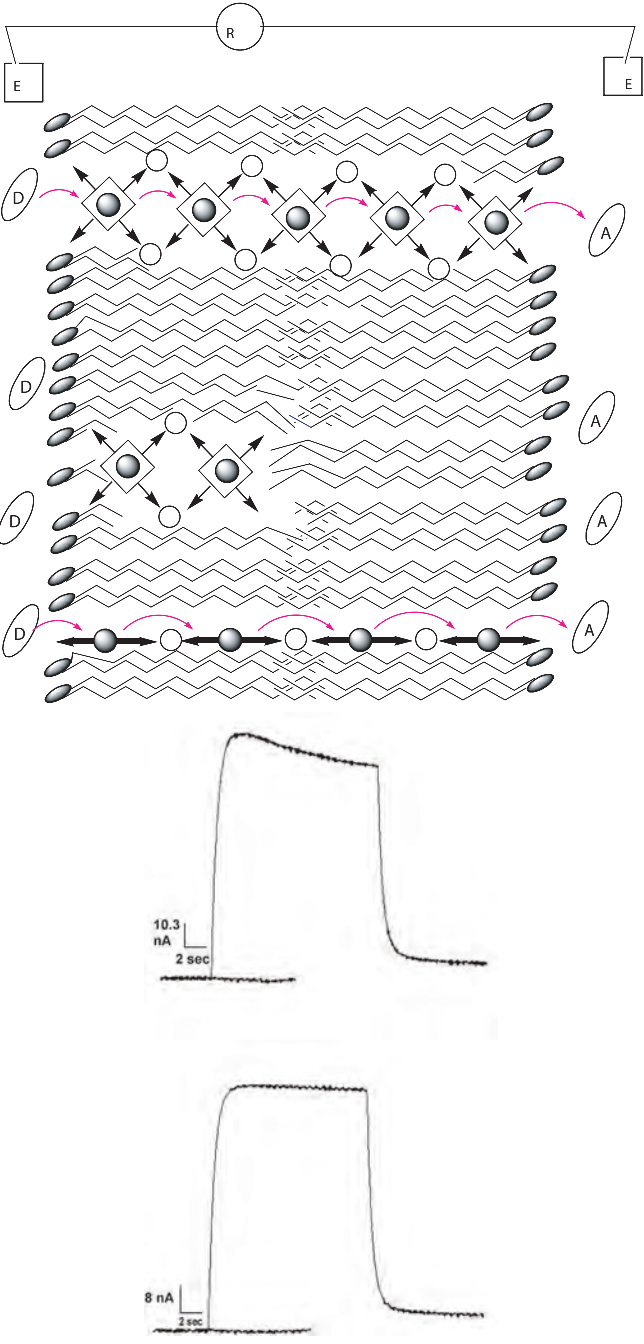
A porphyrin appended with four meso perylene imides also aggregates to form nanoparticles, but in this case there is likely a much greater degree of organization than in the previous system [104, 334]. These particles display photonic properties that depend on the aggregation state as well as the component molecule. Porphyrins have also been used as a means to organize Au nanoparticles [335].

7.1. Membranes: Molecular Electronics

Molecular ionic transistors. Lipid bilayer membranes and vesicles are self-organizing systems that mimic cell and organelle walls. The trans-membrane distance is ~8 nm. Again, mostly because of the relevance to photosynthesis, the reactivity and function of porphyrins in bilayer membranes and vesicles have been studied for more than 30 years

[336, 337], especially in terms of interfacial electron transfer, trans-membrane electronic and ionic currents, and redox chemistry. Early on it was realized that porphyrins partition into the bilayers with some degree of order—into the polar, ester group region of the head-group and perpendicular to the bilayer-water interface. The somewhat serendipitous discovery of a photo-gated *ion-conducting* transistor in the late 1980s [257–259] dovetailed well with the electrical circuit models of lipid bilayer function first proposed almost two decades earlier (e.g., [336, 337]). The charge-sensitive ion-conducting device (CSIC) was composed of lipophilic anions and porphyrins in a lipid bilayer. In the dark, with an applied potential of 40 mV, there is a space-charge limited conductance of the lipophilic anions [256]. Upon illumination with laser light in the absorption region of the macrocycle or white light, interfacial electron transfers from the lattice of porphyrins on both sides of the bilayer to aqueous electron acceptors resulted in two phenomena that allowed the conductance of the system to increase by several orders of magnitude. (1) The resultant porphyrin cation lattices (one on each side) significantly reduced the space-charge that limited the conductance of the lipophilic anions across the bilayer; and (2) the porphyrin cations now paired with the lipophilic anions to form an 'ion chain' which further reduced the barrier for ions crossing the hydrocarbon core of the membrane [259, 338]. Of course the stability of this system is limited by the stability of the membrane, and the response time is limited by the dynamics of assembling the ion chain. The inclusion of a protonophore results in a system that can photochemically pump protons to form a potential gradient [339, 340] across the membrane—one of the first self-organizing mimics of the essential outcome of photosynthesis which drives the synthesis of ATP. Other bilayer conducting systems with C_{60} and C_{70} fullerenes also serve as a basis for molecular electronics designs [341].

A molecular electronic transistor. The inclusion of a self-assembled membrane-spanning tape of porphyrins results in a significant improvement of the above system (Scheme 2) [98], and represents a molecular electronic device with all four levels of structure described in the introduction. By pre-assembling the conducting supermolecule, the gating time is significantly reduced, and the system need not rely on the movement of large ions across the viscous bilayer. Thus, when an electron donor is placed on one side of the bilayer and an electron acceptor on the opposite side, there is a chemical potential defined by the redox potentials of the donor and acceptor. Applying a voltage to this system results in no measurable conductance. Upon illumination with white light, the *electronic* conductance across the membrane increases by 50- to 1000-fold over controls without the donor or without the acceptor and with no applied voltage. This is an example of a self-organized, molecule-based photo-gated transistor, in this case driven by the electrochemical potential between the donor and acceptor. The self-assembled tapes are formed either by complementary H-bonds or by metal ion coordination. In addition to the advantages and limitations stated in the introduction, the benefit of self-assembly in this case is that the length of the tape is dictated by the width of the membrane. The water, phosphates, and esters compete for the hydrogen bonds and destabilize the coordination bonds. The electron donor and acceptor serve as the source and the drain, respectively, and the system is gated by light. This system also demonstrates that the interconnections to nanoscaled devices need not be nanoscaled *a priori*.



Scheme 2. Type-7C self-assembled linear polymers span an ~8 nm lipid bilayer parallel to the hydrocarbon chains (top and bottom). Not all supermolecules span the bilayer (center). Upon illumination with white light, the excited-state zinc porphyrin transfers an electron to an aqueous electron acceptor anthraquinone sulfate (A). The hole then hops across the supermolecule until quenched by an electron donor $K_4Fe(II)(CN)_6$ (D). Saturated calomel electrodes (E) reside in 0.1 M KCl solutions on each side of the bilayer, and an operational amplifier (R) measures the conductance. Conductance from 7A-type tape (top), and 7C-type tape (bottom). The baseline traces represent controls with no acceptor.

7.2. Vesicles

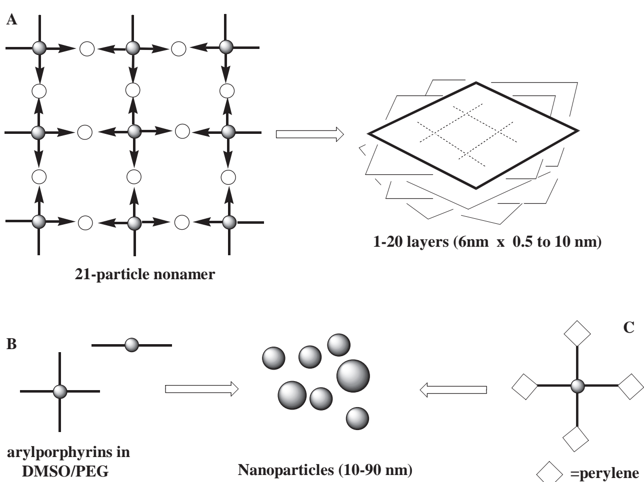
Another elegant example of the formation of potential gradients across membranes of vesicles uses a covalently bound porphyrin-vinyl-fullerene triad and similar molecules. Though these are molecular entities, they can be self-organized in bilayers of vesicles so that they mediate trans-membrane electrical currents upon illumination. The current then generates a potential that can drive the synthesis of ATP [78]. This is a dramatic example of the combined power of organic synthesis (primary structure) coupled with the self-organizing properties of lipids. Through the years there have been many other reports on the activity of porphyrins in membranes such as cytochrome P450 mimics (e.g., [81, 211]). A porphyrin bearing eight dendrons terminated with eight acetylenes can be self-encapsulated upon polymerization of the acetylenes using a Grubb's catalyst. The removal of the porphyrin core leaves a hollow dendrimer capable of recognizing a variety of porphyrins [71]. This remarkably effective example of molecular imprinting works because of the three-dimensional molecular organization of the dendrimer. But, the focus here is on self-assembled multiporphyrinic systems. Liposomes composed of porphyrins bearing long-chain hydrocarbon-substituted imidazoles [253, 342] have been reported.

7.3. Aggregates of Supermolecules

Remarkably, the self-assembly of 3 × 3 nonameric arrays can be accomplished by the stoichiometric addition of 12 Pd(II) ions to four "L"-shaped porphyrins that serve as corners, four "T"-shaped porphyrins that constitute the sides, and one "+"-shaped central porphyrin (see Section 3.1) [99]. These nonameric arrays can then stack to form columnar aggregates (Scheme 3A) that are ~7 nm in diameter by ~1 nm tall [100, 115]. These columnar stacks exhibit properties unique to this scale and degree of supramolecular order in that they are remarkably luminescent [104]. There are numerous papers on the aggregation of various porphyrin derivatives (neutral, negatively, and positively charged) where the quantum yield and lifetimes are ~10 times less than the individual porphyrin (e.g., [80, 262, 271–273]). This is in marked contrast to the self-assembled nonamers and columnar stacks of nonamers where both the heavy atom effect and aggregations should lead to quite meager luminescence, but instead the luminescence is only quenched by ~ 50%. This observation further indicates a high degree of order in the columnar stacks. These nanoscaled materials are stable in air at room temperature for years without detectable changes in their optical or morphological character [104].

7.4. Themes and Trends

Porphyrins have been known to aggregate since their first isolation and synthesis. The efficiency in harvesting solar energy, for example, arises from the specific alignment and organization of chlorophyll pigments in antenna complexes and reaction centers. Since many nanotechnological applications of porphyrins require narrowly dispersed nanoaggregates, there is a need to predictably and reliably control the size of the particles. Encapsulation of aggregates is an obvious method, but this may not be appropriate for all applications. There have been a few recent reports on the controlled formation of porphyrin nanoparticles with predictable size without resorting to an external matrix.



Scheme 3. Other porphyrin aggregates.

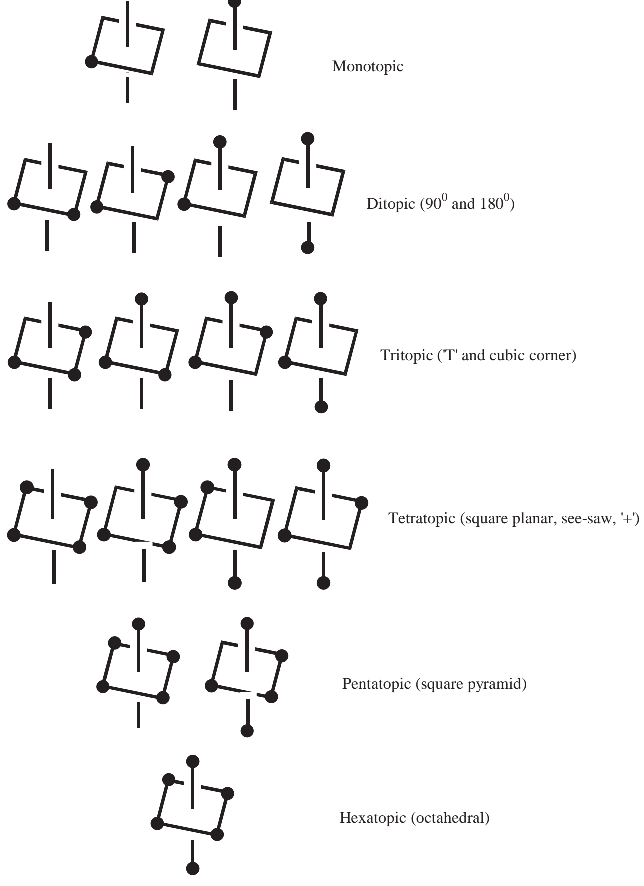


Figure 15. Topologies of a metalloporphyrin bearing four intermolecular binding motifs at the meso positions.

8. SUMMARY

After nearly 40 years of intense research, synthetic supramolecular chemistry has developed a wide variety of tools, methods, and strategies to form a staggering number of self-assembled and self-organized nanoscaled entities with diverse functions. Because porphyrins are rigid molecules, they have predictable shapes and orientations; therefore, these molecules are very often used as techtons. Porphyrins can act as monotopic caps, as linear linkers, as 90° turns, as bifurcating "T"-shaped crossroads, as square planar linkers or centers, and metalloporphyrins can serve as square pyramidal components, or as octahedral components (Fig. 15). Obviously, incorporating more complex moieties capable of more than one intermolecular interaction (such as meso 3,5-dicarboxyphenyl- and 3,5-dipyridylphenyl-) or attaching these molecular recognition moieties to the pyrrole positions will significantly increase the number of topologies available for the design of supramolecular porphyrinic systems. Coupling these porphyrin topologies with the various coordination geometries of transition metals and/or the various geometries of other multitopic ligands can result in supramolecular systems that are only limited by one's imagination. The requirements of the application dictate the design of self-assembled or self-organized systems such as porphyrins, but because of the rich supramolecular chemistry of porphyrins these requirements can be met. The resultant nanoscaled materials can have a wide variety of properties as photonics, catalysts, sensors, and sieves—each of these functions can be fine-tuned by modifications of either the macrocycle or the bound metal ions.

Recent endeavors into the formation of dynamic combinatorial libraries may afford a new means to find multiporphyrin arrays that have unimagined or optimal structures, with unimagined or optimal functions [171, 343]. Materials that switch their structure as a response to some environmental factor or a chemical entity [97, 344] can also be formed with porphyrinoids, which would then serve as a reporter of the structural change. Finally, methods of porphyrin synthesis have facilitated their use both in the lab and for commercial applications [94, 345].

GLOSSARY

Photonic The interplay between photophysical properties of a molecule or material and the electronic properties of the material, such as in photoinduced electron or energy transfer.

Self-assembly The spontaneous association of molecules and/or ions to form a specific supramolecular entity.

Self-organization The spontaneous association of molecules and/or ions to form polymeric materials, or dynamic two-dimensional systems such as liquid crystals.

Supramolecular Referring to a discrete entity containing two or more molecules/ions associated by intermolecular forces (such as hydrogen bonding, coordination chemistry, and electrostatic interactions) in a specific geometric arrangement.

ACKNOWLEDGMENTS

1. INTRODUCTION

The emerging fields of nanoscience and nanoengineering are leading to unprecedented understanding and control over the fundamental building blocks of all physical matter. Today, nanophase engineering expands in a rapidly growing number of structural and functional materials, both inorganic and organic, allowing the manipulation of mechanical, catalytic, electrical, magnetic, optical, and electronic functions. The synthesis of nanophase or cluster-assembled materials is usually based upon the creation of separated small clusters which are then fused into a bulk-like material or as a thin film or even by embedding into a solid matrix, materials like polymers or glass either in a disordered manner or in an ordered array.

There is a need to learn how to manipulate nanosized particles and form the ensemble into periodically ordered particulate materials for application into devices making use of the special physical properties that arise due to the nanometric crystallite sizes, like the quantum effects, for example. From recent developments in the cluster source technologies (thermal, laser vaporization, aerosol techniques, chemical vapor deposition, and sputtering) [1–4], it is now possible to produce intense cluster beams of any materials, even the most refractory or complex systems, for a wide range of sizes from a few atoms to a few thousand atoms [5].

Significant progress in the organization of semiconductor quantum dots (QD) has been made by employing a variety of microelectronic fabrication techniques [6–10], but the most widely used strategy employs the deposition of a narrower bandgap, compressively strained epilayer over a wider bandgap substrate, which results in the spontaneous nucleation (self-assembly) of coherently strained three-dimensional islands on top of a thin ($\sim$1 nm), two-dimensional "wetting layer." Subsequent deposition of substrate material to encapsulate the QD produces a fully three-dimensional confinement potential. This approach however, is, outside the scope of the present review where we will concentrate on the fabrication of ordered layers or structures from colloidal particles.

An elegant method to organize nanometric particles is by the so-called "self-assembly methods often inspired by nature (biomimetic processes). When self-assembly is used to organize nanomaterial into a useful form, irrespective of whether the structures so formed are points, lines, layers, or composites, they are going to be periodic in arrangements, since such arrangements minimize the free energy of the systems. Methods developed to produce three-dimensional, bulk-like hierarchical structures include biomimetic methods, which use polypeptides as building blocks, and amphiphile and colloidal templating, which use amphiphilic or colloidal mesophases as templates for inorganic mesoporous materials. Designing finite mesostructures with a given geometry is the future challenge to make use of the special properties arising due to the scaling of the particle sizes for applications. Ordered assemblies of nanometer-sized particles are thus an interesting class of nanomaterials that provide exceptional potentials to achieve one-two-and three-dimensional structures for a wide variety of applications ranging from photonic devices to memory devices, two-dimensional arrays of magnetic nanoparticles [11–13], or single-electron microelectronic devices, amongst others [14–16]. In order to make full use of this potential

for materials engineering, it is important to identify and gain control over the relevant growth and ordering parameters both during the formation of ordered structures as well as after the growth process, so that the structures so formed do not get distorted.

This is a field in its nascent stage and experimentalists are still struggling to build up on the ideas propagated by the theorists to develop the complex technology required to give two- or three-dimensional structures to a material on the nano or micron scale (in this case the primary materials are of nanoscopic length scales). More and more interesting structures, prepared by a variety of methods twinned around "self-assembly" methods, are being reported regularly in the literature. Self-assembly and self-organization are concepts that are broadly used over a whole range of fields including physics, chemistry, biology, and engineering. Nanoscale self-assembly is a concept that nature has been making use of since the beginning of life, and it is only recently that we have started realizing the potential of utilizing this phenomenon for the artificial control of matter [17].

Letting aside the self-assembly or self-organization processes, even nanotechnology did not emerge as an experimental science before the 1980s due to the unavailability of suitable tools to allow researchers to observe—let alone manipulate—individual atoms. It evolved dramatically with the invention of two new microscopy techniques: atomic force microscopy (AFM) and scanning tunneling microscopy (STM). Both these techniques were a radical departure from previous types of microscopy, which worked by reflecting either light (in the case of optical microscopes) or an electron beam (in the case of electron microscopes) off a surface and onto a lens. But no reflective microscope, not even the most powerful, could image an individual atom. The discovery of the STM got scientists and engineers to look into the self-organization processes of nanoscopic matter more closely, as STM brought in the possibility of visualizing at the nanoscopic levels and also the possibility of moving atoms to structure them into useful forms. Direct writing of nanoscopic features with atoms is a very slow process that is normally achieved, for example, by utilizing tools like the scanning probe microscope (SPM). Thus, a more practical method is albeit—the use of natural forces to structure nanoscopic features. With the discovery of other microscopic tools like AFM, and the improvement of the electron microscopy tools further developed the possibilities of visualizing and implementing the experiments designed by researchers which has given boosted efforts to explore the immense possibilities this field has in reserve.

Two approaches for the building up of nanoscopic features have been envisaged: the so-called "top-down" method and "bottom-up" methods. In the "top down" methods, the features are written directly onto a substrate, for example, by electron beams, and then by applying appropriate etching and deposition processes, the nanoscopic features are engraved. In the "bottom-up" approach, nanocomponents are made from precursors in the liquid, solid, or gas phase employing either chemical or physical deposition processes that are integrated into building blocks within the final material structure. The "bottom-up" approach, or simply the assembly from atoms, include wide-ranging methods encompassing supramolecular chemistry to biomimetic processes to template synthesis, amongst others. The aim of this article is to consider the "bottom-up" approach for building up nanostructures focusing on some of the self-organization methods that are used in structuring colloidal nanoparticles into regular films, arrays, or three-dimensional structures. This article will attempt to distinguish between the self-assembly processes (that is often misconceived in some experiments reported in the literature) from the self-organization of colloidal nanoparticles.

2. SELF-ASSEMBLY AND SELF-ORGANIZATION

Organization during self-assembly processes is driven mainly by competing molecular interactions like hydrophobic versus hydrophilic components, gravitational, van der Waals, or Coulombic interactions. Self-assembly is an assembly process in which only the constituents of the final structure take part, that is, get incorporated into the resulting structure [18]. Self-organization, in retrospect, is defined as a mechanism for building patterns, processes, and structures at a higher level through multiple interactions among the components at the lower level(s), where the components interact through local rules that do not explicitly code for the pattern [19–20]. In colloidal materials, self-assembly process has often been related to describe the growth of nanoparticles, for example, of controlling the size of the particles by self-organization of polymers on these growing particles and has to be clearly differentiated from the self-organization processes of the colloidal particles into either two- or three-dimensional structures.

The phenomena of pattern formation and self-organization occur as natural responses of complex systems to strong external stimulation. The collective interaction between system components under external driving forces, which drive the system far from equilibrium, results in the self-organization of its constituents [21–22]. Some of the salient features of this viewpoint can be found in the behavior of chemical [23–24], liquid crystal nematics [25–26], and fluid systems [27]. It has also been recognized that condensed matter systems show a rich variety of patterns and self-assembled microstructures under conditions as diverse as solidification [28], electro-chemical deposition [29], plastic deformation [30–31], surface modifications [32], rapid laser heating [33], irradiation by energetic particles [34], magnetic domains [35], and more recently, atom deposition into self-assembled monolayers [36]. All these phenomena are currently being revisited, as self-assembly is nothing new; for example, lustre decoration of medieval and renaissance pottery consists of self-assembled silver and copper nanocrystals within the glassy phase of the ceramic glaze. A peculiar property of this lustre was enumerated to arise due to the high density of pseudo-spherical nanocrystals and their locally homogeneous distribution in the ceramic [37–39]. Another historic example of self-assembly (or even self-organization) of nanoparticles is found in the Maya blue paints [40]. Studies of authentic samples from Jaina Island show that the material is made of needle-shaped palygorskite (a clay) crystals that form a superlattice with a period of 1.4 nm, with intercalates of amorphous silicate

substrate containing inclusions of metal (Mg) nanoparticles. The beautiful tone of the blue color is obtained only when both these nanoparticles and the superlattice are present together, as has been shown by the fabrication of synthetic samples.

2.1. The Self-Assembly Process

As explained earlier, self-assembly in a general sense, might be defined as the spontaneous formation of complex hierarchical structures from predesigned building blocks, typically involving multiple energy scales and multiple degrees of freedom. It is also a very general principle in nature, as seen in the formation for example, of membranes from lipid molecules or the living cell as probably the most important paradigm [41]. Self-assembly has been defined by Kuhn and Uhlman as a 'process in which supramolecular hierarchical organization is established in a complex system of interlocking components' [42]. Self-assembled monolayers (SAMs) have been studied in great details by surface scientists by using different types of molecules on a host of different substrates. Detailed description and discussion on the SAMs are outside the scope of this article, but a comprehensive report of SAMs as described by surface scientists have been recently published [43]. As an example, the self-assembly can be achieved through an alkane chain typically with 10–20 methylene units that can be given a head group with a strong preferential adsorption to a chosen substrate. For example, thiol (S-H) groups adsorb readily from a solution onto a gold surface creating a dense monolayer with the tail group pointing outwards from the surface. Numerous work, both calculations [44] and experiment [45], has been reported describing the self-assembly of thiol molecules to control gold nanoparticle sizes during synthesis [46] and/or during the assembly of these particles on a substrate including a milestone review recently published by Brust and Kiely [47].

2.2. Surface Modification of Nanoparticles

Particles in the nanometer-size range have a strong tendency to agglomerate due to van der Waals interactions. It is therefore important to develop synthetic methods by which the particles can be stabilized, that is, where repulsive forces between the particles can be provided to balance this attraction (Fig. 1(A)) [48]. Generally two types of stabilization are used to prevent agglomeration of nanoparticles, namely, electrostatic stabilization and steric stabilization by adsorbed molecules or steric hindrance [49–50]. Electrostatic stabilization involves the creation of an electrical double layer arising from ions adsorbed on the surface and associated counterions that surround the particle. Thus, if the electric potential associated with the double layer is sufficiently high, the Coulombic repulsion between the particles will prevent their agglomeration (Fig. 1(B) and Fig. 2) [51–52].

Steric stabilization can be achieved by the adsorption of large molecules such as polymers at the surface of the particles (Fig. 3). Indeed, the coil dimensions of polymers are usually larger than the range over which the attraction forces between colloidal particles are active. Two distinct effects describe this type of stabilization (the volume restriction contribution and the osmotic diffusion), and they both contribute to the interaction free energy [46, 53–54]. First, the fact that the adsorbed molecules are restricted in motion causes a decrease in the configurational entropic contribution to the free energy (Fig. 3). Second, the local increase in concentration of polymer chains between approaching particles results in an osmotic repulsion, since the solvent reestablishes equilibrium by diluting the polymer molecules and separating the particles. This can be described by the energy of free mixing of polymer segments and solvent molecules, calculated by the Flory–Krigbaum theory [55].

The conformation of adsorbed polymers tends to be controlled by the strength of segment/surface interactions [56], which may be described by the classical loop-train-tail model [57–58]. For an effective particle stabilization, it is important that the polymer form a complete, dense layer around the particle [59]. Then, the polymeric stabilizer must have sufficient tail length and adsorb uniformly enough to screen the attractive interaction between the particles.

Another requirement for good particle stabilization is the use of appropriate solvents. The stabilizing polymer has to possess high affinity with the solvent in order to solvate the particles and form an extended layer for screening the van der Waals attraction between the particles. It is well known, however, that adsorption is generally stronger when the affinity of the polymer to the solvent is low [60–61]. Therefore, block or graft copolymer micelles, in the presence of a selective solvent that solubilizes one of the blocks,

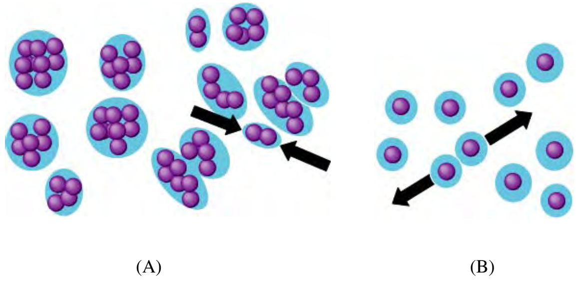

Figure 1. Particles in a colloid (A) uncharged particles are free to collide and agglomerate and (B) charged particles repel each other.

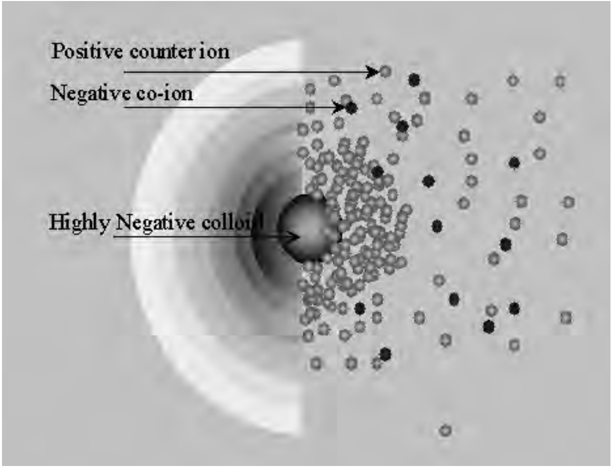

Figure 2. Schematic representation of the stabilization of a nanoparticle by charging the surface with counter ions.

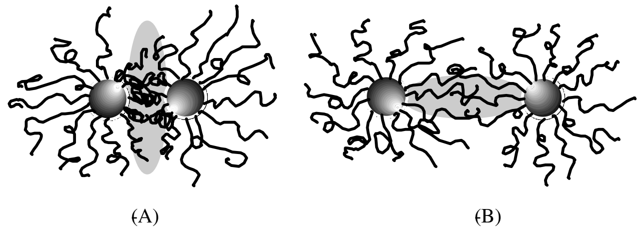

Figure 3. Steric stabilization of metal colloid particles by polymers: (A) entropic effect, (B) osmotic effect.

lead to expanded chains which occupy more surface area. In the case of polymers with strong anchoring groups, spontaneous adsorption occurs from good solvent [46]. De Gennes has discussed the density profile of polymers attached to the surface by one end and in contact with an appropriate solvent [62]. Another important advantage of covalently attached polymers is that the resulting interaction with the particle surface is stronger and desorption cannot occur by solvent effects or variations in temperature [63–64].

As previously mentioned, alkanethiols spontaneously self-assemble onto colloidal gold particles and this capping of gold particles by alkanethiols are sometimes termed three-dimensional self-assembly, which is often differentiated from the so-called two-dimensional self-assembly on gold thin films [65–66] or alkylsilanes on silica films. To differentiate between the arrangement of nanoparticles into ordered structures and the passivation of nanoparticles by polymeric entities [67], it is our belief the stabilization of nanoparticle growth or agglomeration by polymers is a *self-assembly process*. For example, the self-assembly on gold particles occurs through a strong thiolate bond between the surfactant and the gold surface which leads to the assembly of these surfactant molecules on the surface of gold nanoparticles [68]. There are numerous reports on the self-assembly of alkanethiols, aromatic thiols, and alkylamines onto gold and silver colloidal particles, which has been reviewed in great detail [47, 69–70]. Figure 4 illustrates an example of surface derivatization of gold and silver particles with three-dimensional SAMs of ω-functionalized thiol molecules.

Analogous to the attachment of organic stabilizers, biological components have also been used for stabilization of these colloids. Typically, wet-chemical preparation of the nanoparticles is carried out in the presence of stabilizing agents (often citrates, phosphanes, or thiols) which bind to the atoms exposed at the surface of the nanoparticles. This capping leads to a stabilization and prevents uncontrolled growth and aggregation of the nanoparticles. In the case of

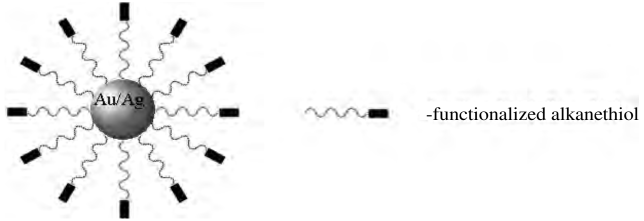

Figure 4. Schematic representation of the surface functionalization of a gold or silver nanoparticle by an alkanethiol.

a labile capping layer such as citrate, biomolecules can be linked directly with a metal particle by exchange reactions with stronger binding ligands. This method is usually applied in the coating of colloidal gold with thiol-containing proteins, for example, immunoglobulins (IgG) and serum albumins, which have cysteine residues that are accessible for the heterogeneous interphase coupling. If no such residues are available in the native proteins, thiol groups can be incorporated by chemical means [71] or by genetic engineering. For example, DNA molecules can be synthesized with alkylthiol groups, and n-alkylthiolated DNA has been used extensively in the preparation of DNA-functionalized gold and semiconductor nanoparticles [72–77]. As an interesting alternative, DNA oligonucleotides, which contain several adenosyl phosphothioate residues at their ends, have also been used to directly interact with the metal surface of nanoparticles [78]. The use of cyclic disulfide linkers [77–78] leads to nanoparticle capping, which are more stable towards ligand exchange than the corresponding conjugates prepared with the conventional reagents that contain a single thiol group or acyclic disulfide units. The greater stability is likely a result of the anchoring of the ligands to the nanoparticles through the two sulfur atoms [77].

Surface functionalized metal nanoparticles have been used for a variety of applications. Terms like "nanofactory" has been often cited, which basically study the reactivity's of functional groups anchored to gold colloidal particles [47, 79]. Another approach to use these self-assembled metal clusters has arisen due to the local field enhancement and nanoscale resonant behavior of metal clusters excited by an electromagnetic radiation. In metal particles, absorption in the UV-visible spectra (with a peak at 520 nm for 10 nm gold particles, for instance) is due to the excitation of a plasmon resonance which corresponds to a collective oscillation frequency of conduction electrons [80]. These absorption spectra can be theoretically explained by the Mie theory [81–82], in which the theoretical absorption spectrum of dilute spherical particles ("surface plasmon resonance") is related to their size, and their frequency-dependant dielectric constant, compared to the surrounding medium [83–84]. Immunogold labeling and immunogold chromatography as well as surface plasmon resonance transduction of metal cluster binding, which has been successfully commercialized using these surface stabilized nanoparticles, is outside the scope of this review [85]. Numerous other applications that include the deposition of these self-assembled nanoparticles have been reported, for example, local plasmon sensor [86], colorimetric DNA analysis [87], optically anisotropic windows [88–89], surface enhanced raman spectroscopy (SERS) substrates [90], amongst others. Several authoritative reviews are available dealing with the self-assembly and self-organization of gold nanoparticles [47, 91]. Self-assembled monolayer formation provides an easy route towards surface functionalization by organic molecules containing suitable functional groups like -SH, -CN, -COOH, -NH_2, and silanes on selected metallic (Au, Cu, Ag, Pd, Pt, Hg, and C) [92], as well as semiconducting surfaces (Si, GaAs, ZnS, CdS, etc.) [93–98]. Self-assembly inside a nanoscale cavity has also been reported where, for example, the reaction between divalent cadmium or zinc with sulfide or selenide is performed in a restricted environment in

the nanometer scale. Examples of nanoscale cavities include porous glasses and xerogels [99], reverse micelles [100], zeolites [101], membranes [102–103], and hollow proteins, amongst others [104]. Yeast and tomato virus, and likely other organisms, produce CdS quantum dots as a detoxification response to an overload of cadmium [105–106]; the CdS thus produced is coated with a particular peptide, which was used as the stabilizing thiol to make CdS quantum dots [107].

3. SELF-ORGANIZATION OF NANOPARTICLES INTO SUPERLATTICE

The general interest in the self-organization of spherical and non-spherical nanoparticles, of late, has arisen due to the possible applications in a wide range of domains [91, 108–110]. Periodic arrays are structures where nanoparticles are arranged in a regular fashion in either two or three dimensions [111]. These structures would be useful for displays, sensors, data storage, or photonic bandgap materials [91]. Monosized spheres of silica and polystyrene have most often been used for studying the self-organization processes, due to their easy availability. On the other side, QDs of semiconducting and metallic materials, due to their potential and already realized applications, as well as fundamental chemical and physical interest, have been studied in great details with some activities on the self-organization phenomena reported [112].

Nonlithographic bottom-up approaches based on self-assembly and self-organization are especially appealing because of their intrinsically low overhead for large-scale production. This approach has been useful in the self-organization of monolayer-protected metal nanoparticles into periodic two-dimensional (2D) arrays, with many of these assemblies demonstrating novel optical or electronic properties as a function of particle size or interparticle spacing [68, 113–116]. Numerous examples of 2D arrays comprised of small ($<$10 nm) gold nanoparticles have been reported, but details on well-ordered 2D arrays of larger gold nanoparticles are not available in the literature. Particles beyond a certain size (about 15 nm) tend to agglomerate into multilayer or three-dimensional aggregates rather than form 2D monoparticulate films [117]. This can be attributed to the large Hamaker constant for gold [118–119] and the rapid increase in van der Waals attraction between particles as a function of size [120], as well as the loss of surfactant chain mobility on the planar facets of the nanoparticles.

Polystyrene (PS) nanoparticles are commercially available and have been used for a wide range of applications ranging from applications in fields of photonics [121–125], nanotechnology [126–132], and life science [133–140] to fundamental studies in the behavior of colloidal suspensions, like the role of hydrodynamic [140–141] and entropic [142] forces and studies on phase transition [143] and crystallization [112] of "model atoms" in two or three dimensions. Irrespective of this plurality of applications, at the focus of these activities is the adsorption of the particles as a 2D layer onto a surface, where, depending on the specific aims of the subject, close-packed ordered arrays or irregular, less densely packed layers are selectively used. The schemes proposed so far for patterning PS particles range from purely physical concepts, such as micro-molding in capillaries (MIMIC) [144] and electrophoresis(to be discussed in a later section) to those combining physical interaction mechanisms like electrostatic or capillary forces with the selectivity of chemically patterned surfaces [145–146]. The self-organization techniques that have been used to build 2D or three-dimensional (3D)-ordered structures are schematically represented in Figure 5 and are discussed in greater details in the next few sections.

3.1. Self-Organization Through Capillary Forces

A comprehensive review of various types of capillary forces on particles has been reported by Kralchevsky and Denkov, which is summarized in Figure 6 [147]. If a droplet of the colloid suspension is dried slowly on an unpatterned polar surface (such as silica), the particles aggregate at the rim of the droplet because of attractive capillary forces between the particles when the water film thickness is in the dimension of the particle diameter, which is schematically shown in Figure 6 [147–148]. The mobility of the electrostatically attached particles is lost after complete drying, suggesting a three-step mechanism for the particle adsorption. First, positioning and adhesion in the suspension liquid are controlled by charge and polar interactions between the substrate and particle surfaces. In the second step, capillary forces between the particles and the surface laterally displace the particles during drying. After complete evaporation in the third stage, an irreversible reorganization of the particle–substrate interface occurs, which prevents resuspension or displacement when resubmerging the assembly into the adsorption liquid. A submonolayer of electrostatically adsorbed particles forms on the charged pattern surface in the bulk phase of the suspension. The submonolayer coverage is caused by Coulomb repulsion of the like-charged particles, which prevents dense packing in the aqueous medium. During evaporation of the suspension, the liquid front moves very slowly over the adsorbed particle layer, and a thin liquid meniscus remains over the particle assembly, which generates attractive capillary forces between the particles, as shown in Figure 6(c).

Because of the slow-moving, droplet front, particles from the suspension do have time to migrate into the thin liquid film at the drying front and aggregate into multilayer over the colloid assembly pattern driven by capillary forces (Fig. 7). Many more factors influencing the particle–surface interactions, such as surface topography and corrugation [149–151] or even nanoscopic air bubbles [152] might have to be taken into account in order to completely understand the ordering phenomena of colloidal nanoparticles through

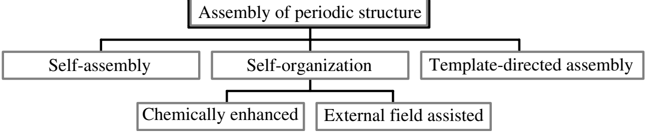

Figure 5. Diagram showing various self-organization techniques reported in the literature.

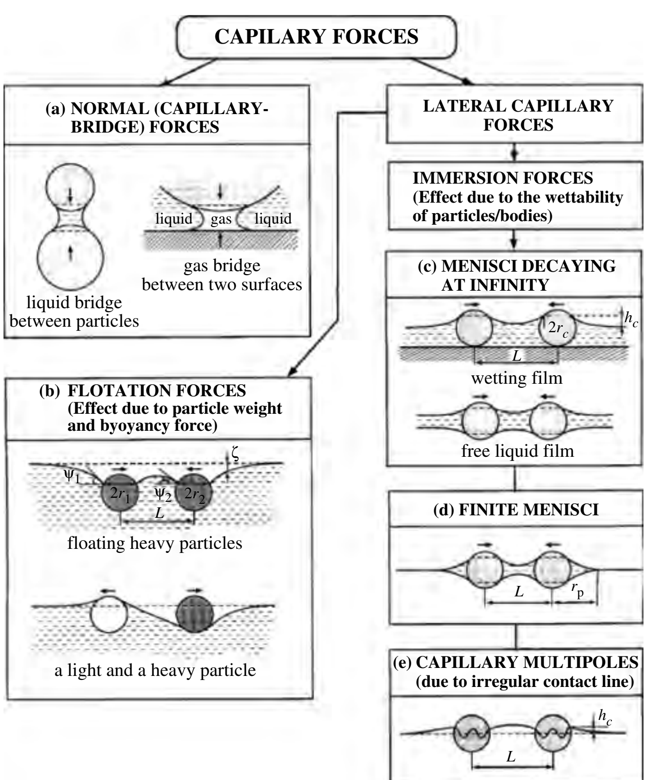

Figure 6. Types of capillary forces: (a) The *normal* capillary forces can be due to either liquid-in-gas or gas-in-liquid capillary bridges, which lead to particle-particle and particle-wall interactions, the force is directed normally to the contact line. In the case of *lateral* capillary forces (b, c, d, e), the force is parallel to the contact line. The interaction is due to the overlap of interfacial deformations created by the separate particles. (b) In the case of *flotation* force, the deformations are caused by the particle weight and buoyancy. In the case of *immersion* forces (c, d, e) the deformations are related to the wetting properties of the particle surface: position and shape of the contact line, and magnitude of the contact angle. When the deformation around an isolated particle is axisymmetric, we deal with "*capillary charges*," one can distinguish cases of infinite (c) and finite (d) menisci. (e) The forces between particles of undulated or irregular contact line can be described as interactions between "*capillary multipoles*," in analogy with electrostatics. capillary forces. Another important factor that should be considered is that during the drying process, the ionic strength of the colloid changes affecting the double-layer thickness and hence the final organization process.

3.2. Template-Assisted

In this section, we review only the approaches that combine templating with attractive capillary forces to assemble particles into complex aggregates with well-controlled sizes, shapes, and internal structures [153–154]. Surface confinement provided by liquid droplets has been used to assemble colloidal particles or microfabricated building blocks into spherical objects [155–157]. In this process, patterned arrays of templates are fabricated in thin films of photoresists (for example, spin-coated on glass, silicon wafer, or quartz substrates), using conventional photolithography techniques used in microelectronics or printing processes. Control over the number of particles in each such template is governed by the size of the particles and the size and shape of the templates [153]. Patterned arrays of relieves on solid substrates have also been exploited to grow colloidal crystals with unusual crystalline order and orientations [149, 158–159].

Templating against opaline arrays of colloidal spheres has also been successfully applied to the fabrication of 3D macroporous structures from a wide variety of materials, including organic polymers, ceramic materials, inorganic semiconductors, and metals (for example, as in Fig. 8) [161–176]. Fabrication based on this approach is remarkable for its simplicity, and for its fidelity in transferring the structure from the template to the replica. The size of the pores and the periodicity of the porous structures can be precisely controlled and readily tuned by changing the size of the colloidal spheres. There is no doubt that a similar approach is extendible to other materials. The only requirement seems to be the availability of a precursor that can infiltrate into the void spaces among colloidal spheres without significantly swelling or dissolving the template (usually made of

polystyrene beads or silica spheres). Some gaseous precursors have also been employed in this process, albeit the initial product deposited on the surfaces of samples might block the flow in of gaseous precursors [175]. Presently, the smallest colloidal spheres that have been successfully used in this method are ~35 nm in diameter [167]; the lower limit to the particle size that can be incorporated into this technique has not been completely established.

In another article, fabrication of germanium inverse opals by a combination of wet-chemical and gas-phase synthesis has been reported by Meseguer et al. [177]. Ge is transparent to infrared radiation (below 0.67 eV at room temperature) and it presents an extremely high refractive index contrast ($n = 4$). This makes Ge inverse opals one of the most promising PBG material made out of a semiconductor. It was reported that the photonic bandgap material formation by the classical infiltration method, using hydrolysis followed by a reduction and the use of chemical vapor deposition (CVD) technique, increased the homogeneity of the germanium layer. In the hydrolysis route, a germanium precursor ($Ge(OCH_3)_4$) was completely infiltrated in the opal voids (in a template made with 870 nm silica particles), followed by a hydrolysis process to obtain GeO_2. Figure 9(A) shows opal voids impregnated with small (~100 nm) GeO_2 microcrystallites. Ge was obtained by a reduction process at 550 °C. To increase the infiltration percentage, the opals are subjected to multiple cycles of hydrolysis followed by a reduction process. The Ge infiltrated opals were then chemically etched to remove silica particles with the same method used for the other inverse opals. In this way, we seek to remove the SiO_2 spheres from the composite and obtain Ge inverse opals. Figure 9(C) shows SEM images of the cleft edge of a Ge inverse lattice. In a further improvement of this classical method, the authors also reported the use of CVD for the infiltration of silica templates made from slightly larger spheres (1200 nm). The germanium precursor, Ge_2H_6 gas, was at first infiltrated into the template placed in a high vacuum cell (5×10^{-6} torr), and then, the sample cell was cooled by using liquid nitrogen, which gave rise to the condensation of the precursor into the opal void volume. Thereafter, upon heating the reactor up to the decomposition temperature of Ge_2H_6, microcrystalline germanium were formed in the pores, as shown in Figure 9. By this method, the authors claim that the Ge filling fraction can be controlled up to 100% of the template pore volume. The infiltrated samples were later chemically etched to obtain a germanium inverse opal with long-range FCC order of the original template.

Recently, Yang et al. demonstrated a simple and convenient method for fabricating hierarchically porous materials by combining colloidal arrays and block copolymers into a single system [176]. In summary, dewetting of colloidal dispersions from contoured surfaces, attractive capillary forces, and geometric templating can be combined to provide an attractive method of assembling colloidal particles into complex aggregates. The success of this organization approach depends on the control of a variety of parameters like the meniscus of the curvature of the rear edge of the liquid slug, concentration, and surface charges on the colloidal particles and the templates. However, though it has not been conclusively proved yet, this method may be limited to a few tens of nanometer regions due to the interaction of the Brownian motion and the capillary forces. One such example of the use of physical templating and capillary forces to assemble monodispersed spherical colloids into uniform aggregates with well-controlled sizes, shapes, and structures is shown in Figure 10 (and also Table 1). When an aqueous dispersion of colloidal particles is allowed to dewet from a patterned solid surface with appropriate relief structures, the particles get trapped and assemble into aggregates whose structures are determined by the geometric confinement provided by the templates. By this method, the capability and feasibility of assembling polystyrene beads and silica colloids (~150 nm in diameter) into complex aggregates which include polygonal or polyhedral clusters, linear or zigzag chains, and circular rings, have been demonstrated and a couple of examples are shown in Figures 11 and 12.

Immobilization of metal colloid particles on a suitable structured matrix using a self-assembly technique is one of the promising strategies for the construction of

porous silicon, anodized alumina, etc.) have also been used as templates for the growth of nanoparticles inside the pores [182]. One such example of three dimensionally arranged gold colloids has been prepared in the nanoscale pores of alumina membranes [181]. Immobilization of the colloid particles performed by vacuum incorporation were achieved by a modification of the inner walls of the porous alumina substrate with alkoxysilanes $Y\text{-}(CH_2)_x\text{–}Si(OR)_3$ and $Y\text{-}(CH_2)_x\text{–}SiR(OR)_2$ bearing suitable functional groups ($Y = NH_2$, SH), followed by anchoring of the colloids by self-assembly onto the modified surface. Well-washed membranes are dark-red in color upon incorporation of gold colloids, and a schematic description of an alumina membrane containing immobilized gold is shown in Figure 13. A part of the sample showing the particles located only near the pore walls is shown in Figure 14(A), which is schematically explained in Figure 14(B). The particles are closely packed, vertically overlapped, and generally observed along the walls.

3.3. Electrostatic Complexation of Nanoparticles with Charged Langmuir Monolayers

The air-water interface has been recognized to be an excellent media for organization of inorganic cations using charged amphiphilic monolayers (Langmuir films) [183].

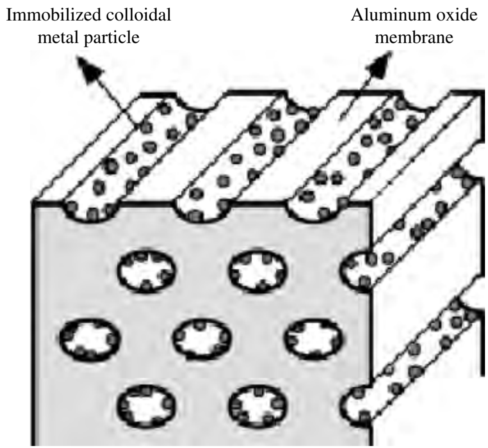

Figure 13. Model structure of a colloid-charged porous alumina membrane. Reprinted with permission from [181], T. Hanaoka et al., *Eur. J. Inorg. Chem.* 807 (1998). © 1998, Wiley-VCH.

This approach has been extended to assemble large inorganic anions [184–185] and biological macromolecules [186–187]. Colloidal particles can apparently be trapped at the liquid surface as a result of the electrostatic and surface tension forces [188–191]. The interaction between the ions/macromolecules in solution and charged lipid Langmuir monolayers drives the organization at the air-water interface. The nanoparticles organized in this fashion by the Langmuir–Blodgett (LB) method can then be transferred into appropriate substrates, for example, carboxylic-derivatized silver nanoparticles can be immobilized at octadecylamine (ODA) Langmuir monolayer surfaces [192–194].

The behavior of particle monolayers at liquid surfaces has also received considerable attention of late but was already studied some 30 years ago [195–196]. Kumaki reported an interesting work on monomolecular PS nanoparticles (~50 nm diameter) monolayers and discussed the possible significance of the surface pressures on the organization of these particles [197]. However, application of the LB technique to colloidal particles led to submonolayers with coverage less than 80% [198]. Only recently, Bardosova et al. [199] reported on the successful Langmuir–Schaefer transfer of monolayers of silica particles modified with 3-aminopropyl groups.

The formation of 2D arrays by self-assembly on solid supports make use of numerous strategies [200–203], for example, a 2D array of colloidal spheres can be formed at the air-liquid interface which can then be subsequently transferred onto a surface of a solid substrate. The surfaces of these colloidal spheres have to be modified such that they will only be partially immersed into the surface of a liquid after they have been spread onto the air-liquid interface through a spreading agent (usually an alcohol) [189]. It is the strong attractive interactions (e.g., those between dipoles induced by the asymmetric interface) among the colloidal spheres that lead to the spontaneous formation of a 2D aggregate at the interface. The morphology of the aggregate usually exhibits fractal characteristics, but it can also be changed by varying a number of parameters such as the size, the number concentration, the surface hydrophobicity, or the charge density on the colloids, and the electrolytic properties of the underlying liquid [189]. In a recent demonstration, for example, Kondo et al. were able to generate 2D arrays of silica colloids (1 μm in diameter) with relatively large domain sizes by controlling the degree to which the silica colloids were immersed into the liquid surface [204]. Deckman et al. [205], Lenzmann et al. [206], and Fulda and Tieke [207] applied the LB film technique in this fashion to obtain polycrystalline 2D arrays of polymer latexes over areas as large as several square centimeters.More recently, Burmeister et al. also demonstrated a similar technique that was capable of forming ordered 2D arrays of colloidal spheres on various types of substrates [208].

Another method that has been largely explored by Nagayawa, Picard, Rakers, et al. [202–203, 209–213], uses the attractive capillary forces among colloidal spheres to organize them into a hexagonal 2D array in a thin film of liquid supported on a flat substrate. In a typical experiment, a liquid dispersion of colloidal spheres is spread onto the surface of a solid substrate. When the solvent slowly evaporates under a controlled condition, these colloidal spheres are self-assembled into a closely packed, hexagonal array, which has also been followed experimentally by using an optical microscope [202, 214]. They found that a nucleus—an ordered region that consists of a number of colloidal spheres—was first formed when the thickness of the liquid layer approached the diameter of the colloids. More colloids were driven toward this nucleus by a convective transport, and eventually organized around the nucleus due to the attractive capillary forces. A flat, clean, and chemically homogeneous surface has to be used in order to generate a highly ordered array with relatively large domain sizes. Solid substrates, such as glass slides or silicon wafers, have been used in this technique. Lazarov et al. have also explored the use of liquids such as prefluorinated oil (F-oil) or mercury as the substrates in forming highly ordered 2D arrays of colloidal spheres [215]. At the air-water interface under appropriate passivation conditions, mid-nanometer-sized gold particles can undergo self-organization into densely packed monoparticulate films [216]. These films, when transferred onto hydrophilic Formvar-coated copper

grids by vertical retraction of immersed substrates, produced monoparticulate films with variable extinction and reflectance properties, related to the hexagonal close-packed arrays that form in a micron length scale. The extinction bands of these arrays shifted by hundreds of nanometers to near-IR wavelengths and broadened enormously with increasing periodicity. Large particle arrays also demonstrated extremely high SERS, with enhancement factors $>10^7$, which were correlated with increasing periodicity.

A slight modification of this technique has been reported by Goldenberg et al. [217] following ideas of Aveyard et al. [218], which seems an interesting method for practical application in building up 2- and 3D lattices of spheres. This simple and fast technique utilizes the nonmiscibility of liquids and trapping particles between two liquids of different viscosity so as to make a monolayer of the film in the liquid interface, which can be suitably transferred onto an appropriate substrate. Goldenberg et al. utilized this technique to organize hexagonally ordered monolayers of hydrophilic micrometer size PS and silica particles at water/alkane interfaces, and to transfer them onto solid substrates. These monolayers showed good diffraction properties as observed by optical microscopy with a Bertrand lens [217]. A schematic representation of this method is shown in Figure 15(A), while a photo of actual latex particles floating on hexane is shown in Figure 15(B); a typical film so formed is shown in Figures 15(C) and 15(D) and the collected particles on the glass in Figures 16(A) and 16(B). The actual experimental condition of the PS particles floating in the water-hexane interface is shown in Figure 17(A), while 17(B) shows the long-range order in these monolayer films.

These methods or a supplement of other methods has been used to make 3D arrays of colloidal nanoparticles.

Sedimentation in a gravitational field is the simplest approach that has been used for the formation of 3D crystalline arrays from colloidal spheres [219–222]. Although it looks simple, the method involves several complex processes such as gravitational settling, translational diffusion (or Brownian motion), and crystallization (nucleation and growth). In addition, these force parameters need to be properly controlled as well as the size and density of the colloidal spheres and the sedimentation rate to succeed in making 3D colloidal lattices. The colloidal spheres can always

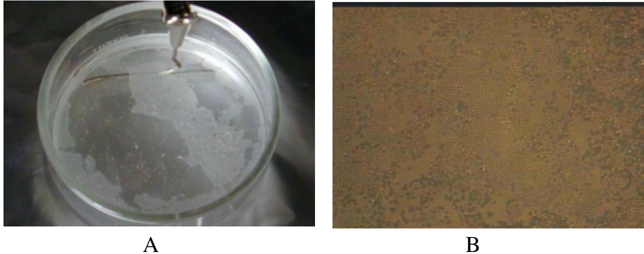

Figure 17. (A) Polystyrene particles spread on a water hexane interface, and (B) the successive film that can be collected from this partially covered layer on a glass slide.

settle completely to the bottom of a container as long as the size and density of these spheres are sufficiently high. Only when the sedimentation process is slow enough, the colloidal spheres concentrated at the bottom of the container will undergo a hard-sphere disorder-to-order phase transition to form a three dimensionally ordered lattice [223–224].

Monodispersed silica colloids are most commonly employed in sedimentation due to the high density of amorphous silica. Opalescent structures (usually referred to as synthetic or artificial opals) have been obtained from these colloidal materials under carefully controlled conditions [225–229]. Two types of crystalline arrays of colloidal spheres (or colloidal arrays) have been extensively studied: the first type includes fcc lattices formed from highly charged colloidal spheres and their volume fractions of colloids are often less than 10%; the second type is a Cubic-close-packed (ccp) structure (also a Face-centered-cubic (fcc) lattice) and its volume fraction of colloids is always close to 74%. It is generally accepted that the 3D crystalline arrays produced by this method have a ccp structure (or a fcc lattice with a packing density of ~74%) similar to that of a natural opal [229–230]. The preference of a ccp structure over a hexagonal-close-packed (hcp) one has been suggested to be a result of the difference in entropy between these two structures [231]. Recently, van Blaaderen et al. demonstrated the use of lithographically defined surfaces as templates to grow 3D crystalline arrays with desired spatial structures [232]. This process is the mesoscopic equivalent of epitaxial growth: highly ordered and well-controlled arrays as large as ~1 cm^3 could be generated. Jiang et al. also developed a layer-by-layer sedimentation method for fabricating ccp arrays of silica colloids; these arrays have a tightly controlled number of layers along the [111] direction [233].

3.4. Chemically Patterned Substrates

Stripes and channels with alternating wetability can also be produced by using wetting instabilities during the LB film transfer that has long been used for building up thin organic coatings of monomolecular layers (monolayers) onto solid substrates [234]. For example, Gleiche et al. [235] used monolayers of L-α-dipalmitoyl-phosphatidycholine (DPPC) on mica to generate a structured surface with a channel lattice exhibiting a high wetability contrast forming a lateral structure, which can be obtained by rapidly withdrawing a mica substrate (1,000 μms^{-1}) at a low monolayer surface pressure and constant temperature. Under these conditions, the film adsorption becomes unstable, leading to periodic interruptions in the molecular deposition which generate regular hydrophilic channels of about 200 nm in width and are separated by hydrophobic stripes of monomolecular height and latitude of about 800 nm. This structured surface can be used as a template to deposit materials along the channels with high adsorption selectivity by making use of the different wetting behavior of the hydrophilic channels and the hydrophobic stripes, for example, by either an anisotropic wetting/dewetting process (determined by the surface structure) or by using capillary (capillary filling) and electrostatic forces.

Gold clusters (Au55) stabilized by an organic ligand shell dissolved in 1-phenyloctane were dropped on the structured mica surface which filled the channels with Au55 clusters as shown in Figure 18. Mostly single, large-cluster aggregates (almost 4 nm in height) were lined up in the channels, but some two-layers were also noticed (see spike structure in Figure 18(B)). In contrast, the DPPC monolayer is virtually not wetted and only a few cluster aggregates are located on the top of the stripe region, resulting in a nearly perfect selective adsorption.

Self-organization on chemically patterned surfaces can be achieved in a rather straightforward way by the use of charged surfaces, as the nanoparticles in suspension are most often charged to prevent coagulation. Substrates are patterned by molecular layers in mesoscale dimensions. Substrates for such chemisorption are usually gold surfaces regiospecifically modified with functionalized thiol molecules by microcontact printing [146] or silica surfaces that have been photo-patterned by a preadsorbed cationic monomer (as shown in Figures 19 and 20) [236]. In these cases, the contrast between covered and uncovered areas, as well as the packing density within the covered regions, depends strongly on the electrochemical parameters of

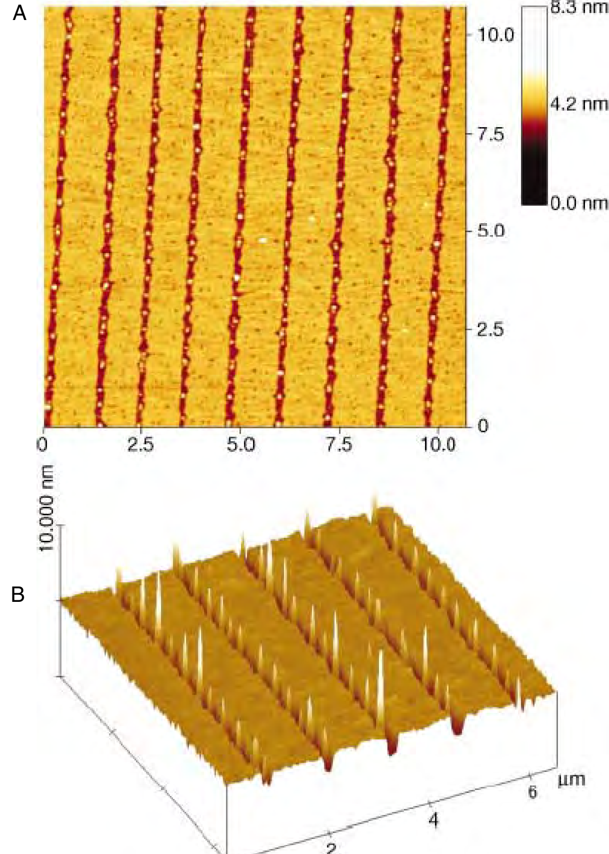

Figure 18. Dynamic scanning force microscopy (SFM) image of liquid-deposited Au55 metal cluster. (A) topography of the selectively adsorbed organic-ligand-stabilized metal cluster. Cluster aggregates (bright spots) were aligned along the channels even when scanning the previously wetted area. the system, such as ionic strength, pH, and effective surface charge. Moreover, only moderate packing density is achieved due to the repulsive forces between the particles [237]. One way to overcome this problem is the application of cationic surfactants that increase the charge shielding and, due to adsorption onto the particle surface, introduce attractive forces such as van der Waals interaction. Recently, Chen et al. demonstrated the validity of this concept [145].

The site-selective assembly of colloidal polymer particles onto laterally patterned silane layers has also been extensively studied for the assembly of colloidal nanoparticles at mesoscale dimensions [145–146, 237–239]. The structured silane monolayers on silicon-oxide substrates are either fabricated by liquid- or gas-phase deposition or a combination of both methods, using different trialkoxysilanes with a photolithographic patterning technique. By using this method, various types of surface functionalization, such as regions with amino functions next to areas of the bare silica surface or positively charged regions of a quaternary ammonium silane surrounded by a hydrophobic octadecylsilane film have been reported (as shown in Figures 21 and 22). Often, photo-protected amino groups were, used which allowed direct photo-patterning after monolayer preparation, leading to free NH_2 groups at the irradiated regions. Depending on the assembly conditions (different surface functionalization, pH, and drying conditions), the particles can be directed selectively onto a specific surface region. The regiospecific assembly of colloidal particles onto laterally structured silane monolayers can generate complex structures. The required monolayer patterns can be obtained by a combination of the industrially well-established photolithography process with the deposition of silanes from the vapor and liquid phase onto technologically and highly

relevant substrates such as silicon with an oxide layer, glass, and quartz. The particle adsorption process driven essentially by electrostatic and polar interactions in combination with adhesion inhibition at hydrophobic surface layers is a self-controllable and highly parallel process which should allow the simultaneous fabrication of many devices in one assembly step with essentially no size limitations from nanometer to the millimeter length scales.

3.5. Optically Directed Self-Organization

At the current stage of development, all of the above-mentioned methods are only capable of generating colloidal arrays built up by small domains, and the largest single domain usually contains fewer than 10,000 colloidal spheres [240]. Most of these methods can only form 2D hexagonal arrays in which the colloidal spheres are in physical contact. As a result, it is very hard to independently vary the lattice constant and the particle size. The approach based on optical forces seems to have the potential to overcome these difficulties [241–242]. In this method, colloidal spheres are organized into a highly ordered 2D structure in a liquid by creating an optical standing wave pattern having a regular array of intensity antinodes. The colloidal spheres are then driven to the antinodes maxima by the optical forces. Depending on how many laser beams are used to create the standing wave, patterns as complex as a quasicrystal have also been produced. As demonstrated by Misawa et al. and by Mio and Marr, the method based on optical forces was also capable of generating an arbitrary 2D or 3D pattern by adding individual colloidal spheres to an array one at a time [243–244].

Several years ago, Ashkin et al. experimentally demonstrated that small particles (25 nm to 10μm) in a suspension could be trapped by a single-focused laser beam [245]. Following their work, many researchers have used optical trapping techniques (also known as optical tweezers) to manipulate micrometer and submicrometer-sized objects [246–247]. Because of their nondestructive, sterile nature, optical tweezers have found great success in manipulating biological systems, including bacteria, viruses, chromosomes, and DNA [248–251]. More recently, Hayward et al. has shown the usefulness of light-induced orientation in what they called "optically tunable micropatterns" using ultraviolet light illumination [252]. Though the mechanism is largely unexplained, it could result from the light-induced changes on the wetting behavior of the substrate—a mixture of optical illumination for chemical patterning [253].

3.6. Electric or Magnetic Field-Assisted Self-Organization

Application of an electric field results in structural transitions in the colloidal suspension because the interparticle electrostatic interactions due to polarization are stronger than Brownian forces. The tendency of particles in suspension to form structures such as chains upon application of an electric field was reported centuries ago by scientists such as Priestly and Pohl [254–255]. Quantitative experiments on the electrorheological effect were first performed by Winslow in 1949, when he reported that suspensions of silica gel particles in low-viscosity oils tend to fibrillate upon application of electric fields, with fibers forming parallel to the field [256]. It was reported that at fields larger than ~3 kV/mm, the suspensions behaved like a solid, which flowed like a viscous fluid above a yield stress that was proportional to the square of the applied electric field. A recent and comprehensive survey of electrorheological (ER) fluids, where the issue of particle aggregation is addressed, is provided by Parthasarathy and Klingenberg [257]. At low fields, below ~100 V/mm, where the interparticle electrostatic interaction energies are low compared to thermal energies, no significant particle association are generally observed and the nanoparticles tend to sediment to the bottom electrode, if their density is larger than the solvent density. However, at field strengths ~1000 V/mm, field-induced structures, such as chains of touching particles, are formed that do not break up due to thermal fluctuations, implying that the electrostatic energy at contact was many times kT [258].

As an example of the ordering of nanoparticles onto structured surface, Kumacheva et al. [259] has reported an experiment with poly(methylmethacrylate) (PMMA) spheres electrodeposited onto Indium tin oxide (ITO)-covered substrates. The speed of colloid crystal growth can be controlled via electrodeposition parameters such as voltage and time, and electrophoretic mobility of the particles, thus control over layer-by-layer deposition is possible. They further reported that the particles get into ordered phase after reaching the electrode, which they attributed to the reorganization of the microspheres in the grooves by squeezing the newly arriving spheres between the already deposited particles, and followed by synergistic particle rearrangement. This resulted in large-scale particle ordering, as is shown in Figure 23(D) for assembly of the colloidal spheres in 4.2 μm-thick grooves.

The use of nonuniform electric fields for the manipulation of μm-sized particles are reasonably well-documented [260–268]. A variety of biological applications including collection, fusion, and separation of biological cells [269], immobilization of DNA [270], and a collection of viral particles [271] have been demonstrated. Dielectrophoresis (DEP) has been used in the assembly of a biosensor by concentrating α-protein-coated latex microspheres in the area between two oppositely charged electrodes [272]. Alignment of nanospheres [273] and dielectrophoresis for the trapping of submicron latex spheres inside a 3-D, multielectrode array [263], and alignment of metallic needle-shaped particles with diameters between 70–350 nm and a few μm in length using interdigitated electrodes has also been reported; an example is shown in Figure 24 [274]. The possibility of, contact-free handling for assembly and mechanical processing of microbeads has been demonstrated [275]. Today DEP has not yet been sufficiently exploited for the self-organization of nanoparticles, though the fundamental principles of DEP are reasonably well-understood. This is an attractive method for the self-organization of nanoparticles and will almost certainly gain more importance in the future works for the self-organization of nanoparticles.

The electric field forces on particles can be controlled by monitoring the charge on the colloidal particles (through the control of the double layer). Recent work within this area, has shown that the electric field is more than just a substitute for gravity, and the formation of highly ordered colloidal layers has been reported for electrophoretic deposition of micrometer-sized silica and polystyrene particles [277–279], and nanometer-sized gold particles [277, 280–281]. The self-organization phenomenon was explained by electro-osmotic or electro-hydrodynamic microflows around the particles, which are induced by the electric field and lead to attractive forces between the particles at the surface [277, 282]. While the exact mechanism of ordering is still open to debate, it is clear that improved ordering results from the fact that the colloidal particles are only weakly bound ("physisorbed") to the substrate and remain fairly mobile. Only after an additional fixing step (e.g., application of a high field), the

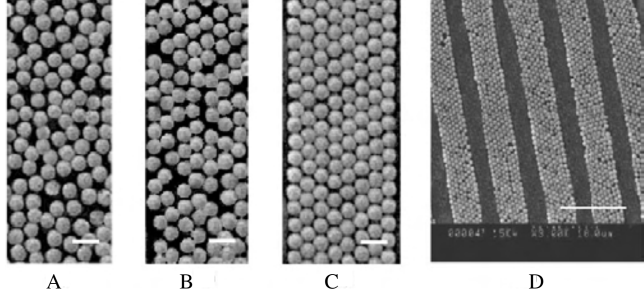

Figure 23. SEM images of the colloidal arrays of latex spheres of PMMA electrodeposited on nonpatterned (A) and patterned (B–D) ITO-coated surfaces. The widths of the grooves are 5.5 μm (B) and 4.2 μm (C, D). The SEM images of the colloidal arrays with the width 4.2 μm were cropped in (A) and (B). Scale bars are 1 μm (A–C) and 10 μm (D). Figure 24. (a) Schematic presentation of the 3D particle organization achieved *via* DEP. The first particles on the plane are pushed to the center of the electrode setup (negative DEP) and form an ordered structure. Particles that later arrive in the vicinity of the electrodes deposit on the top of the 3D structure, creating additional layers. (b) A freestanding, pyramid-shaped structure of silica particles is shown as a result of dielectrophoretic organization. (c) The structure collapses immediately after the electric field is switched off. (d) SEM image of a 3D, freestanding formation of silica particles in the area between two long and parallel electrodes. Reprinted with permission from [276], A. Docoslis and P. Alexandris, *Electrophoresis.* 23, 2174 (2002). © 2002, Wiley-VCH.

colloidal film is anchored to the substrate. Based on these ideas, it has been proposed that highly ordered multilayers of colloidal particles could be grown by using dc or low frequency ac fields (one such example is shown in Figure 25 [277]).

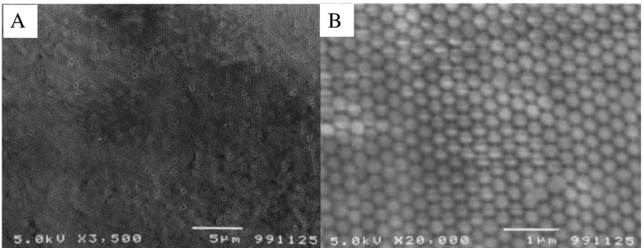

Figure 25. (A) Large single domain of the opal made of 300 nm silica spheres. The long-range ordering can be observed over 100 μm. The sample for the SEM observation was derived by carefully removing one substrate of the sandwich-like cell. (B) Hexagonal arrangement of the silica spheres with excellent arrangement was observed. It was found that the domain size exceeds 100 mm. The hexagonal arrangement was assigned to the close-packed surface of a face-centered cubic or hexagonal close-packed structure. It is interesting to note that opaline materials synthesized by conventional sedimentation methods show both the hexagonal and tetragonal arrangements. Reprinted with permission from [230], H. Miguez et al., *Langmuir* 13, 6009 (1997). © 1997, American Institute of Physics.

Magnetic fields can, in principle, be used to direct particles onto a substrate, making use of the motion of magnetic particles in magnetic field gradients [283], and there have been reports where magnetic field forces have been used to direct the colloidal crystal formation [284]. In a recent publication, Bizdoaca and Lin et al. have reported on the fabrication of grids of micrometer-sized core-shell particles, utilizing magnetophoretic deposition techniques in a water-based colloidal suspension with core-shell type spherical polystyrene particles of 640 nm diameter core, covered with a shell of five layers of 12 nm diameter Fe_3O_4 nanocrystals. The separation and length of the individual chains were tuned by the magnetic field [285–286]. Magnetic field forces may play an important role in the organization of colloidal nanoparticles into ordered arrays most likely in conjunction with electric field forces.

3.7. Biologically Assisted

Nature allows structural building blocks to hierarchically organize into an ensemble with an atomic order resolution, which are formed spontaneously with high accuracy and minimum energy similar to the bottom-up self-organization process [287]. On the contrary, it is quite difficult for chemists to achieve the total synthesis and structural control of macromolecules by covalent chemical synthesis methods only [288]. Nobel Laureate Jean-Marie Lehn used the words of Leonardo da Vinci 'Where nature finishes producing its own species, man begins, using natural things and with the help of this nature, to create an infinity of species,' while, writing about the perspectives on the future and perspectives of supramolecular chemistry [289]. Natural evolution has led to highly functional assemblies of proteins, nucleic acids, and other (macro)molecules which perform complicated tasks that are still difficult to emulate. For example, the 20-nm ribosome particle is an effective supramolecular machine which spontaneously self-assembles from more than 50 individual protein and nucleic acid building blocks, thereby impressively demonstrating the power of biologically programmed molecular recognition [290–292]. The bacterial flagellar motor, which is 30 nm in diameter, resembles the electric rotary motor [293–295], while muscle proteins resemble a linear motor, but the "engine" size is approximately 30 nm [296]. Assemblies of these proteins are self-assembled molecular machines that are small in size with highly efficient energy transduction properties. These characteristics make proteins good solutions for constructing sophisticated devices on the nanometric scale.

Protein molecules have the ability to build nanometer-sized supramolecules by self-assembly, which can themselves create higher order structures like cell components. Some of the schemes that attach protein molecules are illustrated in Table 2. Mirkin et al. [75] and Alivisatos et al. [297] have showed that complementary DNA oligonucleotides offer possibilities for self-assembled nanoparticles. Protein-based conjugation offers various advantages like a large number of complementary systems with a wide range of free-association energies are synthetically available, and the systems are well known in biochemistry and molecular immunology which can be handled by standard procedures [298–299]. From a materials science point-of-view,

Table 2. Various Methods to Attach Protein to Self-Assembled Surfaces

Functional side group on peptide	Available surface derivatization	Type of binding
	Natural	
-COOH (carboxylic acid) Asp	Amino	Electrostatic covalent amide (after carboxy activation)
NH_2 (amino) Lys, Gln, Arg	Carboxylic acid, active ester, epoxy	Electrostatic covalent amide
-SH (thiol) Cys	Maleimide	Covalent thio-ether
-OH Ser, Thr	Epoxy	Covalent ether
	Synthetic	
His-Tag	Ni-NTA Complex	Coordination complex
Strep-Tag	Strep-Tactin, Streptavidin	Supramolecular complex
Biotin	Streptavidin	Supramolecular complex

polypeptides offer many advantages over conventional synthetic polymers due to their inherent ability to adopt stable conformations and self-assemble into precisely defined structures that allow unprecedented control over materials morphology and properties. Synthetic strategies for the preparation of polypeptides can be divided essentially into three classes: ring-opening polymerization, solid-phase synthesis, and protein engineering. Recent advances in these methods have allowed the preparation of (poly)peptides and (poly)peptide hybrids, which can be assembled in a controlled fashion into supramolecular architectures and materials that mimic the structure and function of proteins [300].

Right from the discovery of the double-helix structure of DNA, biology has evolved from a purely descriptive and phenomenological discipline to exact science in the molecular regime, and recombinant DNA technology has brought insights into the basic principles of many biochemical processes and is also shaping developments in modern biotechnology. Today, we can genetically engineer relatively simple bacterial cells, and hopefully, in the future, we will be able to tailor complex organisms. In view of such revolutionary developments, scientists and researchers have reported wide-ranging developments in the fusion of biotechnology with nanoparticles, since biomolecular components have typical size dimensions in the range of about 5 to 200 nm [301]. The concept of DNA hybridization-based self-organization of molecular compounds has been applied to the assembly of DNA-derivatized gold colloids [75, 297, 302]. Such defined arrangements of nanocrystal metal clusters (quantum dots) have been investigated for their novel physical properties and possible applications in the field of opto-electronic technology [303–306]. For this, superlattices or quantum dot molecules are necessary, in which crystallites from different materials are spatially assembled to tailor the properties. Recently, Takahagi et al. [307] described the fabrication of 3D particle structures based on DNA hybridization. The results indicate that DNA hybridization is a very useful method for assembling nanoparticles into a 3D nano-structure. To fabricate this structure, two colloidal gold suspensions containing particles of 9 nm and 20 nm in diameter, and oligonucleotides that are functionalized by heptanethiol at their 5′ termini were used by the authors. The thiol group at the end of the oligonucleotides was adsorbed to the particle surfaces by a chemical bond upon mixing with the colloidal gold suspension, resulting in oligonucleotide monolayers on the particles. The 9-nm particle suspensions were mixed with thiol-5′-GGTCGGCACA-3′, and the 20 nm particle suspension was mixed with thiol-5′-TGTGCCGACC-3′. After keeping for 48 h at room temperature, the two mixture suspensions were blended and diluted at pH 7. A 3D structure has formed with alternating superposition of the big and small particles. Though the internal structure cannot be observed with SEM, the 20 nm gold particles can be seen to exclusively connect with the 9 nm particles on their surfaces. These results suggest that the internal structure of DNA-linked particles might consist of alternating small and large particles, and 3D particle networks had formed.

The highly specific recognition properties of antibodies and antigens can be used to assemble a wide range of nanoparticle-based structures with specific cross-linking, compositions, and macroscopic architectures; for example, IgE and IgG antibodies have been used to attach on surfaces followed by interparticle conjunction in the presence of bivalent antigens with appropriate double-headed functionalities [297]. Similarly, streptavidin/biotin cross-linking has been used to bind nanocrystals onto a substrate [299]. Some protein-supramolecules have the ability to accommodate inorganic materials and this process is called biomineralization. Their surfaces are thus designed to sequester inorganic materials into composites like seashells or bone [308]. This biomineralization process has been used to make proteins that accommodate nanometer-size inorganic quantum dots [300]. As proteins are more easily damaged or destroyed compared to inorganic materials, there are several potential means to eliminate the protein moiety from an assembled array by heat treatment and UV irradiation, or through other chemical means.

Combining the abilities of proteins to self-assemble, organize materials, and then be selectively eliminated, it is expected that nanometer-size inorganic materials can be positioned by protein supramolecules into nanostructures. The protein, therefore, acts as a temporary scaffold, which determines the nature of the final structure without being part of it. As a feasibility study of this method, the ferritin molecule assembly was employed to make an array of inorganic nano-dots suitable for a quantum electronic device. Several methods have been reported to obtain arrays of ferritin molecules and it has become possible to make large 2D crystals or arrays of ferritin at an air-water interface [309–313].

Another process has been proposed which exploits protein molecules as scaffolds for producing inorganic, functional nanostructures on a flat surface. An array of conductive FeO dots with a diameter of approximately 6 nm was fabricated and a hexagonally packed array of ferritin molecules was formed at an air-water interface by self-assembly. Following this, the ordered ferritin was transferred onto a modified Si surface and then the protein shell of the ferritin molecule was eliminated by 450 °C heat treatment

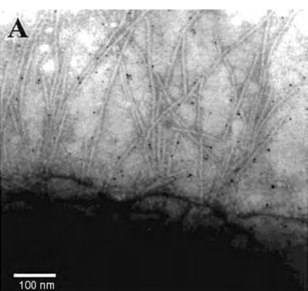
under nitrogen, which resulted in an ordered array of conducting nano-dots bound to the Si surface [314]. Combining this result with the fact that ferritin molecules have the ability to accommodate various metals and metal complexes, it is possible to organize nano-dot arrays suitable for quantum electronic devices by the so-called bio-mimetic “Bio Nano Process” method [315–321]. As the ferritin molecules are produced from the same gene, the cavity size of each apoferritin molecule is identical and hence, the nanoparticles so produced are expected to be identical in size—a key requirement in producing quantum opto-electronic devices. Combined with the self-assembly of the protein, it may be possible to build more complex functional inorganic nanostructures on a flat surface than simple arrays.

Nanoscale-ordered arrays of metal and semiconductor quantum dots have been fabricated by binding presynthesized nanoparticles onto crystalline protein templates made from genetically engineered hollow double-ring structures called chaperonins [322]. Using structural information as a guide, a thermostable recombinant chaperonin subunit was modified to assemble into chaperonins with either 3 nm or 9 nm apical pores surrounded by reactive thiols. These were crystallized into 2D templates up to 20 μm in diameter. The periodic solvent-exposed thiols within these crystalline templates were used to size-selectively bind and organize either gold or CdSe-ZnS quantum dots into arrays.

The cell membrane is another example of a self-assembled system. Simplified models of cell membranes consider solid-supported membranes as model systems for fundamental biophysical research, biosensors, and the design of phantom cells exhibiting well-defined adhesive properties and receptor densities [323]. Several strategies for the assembly of biomembranes onto various solid supports have been reviewed in great detail [324–328]. The major techniques are direct vesicle fusion [329], the LB technique [330], and molecular self-assembly from dilute organic solutions [331]. Three types of supported membranes can be assembled [332]:

(a) supported, lipid bilayer membranes prepared by vesicle spreading or LB deposition at hydrophilic surfaces,
(b) covalently tethered SAMs of functionalized lipid derivatives, prepared by coadsorption of membrane-forming components,
(c) asymmetric or hybrid bilayer membranes, composed of an outer lipid layer and an inner SAM. The most natural membrane bilayer environment is the first approach.

Another innovative approach has been reported by Walboomers et al. [333] and Britland et al. [334], where they have demonstrated that cells can be “contact-guided” along deep grooves on a patterned surface without any chemical treatments to the surface itself. Britland et al. [334] modified glass substrates with both chemical and topographical cues. The chemical adhesive tracks were patterned both parallel and perpendicular to the topographical grooves with laminin, an ECM protein carrying the RGD peptide sequence. The cells were found to orient along chemical adhesive track when the grooves on the substrate are less than 500 nm in depth. For deeper grooves, the contact guidance by the topography dominates the cellular behavior (alignment). If nanoparticles are attached to the cells, then by virtue of the cell alignment, the particles will get aligned into the structure that has been engraved, analogous to reports on decorating such structures by capillary forces that are quite difficult to control.



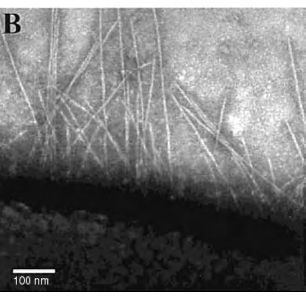


Figure 26. Typical TEM images of sectioned areas of (A) pili of the *E. coli* ORN178 strain bound with m-AuNP; (B) the *E. coli* ORN208 strain deficient of the *fimH* gene without m-AuNP binding. In another recent article, biodirected epitaxial nanodeposition of polymers was achieved on a template with an oriented molecular surface. *Acetobacter xylinum* synthesized a ribbon of cellulose I microfibrils onto a fixed, nematic, ordered substrate of glucan chains with unique surface characteristics. The substrate directed the orientation of the motion due to the inverse force of the secretion during biosynthesis, and the microfibrils were aligned along the orientation of the molecular template. This approach also promises some outstanding possibility of self-organization of nanoparticles [335]. Bacteriophages offer another way to form large-dimension, patterned assemblies by engineering the phage to specifically bind functional components, as has been done for a variety of inorganic materials [336]. Because the phage is strongly bound to the inorganic components, the phages are participants rather than bystanders in the assembly process. Relatively small (~20 nm in diameter) particles are easily organized into the layered structure formed by the viral rods, leading to well-populated lines only a few tens of nanometers across, spaced by the length of the bacteriophages. In a recent article recently published, Lin et al. has mannose-encapsulated gold nanoparticles to type 1 pili in *Escherichia coli* [337]. Type 1 pili are filamentous, proteinaceous appendages that extend from the surface of many gram-negative organisms and are composed of FimA, FimF, FimG, and FimH proteins. FimA accounts for more than 98% of the pilus protein, and FimH is uniquely responsible for the binding to D-mannose (Fig. 26).

4. CONCLUSIONS

The synthesis of nanostructured materials with tunable properties is central to the development of varying applications in nanoscale science and technology. The convergence of physics, chemistry, and biology will actually lead to an explosive increase in possibilities of R&D directions. Choices will be difficult and sometimes limited by the breadth of expertise available. Encouragement of

multidisciplinary and multilaboratory collaborations would accelerate progress to the benefit of all. Through devices such as quantum well lasers and their enabling roles in applications, ranging from telecommunications to home entertainment, it is evident that nanotechnology has and is having a major impact on our daily lives which will only multiply over the decades ahead. Self-assembly of nanometric particles will definitely play an important role in this. Non-lithographic approaches based on thermodynamically driven self-organization processes are especially appealing, because of their potential for large-scale production with very small infrastructure investments. The spontaneous organization of monolayer-protected metal nanoparticles into periodic 2D arrays is archetypal of this approach, with many of these arrays demonstrating novel optical or electronic properties as a function of particle size or interparticle spacing. Stabilized particles beyond a nanometric-size threshold become increasingly prone to multilayer or 3D aggregate formation, which can be attributed to the rapid increase in van der Waals attraction and the loss of surfactant chain mobility on the planar facets of the nanoparticles as a function of size.

The other approach of positioning molecules ranging from small alkanethiols to larger biosystems, such as proteins or DNA on surfaces that can be used as a generic approach to position other molecules such as enzymes, collagens, fibronectin, or synthetic moieties, is another interesting possibility to assemble ordered structures. As the interdisciplinarity of this field develops further, we will see the birth of innovative techniques aimed at mimicking nature. An interesting article on the biomimetic approach to produce materials has been published recently [338]. The interface between biological systems and functional semiconductors remains a relatively unexplored area that requires research in the near future. The ability of electronic/optical devices to sense minute samples of biological/medical materials *in-situ*, and to relay this information to a central location opens up possibilities for quick diagnostics and the remote monitoring of patients.

A research field, which is not yet treated in detail, is the influence of size and ordered arrangement of particles in layers on the heat conductivity. The phonon heat conduction mechanism in nanostructures differs significantly from the behavior in bulk material. Phonon size effects include increased phonon scattering at grain boundaries, modification of the phonon dispersion relation, and phonon rarefaction surrounding small structures have been predicted and also observed experimentally [339–340]. It also seems that change of the phonon spectrum, due to confinement effects, could lead to phonon-phonon part of the thermal conductivity, like it occurs in superlattices. The fact that thermal transport properties in nanostructured materials are affected by the size opens up new possibilities for material scientists to engineer structures adapted to the desired properties depending on its applications. Provided we understand the phenomena in detail, one can engineer the structure of the materials by assembly of particles in such a way that the phonon conduction (phononics or phonon engineering) in different directions could be possible. For microelectronics, phonon engineering can provide improved device design to minimize the impact of adverse size effects on the device temperature [341].

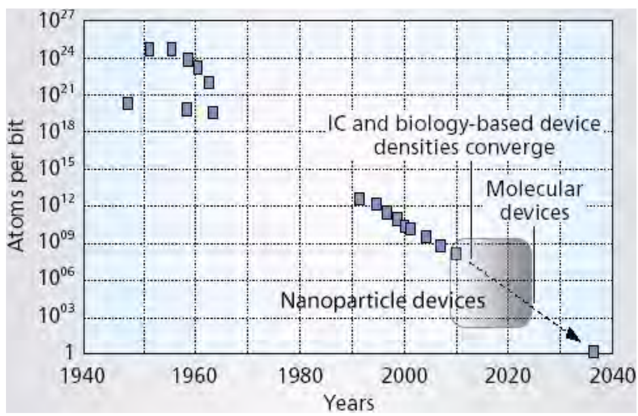

Figure 27. Moore's law predictions. Adapted with permission from [342], V. V. Khirnov and D. J. C. Herr, *Computer*, January 2001, 34. © 2001, IEEE.

The extension of Moore's law is expected to continue until the next decade (as shown in Fig. 27) with devices in their present form, which will ultimately give way to disruptive technologies involving nanoparticles, single molecule electronics, and single electron transistors [342]. Again, there will be a need for the design of complex novel architectures to accommodate these new devices with novel materials and gate designs and interconnects. Today, the major shortfall of nanoscience and nanotechnology is the lack of understanding of the physics of the interaction of objects (surfaces, particles, individual molecules) at the nanoscale. Questions need to be answered regarding how nanoparticles can be stabilized, and in what media, how nanoparticles interact and influence each other, what proportions in a hybrid system make a critical difference, and how the ordered structures can be created and retained. How can these characteristics be predicted? This area of "Extreme Nanotechnology" requires vast amounts of imagination and intuition if nanoscience research is to have any practical impact on human lives. Its potential is enormous, and the need to understand underpinning nanoscience should be properly supported so that the bottom-up nanoscience and nanotechnology is not overshadowed by the reluctance to invest in revolutionary technologies, since the benefits from this area will be considerable in the long run.

GLOSSARY

2D arrays Two dimensional arrangement of nanoparticles.

3D structures Three dimensional arrangement of nanoparticles.

Acetobacter xylinum It is a gram negative bacterium and is unique in its prolific synthesis of cellulose.

Atomic force microscopy (AFM) An instrument able to image surfaces to molecular accuracy by mechanically probing their surface contours. A kind of proximal probe.... A device in which the deflection of a sharp stylus mounted on a soft spring is monitored as the stylus is moved across a surface. If the deflection is kept constant by moving the surface up and down by measured increments, the result

(under favorable conditions) is an atomic-resolution topographic map of the surface. Also termed a scanning force microscope.

Biomimetic Imitating, copying, or learning from nature. Nanotechnology already exists in nature; thus, nanoscientists have a wide variety of components and tricks already available.

"Bottom Up" method Building larger objects from smaller building blocks. Nanotechnology seeks to use atoms and molecules as those building blocks. The advantage of bottom-up design is that the covalent bonds holding together a single molecule are far stronger than the weak.

Chemical vapor deposition (CVD) A chemical reaction that transforms gaseous molecules, called precursor, into a solid material, in the form of thin film of powder, on the surface of a substrate.

Coulombic repulsion If bonds in the molecule are polar, partial electrostatic charges will reside on the atoms. This electrostatic interaction is represented with a Coulombic potential function according to Coulomb's law. The repulsion due to this electrostatic interaction is termed as Coulombic repulsion.

Deoxyribonucleic acid (DNA) A macromolecule consisting of one or two strands of linked deoxyribolucleotides.

Dielectrophoresis (DEP) The lateral motion imparted on uncharged particles as a result of polarization induced by non-uniform electric fields.

Electrostatic stabilization Electrostatic stabilization is used to prevent agglomeration of nanoparticles by absorbed molecules. It involves the creation of an electrical double layer arising from ions absorbed on the surface and associated counter ions that surround the particle. Thus if the electric potential associated with the double layer is sufficiently high, the Coulombic repulsion between the particles will prevent their agglomeration.

Escherichia coli It is one of hundreds of strains of the bacterium. Although most strains are harmless and live in the intestines of healthy humans and animals, this strain produces a powerful toxin and can cause severe illness.

Extracellular matrix (ECM) protein Example: procollagen peptide 1 (P1CP), procollagen peptide 3 (P3P), hyaluronic acid (HA).

IgG immunoglobulins Immunoglobulins are thiol-containing plasma proteins, which include all antibody molecules. Members of the immunoglobulin super family share structural and genetic features with immunoglobulin molecules and contain at least one immunoglobulin domain. An immunoglobulin domain is made of two □-pleated sheets held together by a disulfide bond.

Langmuir–Blodgett The name of a nanofabrication technique used to create ultrathin films (monolayers and isolated molecular layers), the end result of which is called a "Langmuir-Blodgett film".

Moore's Law Coined in 1965 by Gordon Moore, future chairman and chief executive of Intel, it stated at the time that the of number transistors packed into an integrated circuit had doubled every year since the technology's inception four years earlier. In 1975 he revised this to every two years, and most people quote 18 months. The trend cannot continue indefinitely with current lithographic techniques, and a limit is seen in ten to fifteen years. However, the baton could be passed to nanoelectronics, to continue the trend (though the smoothness of the curve will very likely be disrupted if a completely new technology is introduced).

Nanocrystals Also known as nanoscale semiconductor crystals. "Nanocrystals are aggregates of anywhere from a few hundred to tens of thousands of atoms that combine into a crystalline form of matter known as a "cluster." Typically around ten nanometers in diameter, nanocrystals are larger than molecules but smaller than bulk solids and therefore frequently exhibit physical and chemical properties somewhere in between. Given that a nanocrystal is virtually all surface and no interior, its properties can vary considerably as the crystal grows in size."

Nanomaterials Can be subdivided into nanoparticles, nanofilms and nanocomposites. The focus of nanomaterials is a bottom up approach to structures and functional effects whereby the building blocks of materials are designed and assembled in controlled ways.

Physisorption (or physical adsorption) Is adsorption in which the forces involved are intermolecular forces (van der Waals forces) of the same kind as those responsible for the imperfection of real gases and the condensation of vapors, and which do not involve a significant change in the electronic orbital patterns of the species involved.

Polymethylmethacrylate spherical particles (PMMA spheres) These particles are inert and nonbiodegradable.

Quantum Describes a system of particles in terms of a wave function defined over the configuration of particles having distinct locations is implicit in the potential energy function that determines the wave function, the observable dynamics of the motion of such particles from point to point. In describing the energies, distributions and behaviours of electrons in nanometer-scale structures, quantum mechanical methods are necessary. Electron wave functions help determine the potential energy surface of a molecular system, which in turn is the basis for classical descriptions of molecular motion. Nanomechanical systems can almost always be described in terms of classical mechanics, with occasional quantum mechanical corrections applied within the framework of a classical model.

Quantum dots (QD) Nanometer-scale "particles" for selectively holding or releasing electrons. It is a particle of matter so small that the addition or removal of an electron changes its properties in some useful way.

RGD peptide Peptides containing the Arg-Gly-Asp (RGD) sequence. They can inhibit platelet aggregation.

Scanning electron micrograph (SEM) The picture formed by the scanning beam of electrons in a scanning electron microscope.

Scanning force microscopy (SFM) The SFM works by detecting the vertical position of a probe while horizontally scanning the probe or the sample relative to the other. The probe is in physical contact with the sample and its vertical position is detected by detecting the position of a reflected laser beam with a photo diode that consists of two or four segments.

Scanning probe microscopy (SPM) SPM technologies share the concept of scanning an extremely sharp tip (3–50 nm radius of curvature) across the object surface. The tip is mounted on a flexible cantilever, allowing the tip to follow the surface profile.

Scanning tunneling microscopy (STM) It is a device that obtains images of the atoms on the surfaces of materials. The governing principle of STM is the quantum tunneling of electrons through a thin potential barrier separating two electrodes. The instrument basically consists of a very sharp tip which position is controlled by piezoelectric elements (converting voltage in mechanical deformation). By applying a voltage between the tip and a metallic or semiconducting sample, a current can flow between these electrodes when their distance is reduced to a few atomic diameters. The amplitude of the current strongly depends on the distance between the tip and the sample, and of course also on the potential difference.

Self-assembly In chemical solutions, self-assembly (also called Brownian assembly) results from the random motion of molecules and the affinity of their binding sites for one another. Also refers to the joining of complementary surfaces in nanomolecular interaction.

Serum albumins Thiol-containing protein. It is a lipid carrier in blood serum.

Surface plasmon resonance (SPR) It is a phenomenon that occurs when light is reflected off thin metal films. A fraction of the light energy incident at a sharply defined angle can interact with the delocalised electrons in the metal film (plasmon) thus reducing the reflected light intensity.

Thiol This is a subclass of chemical compound that contains sulphur, esp. denoting that a compound is derived from a specified compound by the replacement of an oxygen atom with a sulphur atom. More specifically a compound that contain

$$-SH \text{ or } -\overset{|}{\underset{|}{C}}-S-\overset{|}{\underset{|}{C}}-$$

are called thiol.

"Top down" method One approach for the building up of nanoscopic features. In this method, the features are written directly onto a substrate for example by electron beam and then by applying appropriate etching and deposition processes, the nanoscopic features are engraved.

Transmission electron micrograph (TEM) In TEM the magnification of the objective remains fixed while the focal length of the projector is changed to vary magnification.

ACKNOWLEDGMENTS

The authors would like to thank the Swiss National program in Nanotechnology (TOP NANO 21; 5971.2 TNS) for financial support. They would also like to thank colleagues and students for assisting in the preparation of this article. Special thanks to Dr. P. Bowen, Dr. R. Houriet, Dr. Y. Houst, and Mr. F. Juillerat for their support and encouragement.

1. INTRODUCTION

There is much interest in recent years in the methods of creating nanometer-scale structures on surfaces to form one- (1D) and two-dimensional (2D) ordered structures. When adatoms are nucleated into ordered arrays of sufficiently small dimensions, quantum mechanical effects determine their properties, for example, in quantum dots or quantum wires. Such formation of ordered nanostructures on surfaces is indeed a challenge in both fundamental and applied science research. Fabrication of uniform-size clusters in the 1 to 2-nm size regime is challenging because fluctuation in size of a few atoms could substantially alter their electronic properties. Such a length scale is important for quantum applications since the Fermi wavelength for most metals is around 1 nm.

The importance of the fundamental properties of nanostructures on surfaces has been highlighted in the National Science and Technology Council report on nanotechnology [1]. Many key questions relate to the structure or arrangement of atoms in a nanostructure. The relative stability of different structural phases is altered in the nanometer regime, affected by both kinetic and thermodynamic factors. Variations may arise due to factors such as surface energies, defects, and electronic quantum-size effects. There is, therefore, a need to map out the kinetics and thermodynamics of phase transformations in nanostructures. For a complete understanding of the physical properties of nanostructures, the structure of the surface must also be determined. Surfaces of nanostructures are likely to vary significantly from the well-characterized bulk structures. Hence, the ability to measure and systematically control the surface will continue to be an important field of research over the next decade.

The direct study of surface nanostructures at the atomic scale became possible with the invention of the scanning tunneling microscope (STM) by Binnig and Rohrer [2]. Recent advances in scanning tunneling microscopy and spectroscopy of nanostructures have been reviewed by Schneider [3], and these techniques provide new opportunities for investigating locally the geometric and electronic properties of nanostructures on surfaces. Ushioda [4] presents an overview of the experimental method and physical principles of STM light emission spectroscopy. By using this new spectroscopic technique, one can obtain the optical emission spectra of individual surface nanostructures that are imaged by the STM. An overview of the status and prospects of STM is presented by Binnig and Rohrer [5]. They suggest the potential applications of the scanning probe microscopies to a relatively broad range of biological, chemical, and technological areas.

The production of semiconductor nanostructures has been under intensive investigation due to its potential for applications in optoelectronic and quantum devices. Techniques such as electron-beam lithography [6] are widely used, but due to the low throughput of such techniques, alternative methods based on self-organization to form large arrays of nanostructures have recently attracted much attention. Most of such work is based on the Stranski-Krastanov (SK) growth of semiconductor thin film on lattice-mismatched semiconductor substrates [7]. The influence of growth temperatures and growth rates, with varying composition and coverage on the size and number of self-assembled islands has been discussed in detail in previous publications [8, 9]. However, there is a significant drawback in the use of self-assembled dots since their sizes are often heterogeneous, resulting in a wide spread of electronic states.

This review will focus on nonlithographic methods of nanostructure formation on single-crystal metal and semiconductor surfaces, with less emphasis on the well-studied III–V alloy semiconductors. Since adsorbate-induced surface reconstructions have been well studied by surface scientists over the past few decades, this review will also exclude such studies where the reconstructed unit cell is generally below 1 nm. The mechanisms for nanostructure formation on surfaces are not fully understood, and this review attempts to classify various adatom/molecule-substrate systems where nanostructure formation is observed in terms of the proposed mechanisms.

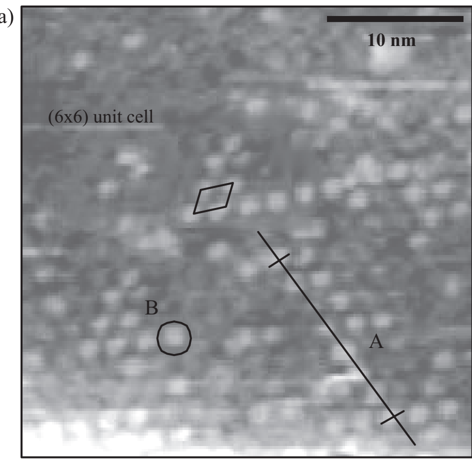
2. SELF-ORGANIZED NANOSTRUCTURES

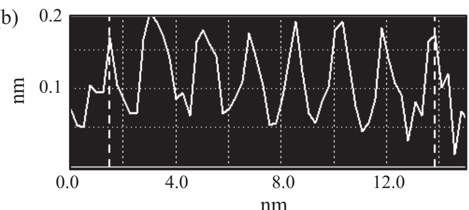
A. Spontaneous Assembly of Nanoclusters

The most well-studied surface reconstruction is perhaps the Si(111)–(7 × 7) surface, which has a unit cell divided into faulted and unfaulted halves [10]. Vitali et al. have demonstrated the formation of a superlattice of metallic nanoclusters, when thallium is evaporated onto clean Si(111)–(7 × 7) surfaces [11]. The metallic nanoclusters comprise nine adatoms each and are trapped within the attractive potential wells in the faulted half of the (7 × 7) unit cell, thus forming an ordered array of two-dimensional nanodot structures.

Li et al. reported the spontaneous assembly of identical-size In nanocluster arrays on Si(111)–(7 × 7) [12]. They show that substrate-induced spontaneous clustering is locally stable but globally metastable. Homogeneous cluster formation can be realized by delicate control of growth kinetics, i.e., within a suitable temperature range (100–200 °C) and deposition rate. If the substrate temperature is too low or the deposition rate too high, the In atoms do not have enough time to arrive at the expected location and form immobile nuclei of smaller sizes. On the other hand, if the substrate temperature is too high, the more energetic In atoms will agglomerate into larger clusters that coalesce into islands.

Si nanoclusters have also been observed to self-assemble on the 6H–SiC(0001)–(3 × 3) Si–rich surface [13]. Regular-sized Si "magic clusters" are ejected when this surface is heated to 950 °C and quenched to room temperature (Fig. 1). The Si clusters spontaneously form a metastable ordered (6 × 6) superstructure and appear to be driven by the need to reduce the dangling bond density per unit cell. These Si magic clusters have been previously reported on the Si(111)–(7 × 7) when it is quenched, although no self-assembly was observed on that surface [14].





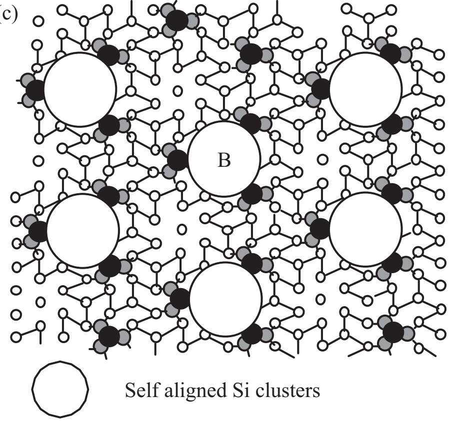


Figure 1. (a) Filled-state 30 nm×30 nm STM image (0.2 nA,–2.8 V) showing initial formation of cluster periodicity after heating the (3 × 3) reconstruction to 95 °C and subsequent cooling for 60 minutes. (b) STM cross-sectional line profile. A showing that the clusters posses a periodicity 6.1 ± 0.1 times that of the bulk. (c) Proposed model of 6H–SiC(001) (6 × 6) reconstruction due to cluster self-assembly. The atoms shown in the third Si adlayer layer represent unrelaxed surface after Si tetramer ejection. B. Surface Lattice Dislocations

Ordered nanocluster formation also has been reported on the Au(111) surface. For instance, Chambliss et al. reported that Ni islands grow with a spacing of 7.3 nm in rows 14.0 nm apart [15]. This regular nucleation is caused by the long-range "herringbone" reconstruction of Au(111), which induces periodic surface-lattice dislocations. Statistics of island size and number show that atoms diffusing on the surface bind at these dislocations with a low sticking probability and act as nuclei for further aggregation. It also has been reported that for Fe [16] and Co [17] deposition on Au(111), islands are nucleated at the elbows of the herringbone reconstruction. However, such preferential nucleation on Au(111) was not observed for other metals such as Al, Cu, Ag [18], and Au [19]. Meyer et al. [20] used their STM images for the Ni/Au(111) system to explain this disparity by proposing a two-step process: first, the place exchange of Ni adatoms with Au surface atoms occurs

at the elbow sites, followed by nucleation of Ni islands atop substitutional Ni atoms. The three metals that form islands at the herringbone elbows all have a higher surface free energy and heat of sublimation than Au, suggesting that place-exchange sites are favored. These place-exchange atoms then act as preferential nucleation sites for subsequent island formation.

Fruchart et al. [21] have harnessed the self-organized arrays of nanosized Co dots on Au(111) to fabricate Co pillars for high-density magnetic storage applications. This is achieved by sequentially depositing a fraction x of an atomic layer of Co and $1-x$ atomic layer of Au. At each step, Co adatoms aggregate on top of the previous dots, gradually forming columns. Helveg et al. [22] used STM to study the atomic scale structure of a single layer of MoS_2 nanoparticles on Au(111) as a model system in hydrodesulfurization catalysis.

C. Adsorbate-Induced Superstructures

The structures of crystalline surfaces are modified by the adsorbates, often by minor rearrangements to accommodate the adsorbate atoms, but sometimes by major restructuring of the surface [23]. Restructuring occurs in order to maximize the bonding and stability of the adsorbate-substrate complex. Thermodynamic processes drive this restructuring wherein stronger adsorbate-substrate bonds form to compensate for the weakening of bonds between the substrate atoms, an inevitable consequence of the chemisorption-induced restructuring process.

By using the Cu surface as an example, the structure of O chemisorption reconstructions on low-index Cu surfaces is well known [24]. O chemisorption on both Cu(110) and (100) surfaces leads to substantial reconstruction of the topmost Cu atom layer. Both reconstructions appear to receive stability from being able to accommodate O–Cu–O building blocks, of the sort needed to construct bulk Cu_2O [25]. The O atoms are fourfold coordinated, but are not quite centered in the Cu tetrahedra. Each O atom achieves a four-coordinate status with reasonable O–Cu bond lengths of 1.85–1.90 Å. On Cu(100), oxygen induces a $(\sqrt{2} \times 2\sqrt{2})$R45°–O reconstruction involving the removal of every fourth Cu [001] atom row. For Cu(110), the (2×1)–O phase is an "added row" structure with every other [001] Cu atom row absent, and O atoms occupy near collinear long-bridge sites in the added rows forming O–Cu–O chains.

One approach to increase the periodicity of the adsorbate-induced superstructures formed into the nanometer scale is the use of high index surfaces. High-Miller-index surfaces appear to exhibit high adatom mobility, and coordinatively unsaturated surface atoms move easily toward new and more bulk-like equilibrium positions. Wee et al. [26] have demonstrated the formation of a series of Cu(210)–$(n \times 1)$O $(n = 2, 3, 4)$ superstructures by using STM and low energy electron diffraction (LEED). Furthermore, they observed that adsorption of O at room temperature, followed by high-temperature annealing, leads to a series of mesoscopic superstructures ordered on length scales ranging between 1.5 to 15 nm [27]. A periodic supergrating for the Cu(110)–(2×1)O system also has been reported with a periodicity of between 6 to 14 nm, depending on oxygen coverage and substrate temperature [28].

Adsorbate-induced 2D nanostructures also have been reported for the Cu(210)–Br and Cu(100)–Br systems. When Cu(210) was dosed with Br at room temperature and subsequently annealed, a mesoscopic triangular checkerboard was observed [29]. The basic triangular unit comprises 4 or 5 atom rows (made up of 10 or 15 atoms, respectively) in the {210} plane, with edges of the triangle along the [001], $[1\bar{2}1]$ and $[12\bar{1}]$ directions. Br is believed to have etched the Cu(210) surface, leaving the mesoscopic checkerboard structure that reflects {210} symmetry.

For the Cu(100)–Br system, a corresponding mesoscopic chessboard structure has been observed [30]. Under these conditions, no desorption of Br was observed. The step edges are oriented along the {100} directions, reflecting the Cu(100) substrate symmetry, and the "white" Br squares have a local $c(2 \times 2)$ reconstruction. It appears that in this system, the adsorption and etching due to bromine provides a mechanism for the development of strain within the mesoscopic islands, thus limiting their island size.

Leibsle and coworkers have templated low-index Cu surfaces with self-assembled arrays of atomic nitrogen islands and then used these islands as masks to fabricate nanoscale structures [31]. Annealing of the Cu(100) surface with 0.5 ML (monolayer) atomic nitrogen coverage results in self-assembled regular island arrays (island size of 5×5 nm^2) of the $c(2 \times 2)$N reconstruction [32]. Nanometer scale lines and 2D arrays of islands of various metals such as Fe, Cu [33], Ag [34, 35], Co [36], have been demonstrated. Similarly, Ag nanostructures on N-modified Cu(111) [37], and Co nanowires on N-modified Cu(110) [38] have been reported. Ohno et al. [39] studied the growth mechanism of Fe nanoisland arrays on Cu(0 0 1)–$c(2 \times 2)$N surfaces where 5×5 nm^2 patches of N-adsorbed $c(2 \times 2)$ structure are squarely arranged and separated by a few nm-wide lines of clean Cu surface. Preferential island growth at the intersections of the clean Cu lines is ascribed to the large sticking probability. Difference of surface strain on the clean Cu lines is the origin of the site selections both for the Fe inclusion in the surface and for the sticking probability of mobile Fe adatoms to the edge of the islands.

The Si(100)–$(2 \times n)$ surface also has been used for the formation of metal nanowire structures. This $(2 \times n)$ reconstruction can be obtained by various methods, such as quenching the sample after flashing and contaminating the surface with small amounts of Ni [40]. Li et al. [41] demonstrated the spontaneous formation of ordered In nanowire arrays on Si(100)–$(2 \times n)$. The deposited in atoms predominantly occupy the normal (2×1) dimer row structure and develop into a uniform array of in nanowires at a coverage of about 0.2 ML. Kida et al. [42] have formed Fe nanowire arrays on a water-terminated Si(100)–$(2 \times n)$ surface. The average wire width was 2 nm and the period was 3 nm, reflecting the $(2 \times n)$ surface reconstruction.

D. Self-Organized Surface Phases

Self-organized surface nanostructures such as atomic wires also may be formed by one element of a binary substrate, without the need of an adsorbate. Soukiassian [43]

has observed the formation of highly stable self-organized atomic lines on cubic β–SiC(100) and has highlighted their potential use in SiC-based nanoelectronic devices. Highly stable and long Si atomic lines are composed of Si dimers and form at the phase transition between the (3×2) and $c(4 \times 2)$ reconstructions by selective Si atom organization [44]. These Si atomic lines coincide systematically with the lateral mismatch between the $c(4 \times 2)$ Si-dimer rows. Their number and spacing can be controlled by annealing time and temperature, resulting in single isolated atomic lines or large superlattices. Carbon atomic chains also have been observed on C-terminated β–SiC(100) [45]. These carbon atomic lines are extremely stable up to 1200 °C, and comprise buckled single bond C–C dimers (sp^3), having a direction perpendicular to the C≡C triple bond dimers (sp) forming a $c(2 \times 2)$ surface reconstruction. The authors suggest that anisotropic (tensile and compressive) surface stress is the main driving force in this carbon $sp \rightarrow sp^3$ diamond-like temperature-controlled transformation.

E. Strain-Relief

Brune et al. [46] have demonstrated the formation of ordered 2D metal nanostructure arrays on substrates with periodic patterns defined by dislocations that form to relieve strain. The strain-relief patterns are created spontaneously when 1 to 2 ML of one material is deposited on a substrate with a different lattice constant, for example, Fe arrays on a 2 ML Cu on Pt(111) (Fig. 2), and Ag arrays on 2 ML Ag on Pt(111). Nedelmann et al. [47] studied the evolution of the strain-induced stripe pattern on Cu/Ni(100). Compressive strain resulting from the 2.6% lattice mismatch between Cu and Ni is relieved by the formation of V-shaped defects in the Cu film. This strain relief mechanism gives rise to a characteristic pattern of orthogonal stripes at the film surface.

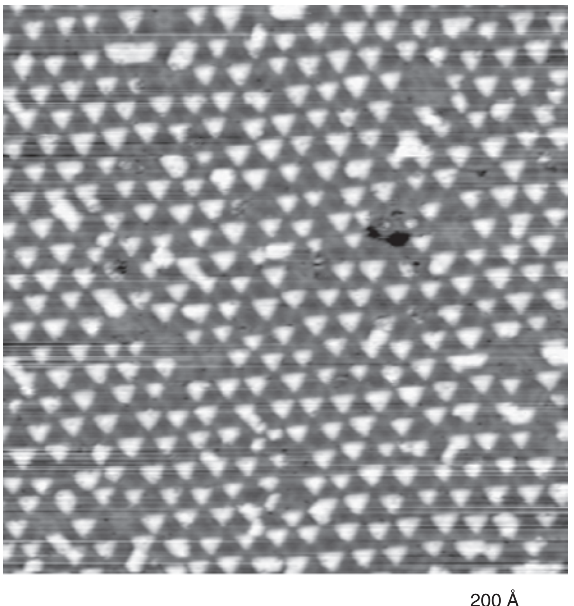

Figure 2. STM image of a periodic array of Fe islands nucleated on the dislocation network of a Cu bilayer on Pt(111) at 250 K. Reprinted with permission from [46], H. Brune et al., *Nature*, 394, 451 (1998). © 1998, Macmillan Magazines Ltd.

Mass selected Ag_7 clusters have been deposited at two different impact energies (20 and 95 eV) on a similar dislocation network formed by evaporating 2 ML of Ag on Pt(111) [48]. The surface has been investigated by low temperature STM as a function of annealing temperature. The clusters adsorption site, stability, and ordering depend on impact energies and annealing temperatures. It was observed that the hcp small triangle and dislocation region of the reconstructed unit cell form preferred pinning centers at low temperature; at higher temperature, most clusters are situated in the fcc hexagon of the unit cell. It is shown that the surface morphologies obtained by energetic cluster deposition are different from those obtained by thermal atom deposition; they depend on impact energy, deposition temperature, and annealing temperature. Although island ordering is not as good as that obtained by atom deposition, the results indicate that the large parameter space in cluster surface collisions (cluster size and impact energy) could be used to tailor metal nanostructures on structured surfaces.

The deposition of Ge on Si(100) leads to strain-induced formation of Ge hut clusters when the Ge film exceeds a critical thickness of 3 to 4 ML [49]. This layer-plus-island growth or SK growth occurs due to the lattice mismatch between Ge and Si, but, because of the initial Ge layer growth, the Ge quantum dots (QD) grown are not isolated. The presence of an adsorbate can alter the nucleation behavior of the Ge dots. Leifeld et al. [50] have shown that with a 0.11 ML precoverage of carbon, Ge dots form below the critical thickness for Ge islanding on bare Si(100). Das et al. [51] showed that by coating the Si surface with a polymer, isolated Ge islands and nanowires can form. This is explained by the fact that with a polymer overlayer, there is no strain-induced lattice mismatch and SK growth is not expected. Either layer-by-layer or Frank van der Merwe growth occurs under wetting conditions, or (3D) island growth, or Volmer-Weber growth occurs under nonwetting conditions. In this case, the authors have used the nonwetting criterion to grow isolated Ge nanoclusters on polymer surfaces.

Strain-induced growth of nanostructures also has been observed in several binary and ternary semiconductor systems. Leonard et al. [52] observed the 2D–3D growth mode transition during the initial stages of growth of highly strained InGaAs on GaAs, and this is used to obtain quantum-sized dot structures. Nözel et al. [53] described the self-organized formation of box-like structures during the interrupted epitaxial growth of strained InGaAs/AlGaAs multiplayer structures on (311)B GaAs substrates. Moison et al. [54] showed that the deposition of InAs on GaAs proceeds first by 2D growth, and above 1.75-ML regular nanometer-scale InAs dots form. Epitaxially self-assembled $In_xGa_{1-x}As$ QD within a GaAs substrate have atom-like properties and potential applications in optical and optoelectronic devices, quantum computing, and information storage [55].

Schmidt et al. [56] present different growth techniques and strategies for achieving different levels of order in the field of self-assembled semiconductor nanostructures. In a first step, they report a significant improvement of the

nanostructure size homogeneity by using either a repetitive desorption and regrowth procedure or by applying extremely low growth rates at high-growth temperatures. With this approach, an InAs/GaAs QD ensemble with a height distribution of ±5%, and a final photoluminescence (PL) peak line width of 19 meV at room temperature was fabricated. Regular square arrays of self-assembled SiGe islands with a strong size and shape homogeneity is achieved by deposition near their thermodynamic equilibrium using liquid phase epitaxy. The combination of self-assembly with conventional prepatterning leads to a long-range lateral order of In(Ga)As QDs on GaAs(001). A 3D crystal is fabricated by stacking multiple layers and vertically aligned In(Ga)As QDs onto a prepatterned GaAs(001) substrate, and good PL properties at room temperature are observed.

3. STEP AND FACET-TEMPLATED NANOSTRUCTURES

A. Stepped Surfaces

Stepped surfaces can serve as templates for producing 1D wires or stripes by decorating the step edges in a step-flow growth mode [57, 58]. Silicon is among the preferred substrates for step-flow growth of quantum wires because of the maturity of silicon-processing techniques in microelectronics. By appropriately controlling the annealing conditions, Viernow et al. [59] have produced highly regular array of steps on vicinal Si(111)–(7 × 7) with steps edges that are atomically straight for up to 2×10^4 lattice sites. The terraces are single domain, which produces a minimum kink width of 2.3 nm (half a 7 × 7 unit cell) and is, therefore, a high barrier for kink creation. Takagi et al. [60] used vicinal Si(111) to fabricate arrays of iron silicide dots of nanometer size on Si(111)– $\sqrt{3} \times \sqrt{3}$Ag substrates. Formation and magnetic properties of the dots have been investigated with STM, LEED, AES, and magnetic *ex-situ* measurements. The dots were found to nucleate preferentially at step edges than on terraces. They were ferromagnetic, and their composition was deduced to be $\sim Fe_3Si$.

Chain-like reconstructions of metals on semiconductors provide a natural vehicle to explore 1D electrons, provided that the electronic states are sufficiently decoupled from each other and from the bulk states of the substrate. Shibata et al. [61] studied the adsorption of Au on vicinal Si(111) by using STM and found ordering of Au in the steps that corresponded to (557) orientation. STM of Au on Si(557) showed double rows of protrusions [62], and 3D x-ray diffraction measurements were used to elucidate the detailed structure of the Au chain [63]. The structure is consistent with the 1D metallic behavior seen by photoemission. A 1D 5 × 2 reconstruction of Gd also has been reported on vicinal Si(111), which had stabilized in single domain form [64]. It contained zig-zag rows of occupied orbitals alternating with rows of unoccupied orbitals, as inferred from spectroscopic STM. Chain-like metal structures also has been observed for the Si(111)–(4 × 1)In system [65].

Nanowires grown by step decoration on metal surfaces also have been demonstrated. Depending on the overlayer–substrate combination, all classical thin film growth modes have been observed in one less dimension. The Cu/Mo(110) system exhibits row-by-row growth along the steps [66]. On the other hand, the Cu/W(110) system displays SK growth [67] and the Co/Cu(111) system island growth [68]. The growth modes are a result of competing effects, such as surface energy, interface energy, misfit strain, and step energy. The quantized electronic states in nanowires fabricated by step decoration have been observed [69].

B. Faceted Surfaces

It can be seen from the above discussion that vicinal surfaces with regular distributions of straight steps can act as natural templates for the growth of 1D nanostructures on surfaces due to their strong uniaxial anisotropy. This is possible if the substrate is stable during adsorption. In many cases, adsorbates induce significant surface faceting to minimize surface energy, and this also can be used for surface nanostructure formation. For example, regular arrays of 1D Ag stripes can be grown by adsorption and annealing of Ag on vicinal Cu(111) [70]. The Ag adlayer induces a periodic hill-and-valley nanostructure with alternating Ag-covered (112)-oriented facets and clean Cu stepped areas. The structure of the Ag-covered stripes is consistent with a rotated, uniaxially compressed, close-packed layer that wets the Cu(112) plane.

Nanoscale surface patterning by adsorbate-induced faceting and selective growth has been demonstrated on the insulator/metal growth system NaCl/Cu(211), which is inherently unstable against lateral pattern formation on the nanometer scale [71, 72]. Cu(211) is a vicinal surface with (111) terraces and intrinsic (100) steps, and restructures upon NaCl deposition when the growth temperature exceeds 270 K. The initially flat surface is transformed into a periodic 1D hill-and-valley structure consisting of (311) and (111) facets. NaCl grows selectively on (311) facets only, thereby creating a regular surface pattern with alternating stripes of bare Cu and chemically inert NaCl-covered areas. A highly regular assembly of three-sided pyramids can be fabricated by growing the ionic insulator NaCl on the kinked metal surface Cu(532) [73]. Only two pyramid faces are covered by NaCl, resulting in an overall surface structure that is modulated in surface chemical behavior. STM shows that electrostatic interactions plays an important role in the binding between an ionic insulator and a stepped or kinked metal template. This criterion provides a means to create nano- to mesoscopic surface structures combined with spatial modulation in surface chemical behavior. Mauch et al. [74] investigated the submonolayer growth of NaCl on Cu(100) by STM and LEED. The initial growth is characterized by decoration of step edges and rather strong restructuring of terraces of the Cu(100) surface. Further deposition of NaCl leads to the formation of narrow NaCl stripes oriented along the $[0\ \bar{1}\ 1]$ and $[0\ 1\ \bar{1}]$ directions. For higher coverages, these stripes form regular patterns with a fivefold superstructure.

Self-organized nanoscale pattern formation has been demonstrated on vicinal Si(111) surfaces via a two-stage faceting transition [75]. All the patterns, consisting of a periodic array of alternating (7 × 7) reconstructed terraces and step-bunched facets, have the same periodicity and facet structure, independent of the miscut angle, while the width of the facets increases linearly with miscut angle. The

pattern formation is attributed to a surface faceting transition that involves two transition stages: the first stage forms a stress-domain structure defining the universal periodicity; the second stage forms the low-energy facets controlling the facet width.

One-dimensional nanostructures of noble metals (Ag, Au) also have been grown on the high index Si(5 5 12) surface [76]. When low coverages (<0.25 ML) of noble metals (Ag, Au) are deposited onto Si(5 5 12) and annealed to 450 °C, they form overlayer nanowires with the periodicity of the Si surface (5.4 nm). At higher coverages and temperatures, significant restructuring occurs leading to the creation of facet planes.

4. MOLECULAR NANOSTRUCTURES

Self-assembly of regular arrays of thermodynamically stable nanostructures from appropriately functionalized molecules is a promising approach to future mass production of nanoscale devices [77]. Molecular self-assembly is the spontaneous association of molecules under equilibrium conditions into stable, structurally well-defined aggregates joined by noncovalent bonds. Molecular self-assembly is ubiquitous in biological systems and underlies the formation of a wide variety of complex biological structures. It has been shown that a self-assembled monolayer of thiolates deposited on suitable substrates could be made into resonant-tunneling transistors.

Molecules adsorbed on surfaces are particularly appealing because their arrangement is directly observable with the STM. For example, 2D supramolecular clusters and chains are observed upon submonolayer deposition of 1–nitronaphthalene (NN) onto reconstructed Au(111) [78, 79]. The molecules become pseudo-chiral upon adsorption. At higher NN coverage (0.3–0.75 ML), well separated molecular double chains are formed, either perpendicular or parallel to the Au(111) reconstruction domains. At low coverages (0.05–0.2 ML), NN forms 2D supermolecular clusters consisting predominantly of 10 molecules (decamers). Their handedness is determined from high-resolution STM images and local-density calculations. Modeling shows that hydrogen bonds cause the observed self-assembly. In contrast to atoms, the intermolecular electrostatic interaction of polar molecules leads to thermodynamically stable structures. Clusters and chains mutually interact via electrostatic repulsion. Comparison of images with submolecular resolution to local density calculations elucidates the thermodynamical stability, as well as the internal structure of the decamers.

Contini et al. [80] studied the adsorption of 2–mercaptobenzoxazole (MBO) molecules (C_7H_5NOS) on Cu(100) at room temperature by STM and found that after 0.8 L exposure, it is possible to locate ordered domains with well-defined parallel rows. After 38 L of deposition the surface appears completely covered by rounded protrusions randomly distributed. These results suggest a SK growth mode: initially an ordered monolayer forms and above this layer other molecules are adsorbed with a random distribution. The aromatic thione MBO molecule presents a S-containing head, which reacts with the Cu surface, and an aromatic ring originating lateral van der Waals interactions and molecular self-organization. A long-range-ordered $p(2\times2)$ structure of MBO on Cu(100) is obtained by MBO sublimation in highly controlled ultrahigh-vacuum conditions. The MBO molecular orbitals and interface electronic levels have been identified by angular-resolved high-resolution Ultra Violet (uv) photoelectron spectroscopy [81]. The role of S as a chemical hook for the molecule to the Cu surface is evidenced, and a comparison with similar compounds suggests that the adsorption mechanism and the related electronic structure are rather general results for π-conjugated molecules with a S-containing head.

STM observations of pentacene molecules on Au(111) at more than a monolayer coverage revealed periodic rows of molecules spaced 61 ± 5 Å apart [82]. These periodic rows consist of flat and edge-on molecules aligned with the initial layer of pentacene. Comparison of STM images and calculations show that the formation of widely spaced periodic rows takes place because of the total free energy gain from commensurate growth on the substrate and bulk pentacene-pentacene interactions. Lopinski et al. [83] demonstrated an approach for fabricating nanoscale organic structures on silicon surfaces, using minimal intervention by the tip of a STM and a spontaneous self-directed chemical growth process. Growth of straight molecular styrene lines, each composed of many organic molecules, and the crystalline silicon substrate determines both the orientation of the lines and the molecular spacing within these lines. This process should, in principle, allow parallel fabrication of identical complex functional structures.

The demand for enantiomerically pure compounds by the pharmaceutical and chemical industries has spurred the development of chiral technologies, which aim to exert control over a chemical reaction by directing its enantioselectivity. Heterogeneous enantioselective catalysis allows the production and ready separation of large quantities of chiral product, while using only small quantities of catalyst. Heterogeneous enantioselectivity usually is induced by adsorbing chiral molecules onto catalytically active surfaces. A mimic of one such catalyst is formed by adsorbing (R, R)–tartaric acid molecules on Cu(110) surfaces, which generates a variety of surface phases, only one of which is potentially catalytically active [84]. Ortega Lorenzo et al. [85] show that the active phase consists of extended supramolecular assemblies of adsorbed (R, R)–tartaric acid, which destroy existing symmetry elements of the underlying metal and directly bestow chirality to the modified surface. The adsorbed assemblies create chiral channels exposing bare metal atoms, and it is these chiral spaces are believed to be responsible for imparting enantioselectivity, by forcing the orientation of reactant molecules docking onto catalytically active metal sites.

Experiments on individual molecules by using scanning probe microscopies have demonstrated a diversity of physical, chemical, mechanical, and electronic phenomena [86]. They have permitted deeper insight into the quantum electronics of molecular systems and have provided unique information on their conformational and mechanical properties. Concomitant developments in experimentation and theory have allowed a diverse range of molecules to be studied, varying in complexity from simple diatomics to biomolecular systems. At the level of an individual molecule,

the interplays of mechanical and electronic behavior and chemical properties manifest themselves in an unusually clear manner.

Reed et al. [87] showed that molecules of benzene–1, 4–dithiol self-assembled onto the two facing gold electrodes of a mechanically controllable break junction form a statically stable gold-sulfur-aryl-sulfur-gold system, allowing for direct observation of charge transport through the molecules. This study provides a quantitative measure of the conductance of a junction containing a single molecule, which is a fundamental step in the emerging area of molecular-scale electronics. De Ventra et al. [88] have performed first-principles calculations of transport through a benzene–1,4–dithiolate molecule with a third capacitive terminal (gate). They found that the resistance of the molecule rises from its zero-gate-bias value to a value roughly equal to the quantum of resistance (12.9 kΩ) when resonant tunneling through the π^* antibonding orbitals occurs. Despite the growing interest in such systems, many fundamental properties of the molecule–substrate interface still are unanswered.

The construction of nanoscale electronic devices involves the fabrication of narrow gap electrodes and subsequent entrapment of a few or a single molecule between the metallic electrodes. The demonstrated techniques for fabricating electrodes include mechanical break junctions, nanopore methods [89], electrochemical plating [90], shadow evaporation [91], electromigration [92], and electron beam lithography [93]. Except for electron beam lithography, all the other techniques have a low yield and involve a series of steps that are difficult to control. Commercial electron beam lithography systems have the ability to focus electrons to diameters less than 10 nm such that metal-insulator-metal junctions for single-molecule electronics could be fabricated. So far, simple and reliable schemes for sub-10 nm and sub-5 nm electrode gaps by using electron beam lithography have been reported [94, 95].

One nm electrode gaps have been successfully prepared by using the combined electron beam lithography and electromigration technique [96, 97]. In this approach, a narrow gold bridge first was fabricated by electron beam lithography. The closely packed gold electrodes (1 nm apart from one another) then were created by the electromigration-induced break-junction technique. Trapping a molecule between two metal electrodes to make nanoscale transistor is a difficult technological challenge. The molecule needs suitable terminations that reliably bind it chemically to the two electrodes, bridging the gap between them. Moreover, there is presently no viable imaging technique for direct confirmation of successful trapping without perturbing the system, and the embedding of molecules could only be indirectly established from its conduction properties.

Lin and Kagan [98] used layer-by-layer self-assembly of metal–metal bonded supramolecules to fabricate lateral nanoelectronic devices. Mercaptoethylpyridine is used to bind to Au substrates and to template the sequential assembly of alternating layers of redox active dirhodium complexes $[Rh_2(DAniF)_2]_2$ $(O_2CCH_2CO_2)_2$ (DAniF = *N*, *N′*–di–*p*–anisylformamidinate) and conjugated organic ligands *trans*-1,2–bis(4–pyridyl)ethylene. Optical spectroscopy and atomic force microscopy show that the structure and composition of these thin films are similar to those found in tightly packed single crystals. Electrochemical studies of these films, grown on Au substrates, reveal a reversible oxidation wave at ~406 mV, corresponding to the one electron oxidation of the Rh_2^{4+} center. This directed assembly technique was used to fabricate lateral nanoelectronic devices in which the supramolecules span the channels. Tailoring the chemistry of the templating ligand enables assembly on desired surfaces, and engineering the chemistry of the supramolecules' dimetal units and coordinating ligands may tune the device characteristics.

Information storage technology relies on multistable systems that can be controllably switched between different configurations of comparable free energy. Multistability is present in many molecular and supramolecular systems through a variety of properties (conformations, redox and spin states, shape and dimensionality) that can be influenced by external stimuli. Cavallini et al. [99] have proposed a novel strategy by using thin films (3- to 35-nm thickness) of each of three amide-based rotaxanes. Rotaxanes are molecules in which a macrocycle is locked mechanically onto a "thread" by two bulky "stoppers." Their architecture, analogous to that of an abacus, suggests that they could be used as switchable components for artificial machines that function through mechanical motion at the molecular level [100]. Controlling such motion in the solid state could be used to store information. The films can be imaged by atomic force microscopy (AFM) in contact mode with a set point force below a threshold value of 2 nN. An increase in the load force to just above the 2-nN threshold results in a mechanical perturbation whose effect is localized at the contact area of the tip. When the tip is continuously scanned along a line, a string of regularly spaced dots appears. The scanning AFM tip gives the energy to the molecules along the line to reorganize into nuclei. As nuclei coarsen by ripening, a characteristic distance emerges. Finally, stable nuclei grow by incorporation of the mobile molecules to form the dots. Writing of multiple dots simultaneously could be achieved by using lithography based on multiple sources of perturbation, for instance by using a stamp. With such an approach, information storage on a thin film could reach densities of 1 to 10 Gbit/in^2.

5. ION-BEAM INDUCED NANOSTRUCTURES

Ion sputtering has been demonstrated as an alternative method for nanopatterning without the need for standard lithographic techniques. Recent studies using the high-spatial-resolution STM and AFM reveal that ion bombardment produces repetitive structures at the nanometre scale, creating peculiar surface morphologies ranging from self-affine patterns to "fingerprint-like" and even regular structures, for instance waves (ripples), checkboards, or pyramids. The phenomenon is related to the interplay between ion erosion and diffusion of adatoms (vacancies), which induces surface reorganization. Valbusa et al. [101] reviews the use of sputter etching to modify *in-situ* surfaces and thin films, producing substrates with well defined vertical roughness, lateral periodicity, and controlled step size and orientation.

In another review, Murty [102] summarizes the ion-solid collision process leading to the ejection of atoms and discusses different aspects of sputtering relevant to applications.

Mayer et al. [103] characterized the development of nanometer scale topography on SiO surfaces as a result of low energy, off-normal ion bombardment, using *in-situ* energy dispersive X-ray reflectivity and AFM. Surfaces roughen during sputtering by heavy ions, with roughness increasing approximately linearly with ion fluence up to 10^{17} cm^{-2}. A highly coherent ripple structure with wavelength of 30 nm and oriented with the wave vector parallel to the direction of incidence is observed after Xe sputtering at 1 keV. A linear model is presented to account for the experimental observations that include roughening both by random stochastic processes and by development of a periodic surface instability due to sputter yield variations with surface curvature that leads to ripple development.

Gago *et al.* [104] reported the production of ordered assemblies of silicon nanostructures by means of irradiation of a Si (100) substrate with 1.2 keV Ar^+ ions at normal incidence. Atomic force microscopy and high-resolution transmission electron microscopy show that the silicon structures are crystalline, display homogeneous height, and spontaneously arrange into short-range hexagonal ordering. Under prolonged irradiation, all dot characteristics remain largely unchanged and a small corrugation develops at long wavelengths. The formation of the dots is interpreted as a result of instability due to the sputtering yield dependence on the local surface curvature.

Grazing incidence small-angle X-ray scattering and AFM have been used to investigate the evolution of Si(100) surface morphology during normal-incidence Ar^+ sputtering as a function of ion energy in the range of 100–500 eV [105]. In the energy range of 100–300 eV, two structures with distinct individual length scales and behaviors form on the surface. The smaller scale (lateral size of 20–50 nm) morphology grows in scattering intensity and coarsens with time, while the larger scale (lateral size of approximately 100 nm) morphology grows in scattering intensity but does not coarsen significantly with time. At higher energies (400–500 eV), sputtering causes the Si(100) surface to become smoother on length scales smaller than 200 nm.

Spectroscopic light scattering was used to monitor periodic ripple evolution on Si(001) *in-situ* during oblique incidence (67.5°) Ar^+ sputtering with an energy of 750 eV [106]. Analysis indicates that, under high flux, the concentration of mobile species on the surface is temperature and ion-flux independent. This is due to an effect of ion collision cascades on the concentration of mobile species. The migration energy on the surface is measured to be 1.2 ± 0.1 eV.

Shang et al. [107] fabricated high-density Si cone arrays with a defined orientation over a large area by ion beam sputtering. The density of the Si cones is as high as 6×10^8 cm^{-2}, and a silicide tip was found on top of each Si cone. The Si cone arrays have a relatively low turn-on field and have potential applications in electronic vacuum devices.

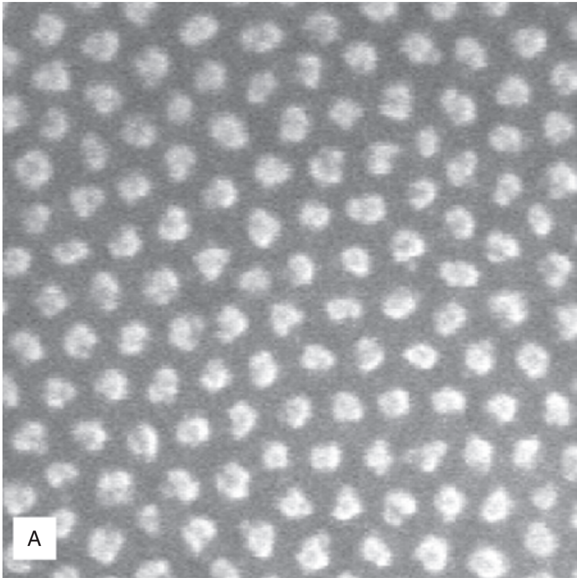
Chason et al. [108] investigated the temperature-dependent roughening kinetics of Ge surfaces during low energy ion sputtering by using energy dispersive X-ray reflectivity. At 150 °C and below, the surface is amorphized by ion impact and roughens to a steady state small value. At 250 °C, the surface remains crystalline, roughens exponentially, with time, and develops a pronounced ripple topography. At higher temperatures, this exponential roughening is slower, with an initial sublinear time dependence. A model that contains a balance between smoothing by surface diffusion and viscous flow, and roughening by atom removal explains the kinetics. Ripple formation is a result of a curvature-dependent sputter yield.

Facsko et al. [109] observed that well-ordered nanoscale islands appear on GaSb (001) surfaces during low-energy normal incidence Ar^+ sputtering. Crystalline dots 35 nm in diameter arranged in a regular hexagonal lattice were produced on the GaSb surface, the formation mechanism replying on the interplay between ion-induced surface roughening and smoothing due to surface diffusion (Fig. 3). The characteristic length of the generated pattern was observed to scale with the square root of ion energy over the energy range 75–1800 eV [110]. Similar nanoscale islands formation on lnP was achieved by Frost et al. when the lnP surfaces were bombarded with oblique incident Ar^+ ions at 500 eV with simultaneous sample rotation [111].

Periodic Co/Pd magnetic nanostructures have been fabricated by depositing perpendicular magnetic films on nanopatterned GaSb(100) substrates formed under normal incidence 420 eV Ar^+ bombardment [112]. Similar stripe domain patterns and reduced coercivity are observed for the as-deposited sample as compared with those for a reference unsputtered substrate. Further processing steps such as etching and polishing will be needed to isolate the magnetic elements from each other in order to make ultrahigh density magnetic storage media.

Ni films grown at room temperature on flat and prenanostructured Cu(001) surfaces have been studied *in-situ* by STM and the magneto-optic Kerr effect [113]. Ar^+ bombardment of 30–45 monolayer thick Ni/Cu(001) films results in the formation of self-organized pseudoperiodic nanostructures. On flat Cu(001), the nanostructuring process rotates the easy-magnetization axis of the 45 monolayer Ni/Cu(001). During the growth of Ni on prenanostructured Cu(001), neither preferential decoration of step-edges by material nor filling of the Cu-craters occurs.

Ion sputtering-induced nanopatterns also have been observed on metal surfaces. The morphology of the Ag(110) surface after Ar^+ ion sputtering has been studied by a variable temperature STM [114]. For ion energies greater than 800 eV and in the temperature range $270 < T_S < 320$ K (where T_S is the sputtering temperature), a peculiar ripple structure well aligned along the $\langle 1\bar{1}0 \rangle$ direction and independent of the ion beam angle has been observed. A simple model of this effect, based on the anisotropy and on the temperature hierarchy of the Ag adatom and vacancy surface diffusion, explains the observed features. The evolution of the Cu(110) surface morphology during low temperature (180 K) ion sputtering also was studied as a function of the incident ion beam angle by means of STM [115]. The morphology was dominated by a ripple structure with the wave vector parallel or perpendicular to the direction of the incident beam. The time evolution of the interface shows that the ripple wavelength increases in time following a scaling law $\lambda \propto t^z$, with $z = 0.26 \pm 0.02$. These results are ascribed to the effect of a Schwoebel barrier on



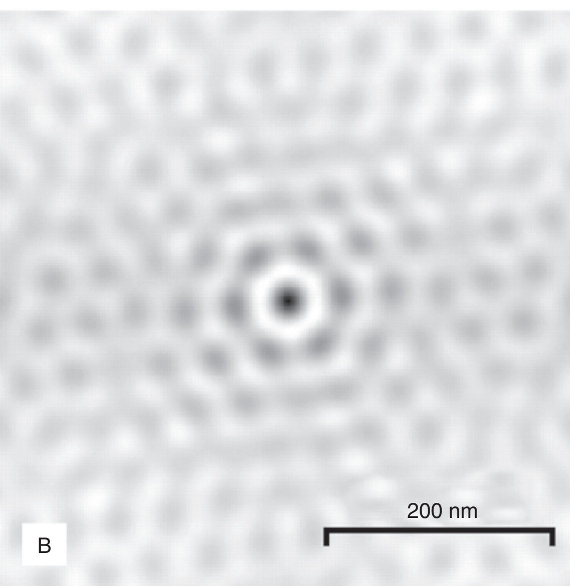


Figure 3. (A) SEM image showing highly ordered cones on a GaSb(100) surface after ion sputtering; (B) the corresponding 2D autocorrelation reveal the regularity and hexagonal ordering of the dots, which extends over more than six periods. the interlayer diffusion of the recoiling atoms produced during ion sputtering.

Nanopatterns on metal surfaces can be created easily by ion sputtering. However, due to the fast diffusion processes characterizing these materials, the nanostructures are often unstable at room temperature and above. This effect prevents the use of such patterned substrates in nanotechnology applications. Sekiba et al. have proposed a simple oxidation process to stabilize these features durably [116]. The method has been tested on Cu, but its generality suggests that it can be applied to many other metals.

Glancing-incidence ion-beam irradiation has been used both to ease kinetic constraints that otherwise restrict the establishment of long-range order and to impose external control on the orientation of nanowire arrays formed during stress-field-induced self-ordering of calcium atoms on a CaF_2(111) surface [117]. The arrays exhibit exceptional long-range order, with the long axis of the wires oriented along the azimuthal direction of ion-beam incidence. Transport measurements reveal a highly anisotropic electrical conductivity, whose maximum lies in the direction of the long axis of the 10.1-nm-period calcium wires.

Kahng et al. [118] show that sputtering-induced nanostructures have an inherently nonlinear origin, first appearing when the nonlinear terms start to dominate the surface dynamics. Depending on the sign of the nonlinear terms, determined by the shape of the collision cascade, the surface can develop regular islands or holes with identical dynamical features. While the size of these nanostructures is independent of flux and temperature, it can be modified by tuning the ion energy. By using numerical simulations with the KS equation, Kim et al. [119] demonstrate that rotated ripple structures (RRS) on sputter-eroded surfaces are potential candidates for nanoscale wire fabrication. The RRS can form when the width of the collision cascade in the longitudinal direction is larger than that in the transverse direction and the incident angle of ion beam is chosen in a specific window. By calculating the structure factor for the RRS, it is found that the RRS are more regular and their amplitude is more enhanced compared with the much studied ripple structure forming in the linear regime of sputter erosion.

Lau et al. report another way of creating nanostructures on surfaces by ion sputtering of strained superlattices that possess periodic interfacial elemental segregation [120]. Arrays of nanoscale depressions were observed during sputtering of Si/SiGe heterostructures by using 500 eV O_2^+ ions at angles of incidence between 46° and 56°, with simultaneous sample rotation in a secondary ion mass spectrometry system. Both AFM and TEM results suggest that these depressions were produced as a result of preferential sputtering of Ge and only occur when there are undulations present at the Si/SiGe interface. The formation of the interface undulation appears to occur in tandem with the increase in the Ge surface segregation at the Si/SiGe interface for layers grown at elevated temperatures.

Manipulating matter at the nanometre scale is important for many electronic, chemical, and biological advances, but present solid-state fabrication methods do not reproducibly achieve dimensional control at the nanometre scale. Li et al. have reported a means of fashioning matter at these dimensions that uses low-energy ion beams and reveals surprising atomic transport phenomena that occur in a variety of materials and geometries [121]. The method is implemented in a feedback-controlled sputtering system that provides fine control over ion beam exposure and sample temperature. They name the method "ion-beam sculpting," and apply it to the fabrication of a molecular-scale hole, or nanopore, in a thin insulating solid-state membrane. Such pores can serve to localize molecular-scale electrical junctions and switches, and function as masks to create other small-scale structures.

6. PHOTON-INDUCED NANOSTRUCTURES

Pulsed-laser irradiation is another method for growing nanoparticles on surfaces [122]. The high photon flux impinging on a target produces the ejection of a high density of neutral atoms, ions, and electrons. The background gas pressure confines the ejected material to a certain distance from the target that can be collected on a substrate or redeposited on the target. Fowlkes et al. [123] used pulsed-laser irradiation to induce the formation of linear arrays of nanoparticles that can extend over millimeter distances. On flat surfaces, the irradiation induces the fragmentation and clustering of a thin silicon film pulsed-laser deposited on silicon into nanoparticles that grow to 30 to 40 nm in diameter. The nanoparticles aggregate into clusters that migrate, forming short curvilinear groups that exhibit a short-range ordering. If a region containing a microscopic roughness is introduced, the nanoparticles are forced to align into long and remarkably straight lines with line spacing very close to the laser wavelength. A close connection is established between the nanoparticle alignment and the evolution of laser-induced periodic surface structures, and the microscopic roughness serves as a trigger to produce the alignment.

Kawamura et al. [124] used femtosecond laser pulses (wavelength ~800 nm) to encode two cross-superposed holographic gratings on silica glass. A variety of periodic nanostructures from a 1D wire array to 2D arrays of holes or islands were formed by changing the energy density and the incidence angle of the irradiation laser beams. The smallest dimensions were a width of ~15 nm for wires and a diameter of ~20 nm for holes. Laser-driven microexplosions occurring within the microcylindrical-lens array created by the first laser pulse are suggested as a mechanism for the formation of these structures. Only two pulses are required to encode these periodic structures, and this method could be applied to the fabrication of photonic crystals and QD or wire arrays.

7. SUMMARY

While lithographic techniques (electron, optical, UV, X-ray, ion projection, etc.) still dominate today in micro- and nanoscale fabrication, this review has focused on methods of self-organized nanostructure formation on surfaces, which could provide an alternative approach to nanodevice fabrication with potentially smaller feature sizes, even approaching the atomic scale. In particular, emphasis is placed on how nanostructures can form spontaneously due to surface dislocations, adsorbates, strain-relief, and the presence of steps and facets. Molecular nanostructures are described because of their potential applications in the biomedical sciences. It also is shown that broad beams of ions and photons can induce nanostructure formation under appropriate conditions.

GLOSSARY

Adsorbate An atom or molecule that adheres to a surface through chemical or physical bonding.

Atomic force microscope (AFM) An instrument that is able to image surfaces to molecular accuracy by mechanically probing their surface contours. A device in which the deflection of a sharp stylus mounted on a soft spring is monitored as the stylus is moved across a surface. If the deflection is kept constant by moving the surface up and down by measured increments, the result (under favorable conditions) is an atomic-resolution topographic map of the surface.

Chemisorption Adsorption in which the forces involved are binding forces of the same kind as those operating in the formation of chemical compounds. Chemisorbed atoms or molecules are therefore more strongly bound to the surface than physisorbed atoms or molecules.

Clusters Aggregates of atoms (or molecules) that contain between three and a few thousand atoms which have properties intermediate between those of the isolated monomer (atom or molecule) and the bulk or solid state material.

Dislocations Linear defects inside a crystal lattice which govern the plastic behaviour of a material. Since dislocations cannot end somewhere inside a crystal, they must either form dislocation loops or reach the surface.

Fermi wavelength At low temperatures the current is mainly driven by electrons with energy close to the Fermi energy; hence the relevant length scale is the Fermi wavelength, typically around 35 nm. In particular, when the dimension of metallic nanowires is comparable to the electron Fermi wavelength, the conductance is quantized and no longer obeys classical Ohm's Law.

Ions An ion is any atom or group of atoms that bears one or more positive or negative electrical charges. Ions are typically formed by the addition of electrons to, or the removal of electrons from, neutral atoms or molecules or other ions.

Mesoscopic The Greek word *meso* means "in between". Mesoscopic physics refers to the physics of structures of intermediate sizes, ranging from a few atomic radii to a few microns. A mesoscopic sample is too big to study its properties by standard methods in the physics of individual atoms, and is too small for the application of the familiar physical laws of the macro world. A macroscopic device, when scaled down to a meso-size, starts revealing the quantum signatures of conventional characteristics. For example, in the macro world, the conductance of a wire increases continuously with its diameter, but in the meso world the wire's conductance is quantized, i.e., the increases occur in steps.

Nanostructures Regular structures formed, for example on a surface, at the nanometer scale.

Photons Energy packets of electromagnetic radiation; light consists of photons.

Scanning tunneling microscope (STM) An instrument that is able to image conducting surfaces to atomic accuracy and has been used to manipulate atoms/molecules on a surface. The normal operation of the device is to maintain a constant tunneling current between the probe tip and the surface kept at constant bias difference, so the vertical movement of the tip maps the surface electronic topography.

Self-organized The spontaneous regular arrangement of atoms, molecules or clusters, for example on a surface, due to interactions between the entities and the surface.

Stranski–Krastanov (SK) growth The growth of 3D islands on a surface after the strain energy exceeds some critical limit of a 2D structure (wetting layer).

Surface facets More stable low index surface planes (with higher atom density) which a high index surface (with lower atom density) often prefers to transform itself into.

Surface steps Discontinuities on a surface typically due to an additional atomic layer. These steps are usually favorable sites for atoms, molecules or clusters to bind at.

1. NANODEVICES AND MODELING

1.1. Why Semiconductor Nanodevices?

We are used to the presence of computer silicon chips in everyday objects—automobile engines, washing machines, and relatively inexpensive children's toys. They are even being inserted into furniture flat-packs to ensure that the components are assembled in the correct order [1]. A common feature of these everyday chips is that they do not need to work at very high speed (relatively speaking in chip terms) and they do not need to be too small in size. These are devices whose size is measured in micrometers (one micrometer equals one-millionth of a meter, or 1000 nanometers), and the prefix "nano" is never applied to them because the prefix "micro" is sufficient to describe their size. However, the rate at which new electronic devices is being developed grows ever larger. There is a need for new scientific measuring instruments and detectors to become more sensitive, and success in the consumer market means that devices must be smaller and more efficient. Their development depends crucially on the development of the individual components which make up the devices, and there is an overall trend for these components also to be smaller and work more rapidly. In particular, developments in the manufacture of thin films have made it possible to fabricate more complex layers of material, down to the limits of a single atomic layer. As described below, these pave the way for the preparation of very small and fast transistors onto chips, leading to devices which operate at very high frequencies.

So what types of new devices are we talking about? The development of mobile telephones affords a very good example of the way in which devices are being developed for minutarization and speed of operation. In any communications channel, a higher bandwidth means that information can be sent faster and in greater amounts, and a higher bandwidth requires that communication channels must be able to handle signals of higher frequency. Frequency is measured in *hertz* (Hz), or cycles per second. Processors in today's personal computers operate at frequencies typically between 500 MHz and 2.5 GHz (1 MHz, or one megahertz, is one million hertz; 1 GHz, or one gigahertz, is 1000 megahertz). The first generation of mobile telephones operated at frequencies between 900 MHz and 1.9 GHz. The new generation of mobile telephones allows much more information to be sent, including photographs, and so much more bandwidth is needed for these devices; a group at the University of Leeds is now working on designing and producing devices which will operate up to 2000 GHz. More bandwidth also means more efficient microwave devices for use in, for example, receivers for satellite TV and radio transmitters [2]. A recent development has taken place in the use of high frequency devices for use in hidden weapons detection; metal detectors cannot locate plastic or ceramic weapons, and X-ray imaging is potentially harmful. To overcome this problem, a group at the Pacific Northwest National Laboratory has developed a method of producing holographic screened images using detectors working at frequencies of typically 100 GHz. An increase in bandwidth will also mean that one day we could have nano cameras circulating through the human body sending information to outside receivers. Another major area of development is in optoelectronic devices, which directly interface optics and electronics. An example of this technology lies in the amplification of optical signals passing through fibers. In long stretches of fiber, for example in undersea communications, optical signals degrade and must be boosted before passing down the next stretch of fiber. Previous methods have relied on the conversion of the weakened optical signal to electrical ones, but a much more efficient system is to allow the optical signal to stimulate semiconducting material which itself will directly generate light for onward transmission. Another application of this optoelectronic technology lies in environmental control through the detection of light which has been degraded by passing through atmospheric polution [3]. However, our old friend silicon (Si) is not efficient at generating light,

and much more efficient semiconductor generators such as gallium arsenide (GaAs) are being developed.

What are the physical processes in our devices which determine how fast they work? The answer contains many strands, but the two main ones are size and material composition. To show how size influences the situation, consider a very basic device consisting of a lump of semiconducting material with two metal contacts at some distance apart on its surface—we will describe more specific and complex devices in some detail later. The device is switched on by applying a voltage across the contacts, and a resulting current is caused by the transit of *electrons* through the material, from one contact to the other. (current is also carried by the *holes* left behind in the lattice structure which electrons have vacated, but more of this later). If we want to use this device for rapid switching, then the speed of this switching (the frequency of which is given by the number of switches per second) depends on how rapidly an electron can pass from one contact to the other. Clearly, by making the device smaller we are able to cut down on the transit time and hence increase the number of switches per second, or the frequency range, of the device, and this is partly why smaller devices are being developed. Higher frequencies mean larger bandwidth, resulting in the ability to send more traffic down a given channel. It is therefore truly remarkable that if we want to increase this traffic then we have to use smaller devices! It is not only the smallness of size that is important in increasing this capacity, but the composition of the material used is also important in reducing transit times. If electrons were swimmers, they would prefer not to swim through a treacle-like substance such as silicon, but they would find the journey much less arduous to swim through a less viscous substance such as gallium arsenide. In material terms, we say that gallium arsenide has greater *mobility* than silicon; we will show later how the value of the mobility is used. This swimming analogy, although extremely simplistic, is quite a reasonable one; as we shall see later, it turns out that in some theoretical process we can treat the electron transport in materials as a fluid flow.

However, it is plain that a further reduction in size must affect the way in which we think of electron transport in our transistors. Let us do a simple calculation involving some typical physical values to illustrate this point. Suppose that in the simple device described above, the distance between the contacts is one micrometer (a micrometer, denoted by the symbol μm, is one-millionth of a meter), and it is one-tenth of a micrometer thick and one centimeter wide (or 10,000 micrometers). Note that one of these lengths is very much larger than the others; we will use this fact when we come to mathematically model such a device. Then the volume of the device is 1000 cubic micrometers (10^3 μm^3). If we take a typical electron density of 100 electrons per cubic micrometer, then at any one time there will be $10^3 \times 10^2 = 10^5$ electrons in the device. We can easily reduce this number by a factor of 10, to a value of 10,000, by just over halving each dimension. Thus we soon get to the stage where, with only 10,000 particles in the transistor at any one time, we can no longer treat the electron flow as we would a continuous fluid. This picture of electron flow as a continuous fluid, together with the use of the Boltzmann transport equation which we will describe later, has been the basis of our efforts to describe the physical nature of electron transport in semiconductors. Any further reduction in size of our devices will mean that we will have to employ drastically new theoretical methods to describe this transport. Extra problems arise if our well-known devices are reduced further in size. The current that such a device is able to pass will be limited if the device is too thin. Further, hotspots with extremely high temperatures can occur in nanoscale devices, and then lattice vibrations will scatter the conduction electrons in an uncontrollable way. It must therefore be clear that there is a limit to which we are able to reduce the size of our well tried and tested devices.

We have described a device containing 10,000 electrons at one time, but amazingly we can create devices which contain only 1 electron at a time, leading to the exciting prospect of single-electron transistors [4–6]. Such devices exploit the essentially quantum nature of electron behavior, because they cannot be treated as classical particles which obey Newton's laws of motion. To illustrate this point, imagine what would happen if you were to suddenly stand up and run into the nearest wall—please, *do not* try this. Experience, and the predictions of Newtonian mechanics, suggests that you will bounce back off the wall. However, quantum theory predicts that electrons can perform the trick of passing through an equivalent wall and travel on the other side. This process is called *tunneling*—they pass through potential barriers that would be impenetrable to them classically. This behavior is exploited in the single-electron transistor, in which an electron can tunnel into a "box" made up of suitably positioned potential barriers approximately 1 nanometer apart. By altering the applied voltage around the barriers, electrons can be made to tunnel in and out of the box one at a time so that the charge inside the box can be counted in discrete units. These electrons can be confined in all three space directions, and for this reason such a device is known as a *quantum dot*. Since electrons traverse the dot one at a time, such an arrangement can be used for extremely sensitive measurements of electric charge. Another exciting possibility is that these dots could be used for manipulating quantum bits that will be needed for the implementation of *quantum computing* [7]. Another exciting prospect arises from the fact that a number of electrons confined within a quantum dot have interactions unlike those seen between electrons in an atom. Effectively, artificial atoms can be created, and an exciting challenge is to make new material composed of these new artificial "atoms." Many problems lie ahead in exploiting these new ideas—for example, how to create these dots to a consistent pattern rather than randomly, how to link these "atoms" together to form new material, and how to do all this at room temperature rather than at the low temperatures required at present. These are physical constructs for which the prefix "nano" really is more appropriate than the prefix "micro."

1.2. Process of Nanodevice Modeling

Novel manufacturing techniques must be developed in order to produce these new nanotransistors, but first new prototypes and experimental devices must be made before they are ready for the mass market. It is extremely expensive

to set up the fabrication tools for these prototype devices, especially if they are found not to work as required. Thus it is no longer economically feasible to fabricate experimental designs without at first producing mathematical models which will predict how these devices will perform. In the same way that new materials and fabrication processes are being developed, so too are new mathematical techniques being developed in order to predict the behavior of these new devices.

There are three main strands to the modeler's task. First, it must be decided what physical processes are to be included, and how to incorporate them into equations. Too many physical effects will make the task cumbersome and impossible to complete, while too few will make the model physically unrealistic. The equations which arise at this stage of the modeling process are almost always nonlinear partial differential equations. The second strand involves the solution of these equations, always assuming of course that they have been set up in a way that they *do* possess a solution. Since the equations are highly nonlinear [for example, the lifetime τ_e appearing in Eq. (4) is itself a function of the solution, whose form must be inserted numerically], then it is possible to obtain exact analytical solutions to the equations only if the physical content is idealized to such an extent that the device is physically unrealistic. Hence, the solution of the equations for realistic devices invariably involves numerical computing techniques. The third strand involves the interpretation of the numerically computed results. Having obtained a numerical solution to the equations which model a particular physical configuration of a device, physical characteristics may then be computed and compared with experimental results, if there are any. If a prototype device has already been manufactured, and the computed results *do not* compare favorably with the measured ones, then the mathematical model must be changed in some way—for example, by modeling extra physics. If the computed results *do* compare favorably, then the modeler will have the confidence to suggest improvements to the physical configuration by suggesting, for example, that doping profiles or device dimensions be changed at manufacture.

We will illustrate the role of device modeling by concentrating on one particular nanodevice—the high electron mobility transistor (HEMT). This is a device which has improved transport qualities compared with the more basic metal Semiconductor field effect transistor (the MESFET) in the way described below. Although these devices are only two of many devices in existence, a description of the process of modeling them illustrates common features applicable to the modeling of many nanodevices. A typical HEMT or MESFET structure is illustrated schematically in Figure 1 and consists of layers of different semiconducting material, together with at least three contacts—the *source*, *gate*, and *drain*. The source and drain are ohmic contacts (that is, they are perfect sources and sinks providing no injection of charge carriers), while the gate is a Schottky contact (a reverse contact bias at such a metal—semiconductor interface blocks the flow of electrons and creates a region that is depleted of electrons; this is modeled using the built-in potential ψ_b introduced in Section 2) [8]. The gate is often recessed into the device as shown. A typical gate length

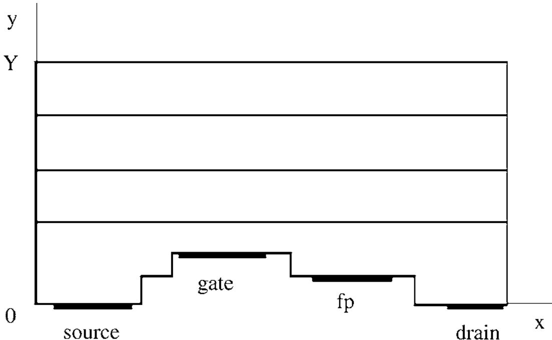

Figure 1. A typical HEMT or MESFET structure showing the source, gate, and drain contacts. There are four layers and two recesses in this figure. A fourth field plate contact (fp) is often added in order to spread the electric field in the device.

usually lies in the range of 100 to 500 nanometers. Voltages V_g and V_d relative to the source are applied to the gate and drain respectively, and a current flows through the device. The current–voltage (I_d–V_d) characteristic curve has a device-dependent profile for a fixed value of V_g. By varying V_g, this characteristic profile is changed because the effect of changing V_g is to cause a larger or smaller electron depletion region around the gate. Generally in a semiconductor, current is carried by both electrons and holes (they are *bipolar* devices), but in the MESFET or HEMT the current is dominated by the electron flow, and hole current is neglected (the *unipolar* model).

The layers of the MESFET consist mainly of *n*- or *p*-type semiconducting material, most often of GaAs which has a higher electron mobility than that of silicon (that is, for given electron density and electric field values, the current is higher). The disadvantage of this device is that the conduction electrons suffer many collisions with the structure of the crystal lattice. This limits the speed at which the device works. A much more efficient arrangement, as far as shorter transit time is concerned, is the HEMT whose structure consists of, for example, GaAs and aluminum gallium arsenide (AlGaAs). This device works because conduction electrons fall into potential wells near the AlGaAs interfaces where they suffer far fewer collisions. These wells are typically only several nanometers wide, and the electrons are able to transit the device virtually unhindered in thin sheets parallel to the interfaces. Again, an analogy of a fluid flow springs to mind here, where rainwater falling onto a roof rolls down into a gutter which carries it quickly away.

A typical HEMT device will consist of many different layers of GaAs and $Al_uGa_{1-u}As$ with differing mole fractions u of Al. The depth of the device in the direction of the axis Oy is typically of an order of magnitude smaller than its length in the direction of the axis Ox. Its length along the third axis Oz (not shown in Fig. 1) is typically many orders of magnitude larger, and it is common to consider only a two-dimensional model for a slice perpendicular to Oz. The modeler may seek to predict the effects of altering many physical parameters of the system; for example, device characteristics may be varied by changing the various physical dimensions of the device, or by changing the number of layers, or by changing the Al mole fractions u of the layers, or by changing the electron doping densities. A fairly recent

development has been to add an extra contact—the *field plate* (denoted by *fp* in Fig. 1) [9, 10]. This has the effect of raising the operating voltages of HEMTs by spreading out hotspots in the electric field.

There are several different levels at which the modeling of devices may be achieved, with the simpler processes not achieving the degree of flexibility required in dealing with multilayer structures. Computer aided design (CAD) packages exist which exploit most of these processes. The first main method to be used was the *equivalent circuit method* [11–14] in which equivalent electric circuits are constructed to mimic device characteristics. Although still used in many CAD packages, it is a very blunt approach and is not capable of taking the subtleties of solid state processes into account. At the other end of the scale is the *Monte Carlo* technique [15–17] in which individual electron paths are computed once all scattering data are given. This approach can produce excellent results but, given the very large number of particles needing to be tracked, it is extremely expensive in computational cost. A third approach, which is the one we shall concentrate on in this work, is that of *semi-classical modeling*. In this method, the Poisson equation is solved together with equations which arise by taking the first few moments of the Boltzmann transport equation. Data for lifetimes, mobilities, etc. are input in numerical form having first been calculated (in previous simulations) using the Monte Carlo technique. This method allows fairly rapid implementation while at the same time allowing subtle solid state processes to be incorporated. One of the simplest methods in this semiclassical approach is the *drift diffusion approximation* [18, 19] in which the Poisson equation is solved along with the current continuity equation. This method produces reasonable results for devices with relatively large physical dimensions. However, for nanodevices which are considerably smaller, in which high electric fields are generated, the *hydrodynamic* model [20, 21] must be used to account for the effect of electron heating. In this approach, the Poisson equation is solved with both the current continuity and energy transport equations. In the case of the HEMT in which quantum wells are formed at the interfaces, we must also solve the Schrödinger eigenvalue equation of quantum mechanics. A number of eigensolutions of this equation are then used to compute the electron number and energy densities at each point in the device.

In Section 2 we introduce the differential equations which describe the hydrodynamic model for the HEMT. In Section 3 we discuss several main methods which are used to obtain numerical solutions of the equations. In Section 4 we will concentrate on the most widely used of these methods, namely, the *finite difference* method. We will discuss the main techniques which are employed in implementing this method and give an example of a solution for a specific multilayer HEMT.

2. EQUATIONS AND THEIR DERIVATION

2.1. Main Equations

When attempting to model a particular device, we must first decide what variables will best describe its physical nature. In semiconductor device modeling, the most natural variables will be the electrostatic potential ψ, electron temperature T_e, electron density n, hole density p, quasi Fermi level $E_F = -q\phi$, total energy density W, electron current density $\mathbf{J}$, electric field $\mathbf{E}$, and the average carrier energy ξ. Not all of these quantities are independent, and the relations between them will be outlined below.

The transport of charge carriers in semiconductors must obey *Maxwell's electromagnetic equations*

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \qquad \nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t}$$
$$\nabla \cdot \mathbf{D} = \rho, \qquad \nabla \cdot \mathbf{B} = 0$$

where $\mathbf{B}$ is the magnetic induction, $\mathbf{D}$ is the electric displacement, $\mathbf{H}$ is the magnetic field, and ρ is the electric charge density. This last equation implies that $\mathbf{B} = \nabla \times \mathbf{A}$ for some vector potential $\mathbf{A}$. The first equation then implies that $\nabla \times (\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t}) = \mathbf{0}$, or equivalently that $\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} = -\nabla\psi$ for some scalar potential ψ. In the modeling of many devices, and especially those being considered here, the term $\frac{\partial \mathbf{A}}{\partial t}$ may be neglected due to its relatively small size, and so the electric field will be given by $\mathbf{E} = -\nabla\psi$. We further assume that the permittivity is independent of time and that polarization due to mechanical forces is negligible, so that we may write $\mathbf{D} = \epsilon_0\epsilon_r\mathbf{E}$ where $\epsilon_0 = 8.85 \times 10^{-12}$ F m^{-1} is the permittivity of free space, and ϵ_r is the relative permittivity of the material (13.18 in the case of GaAs). The third of the four Maxwell equations then gives $\nabla \cdot (\epsilon_0\epsilon_r\nabla\psi) = -\rho$. If N_D is the doping density imposed at manufacture, then we may write $\rho = q(N_D - n)$ where $q = 1.6 \times 10^{-19}$ C is the magnitude of the electron charge. We finally have Poisson's equation

$$\nabla \cdot (\epsilon_0\epsilon_r\nabla\psi) = -q(N_D - n) \tag{1}$$

The starting point for the modeling of the transport dynamics is the Boltzmann transport equation

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\partial f}{\partial \mathbf{k}} \cdot \frac{\partial \mathbf{k}}{\partial t} + \frac{\partial f}{\partial \mathbf{r}} \cdot \frac{\partial \mathbf{r}}{\partial t} = 0 \tag{2}$$

for the distribution function $f(\mathbf{k}, \mathbf{r}, t)$ which is given in terms of the particle momentum $\hbar\mathbf{k}$, position $\mathbf{r}$, and time t. The interpretation of this function is that $f(\mathbf{k}, \mathbf{r}, t)\mathbf{d}^3\mathbf{r}\mathbf{d}^3\mathbf{k}$ is the number of particles in the space region $\mathbf{d}^3\mathbf{r}$ at position $\mathbf{r}$ and momentum region $\mathbf{d}^3\mathbf{k}$ at momentum $\hbar\mathbf{k}$ at time t, where $2\pi\hbar$ is Planck's constant $h = 6.624 \times 10^{-34}$ J s. We then take a *moment* of this equation by multiplying through by some function g of the variables and integrating over all $\mathbf{k}$-space [22]. We take the first three moments of this equation by taking $g = 1$, $m\mathbf{v}$, and $\frac{1}{2}mv^2$ in turn, where m and $\mathbf{v}$ are the particle mass and velocity respectively. Then using various simplifying assumptions [23, 24] we obtain the following set of equations:

(i) *the continuity equation for electrons*

$$\frac{\partial n}{\partial t} = \frac{1}{q}\nabla \cdot \mathbf{J} \tag{3}$$

Normally, terms involving generation and recombination rates for charge carriers are present on the right hand side of this equation. However, they are neglected here for the unipolar MESFET model.

(ii) *the energy transport equation*

$$\frac{\partial W}{\partial t} = \mathbf{J} \cdot \mathbf{E} - \frac{(W - W_0)}{\tau_e} - \nabla \cdot \mathbf{s} \tag{4}$$

Here, the term $\mathbf{J} \cdot \mathbf{E}$ represents the Joule heating (in any conductor carrying a current, heat called the Joule heat is produced). The second term on the right hand side of this equation represents the relaxation of the total energy density W back to the equilibrium energy density W_0. If we write $W = n\xi$, then the energy relaxation lifetime τ_e is generally found to be a function of ξ. The quantity $\mathbf{s}$ is the energy flux described below.

2.2. Subsidiary Equations

We first consider the set of equations in relation to MESFET modeling, in which there are no quantum wells formed at the layer interfaces. In this case there is no need to solve the Schrödinger equation explicitly. For the *nondegenerate approximation*, which is valid when the pure semiconductor is not too highly doped with impurities, the electron density is given by the simple exponential form

$$n = N_c \exp\left(\frac{q}{k_B T_e}(\psi - \phi)\right) \tag{5}$$

Here, $k_B = 1.38 \times 10^{-23}$ J K^{-1} is the Boltzmann constant, and $N_c \equiv 2(2\pi m^* k_B T_e h^{-2})^{1.5}$ where m^* is the effective mass of the electron. In this nondegenerate case, the expression for the current density $\mathbf{J}$ in Eq. (3) and the energy flux $\mathbf{s}$ in Eq. (4) can be written

$$\mathbf{J} = -qn\mu\nabla\psi + k_B\mu T_e \nabla n + ak_B\mu n\nabla T_E + bk_B T_e n\nabla\mu \tag{6}$$

$$\mathbf{s} = -\mu W\mathbf{E} - \frac{k_B}{q}\nabla(\mu W T_e) \tag{7}$$

where μ is the electron mobility. The various terms on the right hand side of Eq. (6) are explained as follows. Remembering that the electric field is $\mathbf{E} = -\nabla\psi$, the first term is $qn\mu\mathbf{E}$ and represents the drift of the charged electrons in this field. The second term represents the diffusion of the particles, irrespective of their charge. The third term is the contribution from the diffusion of the energy, and the fourth term should really be included as part of the term involving ∇n. The expression for $\mathbf{s}$ is similarly interpreted; the first term is the energy drift and the second is the energy diffusion. The values of the constants a and b are taken differently by several authors. Tang [25] takes $a = 1$ and $b = 1$, McAndrew et al. [26] and Selberherr [27] take $a = \frac{1}{2}$ and $b = 0$, and Snowden and Loret [28] and Feng and Hintz [29] take $a = 1$ and $b = 0$. The position-dependent average electron energy ξ is normally given by

$$\xi = \frac{1}{2}m^* v^2 + \frac{3}{2}k_B T_e$$

and it is usual to omit the kinetic energy term $\frac{1}{2}m^* v^2$ which is typically an order of magnitude lower than the thermal energy. Since ξ is the average electron energy, we further have $W = n\xi$ for the total electron energy.

2.3. Physical Data

The above expressions require that the electron mobility μ, effective mass m^*, and lifetime τ must be specified in terms of ξ. These specifications are obtained using Monte Carlo simulations and experimental data on the steady state transport charateristics of the bulk material. This provides data for ξ, τ, m^*, and other quantities in terms of the static electric field E_{ss} which then acts as an intermediate variable. The electron mobility is given by

$$\mu = \frac{300\mu_0}{T_0}\left(\frac{1 + \frac{v_s E_{ss}^3}{\mu_0 E_0^4 (1 - 5.3 \times 10^{-4} T_0)}}{1 + (E_{ss}/E_0)^4}\right) \tag{8}$$

where the parameters take the values shown in Table 1 for several materials. For $Al_uGa_{1-u}As$, we take [30] $m^* = (0.067 + 0.083u)m_e$ where $m_e = 9.11 \times 10^{-31}$ kg is the electron rest mass, and $\epsilon_r = 13.18 - 3.12u$. Similar expressions apply for InGaAs.

In the case of the HEMT, we have quantum wells formed at the interfaces of the different material layers, and so the Schrödinger equation must be solved for the discrete eigenstates which result from these wells. We may explain the physical nature of these wells by studying the nature of the energy levels allowed to electrons in a semiconductor. When the Schrödinger equation is solved for a potential caused by a periodic crystal lattice, the energies allowed to the electrons fall into bands, separated by forbidden bands. Electrons which are free to move through the crystal have energies in the *conduction band*. These electrons can lose energy, for example through emitting photons or by colliding with the crystal lattice, and fall into the next lowest band—the *valence band*—where they are tied to the lattice sites. They may also be knocked out of these sites to become conduction electrons again. If E_c is the lowest allowed energy in the conduction band, and E_v is the highest in the valence band, the above generation and recombination processes will depend on the value $E_g = E_c - E_v$ of the energy gap between the two bands. When two different materials with different energy gaps are brought together there will be a mismatch in their values of E_c. The discontinuity step E_h in these values gives rise to the quantum wells, and its value again depends on the mole fraction u of Al or In in the $Al_uGa_{1-u}As$ or $In_uGa_{1-u}As$. We take [30] $E_h = 0.65(1.155u - 0.37u^2)$ for an $Al_uGa_{1-u}As$–GaAs interface.

2.4. Schrödinger Equation for the HEMT

The modeling and numerical simulation of the HEMT involve an extra degree of difficulty, because quantum wells are formed at the interfaces of the different materials,

Table 1. Values of the parameters used in the expression for the electron mobility μ for several materials.

Material	E_0 (V m^{-1})	v_s (m s^{-1})	μ_0 (m^2 V^{-1} s^{-1})
GaAs	4.0×10^5	8.5×10^4	0.8
AlGaAs	7.0×10^5	5.0×10^4	0.2
InGaAs	3.0×10^5	1.0×10^5	1.0

and so the energies allowed to the electrons are partially quantized there. The quantized energy levels $\lambda_{(\nu)}$ with corresponding eigenfunctions $\xi_{(\nu)}$ satisfy the Schrödinger equation

$$-\frac{\hbar^2}{2}\nabla\cdot\left(\frac{1}{m^*}\nabla\xi_{(\nu)}\right)+q(V_{xc}+E_c)\xi_{(\nu)} = q\lambda_{(\nu)}\xi_{(\nu)} \qquad (\nu=0,1,2,\dots) \tag{9}$$

where $E_c = E_h - \psi$ is the conduction band minimum and V_{xc} is the exchange correlation energy. This last term arises purely as a quantum effect and comes when we change from a single-particle description to a many-particle description. Its form may be approximated by [31]

$$V_{xc} = -\left(1+0.03683 r_s \ln\left(1+\frac{21}{r_s}\right)\right)\left(\frac{2}{\pi\alpha r_s}\right)R_y^* \tag{10}$$

where

$$\alpha=\left(\frac{4}{9\pi}\right)^{1/3} \qquad a^*=\frac{4\pi\epsilon_0\epsilon_r h^2}{q^2 m^*} \qquad r_s=\left(\frac{4}{3}\pi a^{*3}n\right)^{-1/3}$$

and $R_y^* = q^2/(8\pi\epsilon_0\epsilon_r a^*)$ is the effective Rydberg constant. Note the careful positioning of the quantity m^* in Eq. (9). This positioning is needed to ensure that the kinetic energy operator is Hermitian (Hermitian operators are necessary because they possess real eigenvalues).

When obtaining a numerical solution of the equations, the most time-consuming part is the solution of the two-dimensional Schrödinger equation. In order to speed up the process, it is convenient to solve the eigenvalue problem in one-dimensional slices perpendicular to the layer structure, that is, along Oy, since the potential varies much more slowly along Ox. Consequently we solve the one-dimensional equation

$$-\frac{\hbar^2}{2}\frac{d}{dy}\left(\frac{1}{m^*}\frac{d\xi_{(\nu)}}{dy}\right)+q(V_{xc}+E_c)\xi_{(\nu)} = q\lambda_{(\nu)}\xi_{(\nu)} \qquad (\nu=0,1,2,\dots) \tag{11}$$

The expressions for the total electron density n and energy density W are more complicated for the HEMT structure, since we must take the contributions from the quantized structure into account. In particular, the electron density n does not obey the nondegenerate expression of Eq. (5). We take the first L eigensolutions (a discussion of how this value is taken is given in the next section) ordered in the sense that $\lambda_{(0)} < \lambda_{(1)} < \cdots < \lambda_{(L-1)}$ and then take integrals involving the density of states. The total electron density is given by $n = n_2 + n_3$ where, outside the well defined by $\lambda_{(L-1)} < E_c$, we take

$$n_2 = 0 \qquad n_3 = N_{c3}F_{\frac{1}{2}}\left(\frac{1}{k_B T_e}(E_F - E_c)\right) \tag{12}$$

where the *Fermi integral* F is defined by

$$F_r(a) \equiv \frac{1}{\Gamma(r+1)}\int_0^\infty \frac{x^r}{1+e^{x-a}}\,dx \tag{13}$$

where $\Gamma(r+1) \equiv \int_0^\infty x^r e^{-x}\,dx$. This replaces the simple exponential form for the nondegenerate case given in Eq. (5). Inside the well we take

$$\begin{aligned} n_2 &= N_{c2}\sum_{\nu=0}^{L-1}|\xi_i(y)|^2 \ln\left(1+e^{\frac{1}{k_BT_e}(E_F-\lambda_{(\nu)})}\right) \\ n_3 &= \frac{1}{2}\pi\left(\frac{8m^*}{h^2}\right)^{\frac{3}{2}}\int_{\lambda_{(L-1)}}^\infty \frac{(E-E_c)^{\frac{1}{2}}}{1+\exp(\frac{1}{k_BT_e}(E-E_F))}\,dE \end{aligned} \tag{14}$$

where the coefficients are defined by $N_{c2} \equiv 4\pi m^* k_B T_e/h^2$ and $N_{c3} \equiv 2(2\pi m^* k_B T_e/h^2)^{1.5}$. Similar expressions hold for the total energy density $W = n\xi = W_2 + W_3$; outside the well we take

$$W_2 = 0 \qquad W_3 = W_{c3}F_{\frac{3}{2}}\left(\frac{1}{k_BT_e}(E_F-E_c)\right) \tag{15}$$

while inside the wells,

$$\begin{aligned} W_2 &= W_{c2}\sum_{\nu=0}^{L-1}|\xi_i(y)|^2\left(F_1\left(\frac{1}{k_BT_e}(E_F-\lambda_{(\nu)})\right)-\frac{1}{k_BT_e}\right. \\ &\qquad \left.\times(E_c-\lambda_{(\nu)})\ln\left(1+e^{\frac{1}{k_BT_e}(E_F-\lambda_{(\nu)})}\right)\right) \end{aligned} \tag{16}$$

$$W_3 = \frac{1}{2}\pi\left(\frac{8m^*}{h^2}\right)^{\frac{3}{2}}\int_{\lambda_{(L-1)}}^\infty \frac{(E-E_c)^{\frac{3}{2}}}{1+\exp(\frac{1}{k_BT_e}(E-E_F))}\,dE$$

where

$$W_{c2} \equiv \frac{4\pi m^* k_B^2 {T_e}^2}{h^2} \qquad \text{and} \qquad W_{c3} \equiv 3\left(\frac{2\pi m^* k_B T_e}{h^2}\right)^{1.5} k_B T_e$$

The complete solution of the equations requires that the boundary conditions be specified. On all of the free surfaces we require that the normal derivatives of ψ, ϕ, and T_e are zero, so that no current or energy flows through these surfaces. On the ohmic source and drain we set ψ equal to the applied voltages V_s and V_d, respectively, while n is set to the doping density. On the Schottky gate we set $\psi = V_g + \psi_b$ where ψ_b is the built-in potential described in Section 1 whose value is taken as −0.8 V, while n is taken as a very small nominal value to account for the depletion region around the gate. The electron temperature T_e is set to the constant lattice temperature T_0 on all three contacts. The eigenfunctions $\xi_{(\nu)}$ are taken to vanish at the extremities of y. If a field plate is incorporated into the structure then we may treat it, in a crude approximation, as a second Schottky gate but with a different value of ψ_b.

The extreme nonlinearity of the problem is now apparent. A study of the close relation between the Poisson equation (1) and the Schrödinger equation (11) illustrates this point very clearly. To solve the Poisson equation for the electrostatic potential ψ we need to know the electron density n on the right hand side of the equation. We calculate n from the solution of the Schrödinger equation using Eqs. (12)–(14), but to solve the Schrödinger equation we need to know ψ because it appears in the potential of that equation (remember that $E_c = E_h - \psi$). Add in the fact that that the equations of current continuity and energy transport also contain these variables, both implicitly and explicitly, and we realize that the only way of solving the equations simultaneously is by numerical means.

3. NUMERICAL METHODS OF SOLUTION

3.1. Overview

The equations described in Section 2 are highly nonlinear: for example, the lifetime τ_e appearing in Eq. (4) is itself a function of the solution, and numerical values of this function must be fed in from experimental data. For any realistic device, therefore, no analytic solutions are possible, and numerical methods must be used. In this section we will outline a number of main numerical methods which have often been used in simulations. One of these—the finite difference method—will be picked out as being the most convenient method to use for many devices, and we will give details of the main techniques for implementing this method in Section 4.

The main solution methods will be illustrated for a situation in which a two-dimensional cross section is appropriate. This situation will apply when, for example, one length (taken as the length in the z direction) is very much larger than the other two—this case will certainly apply, for example, in HEMT or MESFET simulations. This condition may not apply in some situations, and the full three dimensional simulation is appropriate there. On the other hand, some simulations of the *p–n* junction use only a one-dimensional model. In all cases, the methods described here for the two-dimensional situation can be extended for a three-dimensional simulation or restricted for a one-dimensional simulation.

3.2. Finite Difference Method

In this method, the space of the device is overlaid with a rectangular mesh whose lines are parallel to the axes Ox and Oy. Meshpoints $x_0, x_1, x_2, \ldots, x_{i-1}, x_i, x_{i+1}, \ldots, x_{NI}$ are taken along the x axis and meshpoints $y_0, y_1, \ldots, y_{NJ}$ are taken along the y axis [32, 33]. Along Ox therefore, there are a total of $(NI+1)$ meshpoints, with $(NI-1)$ being internal, and there are NI intervals. Any function $f(x, y)$ which appears in the defining equations is then evaluated at any of the $(NI+1) \times (NJ+1)$ meshpoints, with the notation that $f_{i,j} \equiv f(x_i, y_j)$. In this way, the governing equations are written down at each meshpoint (i, j), and a set of simultaneous equations is obtained for the values of the various physical quantities at each meshpoint: for example, the total electron density n will take the $(NI+1) \times (NJ+1)$ values $n_{i,j}$. The exact ways in which the partial differential equations are written in terms of the discretized values, and the ways in which the resulting nonlinear finite difference equations are solved, are the subjects of a vast body of ongoing research.

The mesh need not be uniform; that is, the mesh spacings need not be all of the same width. We will use the notation that the mesh spacings along Ox and Oy are $h_i \equiv x_{i+1} - x_i$ and $k_j \equiv y_{j+1} - y_j$, respectively, so that, for example, h_i and h_{i-1} are not necessarily equal. It is convenient to use such a nonuniform mesh in devices in which a variable is rapidly changing in some regions and is slowly changing in others. The competing needs for numerical accuracy and speed of solution require that as many meshpoints as possible are used in these regions of rapid change while relatively few are used in the other regions. As the numerical solution progresses, certain mechanisms are employed to check whether or not extra meshpoints should be inserted at various positions. Since the overall size $(NI+1) \times (NJ+1)$ of the mesh determines the speed of solution of the equations, extra meshpoints should not be inserted in regions where they are not needed.

It is often convenient to specify the value of a physical quantity, not at the meshpoint itself, but at the halfpoint which lies equidistant between two meshpoints (we will see this in the specification of the current density **J** later). In this case, the obvious notation to use is $f_{i+(1/2),j} \equiv f(x_i + \frac{1}{2}h_i, y_j)$ and $f_{i,j+(1/2)} \equiv f(x_i, y_j + \frac{1}{2}k_j)$. This notation allows various derivatives to be discretized in a simple manner (for simplicity we will temporarily use one-dimensional notation to describe this process). To obtain the first derivative of the function f at meshpoint i we expand both $f(x_{i+(1/2)})$ and $f(x_{i-(1/2)})$ about $x = x_i$. On subtracting the resulting equations and neglecting the term $-(h_i - h_{i-1})f_i''/4$ and terms involving higher orders of h_i and h_{i-1}, we obtain

$$f_i' = \frac{f_{i+\frac{1}{2}} - f_{i-\frac{1}{2}}}{\frac{1}{2}(h_i + h_{i-1})} \tag{17}$$

A similar expression for the second derivative of f at x_i may be derived in the form

$$f_i'' = \frac{\frac{1}{h_i}f_{i+1} - (\frac{1}{h_i} + \frac{1}{h_{i-1}})f_i + \frac{1}{h_{i-1}}f_{i-1}}{\frac{1}{2}(h_i + h_{i-1})} \tag{18}$$

These two expressions are greatly simplified if a uniform mesh is used: with $h_i = h_{i-1} \equiv h$, we have

$$f_i' = \frac{f_{i+\frac{1}{2}} - f_{i-\frac{1}{2}}}{h} \qquad f_i'' = \frac{f_{i+1} - 2f_i + f_{i-1}}{h^2}$$

However, if a uniform mesh is used with a sufficient number of meshpoints in regions of rapidly changing variables, then an unnecessarily large number will be inserted in regions where they are not needed. The modeler must decide whether to use too many meshpoints using the simplification of code involving a uniform mesh, or a smaller number of meshpoints using a nonuniform mesh with a resulting complication of the numerical code.

Discretization of the boundary conditions is necessary, and the exact way in which this is done can have an important bearing on the accuracy of the solution. The simplest boundary condition occurs when the value of a quantity is given at a boundary point; for example, the value of the electron temperature T_e may be specified at the contacts. In other cases, the value of the *outward* derivative of the quantity may be specified. The simplest and least accurate method is to use at the end $x = x_0$, for example, the two-point expression $f_0' = (f_0 - f_1)/h_0$. A more accurate expression is the Newton formula

$$f_0' = -\frac{h_1(h_1 + 2h_0)f_0 - (h_0 + h_1)^2 f_1 + {h_0}^2 f_2}{h_0 h_1 (h_0 + h_1)}$$

which involves the value of the function at three points.

The finite difference method can be applied most usefully in situations where the boundaries of various regions

of the device are all parallel to the rectangular axes Ox and Oy, and this is particularly true in the case of MESFET and HEMT modeling. In this situation the boundary conditions are relatively simple to implement. In the case of the HEMT, the interfaces between the various layers of different material are all parallel to one axis (the x-axis Ox). This greatly simplifies the solution of the Schrödinger eigenvalue equation because although a full two-dimensional solution may be obtained, considerable saving may be made in the simulation time if the equation is solved in one-dimensional slices perpendicular to the layer structure. The use of the finite difference approach is very well suited to this construction. This is the most widely used method, and we will describe methods of implementing this method more fully in Section 4.

However, when the device under consideration is not regularly shaped, implementation of boundary conditions along irregularly shaped boundaries becomes difficult when we try to impose a rigid rectangular mesh which is parallel to only two fixed directions. Other methods are then needed, and we will briefly describe two of them—the finite element method and the boundary element method.

3.3. Finite Element Method

This method is particularly suited in application to devices which have irregular geometries, that is, those in which boundaries and interfaces are not parallel to an obvious set of fixed rectangular axes [27, 34–39]. The region of the device is partioned into a finite set of nonoverlapping subregions, or *elements*. In order to apply this method to finding the solution $f(x, y)$ of a certain differential equation it is necessary to approximate f by a simple function defined in each element. Suppose that we are using triangular elements, and a typical triangular element (e) has vertices A, B, and C. The simplest such approximate function defined on triangle ABC is a linear function

$$f_{(e)} = a_0 + a_1 x + a_2 y \tag{19}$$

where a_0, a_1, and a_2 are constants. Such a function is defined on each element (e). Another way of writing this expression is in the form

$$f_{(e)} = N_A(x, y) f_A + N_B(x, y) f_B + N_C(x, y) f_C \tag{20}$$

where f_A, f_B, and f_C are the values of f at A, B, and C respectively, and the functions $N_A(x, y)$, etc. are called the *shape functions*. These shape functions are chosen in such a way that $N_A(x, y) = 1$ when the values of x and y are the coordinates of the vertex A, and $N_A(x, y) = 0$ at all the other vertices of the element. The chosen shape functions must be linear if the expressions in Eqs. (19) and (20) are to be consistent. The next step is to substitute the expression for $f_{(e)}$ into the differential equation satisfied by the function f. An appropriate use of the divergence theorem then produces three simultaneous equations containing f_A, f_B, and f_C on the element (e). This process is done on each element, and the resulting sets of equations are then *assembled* to produce a set of M simultaneous equations for the values of f at each of the total of M vertices. This assembly process is really a matter of bookkeeping, since a vertex will be a member of several elements, and a record has to be kept of all the elements which contain a given vertex.

Standard procedures are then used to solve the set of simultaneous equations for the values of f at each vertex. Clearly, it is advantageous to keep the value M as small as possible, consistent with accuracy, and an important part of the finite element method lies in choosing the initial triangulation [34]. A further important aspect of this method is that the mesh must be refined in certain regions where, for example, the electric field is high. This refinement leads to the insertion of extra vertices resulting in a greater number of triangular elements. Triangular elements are the simplest shapes, and it is possible to extend this triangulation method by inserting extra vertices at the midpoints of the edges. However, triangular elements are not the only ones which may be used. For example, in the case of the MESFET or HEMT in which all boundaries are parallel to either Ox or Oy, rectangular elements may be used. If a typical rectangular element (e) has vertices A, B, C, and D at its corners, then a bilinear function

$$f_{(e)} = a_0 + a_1 x + a_2 y + a_3 xy$$

can be used. The use of rectangular elements rather than triangular elements in appropriate circumstances will reduce the number of vertices needed and hence reduce the computational cost of the simulation.

The finite difference method is easier to code than the finite element method. However, once coded, the finite element method is very adaptable in that it is easy to incorporate changes in geometry and the shape functions. Finite difference methods require much less storage space for bookkeeping arrays, but in these days of inexpensive computer memory the storage requirement of the finite element method presents no problem.

3.4. Boundary Element Method

The basic idea behind this method is that we obtain a set of equations for the discretized variables only at points around the boundary of the device. Clearly, this reduces the number of discretized equations which must be solved. Once the values on the boundary have been determined, it is then possible to determine the values on the internal meshpoints by performing integrals. We will outline this method in the case of obtaining a numerical solution of the Poisson equation

$$\nabla \cdot (\epsilon \nabla \psi) = 0 \tag{21}$$

in which the permittivity ϵ may be a given function of ψ: $\epsilon \equiv \epsilon(\psi)$.

First consider the solution of the Laplace equation

$$\nabla^2 u = 0 \tag{22}$$

for the function u in some internal two-dimensional region Ω. The value of the function is given on some parts of the boundary $\partial\Omega$ and its derivative is given on other parts of $\partial\Omega$. We start with Green's theorem in the form

$$\int_{\partial\Omega} \left(u \frac{\partial v}{\partial n} - v \frac{\partial u}{\partial n} \right) dl = \iint_{\Omega} (u \nabla^2 v - v \nabla^2 u)\, ds \tag{23}$$

where we choose the second function v to be such that $\nabla^2 v = \delta(\mathbf{r}_0 - \mathbf{r})$. Here, dl is the infinitesimal increment of length along the boundary, ds is the infinitesimal element of surface area, δ is the Dirac delta function, and $\mathbf{n}$ is the outward normal to $\partial\Omega$. Then Eq. (23) becomes

$$\int_{\partial\Omega}\left(u\frac{\partial v}{\partial n}(\mathbf{r}_0,\mathbf{r}) - v(\mathbf{r}_0,\mathbf{r})\frac{\partial u}{\partial n}\right) dl = \psi(\mathbf{r}_0)\iint_{\Omega}\delta(\mathbf{r}_0,\mathbf{r})\, ds = \eta(\mathbf{r}_0)\psi(\mathbf{r}_0) \qquad (24)$$

where $\mathbf{r}_0$ is any point inside or on the boundary of the region. If we choose v such that $v(\mathbf{r}_0,\mathbf{r}) \equiv v(|\mathbf{r}-\mathbf{r}_0|)$, then it may be shown that the function η is given by

$$\eta(\mathbf{r}_0) = \begin{cases} 2\pi & \text{for } \mathbf{r}_0 \epsilon \Omega \\ \theta & \text{for } \mathbf{r}_0 \epsilon\, \partial\Omega \\ 0 & \text{otherwise} \end{cases}$$

In this expression for η, θ is the angle between the tangents to the boundary curves on opposite sides of $\mathbf{r}_0$ on the boundary, so that boundaries with corners of any angle may be considered. In particular, if the boundary is smooth at $\mathbf{r}_0$ then $\theta = 2\pi$. It further follows from the defining conditions on v that $v(\mathbf{r}_0,\mathbf{r}) = \ln|\mathbf{r}-\mathbf{r}_0|$. We may now apply this to the solution of the Poisson equation (21). If we take $u \equiv \int^{\psi}\epsilon(\phi)\, d\phi$ and define the function h by $h(\psi) \equiv u/\psi$, then Eq. (21) implies Eq. (22), and Eq. (24) may be written

$$\int_{\partial\Omega}[\psi(\mathbf{r})h(\psi(\mathbf{r}))\ln'|\mathbf{r}_0-\mathbf{r}| - \psi'(\mathbf{r})\epsilon(\psi(\mathbf{r}))\ln|\mathbf{r}-\mathbf{r_0}|]\,dl = \eta(\mathbf{r}_0)\psi(\mathbf{r}_0)h(\psi(\mathbf{r}_0)) \qquad (25)$$

The boundary is now discretized into N elements, and Eq. (25) is then written down at the midpoint of each element. This provides N simultaneous nonlinear equations for the $2N$ values of ψ and ψ' at these boundary nodes. However, the number of unknowns is actually N because either ψ or ψ' is given at each node. Once the values on the boundary have been found, the value at any interior point $\mathbf{r}_0$ may be found using Eq. (25) with $\eta(\mathbf{r}_0) = 2\pi$. Further details on the boundary element method may be found in the works of Ingham [40] and Kelmanson [41].

3.5. Time Discretization

When modelers turn their attention to a particular device, they are interested in obtaining numerical solutions for two main modes of operation. The first mode is the *steady state* mode in which, after a certain time has elapsed since switching on the device, it has reached a steady state in which none of the internal variables change with time (this obviously does not apply to devices which operate in oscillator mode). The second mode is the *transient* mode in which numerical results are obtained for the period prior to the steady state mode. This clearly introduces an extra degree of complexity into the simulation, since the number of variables which describe the internal state of the device must be supplemented by the time variable t.

An appropriate time discretization of the equations must be made when we are looking for the transient solution. Take a time step Δt. Then we will use the notation that a function f evaluated at the pth time point given by $t = p\Delta t$ will be denoted by f^p. Suppose, for the sake of illustration, that the current density $\mathbf{J}$ is a function of the electrostatic potential ψ, quasi Fermi level E_F, electron temperature T_e, and electron density n: $\mathbf{J} \equiv \mathbf{J}(n, \psi, E_F, T_e)$. Its value at meshpoint (i, j) at this time is $\mathbf{J}^p_{i,j} \equiv \mathbf{J}(n^p_{i,j}, \psi^p_{i,j}, E^p_{Fi,j}, T^p_{ei,j})$. Then if we discretize the current continuity equation (3) in the form

$$\frac{n^{p+1}_{i,j} - n^p_{i,j}}{\Delta t} = \frac{1}{q}\nabla\cdot\mathbf{J}^p_{i,j}$$

we have an equation which is simple to solve for $n^{p+1}_{i,j}$ in terms of quantities evaluated at the earlier time point:

$$n^{p+1}_{i,j} = n^p_{i,j} + \frac{\Delta t}{q}\nabla\cdot\mathbf{J}^p_{i,j}$$

This explicit equation is trivial to iterate since the right hand side is a function of the variables which are calculated at the earlier time point. Unfortunately, the method will give a solution which diverges from the true solution unless the time step Δt is excessively small [42]. The fully implicit Crank–Nicholson scheme [32]

$$n^{p+1}_{i,j} = n^p_{i,j} + \frac{\Delta t}{2q}(\nabla\cdot\mathbf{J}^{p+1}_{i,j} + \nabla\cdot\mathbf{J}^p_{i,j})$$

will provide greater accuracy and better convergence, but it is difficult to implement since the right hand side now contains all of the variables for which we are solving at the new time point $(p+1)$. A scheme which is easier to implement is the *semi-implicit* scheme in which the only variable involving the new time point on the right hand side is n itself [29, 43]:

$$n^{p+1}_{i,j} = n^p_{i,j} + \frac{\Delta t}{2q}(\nabla\cdot\mathbf{J}(n^{p+1}_{i,j}, \psi^p_{i,j}, E^p_{Fi,j}, T^p_{ei,j}) + \nabla\cdot\mathbf{J}(n^p_{i,j}, \psi^p_{i,j}, E^p_{Fi,j}, T^p_{ei,j}))$$

This is an equation which is implicit in the variable n but explicit in all of the other variables. It does not have the full accuracy and convergence of the fully implicit scheme, but this limitation can be avoided when the space discretization of $\mathbf{J}$ involves a basic upwinding scheme using the Bernoulli function. This scheme will be detailed in Section 4.

4. FINITE DIFFERENCE METHODS

4.1. Overview

Because the geometries of many devices have a rectangular structure, the use of finite differences seems to be the most appropriate approach to use [44–48] and is certainly the most widely used. In this section we will describe some of the more important aspects of the finite difference approach in their applications to device modeling. The initial problem in implementing this approach is how to actually construct the initial mesh, and how it may subsequently be modified as the numerical solution progresses. However the mesh is constructed, the net result is that sets of nonlinear equations are formed which must be solved for the finite number of discretized variables. The main method used is the *Newton*

method, and this method will be outlined with particular reference to device simulation. We will not describe the details of the solution of the equations which result from the application of the Newton method, since details are described in many standard texts [49].

The regular nature of the device geometry also lends itself to the method of *multigrids*, in which an exact solution on a relatively coarse mesh is transferred onto successively finer meshes; this often produces a rapid and accurate solution to the numerical problem.

Any simulation involving the flow of some quantity, whether it be flow of fluid or flow of electrons, benefits from using a discretization involving the technique of *upwinding*. This produces more satisfactory convergence and accuracy properties and will be described in this section.

We discuss the discretization of the Schrödinger equation with particular reference to ensuring that its Hermitian properties are preserved. In all cases, our methods will be illustrated for cases in which two-dimensional approaches are appropriate. Straightforward extensions and restrictions will apply in three-dimensional or one-dimensional cases. Finally, we show how these techniques may be implemented by presenting simulation results for a typical HEMT structure.

4.2. Mesh Construction

We first describe the construction of the mesh used to overlay the device. We need a rectangular mesh which fits with the various physical edges, corners, and interfaces of the device, and one which is capable of being upgraded (downgraded) when it is found that more (fewer) meshpoints are needed in certain regions. Hence, a routine involving dynamic allocation of memory is needed, and the specification of a meshpoint must include links to neighboring meshpoints together with the values of the physical variables there. For example, using the C programming language, we may specify a meshpoint in a two-dimensional mesh as indicated in Table 2. Other quantities may be included in the definition; for example, the components E_x and E_y of the electric field, and the *status* of the meshpoint (interior, exterior, or edge) used in the bookkeeping of the mesh. If a three-dimensional mesh is needed, the typedef definitions will include extensions such as *struct something *up; struct something *down; double z;* etc. Meshpoints are initially assigned to the various corners of the device shown in Figure 1, to the edges of the contacts, and also to the intersections of the layer interfaces with the device edges. Meshpoints are created on opposite edges corresponding to each created meshpoint, and the connections are made. We must then decide on the maximum values of the intervals h and k of the initial mesh, and extra meshpoints are inserted into the basic mesh to ensure that the edge lengths of each new interval are below these maximum values. As the iterations proceed, checks may be made at intervals to determine whether new meshpoints need to be inserted; for example, if the difference in the value of ψ between consecutive meshpoints is greater than some predetermined value then an extra mespoint is inserted midway between the two, and a new line of meshpoints is then drawn through the inserted point. In the same way, unwanted meshpoints may be removed if they are not needed. In both cases, links must be re-established between new adjacent meshpoints.

Table 2. Specification of a meshpoint using the C programming language, indicating typical values defined at a point together with links to four neighboring meshpoints.

```
typedef struct something {
        double x, y;
        double h, k;
        struct something *north;
        struct something *south;
        struct something *east;
        struct something *west;
        double psi, EF, Te;
        etc....................
} meshpoint;
```

In this method, if a new meshpoint is needed, for example, near a gate edge, then a whole line of new meshpoints is inserted. This procedure will put extra meshpoints in regions where perhaps they are not needed, for example, near the far edges of the device. One way of eliminating this problem is to use the *method of boxes* [50] in which meshlines are terminated so that they do not continue into these regions; such a method eliminates unwanted meshpoints but requires extra bookkeeping resources. The method we have described in detail above lies midway in complexity between the method of boxes and that of using a fixed uniform rectangular mesh with no refinement.

4.3. Newton Method

However the mesh is constructed, the values of all the variables which describe the system are given at each meshpoint. Since the partial differential equations which describe the system are second order in the space derivatives and are written down at each internal meshpoint, the result is a set of equations at each point which includes contributions of quantities at the four nearest neighbors of the point. For example, by a simple extension of Eq. (18), a quantity $\nabla^2 f$ will be discretized at the internal meshpoint (i, j) by the five-point formula

$$\nabla^2 f_{i,j} = \frac{\frac{1}{h_i} f_{i+1,j} - (\frac{1}{h_i} + \frac{1}{h_{i-1}}) f_{i,j} + \frac{1}{h_{i-1}} f_{i-1,j}}{\frac{1}{2}(h_i + h_{i-1})} + \frac{\frac{1}{k_j} f_{i,j+1} - (\frac{1}{k_j} + \frac{1}{k_{j-1}}) f_{i,j} + \frac{1}{k_{j-1}} f_{i,j-1}}{\frac{1}{2}(k_j + k_{j-1})} \tag{26}$$

Hence the value of $\nabla^2 f_{i,j}$ involves the values of f evaluated at the five meshpoints (i, j), $(i-1, j)$, $(i+1, j)$, $(i, j-1)$, and $(i, j+1)$. In the approach we are discussing here, the governing equations at the internal points are the Poisson equation, the current continuity equation, and the energy transport equation described in Section 2. These will be supplemented by the equations for the boundary conditions on the edges. Hence there will be three equations written down at each meshpoint, and so there will be three dependent variables for which we must solve at each meshpoint. We will take these as the electrostatic potential ψ, quasi Fermi level

E_F, and the electron temperature T_e. It is true that quantities such as the total electron density n, electron energy density W, and many other quantities enter the calculation and need to be found. But all of these extra quantities are effectively intermediate variables in the calculation. Writing $N \equiv (NI+1)(NJ+1)$ for the total number of meshpoints in the mesh, which has $(NI+1)$ and $(NJ+1)$ points along Ox and Oy respectively, we must solve for a total of $3N$ quantities $\psi_{i,j}$, $E_{Fi,j}$, and $T_{ei,j}$, $(i=0,1,\ldots,NI; j=0,1,\ldots,NJ)$. These equations are highly nonlinear, and the method which is used most widely for solving them is the Newton method [49], or some variant of it. This method will be outlined now. Suppose we have $3N$ nonlinear equations for $3N$ unknowns x_i,

$$F_1(x_1,x_2,\ldots,x_{3N})=0 \quad F_2(x_1,x_2,\ldots,x_{3N})=0 \quad \cdots F_{3N}(x_1,x_2,\ldots,x_{3N})=0$$

which can be written more compactly in vector notation as

$$\mathbf{F}(\mathbf{x})=\mathbf{0} \tag{27}$$

where both $\mathbf{F}$ and $\mathbf{x}$ are $3N$-component vectors. These equations will be iterated to a solution. Let $\mathbf{x}^r$ be the solution vector obtained after r iterations, and let us look for a better solution $\mathbf{x}^{r+1}=\mathbf{x}^r+\delta\mathbf{x}^r$. Then expanding in a Taylor series up to the first order,

$$\mathbf{0}=\mathbf{F}(\mathbf{x}^r+\delta\mathbf{x}^r)\approx\mathbf{F}(\mathbf{x}^r)+\mathbf{J}^r\delta\mathbf{x}^r$$

where $\mathbf{J}^r$ is the $3N\times 3N$ Jacobian matrix whose elements are $(\mathbf{J})_{ij}\equiv\partial F_i/\partial x_j$ evaluated at the rth iteration. Hence the correction $\delta\mathbf{x}^r$ to the rth step satisfies the equation

$$\mathbf{J}^r\delta\mathbf{x}^r=-\mathbf{F}(\mathbf{x}^r) \tag{28}$$

so that a better estimate of the solution is

$$\mathbf{x}^{r+1}=\mathbf{x}^r-(\mathbf{J}^r)^{-1}\mathbf{F}(\mathbf{x}^r) \tag{29}$$

Hence starting with an initial guess $\mathbf{x}^1$, Eq. (29) is iterated until some suitable stopping criterion is met, for example, until all of the residuals $|F_i(\mathbf{x}^r)|$ become smaller than some prescribed values. At each iteration number r, we must solve the set of $3N$ linear equations (28) for the $3N$ values δx_1^r, $\delta x_2^r,\ldots,\delta x_{3N}^r$. On applying this process to our device problem, we see that this amounts to solving a set of $3(NI+1)\times(NJ+1)$ equations for the same number of unknowns. Even taking a rather coarse mesh with $NI=NJ=99$, for example, we see that this amounts to solving 30,000 equations for 30,000 unknowns, or equivalently inverting the $30{,}000\times 30{,}000$ matrix $\mathbf{J}^r$ at each iteration. However, we have seen that each equation written down at internal meshpoint (i,j) involves the values only at that point and its four nearest neighbors, so that most of the elements of $\mathbf{J}^r$ are zero. It is then appropriate and common to use *sparse matrix theory* [51] in the solutions of Eq. (28).

A simplification may be made in the case of our device modeling. We are solving for a set of three quantities ψ, E_F, and T_e at each meshpoint, and we may form a three-component vector $\mathbf{y}_{i,j}$ at each meshpoint: $\mathbf{y}_{i,j}=(\psi_{i,j},E_{Fi,j},T_{ei,j})$. We also have three equations $\mathbf{F}_{i,j}=(F_{1i,j},F_{2i,j},F_{3i,j})=\mathbf{0}$ at each meshpoint (i,j). We therefore have N vector equations, each with three components,

$$\mathbf{F}_{i,j}(\{\mathbf{y}_{r,s}: r=0,\ldots,NI;\quad s=0,\ldots,NJ\})=\mathbf{0}$$
$$(i=0,\ldots,NI;\quad j=0,\ldots,NJ).$$

Although this may appear to be merely a change of notation, this form of the problem does lead to a useful modification of the solution in that, in further neglecting the four contributions $\mathbf{y}_{i-1,j}$, $\mathbf{y}_{i+1,j}$, $\mathbf{y}_{i,j-1}$, and $\mathbf{y}_{i,j+1}$ to the resulting equations, we need only invert a 3×3 matrix at each meshpoint [52]. It can be shown that this procedure leads to the same solution, but at a slightly slower convergence rate.

Mention has been made of the initial guess $\mathbf{x}^1$, and the successful convergence of this method depends crucially on this initial guess [53]. Even for a "good" initial guess, the iteration process is fragile in the early stages, and all too often the process fails. To overcome this, the update process is replaced by

$$\mathbf{x}^{r+1}=\mathbf{x}^r+\alpha^r\delta\mathbf{x}^r$$

where $0\le\alpha^r\le1$. In the early stages of the iteration, the value of α^r is taken to be very small, typically 0.001. The value is allowed to increase as the iterations progress. Either this can be done manually or its value can be determined using the values of the residuals; if a residual suddenly increases then the value of α is reset to a smaller value. In any event, a value of typically 0.4 is usually the maximum sustainable value for α^r in order that the iterations continue without failing [54].

4.4. Multigrid Method

The multigrid method applied to device simulation can considerably speed the process of solving the resulting set of nonlinear simultaneous equations in the $3(NI+1)\times(NJ+1)$ variables $\psi_{i,j}$, $E_{Fi,j}$, and $T_{ei,j}$ $(i=0,\ldots,NI;\ j=0,\ldots,NJ)$. For simplicity of notation, we will describe the method applied to solving for a single function ψ on a one-dimensional grid; its extension to the problem of solving for more functions on two or three problems is straightforward.

Consider a progression of G meshes, or *grids*, $g=1,2,\ldots,G$. Grid (g) will have an even number N_g of intervals; that is, it will have (N_g+1) meshpoints. Grid $(g+1)$ is obtained from grid (g) by halving each interval of grid (g) so that grid $(g+1)$ will have $N_{g+1}=2N_g$ intervals. Thus if grid (1) has 25 intervals, grid (4) will have 200 intervals. Hence grid (1) is the coarsest grid, and we wish to eventually have a device solution on the finest grid (G).

In the *full approximation storage method* of Brandt [55], an exact solution is obtained on the coarsest grid (1): this should not prove too onerous if the value of N_1 is small enough. The solution is then imposed on grid (2) and a small number of iterations (perhaps 20) is performed on this grid. The new approximate solution is then imposed back onto grid (1) and an exact solution is refound. Haven't we found this already? No, because as we shall see, we will obtain the exact solution to a slightly different equation. The process is repeated up to grid (3) with a small number of iterations performed on each grid which is visited on the upward and downward paths. The process is repeated in stages until

the final fine grid (G) is reached. Thus for four grids, the sequence of visits will be $1 \to 2 \to 1 \to 2 \to 3 \to 2 \to 1 \to 2 \to 3 \to 4 \to 3 \to 2 \to 1 \to 2 \to 3 \to 4$ with exact solutions being found on grid (1) and a finite number of iterations performed on all the other grids.

A sequence of equations is iterated on each grid. Suppose that the equation we wish to solve is written formally as $L\psi = 0$ where L is the appropriate differential operator. For example, if we are solving the Laplace equation $\nabla^2\psi = 0$ then L is the Laplacian ∇^2. This equation is discretized on grid (g) as

$$L_{(g)}\psi_{(g)} = 0 \tag{30}$$

where $L_{(g)}$ is the discretization of L on that grid. For example, if L is the Laplacian, then $L_{(g)}$ will be the difference operator given in Eq. (18). Our goal will therefore be to solve Eq. (30) on the fine grid (G). We must first decide how to take our solutions between successive grids. The *restriction operator* R takes a value of ψ from a grid (g) to the next coarse one ($g - 1$). An example of such an operator is the *half-weighting* process

$$\begin{aligned}\psi_{(g-1)j} &= \frac{1}{2}\psi_{(g)2j} + \frac{1}{4}\psi_{(g)2j+1} + \frac{1}{4}\psi_{(g)2j-1} \qquad \text{internally}\\ &= \psi_{(g)2j} \qquad \text{on boundary}\end{aligned}$$

(remember, we are using a one-dimensional illustration in which j labels the meshpoint). The reverse *prolongation operator* P takes a solution from grid ($g - 1$) onto the next fine grid (g). *Half-weighting* prolongation takes the form

$$\begin{aligned}\psi_{(g)2j} &= \psi_{(g-1)j}\\ \psi_{(g)2j+1} &= \frac{1}{2}(\psi_{(g-1)j+1} + \psi_{(g-1)j})\end{aligned}$$

We iterate a succession of equations on each grid. The original equation (30) is generalized to

$$L_{(g)}\psi_{(g)} = f_{(g)} \qquad (g = 1, \ldots, G) \tag{31}$$

where the functions $f_{(g)}$ are calculated on the downward paths as

$$f_{(g-1)} = L_{(g-1)}(R\psi'_{(g)}) + R(f_{(g)} - L_{(g)}\psi'_{(g)})$$

where $\psi'_{(g)}$ is the *approximate* solution to Eq. (31) and R is the restriction operator. The functions $f_{(g)}$ are initialized to zero on the first upward path and are generated on the downward paths. An exact solution is found only on the coarsest grid, and a small number of iterations are performed on each visit to finer grids.

The effort in programming this method is rewarded by achieving fast solution times. It was found [56] that this method produced a solution with a speedup of 4.9 times on a corresponding simple nonmultigrid method. Care must be taken in choosing the coarsest grid when applying this method to device modeling. Clearly, this grid should be as coarse as possible in order that the task of finding an exact solution on this grid is not too onerous. However, the grid must be fine enough to take in all of the physical features of the device. For example, it would not be acceptable to take a grid so coarse that the boundaries between three consecutive layers fell into one mesh interval.

4.5. Upwinding and the Bernoulli Function

The use of the method of upwinding is very common in numerical simulations of fluid flows [57–60] and is applicable to the study of electron flow in semiconductor devices [61]. There is a very simple physical idea behind this technique. Suppose that a particular quantity V is to be evaluated at the midpoint of an interval, that is, halfway between two meshpoints x_i and x_{i+1}. A crude estimate will give equal relevant contributions from both meshpoints. However, if an electric field exists (as it always does in our devices), then the value of V at the midpoint will be influenced more strongly by conditions at one meshpoint than the other—in effect, this “influence” will be swept to the midpoint by the electric field. A simple calculation will illustrate this point. Consider a simplification of the expression in Eq. (6) for the current density, for a one-dimensional case in which T_e is constant:

$$J = -qn\mu\frac{d\psi}{dx} + k_B\mu T_e\frac{dn}{dx}$$

Assume that $E = -\frac{d\psi}{dx}$, and J and μ are constants in the interval. Then we have a simple linear first order differential equation

$$\frac{dn}{dx} + \left(\frac{qE}{k_BT_e}\right)n = \frac{J}{\mu k_BT_e}$$

which has the solution

$$n = Ae^{-\frac{qE}{k_BT_e}x} + \frac{J}{q\mu E} \qquad (E \neq 0) \tag{32}$$

where A is an arbitrary constant. If we write down this solution at both x_i and $x_{i+1} = x_i + h_i$, we can solve the resulting linear simultaneous equations for A and J. On substituting these values back into Eq. (32) and defining $P \equiv qEh_i/k_BT_e$, we finally have the result

$$\frac{n - n_i}{n_{i+1} - n_i} = \frac{1 - e^{-P\frac{(x-x_i)}{h_i}}}{1 - e^{-P}} \tag{33}$$

The quantity P is called the *Peclet number*, and it has the same sign as the electric field E. The interpretation of this result is as follows: if P is large and positive (that is, the electric field is large and in the positive Ox direction), then the exponential terms in Eq. (33) are very small, giving $n \simeq n_{i+1}$. Thus in this case the value of n at any point in the interval is more strongly influenced by its value at x_{i+1}. On the other hand, if the electric field is reversed so that P is large and negative, then $n \simeq n_i$, and the value of n at any point in the interval is more strongly influenced by its value at x_i. If the electric field is zero, then Eq. (33) gives the linear relation

$$n = n_i + \left(\frac{x - x_i}{h_i}\right)(n_{i+1} - n_i)$$

[we must let $P \to 0$ in Eq. (33) to obtain this result]. For x midway between x_i and x_{i+1}, this result for $E = 0$ gives $n = \frac{1}{2}(n_i + n_{i+1})$ as expected.

This is the basic idea behind the Scharfetter–Gummel approach [62], in which errors and instabilities can arise in iterative procedures unless an exponential variation is taken

between meshpoints. On making the same assumptions as above, namely, that $E = -\frac{d\psi}{dx}$ is a constant in the interval (x_i, x_{i+1}) (this is a weaker condition than assuming that ψ itself is a constant in the interval), we find that the current density along Ox at the half-point $(i+\frac{1}{2}, j)$ is

$$J_{xi+\frac{1}{2},j} = \frac{\mu_{i+\frac{1}{2},j} k_B T_e}{q h_i} \left(B(-P_{i+\frac{1}{2},j}) n_{i+1,j} - B(P_{i+\frac{1}{2},j}) n_{i,j} \right) \tag{34}$$

where

$$P_{i+\frac{1}{2},j} \equiv \frac{q}{k_B T_e} (\psi_{i,j} - \psi_{i+1,j})$$

and B is the *Bernoulli function* defined by

$$B(t) \equiv \frac{t}{e^t - 1} \tag{35}$$

Again, the sign of $P_{i+(1/2),j}$ is determined by the sign of $E_{xi+(1/2),j} = (1/h_i)(\psi_{i,j} - \psi_{i+1,j})$, and so result (34) may be interpreted in light of the brief description given above of the upwinding process. We may form similar expressions for $J_{xi-(1/2),j}$, $J_{yi,j+(1/2)}$, and $J_{yi,j-(1/2)}$. The expression for $\nabla \cdot \mathbf{J}$ in the current continuity equation (3) is then discretized using

$$\nabla \cdot \mathbf{J}_{i,j} = \frac{1}{h_i}(J_{xi+\frac{1}{2},j} - J_{xi-\frac{1}{2},j}) + \frac{1}{k_j}(J_{yi,j+\frac{1}{2}} - J_{yi,j-\frac{1}{2}})$$

The Bernoulli function has the properties that $B(t) > 0$, $B(0) = 1$, $B(y) \to 0$ as $t \to \infty$, and $B(t) \to -t$ as $t \to -\infty$. In any numerical implementation using the function $B(t)$, care must be taken to avoid overflows and underflows when evaluating the function. Selberherr [20] approximates this function by

$$B(t) = \begin{cases} -t & \text{for } t \le t_1 \\ \frac{t}{e^t - 1} & \text{for } t_1 < t \le t_2 \\ 1 - \frac{1}{2}t & \text{for } t_2 < t \le t_3 \\ \frac{te^{-t}}{1 - e^{-t}} & \text{for } t_3 < t \le t_4 \\ te^{-t} & \text{for } t_4 < t \le t_5 \\ 0 & \text{for } t_5 < t \end{cases}$$

where the values of $t_1, \ldots, t_5$ delimit certain regions of the t-axis. A clever aspect of this method is that $t_1, \ldots, t_5$ are determined by the particular machine on which the numerics are performed; for example, the value of t_1 may be found by asking the machine to solve the equation $-t = t/(e^t - 1)$ to its own accuracy. The author found the values $t_1 = -t_4 = -22.874$, $t_2 = -t_3 = -2.527 \times 10^{-3}$, and $t_5 = 89.416$ when implementing the routine on a PC.

The above discussion concerned the case in which the electron temperature T_e was constant. This situation does not apply in realistic devices, and so the result in Eq. (34) must be modified. In this more general case, influences will be propagated not only by the electric field but also by the temperature gradient. It can be shown [63] that the generalization is

$$\begin{aligned} J_{xi+\frac{1}{2},j} = {} & \frac{k_B}{h_i} \mu_{i+\frac{1}{2},j} \\ & \times \left[C_a\left(\frac{q}{k_B}(\psi_{i+1,j} - \psi_{i,j}), T_{ei+1,j}, T_{ei,j} \right) n_{i+1,j} \right. \\ & \left. - C_a\left(-\frac{q}{k_B}(\psi_{i+1,j} - \psi_{i,j}), T_{ei,j}, T_{ei+1,j} \right) n_{i,j} \right] \end{aligned} \tag{36}$$

where the function C is defined as

$$C_a(x, T_1, T_2) \equiv t(T_1, T_2) B\left(\frac{x - a(T_1 - T_2)}{t(T_1, T_2)} \right)$$

and the function t is defined as

$$t(T_1, T_2) \equiv \frac{T_2 - T_1}{\ln T_2 - \ln T_1} \qquad \text{for } T_1 \ne T_2$$

The quantity a is that which appears in the coefficient of ∇T_e in Eq. (6); the value of b in that equation has been taken as zero. It can be shown that the function $t(T_1, T_2)$ is actually a *mean value* of T_1 and T_2 which lies between their arithmetic and geometric means. Similar expressions can be written for $J_{xi-(1/2),j}$, $J_{yi,j+(1/2)}$, and $J_{yi,j-(1/2)}$ so that $\nabla \cdot \mathbf{J}$ may be evaluated. The result in Eq. (36) has been derived for the electrons in HEMTs and MESFETs. However, it is equally valid for electron and hole currents in bipolar devices when the appropriate electron and hole densities are used.

4.6. Solution of the Schrödinger Equation

The numerical solution of the Schrödinger equation presents one of the largest costs in computing time when performing the complete numerical simulation. Before each of the Newton iterations described previously, we must first solve the Schrödinger equation in order that its solutions may be used to update the values of $n_{i,j}$ and $W_{i,j}$ of the electron density and electron energy density at each meshpoint using Eqs. (12)–(16). Trellakis and Ravaioli [64] have developed a fast way of producing a three-dimensional spectral solution of the Schrödinger equation, and Grinstein et al. [65] have solved the equation using a multigrid method. Whatever method is used, the cost of the solution may be reduced by calculating as few eigensolutions as possible consistent with accuracy of solution [66].

The cost may also be reduced by solving the equation in one-dimensional slices perpendicular to the layer structure, and this is the method which will be described here. In this method it is assumed that changes in potential occur much more rapidly along Oy (across the layer structure) than along Ox where device lengths are much larger. We proceed by discretizing Eq. (11). The first term in the equation is the kinetic energy contribution, and it has been written in such a way as to preserve its Hermitian character since the effective mass m^* is a function of position (Hermitian operators are necessary because they possess real eigenvalues). Discretization of this operator must be done so that its

Hermitian character is preserved [67]. Halfway discretization gives

$$-\frac{\hbar^2}{2}\left(\frac{\left(\frac{1}{m^*}\frac{d\xi_{(\nu)}}{dy}\right)_{j+\frac{1}{2}} - \left(\frac{1}{m^*}\frac{d\xi_{(\nu)}}{dy}\right)_{j-\frac{1}{2}}}{\frac{1}{2}(k_j + k_{j-1})}\right)$$

and, on completing the process, Eq. (11) becomes

$$a_j\xi_{(\nu)j-1} + b_j\xi_{(\nu)j} + c_j\xi_{(\nu)j+1} = \lambda_{(\nu)}\xi_{(\nu)j} \tag{37}$$

where the coefficients a_i, b_i, and c_i are defined as

$$c_j \equiv -\frac{\hbar^2}{qk_j(k_j + k_{j-1})m^*_{j+\frac{1}{2}}}$$

$$a_j \equiv -\frac{\hbar^2}{qk_{j-1}(k_j + k_{j-1})m^*_{j-\frac{1}{2}}}$$

$$b_j \equiv -(a_j + c_j) + V_{xci,j} - E_{hi,j} - \psi_{i,j}$$

Equation (37) is a set of linear equations for the $\xi_{(\nu)j}$ and can be written in the matrix form $\mathbf{A}\xi_{(\nu)} = \lambda_{(\nu)}\xi_{(\nu)}$ where the matrix $\mathbf{A}$ is defined by

$$\mathbf{A} = \begin{pmatrix} b_1 & c_1 & 0 & 0 & 0 & \cdots & 0 \\ a_2 & b_2 & c_2 & 0 & 0 & \cdots & 0 \\ 0 & a_3 & b_3 & c_3 & 0 & \cdots & 0 \\ 0 & 0 & a_4 & \ddots & c_4 & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots & \vdots \\ 0 & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \end{pmatrix}$$

This matrix is tridiagonal, but it is only symmetric if the mesh is uniform. Its eigenvalues can be found using a QL algorithm with implicit shifts [49]. This algorithm exploits the fact that we can write A = QL where Q is an orthogonal matrix, and L is a left triangular matrix with zeros above the diagonal. If these eigenvalues are then put into ascending order, we only need to solve for the first L of the corresponding eigenfunctions for use in evaluating n and W. This is done by solving the equations using the Newton method with an initial guess [56]

$$\xi_{(\nu)j} = \sin\left(\frac{\nu\pi j}{NJ}\right) \qquad (\nu = 0, \ldots, L-1; \quad j = 0, \ldots, NJ)$$

4.7. Example Solution

We end by giving an illustration of the type of output we may expect from the numerical modeling of a typical HEMT structure; we present a solution for a simple five-layer HEMT with one recess and no field plate. The structure will consist of layers of—starting with the layer closest to the edge containing the contacts—GaAs, AlGaAs, InGaAs, AlGaAs, and GaAs. In each AlGaAs layer the mole fraction u is taken as 0.23, while the In mole fraction of the InGaAs is taken as 0.2. The overall length along the contact edge is 1400 nm, the overall thickness of the device is 250 nm, and the depth of the recess is 25 nm. Since the results presented here are for illustrative purposes only, we will not state the remaining physical data for the device. The results of any simulation will present the device modeler and designer with a vast amount of data to analyze, and one of the most useful ways of describing these data is by graphical plotting. Figure 2 illustrates just one set of data—that of the conduction band profile E_c throughout the device—when the source and gate voltages are set to 0.0 V and the drain voltage is set to 2.0 V. A total of 10 eigensolutions ($L = 9$) was used in this solution. This particular plot illustrates in a very clear way the quantum well structure of the device. Such plots of the quantity E_c and all of the other parameters of the system—for example, the electron density n and the electric field $\mathbf{E}$—must be carefully examined by the designer in order to achieve a full picture of the operation of the particular device being modeled.

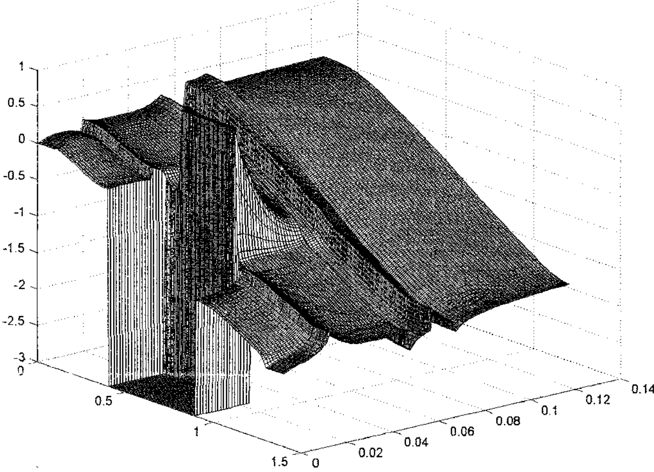

Figure 2. A plot of the conduction band profile E_c for a five-layer HEMT with one recess and no field plate. The horizontal axes are in units of micrometers, and the vertical axis is in units of eV. The plot along Oy has been truncated to 0.14 micrometers in order to show the quantum well structure more clearly.

GLOSSARY

Bandwidth The range of frequencies in a spectral line for which its Fourier transform has significant values.

Bipolar devices Devices in which both electron and hole transport are important.

Hermitian operator An operator A is hermitian if the inner product of any vector **v** with A**v** is real. Such an operator possesses real eigenvalues.

High electron mobility transistor (HEMT) This is a MESFET containing layers of material which give rise to quantum wells at their interfaces.

Metal semiconductor field effect transistor (MESFET) Uses a metal to form a Schottky gate.

Mobility The ratio of the average particle drift velocity to the applied electric field.

Nondegenerate approximation Applies when Fermi integrals can be approximated by exponential functions, mainly in cases where doping densities are not too high.

Schottky effect The lowering of the potential barrier when negative charges are brought near a metal interface and an electric field is applied.

Tunneling In quantum mechanics, the ability of an electron to cross a potential barrier which would be impenetrable using classical theory.

1. INTRODUCTION

With the development of human society, both the amount and the type of pollutants are increasing in the ground, air, and water systems. Pollutants usually are toxic organic chemicals emanating from various sources and include industrial products and by-products. Halogenated organic chemicals and commercial colorants are two main types of pollutants threatening the well-being of human society. However, hazardous organic molecules can be rendered nontoxic and broken down to carbon dioxide, water, or simple mineral acids, etc., by a degradation treatment [1]. Increased public concern for environmental cleanup has promoted the development of highly efficient photocatalysts that can participate in detoxification reactions. Environmental remediation by photocatalysts comes with several advantages: direct conversion of pollutants to nontoxic by-products without the necessity for any other associated disposal steps; use of oxygen as an oxidant and elimination of expensive oxidizing chemicals; the potential of using free and abundant solar energy; self-regeneration and recycling of the photocatalyst, etc. It is, therefore, no surprise that the research and development activities in this field have been very vigorous in recent years.

Semiconductor nanoparticles are successfully utilized in photocatalytic applications [2–10]. Colloidal semiconductors were first introduced in 1976 [11]. Since then, the promising application of nanoparticles in photocatalysis has achieved great attention and been extensively investigated. This is in addition to their application in photovoltaics and electronic devices, etc. The semiconductor catalysts form a heterogeneous photocatalysis system with pollutant molecules and exhibit a high degradation effectiveness. The selection of semiconductor nanoparticles for photocatalysis is based on several aspects that will be described later.

Semiconductors make generation and transfer of charge carriers possible with the assistance of extra energy. For photocatalysis, electrons and holes are crucial for reduction and oxidation reactions, respectively. Thus, the capability to supply charge carriers is a basic consideration when a catalyst is being selected. Electronically, the three common types of material are metal, insulator, and semiconductor. They are categorized by the electric conduction that is related to the electron energy. The conduction and valence bands are the two main energy bands. The lowest point of the conduction band and the highest point of the valence band are the conduction band edge and the valence band edge, respectively. The separation between the conduction band edge and valence band edge is called the band gap or energy gap, within which no electronic state exists. For metals, the electronic states form a continuum, and no energy gap exists between the two band edges. The electrons in a partly filled conduction band and holes in a valence band contribute to the electric current because they have sufficient mobility. Metals are a good conductor because their conduction bands are partly filled with electrons. It is extremely hard to form mobile electrons and holes in insulators because either their conduction band is empty, with a band gap too large to excite electrons, or both conduction and valence

bands are fully occupied by electrons with no electronic state left in the conduction band. Although semiconductors also have empty conduction bands at absolute zero, the magnitude of the band gap is smaller than that of insulators, so electrons can be excited into the empty conduction band, leaving holes in the valence band for electronic balance if extra energy equal to or greater than its band-gap energy is provided. Therefore, semiconductors can provide both electrons and holes. Furthermore, semiconductors with band gaps large enough for the redox potential of the $H_2O/^{\bullet}OH$ couple (~ -2.8 eV) to lie within them can be viable for photocatalysis processes [12] because, in such cases, excited electrons and holes can be transferred to the pollutant to participate in the reduction and oxidation reactions, respectively, that occur on the catalyst surface. A detailed mechanism of photocatalysis is discussed in Section 3.

Particles with sizes less than several tens of nanometers (1 nm $= 10^{-9}$ m) are known as nanoparticles. They are in powder form or are nanocrystalline thin films on certain supports. Nanoparticles are distinguished from bulk by their high surface-to-volume ratio of nanoparticles that causes the structural and electronic changes that, in turn, induce other properties to become different from those of the bulk. Unique photophysical, photochemical, photoelectronic, and photocatalytic properties can occur in semiconductor nanoparticle systems [8, 13–17]. The differences can be found at both equilibrium and nonequilibrium states, including thermodynamics and kinetics [18, 19]. They critically depend on particle size, shape, and surface characteristics. Lower melting temperatures [20], altered phase transformation behaviors [19, 21], and nonlinear optical phenomena [22, 23] have been observed in nanoparticles. More pertinent to our discussion, with the decrease of particle size, an extremely high surface area-to-volume ratio is obtained, leading to an increase in surface-specific active sites for chemical reactions and photon absorption to enhance the reaction and absorption efficiency. The enhanced surface area also increases surface states, which changes the activity of electrons and holes and affects the chemical reaction dynamics. For instance, the constant of the charge carrier transfer rate is relatively higher in nanoparticles than in bulk. When particle size decreases below the Bohr radius of the first excitation state, the quantum size effect could occur because of the confinement of charge carriers [12, 24, 25]. Such particles are also referred to as quantized or Q-particles. The quantum size effect splits both conduction and valence bands into discrete electronic states [26], and the size dependence of optical and electronic properties becomes much more pronounced. For instance, size quantization can increase the band gap of photocatalysts to enhance the redox potential of conduction band electrons and valence band holes [27]. Finally, nanoparticles can lead to the possibility of indirect electron transitions at the boundary of the crystals and realize the essential enhancement of light absorption. More details on the significance of nanoparticles are presented in Section 4.2.

In this review we will cover the most frequently used nanoparticles. They include oxides (TiO_2, ZnO, Fe_2O_3, WO_3, SnO_2, Ag_2O, V_2O_5, $SrTiO_3$), sulfides (ZnS, CdS, MoS_2, Cu_xS, Ag_2S, PbS), selenides (CdSe, PbSe, HgSe), iodides (AgI), and modified systems such as coupled semiconductor systems (CdS/TiO_2, $CdSe/TiO_2$, SnO_2/TiO_2, ZnO/TiO_2, ZnO/CdS), etc. Among them, TiO_2 nanoparticles and modified TiO_2 nanoparticles are presented in much more detail because they are the most extensively studied and most efficient photocatalysts [28–30]. Other semiconductor nanoparticles generally have less photocatalytic activity than TiO_2, and some have problems associated with stability, reactivity, etc. [10]. Fe_2O_3 easily undergoes photocathodic corrosion [12], and its active form α-Fe_2O_3 also has high selectivity for the reactant [31]. ZnO is not stable in water, and $Zn(OH)_2$ can be formed on its surface, which is detrimental to its photoreactivity [30]. CdS, PbS, and CdSe are not only toxic but also unstable and undergo photoanodic corrosion in aqueous media [32].

TiO_2 is an important semiconductor oxide photocatalyst because of its chemical stability, nontoxicity, low cost, and high catalytic performance. TiO_2 occurs in three main crystal structures at normal pressure: anatase, rutile, and brookite. Although commercial standard Degussa P25 is composed of 80% anatase and 20% rutile, anatase is believed to have the highest photoreactivity [16, 33–35]. Anatase belongs to the $I4_1/amd$ space group and has a tetragonal structure. Figure 1 [36, 37] is a schematic of the anatase structure, and it gives the calculation for the a and c values. Ti is in an octahedron of two apical and four equatorial oxygen atoms. The neighboring octahedra share adjacent edges. TiO_2 became the focus of attention in 1972 with the discovery of photoelectrochemical splitting of water by TiO_2 [38]. Early studies were mainly related to photovoltaics for energy conversion [39, 40]. It has only been in the past decade that a large number of research papers on TiO_2 photocatalysis have been published. This activity has continued, and various scientists are engaged in research to improve the photocatalytic performance of TiO_2.

2. SYNTHESIS OF SEMICONDUCTOR NANOPARTICLES

2.1. Requirements

The earliest synthesis of nanoparticles can be tracked back to the formation of relatively monodispersed colloids of gold nanoparticles reported by Faraday in the nineteenth century. With the appearance of new semiconductor photocatalysts and miniaturization of electronic devices, smaller nanoparticles are preferred. More interestingly, the methods that can produce very fine particles (1–25 nm) are intensively pursued because of the unique properties of these nanoparticles. Currently, a variety of synthesis methods are being used for the preparation of semiconductor nanoparticles. They include both the chemical methods and the physical approaches. Ideally, the methods employed for synthesis are expected to form nanoparticles with monodispersion or narrow size distribution and to easily modify particle properties, such as size, surface, doping, etc., during the synthesis. Not only are these requirements useful for the

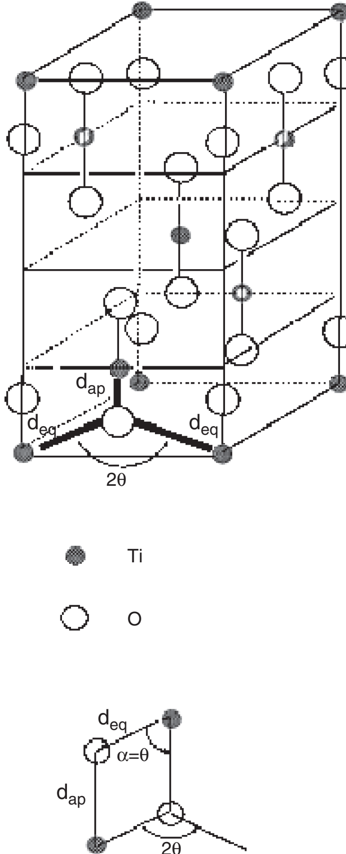

Figure 1. TiO_2 anatase structure. The lattice constants *a* and *c* are expressed as $a = 2d_{eq} \sin\theta$ and $c = 4(d_{ap} + d_{eq} \cos\theta)$, respectively, where d_{eq} and d_{ap} are equatorial and apical Ti-O bond lengths, respectively. d_{eq} is 1.934 Å and d_{ap} is 1.980 Å for anatase [37]. θ is the O-Ti-O angle, which is formed by one apical and one equatorial Ti-O bond. improvement of semiconductor photocatalysis; they are also needed in the fabrication of semiconductor devices. However, most of the methods can only produce nanoparticles with near monodispersion or relatively narrow size distribution due to the fluctuations in growth conditions such as gas flow, growth temperature, or dispersion of precursors. Therefore, a well-controlled synthesis process is still a challenge.

2.2. Chemical Methods

These methods utilize chemical precursors and chemical reactions to produce nanoparticles. They include various modifications of chemical vapor deposition [41–46], sol–gel [47–52], chemical impregnation [53], coprecipitation [54, 55], hydrothermal methods [56–59], flame synthesis [60–63], and traditional or novel chemical reactions [64, 65]. There are several good review papers describing some of these techniques [64, 66, 67]. In the following section two of the most used techniques for nanoparticle synthesis, the metallorganic chemical vapor deposition (MOCVD) and sol–gel techniques, are described.

2.2.1. MOCVD

The basic idea in utilizing MOCVD is that in this process the chemical reactions among precursors occur at a certain temperature in either a vertically or horizontally aligned hot wall chamber. Therefore, no postsynthesis processes like calcination, centrifugation, or hydrothermal processing are required for crystallization or particle refinement. The control of size distribution can be achieved by controlling the temperature of the reactor and/or the flow rate of the precursors. Dopants can also be easily introduced into the reactor through a solid source, separated from the other liquid-precursor, or mixed in with the precursor. Figure 2 is a schematic of a MOCVD system for the preparation of TiO_2 nanoparticles. The most frequently selected Ti precursors are titanium tetraisopropoxide (TTIP) and $TiCl_4$. TTIP is preferred because $TiCl_4$ produces HCl as a toxic by-product. The carrier gas for the precursor can be an inert gas, such as Ar, or other nonreactive gases. In some cases the carrier gas also participates in the chemical reaction. The formation of TiO_2 nanoparticles is basically divided into four stages [41–43, 46]: (I) Introduction of mechanically mixed Ti precursor vapor (with carrier gas) and O_2 from the low-temperature region, (II) production of TiO_2 monomers based on the reaction of TTIP or $TiCl_4$ and O_2 in the higher-temperature region, (III) condensation of TiO_2 monomers to form larger clusters by homogeneous nucleation in the gas phase based on a collision mechanism, (IV) formation of TiO_2 particles in the gas phase and on the substrates after attachment of large clusters to the substrate. Therefore, the reaction and condensation are two crucial stages in the formation of semiconductor nanoparticles by MOCVD. Either thin films [68–70] or free-standing nanoparticles [41–46] can be deposited on certain substrates, depending upon the experimental conditions, such as deposition rate and temperature.

2.2.2. Sol–Gel

The main advantage of this process is that it makes it easy to prepare nanocomposite materials such as organic-coated nanoparticles and nanoparticles in an organic network. The process starts with a precursor solution, and the solvent can

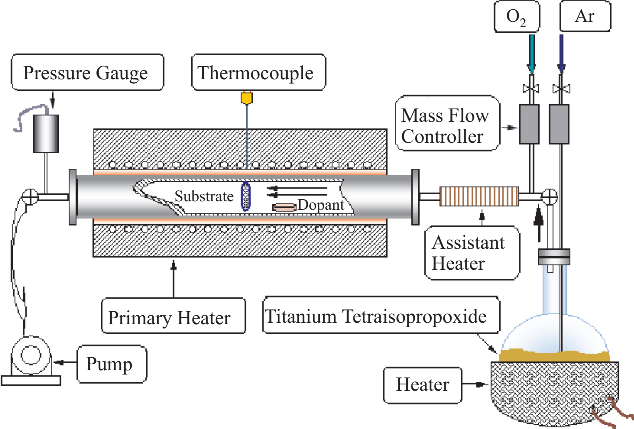

Figure 2. MOCVD system schematic for the synthesis of TiO_2 nanoparticles.

be ethanol or alcohol, etc., which has a low evaporation point. For the purpose of surface modification or doping, organic material or dopant precursor solutions can be mixed with the initial solution. The chemical reactions are carried out by dip-coating precursor solutions on desired substrates in a hood (usually at room temperature). In most cases, the samples are required to rest in the hood for enough time to dissipate gas-phase by-products and to remove excess solvent. The as-grown nanoparticles are amorphous, and a calcination process is needed to form crystals. Thus, the sol–gel process is normally followed by heat treatment for crystallization. Nanoparticles or nanophase films are achieved after calcination. Furthermore, to obtain fully crystallized ultrafine nanoparticles (1.5–5 nm), the particle growth of metal oxides in sol–gel can be inhibited by replacing the surface hydroxyl group before annealing with another functional group. This can produce small secondary-phase particles to restrict the advancement of grain boundaries at high temperatures [50].

2.3. Physical Methods

In general, thermal evaporation and sputtering are two primary physical approaches for the synthesis of semiconductor nanoparticles. For these methods, a relatively strict vacuum environment is required compared with the chemical methods to prevent contamination of the sample, the evaporation source, or the sputtering source. Most nanoparticles synthesized by these methods are in film form on certain specific substrates.

Vacuum thermal evaporation is a process in which evaporated flux from a desired material source is allowed to condense on a substrate. According to the different energy sources for the evaporation, this method is usually categorized as resistive evaporation, electron beam evaporation, ion vapor evaporation, cathodic arc deposition, or laser ablation. Detailed descriptions of these methods can be found in [71] and [72]. Typically, these evaporative deposition methods are performed in high vacuum without a gas atmosphere because the evaporated flux has low energy and a short mean free path. However, if an inert gas is used during the evaporation, the evaporated flux loses its energy quickly by collision with gas molecules. This results in the formation of powder by condensation. This process is also known as inert gas condensation (IGC) [72].

In sputtering, plasma is generated between an anode and a cathode. A large positive bias on the cathode, which is also the target to be sputtered, attracts the ions to the target. The ions accelerate across a dark space and impinge on the target, causing the target atoms to sputter. The sputtered flux can be deposited as a thin film and, depending upon the temperature and pressure, can form a nanostructured thin film. Moreover, the sputtered flux can be thermalized by collision with the sputtering gas such that nanoparticles are obtained. Specifically, TiO_2 thin films have been deposited by reactive magnetron sputtering [73], and CdTe quantum dots were synthesized by RF magnetron sputtering [74–76]. Ordered semiconductor dots were also formatted by ion-beam sputtering [77, 78].

3. MECHANISM OF NANOPARTICLE PHOTOCATALYSIS

3.1. General Description

Photocatalysis can be a homogeneous or a heterogeneous process. Homogeneous photocatalysis is a process that utilizes oxidizers such as O_3 and H_2O_2, while simultaneously coupling with light for the mineralization of organic molecules. However, photoreaction with the irradiation of semiconductor nanoparticles is heterogeneous photocatalysis and does not require oxidizers. Instead, it takes advantage of excited electrons and/or holes from nanoparticles to alter the kinetics of chemical reactions. At the end of each catalytic cycle, nanoparticle photocatalysts can usually be regenerated. It is normally supposed that a good photocatalyst always accelerates the reaction rate if there is no special restriction. A comprehensive description of homogeneous and heterogeneous photocatalysis systems can be found in [3]. Heterogeneous photocatalysis is categorized as a sensitized reaction or a catalyzed reaction, based on the origin of the electrons and holes. If the generation of charge carriers is initiated from absorbate species and they are transferred to the catalyst at ground state, which then takes part in the reaction, then the process is a catalyzed photoreaction. On the other hand, if initial photoexcitation occurs from a nanoparticle catalyst and charge carriers are transferred to ground-state molecules, the process is called a sensitized photoreaction [29].

The whole process of nanoparticle photocatalysis is simplified to electronic excitation, trapping, recombination, interfacial charge transfer, and chemical reactions. The slowest kinetic process becomes the rate-limiting step and has the most influence on the resulting photocatalytic activity. The final efficiency of the chemical reaction is the overall interaction of these theoretically divided parts. They are dynamically connected to each other with a certain sequence to complete the photocatalysis process. For simplicity, a heterogeneous photocatalysis process is expressed by Eqs. (1) to (5):

Electronic excitation:

$$\left|\mathrm{NP} + h\nu \rightarrow e^-_{\mathrm{cb}} + h^+_{\mathrm{vb}}\right| \tag{1}$$

Charge trapping:

$$\left|\begin{array}{l} e^-_{\mathrm{cb}} \rightarrow e^-_{\mathrm{tr}} \\ h^+_{\mathrm{vb}} \rightarrow h^+_{\mathrm{tr}} \end{array}\right| \tag{2}$$

Charge recombination:

$$\left|\begin{array}{l} e^-_{\mathrm{cb}} + h^+_{\mathrm{vb}}(h^+_{\mathrm{tr}}) \rightarrow \text{photons/phonons} \\ e^-_{\mathrm{tr}} + h^+_{\mathrm{vb}}(h^+_{\mathrm{tr}}) \rightarrow \text{photons/phonons} \end{array}\right| \tag{3}$$

Interfacial charge transfer:

$$\left|\begin{array}{l} e^-_{\mathrm{cb}}(e^-_{\mathrm{tr}}) + \mathrm{A} \rightarrow \mathrm{A}^- \\ h^+_{\mathrm{vb}}(h^+_{\mathrm{tr}}) + \mathrm{D} \rightarrow \mathrm{D}^+ \end{array}\right| \tag{4}$$

Chemical reactions:

$$\left|\mathrm{D(A)} \xrightarrow{\text{oxidation (reduction)}} \mathrm{Min}\right| \tag{5}$$

where NP and Min stand for nanoparticles and mineralized products (including H_2O and CO_2), respectively. A and D are acceptor- and donor-type chemical substrates on the surface of nanoparticles, respectively. A pictorial diagram of these processes is shown in Figure 3 [79]. The details for photocatalysis will be discussed step by step in the following sections. The mechanism to be discussed is general and fundamental. Specific photocatalysis cases for modified nanoparticles are included in Section 4.

3.2. Electronic Excitation

In photocatalysis processes, electronic excitation is the initial step for producing highly reactive and electronically excited states by photon absorption. Photoexcitation can occur from either nanoparticle catalysts or adsorbate molecules. Details of molecular electronic excitation are presented in Section 4.4.4. The excitation in semiconductor nanoparticles is addressed in the following section.

Semiconductors have an energy band gap (E_g) that ranges from the top of a filled valence band to the bottom of a vacant conduction band. Figure 4 shows the potential positions of valence and conduction bands for several semiconductors [29]. These data are for bulk materials. Nanoparticles have a small blue shift of the band gap, and, especially for Q-particles, the band gap increases with decreasing particle size [80, 81]. Electrons in the valence band require a certain energy to overcome the band gap and arrive at the conduction band. Photons that have energy ($h\nu$) equivalent to the band-gap energy can excite the electrons. With the interaction between incident light and nanoparticles, electron and hole pairs can be simultaneously generated because the same number of positive holes are left in the valence band to keep the nanoparticles electrically neutral upon the excitation of negative electrons to the conduction band. According to the semiconductor band-gap theory, direct and indirect absorption processes can occur in direct and indirect band-gap semiconductors, respectively. There is no phonon, which is the energy of lattice harmonic oscillation, involved in direct photon absorption to create free electrons and holes. Extra phonon energy is absorbed or emitted to excite electrons for momentum and energy conservation in an indirect absorption process. Indirect interface absorption can be induced in both direct and indirect band nanoparticles because large amounts of surfaces and grain boundaries help the electron transition and thus enhance the light absorption.

The rate of charge carrier generation is closely related to the efficiency of photon absorption. The photon absorption is a function of active absorption area and the band gap of nanoparticles. Smaller particles have a larger surface area and can provide more absorption sites to increase the absorbed photon numbers in a given time. Also, as mentioned above, nanoparticles can increase the possibility of indirect interface electron transition to increase the light absorption. The photoresponse can be extended to longer wavelengths by dye sensitization, attachments of foreign species on the surface, and band-gap narrowing by doping, etc., so that charge carriers are more easily produced with lower-energy irradiation.

3.3. Charge Carrier Transfer

3.3.1. Trapping

The photoexcited free electrons and holes experience charge trapping and recombination during their bulk migration and interfacial transfer for chemical reactions on the surface of nanoparticles. The separated charge carriers have a lifetime on the order of nanoseconds to undergo transfer [82].

Therefore, the charge trapping and recombination processes in this period are critical. They greatly affect the final total number, lifetime, and dynamics of free charge carriers on the surface of nanoparticles to change the photoreactivity because trapping is helpful for charge carrier separation and negates the carrier losses due to recombination. The dynamics of the charge carrier trapping process has been studied with various methods, especially time-resolved techniques. A stochastic kinetic model was used to interpret the charge-trapping process in colloidal TiO_2 particles [83]. Picosecond and femtosecond transient absorption spectroscopy has also been utilized to investigate the trapping processes in ZnO and TiO_2 nanoparticles [9, 79, 84, 85]. Laser flash photolysis has been performed to study the electron trapping in WO_3 [86, 87], SnO_2 [88], and ZnO [89–91]. Time-resolved photon echo experiments were done to deduce the trapping time of CdSe nanoparticles [92]. The trapped charge carriers can be characterized by electron paramagnetic resonance (EPR), absorption spectroscopy, and emission methods because their existence is sufficiently long and can be from microseconds to seconds [9].

The trapping sites can be surface defects, lattice sites, and dopants in nanoparticles. The surface in nanoparticles is large and is usually not ideal or regular. The nature of surface defect sites is related to the preparation method and can be changed by various surface modification methods (Section 4.4). The surface irregularities, such as vacancies, and coverage of foreign species, form surface defect sites which, in turn, introduce surface electron states into the band gap of semiconductor nanoparticles. They become important localized trapping centers for charge carriers by the energy difference between the trap and the bottom of the conduction band or the top of the valence band. Charges trapped at the surface of CdS single-crystal electrodes were shown by photoreflectance spectroscopy [93]. Both low-temperature EPR [94] and ambient-temperature spin-trap EPR [95] showed that holes can be trapped as surface-bound $O^{\bullet}$ or $^{\bullet}OH$ radicals in the presence of O_2 and H_2O on the surface of TiO_2. Moreover, the absorbed O_2 molecules on the surface are very important electron traps for forming O_2^- in most photocatalytic reactions [96, 97]. The lattice sites, such as host atoms and oxygen vacancies, can also become trapping centers. Some trapping in the lattice sites may cause chemical changes. Time-resolved analysis showed that CdS nanoparticles have chemical changes caused by reactions between trapped electrons and the Cd^{2+} site [98–101]. The chemical changes can be found elsewhere for CdSe [101] and PbS [102]. EPR studies showed that Ti^{4+} can trap electrons to form Ti^{3+} within anatase TiO_2 particles [103–106]. Oxygen vacancy is also implicated in electron trapping in TiO_2 [107]. The most interesting and significant trapping is from dopants. The impurities can be added as dopants during or after synthesis of nanoparticles. Dopants as trapping sites are limited to a certain concentration beyond which recombination becomes dominant because a high density of trapped charge carriers also increases the possibility of recombination with following opposite charge carriers generated by the photon.

Trapping can form shallow traps and deep traps. Trapping on surfaces is determined by the surface properties. The basic hydroxide groups on TiO_2 surfaces can cause deep traps for valence band holes [9]. Trapping by dopants depends on the potential of dopants in the band gap of semiconductors. Trapping from dopants that have a potential energy just below the conduction band or just above the valence band is considered shallow trapping; otherwise it is deep trapping. Shallow trapping is preferred for photoreactivity enhancement. Although deep trapping can also extend charge carrier lifetime, it may cause lowering of the redox potential of nanoparticles and cause a decrease in photoreactivity [12].

The trapping times for electrons and holes are different. Generally, electrons are easier and quicker to trap than holes. The hole and electron trapping time in CdS nanoparticles was found to be 1 ps [108] and 100 fs or less [109, 110], respectively. The trapping of holes generally occurs within 250 ns [10, 29], but electron trapping is usually completed within 180 fs for TiO_2 and most other semiconductor nanoparticles [104]. This is compatible with the results of a femtosecond time-resolved diffuse reflectance spectroscopy study for wet and dry Q-TiO_2 and dry P25 particles which showed that electron trapping takes place in less than 200 fs in all three samples [111]. However, a discrepancy in trapping time still exists. Longer electron trapping times of 0.5 to 8 ps for CdSe [92] and 30 ps for CdS [108, 112] were reported. The difference may be caused by the quality of samples, the nature of the nanoparticles, and trapping states (shallow traps or deep traps) [18].

Trapped electrons and holes are likely to be released. Free electrons or holes with extended lifetimes will participate in chemical reactions. If trapped electrons and holes are also to contribute to the reactions, first of all they have to be detrapped from trapping sites and obtain sufficient mobility for transfer without being recombined before reaching the reactants. This condition requires that trapped charge carriers have survived for a long time.

3.3.2. Recombination

The excited electrons and holes are thermodynamically unstable and have a tendency to recombine to lower system energy. This process is called charge carrier annihilation or recombination. Recombination can be radiative or radiationless. Radiative recombination emits light (photons), and radiationless recombination emits heat (phonons). Time-resolved techniques are used to study the recombination processes.

Surface recombination and volume recombination are two events for electronic decay in nanoparticles. The recombination strongly depends on particle size. For particles with sizes larger than several tens of nanometers, including bulk, volume recombination is dominant. Volume recombination is the direct or indirect recombination between conduction-band electrons and valence-band holes. After excitation, electrons and holes have electronic relaxation to the bottom of conduction and the top of valence bands, respectively. The relaxation process occurs on the order of 100 fs by interaction between electrons and phonons. Direct recombination of charges in the bands could occur, and it is often radiative with intense band edge luminescence if there are only a few or no electronic states within the band gap [18]. This would last for nanoseconds. With the increase

in band-gap states, volume recombination is dominated by direct exciton-exciton annihilation rather than recombination of trapped charge carriers. When there are electronic states induced by surface defects and dopants in the band gap, part of the conduction band electrons and/or valence band holes can be trapped during their movement back to a lower energy state. The trapped charge carriers then undergo radiative or irradiative recombination. This recombination can happen between conduction-band electrons and trapped holes, valence holes and trapped electrons, and trapped electrons and trapped holes. The recombination rate is slower than that of direct annihilation [18] and is related to the trapping depth. However, when particle size decreases below several nanometers and causes a high density of charge carriers on the surface, surface recombination starts to take place. Surface recombination refers to the decay between surface trapped electrons and holes, surface nontrapped electrons and holes, or surface trapped and nontrapped charge carriers. Therefore, a size window exists for nanoparticles to have a low rate of charge carrier decay beyond which volume recombination and surface recombination will become too large for large and ultrafine particles, respectively.

First-order and second-order recombinations are two primary kinetic processes. Second-order recombination is faster than first-order recombination. Serpone et al. proposed a model of recombination kinetics for trapped electrons and trapped holes based on the results of time-resolved emission decays. They demonstrated that the decay is first order in 2.1-nm TiO_2, whereas second-order decay occurs for 13.3 and 26.7 nm [79]. The equations are

First-order recombination:

$$I(t) = A' \exp(-k_r t)$$

Second-order recombination:

$$I(t) = \frac{A}{(1 + ([e^-/h^+]/VN)k_t t)^2}$$

where $I(t)$ is the ratio of the average concentration of electron/hole pairs at times t and 0 ps, A and A' are constants, k_r is a rate constant, $[e^-/h^+]$ is the average concentration of charge pairs at time t, V is the particle volume, and N is Avogadro's number. Earlier, picosecond and nanosecond transient absorption methods showed second-order decay of trapped electrons in TiO_2 [83], which was confirmed by femtosecond time-resolved diffuse reflectance spectroscopy by Colombo and Bowman [111] and other researchers [113].

The decay time of the charge carrier is quantitatively studied. EPR measurements showed that the recombination of shallow trapped and deep trapped charge carriers for Cu_2S nanoparticles are 1.1 ps and 80 ps, respectively [18]. Femtosecond transient absorption/bleach spectroscopy indicated that deep trapped electrons recombine with associated recombination times greater than 1 ns in Ag_2S nanoparticles [18]. Decay times for 2.1-, 13.3-, and 26.7-nm TiO_2 were determined to be 67, 405, and 66 ps, respectively, by transient emission decays [79]. The dependence of the recombination rate on the particle size is consistent with the size window for volume recombination and surface recombination, as discussed above.

3.3.3. Interfacial Transfer

Interfacial transfer is not only the continuation of bulk migration; it is also a process connected to the chemical reaction. To participate in the chemical reaction, electrons or holes must undergo interfacial transfer to the acceptors or donors attached on the nanoparticle surface, in addition to their bulk migration. The driving force for the electron transfer is the energy difference between the conduction band (or energy of trapped electrons) and the reduction potential of the acceptor redox couple. Similarly, the driving force for the hole transfer is the energy difference between the valence band (or energy of trapped holes) and the oxidation potential of the donor redox couple. As mentioned above, before the charge carrier transfer on the particle surface, the photogenerated electrons and holes have to move from the bulk to the surface by diffusion. The time of bulk migration is largely dependent on the mobility and lifetime of charge carriers and particle size. The average times of electron and hole migration from bulk part to the surface for 2.1-, 13.3-, and 26.7-nm TiO_2 are 0.05, 1.8, and 9.9 ps, respectively [103, 104]. The overall efficiency of interfacial transfer is determined by the competition between recombination and trapping followed by the competition between recombination of trapped carriers and interfacial charge transfer [12, 114]. The interfacial electron transfer directly competing with the recombination process was also verified by Kamat et al. [115] and other scientists [111].

Size and surface characteristics of nanoparticles have an extremely special role in interfacial charge transfer. The main reason for this is that the trapping and recombination processes are critically affected by surface-related factors, as mentioned earlier. For Q-particles, one additional reason for this is the increase in charge carrier potential, which can increase the driving force of transfer due to the band-gap enlargement. The electron transfer process from CdS nanoparticles to surface-absorbed viologens was investigated, and the ratio of recombination rate constant to electron transfer rate constant was found to be dependent on the particle size. It increases by a factor of 20 with a doubling of particle radius [116]. The interfacial hole transfer dynamics of P-25 TiO_2/SCN^- was probed as a function of thiocyanate ion concentration on the surface by femtosecond time-resolved diffuse reflectance spectroscopy because of the hole-scavenging capability of SCN^- [111]. The repression of e^-/h^+ recombination is also contributed by valence-band h^+ consumption in the oxidation of H_2O_2 by terephthalic acid fluorescence probing [117]. The enhancement of electron transfer on the surface of semiconductor Q-particles is attributed to both an increase in electron energy in the conduction band and changes in the physical and chemical nature of the surface, such as change in surface charge and increase in chemical nonstoichiometry [118]. Generally, the rate constant of interfacial electron transfer is determined to be greater than 5×10^{10} s^{-1} [119–121].

3.4. Chemical Reactions

3.4.1. Pollutants

The surviving electrons and holes may accelerate or initiate the photoreactions by interfacial charge transfer to chemical substrates. The type of chemical depends on the

selectivity of semiconductor nanoparticles, most of which have low selectivity. Nanoparticle photocatalysts can join in many chemical reactions, among which pollutant degradation is of the most concern for environmental protection.

Organic and inorganic compounds are two types of common pollutants. Organic compounds include halogenated organics {chlorophenols (CP) [2-CP, 4-CP, pentachlorophenol], chlorinated compounds [polyvinyl chloride, chlorinated dioxins, chlorinated dibenzofurans, trichloroethylene (TCE), and DDT], fluorophenol [*m*-fluorophenol], and PCBs, etc.} and commercial colorants {dyes [naphthol blue black, acid orange 7, disperse blue] and pigments}. Inorganic compounds include heavy metal species (Pb^{2+}, Sn^{4+}, As^{5+}, Hg^{+}) and ammonia, etc. Table 1 contains a list of typical organic pollutants ([12] and references therein).

3.4.2. Advanced Oxidation Processes

The function of photocatalysis in chemical reactions is versatile. First of all, there are two types of photocatalysis, homogeneous and heterogeneous. In homogeneous photocatalysis, reactions are oxidative because of the direct oxidizing agents (O_3, H_2O_2, O_3/H_2O_2, etc.). For heterogeneous photocatalysis, which involves semiconductor nanoparticles, the reaction type largely depends on the redox potential of chemical molecules. If the redox level is below the conduction band edge of nanoparticles, reduction reaction can take place. On the other hand, oxidation reaction will occur if the redox level lies above the valence band edge. In the case of redox levels nearly centered in the band gap, both oxidation and reduction reactions could occur. As a result, nanoparticles are capable of photodecomposition of small inorganic molecules, photooxidation of organic and inorganic species, and photoreduction of organic and inorganic species. Extensive examples of reaction types over TiO_2 were given by Howe [30] and Linsebigler et al. [29]. From the viewpoint of pollutant remediation, most reactions are oxidation reactions.

Photocatalysis is an advanced oxidation process (AOP), as are radiolysis [122–126], sonolysis [127–131], and other methods [9]. These oxidation processes are distinguished from each other by the way hydroxyl radicals ($^\bullet OH$) are generated because they have common $^\bullet OH$ as a primary oxidation agent to make the oxidation reaction possible in an aqueous system. Radiolytical processes produce $^\bullet OH$ by the irradiation of water with γ-ray or high-energy electron beams from ionizing radiation sources. Sonochemical methods use ultrasound to sonicate water in the presence of dissolved gas to form bubbles first and then dissociate H_2O to form $^\bullet OH$. A photocatalysis reaction forms $^\bullet OH$ by the incorporation of water with holes that form because of the irradiation of direct oxidizing agents in homogeneous systems or nanoparticles in heterogeneous systems. In addition to $^\bullet OH$ radicals, direct h^+ from catalyst and hydrogen peroxide radicals ($HO_2^\bullet$, $^\bullet O_2^-$) can also be possible oxidizing agents for heterogeneous photocatalysis. $^\bullet OH$ is considered to be a very active and effective chief radical for the oxidation of organic molecules in aqueous slurry systems. The existence of $^\bullet OH$ can be detected by radical detection methods with electron spin resonance spectroscopy [132–135] and other analysis techniques [136–138]. Extensive studies in the field of AOP photocatalysis have been conducted [3, 9, 139, 140]. By photocatalytic reaction, hydrogen, oxygen, and carbon are transformed into H_2O and CO_2. In addition to this, other typical elements in organic contaminants, such as nitrogen, sulfur, phosphorus, and halogen, can form NO_3^-, SO_4^{2-}, PO_4^{3-}, and other acid minerals by oxidation processes.

Liquid-solid and gas-solid are two representative heterogeneous photocatalysis reactions for pollutant remediation in water and air, respectively. Vast amounts of photocatalysis research have dealt with the liquid phase [2, 5, 7], with relatively less work carried out on gas-phase systems [7, 140–145]. For gas-phase reactions, O_2, which is adsorbed with H_2O molecules on the catalyst surface, can largely improve the oxidation reaction. Although O_2 molecules are not only electron scavengers but also the main radicals with oxygen-derived formations ($^\bullet O_2^-$ and $HO_2^\bullet$, etc.) that oxidize organic molecules, the existence of O_2 alone is found to be inefficient for oxidation. H_2O is necessary to improve photooxidation reactions in gas-phase systems. The role of H_2O in the gas-phase reaction is complicated and still not very clear. Fourier transform infrared studies revealed that the photodegradation rate of 4-CP was dramatically enhanced in the presence of water, but the action of water was not known [146]. Water was determined to form $^\bullet OH$ with holes, but it was not confirmed to be responsible for the oxidation of TCE as studied by the effect of different water vapor pressures on the photoreactivity of TiO_2 [147, 148]. The initial oxidation of TCE was due to oxygen-derived radicals but not $^\bullet OH$ radicals. This result was obtained by the investigation of the photoreactivity of hydroxylated TiO_2, with the use of isotopically labeled oxygen and water [29]. The presence of water was found to be helpful for the removal of reaction intermediates or products from the TiO_2 surface to prevent poisoning in both gas and liquid phases [149]. However, for the liquid phase reaction, both O_2 and H_2O were required for the photooxidation process. O_2 is mainly responsible for scavenging of electrons, and water is used for $^\bullet OH$ formation, so that oxidation reactions can be successfully completed. As mentioned above, $^\bullet OH$ radicals are the primary oxidation agents in this case. The aqueous reaction is commonly used for water purification. The reaction pathways in heterogeneous photocatalysis are complicated. For different pollutants and catalysts, the reaction pathways may be different.

4. ENHANCEMENT OF PHOTOCATALYTIC ACTIVITY

4.1. Quantum Yield

Photodegradation of pollutants is a direct way to examine the performance of semiconductor nanoparticles for photocatalysis. Quantum yield (quantum efficiency) is a criterion for measuring the efficiency of a photocatalytic reaction. It is defined as the number of consumed or destroyed molecules per absorbed photon [150]. In the case of multiple reactants, quantum yield is sometimes based on the consumption of a particular reactant. Nevertheless, precise determination of actual absorbed photons is much more difficult in heterogeneous than in homogeneous media because of the light

Table 1. List of typical organic compounds.

Chlorinated aromatics	Nitrogenous compounds	Hydrocarbons, carboxylic acids, alcohols, halocarbons, and heteroatom compounds
2-Chlorophenol	2-, 3-, and 4-Nitrophenol	1,3-Butadiene
3-Chlorophenol	2,5-Dinitrophenol	1,2-Dibromoethane
4-Chlorophenol	Trinitrophenol	2,2,5-Trimethylpentane
2,4-Dichlorophenol	Atrazine	2-Ethoxyethanol
3,4-Dichlorophenol	Dimethylformamide	2-Methoxyethanol
2,6-Dichlorophenol	Nitrobenzene	Acenaphthene
2,4,5-Trichlorophenol	4-Nitrophenyl ethylphenylphosphonate	Acetone
Pentachlorophenol	4-Nitrophenyl diethyl phosphate	Benzene
Chlorobenzene	4-Nitrophenyl isopropylphyl-phosphonate	Ethylbenzene
1,2,4-Trichlorobenzene	Azobenzenes	Benzoic acid
1,3-Dichlorobenzene	Cyclophosphamide	Bromoform
1,2-Dichlorobenzene	EDTA	Catechol
1,4-Dichlorobenzene	Methyl orange	Cresols
2,3,4-Trichlorobiphenyl	Methylene blue	Cyclohexane
2,7-Dichlorodibenzo-*p*-dioxin	Methyl viologen	Diethyl phthalate
2-Chlorodibenzo-*p*-dioxin	Monuron	Di-*n*-butyl phthalate
2,4,5-Trichlorophenoxyacetic acid	Nitrotoluene	Ethylene
2,4-Dichlorophenoxyacetic acid	Picoline	Formaldehyde
Hexachlorobenzene	Piperidene	Hexane
PCBs	Proline	2-Propanol
DDT	Pyridine	Malathion
Chlorinated surfactants	Simazine	Methanol
	Theophylline	Methyl vinyl ketone
Chlorinated aliphatic	Thymine	Naphthalene
and olefinic compounds	Trietazine	Phenol
1,1,1-Trichloroethane		Polynuclear aromatics
1,1,2,2-Tetrachloroethane		Propene
1,1,1,2-Tetrachloroethane		*tert*-Butyl alcohol
1,1,2-Trichloroethane		Toluene
1,1,2-Trichloro-1,2,2-trifluoroethane		Xylene
1,1,1-Trifluoro-2,2,2-trichloroethane		1,3-Diphenylisobenzofuran
1,1-Difluoro-1,2,2-trichloroethane		Bromodecane
1,1-Difluoro-1,2-dichloroethane		Bromododecane
1,1-Dichloroethane		Dodecanol
1,2-Dichloroethane		1-Propanol
1,2-Dichloroethylene		Fluorophenols
1,2-Dichloropropane		(4-Thiophenyl)-1-butanol
bis(2-Chloroethyl) ether		4-Hydroxybenzyl alcohol
Carbon tetrachloride		Acetic acid
Chloroacetic acid		Acetophenone
Chloroethane		Adipic acid
Chloroform		Alkylphenols
Methylene chloride		1-Butanol
Tetrachloroethylene		Butadiene
Trichloroethylene		Butyric acid
Chloral hydrate		Cyclohexene
Chloranil		Cyclohexanedicarboxylic acid
Chloroethylammonium chloride		Dibromomethane
Dichloroacetic acid		Diphenyl sulfide
Trichloroacetic acid		Dodecane
		Dodecyl sulfate
		Dodecylbenzene sulfonate
		Ethane
		Ethanol
		Ethyl acetate
		Formic acid

reflection and scattering on the surface of nanoparticles, absorption by the supports, and/or transmission in transparent colloidal sols. It is, therefore, ideally assumed that all of the photons are absorbed. The yield, therefore, is the apparent quantum yield. It is the most frequently used and can be calculated from experimental degradation rate curves. Another widely used criterion is the apparent reaction rate constant, because most photodegradations of dilute organic reactions are pseudo-first-order. However, significant variations in apparent quantum yield of the same catalyst for the same type of reactant in different photosystems were observed [151–153]. A perfect measurement should give consistent photocatalytic activity in different test conditions. It turns out that neither the apparent reaction rate constant nor the apparent quantum yield can fully reflect the intrinsic efficiency of nanoparticles. It was found that apparent quantum yield changes with the geometric size of the reaction zone [154], whereas the apparent reaction rate constant varies with the concentration of the catalyst and the power of irradiation [155]. They only provide apparent photocatalytic activity and can be used to compare relative photoreactivities in the same laboratory.

The factors affecting the apparent photocatalytic activity can be either operational variables or the quality of nanoparticles. The operational variables are external factors, such as irradiation conditions, photoreactor features, and other experiment parameters (amount of catalyst, pH value, temperature, and volume of the solution, etc.). For instance, the photodecomposition rate of water by Pt-RuO_2/TiO_2 was shown to be a linear function of the irradiation intensity, an exponential function of reaction temperature, and an exponential function of steady-state pH value [156]. The oxidation rate of phenol in aqueous solution with anatase TiO_2 was also affected by the initial pH of the suspension and the presence of Cl^- and H_2O_2 [157]. To find intrinsic photoreactivity, the same quality of photocatalyst is used while experimental conditions are varied.

Radiation conditions and photoreactor features are unstable aspects varying the apparent photoreactivity. For solution degradation experiments, three typical photoreactors are used: annular photoreactors, flat-plate reactors, and optical fiber reactors [158]. These reactors were described in detail by Howe [30]. The actual light absorption does vary with irradiation conditions, concentration of particles in solution, and photoreactor features. The irradiation conditions include uniformity of photon absorption in solution and other properties (wavelength, intensity, etc., of the incident photons). Light with a wavelength longer than the absorption edge of nanoparticles will be less energetic. An increase in light intensity can speed up the absorbed number of photons in unit time and vary the steady-state concentration of active radicals to change the photoreactivity. The rate of photochemical reaction on the surface was approximated as either a linear [144] or a square root function of irradiation intensity [159]. Radiant flux profile is not a constant, especially in large annular reactors and thick slurries, because of the resistance of light transfer. Therefore, particles in different positions of the reactor may have different absorption rates. The nonuniformity of radiation distribution affects reaction kinetics, and the overall quantum yield is decreased by increased reaction zone thickness [160]. The effect of catalyst concentration on the light absorption is not linear. With the increase in particle concentration, light absorption could be correspondingly enhanced because more absorption sites are active. But the resistance of light transfer becomes high when particles become thick. In this case, the farther the particles are from the illumination source, the lower the absorption coefficient. This situation is more noticeable in annular photoreactors than in others in which particles are coated with thin films.

The apparent kinetics of the degradation reaction is also a function of the amount of catalyst, pH value, temperature, volume of the solution, and foreign species in the solution. Increases in particle amounts to enhance the light absorption, as mentioned above, can supply more charge carriers. The same amount of particles and a different volume of solution give different particle concentrations and affect the degradation rate. The pH value can vary the surface charge and possibly change the band energies of metal oxide semiconductors with 0.059 mV/pH unit [9]. Higher pH values can provide more OH^- and form more $^{\bullet}OH$, which increase the oxidation reaction rate. Higher temperatures are favorable for endothermic reactions. The temperature factor can be avoided by cooling degradation cells with cold water or air to keep their temperature constant. Finally, there are other factors that affect the degradation results, including supplied oxygen and the presence of foreign ions in the solution. O_2 is an electron scavenger and is helpful for charge carrier separation. No slurry photooxidation reactions can be completed without O_2. The oxidation reaction rate on TiO_2 is related to the reduction rate of O_2 by electrons. Furthermore, the rate of radiationless

recombination was enhanced if the reduction rate was not sufficiently high [161–163]. Actually, photooxidation experiments are always supplied with saturated O_2, so the effect of O_2 can be minimized.

Precise quantum yield measurements are carried out to obtain intrinsic photocatalytic activity. The measurements are based on the approach of intrinsic reaction kinetics or the redefinition of quantum yield for the correction of apparent photocatalytic activity. In fact, it is very difficult to correct all of the operational variables to achieve intrinsic photoreactivity. Most efforts focus on the effects of irradiation conditions and photoreactor features because conditions such as amount of catalyst, pH value, temperature, and volume of solution are relatively easy to control and repeat precisely in different systems. As a result, irradiation and photoreactor factors are theoretically minimized to make the derived intrinsic photodegradation rates by a particular photocatalyst independent. Some attempts have been made to obtain a universal mean of photocatalytic activity. The ratio of hydrogen production rate per unit mass of catalyst to the transmittance of incident light through slurry solution was defined as the intrinsic production rate of hydrogen in the photocatalytic cleavage of water. This production rate was not dependent on reactor geometry and catalyst loading [156]. A kinetic model, comprising a single equation for low and high irradiation conditions, was successfully applied to the photodegradation of trichloroethylene in water [164]. Relative photonic efficiency, as a correction factor, was suggested for the comparison of photocatalytic activities of different photocatalysts by Serpone [165]. Recently, a correction factor representing the ratio of the radical generation rate in the laboratory to that in reference-ideal photocatalytic reactors has been introduced to obtain the intrinsic reaction rate constant from the measurement of the apparent reaction rate constant. The intrinsic constant was found to be independent of the reactor size, light power, and catalyst concentration [160].

The overall intrinsic value of photocatalytic activity clearly relies on the quality of the nanoparticles. The quality is defined by multiple factors, such as the efficiency of the photocatalytic reaction process, the wavelength range of response, the stability of particles under irradiation, and the selectivity of the reactants. For example, most semiconductor nanoparticles have large band gaps, which limit their use with short-wave irradiations such as ultraviolet light. Shifting the absorption edge to longer wavelengths can increase the photoabsorption efficiency, and visible light absorption in particular can greatly extend the application of catalysts to sunlight. Improving photoreactivity is always a challenge in the area of photocatalysis. The quality of nanoparticles varies with the structure, size, shape, doping, and various surface modifications of the particles. The enhancement of quantum yield is based on these interior factors. These issues are discussed in Sections 4.2–4.4.

4.2. Structure and Size Effects

4.2.1. Purpose

The significance of nanoparticles for photocatalysis was mentioned in the Introduction. In the following, the structural, electronic, and optical properties of nanoparticles, especially quantum-sized particles, Q-particles, will be discussed further. Because of the specialty of Q-particles, their properties have more influence on quantum yield than do the properties of common nanoparticles. Thus, understanding quantization effects is the prerequisite to studying the size effects on the photoreactivity of nanoparticles. Enhancement of photoreactivity can be expected by structure and phase selection, as well as size modification. Four aspects are considered to be helpful for photoreactivity improvement with a decrease in particle size: (1) increasing redox potential by band-gap enlargement, (2) shortening the pathway of charge transfer, (3) decreasing volume recombination, and (4) enhancing light absorption and the effective reaction area with increased surface area.

4.2.2. Structural Change

Nanoparticles can be amorphous or crystalline, depending upon the synthesis methods and conditions. Atoms in an amorphous structure have only short-range order because the atoms do not have enough activation energy and/or time for diffusion during synthesis. Amorphous particles can be crystallized if proper treatment is used to meet the energy requirement. Crystals are either polycrystalline or single crystalline, which have Bravis lattice structures with atoms in ordered sites. Polycrystals are composed of single crystals with different orientations separated by grain boundaries. For crystals, different structures or phase transitions could occur with changing temperature, pressure, and composition. For instance, TiO_2 crystals can be in at least eight formations: anatase, rutile, brookite, α-PbO_2, β-VO_2, hollandite, fluorite, and baddelleyite (ZrO_2) [19, 166, 167]. Anatase, rutile, and brookite are known to be relatively simple structures at normal pressure.

The surface structure of nanoparticles is different from that of bulk. In nanoparticle systems, atoms always terminate with a surface, and the surface area thus becomes extremely large. Moreover, the periodic arrangement may become different at the surface to meet the requirement of minimization of the overall system energy. It is called structural relaxation and can be achieved by surface reconstruction and lattice distortion. Once a surface is created, the surface accumulates unbalanced electric charges and has a composition different from that of the bulk counterpart. For instance, oxide surfaces nonstoichiometrically have excess oxygen with dangling bonds. Surface free energy and surface stress are two crucial factors for surface relaxation. Surface excess free energy is generated because of the deviation of surface electronic structure from that of bulk. It is quantitatively equal to the total energy difference between nanoparticles and bulk of the same amount, divided by the surface area. Surface stress is produced because of the force exerted among excess dangling bonds on the surface, and it is given as the force per unit length. The surface atoms can reconstruct or rearrange themselves when the difference between surface stress and surface free energy is large [168, 169]. The lattice distortion or reconstruction occurs to reduce dangling bonds on the surface and to relax the lattice of nanocrystals. With the decrease in particle size, more distorted lattice cells appear because of the surface stability. The crystal structure thus tends to be hard to identify

because the lattice is so distorted and so many atoms are displaced. Banfield and Zhang proposed a molecular dynamics simulation of a structural model for nanosized TiO_2 [19]. Dangling oxygen ions that prefer to form bridged oxygen pairs on the surface are the key to the structural change. By structural relaxation, the interatomic distance between two titanium atoms on the surface is either shortened when the surface tensile stress exists or enlarged when compressive stress forms to lower the system energy. The surface structure was clearly identified as being composed of three layers: surface, near surface, and interior. The lattice is most distorted on the surface layer and then gradually reaches the bulk structure at the interior layer. The interior layer decreases with the decrease in particle size and finally disappears when TiO_2 nanoparticles are very fine.

Phase structure and composition affect the photoreactivity. Iron oxide has Fe_2O_3, α-Fe_2O_3, β-Fe_2O_3, and γ-Fe_2O_3 structure formations, of which α-Fe_2O_3 is the most stable and effective catalyst [170]. However, α-Fe_2O_3 was found to be active only for the oxidation of sulfite, oxalate [170], and iodide [171] but not for the oxidation of cyanide [172] and the formation of H_2O_2 [31]. A significant increase in activity of TiO_2 nanoparticles for the degradation of phenol was observed with a decrease in amorphous content, although the size of particles with amorphous content was smaller than that of the completely crystallized sample [173]. One possible reason for this was that the amorphous phase acted as a recombination center to decrease the number of photogenerated electrons and holes. Anatase is believed to have a higher photoreactivity than rutile. The effect of anatase mass fraction on the photodegradation of methylene blue and photodecomposition of ammonia gas was investigated, and it was found that the particles with a larger percentage of anatase had higher reactivity [174]. However, commercial standard Degussa P25 is composed of 20% rutile and 80% anatase, and the small content of rutile is demonstrated to have improved photoreactivity.

4.2.3. Quantization Effects

Decreasing particle size leads to a larger surface area and introduces more electronic states and unbalanced charges onto the surface. The structural changes are the basis of unique properties of semiconductor nanoparticles because surface structure and particle size greatly affect electronic structures, which in turn have effects on physical and chemical properties. Consequently, with the reduction of particle size, many novel properties can be observed. Quite drastic property changes, known as size quantization or quantum-size (Q-size) effects, occur because of the spatial confinement of charge carriers when the particle size decreases to less than the Bohr radius of the first excitation state [175].

There are discrepancies for the critical particle size or the threshold of Q-size effects. First of all, the critical size varies with the type of the particle because of the difference in effective charge. Q-size effects were observed by Henglein when the size of CdS particles was below 10 nm [175]. Quantization of MoS_2 nanoparticles occurred within 2 nm [176]. The critical size for TiO_2 was considered to be 10 nm [30]. However, even for the same particles, differences in critical size still exist. The first excitation value of TiO_2 was determined to be 0.75–1.9 nm [177], but various values for the size quantization regime were reported, including $\leq$53 nm (especially $\leq$10 nm) [105], 2.5–10 nm [178], and 2–50 nm [26], etc. More detailed descriptions of the size discrepancies can be found in [10]. The different results for size threshold determination can be caused by variations in surface characteristics, the shape of particles, the precision of measurement, or other undetermined factors.

Electronic properties of nanoparticles are strongly affected by size quantization. Q-particles are actually molecular clusters without complete electron delocalization. They have discrete or quantized energy levels for both conduction band electrons and valence band holes because the charge carriers are confined in potential walls with very small dimensions less than their de Broglie wavelength. This situation is like simple particles in a box. Serpone et al. demonstrated that semiconductor nanoparticles with a few molecular units can maintain discrete lowest unoccupied molecular orbitals (LUMOs) and highest occupied molecular orbitals (HOMOs) [25]. Thus, the electronic structure of nanoparticles can be studied with the molecular orbital (MO) method. The MO model for particles grown with N monomeric units was schematically illustrated by Hoffmann et al. [12], as shown in Figure 5. By the semiempirical MO approach, the influence of surface structures on the electronic state of CdS was directly calculated, and low-coordinated Cd atoms were found to produce surface states [179].

Optical absorption and photoluminescence are dependent on particle size. With a decrease in nanoparticle size, the effective band gap increases because photoexcited electron and hole pairs have insufficient space to coexist within the ultrafine particles. The change in band-gap energy is a strict function of particle size and the effective mass of charge carriers. By using the exciton model, Brus derived the first excitonic state of a semiconductor cluster [80, 81]

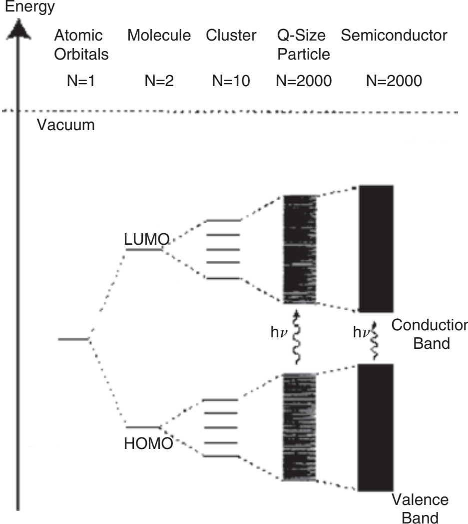

Figure 5. Molecular orbital model for electronic structure change with the growth of particle size. Reprinted with permission from [12], M. R. Hoffmann et al., *Chem. Rev.* 95, 69 (1995). © 1995, American Chemical Society.

as expressed by

$$\Delta E_g = E_g(R) - E_g(R = \infty) = \frac{\hbar^2 \pi^2}{2R^2 \mu} - \frac{1.8e^2}{\varepsilon R}$$

where $E_g(R)$ and $E_g(R = \infty)$ are band gaps of nanoparticles and the bulk state, respectively, R is the nanoparticle size, ε is the relative dielectric constant of the semiconductor, and μ is the exciton reduced mass, with a value of $(1/m_e + 1/m_h)^{-1}$ (m_e and m_h are the effective masses of electron and hole, respectively). The equation shows that nonnegligible band-gap energy change takes place and pronounced blue shift of the absorption threshold occurs in very fine particles, typically Q-particles. For comparison, the size dependency of the band gap is illustrated in Figure 5. Experimentally, the absorption as a function of particle size in CdS nanoparticles was observed and explained by Brus [80, 81], Henglein et al. [180, 181], and other scientists [179, 182, 183]. The comparison of absorption of ZnO with different particle sizes was made by Kamat et al. [89, 184]. Also, similar effects can be seen from other nanoparticles, such as MoS_2 [185], PbS [182], HgSe [186], PbSe [186], and CdSe [187]. For TiO_2, a 0.15-eV band-gap blue shift of 2–4-nm anatase and a 0.1-eV shift of 2.5-nm rutile were reported [177]. TiO_2 nanoparticles showed a blue shift in the absorption spectra with decreasing size, and the band gap increased from 3.027 to 3.167 eV with the particle size ranging from 39 to 3 nm [188]. However, no blue shift of 1.5-nm TiO_2 was reported, and the disability of the effective mass approximation in the band-gap energy change is a possible reason for this [189]. Different photoluminescence properties are observed in fine nanoparticles, and a large blue shift is indicated by different colors of Q-particles. For instance, CdS became colorless from a normally yellow color when the particle size was less than 2.2 nm [190].

4.2.4. Size Optimization

Size effects on the photocatalytic activity originate primarily from size quantization and size-related surface characteristics such as surface area and defects. With a decrease in particle size, charge carrier transfer can be accelerated because of either the ultrafine diameter of the crystals or the elevation of the redox potential of charge carriers by band-gap enlargement. At the same time, small particles offer increased light absorption area and active reaction sites due to larger surface area. For example, the adsorption rate and adsorbability of methylene blue (MB) were found to increase with the size reduction of TiO_2 nanoparticles [191]. However, decreasing particle size does not necessarily enhance the activity of nanoparticles. When particle size is reduced below a certain value, and most photogenerated electrons and holes are close to the surface, surface recombination will dominate, which shortens the lifetime of charge carriers. Moreover, blue shift of the band gap hampers the extension of the light absorption range and decreases the light absorption efficiency under the same irradiation energy range. These causes are unfavorable for the improvement of photoreactivity, so Q-particles do not necessarily show increased photoreactivity. Thus, the size dependency of photoreactivity is due to several competing factors, and an optimal size can be selected for the highest photocatalytic performance. Furthermore, size is one of the most important factors affecting the rate-limiting step. For instance, ZnO Q-particles may show enhanced photoefficiency for systems that have a rate-limiting step of interfacial charge transfer [192]. One more point should be mentioned here: that the photoreactivity may vary even for the same type of particles with the same size, because of the different preparation methods, which may cause the surface characteristics to be different.

Size effects on the photocatalytic activity of nanoparticles are investigated in various reaction systems. Anpo et al. [105] observed blue shift of the absorption edge and increased photocatalytic efficiency of TiO_2 for the photohydrogenolysis reaction of CH_3CCH in water with a decrease in anatase particle diameter from 53 to 3.8 nm, especially below 10 nm. This result was attributed to the enhancement of activity of charge carriers and/or suppression of radiationless transfer of the absorbed photon energy because of size quantization-related electronic structure modification. Improved catalytic efficiency with finer TiO_2 particles was also reported for the degradation of phenol [173] and MB [174, 191]. However, a linear increase in the degradation rate as a function of the anatase crystalline size, which was changed by varying the calcination temperature, was also reported [193]. Wang et al. demonstrated that photocatalytic activity could not monotonically increase with a decrease in particle size, and 11 nm was the optimal size of TiO_2 nanoparticles synthesized by hydrothermal methods for the decomposition of chloroform [48]. Particles with a larger or smaller size could have decreased photoreactivity due to the deficient surface area and high charge carrier recombination rate, respectively. These discrepancies can be understood based on the chemicals to be degraded, preadsorption of chemicals, actual activation surface area, number of surface states, and other factors.

4.3. Dopant Effects

4.3.1. Purpose

Dopants as foreign elements in nanoparticles are commonly used to enhance the photocatalytic activity. Cation, anion, and co-doping are common. Dopants can be introduced into nanoparticles either during the synthesis or after synthesis by processes such as ion implantation [194], thermal diffusion [195], or conventional solid-state reactions [196]. The dopant sources (precursors) are either ion compounds or neutral atoms, which can interact with the host lattice to build chemical bonds. Thus, the type of doping in this section refers to the final dopant chemical state(s) in the semiconductors. Dopants change the lattice thermal dynamics [197–200], electronic structures [201–203], and photocatalytic properties, etc., of semiconductor nanoparticles. Enhanced photocatalytic activity is expected by doping. In this situation, dopants might (1) increase charge separation efficiency by charge carrier trapping; (2) mediate interfacial charge transfer; (3) improve light absorption and change photoluminescence properties by introducing electronic states in the band gap or extend the light absorption range by narrowing the band gap; (4) reduce the particle size or change the phase composition. For doping, not only the enhancement of photoreactivity but also the effect on

visible light absorption is of interest. The actual role of dopants during the heterogeneous photocatalytic reaction is determined by their nature, position, and concentration in nanoparticles.

The natural properties refer to potential energy levels and oxygen affinity (for cations), etc. Dopants act as shallow traps of electrons if their energy level is near the conduction band of nanoparticles. They act as deep traps of electrons if their energy level is far below the conduction band of nanoparticles. Similarly, shallow trappings become possible if the dopant level is just above the valence band, and deep hole trappings are possible if the dopant level is far above the valence band. Shallow trapping increases the lifetime of charge carriers by successful separation of electron-hole pairs. However, deep traps reduce the energy difference between redox potential and trapped electrons or holes to slow down the charge carrier transfer, which is a crucial step for the overall reaction rate. As discussed in Section 3.3.1, the potential energy level of dopant in the semiconductor band gap should be considered. Accordingly, the dopants that introduce deep trapping are not suitable for the improvement of photoreactivity.

The dopants can be on the surface or in the lattice. The cases of dopant with high concentration on the surface are exclusively analyzed in Section 4.4 as surface modifications. Inside the lattice the dopant can be substitutional, interstitial, or on both sites. The effect of dopants on photoreactivity critically depends on their location and coordination in the particles. For example, substitutional dopant ions contribute mostly to the change in electronic structure and an increase in light absorption efficiency. Thus, determination of dopant position is necessary for investigations of the role of the dopant. However, the locations of dopant ions are affected not only by the nature (such as ionic radii) and concentration of ions, but also by the synthesis method. For dopant ions with sizes comparable to those of host ions, it is easier to occupy the host sites, as opposed to those that have radii much larger or much smaller than that of the host. The amount of dopant in the lattice is limited by the maximum equilibrium solid solubility limit of the dopants in the semiconductor nanoparticles. For different synthesis processes, dopant position also changes. Dopant ions may only be absorbed on the surface of particles during the initial hydrolysis step in the sol–gel method, and some of these ions are then incorporated into substitutional or interstitial sites of TiO_2 or form separate dopant-related phase(s) during calcination [30]. Recently, Li et al. [45] indicated that metal ions were in the lattice of TiO_2, and no dopant accumulation was detected on the surface for the low-level doping of metal ions by MOCVD. The method dependency of dopant position is one of the reasons why contradicting results for the same type of dopant ion, even with the same concentration levels, were reported by different researchers. For example, there is disagreement about whether Cr^{3+} dopant enhances or inhibits the photoreactivity of TiO_2 [204–207]. It is important to locate the dopant position. The location of 1% Fe in TiO_2 prepared by sol–gel dip coating was studied by Fourier transforms of extended X-ray absorption fine structure (EXAFS) analysis. EXAFS showed that Fe was incorporated completely into substitutional sites in the anatase lattice when high annealing temperatures were used [30].

Dopants can enhance the photoreactivity only within a certain range of concentration. As mentioned in Section 3.3, both too low and too high dopant concentrations are not desired, because of either insufficient amounts for achieving dopant effects or deterioration of photoactivity caused by fast recombination of charge carriers. The increased recombination may come from the recombination between trapped charges and subsequent photon-generated counterpart charges and/or recombination between trapped electrons and trapped holes through quantum tunneling [208] if the dopant traps both electron and hole. Thus, there exists an optimal dopant concentration that realizes the highest photoreactivity. The optimal dopant is size dependent. By studying the degradation efficiency of $CHCl_3$ with Fe^{3+}-doped TiO_2 nanoparticles, Zhang et al. [49] found that the optimal Fe^{3+} doping level decreased with increasing particle size, and it decreased from 0.2 at% for 6 nm to 0.05 at% for 11-nm particles. They reasoned that for the same dopant concentration, the larger particles have a higher possibility of multiple trappings of charge carriers because the average path length becomes longer and multiple trappings will lead to a high volume recombination rate. The limit of dopant concentration is not the same for different aspects of dopant effects. The optimal concentration for trapping efficiency might not be the one for the highest light absorption. Thus, an increase in light absorption does not necessarily mean the improvement of overall quantum yield, which is mainly dependent on the limiting steps of photocatalysis.

Doping-induced visible light absorption is of extreme interest. Although the band-gap narrowing can cause lower photoredox potential energy, which reduces the transfer rate of charge carriers, the increased photon absorption efficiency or generation rate of charge carriers usually can compensate for the negative effect and largely enhance the overall photoreactivity. As Asahi et al. [209] analyzed for doped TiO_2, to realize visible light reaction, the requirements for dopants in general semiconductor systems are: (1) doping must produce electronic states in the band gap of nanoparticles; (2) the redox potential of $H_2O/{}^{\bullet}OH$ should be within the band gap of doped nanoparticles to make photoreaction possible; (3) the doping-induced states should be very shallow, either below the conduction band edge or above the valence band edge. Additionally, only substitutional dopants can have a strong enough interaction with conduction-band electrons or valence-band holes to substantially modify the electronic structure of the host. The detailed mechanism of dopant-induced visible light absorption will be individually analyzed for cation doping and anion doping in the following sections.

4.3.2. Cation Doping

Metal ions have been extensively used for cation doping. The dopants cover primary metal ions, transition metal ions, and lanthanide ions (e.g., Nd^{3+}, Os^{3+}, Re^{5+}). Potential energy levels of some frequently used metal ions in the band gap of TiO_2 nanoparticles are schematically shown in Figure 6 [47]. Valence values of dopants less than and larger than that of Ti^{4+} are known as n- and p-type doping, respectively. An early comprehensive metal ion doping

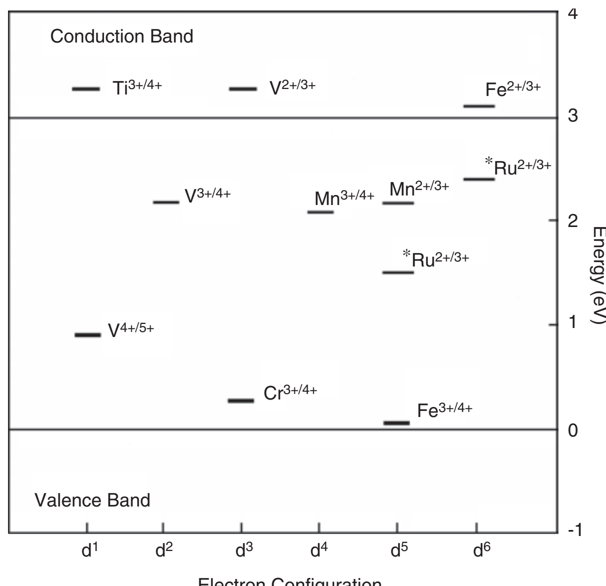

Figure 6. Energy levels of some metal ion dopants in the band gap of TiO_2 nanoparticles. Reprinted with permission from [47], W. Choi et al., *J. Phys. Chem.* 98, 13669 (1994). © 1994, American Chemical Society.

study was carried out by Choi et al. for 21 different ion-doped Q-TiO_2 [47]. Among metal ion dopants, the influence of transition metal ions on the photoreactivity of semiconductor nanoparticles is frequently studied because transition metals are known for their d-electronic configurations, which are helpful for the electronic structure modification of semiconductor nanoparticles.

Fe^{3+}, Cr^{3+}, and V^{4+} are the metal ion dopants that are used most often. There are no general agreements about whether they can enhance the photoreactivity of nanoparticles or not.

(1) Fe: Fe^{3+}-doped TiO_2 showed increased photoreduction of N_2 [210, 211] and methyl viologen [212]. Fe^{3+}-doped (0.11 to 1.76 wt%) TiO_2 prepared by coprecipitation exhibited high photoreduction of sodium nitrite because of the extended lifetime of electron-hole pairs and an increased diffusion length of electrons [213]. The same range of Fe was also indicated as the optimum iron content for TiO_2 prepared by the sol–gel method [213]. Also, negligible activity was found for very high Fe concentrations, and this was attributed to the photon absorption of aggregated iron oxide on the surface of TiO_2 due to too high dopant concentration. Doping Fe^{3+} at 0.5 at% in Q-TiO_2 was good for both oxidation of chloroform and reduction of tetrachloride [47]. Laser flash photolysis and time-resolved microwave conductivity measurements confirmed that the lifetime of electrons in doped particles increased from 200 μs to 50 ms. Low doping concentration (0.15 and 0.5 wt%) Fe doping showed considerably better performance for the degradation of maleic acid compared with pure TiO_2 [214, 215], and 0.75 at% Fe was also found to be an optimal concentration for increasing photoxidation of certain pyrimidine bases [216]. However, Fe-doped TiO_2 has only little influence [54, 217] or detrimental effect on the photodegradation of phenol [45, 218].

(2) Cr: TiO_2 doped with Cr^{3+} was found to induce visible light cleavage of water [204] and an increased reduction rate of N_2 [54]. In contrast, detrimental effects of Cr^{3+} doping were found by Herrmann et al. for the oxidation of liquid cyclohexane [206] and hydrocarbons [219]. Cr^{3+} was incorporated in substitutional sites of Ti^{4+} by ion implantation, which made remarkable decomposition of NO in visible light range possible [207, 220, 221]. But the photoreactivity in visible light was 25–1000 times lower than that under UV irradiation, although Cr^{3+}-doped TiO_2 could absorb visible light [205]. EPR study indicated a detrimental effect of the Cr^{3+} for the degradation of dimethylsulfoxide (DMSO) [222]. Similarly, Cr^{3+}-doped TiO_2 was also found to show no improvement for rhodamine B (RB) degradation because of the reduced lifetime of charge carriers [223].

(3) V: Vanadium commonly has V^{3+}, V^{4+}, and V^{5+} valence states. The photoreactivity of V^{3+}- and V^{4+}-doped Q-TiO_2 underwent very similar enhancement because V^{3+} was easily oxidized to V^{4+}, which can trap both electron and hole. V^{5+} doping also increased the photoactivity, but it was not as efficient as V^{3+} and V^{4+} doping because V^{5+} trapped only electrons [47]. Moreover, V ion-implanted TiO_2 also showed high photoactivity under visible light irradiation [220, 221]. However, Hoffmann et al. [224] performed a detailed investigation of vanadium-doped TiO_2. The coprecipitation methods followed by various temperature heat treatments showed different vanadium existence states, including surface-bound VO^{2+}, surface V_2O_5 islands, interstitial V^{4+}, and substitutional V^{4+}. All of these vanadium forms promoted charge carrier recombination and reduced the photoreactivity of TiO_2. Statistically, from the above examples, these three transition ions have either detrimental effects or positive functions with a competitive quantity of cases. It is hard to predict their effects in different reaction systems.

Many other cases of transition metal ion doping has been investigated. For example, Cu^{2+}-doped ZnS was found to have a visible light response and high photoreactivity [225]. Ni^{2+}-doped ZnS showed a visible light response and a narrowed band gap (2.3 eV) [226]. It had high efficiency for the photocatalytic H_2 evolution under visible light irradiation. Low levels of Ag^{+}-doped CdS showed enhanced efficiency for the oxidation of aniline, and its luminescence was quenched by absorbed aniline because efficient charge transfer occurred at the Ag_2S/CdS interface [227]. But, at a high concentration, the surface of CdS had Ag_2S, which prevents holes from interacting with reactant and reduced photoreactivity. Mn^{2+}-doped TiO_2 was tested to have low efficiency on DMSO degradation [222]. Mo^{5+} (>1 at%) was declared to increase RB adsorption on the surface of TiO_2 and enhance the photoreactivity [223].

There has been relatively less literature about primary group metal ion and lanthanide ion doping. Wang et al. [228] found that the photoresponses of Eu^{3+}-, La^{3+}-, Nd^{3+}-, and Pr^{3+}-doped TiO_2 nanoparticle electrodes for the degradation of RB were much stronger than that of undoped TiO_2. Sm^{3+} showed little increase because of the efficient separation of charge carries. Li et al. [45] confirmed the significance of Nd^{3+}-doped TiO_2 for the degradation of 2-chlorophenol. High-level doping (20 mol%) of alkaline earth ions (Ca^{2+}, Sr^{2+}, Ba^{2+}) doubly increased the photoreactivity of anatase, whereas 2-mol% of doping exhibited only half the enhancement for the destruction of oxalic acid [229].

Dramatic reduction of particle size by a high content of dopants and its related high adsorption rate could be the reason for this, although the doped TiO_2 had substantial amorphous parts.

Low concentrations of metal oxides, sulfides, or selenides can also be doped as ions into the nanoparticles. The optimal concentration, 1.5–3 mol% Nb_2O_5, was determined to be helpful in TiO_2 for the degradation of 1,4-dichlorobenzene (DCB) [230]. But Nb_2O_5-doped nanocrystalline WO_3 thin films had decreased photoreactivity with increases in Nb_2O_5 concentration due to an increased amorphous phase [231]. Studies of Nb_2O_5-doped TiO_2 can also be found elsewhere [232–234]. WO_3-doped TiO_2 exhibited high photoreactivity for the degradation of DCB, and the optimal content of dopant was 3 mol% [235]. The enhancement was attributed to the increased electron transfer rate from TiO_2 to trapped in W^{5+}. Al_2O_3 doping was selected to suppress the photocatalytic activity of rutile pigment for the oxidation of alkyd resins because Al_2O_3 could provide recombination sites [236]. Moreover, Al_2O_3 in the bulk of TiO_2 was considered a much more efficient recombination center than that on the surface. Doping of NiO in $SrTiO_3$ powder was found to have a photoactivity 100 times higher than that of $SrTiO_3$ alone for decomposition of both vapor and liquid water [237, 238].

Appropriate metal ion doping can make visible light absorption of nanoparticles possible. Doping Mn^{2+} ($<1\%$) is known to show orange luminescence or red shift of absorption for large band-gap semiconductors such as CdS and ZnS [239–242]. Cu^{2+}- and Ag^{+}-doped CdS exhibited a dopant concentration dependency of photoluminescence [243]. $Mg_xZn_{1-x}O$ nanoparticle thin films had band-gap reduction under certain heat treatments [244]. Furthermore, Serpone et al. [245] systematically studied the photoconductivity of TiO_2 colloids doped with Fe^{3+}, Cr^{3+}, and V^{5+} cations. All doped samples successfully showed an extended absorption threshold in the visible range, and the Cr^{3+}-doped sample had the largest red shift, with an absorption edge around 600 nm. By an implantation doping method, Anpo et al. [207, 220, 221] noticed that V^{4+}, Cr^{3+}, and several other transition metal ions remarkably shifted the absorption edge of TiO_2 into the visible region. The electronic structure of doped nanoparticles is the key to understanding the origin of visible light absorption. Recently, a theoretical calculation for the electronic structure of transition metal-doped TiO_2 (rutile) has been made by Umebayashi et al. [246]. They used a super-cell approach with a band calculation to obtain the electronic structures of rutile doped with transition metals (Fe, Cr, V, Mn, Co, Ni). The *ab initio* band calculations were done by the full-potential linearized-augmented-plane-wave (FLAPW) method. The calculated electron density maps (not shown) and the density of states (DOSs) for doped TiO_2 (Fig. 7) indicated that the electronic level introduced by 3d metal doping in the band gap or valence band was due to the t_{2g} state of the dopant. For Fe, Cr, V, and Mn doping, the t_{2g} state lies within the band gap of TiO_2. But the level of Co is located at the top of the valence band, and Ni has contributed only to the valence band formation.

4.3.3. Anion Doping

There are fewer reports about anion doping than there are about cation doping. This type of doping uses C, N, F, P, S, etc., to substitute anions of semiconductor nanoparticles and to achieve high photoreactivity and/or visible light response.

Doping F achieves high photoreactivity. The effect of F on the photoreactivity of TiO_2 was first reported by Hattori et al. [247, 248]. Trifluoroacetic acid was added to the starting solution to prepare F-doped nanocrystalline TiO_2 thin films by sol–gel. It was found that F doping increased the absorption coefficient for ultraviolet light because it improved film densification and crystallinity. The photocurrent measurements confirmed a high electron-hole generation rate. F doping also created trapping sites to increase the lifetime of charge carriers. The significantly enhanced overall photoreactivity for the oxidation of 1,3,5,7-tetramethylcyclotetrasiloxane (TMCTS) was mainly attributed to the increased trapping rate of charge carriers on the surface. However, in this case, they did not test the visible light absorption properties. Recently, F-doped TiO_2 prepared by hydrolysis showed that fluoride ions not only suppressed the formation of the brookite phase and prevented phase transition of anatase to rutile, but also exhibited stronger absorption in the UV-visible range with a red shift [249]. The photoreactivity of doped samples was higher than that of Degussa P25 when the molar ratio of NH_4F to H_2O was in the range of 0.5–3.

S doping has also been studied. Aiming at band-gap narrowing of TiO_2, Umebayashi et al. [196] found that doping S into TiO_2 to form Ti-S bonds caused lower-energy absorption compared with a pure sample. The band-gap study was based on the *ab initio* band calculations and the comparison of DOS. It revealed band-gap narrowing, which was caused by the mixing of S 3p states with the valence band of TiO_2 to significantly modify the electronic structures. The detailed effects of S on the electronic structure of TiO_2 were also investigated elsewhere [250–252].

Substitutional N is believed to be most effective for both band-gap narrowing and photoreactivity improvement. Asahi et al. [209, 253] calculated DOSs with substitutional doping of C, N, F, P, or S for O in the anatase TiO_2 by using FLAPW with the local density approximation (LDA), as shown in Figure 8. Their method indicated that substitutional N is more effective than interstitial for band-gap narrowing because its p states can interact with O 2p states to change the band structure. Compared with N, the states introduced by C and P are deep in the gap and have no benefit for the photoreaction. S has band-gap narrowing effects similar to those of N, but it is difficult to accommodate on the O sites because of its large ionic radius. The photodegradation of MB and acetaldehyde gas under irradiation with visible light with a wavelength less than 500 nm showed increased photoreactivity of $TiO_{2-x}N_x$.

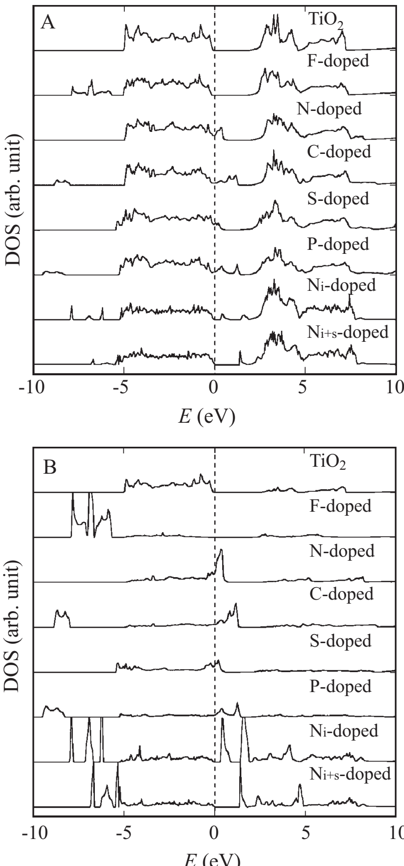

Figure 8. (A) Total DOSs of doped TiO_2 anatase. (B) FLAPW calculation of projected DOSs into the doped anion sites. N_i and N_{i+s} are interstitial N and both interstitial and substitutional N, respectively. The rest of the dopants are in the substitutional sites. Reprinted with permission from [209], R. Asahi et al., *Science* 293, 269 (2001). © 2001, American Association for the Advancement of Science.

4.3.4. Co-Doping

To improve the photocatalytic activity of semiconductor nanoparticles, co-doping methods have been attempted that use multiple dopants instead of a traditional single dopant.

Trapping of both electrons and holes can be achieved by co-doping. Although doping with Zn^{2+} or Fe^{3+} alone had little effect on photoreactivity, TiO_2 co-doped with both was found to noticeably promote the anatase-to-rutile phase transformation [254] as well as to greatly increase the photodegradation rate of phenol, with maximum photoreactivity occurring at 0.5 mol% Zn^{2+} + 1 mol% Fe^{3+} doping [255]. The enhancement was explained based on the charge carrier separation. Photogenerated electrons and holes in TiO_2 were efficiently separated by transferring holes to the valence band of ZnO and electrons to the conduction band of Fe_2O_3 because the valence band edge of ZnO is higher and the conduction band edge of Fe_2O_3 is lower than that of TiO_2. Interestingly, Eu^{3+}- and Fe^{3+}-co-doped TiO_2 nanoparticles also showed increased photoreactivity for degradation of chloroform in solution compared with undoped and monodoped samples, and the optimal concentration was 0.5 at% Eu^{3+} + 1 at% Fe^{3+} [256]. In this case, Fe^{3+} trapped holes and Eu^{3+} served as an electron trap. Simultaneous trapping of holes and electrons increased the number and lifetime of charge carriers on the surface.

Co-doping can largely improve the visible light response and photoreactivity of nanoparticles under visible light irradiation. Single-crystal $SrTiO_3$ doped with equal amounts of La and Cr, such as $SrTiO_3$:$LaCrO_3$, was determined to have an extended absorption range (<560 nm). The strong visible light absorption was attributed to the charge transfer from Cr^{3+} to Ti^{4+} [257]. However, the band-gap changes of these samples were not measured. Recently, Kato and Kudo [258] investigated the Sb^{5+}- and Cr^{3+}-co-doped TiO_2 (rutile) and $SrTiO_3$ systems. Intensive absorption was found in the visible light range. The band gap decreased to 2.2 and 2.4 eV for TiO_2 and $SrTiO_3$, respectively. Moreover, TiO_2:Sb/Cr showed broad photoemission at 828 nm, and $SrTiO_3$:Sb/Cr had a ruby-line emission at 790 nm. Under visible light irradiation, both evolution of O_2 from an aqueous silver nitrate solution with co-doped TiO_2 and evolution of H_2 from an aqueous methanol solution with co-doped $SrTiO_3$ showed increased reaction rates compared with TiO_2 doped with only Cr^{3+} and pure $SrTiO_3$. The increased photoreactivity was due to the suppression of forming recombination centers (Cr^{6+} and oxygen defects) in the lattice by the coexistence of Sb^{5+} and Cr^{3+}, because doping Cr^{3+} alone in the Ti^{4+} sites could cause the appearance of Cr^{6+} and/or oxygen to satisfy the electric charge balance.

4.4. Surface Modifications

4.4.1. Purpose

To increase the overall photocatalytic activity, various selective surface modifications have been developed. Metals, semiconductors, organic materials, and ion complexes are

deposited, mixed, or absorbed on the surface of semiconductor nanoparticles to achieve novel properties by charge transfer and electronic interaction between the surface attachment and the host semiconductor. The benefits of surface modification are (1) efficient charge carrier separation by improved charge transfer between the core semiconductor and its surface attachment, (2) solar energy absorption by surface sensitizer or narrower band-gap semiconductor, (3) change of the selectivity or reaction yield, (4) increased adsorbability of the surface. Thus, high overall efficiency of photocatalytic activity of nanoparticles is expected by surface modifications.

Coupled and capped models are two general surface modified systems. Geometrically, the surface of the host nanoparticles is only partly covered by the attachment in a coupled system, whereas the entire surface is completely surrounded in a capped system. For systems involving thin films, they usually have patterned, pillared, laminated, or intercalated structures or form composite films with different phases to achieve coupled or capped effects.

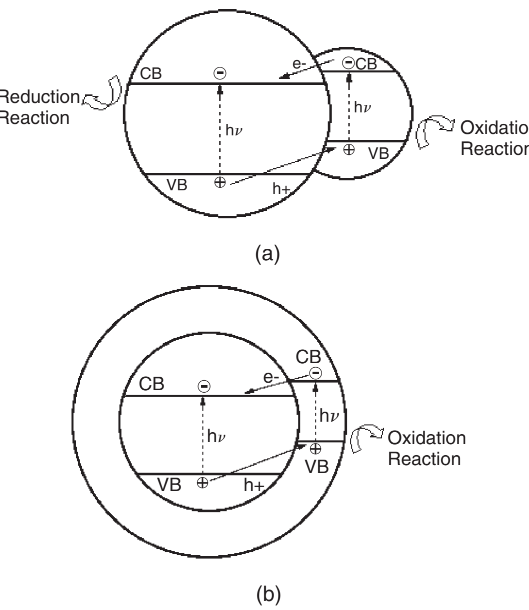

Figure 9. (a) Electron and hole transfer in a coupled semiconductor system. Both electron and hole can have the chance to participate in reactions. (b) Electron and hole transfer in a capped semiconductor system. Whether both electron and hole can have the opportunity to be in reactions is a function of the outside semiconductor thickness.

4.4.2. Composite Semiconductors

Composite semiconductor systems are formed by the deposition of one or more semiconductor layers on the surface of host semiconductor nanoparticles. Typically, these semiconductors are either coupled or capped together. The semiconductors contacting each other must have different band energy levels, so that they can make the charge carrier transfer between them possible. According to this requirement, insulators such as Al_2O_3, SiO_2, and CeO, which have larger band gaps, are also utilized with semiconductors to improve the charge transfer. The composite semiconductor conception was introduced by Nozik with a diode composed of sandwich p- and n-type semiconductors [259].

The mechanism of charge transfer is similar in dual coupled and capped semiconductors, except for the fate of charge carriers. In coupled systems, electrons and holes can be generated in both semiconductors. The electrons in a higher conduction band are injected into the lower conduction band, and holes in a lower valence band transfer to the higher valence band. Both electrons and holes can be utilized for the photoreactions because both semiconductors are exposed to the reactants. The principle of charge transfer in this system is sketched in Figure 9a. However, in capped semiconductor systems the shell semiconductor has sufficient thickness, which is comparable to the radius of the core semiconductor, so that the core and shell semiconductors can maintain their individual identities [260]. The diagram of charge transfer in capped systems is shown in Figure 9b. It can be seen that only one of the photogenerated charge carriers can access the surface reactions while the opposite charge transfers to the inner semiconductor occur. In this case, the selectivity of interfacial transfer is improved, and the oxidation or reduction reaction is enhanced. However, the problem is that this semiconductor system is only suitable for one type of reaction because one of the charge carriers is not utilized. According to the mechanism of composite semiconductors, insulators such as Al_2O_3, SiO_2, and CeO_2, which have very large band gaps, are also utilized with semiconductors in the coupled and capped systems to improve the charge transfer efficiency.

Various dual coupled semiconductor systems have been applied in photocatalysis. Coupled CdS/ZnO [261, 262], Cd_3P_2/ZnO [263], ZnSe/ZnO [89], and ZnS/ZnO [264] were designed to change the photocatalytic activity of ZnO. The CdS-coupled ZnO system showed that charge injection from CdS to ZnO occurred within 18 ps, and an increased photon absorption efficiency was observed [262]. A nearly 10-fold increase in quantum yield for the oxidation of SCN^- with ZnSe-coupled ZnO was obtained [89]. Visible emission of ZnO was quenched by hole transfer to ZnS, but fast radiationless recombination took place at the interface [264]. Likewise, photoreactivity of CdS, ZnSe, and ZnS [264] nanoparticles can be modified by ZnO on their surfaces. AgI was coupled with CdS to compensate for the disadvantage of the large band gap of AgI, and the injection rate of electrons from CdS to AgI was determined to be 2.2×10^7 s^{-1} [265]. The Ag_2S/AgI system was also studied [14]. For TiO_2, Cd/TiO_2 and CdS_3P_2/TiO_2 are commonly selected to enhance its catalytic activity because CdS and CdS_3P_2 have relatively shorter band gap values and respond to lower-energy light. The long-wavelength response of CdS/TiO_2 was earlier found by the evolution of H from alkaline solution with the irradiation of visible light [266]. The photoexcited electron-hole pairs from CdS can quickly transfer to the TiO_2 conduction band at a transfer rate of 5×10^{10} s^{-1} [265]. The electrons in the TiO_2 conduction band and the holes in the CdS valence band are responsible for redox reactions. Enhanced photoreduction of methylviologen in CdS/TiO_2 systems was observed [261]. SnO_2/TiO_2 coupled bilayer systems have been designed particularly for efficient charge separation. This type of nanostructured thin film on optically transparent electrode (OTE) showed an extended photon response and a significantly higher photooxidation rate than

only SnO_2 or TiO_2 for a textile azo dye, naphthol blue black (NBB) [267]. The addressed highest enhancement was seen when the amount of SnO_2 was higher than TiO_2 in the composite. The result was attributed to the efficient charge separation by electrons flowing from TiO_2 to OTE through SnO_2 with the existence of electrochemical bias. However, the disadvantage is that electrons cannot be utilized. Patterned TiO_2 stripe films formed on a SnO_2-film-coated soda lime glass substrate are synthesized to solve that problem. Very high photocatalytic activity was reported for gas-phase oxidation of acetaldehyde [268] and dehydrogenation of liquid methanol [269]. Similarly, both electrons and holes could be used in a bicomponent system of SnO_2 thin films partly covered with TiO_2 on glass slides, and an increased photooxidation rate of phenol solution was achieved [270]. SiO_2/TiO_2 is another system that is used in photocatalysis. Surface bond-conjugated anatase on silica nanoparticles was reported to have enhanced photoreactivity compared with Degussa P25 for the photodegradation of azo dyes, because of increased adsorption of reactant molecules of TiO_2 [271]. The use of SiO_2 substrate for TiO_2 also showed increased photoreactivity for the oxidation of propane [272–274] and the reduction of ammonia [274]. Besides the examples given above, other coupled systems can be seen elsewhere, such as ZnO/TiO_2 [275, 276], CuO/TiO_2 [277], etc.

Some capped dual semiconductors are also used in photocatalysis. TiO_2 (8–10 nm)-capped SnO_2 nanoparticles showed improved charge carrier separation, which was confirmed by laser flash photolysis [260]. The quantum yield of TiO_2/SnO_2 for photooxidation of I^- and SCN^- had a 2–3 factor increase compared with SnO_2 by itself. Moreover, TiO_2-capped SiO_2 exhibits as good a photocatalytic activity as TiO_2 because of the TiO_2 capping effects [260]. Aimed at visible light response, α-Fe_2O_3 capped by TiO_2 was synthesized and studied [278]. To improve the separation of catalysts in treated water, magnetic Fe_3O_4 was used in the photocatalyst TiO_2 to form a TiO_2-capped Fe_3O_4 system [279].

In addition, multiple-layer coupled or capped semiconductor systems are designed. A core semiconductor is used, with its surface covered by several layers of another semiconductor, on which multiple layers of core semiconductor material are then deposited as the outermost shell. The first three-layered structure was reported and described by Weller et al. [280, 281] for CdS/HgS/CdS systems in which core CdS was the Q-particle. It is also known as quantum dot quanta well (QDQW).

4.4.3. Metal/Semiconductors

The addition of metal atoms to the surface of nanoparticles changes the surface characteristics, which in turn alter the photocatalytic activity. In particular, noble metals (Pt, Ag, Au) are most often selected in this approach because they themselves are catalysts. The enhanced photoreactivity of semiconductors by loading of metal was first found for the photodecomposition of H_2O into H_2 and O_2 in Pt/TiO_2 systems by Sato et al. [282].

The principle of charge transfer in metal-deposited semiconductor systems is similar to that of a metal-semiconductor diode. The contact is either Schottky barrier or Ohmic contact, depending on the difference in Fermi energy levels of the two materials before they contact each other. If the Fermi level of the metal is lower or the work function of the metal is larger than that of the semiconductor, electrons will flow from the semiconductor to the metal by diffusion and/or drift (in case of bias) until a steady state is reached. At equilibrium, Fermi levels in two junction parts are the same and the accumulated opposite interior electric field stops the charge from moving. Thus, extra electrons accumulate on the metal side and charge pairs generated in the semiconductor are quickly separated. This type of junction is known as a Schottky barrier. In contrast to the Schottky barrier, Ohmic contact is created if the work function of the semiconductor is larger than that of the metal. It has extra electrons accumulated in the semiconductor conduction band. Figure 10 is a Schottky barrier in a metal-semiconductor photocatalysis system [29]. The metal-semiconductor system used for photocatalysis has a large area of uncovered semiconductor surface with only a small area dispersed with metal atoms. Thus, both electrons and holes can be utilized.

Pt, Ag, and Au are the most frequently used noble metals in metal-semiconductor systems because of their high effectiveness compared with other metals. Ag/TiO_2 was found to be efficient for the reduction of bis(2-dipyridyl)disulfide because the recombination of charge carriers was minimized by moving electrons to the silver [283, 284]. Sol–gel-derived Pt/TiO_2 showed high photoactivity for the oxidation of 4-nitrophenol [285]. Other metals such as Cu, Ni, etc., are also used.

4.4.4. Surface Sensitization

Photosensitization methods are commonly chosen to enhance the photoreactivity of nanoparticles. "Photosensitization" refers to the process in which electrons or holes are generated from certain attachments on the surface of nanoparticles, and electrons are then transferred to the conduction band of a semiconductor that has lower potential energy. The injected electrons then participate in the

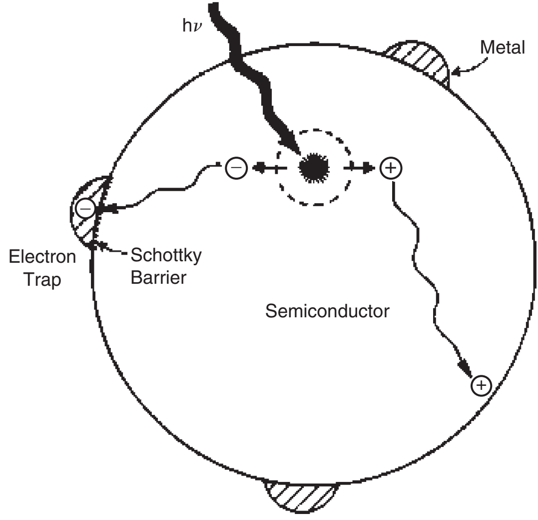

Figure 10. Shottky barrier in a metal-semiconductor photocatalysis system. Reprinted with permission from [29], A. L. Linsebigler et al., *Chem. Rev.* 95, 735 (1995). © 1995, American Chemical Society.

Table 2. Photoreactivity enhancements of typical semiconductor nanoparticles.

TiO_2	ZnO	Fe_2O_3	WO_3	SnO_2
Preferred structure	Doping	Preferred structure	Doping	Surface modification
Anatase [16, 33–35, 173, 174]	Ni^{2+} [226]	α-Fe_2O_3 [170, 171]	Nb_2O_5 [231]	TiO_2 [260]
	Cu^{2+} [225]			CrO_x [346]
Doping	Surface modification	Surface modification	Surface modification	Ag_2S [294]
Al_2O_3 [236]	Al_2O_3 [312]	Al_2O_3 [320]	TiO_2 [337]	CdS [294]
Ca^{2+} [229]	α-Fe_2O_3 [313]	TiO_2 [278, 321]	ZrO_2 [338]	Sb_2S_3 [294]
$V^{3+,4+,5+}$ [47, 220, 221, 245]	WO_3 [313]	TiO_2/SiO_2 [322, 323]	Nb_2O_5 [338]	PbS [294]
$V^{3+,4+,5+}$ [224][a]	In_2O_3 [314]	NH_4Cl [324, 325]	WS_2 [339, 340]	Bi_2S_3 [294]
Cr^{3+} [54, 204, 207, 220, 221, 245]	SnO_2 [290, 315]	$Au + Al_2O_3$ [326]	Pt [341]	$Ru(bpy)_3^{2+} + Pt$ [347]
Cr^{3+} [205, 206, 219, 222, 223][a]	Cd_3P_2 [263]	Au [327, 328]		$Ru(bpy)_3^{2+} + Pt + RuO_2$ [347]
Mn^{5+} [223]	CdS [261, 262, 294, 313]			Pd [348]

chemical reactions. In such cases, the photocatalytic process is indirect. According to the definition of surface sensitization, the surface attachments can be narrow band-gap semiconductors and organic molecules, which can be easily excited with the irradiation of low-energy light. The composite semiconductor systems are described in Section 4.4.2. Semiconductors with organic absorbates or ion species on the surface are the focus of this section. The primary purpose of sensitization is to enhance the light absorption of large-band semiconductors because the most used sensitizers have a broad light response range. Visible light absorption is of special interest.

There are several chemical sensitizers suitable for the surface modification of nanoparticles. Organic dyes are selected most often. The most utilized dyes are $Ru(bpy)_2^{2+}$-related ruthenium organic complexes because of their strong visible light response, easy interaction with semiconductor surfaces, and resistance to ligand substitution [9]. Other dyes, such as anthracene-9-carboxylate, chlorophyll a and b, chlorophyllin, cresyl violet, cyanines, erythrosine B, eosin, phenylfluorone, rhodamines, rose bengal, squaraines, thionine, and transition metal cyanides, etc., with a profound light response in the visible region are also commonly selected to improve the photoreactivity of nanoparticles [9]. Of course, the overall evaluation of the efficiency of these sensitizers is based not only on light absorption but also on the charge injection effectiveness, which is a function of energy levels of the dye and interaction between the dye and the surface of nanoparticles.

Electronic excitation in the sensitizer is the first step in initiating photocatalytic reactions. A molecular excitation diagram is shown in Figure 11 [29]. S_0 is the ground state of electrons (usually at room temperature). S_1 and S_2 are two singlet excited states. T_1 is the triplet excited state. The energy levels among them have a relation of $S_2 > S_1 > T_1 > S_0$. With the irradiation of incident photons, the electrons in molecules are excited from S_0 to S_1 and/or S_2. The excitation from S_0 to T_1 is spin forbidden according to the selection rules. The excited electrons can directly transfer from singlet states to the conduction band of semiconductors or indirectly through the triplet excited state to the conduction band. The rest of the excited electrons will undergo radiation decay to ground state by different mechanisms, such as fluorescence and phosphorescence.

The interaction between the sensitizer and semiconductor surface largely determines the charge injection efficiency. The surface photochemical reactions of nanoparticles affect the behavior of excited sensitizers. Lower photoemission yield occurs in reactive nanoparticles such as TiO_2, which can directly participate in photochemical reactions. Thus, in this situation, the efficiency of charge transfer to the nanoparticles is greater than that in nonactive insulator systems such as silica and alumina, which provide only a two-dimensional environment to affect and control the photochemical reactions. Kamat has published a review of the photochemistry of nonreactive and reactive semiconductor surfaces [184].

4.5. Example List

According to the photoreactivity enhancement methods discussed above, the examples are categorized for easy indexing. Table 2 is a list of the possible doping and surface modifications for typical semiconductor nanoparticles. It should be mentioned that the photocatalytic property in each case is based on a specific reaction system, and it may vary with the change of target chemicals. From this list, the importance of TiO_2 nanoparticles for photocatalytic uses is obvious.

5. PROSPECTS FOR TiO_2 NANOPARTICLES

TiO_2 is the most promising photocatalyst compared with the rest of semiconductors, and thus it is necessary to get a perspective of the likely future trend of TiO_2 nanoparticles. Currently, research is focusing on the enhancement of TiO_2 photocatalytic activity by various methods, as discussed above. However, impediments still exist: (1) the quantum yield of TiO_2 is low and it needs to be further enhanced; (2) the homogeneity of nanoparticle distribution is not very satisfying and should be improved by the development of new synthesis methods; (3) the application of TiO_2 is primarily limited to short-wavelength light irradiation; visible light absorption still poses a challenge.

6. SUMMARY

In this review, we mainly addressed the synthesis methods, photocatalysis principles, and approaches to the enhancement of the catalytic activity of semiconductor nanoparticles. The position of TiO_2 nanoparticles in the area of semiconductor photocatalysis was particularly emphasized. For each section, typical examples were given.

GLOSSARY

Band gap Energy difference between the lowest point of the conduction band and the highest point of the valence band of a semiconductor.

Doping A method to introduce foreign element(s) into the host material. Such methods include ion implantation, thermal diffusion, and conventional chemical reactions.

Heterogeneous photocatalysis A function altering the rate of chemical reactions or their generation under the irradiation of light in the presence of semiconductor photocatalysts.

Metallorganic chemical vapor deposition (MOCVD) A synthetic technique which utilizes chemical reactions among precursors (typically, a metallorganic complex is selected as primary precursor) at a certain growth temperature in a vacuum chamber to condense particles or thin films on substrates.

Photocatalyst A substance that is able to change the rate of chemical reactions by the absorption of light quanta.

Quantum yield A criterion measuring the efficiency of photocatalyst. It is the number of reacted molecules of a given product in a chemical reaction per absorbed photon at a certain given wavelength.

Sensitizer An agent absorbing light and subsequently initiating a photochemical or photophysical changes in the reaction system and itself not being consumed therewith. It is commonly utilized to enhance the properties of other photocatalysts.

Size quantization A phenomenon related to a drastic difference of properties occurring in ultrafine nanomaterials compared with bulk formations due to the spatial confinement of charge carriers when the size decreases to be smaller than the Bohr radius of the first excitation state.

Sol–gel technique A synthetic method that uses chemical reactions from precursors to form a sol (a system composed of particle-phases dispersed in a media liquid phase) and/or gel (a colloidal system constituted as a coherent structure interpenetrated by the dispersion medium) followed by drying and annealing to obtain nanostructured products.

Sputtering A synthetic technique which takes advantage of plasma generated between an anode and a cathode (target being sputtered) in a certain deposition gas in the vacuum system to deposit target materials on a substrate to usually form thin films.

Surface modification A method utilizing and attaching single or multiple second material(s) on the surface of host material to change the electronic, optical, photocatalytic, etc., properties of the host.

1. INTRODUCTION

The majority of current integration circuits, including memories, microprocessors, and signal processors, are manufactured in CMOS technologies. The acronym CMOS stands for the complementary metal-oxide-semiconductor which is constructed by a *p*-channel and an *n*-channel metal-oxide-semiconductor field-effect transistor (MOSFET) on the same substrate. A typical *n*-MOSFET is shown in Figure 1, where SiO_2 serves as the insulator and the aluminum metal plate serves as the gate electrode. A *p*-channel device is obtained by interchanging the *n* and *p* regions. The functioning mechanism of the *n*-MOSFET is to control the electron concentration in the conduction channel by the electric field of the gate bias (thus the so-called field effect) which is insulated from the channel by an insulator. When the gate bias is larger than the threshold bias $V_{\rm th}$, the conduction band edge of the conduction channel becomes low enough (close to the Fermi level E_f; see Fig. 2) that the original *p* material is now populated with electrons (material type inverted). Electrons from the source can then transport to the drain fluently when a drain bias is applied.

Information technology has been rapidly advancing due to the electronic representation, information processing, and communication in a low-cost, high-speed, very compact, and highly reliable fashion [1–3]. The chip component density has been following Moore's law and roughly doubles every other year over the last three decades. Figure 3 shows the number of components per integrated circuit (IC) [4]. As the number of transistors integrated in a circuit continues to increase, discrete device dimensions have begun to reach the nanometer regime. Such a down-scaling progress of individual device components has been tremendous over the past 20 years [5]. A 1.0-μm gate length MOSFET was reported in 1974 by Dennard et al. [6], a 0.1-μm gate length by Sai-Halasz et al. [7] in 1987, a 70-nm gate length by Hashimoto et al. [8] in 1992, a 40-nm gate length by Ono et al. [9] in 1995, and a 30-nm gate length in 1998 by Kawaura et al. [10]. Vertical *p*-MOS transistors also have been extensively investigated, and transistors with channel lengths of 130 and 100 nm based on Si as well as GaAs have been fabricated [11–16]. However, the advancing multimedia infrastructure and service in the future demand further reduction in the chip size [2, 17, 18]. Moreover, the demanding field of optical devices is vast as well [19, 20].

The size-induced metal–insulator transition in mesoscopic conductors was discussed for designing new, even smaller, and simpler transistors [21]. Tunneling-control functional, quantum interband coupled multifunction, resonant electron-transfer, quantized-energy logic/memory, coupled quantum-dot, quantum-wave structure functional, single-electron transistor (SET) logic, and CMOS coupled single-electron devices were studied to develop novel devices for information processing which control quantum phenomena to realize low power consumption, high-speed, and multi-functional operations [22]. Zero-dimensional structures formed by lateral confinement of two-dimensional electron gas were analyzed for the SET [23]. It was suggested that the most promising avenue for downscaling to go beyond CMOS is the quantum dot IC technology [24–36]. The advantages and drawbacks of the low-dimensional quantum devices were discussed [37]. Silicon single-electron tunneling devices were discussed in terms of their graceful assimilation into the current silicon ultra-large-scale integration world [38]. Evaluation of the heterostructures was reported [39, 40]. Three nanoscale devices, that is, CMOS, resonant tunneling diodes, and quantum cellular automata, against

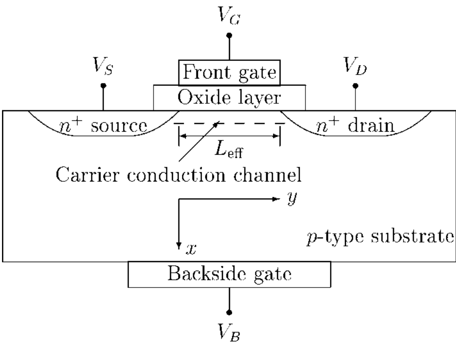

Figure 1. An n-channel metal-oxide-semiconductor field-effect transistor.

a standard computing task were evaluated showing the difficulties in the implantation of the state of the art quantum devices [41]. The application of SETs to high-speed devices will be possible but very difficult [42]. The issue was further discussed by Thornton [43] concerning quantum interference transistors, ballistic transmission devices, resonant tunneling quantum dot devices, Coulomb blockade, and SETs. Bohr [44] and Korotkov [45] described basic device and circuit requirements for electronic logic and memory products for evaluating nanotechnology options such as carbon nanotube field-effect transistors, nanowire FETs, SETs, and molecular devices as possible future replacements for Si MOSFETs. Experiments and simulations show the noise and the uncertainty in determining the geometry of the fabricated circuit [46]. There are technical issues like the very challenging degree of material perfection [33, 47] and necessary design trade-offs in oxide, channel, and storage-dot dimensions [48].

There were also positive observations [49]. Nippon Telegraph and Telephone Corporation has fabricated a prototype SET which allows electric current to be controlled electron-by-electron and has confirmed that the device operates even at temperatures near room temperature [50]. Single-electron charging effects in Si MOS devices were examined and a promise of the application of single-electron technology to more integrated circuitry was concluded [51].

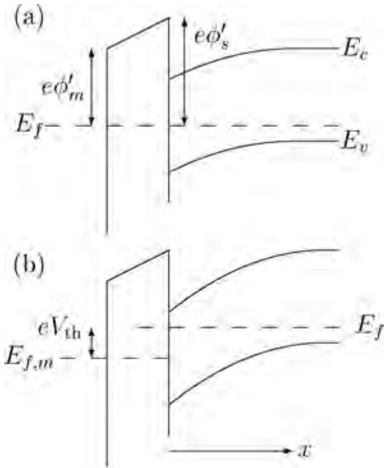

Figure 2. Energy band structures of an n-MOS structure under the gate bias of (a) $V_G = 0$, (b) $V_G = V_{\text{th}}$.

A similar conclusion was derived by Lee and Park from their research activities in the field [52]. Moreover, we have room-temperature single-electron storage effects that support the pursuit of large-area devices operating on the basis of Coulomb blockade phenomena [53]. Possible are single-shot readout using the radio-frequency SET [54], Si nanocrystal memory cell with room-temperature single-electron effects [55], Si nanocrystal floating gate memories [56], hexagonal binary decision diagram quantum logic circuits using Schottky in-plane and wrap-gate control of GaAs and InGaAs nanowires [57], and silicon single-electron memory and logic devices for room temperature operation [58]. Excellent charge stability drifting by less than $0.01e$ over weeks in Si-based single-electron tunneling transistors (SETTs) was reported, making the devices more robust with respect to voltage-induced instability [59]. A rather bright side of the small transistor is the silicon single-electron charge-coupled device on a silicon-on-insulator (SOI) wafer [60].

Yet the most encouraging positive news came from the advancing semiconductor industry: IBM announced its strained silicon in which electrons experience less resistance and flow up to 70% faster, which can lead to chips that are up to 35% faster, without having to shrink the size of transistors [61]. Meanwhile, Intel now has the technology to make processors 10 times faster than today's speediest Pentium 4, ensuring continued PC performance growth through at least the end of this decade. The transistors are just 70 to 80 atoms in width and 3 atoms thick, which was announced at a semiconductor conference in Kyoto, Japan [62]. The achievement is important because it suggests that semiconductor makers will be able to keep pace with Moore's law until the end of the decade using roughly the same materials and manufacturing techniques used today.

Here we review the progress in the research field of semiconductor three-dimensional-nanoscale transistors. In other words, we concentrate on those structures in which the length, the width, and the depth of the conduction channel are all in the nanoscale. A most prominent device is called the single-electron transistor, which can be metallic as well as

semiconducting [63]. It is to a large degree still a transistor in the conventional sense. It is, however, so small in size that it can handle one single electron at a time [64–66]. By typing the keywords semiconductor + single + electron + transistor in to INSPEC, you can find that the number of publications per year in this field is booming. Such an impressive advance is synchronous with the fast development of nanofabrication technology during the last decade by producing artificial three-dimensional semiconductor nanostructures using laser crystallization [67], zone-melting recrystallization [68], molecular-beam epitaxy [69], metal-organic chemical vapor deposition, and chemical-beam epitaxy [70]. Accurately controlled feature sizes as small as monolayers of atoms in the growth direction for dissimilar semiconductor materials, or heterostructure systems, have been achieved. Nanoscale lithography and patterning by electron-beam (EB) lithography have also been highly developed [71]. Twenty nm resolution of electron lithography for the nanodevices on ultrathin SOI film was reported [72]. Patterning metallic and semiconducting nanostructures using local oxidation mediated via a voltage between a conducting surface and a close-by tip of an atomic force microscope (AFM) was developed especially for III–V [73]. Scanning probe microscope (SPM) lithography, which uses a SPM as a pattern delineation tool, would be one of the most promising candidates for the mass production tool [74].

In the following sections, we go through semiconductor systems of III–V, VI, carbon nanotubes, and others like organic thin films [75].

2. THEORETICAL CONSIDERATIONS OF DEVICES

The first step of the transistor minimization is the reduction of the channel length. As discussed in the previous section, the effective channel length approaches 10 nm [76]. At the same time, the source and drain junction depths are also being drastically reduced. The thickness of the conduction channels in Si-based MOSFET and III–V-based high-electron mobility transistors (HEMTs) is only about 10 nm. On the other hand, the width of the conduction channel must be greatly reduced for the sake of total component miniaturization. Eventually the conduction channel is to take the form of a short quantum wire or, effectively, a three-dimensional quantum dot, with a nanoscale in its width, thickness, and length.

Let us try to elaborate the relevant physics. When transistors are down-scaled and their characteristic dimensions reach the nanometer regime, quantum effects become dominant [77, 78]. The size effects of nanometer structure devices are reviewed including drift velocity overshoot, the hot electron effect, and high field transport, and a single quantum well transistor [79] and then single quantum well devices (e.g., metal-insulator-semiconductor FETs [80, 81], single quantum well transistors [82, 83], and HEMTs [84], and AlGaAs/GaAs heterostructure bipolar transistors [85]) were proposed. For nanoelectronic devices, a spectrum of modeling tools of varying degrees of sophistication is required to meet the needs of the various stages of quantum device development [86]. Reviews of recent developments in experiments and theories of the Coulomb blockade phenomenon were given [87, 88].

Though orthodox-theory-based models can explain the principal physical features of the device characteristics, a large number of observations cannot be quantitatively understood. Theoretically, the reduction in the carrier transport route (conduction channel) results in greatly enhanced direct tunneling between the source and the drain. However, direct tunneling is not likely to be a principal reason for deteriorating the transistor function. A transistor having a 40-nm gate works at room temperature with a threshold bias of 0.4 V [9]. It was shown theoretically that the quantum effects improve the functionality. In one nanoscale MOSFET, the semiclassical method indicated a negative threshold gate bias, whereas quantum confinement effects hold the threshold gate bias at the reasonable circuit level [89]. In addition, the quantum effects also suppress the direct tunneling current significantly [90].

The most prominent effect appearing in a nanoscale transistor is of course the Coulomb blockade effect. When one electron arrives at the conduction channel, its Coulomb potential lifts up the local potential energy so that the later electrons become scattered. For a nanoscale conduction channel, the potential energy changes very significantly so that the scattering is very strong. In other words, the transport of other electrons becomes blockaded. Figure 4 shows a typical drain current as a function of the source-drain and gate voltages.

Theoretically, the Coulomb blockade process is more involved. We consider two electrons. As fermions, the total wave function of the two-electron system is written as

$$\frac{1}{\sqrt{2}}\begin{vmatrix} \psi_i(\mathbf{r}_1) & \psi_i(\mathbf{r}_2) \\ \psi_j(\mathbf{r}_1) & \psi_j(\mathbf{r}_2) \end{vmatrix} \tag{1}$$

because of the antisymmetric property, where $\psi_i(\mathbf{r})$ is the one-electron eigenstate. The matrix element of the Coulomb

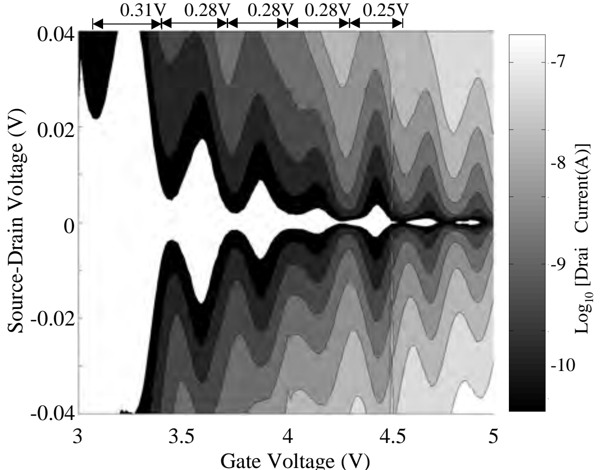

Figure 4. Drain current contour plot of a device at the source–drain voltage and gate voltage plane. The measurement temperature was 20 K. Reprinted with permission from [89], Y. Fu et al., *Superlattices Microstruct.* 28, 177 (2000). © 2000, Elsevier Science.

interaction between the two electrons is

$$V_{ij} = \frac{e^2}{4\pi\epsilon}\int d\mathbf{r}_1\, d\mathbf{r}_2 \frac{|\psi_i(\mathbf{r}_1)|^2|\psi_j(\mathbf{r}_2)|^2}{|\mathbf{r}_1 - \mathbf{r}_2|} - \frac{e^2}{4\pi\epsilon}\int d\mathbf{r}_1\, d\mathbf{r}_2 \frac{\psi_i^*(\mathbf{r}_1)\psi_i(\mathbf{r}_2)\psi_j(\mathbf{r}_1)\psi_j^*(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} \quad (2)$$

The first integral is the direct Coulomb interaction between two charges while the last one is the exchange energy.

Consider the case that one electron, ψ_i, already occupies the central conduction channel. Another electron ψ_j is in the source. The Coulomb interaction that electron ψ_j experiences is the direct Coulomb interaction, since the exchange energy is zero due to the spatial separation between ψ_i and ψ_j. The conclusion is valid when the number of electrons in the conduction channel is larger than 1.

However, the Coulomb interaction on electron ψ_j changes during its transmission from the source to the conduction channel. Consider that electron ψ_j arrives at the conduction channel. If the two electrons occupy the same energy state (i.e., $i = j$), it is immediately concluded that $V_{ij} = 0$. In other words, each energy state can be occupied by two electrons and the potential energy of the system is unchanged (the sum of the direct Coulomb interaction and the exchange energy is zero).

When $i \neq j$, assume that one state is s-type and the other is p-type. A cylindrical conduction channel can be divided into two identical parts, Ω_1 and Ω_2, according to the sign of the p-state. The spatial integration in the exchange energy becomes

$$\int_{\Omega_1+\Omega_2} = \int_{\Omega_1}\int_{\Omega_1} + \int_{\Omega_1}\int_{\Omega_2} + \int_{\Omega_2}\int_{\Omega_1} + \int_{\Omega_2}\int_{\Omega_2} \quad (3)$$

and notice that

$$\begin{aligned} F(\mathbf{r}_1 \in \Omega_1, \mathbf{r}_2 \in \Omega_1) &= -F(\mathbf{r}_1 \in \Omega_1, \mathbf{r}_2 \in \Omega_2) \\ &= F(\mathbf{r}_1 \in \Omega_2, \mathbf{r}_2 \in \Omega_1) \\ &= -F(\mathbf{r}_1 \in \Omega_2, \mathbf{r}_2 \in \Omega_2) \end{aligned} \quad (4)$$

where

$$F(\mathbf{r}_1, \mathbf{r}_2) = \frac{\psi_i^*(\mathbf{r}_1)\psi_i(\mathbf{r}_2)\psi_j(\mathbf{r}_1)\psi_j^*(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} \quad (5)$$

It is thus concluded that the exchange energy is zero when one electron occupies the s-state and the other electron occupies the p-state. The two electrons interact with each other via direct Coulomb interaction.

Here we see the necessity of the wave packet model on the electron transport, which makes the theoretical investigation extremely complicated. In the following, however, we review the progress of theoretical work thus achieved.

2.1. Semiclassical and Phenomenological Approaches

The Poisson equation and the master equation based on the semiclassical theory were used to analyze a SET with Schottky tunnel barriers [91]. Through solving a set of device equations, the basic characteristics of a nanoscale MOSFET were simulated and then analyzed [92]. A single-electron simulator was integrated into a SPICE-type conventional circuit simulator to study single-electron multiple tunnel junctions [93]. A kinetic approach based on a master equation models the injection and ejection of electrons into and from the quantum dot [94]. A reduced master equation analysis was discussed to avoid the computational cost of the full master equation method [95]. There was another phenomenological approach based on quantum mechanical considerations [96], and the model was further developed into the Monte Carlo model where the current is computed by counting the sequential tunneling of electrons through the energy level of the dot [97]. Circuit models have also progressed [98]. Using a master equation model and taking into account the discreteness of quantum levels and the finiteness of scattering rates, Saitoh and Hiramoto analyzed the Si SET [99]. The binding of equal numbers of electrons and holes on two islands of the coupled SETs leads to a Coulomb blockade due to the electron–hole pairs [100]. The single-electron tunneling junction was modeled by a nonlinear capacitor based on physics-based Monte Carlo simulations [101]. A simple SET model was obtained based on a numerical solution of the Poisson equation [102].

A semiclassical tunnelling model was developed where the tunnel rates through junctions are determined by directly calculating a golden rule equation [103]. A semiclassical numerical golden rule calculation for SET simulations was reported [104]. Zero-bias current in a SET was calculated based on the semiclassical model [105]. Photoirradiation effects in a single-electron tunnel junction array were calculated by a Monte Carlo method [106]. A self-consistent approach to the Poisson and Schrödinger equations was applied to calculate the confinement potential and determined the conditions for single-electron tunneling [107]. Similar self-consistent calculation was formulated to obtain the charging energy required to add a single electron to a quantum dot which is electrostatically coupled to leads and a gate electrode [108]. Quantum wave transport of carriers was studied numerically in a nanoscale n-Si MOSFET [109]. A linear-response approach to simulate the conductance of semiconductor single-electron transistors at the solid-state level was reported [110] and a multidimensional secant approach calculated self-consistent electron densities in a quantum dot weakly coupled to a macroscopic reservoir [111]. Vertical quantum dots were also studied [112]. Currents and their fluctuations in two capacitively coupled single-electron transistors were studied within the sequential tunneling approach [113]. The electronic transport properties of parallel coupled SETs at strong coupling under asymmetrical voltage bias were investigated theoretically, where it was found that the binding of electrons and holes on the two islands of the coupled SETs is the key element that governs the transport characteristics [114]. An extended Hubbard model with interdot electron–electron interactions was presented to study the conductance through a coupled triple-dot system [115]. Using a simple model of hard wall confinement potential for quantum dots, pillar-shaped quantum dots for single-electron tunneling transistors operating at higher temperatures were suggested [116]. Current-density-functional theory was used to calculate the

electronic structure of two-dimensional quantum dots containing up to 58 electrons [117]. Cotunneling and renormalization effects for the single-electron transistor were studied by a diagrammatic expansion of the reduced density matrix up to fourth order in the tunneling matrix elements [118]. The Monte Carlo method was used to simulate SETs including inelastic macroscopic quantum tunneling of charge [119].

As complicated as the quantum process is in SET, there was an analytical SET model for realistic SET circuits [120], and an analytical I–V model for SETs was set up to be incorporated into a conventional circuit simulator, such as SPICE [121]. A SPICE model for the single-electron tunnel junction was also set up [122]. The macroscopic modeling of silicon devices to include quantum mechanical corrections in the classical transport framework was discussed, and both device and circuit models were provided [123].

2.2. Nanosystem Designs

A silicon effective quantum dot was theoretically designed using oxidation-induced strain [124]. A SET on a SiGe/Si vertical structure transistor was studied with a side contact for easier control of the depletion region by the gate voltage [125]. The single-electron device was controlled using environmental impedance modulation [126].

2.3. Other Relevant Issues

Extended theoretical works were also published discussing quantitative two-dimensional carrier profiling in MOS [127], observation of quantum fluctuations of charge on a quantum dot [128], dynamic input capacitance of SETs, and the effect on charge-sensitive electrometers [129]. Non-Gaussian distribution on nearest-neighbor Coulomb peak spacings in metallic SETs was observed and attributed to impurity-specific parametric charge rearrangements close to the transistor [130].

2.4. Circuit Designs

There are extended works as well aimed at the design issues of the SET circuit (e.g., effects of quantum dot radii and densities on the fabricated memory characteristics) [131]. Considerations of the realization of a GLSI processor based upon nanoelectronic devices [132], massively parallel algorithms for simulating large-scale nanoelectronic networks based on the single-electron tunneling effect [133], and a single-electron device and circuit simulator with a new algorithm to incorporate cotunneling [134] were reported.

3. DEVICES BASED ON III–V SEMICONDUCTORS

3.1. Physical Processes

Individual hopping events in the flow of current (approximately one electron per second) along a single chain of localized states modulate the conductance of a ballistic constriction formed in a GaAs/$Al_xGa_{1-x}As$ split-gate transistor [135]. Besides the well-known Coulomb blockade effect, there are other related physical processes (e.g., Coulomb charging effects in an open quantum dot device) [136]. The Coulomb blockade effect from weak to strong coupling regimes was investigated in a small two-dimensional electron gas island in a AlGaAs/GaAs heterostructure [137].

3.2. Device Fabrications

Advances in the epitaxial synthesis of 10-nm-scale quantum dot (QD) and wire structures were reviewed recently [138]. The basic setup of the devices is the two-dimensional electron gas (2DEG) formed at the GaAs–AlGaAs or other III–V-based heterointerfaces. In general, the thickness of the 2DEG is about 10 nm. Different techniques have been developed to either isolate one small spatial region ($\sim 100 \times 100$ nm^2) of the 2DEG (quantum dot) from the rest 2DEG or first form a narrow quantum wire (about 100 nm wide) and then cut the wire into pieces. The advantage of thus fabricated quantum dots is the precision control over the spatial position of the dot. However, the dot size is large (about $100 \times 100 \times 100$ nm^3). The second category of forming the quantum dots is epitaxially growing a monolayer material on a lattice-mismatched substrate. The monolayer material self-assembles into small quantum dot structures due to the lattice mismatch. The most successful system is self-assembled InAs quantum dots on GaAs which has already been widely used in optoelectronics. The dot size can reach $10 \times 20 \times 20$ nm^3. However, the spatial positions of the dots cannot be properly controlled. Moreover, the dot size is not uniform.

3.2.1. Multiple Gates

With a suitable bias, a metal gate can deplete the carriers underneath. By configurating the geometry of the gate or using multiple gates, quantum dot or quantum wire can be fabricated out of the 2DEG. Multiple-gate quantum dot devices on shallow GaAs–AlGaAs heterostructures were reported [139]. A SET was formed by placing a nanoscale single barrier inside the gap of a conventional split-gate FET [140]. Two tunnel barrier gates for quantum wire and a center gate for a quantum-dot-potential control were applied to fabricate a GaAs-based SET which showed a proper inverter operation at 1.6 K and realized a logic transfer gain of larger than unity (1.3) [141]. Capacitively and resistively coupled single-electron transistors were fabricated using GaAs/AlGaAs 2DEGs and metal Schottky gates [142]. The device configuration is schematically represented in Figure 5. The basic idea is that gates V_1, V_2, V_3, and V_4 deplete the carriers underneath so that the carriers surrounded by the gates become spatially isolated, forming the desired quantum dot. Gates V_{g1} and V_{g2} control the number of carriers in the quantum dot region. A chromium thin-film resistive gate was connected directly to the mesoscopic island formed between two ultrasmall Al/AlO_x/Al tunnel junctions forming a resistive SET [143]. A parallel quantum-dot configuration defined by multiple gates in the two-dimensional electron gas of a GaAs–$Al_xGa_{1-x}As$ heterostructure was reported [144].

3.2.2. Etching and Selective Molecular Beam Epitaxy

The electric field created by a metal line is very diffused so that the quantum dot system fabricated by metal gates is first of all shallow. Second, the space of the depleted

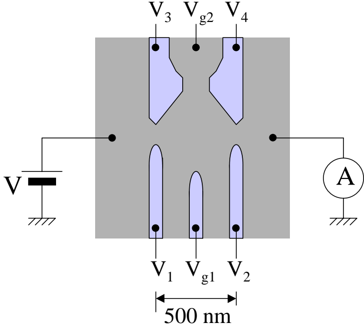

Figure 5. Schematic configuration of a typical multiple-gate SET system with measurement setup. Reprinted with permission from [142], F. Wakaya et al., *Superlattices Microstruct.* 27, 603 (2000). © 2000, Elsevier Science.

area is also wide so that it is difficult to have a good coupling between carriers confined in the quantum dot and in the surrounding area. Etching and selective molecular beam epitaxy (MBE) growth are used to shape the 2DEG into a quantum wire structure with well-defined edges. A typical example is demonstrated by Figure 6, where a quantum wire having a cross section of only 80×10 nm^2 was produced and a GaAs/InGaAs/AlGaAs-based SET thus formed showed clear Coulomb-blockade oscillations [145]. The SET has been designed by three-dimensionally solving Schrödinger and Poisson equations [146].

A SET was produced by etching narrow trenches in a AlGaAs/GaAs heterostructure and defining a channel and six in-plane gates in the two-dimensional electron gas [147]. Using electron-beam lithography and reactive ion etching, conducting wires, rings, and dots with lateral dimensions ~50 nm were fabricated [148]. A parallel dot structure was also fabricated [149]. The SET structure is schematically represented in Figure 6. InGaAs coupled quantum structures were grown by selective MBE on specially designed patterned InP substrates [150]. By mechanically scratching the surface of a GaAs/AlGaAs heterostructure with an AFM, an energy barrier for the two-dimensional electron gas is formed, and thus the SET was formed [151]. The AFM was used for its very accurate movement to position the prefabricated nano-objects into a small gap between two metal electrodes [152]. Fundamental results obtained in an AFM chemically induced direct nanolithography process were presented for fabricating nanoscale devices such as SETs and quantum effect electronic devices [153].

3.2.3. Point Contacts

Side-gated point contact structures in delta-doped layers have been used to form single-electron tunnel junctions [154]. Point contact MOSFETs with extremely narrow channels showed Coulomb blockade oscillations at room temperature, and at low temperatures, negative differential conductances and fine structures are superposed on the device characteristics [155].

3.2.4. Self-Assembly

Self-formed GaAs quantum nanostructures are realized by selective area (SA) metal organic vapor phase epitaxy (MOVPE) [138]. Semiconductor nanostructures are realized by patterning AlGaAs/GaAs heterostructures with an AFM [156, 157]. Quantum dots were fabricated by MBE on prepatterned GaAs substrates [158–160]. Quantum antidot arrays of circular shape by etching and quantum wire transistors were fabricated on InAs/$Al_{0.5}Ga_{0.5}Sb$ heterostructures [161]. Vertical quantum dot single-electron resonant tunneling transistors were reported which move from the few-electron to the several- and many-electron regimes to study the spin-polarized droplet [162]. Negative differential resistance due to the spin-polarized detection of electrons combined with a long spin relaxation time in the dot was reported in the SETs containing a few electrons and spin polarized source and drain contacts were formed in GaAs/GaAlAs heterojunctions using metallic gates [163].

Electronic and optoelectronic properties of self-assembled semiconductor structures were studied [164, 165]. A single self-assembled InAs dot in split-gate delta-doped channel transistor structure was reported [166].

3.2.5. Combination of Techniques

Nanostructures were formed in InGaAs-based modulation doped heterostructures using Ga focused ion beam implantation [167]. A SET was fabricated by current-controlled local oxidation of a two-dimensional electron system [168]. A quantum point contact was defined by lithography with an AFM and subsequent wet-chemical etching [169]. Laser-written *p*-doped lines were used to define a dot with a diameter of about 70 nm and to insulate it from the in-plane gates [170]. SETs with asymmetrical tunnel barriers were proposed [171].

Self-assembling InAs quantum dots were formed in combination with SA-MOVPE on masked (001) GaAs substrates [172]. AFM oxidation was applied for the direct oxidation of a thin InAs layer to fabricate a SET from an InAs/AlGaSb heterostructure [173]. A single self-assembled InAs dot in a split-gate delta-doped channel transistor structure was reported [174]. Experimental and simulated results of a room temperature single-electron transistor formed by an AFM and scanning tunneling microscopy (STM) nano-oxidation process were reported [175].

3.2.6. Traps

The current through transistor switches between trapping and detrapping of a single electron in the trap level was studied [176], and random telegraph signals from these traps using a SETT formed in the GaAs/$Al_xGa_{1-x}As$ heterostructure were studied [177].

3.3. Characterizations

There are a number of very effective ways to characterize the SET devices: nondestructive room temperature characterization using contactless photoreflectance [178], electromodulation and surface photovoltage spectroscopy [179], transport spectroscopy [180], complex impedance spectroscopy and scanning tunneling spectroscopy [181], SET capacitance spectroscopy to measure the flow of charge to and from a quantum dot [182]. Noise of single-electron transistors was measured using a transimpedance amplifier [183]; shot noise in Si-based single-electron transistors was measured in 2–12 MHz at 1.5 K with a lock-in technique [184].

3.4. Applications

A charge transformer was proposed for noise matching single-electron transistor amplifiers to high-capacitance devices [185]. Present status and future prospects of resonant tunneling hot electron transistors (RHETs) were discussed to develop room temperature quantum functional bipolar transistors and quantum box devices based on the RHET technology for the ultrasmall limit of electron devices [186].

A transmission-type radio-frequency SET (rf-SET) based on an AlGaAs/GaAs heterostructure was tested and its application to investigating high-frequency (up to 1 MHz) charge noise in an AlGaAs/GaAs quantum dot [187] was reported. Double quantum dots were used as a highly sensitive submillimeter-wave detector [188].

4. DEVICES BASED ON IV SEMICONDUCTORS

4.1. Theoretical Considerations

The quantum gates of coupled quantum dots were studied theoretically when charging effects can be observed, which shows that the charged states in the qubits can be observed by the channel current of the MOSFET structure [189]. A strain-induced effective Si quantum dot was theoretically proposed [124]. A Si SET was studied by solving a master equation, assuming that the potential barrier has a parabolic potential [190].

4.2. Device Fabrications

A brief survey of different realizations of single-electron devices fabricated in SOI films was presented [191]. For industrially acceptable techniques, a contact pattern mask with nanometer-size slits was fabricated by combining conventional photolithography with anodic oxidation of metal sidewalls [192]. There are quite extended fabrication methods: reducing MOSFET size [193], a SET with a single-island format [194], Si nanoscale point contact channels on the SOI substrate showing room temperature Coulomb blockade [195], 10-nm-scale lithographic techniques to fabricate electrically variable shallow junction MOSFETs, and lateral hot-electron transistors which predict the limitation of MOSFET miniaturization to be around 5 nm in the source-drain tunneling scheme [196]. Since nanoscale-gate-length MOSFET devices require extremely shallow source/drain extension regions with a junction depth of 20–30 nm [2], a 70-nm n-MOSFET fabrication with 12 nm n^+–p junctions was reported by using As_2^+ low energy ($\leq$10 keV) implantation [197]. Due to the limitation of SiO_2 as the gate insulator, an organic self-assembled monolayer of alkyltrichlorosilanes was used as the gate insulator in a hybrid organic/silicon nanometer-size FET having a gate length of 25 nm [198]. MOSFETs with single {111}-facetted silicide/silicon joints have been fabricated on SOI substrates using cobalt silicide for reducing the series resistance [199].

4.2.1. Multiple-Gate Systems

Periodic current oscillations due to the single-electron charging effect have been observed in a Si quantum dot realized in the inversion layer of a Si-MOSFET with a dual-gate structure [200]. Multiple-gate [201] and side-gate systems [202, 203] were also studied. A strong suppression of short-channel effects at room temperature and clear conductance oscillations at liquid helium temperatures on a submicrometer MOSFET equipped with a gate on three sides of the channel were reported [204]. The fluctuations of Coulomb-blockade peak positions were studied in a Si quantum dot defined by patterning the 2DEG of a silicon MOSFET using stacked gates [205]. Metal based SETs were also reported [206, 207]. Ultrasmall quantum dots were formed in SOI material by a metallic top gate and an in-plane gate [208]. A SET was formed with two gate inputs [209]. There were also split-gate Si MOS quantum dot structures [210]. A dual-gate-controlled SET with coupled dot geometry was fabricated on a SOI structure [211].

Later on, modification of the tunneling barrier in a nanocrystalline silicon SET due to different oxidation processes was investigated [212].

4.2.2. Etching and Lithography

EB lithography [213], reactive ion etching (RIE), and thermal oxidation [214] are normally standard in Si-based systems [215]. Si nanodot and nanowire memory transistors with side gates were fabricated using an inorganic EB resist process [216]. Transistors consisting of quantum dots formed using EB nanolithography and RIE show the oscillation of the drain current as a function of the gate voltage at temperatures up to 170 K and drain biases up to 80 mV [217]. Single-charge detection in Si-wire MOSFETs fabricated on a SOI wafer was investigated [218]. Two potential barriers were induced by direct EB irradiation [219]. Atomic fabrication of a silicon based quantum computer was demonstrated [220]. More delicate recipes of SET by combining different techniques including dry etching, inductively coupled plasma sources, and a self-aligned process with a shadow mask were reported [221]. A SET was obtained by bonded and etched back silicon on insulator material [222]. A Si quantum wire with a gate-electrode and a Si SET using SIMOX substrates and electron-beam lithography

were reported where quantized conductance in the wire up to 100 K and periodic conductance oscillation in the SET at room temperature were clearly observed [223, 224]. A similar system was reported elsewhere [225]. A Si SET was fabricated using EB nanolithography combined with an image reversal process and a dry etching technique for room temperature operation [226]. Anisotropic etching was developed to fabricate Si nanostructures for SET applications [227]. SPM-based fabrication techniques of nanostructures by local oxidation of silicon in ambient atmosphere were investigated [228]. Imprint lithography in polymethylmethacrylate on silicon and on gold substrates was reported to have a feature size of sub-10 nm [229]. The inevitable parasitic MOSFETs on Si SETs, which were fabricated in ultrathin Si of a SOI substrate by pattern dependent oxidation (PDOX), were carefully studied and their effects on SETs were found to be reduced by the back gate [230]. A SETT was fabricated by EB lithography, anisotropic RIE, and low temperature oxide deposition [231]. Doped-thin-Si-film SETs were fabricated from a highly doped Si film in a SOI substrate by EB lithography with a high-resolution resist (calixarene) and dry etching with CF_4 gas [232]. A novel method of fabricating a nanoimprinting mold for a single-electron device was proposed which makes use of the peculiarity of anisotropic wet chemical etching [233]. There were also Si nanodevices by optical lithography [234].

4.2.3. Point Contacts

Silicon SETs have been fabricated in the form of point contact MOSFETs with various channel widths using EB lithography and anisotropic etching techniques on SOI substrates [235], which is schematically presented in Figure 7. The dot size, as small as 5.3 nm in a silicon point contact channel, showed a negative differential conductance due to quantum levels up to 25 K [236]. For a similar point contact MOSFET and the gate oxide by CVD instead of thermal oxidation, it was found that the single-electron addition energy is about 259 meV and the dot diameter is less than 4.4 nm [237]. A Si SET with in-plane point contact metal gates was reported [238].

4.2.4. Si Nanocrystals

Rather early there was a report about silicon islands by laser recrystallization [239]. A nanoscale polysilicon dot as the floating gate embedded between the channel and the control gate was used to fabricate a room-temperature silicon SET memory [240–243]. Si SETTs with nanoscale floating dot gate stacked on a Coulomb island by a self-aligned process [244]. A two-terminal nanocrystalline silicon memory device at room temperature was reported [245]. A self-assembled Si quantum dot transistor was fabricated showing room-temperature oscillations in the drain current [246]. Storing electrons in and erasing from Si nanocrystal dots of diameter 8 ± 1 nm deposited by plasma decomposition of SiH_4 were demonstrated in dot-based memory devices at 77 K [247].

A novel memory was based on nanocrystalline Si which acts as a floating gate in large area MOSFETs [248] and a single polysilicon dot was defined by EB lithography over a narrow SOI channel [242, 248, 249]. Si nanocrystals were deposited by very-high-frequency plasma decomposition of silane, resulting in an average dot diameter of 8 nm and a source–drain electrode separation of 30 nm, and a gate electrode is employed so that the charge states in quantum dots can be controlled [250] (see Fig. 8). Si SET memory using a multiple-tunnel junction was also fabricated by EB direct writing [251], and the experimental works have been carefully analyzed theoretically [252–255]. The nanocrystal was then further processed into single-electron nonvolatile memory devices [256]. Microcrystalline silicon thin films were prepared at 300 °C on glass and its application to SET was investigated [257]. A germanium nanocrystal quasi-nonvolatile memory device which consists of a MOSFET with Ge charge traps embedded within the gate dielectric was reported [258]. The electron charging or discharging of the silicon QDs in MOSFETs with the QD layer floating gate were utilized for memory operation [259]. The operation of a Si MOSFET with an array of Ge self-assembled QDs embedded into the active channel showed oscillations caused by Coulomb interaction of holes at $T \leq 200$ K [260]. The device is not only limited to SETs. A double-SiO_2-barrier MOSFET with a poly-Si dot was reported [261]. Si quantum dots fabricated by PDOX in silicon [262], and the origin of the potential profile in such silicon SETs, were investigated by making use of the geometric structure measured by AFM, the bandgap reduction due to compressive stress generated during PADOX

obtained using a first-principles calculation, and the effective potential method [263]. Electrochemically etched silicon was dispersed into a colloid of ultrasmall (about 1 nm) silicon nanoparticles [264]. Nanocrystalline Si dots were also formed by annealing a thin film of SiO_x ($x < 2$) with which room-temperature single-electron narrow-channel memory with silicon nanodots was obtained [265]. Silicon nanocrystal was also used as floating gates to control Coulomb blockade oscillations in silicon SETs [266]. High-spatial-density nanocrystals were formed using a thin layer of amorphous $Si_{0.7}Ge_{0.3}$ deposited on SiO_2 [267]. SETTs were composed of thin polycrystalline silicon films patterned by EB lithography and thermally grown oxidized film [268].

4.2.5. Combination of Dual-Gate and Nanocrystal

Fabrication and low-temperature transport properties of dual-gated SETs were studied based on a QD formed by SA growth of MOVPE [269]. SETs were fabricated in solid phase crystallized polycrystalline silicon films deposited on SiO_2 layers grown on silicon substrates and lateral side-gated nanowires [270]. In a trench (150–600 nm wide) defined inside a large "inversion" gate electrode into which nanocrystalline Si (8 ± 1 nm diameter) was deposited by remote plasma enhanced chemical vapor deposition, a two-gate single-electron memory device with an active area of 1.5×10^{-10} cm^2 was processed to study the Si/SiO_2 interface in SOI nanoscale channels and nanocrystalline Si dots [271].

4.2.6. Impurity and Trap

In 1988, Uren et al. discussed the random telegraph signal in the drain current of submicrometer Si MOSFETs and suggested sequential two-electron capture involving individual Si/SiO_2 interface states which can exist in two or more charge-equivalent, metastable states [272]. The Coulomb energy induced by the transfer of a single electron into an interface trap in MOSFETs was measured by random telegraph signals [273]. Coulomb blockade of a single quantum dot formed by an impurity potential in low-mobility, nanometer size Si MOSFETs was reported [274].

4.3. Characterizations

Low-dimensional p-channel Si MOSFETs with a source/drain width of 100 nm formed by selective focused-ion-beam implantation were fabricated and Coulomb blockade phenomena were examined as a function of channel length [275]. A similar technique was used to fabricate SETs operating at room temperature [276]. Influence of background charges on Coulomb blockade in quantum dots was studied in order to understand the sensitivity of the system to changing background charges due to freezing out or capture of single electrons in the vicinity of the devices in the substrate or the buried oxide of the SOI material [277]. The potentialities of different techniques for detecting signals from barrier structures in a scanning electron microscope were discussed [278]. A silicon nanowire memory utilizes surface charging and its operation analysis by scanning Maxwell-stress microcopy [279]. Oxide trap properties were extracted from the temperature dependence of random telegraph signals in submicrometer MOSFETs [280]. Random telegraph noise was used to study the Coulomb blockade phenomena at room temperature [281]. Si nanostructures were characterized by cross-sectional transmission electron microscopy [282]. There were discussions about strategies for measuring currents from single-electron devices [283]. An asymmetric tunnel barrier in a Si SET was characterized from the strong asymmetry in conductance versus source–drain voltage [284].

4.4. Circuit Applications

From the engineering point of view, it was concluded that memories seem to be one of the most promising large scale SET applications, particularly when granular films are used, in the range of today's process technology [285]. A silicon single-electron memory consisting of three integrated silicon nanowires was demonstrated [286].

On the circuit level, a programmable NAND/NOR logic gate, threshold logic gates, and parallel counters using resonant tunneling transistors were reported [287]. Boolean logic functions were implemented in the so-called quantum-dot cellular automata [288]. A merged SET and MOS transistor logic was introduced for a SET-to-CMOS interface circuit as well as for a basic element for multiple-valued functions [289, 290]. A Si complementary single-electron inverter with two identical SETs was fabricated on a SOI substrate, and input–output transfer with a voltage gain larger than unity is demonstrated at 27 K [291]. A silicon SETT, which shows an inverting voltage gain greater than unity and as high as 3.7, has been fabricated [292]. Voltage gain of Si SETs fabricated by PDOX was investigated and used to evaluate the performance of the n-MOS type inverter with resistive load [293]. There was also vertical PDOX [294]. The SET was used as a Schmitt trigger with excellent noise immunity [295]. Programmable SET logic was demonstrated for low-power intelligent Si large-scale integration [296]. Silicon-based few-electron memory operated with write times as short as 10 ns and voltages of less than 5 V at 4.2 K, and operation persisted to 45 K [297]; then a 3×3-bit Coulomb blockade memory cell array was demonstrated [298]. MOS-integrated metallic single-electron memories were also reported [299].

Multiple-valued memory operation was successfully demonstrated by combining a SET and a MOSFET which is schematically shown in Figure 9 [300], where the source of the MOSFET with a fixed gate bias V_g is connected to the drain (d) of the SET. As discussed previously, the SET drain current I_d increases and decreases periodically as a function of the SET gate bias V_{gs} (the SET source, s, is grounded; see Fig. 9). However, the I_d has such a large dependence on the drain voltage V_{ds} that the peak current is almost proportional to V_{ds}, and the valley current increases more rapidly when the Coulomb blockade breaks. The MOSFET connected to the SET eliminates this large V_{ds} dependence by keeping V_{ds} nearly constant around $V_g - V_{th}$, where V_{th} is the threshold voltage of the MOSFET. This $V_g - V_{th}$ is set low enough to sustain Coulomb blockade. By connecting the SET gate to the MOSFET drain, the peak negative differential resistance (NDR) characteristic in Figure 9b is obtained. If a constant-current source I_0 is connected to the

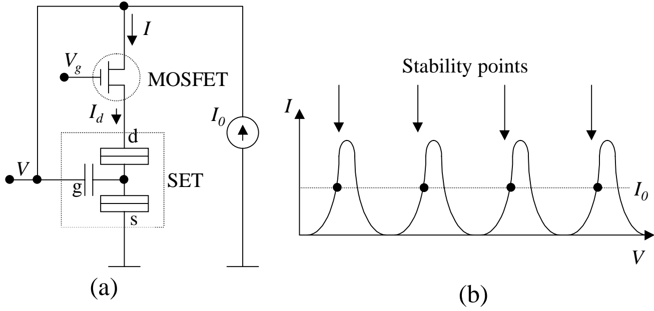

Figure 9. (a) Schematic drawing of the multiple-value NDR device comprising a SET and a MOSFET. (b) Expected I–V characteristics of the device. Reprinted with permission from [300], H. Inokawa et al., *Appl. Phys. Lett.* 79, 3618 (2001). © 2001, American Institute of Physics.

combined SET-MOSFET device, the periodic nature of the I–V characteristics results in a number of stability points, which enables multiple-valued memory operation. The number of peaks is infinity in principle but is in practice limited by the breakdown voltage of the MOSFET drain or SET gate. Another SET application is the so-called exclusive-OR (XOR) function as shown in Figure 10 by utilizing the oscillatory conductance characteristics due to the Coulomb blockade [301].

There was SET-based circuit design [302], and a new strategy of constructing logic trees with SETs and their complementary SETs both working as pull-down devices was reported [303]. In the case of arrays of nanometer-size metallic dots on a SiO_2 substrate, a drastic reduction of the V_{th} dispersion in these highly disordered arrays can be achieved by a special design [304]. A single-electron neuron device was described [305]. The low-charge limit in SET memory devices was discussed [306]. A single-transistor memory structure, with changes in threshold voltage exceeding approximately 0.25 V corresponding to single-electron storage in individual nanocrystals, operating in the sub-3 V range, and exhibiting long term to nonvolatile charge storage, was reported [307]. Concerning the low driving capability of SET devices, it was experimentally demonstrated that the direct transmission of SET signals to the conventional MOSFET current is possible, so that the output impedance can be transformed locally or globally from high to low in the SET-device circuits hybridized with CMOS devices [308]. A cryogenic voltage amplifier using GaAs FETs couple to a superconducting SET inside a dilution refrigerator was developed to extend the maximum output

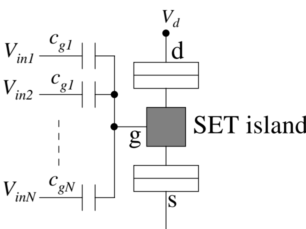

Figure 10. Multi-input-gate SET that implements the XOR function. Reprinted with permission from [301], Y. Takahashi et al., *Appl. Phys. Lett.* 76, 637 (2000). © 2000, American Institute of Physics.

frequency of the SET, normally less than a kilohertz, up to 1 MHz [309]. SET based on a gated silicon nanowire has been used to make a memory together with an electrometer detector to read the memory state [310]. EEPROM based on Si quantum dots on oxide–nitride tunneling dielectrics was fabricated [311].

A design of an optically driven quantum dot quantum computer was proposed based on n-type SETs [312].

Fundamental calculations on the circuit level were conducted: Effects of dot size and dot size distribution on electron number control in silicon floating dot memories at room temperature were investigated by numerical calculation [313]. A functionally complete set of complementary logic circuits based on capacitively coupled single-electron transistors (CSETs) was numerically simulated [314]. A high-speed simulation technique for logic circuits comprising SETs was proposed [315]. A new complementary digital logic based on resistive CSETs was proposed and its basic characteristics were numerically analyzed using the Monte Carlo method [316]. The use of nanoelectronic structures in cellular nonlinear network architectures, for future high-density and low-power CMOS-nanodevice hybrid circuits was simulated [317]. An approach to computation with single-electron circuits was discussed in which information encoded in sensitive circuit signatures was adaptively tuned by adjusting circuit variables to achieve a computationally useful goal [318]. Simulations of SET memory were discussed based on experiments and achievable nanotechnologies [319]. Simulated annealing was proposed as a simulation method for single-electron tunneling devices and circuits, with acceptable computation time when cooling schedule and cooling parameters are appropriately chosen [320].

4.5. Single Hole Transistors

An electron-based SET is normally concentrated. However, studies on hole-based systems were also conducted (e.g., single-hole transistors [321, 322], room-temperature single-hole silicon memory cells [323]). At $4 < T < 100$ K, single-electron and single-hole transport through the lithographically defined dot were reported [324]. Dual-gate quantum dot transistors have been fabricated in n- and p-type strained SiGe on SOI [325].

5. NITRIDE AND OTHER SYSTEMS

5.1. GaN

GaN quantum dots were formed on an AlGaN/SiC substrate by gas-source molecular beam epitaxy using a self-assembling technique with Ga droplets showing Coulomb blockade phenomena with negative conductance at 2.7 K and a clear Coulomb staircase at 200 K [326].

5.2. SiN and SiC

High-density Si pillars were formed using thermally grown SiN nuclei and furnace oxidation [327]. Silicon nitride barrier layers of 2 nm thickness were used to form silicon nanopillars for SET [328]. Multiple-valued memory operation was reported in SiN-based single-electron memory

[329]. Single-electron memory using carrier traps in a silicon nitride layer was reported [330].

Single-hole transistor operation and infrared induced emission were obtained with 6H-SiC diffusion nanostructures [331].

5.3. Carbon Nanotubes

Electronics of single-wall carbon nanotubes was discussed [332, 333]. A 0.4 μm long semiconducting single-walled carbon nanotube reveals single-electron charging at temperatures up to 160 K [334]. Similar works were reported [335]. A SET was fabricated using the single-wall carbon nanotube grown directly on to the Si AFM tip and TiO_x lines as the tunnel junctions which showed room temperature Coulomb oscillation with periods of 1 V [336]. The Coulomb blockade effects were observed in a metal-on-tube metal/multiwall carbon nanotube/metal structure (metal = Ti or Pt/Au) [337], and a multiwalled carbon nanotube between two gold electrodes at the SiO_2 surface [338]. Electrical transport properties of intramolecular *p*–*n*–*p* junctions formed on individual semiconducting carbon nanotubes were reported, and well-defined and highly reproducible SETs with much smaller size than the geometrical length of the nanotube were obtained [339]. Single-electron tunneling through amorphous carbon dots array was reported [340].

5.4. Molecular Devices

A molecular device based on single molecule (Fig. 11) [341–344] or molecular strands [345–347] has been advancing rapidly. The possibility of atom/molecule switching devices, atom relay transistors (ART), and molecular single-electron switching with total dimensions of a few mm and an operation speed of more than terahertz (10^{12}) to supersede the present MOS devices and to establish the new era of atom electronics were discussed [348], and devices based on ART will be important in switching speed performance [349]. Quantum computing devices implemented into the same substrate as the widely used LSI circuits are discussed [350]. A variety of molecular organic semiconductors have been investigated for electronic applications [351].

5.5. Metallic Devices

Single-electron memory utilizing a Schottky in-plane gate quantum wire transistor with nano-Schottky metal dots whose position and size can be precisely controlled was

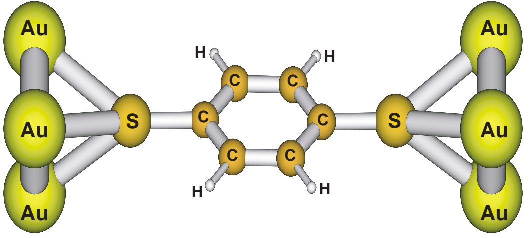

Figure 11. Structure of a single molecular device connected to two atomically sharp gold electron reservoirs. Reprinted with permission from [408], Y. Luo et al., *J. Chem. Phys.* 117, 10283 (2002). © 2002, American Institute of Physics.

realized [352]. The offset charge noise in metallic SET devices fabricated on dielectric substrates was experimentally studied [353, 354]. Background charge rearrangements in metallic SETs were modeled in two-level tunneling systems as a Poisson process [355]. A SET was made from a cadmium selenide nanocrystal [356].

Metal-based SETs were fabricated by the step-edge cutoff process [357]. An aluminum SET was bonded to an InP HEMT for high frequency applications [358]. There were multilevel SET devices with Au–SiO–Al and Al–AlO_x–SiO–Al overlap capacitors [359]. And a self-aligned metallic SETT was fabricated on a separated-by-implanted-oxygen substrate, where an array of 10–50 gold islands of 1–3 nm diameter was isolated between source and drain electrodes on a silicon nanowire [360]. Fabrication of metallic SETTs has been developed using different lithography steps for the preparation of the different layers [361]. A few tens of nm wide oxidized metal line was formed using a STM tip and an AFM cantilever as a cathode, which works as an energy barrier for an electron in SETs [362].

5.6. Ferromagnetic Devices

There was also ferromagnetic dot structure embedded in split-gate quantum wires on AlGaAs/InGaAs/GaAs pseudomorphic HEMT by two-step surface modification with STM [363].

6. OTHER SINGLE-ELECTRON TRANSISTOR APPLICATIONS

Besides circuit applications, the status of the understanding of SET devices with respect to their applicability in metrology was reviewed [364], and the study of SET for metrological application was conducted [365]. Electron pumps consisting of two Coulomb blockade devices have been realized using highly doped SOI material [366]. The behavior of a single-electron pump operated by sinusoidal signals was analyzed [367]. SETs were studied as far-infrared photon detectors [368]. A modified rf-SET technique was proposed to measure the transmission of the rf signal, having advantages such as simpler circuits and clear frequency resonance as compared with the reflection measurement by rf-SETs [369]. Charge sensitivity of rf-SETs was discussed [370]. Constructed with highly doped silicon nanowires, an electron detector can recognize the presence or absence of a single excess electron on a storage node at a temperature of 4.2 K [371]. Quantum dot structures measuring Hamming distance for associative memories were proposed and analyzed [372]. A scanned probe microscope capable of mapping static electric fields and charges with 100-nm spatial resolution and a charge sensitivity of a small fraction of an electron was reported using SETs [373]. Aluminum SETs were used to measure, with extremely high sensitivity, the fluctuation of charge in semiconductor quantum dots [374]. A SET has been used to detect chemical potential variations of the 2DEG [375, 376]. Si nanocrystals in close proximity (1.5–4.5 nm) of a transistor channel lead to plateaus in

Dual-gate and nanocrystal	Si, SiO_2, and SOI	dual-gate and selective area MOVPE [269], remote plasma enhanced chemical vapor deposition [271]	1.5×10^{-10} cm^2 [271]	
Impurity and traps	Si/SiO_2 interface states	Si MOSFET [272–274]	submicrometer [272], nanometer [274]	

threshold voltage at low temperatures due to single-electron effects [248]. The process of evolving from the few-electron regime to the several-electron regime, and then the many-electron regime, was studied in an artificial-atom vertical SET [377]. A SET was used to measure the superconducting energy gap as a function of the external magnetic field for various samples of mesoscopic sizes [378]. The influence of electron-beam writing on the creation of charge trapping centers which cause $1/f$ noise in SETs was discussed [379]. Single-electron tunneling transistors were used as electrometers to verify proper switching of the quantum dot cellular automata cell [380]. A SET electrometer was used to measure the destruction of charge quantization in a single-electron box [381]. Phase-coherent transport was studied in T-shaped quantum dot transistor [382].

7. FUNDAMENTAL PHYSICS

In addition to the device-application-orientated research, fundamental physics investigation utilizing SET devices has also been extensive. Transport in silicon/germanium nanostructures was studied [383]. Strain caused by inserting $Si_{1-x}Ge_x$ can significantly improve the device performance; it is also compatible with existing Si industrial technology [384]. Cotunneling thermopower of SETs was studied [385]. Electron–electron interaction to the high energy tail of the electron energy distribution was studied in nano-MOSFETs [386]. Spring constant and damping constant tuning of nanomechanical resonators using a SET was reported [387]. The lifetime of the emission of a single electron stored in a nanocrystalline Si dot has been studied [388]. Quantum chaos observable in both open and closed systems realized in $GaAs/Al_x/Ga_{1-x}As$ microstructures was reviewed [389]. Dynamical offset charges in SETs were investigated [390]. Kondo physics in the SET with ac driving was studied using a time-dependent Anderson Hamiltonian [391], and measurements of the Kondo effect on SETs were reported [392], reviewed, and compared with theoretical analysis [393]. There were works on the temperature dependence of $k_B T_c$ noise in Coulomb blockade regime [394], quantum storage effects in n-AlGaAs/GaAs heterojunction FETs with embedded InAs QDs between the gate and 2DEG [395] (similar work was reported by [396]), Fano resonances in electronic transport through a SET [397], spin-dependent Coulomb blockade in a SOI-based SET [398], single-spin measurement using SETs to probe two-electron systems [399], and single-electron–hole recombination and photon-pumped current in an asymmetric Si SET [400]. Temperature and voltage dependence of the cotunneling current were analyzed in comparison with inelastic cotunneling theory [401]. The electron–phonon coupling in SETs was studied [402]. Magnetotransport properties of an AlGaAs/GaAs double-barrier resonant tunneling transistor with sub-μm lateral dimensions (where lateral confinement causes quasi-zero-dimensional quantization) were studied [403]. Photocurrent generation in single-electron tunneling transistors was studied theoretically [404]. Confinement enhancement induced by the charge distributed in the floating dot on top of a channel quantum dot in stacked quantum dot transistors was carefully examined [405]. The resistively coupled SET was studied including the Nyquist noise of the coupling resistance [406]. The displacement current in SET was calculated [407].

8. SUMMARY

The rapid advancing information technology demands reductions in the chip size and increases in the density of components per IC. The chip component density has been following Moore's law and doubled roughly every other year over the last three decades. A most prominent discrete component that already reaches nanoscale is the single-electron transistor, which to a large degree functions like a conventional transistor but is so small that it handles a single electron at a time.

The SET has been extensively studied. Its current research and development are largely concentrated on the device design and optimization. There are basically two types of quantum dots in SETs. The first type of quantum dot is defined by either gates or etching, with the advantage of position control and the disadvantage of large dot size. Small dot size is required for high temperature operation. The second type of quantum dot utilizes the self-assembling process of crystalization of one semiconductor on a different one (e.g., Si nanocrystals on SiO_2 and InAs quantum dots on GaAs substrate). The dot size is very small, but the dots are randomly positioned. Precise control over the dot spatial position is required for IC fabrication.

Tables 1 and 2 list details of important III–V and VI semiconductor materials/heterostructures used for fabricating nanoscale transistors, fabrication processes, Coulomb blockade temperature and feature size, and published major applications of these devices.

GLOSSARY

Coulomb blockade When the spatial area that contains the electron charges is small enough, an extra electron charge added to the area significantly increases the Coulomb potential energy of the area so that this area becomes a classical-forbidden region for other electron charges (blockaded).

Moore's law The chip component density of an IC roughly doubles every other year.

Nanofabrication technology To produce low-dimensional feature size in the nanoscale. Molecular beam epitaxy is one example that can grow one-dimensional structure with atomic monolayer (about 0.2 nm) feature size. Current quantum dot self-assembly can produce a three-dimensional quantum dot artificial atom with a volume of 1000 nm^3.

Scale of integration The complexity of a logic system is represented by its component density. A circuit containing between 100 and 1000 logic gates is classified as a large-scale integrated circuit; a circuit with more than 1000 gates (up to 100,000 or more) is classified as a very-large-scale integrated circuit. Processes that produce more than 10^6 devices on an IC are classified as ultra-large-scale integrated circuits.

Single-electron transistor A transistor that is small enough to handle one electron at a time.

1. INTRODUCTION

The demands for faster operation and less heat dissipation are among the major factors determining the development of modern electronics. The trend toward miniaturization, dominating the technological progress of the past decades, corresponds to these needs. There is, however, a fundamental size limit beyond which the behavior of a physical system is no longer governed by classical laws. This limit, the border of the quantum realm, is reached when the sizes of elements become comparable to atomic dimensions or the number of electrons involved is just a few. In the case of semiconductor heterostructures these ultrasmall elements can be considered as more or less regular boxes for carriers, in particular for electrons, holes, or excitons. As the effective mass of electrons in many semiconductors is considerably smaller than the free electron mass, the quantization effects in these materials are significant for spatial confinement of nanometer scale.

Actually, the size of individual elements making up computer microchips, currently produced by photolithography techniques, is usually not smaller than the shortest wavelength of visible light ($\sim$380 nm). Lithography using ultraviolet or X-rays still encounters strong technical complications and is not yet acceptable for wide commercial use. Also electron-beam or ion-beam lithography, allowing for far higher resolution, is inconvenient for industrial production as they resemble rather rewriting by pencil in comparison to the photocopy-like performance of photolithography. Thus, typical single microstructures (e.g., transistors in microchips) are still rather far from the range of quantum mechanics, and classical intuitions about physical mechanisms are roughly applicable for their description. The same holds true for currently fabricated elements for so-called nanotechnology—news on nanoengines and other ultraprecise mechanical devices concern objects of micrometer rather than really nanometer scale; hence they fall again into the classical range.

On the other hand, the rapid development of the semiconductor technology, including epitaxy techniques for preparation of even single-molecular layers of materials, lithography methods, and advances in controlling self-aggregation processes, results in quite new possibilities for artificial creation of ultrasmall physical systems with controlled properties. The performance of these nanometer-scale objects meets with limitations imposed on the small systems by quantum mechanics and description of the processes taking place on these extremely small scales taken from the macroscopic physics is irrelevant when both their optoelectronic properties as well as mechanical behavior are concerned. This scale of miniaturization seems to be the natural limit for classical microelectronics.

For systems of nanometer dimensions the classical description is very misleading but their quantum properties open the possibilities both for deep understanding of the fundamental laws of nature and for new applications that could not be thought of on the classical grounds. Indeed, the practical realization of quasi-two-dimensional electron gas in semiconductor heterostructures, with electrons confined in a few nanometers wide layer (thickness of order of the electron de Broglie wavelength in semiconductor) resulted in such discoveries as the quantum Hall effect, which revealed sharply the unusual quantum nature of geometrically confined systems. The fractional quantum Hall effect and further experiments with so-called Hall metal [1] suggest even an essential development of quantum theory and lead to exotic new two-dimensional (2D) particles—composite fermions instead of simple 3D electrons.

Since the early 1980s the rapid progress in laboratory techniques of confinement of electrons, first in a plane, as in Hall configurations, and further in remaining directions, has led to creation of more fine objects called quantum wires [2], in which electrons move freely only in one direction, and finally semiconductor quantum dots (QDs) [3–6]

with electrons closed in small boxes of dimensions of tens or even a few nanometers. These completely confined electrons in artificially constructed boxes resemble the ordinary atoms; hence frequently QDs are called artificial atoms, and they reproduce many properties from atomic physics. QDs seem to be, however, much more flexible in comparison with atoms—QDs do not contain nuclei inside, so they can confine an arbitrary number of electrons, starting from one to hundreds or thousands closed in small spatial volume. In addition, as opposed to natural atoms, their shapes and various other properties can be modeled at the stage of preparation.

2. MANUFACTURING METHODS

Unlike quantum wells, where the motion of carriers is restricted to a plane through the crystallization of thin epitaxial layers, the creation of quantum wires or dots, which confine the carriers in the space with at least two of three dimensions limited to the range of the de Broglie wavelength, requires far more advanced technology. Currently there are a lot of methods of manufacturing QDs. Let us briefly describe them (see [7–9]).

2.1. Etching

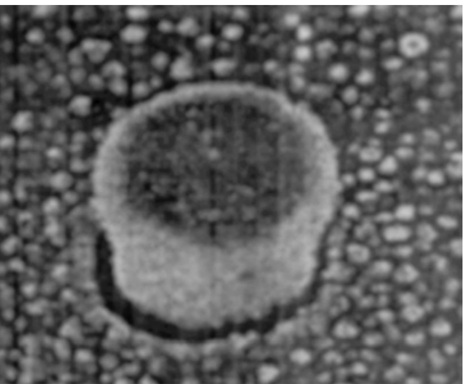
The earliest method of manufacturing QDs was implemented by Reed et al. [3], who etched them in a structure containing two-dimensional electron gas. Subsequent steps of this process are shown in Figure 1a. The surface of a sample containing one or more quantum wells is covered with a polymer mask, and then partly exposed (1). The exposed pattern corresponds to the shape of the created nanostructure. Due to the required high resolution, the mask is not exposed to visible light, but to the electron or ion beam (electron/ion beam lithography). At the exposed areas the mask is removed (2). Later, the entire surface is covered with a thin metal layer (3). Using a special solution, the polymer film and the protective metal layer are removed, and a clean surface of the sample is obtained, except for the previously exposed areas, where the metal layer remains (4). Next, by chemically etching the areas not protected by the metal mask (5), slim pillars are created, containing the cut-out fragments of quantum wells (6). In this way, the motion of electrons, which is initially confined in the plane of the quantum well, is further restricted to a small pillar with a diameter of the order of 10–100 nm. Due to the simplicity of the production of thin, homogeneous quantum wells, GaAs is the most commonly used material for creating dots by means of etching. Figures 1b and 2 (upper) present the pictures of real dots obtained using this method.

B* 38, 2172 (1988). © 1988, American Physical Society.

2.2. Modulated Electric Field

Another method consists in the creation of small electrodes over the surface of a quantum well by means of lithographic techniques. Application of an appropriate voltage to the electrodes produces a spatially modulated electric field, which localizes the electrons within a small area. The lateral confinement created in this way has no edge defects, which are characteristic for the etched structures. The process of spreading a thin electrode over the surface of a quantum well may produce both single QDs [10] and large arrays (matrices) of dots [11–14].

Modulation of electric potential, produced by applying a voltage to an electrode, can be realized by the previous preparation (using a lithographic technique) of a regular array of islets of nonmetallic material (e.g., of the barrier material) on the surface of the sample. As a result, the distance between the electrode (overlaying the surface with the islets) and the plane of the quantum well is modulated, and



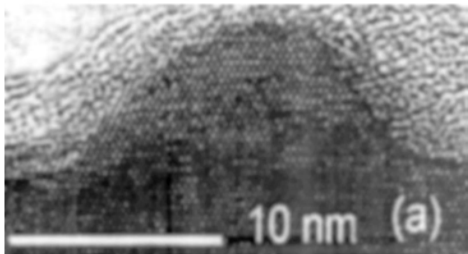


Figure 2. Micrographs of single dots. Upper—etched. Reprinted with permission from [154], S. Tarucha et al., *Phys. Rev. Lett.* 84, 2485 (2000). © 2000, American Physical Society. Lower—self-assembled. Reprinted with permission from [220], P. Fry et al., *Phys. Rev. Lett.* 84, 733 (2000). © 2000, American Physical Society.

the electrons are bound in small areas under the prepared islets. A photograph of a matrix of such dots, together with the profile of the confining potential, is shown in Figure 3a.

Instead of modulating the distance between the electrode and the well, it is also possible to build a pair of parallel, thin electrodes above the well. The lower one can have regularly placed holes which is where QDs are to be created [15, 16]. A voltage applied to the pair of electrodes results in the change of both the dot size and the depth of the confining potential. The potential depth influences the number of confined electrons. However, when an additional electrode is introduced between the quantum-well layer and the doped layer, the number of electrons and the potential depth can be changed independently. Even more complicated systems of microelectrodes are currently also applied [17].

2.3. Interdiffusion between the Barrier and the Quantum Well

QDs can be obtained also by local heating of a quantum well sample with a laser beam [18]. The laser beam guided along a rectangular contour surrounding an unilluminated area of a diameter of 300–1000 nm causes a rapid interdiffusion of atoms between the well and the barriers, which creates a local modulation of the material band structure (i.e., the potential barrier) which surrounds the unilluminated interior of the rectangle. For larger dimensions of the illuminated rectangle the obtained effective potential which confines the electrons is flat inside the rectangle and steep near the edge. With the decrease of the illuminated rectangle, the confined area shrinks. According to the authors of [18], for dimensions near 450 nm the effective potential confining electrons is close to an isotropic parabola. However, it should be mentioned that details of the electron confining potential in a QD of any type cannot be measured directly (except for the geometric dimensions) and are

Lett.* 58, 2018 (1991). © 1991, American Institute of Physics.

alternatively obtained through an interpretation of various indirect effects, which are related to the electronic structure of a QD.

2.4. Semiconductor Microcrystals

It is also possible to create QDs in the form of semiconductor microcrystals. In the first experiment based on this idea, carried out by Ekimov et al. [19], silicate glass with ca. 1% addition of the semiconducting phase (CdS, CuCl, CdSe, CuBr) was heated for several hours at high temperatures, which led to the formation of appropriate microcrystals of almost equal sizes, depending on the temperature and heating time. Radii of these dots measured in different samples varied in the range of 1.2–38 nm.

2.5. Selective Growth

The next method is the selective growth of a semiconducting compound with a narrower bandgap (e.g., GaAs) on the surface of another compound with a wider bandgap (e.g., AlGaAs) [20]. Restriction of growth to chosen areas is obtained by covering the surface of the sample with a mask (SiO_2) and etching miniature triangles on it. On the surface not covered with the mask the growth is then carried out with the metal-organic chemical vapor deposition method (MOCVD), at a temperature of 700–800 °C. The crystals created have a shape of tetrahedral pyramids and hence, when the first crystallized layers are the layers of the substrate compound (AlGaAs), and only the top of the pyramid is created of GaAs, it is possible to obtain a dot of an effective size below 100 nm. Pictures of such dots, and the configuration of layers GaAs/AlGaAs, are shown in Figure 3b.

2.6. Cleaved Edge Overgrowth

Quantum dots may appear at the intersection of three orthogonal quantum wells [21]. The technology consists of growing subsequent quantum wells on a cleaved edge of a previously existing well [22, 23]. In this way, localization of carriers on a scale of a few nm may be achieved.

2.7. Interface Fluctuations

Thickness fluctuations of a quantum well induce effective potential fluctuation and appearance of localization centers for carriers [24, 25]. Such “natural” quantum dots have low localization energy (~10 meV) and large size fluctuations. Photoluminescence data prove the existence of zero-dimensional density of states, conforming with a model of 1 monolayer thick islands of lateral extension of several tens of nanometers [26].

2.8. Self-Organized Growth

Another very promising method is the self-crystallization of QDs [27]. When lattice constants of the substrate and the crystallized material differ considerably (7% in the case of GaAs and InAs, the most commonly used pair of compounds), only the first deposited monolayers crystallize in the form of epitaxial, strained layers with the lattice constant

equal to that of the substrate. When the critical thickness is exceeded, a significant strain which occurs in the layer leads to the breakdown of such an ordered structure and to spontaneous formation of randomly distributed islets of regular shape and similar sizes, called self-assembled quantum dots (SADs). The shape and average size of islets depend on the strain intensity in the layer related to the misfit of lattice constants, the temperature at which the growth occurs, and the growth rate. The phase transition from the epitaxial structure to the random arrangement of islets is called the Stranski–Krastanow transition [28].

Figure 4 presents subsequent phases of the creation of islets for a pair of compounds with the misfit of lattice constants: InAs and GaAs, where the transition occurs at the 1.8 monolayer deposition. In Figure 2 the micrograph of a single self-assembled dot is presented.

When the process of crystallization is terminated shortly after reaching the phase transition, islets evolve to a quasi-equilibrium state in which they assume the shape of pyramids [29–32] or flat, circular lenses [33–35] formed on a thin layer of InGaAs (the wetting layer).

Raymond et al. [35] report growth of self-assembled dots in the shape of lenses with ~36 nm diameter and ~4.4 nm height (with fluctuations of 5–10%). Marzin et al. [32] obtained dots in the shape of regular pyramids with a square base of ~24 nm side length and ~2.8 nm height (with fluctuations of ~15%), and a distance between neighboring dots of ~55 nm. Ultrasmall pyramidal dots of less than 10 nm dimensions were also obtained in a InAs/GaAs interface [29].

Small sizes of the SADs, homogeneity of their shapes and sizes in a macroscopic sample, perfect crystal structure without edge defects, as well as the convenient growth process, without the necessity of any precise deposition of electrodes or etching, are among their greatest advantages which bring hope regarding their future application in electronics and optoelectronics.

More examples of quantum dots obtained by different techniques from different materials are given in Table 1.

3. SPECTROSCOPY OF QUANTUM DOTS

3.1. Optical Spectroscopy

Three-dimensional confinement of carriers and the resulting δ-shaped density of states manifests itself in the appearance of sharp lines in the optical spectra of quantum dots.

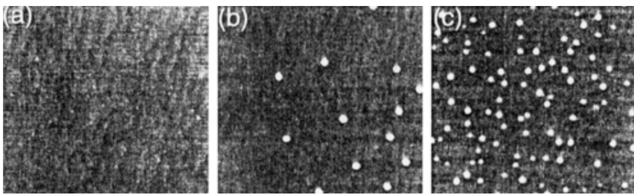

Figure 4. Evolution of islets—self-assembled quantum dots (white circles), in the molecular beam epitaxy growth of InAs on GaAs surface. Subsequent pictures correspond to the increasing coverage of 1.6, 1.7, and 1.8 monolayer; size of presented areas: 1×1 μm^2. Reprinted with permission from [27], P. Petroff et al., *Superlattices Microstructures* 15, 15 (1994). © 1994, Elsevier Science.

In a photoluminescence (PL) measurement, the emission intensity from a sample is measured as a function of the detection energy. This PL radiation from QDs is caused by recombination of trapped electron–hole pairs (i.e., excitons; see Section 4.2).

PL experiments on etched dots [36–39] show a peak at the energy corresponding to the interband transition, increasing with decreasing dot diameter. At higher excitation energy another (redshifted) line appears, due to transition involving a biexciton state. Appearance of further (blueshifted) lines accompanies the saturation of the single-exciton lines and corresponds to recombination from higher excitonic levels. These lines split in nonzero magnetic field due to lifting the degeneracy of the levels [35].

Self-assembled dots have much stronger quantization effects (larger interlevel distance) due to their reduced size. This should lead to more clear photoluminescence features. The PL measurements on such dots (InAs/GaAs [40–44], InGaAs/GaAs [34, 45], InAlAs/AlGaAs [46]) show a distinct feature, shifted by a few hundreds of meV (the exciton binding energy) from the wetting layer. The excited state recombination appears at higher excitation power and is shifted by a few tens of meV, indicating large energy separation from the closest bright exciton state (a state with allowed radiative transition).

The resolution of the PL spectra is limited by the nonuniform size of the dots in the investigated ensemble, leading to inhomogeneous broadening of spectral peaks. This may be overcome by using a modified technique, spot focus cathodoluminescence [47], or by preparing small mesas containing a small number of dots [32, 48]. For decreasing number of dots [33], the initial wide Gaussian peak evolves into a series of densely packed narrow lines separated by an interval much smaller than the calculated [32, 49] interlevel spacing, hence corresponding to the ground-state transition from different dots. On the grounds of such spectra, it is possible to evaluate the homogeneous broadening of spectral lines due to the intrinsic decoherence processes.

The PL spectra not only show the structure of the ground and excited zero-dimensional states but also provide information on relaxation processes. Higher excited states appear before saturation of the ground state transition which indicates a slowdown of relaxation [44, 50].

An alternative experimental technique, of not less importance than PL, is photoluminescence excitation (PLE). In this method, the detection energy is fixed and the luminescence intensity is investigated as a function of the excitation energy. In this way, one can study the capture of carriers and their relaxation to the optically active state (usually ground state). It turns out [51, 52] that PLE spectra of ensembles of dots contain a series of longitudinal optical (LO) phonon resonances instead of the excited dot state. This results from the fact that apart from the existence of an optically active state at the detection energy and a nonvanishing density of states at the excitation energy (which is guaranteed by the size and shape fluctuation in the dot ensemble) an efficient relaxation mechanism must be provided which is the case only around the LO phonon energy [53, 54] (bottleneck effect; see Section 4.6 for a discussion).

Table 1. Selected examples of quantum dots.

Fabrication method	Material	Size	ΔE	Ref.
Cleaved edge overgrowth	GaAs/AlGaAs	$7 \times 7 \times 7$ nm		[22]
Interface fluctuations	GaAs/AlGaAs	~100 nm	6 meV	[26]
Interface fluctuations	GaAs/AlAs	~100 nm		[89]
Interface fluctuations	GaAs/AlGaAs		2 meV	[55]
Electric field	Si	150 nm		[15]
Selective growth	GaAs/AlGaAs	<100 nm		[20]
Selective growth	GaAs/AlGaAs	$25 \times 25 \times 15$ nm		[215]
Etching	InAs/GaAs	40–90 nm	4–9 meV	[38]
Etching	InGaAs/AlGaAs	500 nm	4 meV	[154]
Etching	Si/SiO_2	$7 \times 7 \times 2$ nm	30 meV	[212]
Interdiffusion	GaAs/AlGaAs	300–1000		[18]
Self-organization	InAs/GaAs		80–90 meV	[41]
Self-organization	CdMnSe/ZnSe	8–10 nm		[216]
Self-organization	InAs/GaAs	17–19 nm	60 meV	[188]
Self-organization	InGaAs/GaAs		100	[58]
Self-organization	CdSe/ZnSe	10×1.6 nm	40 meV	[55]
Self-organization	GaN/AlGaN	40×6 nm		[217]
Self-organization	Ge/Si	150×15 nm		[218]

Note: ΔE is the confined energy level separation

3.2. Single Dot Optical Spectroscopy

Improvement in the sample preparation and optical focusing techniques leads to the possibility of single dot spectroscopy [55, 56]. A spatial resolution high enough to probe a single dot may be achieved by near-field optical techniques [57]. Such single-dot experiments provide much more detailed insight into the states of the confined carriers and their interaction with environment.

The single dot optical spectra show features related to the shell structure of the carrier levels [58]. Polarization of the PL signal has been studied [59]. Large self-assembled dots prove to be optically anisotropic [60]. By breaking the dot symmetry with magnetic field it is possible to get information also on dark exciton states [61]. Single dot spectroscopy allows one to study in detail the structure of few-particle states (charged excitons and multiexciton states) [62–69] and the dependence of the spectrum on the number of confined carriers [70]. Additional information about the spectrum (fine structure, few-particle effects) is provided by measurements in magnetic fields (magnetospectroscopy) [71–73]. It turns out that emission from the biexciton ground shell is correlated with the value of the g factor which suggests the effect of dopants on the dot spectrum and its magnetic properties [74, 75]. A nearby defect increases also the coupling to LO phonons and in this way affects the phonon-assisted transitions [76]. Information on the mechanisms of creation of biexciton states has been obtained [77, 78]. Spectra of single "artificial molecules" (coupled dot systems) are also investigated [79].

Homogeneous broadening of single-dot spectral lines yields information on the lifetime of the states and the effects of coupling to the environment, including relaxation mechanisms [57, 80–85]. A direct insight into the system evolution and coherence times is possible by time-resolved spectroscopy methods [56, 86–89]. It was suggested that the linewidth of quantum dots may be to some extent controlled [90].

Single dot experiments on single-photon level yield data on statistics (correlations) of emitted photons [91–94].

3.3. Capacitance Spectroscopy

In capacitance spectroscopy experiments, the capacitance of a quantum dot system is measured as a function of the bias voltage applied. As the capacitance is proportional to the density of states of the dot, the measured differential signal shows oscillations corresponding to the energies of confined carriers [11, 95, 96]. The measured energy differences consist of energy differences of single-particle states and charging energies, related to carrier–carrier repulsion (Coulomb blockade effect).

A more sophisticated variation of this method, single-electron capacitance spectroscopy, allows one to observe ground state energies of multielectron dots by adding electrons one-by-one (with changing the gate bias voltage) to the initially empty dot and measuring the single-electron charging energy (chemical potential) [10, 17, 97, 98].

As the optical methods (far infrared absorption) probe only the center of mass mode of the confined multielectron system (Kohn theorem; see Section 4.3), the capacitance spectroscopy methods are an important tool for investigating the properties of large, multielectron QDs. It is, however, employed also as a complementary method to study the spectral properties of small, self-assembled dots [99–105]. It may be applied to study capacitance associated not only with electrons but also with holes [106, 107]. The time-resolved version of the capacitance spectroscopy has been applied to study the electron escape processes from a InAs quantum dot in an electric field [108], demonstrating the presence of both tunneling and thermally activated processes.

3.4. Transport Spectroscopy

The idea of transport spectroscopy consists in measuring the tunneling current through a dot or a system of dots as a function of the bias voltage applied by external electrodes.

The tunneling current peaks reveal information on the dot spectra and on the charging effects for multicarrier states.

The measurements in a vertical setup (current along the strongest confinement axis) on etched dots in the charge accumulation regime (reverse bias, emitter barrier more transparent than the collector one) [109–114] showed single-electron charging features and revealed information on the many-particle ground state. Other experiments performed on a similar structure, with an additional side electrode, yielded information about many-particle states of a controlled number of confined carriers [115–117].

Spectra of InAs/GaAs self-assembled quantum dots have been obtained by vertical tunneling spectroscopy with forward bias [118, 119]. The results show distinct peaks corresponding to the confined single-electron states in spite of a large number of dots in the mesa (only a few dots from the ensemble contribute).

Vertical tunneling measurements were performed also on single self-assembled dots (Si/SiO_2 [120], InAs/GaAs in a mesa structure [121], ultrasmall Si dots [122], PbS by scanning tunneling spectroscopy [123]).

The spectroscopy in the lateral setup was applied to dots defined by electric field gating in a 2D electron gas to study spectra of the 0D states, Coulomb interactions between carriers, and various tunneling channels [124–128]. Transport measurements in this setup have been performed also on 2D electron gas in close contact with a sheet of self-assembled dots [129, 130].

With transport spectroscopy on various materials it was possible to detect maximum density droplet states in many-electron quantum dots [131], to probe the confined carrier wavefunctions [132], to identify the contribution from different confined states [133] and from elastic and inelastic tunneling [134], to test the coherence of charge transfer [135], and to estimate g factors [136]. By using spin-polarized injection, not only Coulomb blockade but also spin blockade effects may be studied [137].

4. MAIN PROPERTIES OF QUANTUM DOTS

In this section we describe the essential properties of QDs. A more exhaustive description may be found in reviews [7–9, 138, 139].

4.1. Single-Particle Spectrum

Owing to full confinement of carriers inside the dots of dimensions of order of 10–100 nm, their properties correspond to discrete quantum levels separated typically with a few or tens of meV in energy (due to usually smaller effective mass of electron in semiconductors in comparison to free electron mass). The discretization of the energy spectrum enhances sharpness of the density of states. In Figure 5, the densities of states corresponding to the reduction of the dimensionality of the systems are presented.

The sharp density of states of QDs makes these systems very attractive for laser applications. And indeed, the first reported QD laser constructions with application of pyramid-shaped InAs/GaAs ultrasmall self-assembled dots

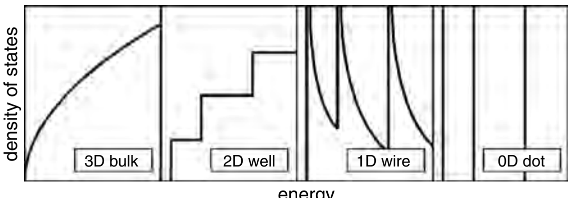

Figure 5. Density of states as a function of energy in systems with different numbers of spatial dimensions: 3D—bulk material, 2D—quantum well, 1D—quantum wire, 0D—quantum dot.

[30, 31] and with lens-shape InAs/InGaAs self-assembled dots [140] revealed better parameters in comparison with even best lasers built on the basis of quantum wells. It concerned both lower threshold injection current and higher temperatures of operating—due to the so-called bottleneck effect corresponding to a significant decrease of the interaction with phonons in the case of confined carriers in comparison to their counterparts in bulk.

At low enough temperatures (several Kelvin) the energy of phonons is too low to excite the electrons in QDs and the strong quantization of energy determines the electronic properties of these systems. The confining potential of QDs is not singular, unlike the Coulomb potential in atoms, and could be expanded in a series with respect to radius—the first term of this expansion is the parabolic potential and it is commonly applied for model investigation of QDs. An advantage of this model potential consists of the possibility of analytical solution of single-electron problem in 2D parabolic confinement even in the presence of perpendicular static magnetic fields. The resulting one-particle states, known as Fock–Darwin levels [141, 142], are presented in Figure 6. The degeneracy of the energy levels in the absence of magnetic field gives rise to the shell structure of the QD spectrum which is present also in real (not necessarily parabolic) systems [100]. In the limit of high magnetic fields

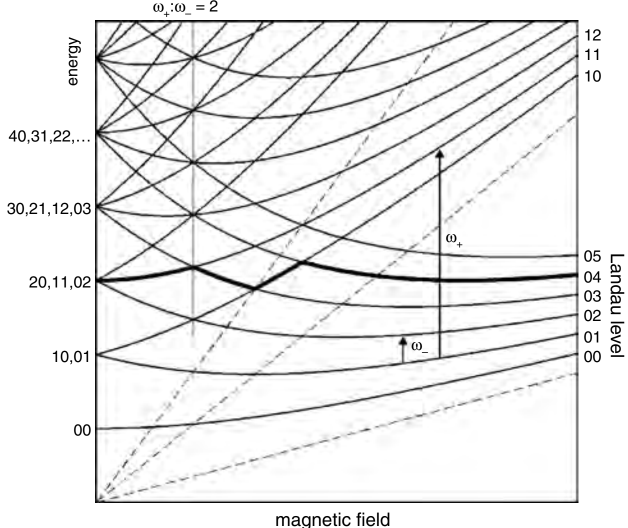

Figure 6. Evolution of the Fock–Darwin energy levels in a magnetic field. Dashed lines—the Landau energy levels; vertical arrows—allowed optical transitions.

the Fock–Darwin states transform into ordinary Landau levels of a free 2D electron in magnetic field, but for lower fields the modifications of Landau levels due to confinement are significant.

In real QDs the lateral confinement potential is a finite well (thus the parabolic approximation holds only for the lowest levels) and for sufficiently high energy originally captured carriers can leave the dot. To analyze such phenomena, the finite well of Gaussian type is usually applied [143], even though for a particular shape of a quantum dot [e.g., pyramid shape for InAs/GaAs self-assembled dots or lens-shaped In(Ga)As/GaAs self-assembled dots] more realistic finite wells are considered. The common feature of all these models is, however, the nonsingular character of the confining potential, which assures that the particularities of the potential well used for modeling do not cause any important qualitative changes.

In a class of semiconductor quantum dots not only electrons but also holes can be trapped (such QDs, like self-assembled InAs/GaAs dots, are sometimes called type I dots, in contrast to the type II dots, e.g., defined by electric field focusing, which have binding potential for only one kind of carrier and repulsive for the other). In contrast to conduction band electrons, a realistic description of valence band holes requires the inclusion of a larger number of sub-bands. The valence band is built from atomic p-type orbitals, and thus its states carry an internal angular momentum equal to unity. In circular dots both the angular momentum length and its projection in the vertical direction are good quantum numbers for a single captured hole, and its states can be assigned to heavy-hole and light-hole sub-bands (also spin-orbit split-off sub-band). In the simplest approach (the effective mass approximation) all sub-bands can be treated independently (it has been suggested that this model may be unexpectedly accurate [144]), but a more accurate description of holes requires taking inter-sub-band mixing into account. The mixing effects increase for larger magnitudes of the hole wave vector and for small dots with a high value of averaged wave vector the sub-band mixing corrections are significant. In self-assembled, strain induced dot structures the inter-sub-band interaction is, however, weakened due to sub-band separations induced by strain inherent to the manufacturing method [145].

4.2. Excitons

Optical excitations in QDs lead to the creation of pairs of particles (electron and hole) which may form charge-neutral states (i.e., excitons). If the confinement potential is attractive for both types of carriers (as it is, e.g., for the self-assembled InAs/GaAs dots) the single-particle shell structure is reflected also in the exciton spectrum, both in the parabolic confinement model [54] and in a more realistic modeling [146]. The hybridization of the nearly degenerate levels forming one shell affects the optical spectra [147] of such two-carrier states. However, unlike in the single-carrier case, the shells are not equidistant due to the decreasing Coulomb energy gain for higher states. The exciton-like complexes and multiexciton states in quantum dots were also investigated [148, 149].

From the point of view of future optoelectronic applications of QDs understanding of their PL properties is very important. The PL spectrum of QDs is much more complicated in comparison with bulk systems or quantum wells. The PL properties of QDs are analyzed very intensively both experimentally and theoretically for various types of QDs, as these phenomena are utilized, for example, in laser constructions [30, 31, 140].

For QDs, instead of a single PL peak as for a quantum well (or bulk), a multipeak structure is usually observed both in the presence and in the absence of a magnetic field [18, 33, 34, 150]. Even for very weakly activated QDs the doublet of PL features occurs. Mutual positions and intensity of particular PL peaks strongly depend on the dot diameter and the magnetic field [18, 42, 151]. There are many approaches for the theoretical investigation of these phenomena [7].

A simplified theoretical model in terms of metastable states can be formulated within the Hartree approach for electric-field-defined dots [152]. The bare lateral potential of this dot is attractive only for either an electron or a hole, contrary to the case of SADs (e.g., InAs/GaAs) where the same empty dot can capture an electron or a hole. If, however, the electric-field-defined dot is filled with an electron, the hole next could also be trapped due to electron–hole attraction. It resembles the similar phenomenon in the case of a charged acceptor or donor in the presence of magnetic field, where a magnetoexciton (i.e., electron–hole pair) can be trapped by the charged defect. In the absence of magnetic field the electron–hole attraction is too weak to overcome repulsion of such a center and the charged donor/acceptor cannot capture an exciton. The mediating role of the magnetic field is clearly connected with its property to enhance localization for both carriers due to diamagnetic effects. In the case of a QD defined by electric field a localized exciton can be formed even in the absence of magnetic field, because the lateral potential of the dot is nonsingular in distinction from a charged donor/acceptor potential. The simultaneous presence of both types of carriers in a small region leads to a strong mutual modification of this nonsingular lateral potential which results in effective confinement for both the electron and the hole in the dot. Moreover, the effective potential can attain the double-well shape, giving rise to a splitting of the excitonic ground state (also unlike a charged donor/acceptor magnetoexciton). Particular properties of effective potentials for an electron and a hole in a QD depend on the geometrical dimension of the QD—cf. Figure 7 (also on the external magnetic field and the activation level) similarly to what is observed in experiments (cf. Fig. 8).

4.3. Many-Particle Effects

In the case of a higher number of carriers captured in a dot, inclusion of the electric interaction for the many-electron system strongly affects the energy levels (e.g., [115, 153, 154]). Due to the fact that the dimensions of QDs are considerably larger than those of atoms, the Coulomb interaction is of much greater importance here. According to the Heisenberg uncertainty principle, the single-particle excitation energy depends on the size L as $\varepsilon \propto 1/L^2$, while the Coulomb interaction energy behaves as $V_C \propto 1/L$. In small

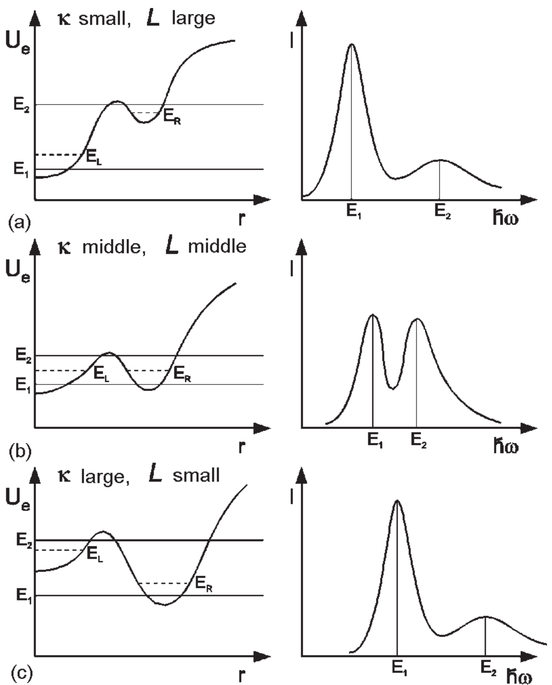

Figure 7. Effective self-consistent potential which acts on the electron U_e (left), and approximated photoluminescence spectrum (right), for three values of κ, that is, the dot size: (a) large dot, $\kappa = 0.4$, (b) medium dot, $\kappa = 0.7$, and (c) small dot, $\kappa = 0.9$ [bare lateral confinement for electron $\sim V \exp(-r^2/L^2)$, $\kappa \sim 1/L^2$].

QDs (e.g., self-assembled dots: $L \sim 20$–40 nm) the relation between ε and V_C is similar to that in atoms, the single-particle levels are relatively strongly separated, and the ground state satisfies the (slightly modified) Hund rules. Thus, while filling the shells of nearly degenerate states at zero magnetic field, ferromagnetic spin alignment is favored. This is, however, not the case for nonzero magnetic field as well as in nonsymmetric (e.g., rectangular) dots, where the shells are split by lifting the degeneracy.

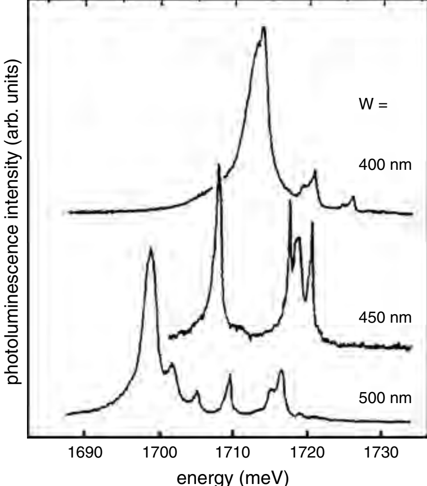

Figure 8. Photoluminescence spectra of single dots with three different diameters; splitting of the PL peak behaves similar to the scheme in Figure 7. Adapted with permission from [151], U. Bockelmann et al., *Solid State Electron.* 37, 1109 (1994). © 1994, Elsevier Science.

On the other hand, in larger dots the interaction between electrons determines the ground state of the system [155–157]. The ground state is a result of the competition between two opposite effects: the Coulomb repulsion favors pushing the electrons apart from one another, whereas the external confinement squeezes electrons in the center of the dot and prevents a large separation between them. This is not the only difference between QDs and ordinary atoms. As the energy scale in atoms is 2–3 orders of magnitude greater than in QDs, the latter are relatively more sensitive to phonons (and also to crystalline disorder) resulting in significant broadening of spectral lines in the QD case (in comparison to atoms). It precludes the usefulness of a simple quantum level picture ("artificial atom" concept) in all the cases when the level separations become comparable with level broadenings.

Under the influence of a magnetic field the electrons are subject to an additional squeezing in the plane perpendicular to the field since the magnetic field term appearing in the Hamiltonian also has the form of parabolic confinement (both for electrons and holes): $1/8m\omega_c^2 r^2$, where ω_c is the cyclotron frequency. In strong magnetic fields, where the magnetic length becomes smaller than the dot diameter (e.g., in a field of magnitude of order of 1 T, the magnetic length is about 25 nm), a dominating single-particle potential is the parabolic Landau potential (of the magnetic field). Thus, following the decrease of the effective dot size with growing magnetic field, the characteristic energy of the electron–electron Coulomb repulsion grows as the square root of the field magnitude. On the other hand, the characteristic kinetic energy scale decreases with an increasing magnetic field. Tuning the magnetic field varies the two energy scales and induces transitions in the ground state.

Detailed theoretical analysis of energy levels including interaction (also in the presence of magnetic field) is done by application of numerical procedures of quasi-exact diagonalization of relevant Hamiltonians or by various versions of Hartree–Fock calculus.

For QDs one can observe a realization of the generalized Kohn theorem—independence of resonant electromagnetic attenuation of electron interaction and number of electrons in the QD. This property corresponds to the separation of the center of mass and relative motion for the electron system in a QD with parabolic confining potential. For far-infrared (FIR) radiation with energy corresponding to interlevel distances in the QD (of order of meV), the wavelength (of order of mm) is far larger than the dot diameter; hence only the center-of-mass dynamics is involved in system response, exactly as for a uniform field. Hence the resonant FIR radiation frequencies correspond only to transitions in the center-of-mass quantum levels of the dot and hence are independent both of interaction and number of electrons. A fair coincidence of experimental data and theoretical predictions for FIR spectroscopy [158, 159]—as presented in Figure 9—is also evidence that the real confinement in QDs is actually close to the parabolic type, for which the separation of the center-of-mass and the relative dynamics occurs.

On the other hand, some features in FIR spectroscopy data, namely the double splitting of frequencies and characteristic anticrossing of resonant lines (cf. Fig. 9a, b, d) occurring for QDs with large number of electrons confined,

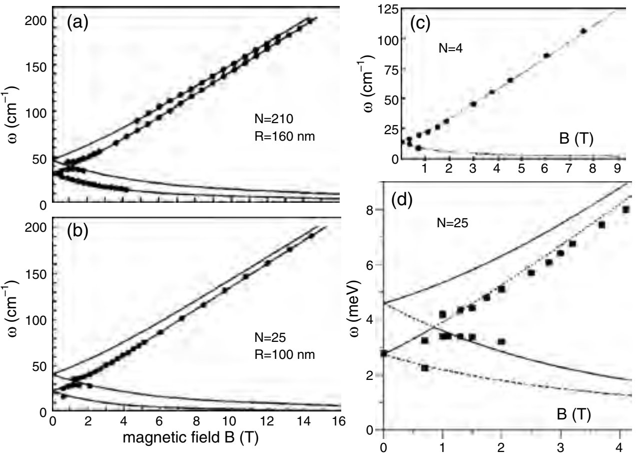

Figure 9. Evolution of the FIR resonance energies for quantum dots in a magnetic field. (a) 210 electrons. (b) 25 electrons. Reprinted with permission from [159], T. Demel et al., *Phys. Rev. indicate a small breaking of the Kohn theorem (inclusion of spin–orbit interaction [160] or confinement nonparabolicity corrections can explain these effects).

Another simple and unique property of the 2D (i.e., planar) parabolic confinement manifests itself in vanishing of effects caused by in-plane electric field even in the presence of perpendicular magnetic field. In the case of parabolic potential the in-plane electric field can be simply removed by an appropriate gauge transformation, which is, however, not the case for other confinement shapes. Therefore, appearance of electric-field-induced shifts of kinetic angular momentum or magnetization can be treated as an indicator of nonparabolicity of the QD confinement.

The electric interaction between electrons in a QD significantly modifies the relative dynamics of electrons. Very spectacular, although not yet confirmed experimentally, are the so-called magic states of QDs [157, 161–163], revealing the composite fermion nature of 2D electrons in planar QDs in the presence of strong magnetic fields. The crucial role is played here by topological phenomena, similar to the fractional quantum Hall effect. The magic states of strongly interacting electrons in QDs were there identified with the so-called compact states of weakly interacting composite fermions. The transformation of an electron system into a composite-fermion system is performed by attaching to each electron an equal and even number of elementary fluxes of a magnetic field. As shown in the exact numeric calculations [164, 165], the eigenstates of the *interacting* electron system are very close to the respective compact states of *noninteracting* composite fermions. The electronic system described in terms of composite fermions is thus an effectively free (noninteracting) system. It should, however, be stressed that the system of noninteracting composite fermions is essentially a many-body system due to intrinsic nonlocality of topological effects. Each of its quantum states is nonlocal and differs strongly from the antisymmetrized product of single-particle electronic states (i.e., the appropriate Slater determinant).

An interesting property of the confined many-electron system is the observation, in very strong magnetic fields, of characteristic features in the capacitance spectrum at fractional filling factors [16], suggesting a close relation with the fractional Hall effect.

In the recent single-electron capacitance spectroscopy experiment [17], the spatial localization of electron wavefunctions has been observed. It has been shown that at low electron densities, the electrons occupy localized sites in the dot, while for larger number of electrons, the states become delocalized. A similar study has also been done on a two-dot system [166] in magnetic field showing splitting of one low-density droplet into two parts for high fields.

4.4. Coupled Dots

Apart from the properties of a single dot, also systems of two coupled dots (artificial molecules) are of interest for their potential applications. A ground state of two electrons in such a system at zero magnetic field is a singlet. However, the singlet–triplet transition takes place at relatively low magnetic field [167], similar to the case of an electron pair in the same dot [168]. Orbital states of an exciton in a double-dot structure may be mapped onto the entangled states of two spins [169], providing formal grounds for applications in quantum information processing. A coupled two-dot system can be used as an exciton storage device. Even though in single self-assembled QD excitons live only for nanoseconds, in a vertically stacked QD pair obtained by the self-assembled strain-induced technique, the electron–hole pair can be stored even for seconds, provided that the electron and the hole are spatially separated (i.e., they are located in distinct dots of the pair). By application of lateral electrical field it is possible to manipulate this exciton by changing localization of both carriers [170]. Long-living metastable states in QD systems are very desired as candidates for future applications as memory elements, especially combined with ultrafast optical coherent switching techniques [171].

4.5. Magnetic Quantum Dots

The properties of carriers confined in quantum dots may be strongly modified by introducing magnetic ions (e.g., Mn^{2+}) into the crystal lattice. The effects appearing in bulk magnetic or semimagnetic semiconductors (e.g., giant Zeeman splitting, formation of magnetic polarons) have been examined for a few decades (see, e.g., [172]). In a quantum dot, a single confined carrier or exciton interacts with the magnetic environment, reflecting the fundamental aspects of magnetic interaction in a nanometer scale confinement. Magnetic interaction between the carriers and the magnetic ions leads to the formation of a magnetic polaron (i.e., to ferromagnetic alignment of spins in a small region of the crystal). Experimental study of self-organized semimagnetic semiconductor quantum dots [173, 174] revealed some information on the properties of confined magnetic polarons and on the

relaxation processes accompanying their formation. Photoluminescence spectra show that the energy shift related to the formation of the magnetic polaron is of order of a few meV, while the formation times, obtained by time-resolved spectroscopy, are of the order of a hundred picoseconds.

4.6. Carrier–Phonon Interaction in Quantum Dots

QDs are not isolated systems. They are embedded in the macroscopic crystal and interacting with other carriers, crystal defects, and lattice excitations. While the former two kinds of interaction may be eliminated by optimizing the manufacturing conditions, lowering temperature, and decreasing the excitation power, the latter is unavoidable, being the most serious obstacle for many future applications and limiting the usefulness of the "artificial atom" analogy.

There are three major mechanisms of carrier–phonon interaction [175]: (1) Coulomb interaction with the lattice polarization induced by the relative shift of the positive and negative sublattices of the polar compound, described upon quantization by LO phonons; (2) deformation potential coupling which describes the band shifts due to lattice compression and is related to longitudinal acoustical (LA) phonons; (3) Coulomb interaction with piezoelectric field generated by shear crystal deformation described by transversal acoustical (TA) phonons. The latter effect is weak in InAs/GaAs QD systems but may be of more importance for the properties, for example, of GaN dots [176, 177]. Moreover, anharmonic interaction between LO and TA phonons [178, 179] (although other anharmonic channels can be also important) leads to another, indirect, coupling between the localized charges and TA phonons, manifesting itself in multiphonon processes.

It was predicted theoretically [180, 181] that phonon-induced relaxation from excited states should be slow due to the bottleneck effect: the trapped carrier wavefunction is localized on approximately 10 lattice constants and high energy acoustic phonons do not effectively couple to carriers due to the wavelength mismatch, while optical phonons have very weak dispersion around $\mathbf{k} = 0$ so that energy conservation would require a strictly defined energy distance between the carrier levels. Experiments on large ensembles of dots show, however, that the carriers relax from the excited states in a few tens of picoseconds by emitting one [182] or more [53] LO phonons. The cascade relaxation rate is limited by the final step, from the lowest excited to the ground state. The observed LO phonon relaxation, apparently contrary to the bottleneck idea, can be explained by the fact that in the large ensemble of inhomogeneously sized dots some of them satisfy the energy conservation [53].

Another manifestation of the carrier–phonon interaction in confined semiconductor systems (similarly as in bulk) are the phonon replicas in the emission and absorption spectra, corresponding to simultaneous photon and phonon absorption or emission. Such phonon-assisted peaks may be found both in ensemble [183, 184] and single-dot [76] experiments. These peaks are much stronger than could be expected on the grounds of the adiabatic theory and much stronger than in bulk—the relevant so-called Huang–Rhys parameter (i.e., the intensity ratio of the satellite phonon-assisted peak to the central peak) is for surprisingly high for QDs. To explain this increase arguments of a geometrical nature were invoked, referring to relative displacement of electron and hole charges in QDs. Due to localization in the same small region of QD, the electron and hole wavefunctions tend to overlap strongly in the ground state of the charge-neutral exciton, which leads to the diminishing of the polar interaction between the exciton and LO phonons [185]. Nevertheless, for, for example, pyramidal shape QDs the geometry leads to more effective separation of electron and hole charges. However, it is still insufficient to explain the high value of the observed Huang–Rhys factor. It was shown that nonadiabatic effects, included via carrier transitions between ground and excited excitonic states, induced by the lattice dynamics [186] or by taking into account the inertial corrections for confined carriers resulting in enhancement of the Fröhlich constant [187], lead to the increase of the phonon-assisted peak strength in better accordance with experiment.

Apart from these incoherent phonon processes, carrier–phonon interaction induces also coherent effects. The FIR magnetospectroscopy of QDs shows distinct anti-crossings of electron [188] or exciton [189] levels each time they are separated by a multiple of the LO phonon energy (Fig. 10). Such anti-crossings are evidence of the presence of polaron states (i.e., coherent superpositions of carrier and LO phonon states). The appearance of such coherent effects is possible because of the quasi-dispersionless character of the strongly coupled LO phonons [190], assuring LO phonon-induced dephasing times longer than any other relevant process.

Thus, there are two aspects of the carrier–phonon dynamics in QDs: According to the coherent polaron idea, the carrier–LO phonon interaction leads to the reconstruction of the spectrum and to the formation of hybrid states. In this picture, the interaction with phonons induces coherent oscillations between the excited state and the ground state accompanied by a phonon [188, 190]. On the contrary, the LO phonon-induced relaxation [53, 182] assumes a non-invertible transition from the excited state to the ground state, after which the final state dissolves in the phonon continuum. Both these aspects may be consistently described in terms of new quasiparticles, polarons, whose definition includes the coherent effects related to LO phonons.

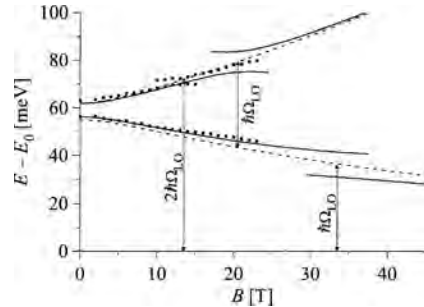

Figure 10. Energy spectrum of the polaron for a single electron in a InAs/GaAs self-assembled dot as a function of the magnetic field. The results of the harmonic approximation (solid lines) successfully reproduce the experimental data [188] (dots). The levels form anti-crossings whenever the electron energy crosses the LO phonon energy (see [191, 221] for discussion and dot parameters).

The polaron levels are shifted with respect to the excitonic ones (the polaron ground state energy is always lower, typically by a few meV, usually not more than 10% of characteristic confinement energy for electrons, and 5% for excitons). Around resonances they show anti-crossings, as observed in the experiment [188]. This effect is present both for charged excitations (excess electrons) and for neutral ones (excitons) [191]. In the latter case the electron and hole wavefunctions overlap to some extent (in self-assembled InAs/GaAs structures) but in a typical dot the Coulomb interaction between the carriers tends to shrink the hole wavefunction, diminishing the charge cancellation effects and strengthening the polar phonon effects. In piezoelectric semiconductors the built-in electric field separates the charges in the growth direction [176, 177] and in the dots created by electric field significant charge separation appears due to the attraction/repulsion of electron/hole by the empty dot. In both these cases the LO phonon effects are increased.

Polarons are not everlasting quasiparticles. They relax due to decomposition of their phonon cloud. These processes, including acoustical phonons, are incoherent due to the existence of a broad, weakly coupled continuum of final states. Such processes are induced both by the carrier–phonon interaction and by the anharmonic phonon–phonon coupling. In the former case, due to the bottleneck effect (i.e., exponential suppression of the coupling to short-wavelength phonons), they are effective only for level spacing around the LO phonon resonance. The latter channel is not affected by the bottleneck and is restricted only by the limited acoustic phonon bandwidth. In a InAs/GaAs SAD, the relaxation typically takes place on the time scale of tens of picoseconds, in agreement with the relaxation experiments [53, 182]. Due to the coherent nature of interaction with LO phonons, any process involving a LO phonon must be actually an at least two-phonon event in which an acoustical phonon participates.

Due to the nanometer scale of confinement, phonon phenomena in QDs differ essentially from those in bulk. The energy scale of the confined carriers is close to the resonance with optical phonons; hence the carrier–LO phonon interaction is in the strong coupling regime leading to considerable modification of the carrier spectrum (i.e., to the polaron effect). The Fröhlich interaction for confined carriers is enhanced by nonadiabatic effects. An electron confined in QD moves with greater quasi-classical velocity than in bulk, thus the inertial local polarization, important for Fröhlich interaction, is enhanced. In contrast to these increased coherent effects, the incoherent carrier–acoustical phonon interaction is diminished due to the typically large interlevel distance compared to the acoustical phonon energy and to the confinement-related bottleneck effect (size incommensurability). These effects are magnified by wide polaron anticrossings in the spectrum induced by the increased Fröhlich coupling and lead to relaxation times of tens of ps (at least one order of magnitude longer than in bulk).

Another phenomenon related to the carrier–phonon interaction is the phonon-induced coherence loss. The recent time-resolved single dot spectroscopy experiment [192] showed a partial decay of the initial signal coherence on a picosecond scale. The coherence loss was then stopped

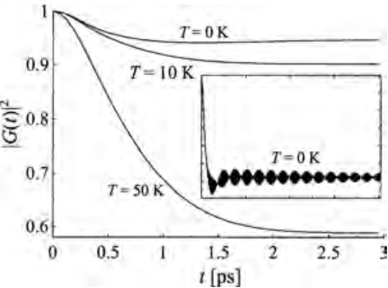

Figure 11. Decoherence of an exciton created in a InAs/GaAs dot by subpicosecond pulse due to interaction with acoustical phonons at different temperatures (theoretical results). The measure of decoherence is the decrease of the correlation function $G(t) = \langle a(t)a^\dagger(0)\rangle$. Inset: Decoherence due to acoustical and optical phonons (at zero temperature). Due to weak optical phonon dispersion the LO phonon beats decay on a much longer time scale.

at a relatively high, temperature dependent level, with a subsequent exponential decay limited by the exciton lifetime (~1 ns) at low temperatures (perhaps influenced also by other effects, like anharmonism). Such a behavior of the system polarization after a short, subpicosecond exciting pulse (modeled by an instant one) was theoretically accounted for, for example, in the single-state (independent boson) model within the linear response regime [185] and then generalized to higher orders and to sequences of pulses [193]. This partial coherence loss is a manifestation of a general dressing phenomenon, where the lattice reaction is a slow process following a fast (nonadiabatic, here of subpicosecond scale) carrier excitation [54]. Due to the slow lattice dynamics, the fast charge excitation must be followed by a relaxation process which may be interpreted as formation of the polarization or deformation dressing (phonon cloud) around the exciton. The time scale of the resulting dephasing, corresponding to the dissipation of an excess energy in the phonon sea, depends on the effective spectral width of the coupled phonon continuum (the most effective in this respect is the LA phonon sea). This process is, in turn, determined by the dot size, similar to the ordinary bottleneck effect. For a typical InAs/GaAs dot, this decoherence time is of the order of a picosecond, while the final degree of the coherence loss strongly depends on temperature and may vary in a wide range (Fig. 11).

5. APPLICATIONS

QDs are promising from the point of view of many state-of-the art and future technology applications. In the rapidly developing new domain of quantum information processing (see, e.g., [194]), a number of proposals based on the unique properties of QDs were put forward. The flexibility and small size of these quantum objects favors their application for definition of so-called qubits—quantum counterparts of classical bits. In such proposals, usually pairs of closely coupled dots (obtained, e.g., by stress-induced spontaneous stacking in the self-organization technology) play the role of two separated and interacting systems in which the entanglement of quantum states could be realized in a controlled manner [169]. Such entangled states, being

nonseparable tensor products of states of subsystems, are crucial for quantum computing. The quantum gate proposals employ dots manufactured in various ways: by electric gate [195], self-organized [196], or multilayered dot systems obtained by an etching technique.

A natural choice for the quantum bit is the spin of a confined electron [195, 197–199]. This choice is favored by long spin decoherence times (of order of microseconds) [171, 200, 201]. In one of the proposals [198, 199] a two-qubit gate is realized by two electrons residing in two coupled dots. The exchange interaction between the electrons may be switched on and off by applying external magnetic field [167], providing an efficient way of generating entanglement and performing two-qubit operations. On the other hand, one-qubit operations are based on the spin coupling with external magnetic field which is very weak in nonmagnetic dots (e.g., InAs/GaAs), leading to slow performance.

Much faster, all-optical operation is possible for a qubit defined by orbital degrees of freedom as, for example, the presence or absence of an exciton in a dot [196, 177]. Conditional two-qubit operations are induced by the dipole interaction when both dots are occupied. Here, however, the information is affected by fast decoherence related mostly to the interaction with phonons.

In order to combine the long decoherence time of the spin with the fast gating provided by strong coupling to the orbital degrees of freedom a new idea was recently put forward, based on the Pauli blocking mechanism [202]. In this proposal, the optically induced excitonic transition leading to dipole interaction (gating) is conditioned on the spin state of an excess electron.

Despite the very rapid progress in nanotechnology the realization of even a small quantum computer is hampered by severe obstacles caused mainly by decoherence processes [203]. So far, coherent control over excitonic states [55] and evidence of Rabi oscillations (an indicator of coherent evolution) [204–207] have been demonstrated. The feasibility of the readout of quantum states is supported by the possibility of converting the state of the dot into currents. In the case of orbital states this was achieved [207] by placing a self-assembled dot in a photodiode. Under external electric field the charge tunnels from the dot contributing to the current. For the spin state, the tunneling current of spin-polarized electrons depends on the state of the localized spin [208].

The quantization of states in a QD leads to the possibility of controlling a current, even of single-electron intensity. This leads to the proposal of QD spin filters and spin memory [209]. The Pauli exclusion principle may also be employed to implement current rectification and spin filtration in doubledot systems [210]. Depending on the polarization of bias voltage applied, either one spin component of the current may flow through the device, or both components are blocked. These proposals, aiming at spintronics applications of QDs, may strongly benefit from application of QDs created in magnetic semiconductor medium (like CdMnTe).

The dot in a diode structure mentioned previously [207] may be used as a highly effective single-electron source. With repeated laser pulses, a photocurrent of controlled intensity is obtained which, potentially, may be spin-polarized by applying polarized laser light. A single-photon source, essential for quantum cryptography applications, is also obtainable in the QD technology. As demonstrated experimentally [211], charging the dots with many charges using a high-intensity laser pulse leads to a single-photon emission at the single-exciton recombination energy.

Other ideas concerning technological applications of QDs, exploring the limits of miniaturization of the classical microelectronics, are related to the single-electron transistor or single-electron memory [212, 213]. In these nanodevices a charge is stored in silicon nanocrystals of a few nanometers diameter. Such a device may be operated at room temperature and can store a single electron for weeks.

The excitonic laser, working within the semiconductor diode scheme and employing recombination of excitons (thus emitting a light corresponding approximately to the forbidden gap of the semiconductor medium), has already been constructed within QD technology [30, 31, 140]. Quantum dots play also a still growing role in the continuously improving constructions of GaN heterostructures for blue lasers.

Another proposal is a version of a far-infrared laser working on transitions between only electronic states of quantum dots (defined by electric field focusing), similar to ordinary molecular lasers. The novelty consists here in a possibility of pumping such a laser by rapid changes of the dot dimension via oscillations of the field which creates the array of dots in the quantum well [214]. The inverse occupation can be achieved due to distinct probability of filling with electrons of upper and lower dot levels. Dots should be, however, created (or changed) very rapidly—nonadiabatically—which is hard to attain in practice.

Even though the practical implementation and, in some cases, even laboratory demonstration of all these novel constructions and ideas needs further technological and theoretical progress, advantages of the next step of miniaturization, toward and beyond the quantum limit, are very attractive. As was noticed in [170], currently the storage of a single bit of information involves millions of atoms, while application of quantum dots would reduce this number to thousands or even hundreds. The semiconductor nanodevices employing QD technology will certainly remain in the mainstream of the technological progress underlying the development of the information society and, possibly, even the forthcoming quantum information breakthrough.

GLOSSARY

Artificial atom See quantum dot.

Artificial molecule A system of closely spaced quantum dots allowing interaction of the localized carriers.

Capacitance spectroscopy An experimental method of inferring on system properties (density of states) based on capacitance changes upon applied voltage.

Confinement potential The effective potential arising from the quantum dot structure, restricting the dynamics of the carriers.

Exciton An electron-hole pair bound by Coulomb attraction (in quantum dots also by the confinement potential). Charged excitons are excitons accompanied by additional charges.

Hole In a semiconductor system, a missing electron in the filled valence band, behaving dynamically as a positive carrier.

Optical spectroscopy An experimental method of inferring on system properties based on luminescence (light emission) upon optical excitation.

Polaron A carrier (or exciton) accompanied by the lattice polarization field induced by carrier-phonon coupling.

Quantum dot (also artificial atom) A modulation by the semiconductor structure (e.g. by composition modification or external electric field) leading to carrier localization on nanometer lengthscale.

Self-assembly (or self-organization) A process in which the strain resulting from the lattice constant misfit between epitaxially grown semiconductor layers is released by aggregation of nanocrystal islands (quantum dots).

Transport spectroscopy An experimental method of inferring on system properties based on the measurement of current flowing through the system while external voltage is applied to the attached electrodes.

1. INTRODUCTION

The ability to control or tailor the conduction and valence band profiles in semiconductor nanostructures—denominated bandgap engineering—has completely changed the physics and technology of semiconductors in the last few decades. An enormous amount of studies, realizations, and achievements have been accumulated during almost 30 years of research on semiconductor nanostructures. The fundamental quantum mechanical properties of condensed matter have been deeply tested. A large variety of new physical phenomena, such as the quantum Hall effect [1], the resonant tunnelling [2], the quantum confined Stark effect [3], and the Coulomb blockade [4], have been demonstrated. Electronic nanodevices using a very small number of electrons or even a single electron have been proposed or realized [5]. Extremely efficient lasers and emitting diodes based on nanostructures covering nearly the full optical spectrum are commercially available.

The band engineering revolution is fully based on the technology of semiconductor heterostructures, which are synthesized crystalline systems composed of more than one coherently grown material. The variation of the composition across the heterostructures, which leads to a spatial localization of the electrons and holes, is used to control the carrier motion and therefore to modify the electronic and optical properties of the system. The band alignment at the heterojunction between two different compounds, which is one of the most relevant parameters for band engineering, determines the spatial position of the lowest energy states for both electrons and holes. Since the spatial overlap of electrons and holes is an unavoidable constraint for all the electro-optical devices, the largest interest is in heterostructures where the lowest energy state for both kinds of carriers is spatially localized in the material with lower bandgap. In fact, this direct alignment holds for the best studied heterojunction, $In_xGa_{1-x}As/Al_yGa_yAs$; in the following we will focus our attention to this case.

Whenever the carrier localization, at least in one spatial direction, becomes comparable or smaller than the de Broglie wavelength of carriers, quantum mechanical effects occur. In this limit the optical and electronic properties of the heterostructure change as a function of the size and the system is called a *nanostructure*. As the size is reduced the electronic states are shifted toward higher energy and the oscillator strength becomes concentrated into few transitions. In order to fix the order of magnitude, let us mention that in the case of most of the semiconductor systems the limit of the *nanoworld* is of the order of few tens of nanometers.

The physics of the quantum size effect relies on the Heisenberg uncertainty principle between the spatial position and kinetic momentum of a quantum particle. It is not possible to measure both the momentum and position of a particle to an arbitrary precision. The product of the standard deviation in space and momentum satisfies the uncertainty relation:

$$\Delta x \Delta p \geq \frac{\hbar}{2} \quad (1)$$

This equation means that the smaller is the carrier localization in the nanostructure, the larger is the spread in the momentum p, or, better said for semiconductor systems, in the crystal momentum $\hbar k$. The energy may still be well defined, but the momentum is not well defined. In bulk systems, for states around the edge of conduction and valence

band, the dependence of the energy on the wavevector k is quadratic,

$$E = \frac{(\hbar k)^2}{2m^*} \tag{2}$$

where m^* is the carrier effective mass. Following this equation, the spread in the momentum $\hbar k$ gives a minimum kinetics energy to the localized particle. This is in contrast with the classical physics, where the lowest energy state in whatever potential corresponds to no kinetic energy. The uncertainty principle of quantum mechanics imposes a positive zero-point energy, which is approximately inversely proportional to the square of the nanostructure size. Therefore the energy of the ground state of electrons and holes in semiconductor nanostructures not only depends on the materials but also on the dimension of the confinement region. The quantum size dependence of the confinement energy is the key to the tunability of the optical transitions in nanostructures.

Nanostructures are classified by the number of dimensions in which the carriers are confined or, alternatively, free to move. In case of confinement in only one spatial direction, the nanostructure is named a quantum well (QW). The carrier motion is frozen in one dimension but electrons and holes can still freely move over the other two directions. Therefore the QW is a quasi two-dimensional (2D) system. A structure which provides carrier confinement in two directions, allowing the motion along the remaining dimension, is called quantum wire (QWR) and it is a quasi 1D system. In the case of confinement in all three spatial coordinates, the nanostructure is denominated quantum dot (QD). QDs are 0D systems since the carrier motion is completely frozen.

Obviously the physics of the nanostructures strongly depends on their dimensionality. This property is elucidated by the concept of electronic density of states (DOS). In a semiconductor structure a given energy usually corresponds to a large number different electronic states resulting from the carrier motion. In a bulk material where the motion can occur in three different directions the density of states increases proportionally to the square root of the energy. In quantum wells the motion in the plane gives a staircase DOS, where each step is associated with a new state in the confining potential. In quantum wires a continuum of states is still present, but strong resonances appear in the DOS associated with the states in the confining potential. Finally in quantum dots only discrete energy states are allowed and the DOS is therefore a comb of delta functions. Quantum nanostructures and their DOSs are illustrated in Figure 1.

The possibility to concentrate the DOS in a reduced energy range is extremely important for a large variety of fundamental topics and device applications. It is at the base of the quantum Hall effect in QW, of the quantization of the conductance in QWR, and of the single electron tunnelling in QDs. In the case of lasers the presence of a continuum DOS leads to losses associated with the population of states that do not contribute to the laser action. Conversely, the concentration of the DOS produces a reduction of the threshold current and enhances the thermal stability of the device operation. Clearly this property is optimized in QD structures. Due to the three-dimensional carrier

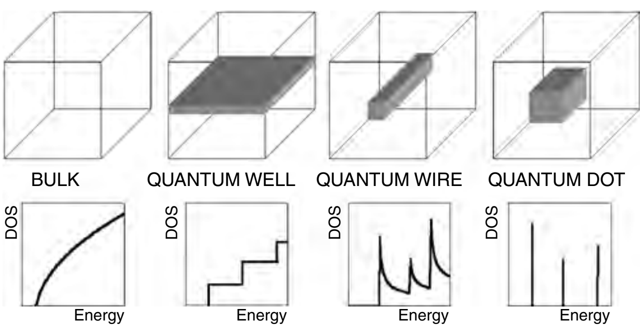

Figure 1. Schematic view and graph of quantum nanostructures and of their density of states.

confinement and the resulting discrete energy spectrum, semiconductor QDs can be regarded as artificial atoms. Nevertheless a QD is a crystalline system which is composed of a large number of unit cells (nearly 10^5). On one side this justifies the description of QD physics by the condensed matter approach (band structure, effective masses, etc.). On the other side this simple consideration suggests a large linear and nonlinear optical susceptibility of QDs, thus explaining the huge interest in QDs in electro-optical device applications.

Historically the research on semiconductor nanostructures was initiated by the discovery of superlattices (a periodic stack of QWs) by Esaki and Tsu in the 1970s [6]. They predicted Bloch oscillations and negative resistance for carriers moving in the superlattices. Few years later Dingle et al. [7] demonstrated that a strong enhancement of the excitonic optical transitions can be obtained in QWs. Rapidly the QWs become the tool for producing semiconductor systems with designed electronic and optical properties. A large variety of new optical phenomena in QWs was demonstrated: the enhancement of the excitonic resonances [8], the quantum confined Stark effect [9], the presence of large optical nonlinearity [10]. These peculiar properties rapidly produced a new generation of electro-optical devices, such as quantum well lasers, optical switches, modulators, and bistable devices [11]. The success of the QW structures is strictly related to the technological progress made in the growth of layered structures. The requirements of controlling the materials composition at the nanometer scale and of maintaining high crystal quality are well satisfied by the epitaxial growth. Several types of epitaxial growth have been developed so far allowing the deposition of defect-free layers down to an atomic level of control.

Very soon it was also realized that the possibility to confine carriers in additional spatial directions will further improve the performances of nanostructure devices. In 1982 Arakawa and Sakaki [12] theoretically demonstrated that the QWR and QD lasers will be far superior to QW lasers. This prediction stimulated a huge effort to produce QWR and QD nanostructures. However, the realization of QWRs and QDs requires the control of the nanostructure geometry not only along the epitaxial growth direction but also along the lateral directions. This achievement has been pursued by different approaches. The first attempts were based on standard semiconductor processing such as lithography for designing the nanostructure geometry and etching for

reducing the lateral dimensions [13]. These methods, in spite of various relevant advantages and some successful results, suffer from the low quality of the processed interfaces and therefore were not very useful for device applications. A completely different route to the production of semiconductor QDs is to use a colloidal chemical synthesis of nanometer crystallites of semiconductors [14]. The colloidal QDs are typically surrounded by dielectrics such as glasses, polymers, or organic solvents. The strength of this approach consists in the control and tuning of the QDs. The main disadvantage is related to the difficulty of integrating the colloidal synthesis with the standard technology of semiconductor devices. The breakthrough in the achievement of QD devices has occurred in the early 1990s with the discovery of the spontaneous formation of QDs by the deposition of highly strained layers during the epitaxial growth [15] or by droplet epitaxy [16]. The self-assembled QDs are coherently grown and show very high crystal quality. There is no processing related damage and the technology of the growth of self-assembled QDs is almost identical to the technology of multilayered deposition developed for the QW devices. These conditions have contributed to a rapid growth of interest for self-assembled QDs, opening the door to the intriguing world of zero-dimensional physics and devices.

This chapter is mainly dedicated to self-assembled III/V QDs (in particular $In_xGa_{1-x}As/Al_yGa_{1-y}As$ systems) which are nowadays one of the major areas of semiconductor research. We will focus our attention to the electronic and optical properties of the semiconductor QDs and in particular on the photoluminescence (PL) characterization of QDs. The analysis of the wavelength, time, and polarization dependence of optical spectra from nanostructures allows one to obtain information on the carrier–photon interaction (optical transition energy, oscillator strength, and nonlinear response), the electronic structure (level positions, density of states, and wavefunction overlap), the carrier dynamics (energy, momentum, coherence, and spin relaxation). Other relevant advantages of optical spectroscopy, with respect to other characterization methods, are its noninvasive nature and the lack of time-consuming sample preparation. Many different spectroscopic techniques have been used for the investigation of semiconductor QDs. Among others let us mention absorption, PL, PL excitation, modulated reflectance, microprobe and near field spectroscopies, magneto-optical measurements, and four wave mixing. Here we will focus our attention on the PL based techniques, which are extremely useful and very common tools, providing ample information ranging from the statistical distributions of QD size to quantum correlations of electronic states in a single QD.

This chapter is organized as follows. Section 2 breifly describes the main aspects of the growth of QD nanostructures, whose electronic structure is discussed in Section 3. A detailed description of the QD photoluminescence is reported in Section 4, where both steady state PL (Section 4.1) and time resolved PL (Section 4.2) are considered. Finally, Section 5 presents some relevant applications and future developments of QD technology.

2. GROWTH

A huge effort has been devoted in recent years to the development and understanding of self-assembling techniques for the fabrication of QD structures. As already remarked, the self-assembling approaches to QD production have the advantage that the structures are formed in the growth environment and no processing is needed either before or after the growth. From the point of view of optoelectronic applications, this is an important advantage. Growth modes which proceed via nucleation at the growth surface of islands, capable of quantum confinement, are the heteroepitaxy of strained layers (Stranski–Krastanow or Volmer–Weber [17]) and droplet epitaxy [16].

The QD growth environment is that of the usual epitaxial techniques [18], like molecular beam epitaxy (MBE) [19]. A more detailed description of the QD growth modes can be found in [20–23].

2.1. Dot Formation via Strained Layer Epitaxy

2.1.1. General Aspects

Three epitaxial growth modes have been classified (Fig. 2): the layer-by-layer growth in lattice matched systems [Frank–van der Merwe (FM)], the island growth mode [Volmer–Weber (VW)], and the layer by layer, followed by island nucleation, growth mode [Stranski–Krastanow (SK)] in lattice mismatched systems [17]. All three growth modes have been observed experimentally, depending on the interface free energy and on the lattice mismatch, in the epitaxy of semiconductors.

In the growth of strained III/V epilayers the SK mode dominates. This gives rise to a growth characterized by nanometer size islands, thus able to induce electronic confinement. Various combinations of III/V semiconductors based on P [24–26], Sb [27, 28] and As [29–32] have shown a SK

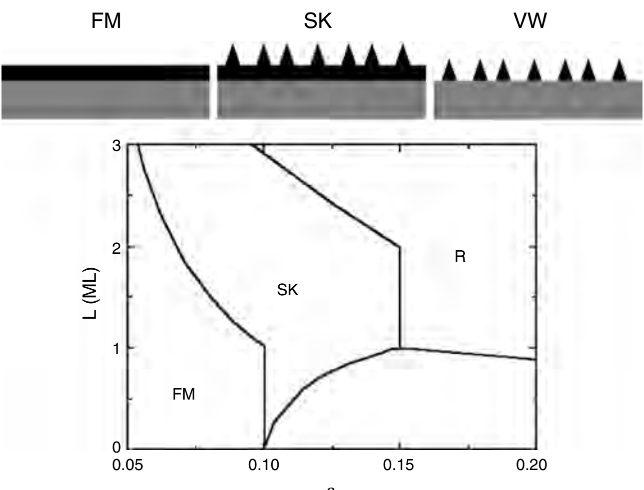

Figure 2. Equilibrium phase diagram in function of the coverage L and the lattice mismatch ϵ calculated using the model reported in [33]. Illustration of the morphology of the surface in the three coherent growth modes (FM, SK, and VW). The R phase is incoherent (large relaxed islands and presence of dislocations).

growth mode. The more widely studied system for optoelectronic applications is $In_xGa_{1-x}As/Al_yGa_{1-y}As$, where the maximum lattice mismatch, between the epilayer of InAs and the substrate of GaAs, is 7%.

A schematic of the SK growth for the typical InAs/GaAs system is reported in Figure 3. In short, the SK growth mode proceeds as follows: after the epitaxial growth of a thin pseudomorphic layer, a two-dimensional layer which "wets" the surface [thus called the "wetting layer" (WL)], the accumulated strain is relieved by the formation of nanometer-scale islands. Thus, a deep change is produced in the characteristics of the epilayer, whose growth switches from layer by layer to islands. This is called the SK transition and happens at a precise epilayer coverage, called critical coverage L_c (see Fig. 3). For the InAs/GaAs system $L_c = 1.5$ monolayers (MLs) [32]. The SK transition, according to [33], can be described as a second order phase transition.

At the early stage of QD formation, the islands can be free of defects. This type of growth produces coherent islands necessary for the fabrication of QDs. Near the critical thickness L_c increasing the coverage gives rise to an increase of the island density, eventually of larger size, without destroying the coherent crystalline growth. On the contrary, when thick layers are grown the islands start to coalesce [34] and defects (like dislocations) are introduced in the structure [30].

The SK formed islands show a pyramidal shape [35], eventually truncated and asymmetric respect to the [110] and [$\bar{1}$10] directions [36]. The exact shape of the QD depends on the surface free energy of the developed facets [37].

A statistical noise affects the size of the grown islands. Typical fluctuation of the self-assembled QD size around the mean is about 10% [38]. A certain degree of control of the shape, size, density, and overgrowth of the dots can be obtained through a suitable variation of the growth conditions. Lateral ordering because of strain fields, preferential nucleation at step edges, and growth on patterned substrates have been reported [20]. Nevertheless the achievement of quantitative control of size and uniformity of QDs is one of the open issues in QD science and technology.

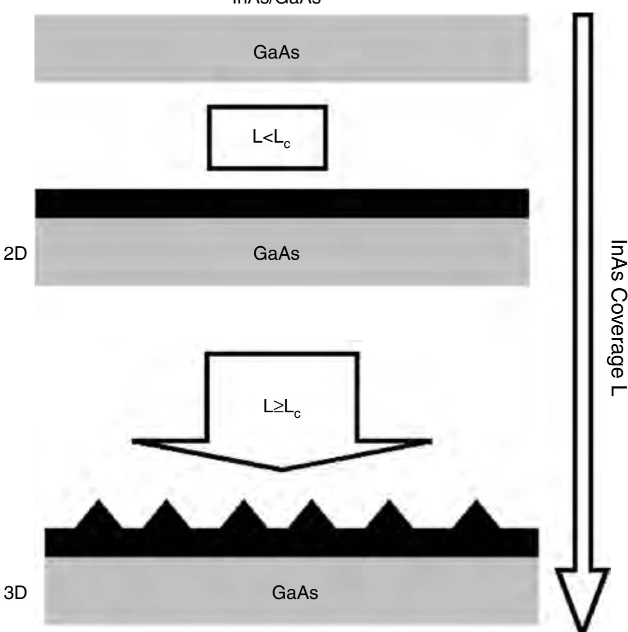

Figure 3. Schematic of the SK growth process.

Multilayer depositions of InAs separated by thin GaAs spacers result in the formation of stacked, vertically aligned, InAs QD columns (Fig. 4). The self-organization of the QDs into vertical columns is driven by the strain fields of the buried islands of the previous QD layer [39, 40]. By subsequent QD layer growth, the QD size becomes more and more uniform within each layer, giving rise to a large reduction of the size distribution. Moreover, the interdot in-plane spacing is made more uniform by stacking, eventually resulting in some kind of lateral ordering [41]. These systems show interesting properties associated with the strain induced by the spatial correlation among different layers.

2.1.2. Theoretical Models

A complete understanding of the mechanisms determining the island nucleation is still a matter of debate. The description is complicated by the coexistence, during the growth, of equilibrium and nonequilibrium effects [33, 42]. Nevertheless, the theoretical equilibrium studies have been quite successful in explaining the key mechanisms of island formation in strained heteroepitaxial systems [33, 43]. By including the effects of in-island strain relaxation and island formation in the determination of the free energy of the heteroepitaxial system, these studies predicted the existence in the equilibrium phase diagram of a range of material constants (namely lattice mismatch and coverage) where stable islands can exist on the surface.

Phenomenologically, the heteroepitaxial growth of a strained film of material A on top of a substrate of material B may proceed in different growth ways, depending on materials and growth conditions: (a) pseudomorphic layer by layer growth, (b) small size islands, or (c) extremely large and defected islands. Daruka and Barabasi modelled this phenomenology by recognizing that the effective distribution of the material A among the three different growth types should be determined by the free energy balance of the whole system. The free energy density of a number L of monolayers of epitaxial strained material A is modelled as

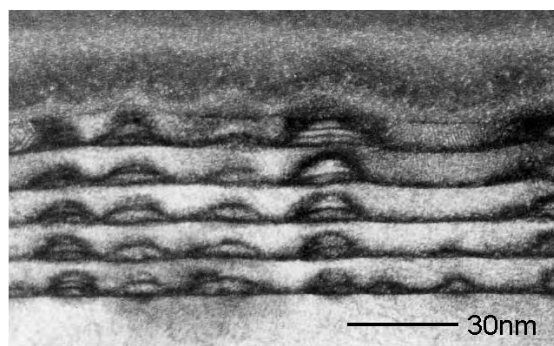

Figure 4. Cross-sectional transmission electron microscope image of a structure consisting of five embedded layers of InAs QDs, separated by 10 nm thick GaAs spacers [110]. Courtesy of G. Salviati.

the sum of the three terms, L dependent, pertaining to the allowed growth modes [33, 44].

The presence of strain drives the system towards an island growth, which, because of symmetry breaking, allows the epitaxial material to relax the strain. Two effects counteract this tendency: the interaction with the substrate, which stabilizes the otherwise unstable (because of accumulation of strain energy) pseudomorphic layer by layer growth at low coverage and low lattice mismatch, and the increase of surface energy due to the expansion of the surface imposed by the island growth.

In the case of typical III–V semiconductor heteroepitaxy, the deposited material A grows, at low mismatch, in the FM mode, thus showing that the interaction with the substrate and the energy cost connected with the increasing free surface due to island nucleation quench the possible strain relaxation permitted by an island mode. Conversely, the VW mode characterizes the growth at high lattice mismatch. Here, the reduction of free energy permitted by the symmetry breaking controls the growth mode. At intermediate lattice mismatch (between 5% and 15%) and coverages larger than unity, the growth mode is dominated by the SK mode. In the Daruka and Barabasi model [33] the insurgency of the island growth mode after an initial layer by layer growth at low coverages is due to the fading interaction of the epilayer with the substrate and to a surface energy cost for the formation of the islands lower than the strain relaxation energy gain connected with the island growth. As the binding energy of the epilayer with the substrate is no longer able to stabilize the pseudomorphic layer (this happens at a certain critical coverage L_c), the extra material A will aggregate in well defined islands, thus showing an SK-type growth. The predicted phase diagram is shown in Figure 2.

In addition to strain energy, binding energy with the substrate, and island surface energy, also stress discontinuities at the island surface edges, surface stress cross-terms, and island–island repulsive interaction have to be taken into account [33]. Substantial refinement of the theoretical model of Daruka and Barabasi [33] can be found in [37] where the surface energies for both the island facets and the wetting layer have been calculated using density-functional theory, and the elastic energy in both the islands and the substrate has been obtained from continuum elasticity theory.

2.2. Dot Formation in the Droplet Epitaxy Mode

New paths for obtaining QDs with novel characteristics, which possibly will give devices with even higher performances, may be provided by the droplet epitaxy (DE) method for the self-assembling [16, 45–50]. The DE method does not rely on the lattice mismatch between the substrate and the epilayer in order to nucleate the islands, thus allowing one to self-assemble QDs in strain-free materials.

The DE process is performed in an MBE system. The DE growth proceeds on a substrate taken at relatively low temperatures (around 180 °C [47]) and consists of two steps. First, a deposition, with the As pressure in the growth chamber depleted, of metallic Ga (or In and Ga in the case of InGaAs dots) which, due to the low growth temperature, leads to the formation of metallic droplets on the top of the growth substrate. Following the deposition of the Ga (or InGa) droplets a high flux As_4 molecular beam is irradiated on the surface leading to the formation of the dots. Subsequent annealing is performed in order to improve the structure.

Structural and electronic differences characterize the DE QDs with respect to standard SK QDs. From a microscopic point of view, the DE QDs are nanocrystal inclusions in the barrier matrix. Their typical dimensions are of the order of 20–30 nm at the base and 12 nm height. It is important to remark that it is possible to grow QDs with or without a WL connecting the QDs (Fig. 5). These latter systems are then a closer approximation to ideal quantum dots than SK QDs.

3. ELECTRONIC STRUCTURE

The accurate prediction of the electronic structure of a semiconductor-embedded self-assembled QD is a highly nontrivial task. Yet it is a crucial prerequisite for understanding the basic optical properties of such systems. Theoreticians who tried to address the problem faced a series of complications. The first one is connected with the low amount of precise structural data available on the "really" grown structures. In addition to QD shape and size, also strain relaxation and composition gradients (for example, In segregation in InAs/GaAs QDs) play fundamental roles in determining the electronic structure of the QDs. Moreover, due to the self-assembling process in the SK mode a residual, thin, 2D QW is present at the base of the QDs, which may affect the QD electronic states. From the theoretical point of view, another problem is given by the low symmetry, no more than C_{2v}, which poses serious difficulties in dealing with excited states such as exciton formation.

The typical procedure followed by all the authors for the electronic structure calculation is to factorize the problem of finding the many-body electronic states in a system with a highly deformed structure in a series of steps:

(a) calculation of the strain profile in the QD material via classical models,
(b) determination of the single electron states in the QD,
(c) inclusion of the many-body effects.

The possibility to factorize the problem in these three levels is given by two approximations, which are justified by the nature of the QD system. The first approximation relies on the observation that, in the self-assembled III–V QDs, the excitonic radius is always larger than the QD dimensions. This means that, in determining the electronic structure of the QD, the major role is played by the confinement energy, leaving to the Coulomb interaction between the carriers only a minor correction, usually treated in a perturbative way.

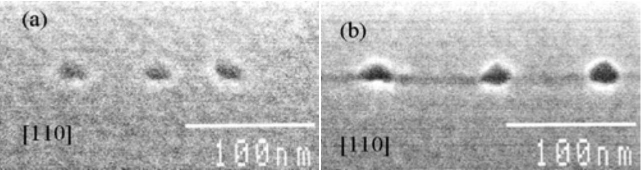

Figure 5. Scanning electron cross-section micrographs of DE QDs without WL (a) and with WL (b). After [50].

The second is that the elastic approximation for the calculation of the relaxed structure is valid (i.e., the electron–phonon interaction is small).

3.1. Strain Calculation

A large strain is present in the SK QDs, which strongly couples to carriers through band structure and piezoelectric effect. Therefore, it is essential to consider the influence of strain on the properties of the dot itself and its surroundings, because the wavefunctions and energies are very sensitive to the underlying strain distribution. As a matter of fact, in the SK QDs the impact of strain on the optical transitions is comparable to that of the carrier confinement induced by the band offset due to the variation of the chemical composition at the heterojunctions [35]. A relevant point is that the strain in the QD is insensitive to the WL primarily because the WL is so thin and also because it is biaxial strained to match the substrate lattice. So the WL is usually excluded from strain field calculations. Several methods can be used to calculate the strain. They can be divided in two main categories: the continuum elastic theory [35, 51, 52] and the atomistic approaches [53–55].

3.1.1. Continuum Elastic Theory

Within the continuum elastic theory (CET) approach, the strain field $\epsilon_{ij}(\mathbf{r})$ for a given structure is obtained by minimizing the total elastic energy U_{CET} [56],

$$U_{\mathrm{CET}} = \frac{1}{2} \sum_{i,j,k,l} \int_V C_{ijkl}(\mathbf{r}) \epsilon_{ij}(\mathbf{r}) \epsilon_{kl}(\mathbf{r}) d(\mathbf{r}) \tag{3}$$

where C_{ijkl} are the crystal compliances. The usually reported procedure to minimize U_{CET} is via numerical (finite differences) methods [35, 52, 57]. A more intriguing way to achieve the minimization of U_{CET} is described by the isotropic elasticity (IE) theory [51, 58]. This approach considers the elastic properties of the QD material as homogeneous and isotropic. This is a quite strong approximation, because the elastic properties of III–V semiconductors are significantly anisotropic. Moreover, the sensitivity of some physical properties (such as effective masses) to strain suggests that anisotropic effects could be important in semiconductor materials. Nevertheless, as shown by [51, 59] the IE is able to reveal the main features of the strain field distribution in QD materials. This is due to the low symmetry of the QD shape, which is the major source of the strain anisotropy in QD structures [59]. IE shows that the elastic field which minimizes U_{CET} can be analytically derived from a scalar potential that obeys a Poisson-like equation with the lattice mismatch acting as charge density. The strain field is analogous to the electric field, thus providing an intuitive way to visualize the distortion around the dot [51].

3.1.2. Atomistic Approach

The elastic energy, in the case of the atomistic approach U_{AT}, is written as a sum of the single atomic contributions. These are in turn determined by the appropriate interatomic potentials which depend on the relative positions of the nearest neighbor atoms. Because III–V semiconductors show covalent bonds with only some partial charge transfer, the more suitable interatomic potential is given by the valence force field (VFF) [60, 61]. The VFF model is a microscopic theory which includes the bond stretching and bond bending contributions to the total energy. The equilibrium atomic positions are then derived through numerical minimization of U_{AT}, thus allowing the determination of the displacement vector field and, in turn, of the strain field [56]. This type of approach becomes necessary when the exact atomic positions are needed for the electronic structure calculation, as in the pseudopotential approach [54, 55].

The strain field calculated with the two approaches has been found to agree reasonably well [52]. The main discrepancy is near the dot boundary, where large strain variation is found in the atomistic approach with respect to the CET [62].

Let us now describe the calculated strain field of an InAs pyramidal QD embedded in GaAs within the CET approach. The local variation of the hydrostatic and biaxial strain [56] is visualized through a linescan passing in the dot center in Figure 6. These strain components define the potential profile for the electrons and the splitting of the light and heavy hole states, respectively. The inner part of the QD contains nearly homogeneous hydrostatic strain, which is almost absent in the barrier. This means that the materials dilation is also confined in the QD. On the contrary, the biaxial strain is transferred significantly from the dots to the barrier and exhibits a distinct minimum in the QD. Thus the deformation of the electronic profile extends deeply in the barrier. The exact shape of the QD does not play a major role in determining the strain field distribution [59], although large changes in the QD aspect ratio do play a role [63]. Additionally, shear strain is present in the structure, which turns out, in QD grown on (100) oriented substrates, to be significantly close to the pyramidal edges. This strain component is responsible for the insurgency of a piezoelectric polarization charge. In fact, the piezoelectric polarization induced by the shear strain tensor components

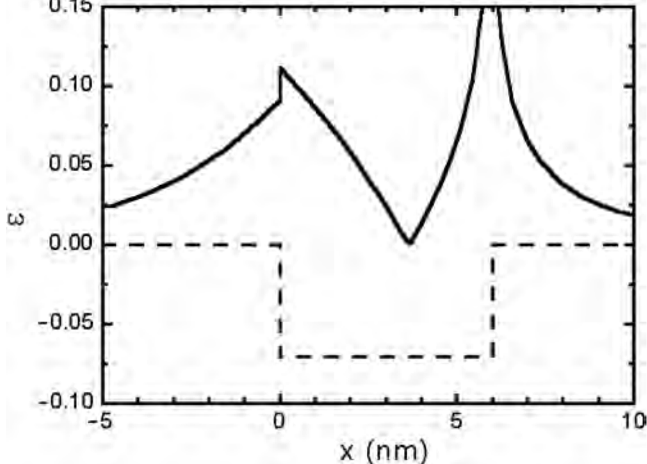

Figure 6. Strain, calculated via IE approach [51], as a function of the coordinate x of the dot axis, for a pyramidal quantum dot with 6 nm height, 12 nm base, and a lattice mismatch 7.2% inside. The dotted line indicates the material dilation, while the continuous line shows the deviation of strain from the purely hydrostatic form.

is given by [56]

$$P_k = e_{1,4}(\epsilon_{ij} + \epsilon_{ji}) \tag{4}$$

where $i \neq j \neq k$ and $e_{1,4}$ is the piezoelectric constant. The divergence of the polarization P_k gives rise to piezoelectric charges spatially distributed around the dot thus contributing to the QD potential profile.

3.2. Energy Level Scheme

3.2.1. Single Electron States

The more widespread method for calculating the electronic energy level scheme in QDs is the effective mass approximation (EMA) [35, 52, 53, 57, 63, 64]. In this approach, the states of the dots are determined by expanding their wavefunctions on a basis containing the zone center (Γ) bulk valence band states (from two to six states, including spin) and the bulk conduction band (two states, including spin),

$$\Psi_i^{\mathrm{EMA}}(\mathbf{r}) = \sum_{n=1}^{N_B} f_n^{(i)}(\mathbf{r}) u_{n,\Gamma}(\mathbf{r}) \tag{5}$$

where $u_{n,\Gamma}(\mathbf{r})$ are the bulk Bloch functions at Γ and $f_n^{(i)}(\mathbf{r})$ are the envelope functions satisfying the equation

$$H_{\mathrm{EMA}} f = Ef \qquad f = [f_1 f_2 \cdots f_{N_B}] \tag{6}$$

The H_{EMA} Hamiltonian contains the contributions coming from the band structure of the heterostructure, the strain field, and the piezoelectric field. The calculation of the strain field is performed usually by solving the elasticity continuum theory problem with numerical methods. Comparison of the changes in the obtained electronic band structure when using the IE analytical solutions or the VFF atomistic method is reported in [65] and in [52], respectively.

Early calculations by Grundmann et al. [35] for InAs/GaAs QDs made use of a three-dimensional EMA single band Scröedinger equation for the electrons and holes moving in the strain-induced potential corresponding to the band edges. The effective masses were different in the island and barrier materials, but the effective mass dependence on the strain was not included.

This approach has been subjected to a number of criticisms, mainly dictated by the model prediction of a single electronic bound state in QD, in poor agreement with the experimental findings. As pointed out in [63], the narrow InAs bandgap leads to significant band mixing, resulting in large strain induced variations of the effective masses. Based on a pseudopotential calculation, the authors of [63] set the electron effective mass $m_{\mathrm{eff}} = 0.04 m_0$, which is the value predicted for bulk InAs under the average hydrostatic strain in the island. This gives two electronic confined levels, in better agreement with the experimental findings.

As matter of fact, the calculation of the QD band structure by solving the decoupled electron and hole problems is not correct in the case of SK QDs. In general, in SK QDs strong mixing of the bands is promoted by the low bandgap of the constituent semiconductors, by the very large strain field, and also by strong spatial variation of the strain field. More reliable results are claimed when using EMA methods with a larger set of bands in the wavefunction expansion given in Eq. (5) [52, 53, 64, 66].

A very different picture comes from the GaAs/AlGaAs QDs grown by droplet epitaxy. Here no particular strain is expected due to close resemblance of the lattice constant of the QD and the material. In this case, a simple one band EMA is sufficient in order to obtain theoretical predictions very close to the observed transitions [67].

Due the confined nature of the QD states, a good reproduction of the band structure in the proximity of the Γ point becomes necessary. In their calculations Stier et al. [52, 68] selected an EMA set of parameters which gave the best available agreement with the bulk band structures calculated from the pseudopotentials within the largest possible region around the Γ-point.

The piezoelectric potential is a crucial ingredient for obtaining the correct description of the QD electronic properties. In the most widely studied case of QDs grown on (100) substrates, the shear strain at the QD edges gives rise to a quadrupolar piezoelectric charge distribution which reduces the symmetry of the QD (in the case of QDs of pyramidal shape the symmetry is lowered from C_{4v} to C_{2v}) [35]. The presence of a piezoelectric field only slightly alters the ground state energies (few meV) while it forces the electron states to prefer the [110] direction and the holes to be more attracted toward the $[1\bar{1}0]$ directions. The effect is more marked on the hole states. This symmetry breaking reduces the overlap between the electron and hole states and has strong effects on the polarization dependence of the optical transition matrix [52, 68]. Its effect is shown in Figure 7 where such reduction can be appreciated both on the band edge profiles and on the ground state wavefunctions.

In Figure 8 the electron and hole energies in pyramidal InAs/GaAs QDs for different sizes, calculated using the CET strain model and the eight band ($N_B = 8$) EMA method [52, 68]. The presence of the WL at the base of the QD was taken into account. The discrete nature of the electronic levels is clearly perceptible. This gives rise, as in the case of atoms, to a well defined shell structure of the electronic levels.

For pyramidal QD with a base b smaller than 10 nm only 1 electronic state is predicted, but for $b = 20$ nm there can be as many as 11 [52]. The ground state of electrons (see Fig. 7) is always s-like, with a shape slightly elongated along the [110] direction. Excited states have p-like symmetries. No intermixing between the QD electronic states and the WL has been found. Holes are generally confined at the bottom of the pyramid. The shape of their wavefunctions strongly depends on the dot size due to pronounced band mixing effects. The wavefunctions of the excited hole states extend into the WL, thus coupling with the 2D quantum well states.

More recently, empirical pseudopotential methods [69] able to calculate the electronic structure of QDs containing $\approx 10^6$ atoms became available [55]. In this pseudopotential approach the wavefunction, $\psi_i(r)$, is a solution of the Schrödinger's equation

$$\left\{-\frac{1}{2}\nabla^2 + \sum_{n\alpha} \hat{v}_\alpha(r - R_{n\alpha})\right\}\psi_i(r) = \epsilon_i \psi_i(r) \tag{7}$$

where $\hat{v}_\alpha(r - R_{n\alpha})$ is the pseudopotential of the atoms of type α and $R_{n\alpha}$ is the relaxed position of the nth atom of type α. The atomic pseudopotentials $\{v_\alpha\}$ are strain

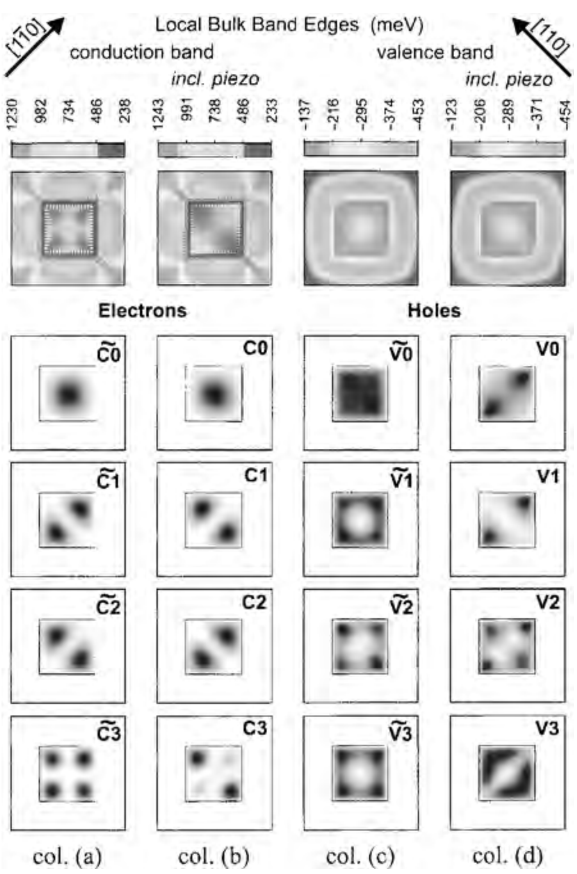

Figure 7. Top row: electron (cols. a,b) and hole (cols. c,d) band edge profiles in a (001) cross section plane 1.0 nm above the WL with and without piezoelectric effect for a square based InAs/GaAs QD. The energies refer to that of the unstrained InAs. Other rows: corresponding probability density of bound states along the same section plane. After [68].

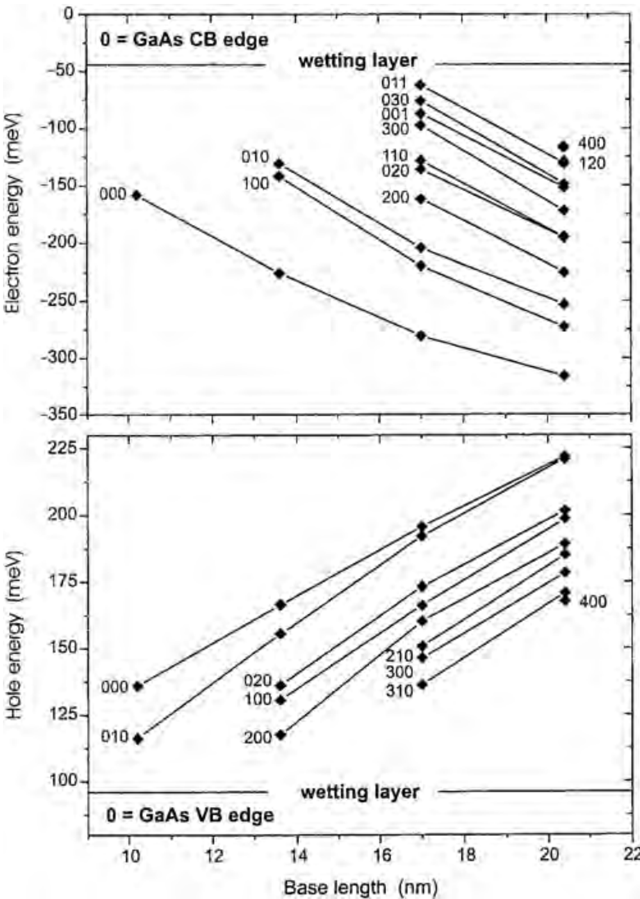

Figure 8. Electron and hole energies in pyramidal InAs/GaAs QDs for different sizes, calculated using CET strain model. The lines connect levels having the same wavefunction symmetry. After [68].

dependent and are carefully fitted [70] to measured bulk bandgaps, effective masses, and first-principles calculations of the band offsets [71] and deformation potentials [72]. The relaxed atomic positions are determined by minimizing the VFF energy, as outlined in the previous section. The main disadvantage of this method is the requirement of large computer time, although some attempts toward a more treatable solution of the problem have been taken [73]. In addition, the pseudopotential approach, in the present version, is unable to treat the piezoelectric field contributions.

The advantage of the pseudopotential method is the ability to take into account the whole band structure of the material when calculating the electronic structure of the confined system. This becomes a crucial point when treating with semiconductors where other minima in the **k** space may contribute to ground state wavefunction [74]. In principle, also the EMA method could give an accurate description of the band structure effect, provided that the number of the Γ functions N_b involved in the calculation [Eq. (5)] is sufficiently large. However, in the EMA calculations the use of more than eight bands becomes rather cumbersome. As shown by Wang et al. [74], $N_b = 8$ becomes, in some cases, an insufficient base for a correct description of the QD electronic structure.

Eventually, the electronic level schemes of a "well behaved" InAs/GaAs QD system, calculated via a pseudopotential method [75] or via the eight-band EMA [52], largely agree [68].

The oscillator strength of the electron–hole transitions can be theoretically determined from the single electron level scheme [52, 63]. In the linear response approximation the resulting spectrum is equivalent to the absorption. A comparison of the oscillator strength spectra with the emission spectra must be performed cautiously because population [76] or many-body effects [77] may substantially change both the energy and the intensity of the transitions.

The electron–hole transition spectra exhibit [52] a large number of lines which reflect the presence of several excited electron and hole states. Some electron states yield a significant oscillator strength with more than one hole state so they contribute to more than one line. Therefore straightforward attribution of a line to a given transition, except the ground state one, is impossible because the peaks are made of a significant number of equal strength electron—hole transitions with no particular dominant transition [52, 78].

A significant decrease of the optical strength of the ground state transitions with increasing dot size has been found, owing to the increasing piezoelectric field which, by symmetry breaking of the hole state wavefunction, reduces the overlap with the electron [52]. Moreover, the

piezoelectric induced symmetry breaking induces a polarization anisotropy between the two directions [110] and [1$\bar{1}$0].

3.2.2. Multiparticle States

As soon as the QD is populated with two or more carriers, the single particle description of the electronic properties is no longer valid. As a matter of fact, the Coulomb energy, the exchange, and the correlation effects between the carriers lead to the formation of distinct many-body states with different energies. Thus a demanding challenge in the QD modeling arises when calculating the optical transitions because, in addition to the shape, size, and composition of the dot, they are also dependent on the population of the dot itself. Multiparticle states have a strong influence not only on the QD optical properties, but also on the way in which a QD is charged. The QD state filling by carrier injection has been calculated, taking into account the many-body effects, by Fonseca et al. [79] who showed that, even in the presence of large state filling, the QD shows a distinct electronic shell structure and that the state filling follows Hund's rule.

Generally speaking, the many-body effects on the QD electronic structures are usually divided into three different contributions, namely: (1) a perturbative part, reflecting carrier–carrier direct Coulomb and exchange energies obtained from fixed single-particle orbitals, (2) a self-consistency correction arising when the single particle orbitals are allowed to adjust to the presence of carrier–carrier interaction, and (3) a correlation correction [80]. This picture is correct since self-assembled III/V semiconductor QDs are always in the strong confinement regime.

The presence of more than one electron–hole (e–h) pair inside the QD strongly modifies the QD radiative emission, leading to the so-called multiexciton transitions [77, 81, 82]. The energy of the photon emitted by the recombination of a single e–h pair depends on the number of carriers filling the QD. The essential physics of the multiexciton transitions can be understood by considering the fundamental recombination from the lowest electron level and the highest hole level if other electron–holes pairs are present in the dot as spectators [77, 81, 83]. Let us consider only the Hartree–Fock energy (thus neglecting correlation effects) of a single configuration of electrons and holes [77, 83]. By indicating with J_{ij} the direct Coulomb interaction and with K_{ij} the exchange interaction between carriers in levels i and j, the recombination energy $E_{eh}^{1\to 0}$ of the single exciton is given by

$$E_{eh}^{1\to 0} = (\epsilon_{e_1} - \epsilon_{h_1}) - J_{eh} \tag{8}$$

where ϵ_{e_1} and ϵ_{h_1} are the single-particle levels. Then the electron–hole recombination in the presence of $N-1$ spectator electrons and holes is [83]

$$E_{eh}^{N\to N-1} = \left[\sum_{i=2}^{N}(J_{e_1e_i} - J_{e_1h_i}) + \sum_{i=2}^{N}(J_{h_1h_i} - J_{h_ie_1})\right] + - \left[\sum_{i=2}^{N} K_{e_1e_i} + \sum_{i=2}^{N} K_{h_1h_i}\right] + E_{eh}^{1\to 0} \tag{9}$$

where e_1 (h_1) is the electron (hole) that recombines and e_i (h_i) are the spectator electrons (holes). Thus the e_1–h_1 transition is shifted in energy with respect to the single exciton transition energy by a quantity depending on the number of spectator charges present in the QD. The sign of this shift depends on the exact material characteristics and on the charge state of the QD [84]. Accurate many-body calculations of ground state transition energies as a function of the number of excitons in the InAs/GaAs QD system can be found in [77, 83]. In this case, multiexcitons transitions occur at lower energy (few meV) with respect to single exciton transition energy. Experimental evidence of multiexciton transition in QDs has been reported by using single QD spectroscopy (see Section 4.1.8).

3.3. Dot–Dot Correlation

As reported in Section 2.1.1, repeated depositions of InAs on thin GaAs spacers result in the formation of stacked, vertically aligned, InAs QDs in a GaAs matrix. The self-ordering of QD columns produces strong quantum mechanical modifications of the electronic structure. Whenever the barrier thickness is thin enough to allow tunneling, a carrier delocalization occurs and the carrier wavefunctions become extended over many QD sites along the column. The coupling between adjacent QDs leads to the splitting of the levels [85, 86] and eventually minibands can open in a QD superlattice [87].

The fascinating concept of self-aligned QD molecule has been introduced [88, 89] and several interesting aspects have been addressed. In connection with the growing interest in quantum information processes, the use of self-aligned QD molecules as quantum gates has been recently proposed and the possibility of entangled states of the electron–hole complex in QD molecules has been reported [90].

It is usually assumed that the hole coupling is weaker than the electronic one, due to the heavier hole masses [40, 86]. However, a detailed study of the electron and hole confinement energies in stacked self-assembled InAs QDs as a function of the layer separation is reported in [91]. It is shown that very little coupling is observed in case of electron levels, while the hole levels are strongly affected by the coupling, which definitively lifts the hole degeneracy. Of consequence, this results in a different character of the electron and hole wavefunctions. It is also shown that the electron wavefunction in a nine-layer structure with an interlayer separation of about 10–15 nm remains localized within each QD, whereas a complete delocalization over the entire dot column is predicted for the hole wavefunction. Only for smaller interlayer separations is the electron wavefunction also delocalized over the coupled QDs.

Carrier delocalization along the QD column modifies the recombination kinetics in stacked QDs, as well [91–93]. An increase of the emission lifetime in stacked QDs has been observed [91, 92]. The interpretation relies on the reduction of the oscillator strength of the exciton inside the QD column [91], also due to the different delocalization between the wavefunctions of electrons and holes [91, 94].

4. PHOTOLUMINESCENCE

The study of the optical properties of semiconductor structures is a very wide topic. It covers a large variety of experimental techniques and it allows one to investigate many

physical aspects ranging from the intimate nature of quantum mechanics to the characterization of impurity contamination and defect content. The optical methods are very often complementary of the electrical measurements, which are the other powerful techniques for the investigation of electronic properties in semiconductors. They offer the advantages of the spectroscopic techniques, that is, the possibility of discriminating over different contributions. A further advantage of many optical methods is the requirement of very small, if any, sample preparation which therefore makes it a noninvasive technique. Among the optical spectroscopies, PL is certainly the most widely used, due to its simplicity and powerfulness.

The PL consists of the spectroscopic analysis of the radiation emitted by a system which has been excited via absorption of light with energy above the absorption edge. The radiation is generated by the radiative recombination of the photoexcited electron–hole pairs. The analysis of the photoluminescence spectrum as a function of different parameters, such as temperature, excitation energy, excitation intensity, and external fields, provides general information on the electronic properties and on the quality of semiconductors and semiconductor heterostructures. Generally speaking, the PL spectroscopies can be divided into steady state (or CW) and time resolved. We will treat separately these two experimental techniques.

4.1. CW Photoluminescence

The CW-PL is a well established technique for the study of semiconductor structures and we refer to [95–98] for general reviews on different types of recombination in semiconductors and also to experimental details of the CW-PL apparatuses. Here we will review only a few experimental aspects that are of peculiar importance for the study of QD structures and then we will refer to the main topics that can be addressed by CW-PL in the study of QD structures.

4.1.1. Experimental

The measurement of QD-PL spectra is commonly performed using conventional optical systems. The exciting source is a laser with energy higher than the energy gap of the confining barrier and the exciting laser beam is focused on a spot of diameter of a few tenths of a millimeter. In this case the QD-PL band is almost unstructured and broad some tens of meV, due to the spread of the QD dimensions. Thus, no special resolution is required for the detection.

More demanding are the optical systems needed to measure the PL spectra of a single or of a few QDs. In order to resolve the single QD emission high spectral and spatial resolution is required. The intrinsic homogeneous linewidth of the fundamental optical transition at low temperature has been found to be as small as 2 μeV. [99]. The need for this high spectral resolution is not very common in the PL study of semiconductor structure and it is related to the atomic-like nature of the QD electronic structures. High spectral resolution apparatuses are obtained by the use of diffractive spectrometers with high focal length [100] and/or inserting a Michelson interferometer in the detection path of a photoluminescence system [101]. At the same time very high spatial resolution is needed for isolating a single QD emission. A submicrometer spatial resolution is required for single QD spectroscopy. This has been realized following different methods. The simplest way is to use a micro-PL apparatus that can allow diffraction limited resolution. To fix the orders of magnitude, let say that a 1 μm spatial resolution allows one to detect one single QD only if the areal density is lower than 10^8 dot cm^{-2}, which is slightly smaller than the achievable QD densities. Fortunately, due to the inhomogeneous size distribution of QDs, the emissions of individual QDs are spectrally separated and even for 10^9 dot cm^{-2} it is possible to isolate a single QD emission with micro-PL techniques after a careful choice of the point on the sample. Nevertheless the control of the areal density down to 10^9 dot cm^{-2} or even lower is not a very simple task for the epitaxial growth of self-aggregated QDs [82]. To further improve the spatial resolution near field optics [102] or sample processing with very small mesas (hundreds of nm) [101] have been used.

Usually, the PL of quantum structures in general and of QDs in particular is excited using photons whose energy is higher than the energy of the bandgap of the barrier of the structure. However, excitation spectroscopy is frequently used for characterizing the complex electronic structure of QDs. Excitation spectroscopy means the study of PL emission as a function of the energy of the absorbed photons. Two main spectroscopic methods have been used so far: resonant PL (RPL) and PL excitation (PLE). PLE measurements are made by monitoring the intensity of a given emission energy (usually within the inhomogeneous broadened QD-PL band) while the excitation energy spans the QD density of states. Peaks in the PLE spectrum are interpreted as resonances in the QD absorption spectrum due to excited states. RPL measurements refer to PL spectrum taken for a given excitation energy which is usually below the absorption edge of the bidimensional WL. The RPL spectrum shows a spectral narrowing due to the selection of a sub-ensemble of QDs which have excited states in resonance with the laser energy. The relationship between RPL and PLE has been recently discussed in [103].

4.1.2. General Aspects

The analysis of the CW photoluminescence spectra of 0D strained epitaxial heterostructures provides important information on the electronic and morphological properties of these systems [21]. In this section we introduce the main aspects of the CW photoluminescence of QDs which will be discussed in more detail in the following sections.

A first example is reported in Figure 9 for the InAs/GaAs system; PL spectra measured for increasing thickness of the deposited layer evidence the morphological changes induced by the coverage variation [104, 105]. At low coverages ($\Theta <$ 1.5 ML) a high energy structure peaked at about 1.45 eV appears, which smoothly shifts to lower energies and whose intensity increases for increasing coverage. This structure, which is attributed to the 2D confined states of the WL, vanishes at coverages just beyond the critical thickness L_c. At this coverage the PL spectra provide some evidence of more confined states due to the islands or QDs. The corresponding PL band is peaked at about 1.215 eV, thus showing that the QD localization energy with respect to the WL

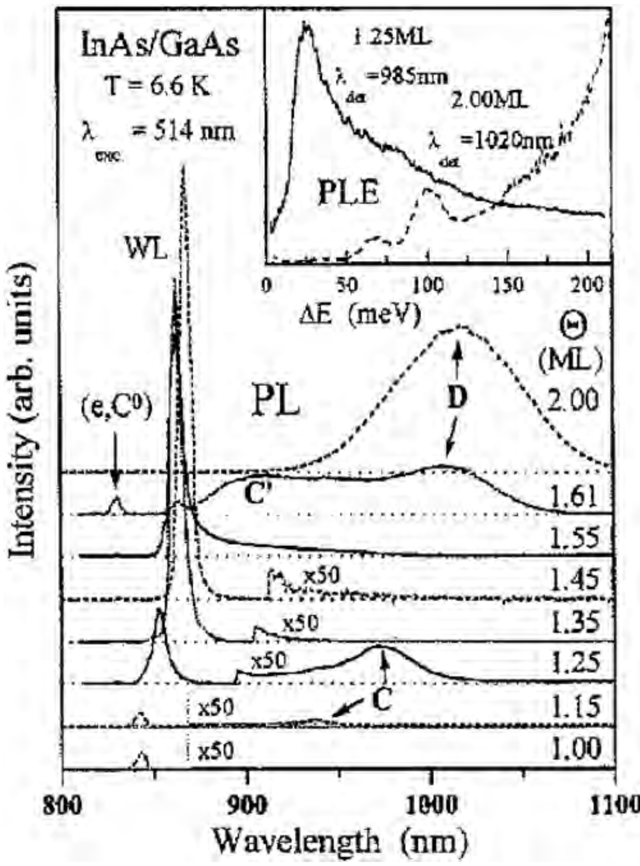

Figure 9. PL and PLE (inset) spectra measured at low temperature ($T = 6.6$ K) of InAs/GaAs samples with different InAs coverages θ; the excitation power density is 5 W/cm^2. C and C′ indicate large and small quasi-3D clusters, D fully developed QDs. For the PLE spectra $\Delta E = E_{\text{excitation}} - E_{\text{detection}}$. Reprinted with permission from [105], T. Ramachandran et al., *J. Crystal Growth* 175/176, 216 (1997). © 1997, Elsevier Science.

ground state is about 200–250 meV. After the SK transition, the narrow peak due to the WL disappears from the spectra measured at low and intermediate excitation power densities, as shown in Figure 9. The WL optical transition, however, still appears increasing the excitation intensities due to the filling of the lower energy confined states [106].

Another interesting feature of the PL spectra consists in providing information on the morphological characteristics of the QDs [107]. Low temperature PL spectra measured on different InAs/GaAs QD structures grown with increasing InAs coverage show that, slightly after the SK transition, the QD PL band slowly shifts toward the red with increasing the coverage. This is proof of the tendency toward the increase in the QD size with the amount of deposited matter (Fig. 10). Analogous results are reported also in Figure 2 of [108].

The low temperature PL spectra measured at low exciting power densities, well before the appearance of the effects related to the excited states, clearly reflect the QD size distribution. The presence of a structured band is usually an indication of multimodal QD size distribution, as evidenced by the correlation between the PL band shape and the size distributions deduced from the morphological

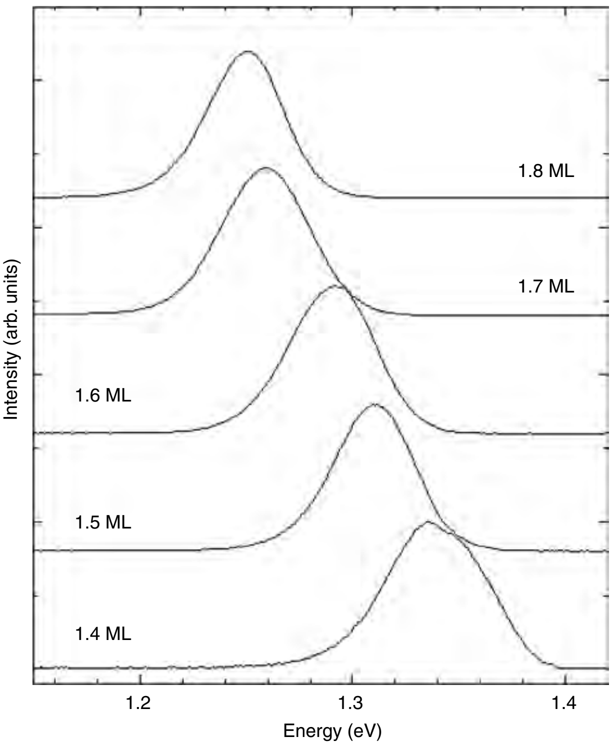

Figure 10. Photoluminescence spectra of InAs QDs grown on (100) substrate with different coverages measured at $T = 2$ K with an excitation power density of 20 W/cm^2. After [121].

analysis of QDs [109]. An example is reported in Figure 11 for InAs/GaAs QDs grown on (311)A and (100) surfaces. Figure 11 shows, for each surface, the histograms of the QD lateral size together with the respective low temperature PL spectra. A well defined bimodal distribution is observed

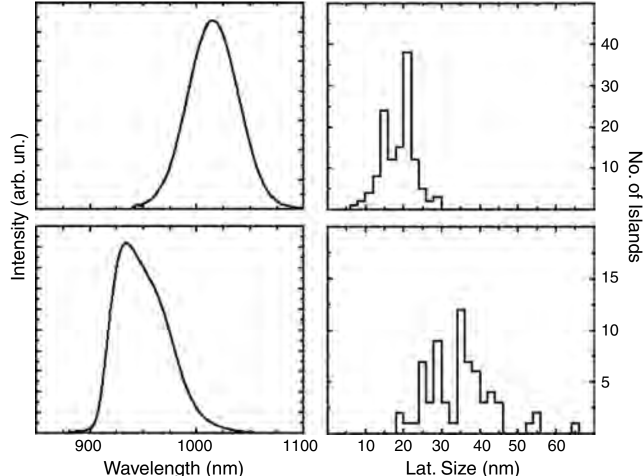

Figure 11. Comparison between the 2 K PL spectra and the lateral size histograms of InAs/GaAs QDs grown on (100) and (311)A substrates. In the left panels the PL spectra are reported: top spectrum (100) sample, bottom spectrum (311)A sample. In the right panels the size histograms are reported: top histogram (100) sample, bottom histogram (311)A sample. Reprinted with permission from [109], S. Sanguinetti et al., *Micron* 31, 309 (2000). © 2000, Elsevier Science.

for the QDs grown on GaAs (311)A and the corresponding PL spectrum shows an asymmetric lineshape with two clearly visible structures. In contrast to the (311)A case, a broad QD size distribution characterizes the (100) sample with a corresponding broad and unstructured band in the PL spectrum.

In analogy with the QW case [98], also in the case of QDs the conduction band and the valence band confinement barriers play an important role in determining the energy of the optical transition. In Figure 12 the blueshift of the PL spectra of InAs/$Al_yGa_{1-y}As$ self-assembled QDs for different Al mole fractions in the barrier are reported [110–112]. The PL spectra show a broad and intense band due to the electron–hole recombination in the dots, whose peak energy shifts from about 1.13 to about 1.55 eV increasing the Al mole fraction y from $y = 0.0$ to $y = 0.8$. The PL band blueshift is likely due to the increase of the potential confining barrier. However, following [110], also the formation of smaller dots when the barrier is formed by the alloy and to the Al incorporation in the dots during the (AlGa)As overgrowth contribute to the blueshift. The two last effects seem to dominate for the higher Al concentrations.

The photoluminescence is one of the few spectroscopic techniques which provide information on the excited electronic states. Both PLE spectra and RPL spectra have been applied to the study of excited states in QDs. One of the most interesting results is the evidence of the so-called quantum size effect. The analysis of the PLE spectra of self-organized InAs/GaAs QDs has shown that the energy of the resonances in the PLE spectra depends on the choice of the detection energy inside the inhomogeneously broadened PL band [103, 113, 114]. This means that, as expected from simple quantum mechanical considerations, the excited state transition energy is a function of the ground state transition energy. These results have been supported by an eight-band EMA calculations for pyramidal QDs [114]. The results of

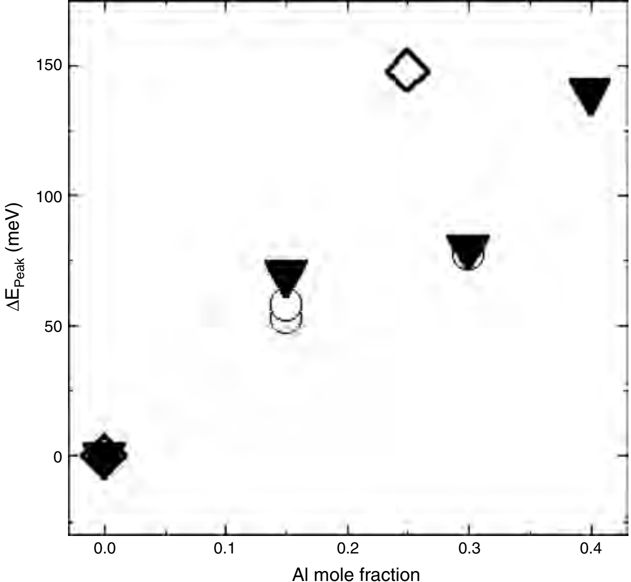

Figure 12. Blueshift the QD PL band as the Al content is increased. Different symbols refer to data taken from [111] (circles), [110] (triangles), and [112] (diamonds).

RPL spectra on InGaAs/GaAs QDs confirm these conclusions [103]. Evidence of the size dependence of the excited state spectrum has been reported also in the case of stacked InAs/GaAs QDs [115].

4.1.3. Study of the Quantum Dot Morphology

As already discussed in the previous sections, the QD morphology strongly influences the CW PL spectra and, of consequence, the PL spectra provide interesting information on the morphological properties of QDs.

In the SK growth regime (see Sections 2.1 and 4.1.2) it is usually assumed that at coverages larger than the critical thickness L_c a layer by layer to island transition sets in the growth process and QDs start to grow superimposed to the interconnecting WL. Obviously L_c is one of the most relevant parameter for the SK QD growth, and, as discussed in Section 4.1.2, it can be estimated from PL measurements. However, different values of the critical thickness for surface elastic relaxation have been reported, ranging from less than 1 to 1.8 MLs. As a matter of fact it is rather difficult to exactly define experimentally the critical thickness, because the determined value of L_c strongly depends on the sensitivity of the technique used [116]. The concept of L_c has been critically commented on in [116], where it has been shown that the critical thickness does depend, even if in a limited range, on the growth conditions and in particular on the growth temperature. The description of the initial stages of QD growth is not univocal, thus evidencing the complexity of the problem. For instance, at coverages just below the critical one, the evidence of some kind of QD "precursors," the so-called "quasi three-dimensional islands," has been reported [104]. These structures thus behave in an intermediate way between WL and QDs. In addition the study of InAs/GaAs QDs grown on nonconventionally oriented surfaces only partially confirms the results of Figure 9 [107]. In fact at coverages lower than the critical thickness weak bands appear on the low energy side of the WL peak whose energy does not seem to change with the coverage (Fig. 13). As discussed in [107], this suggests that in these systems the QD self-assembling starts well before a truly

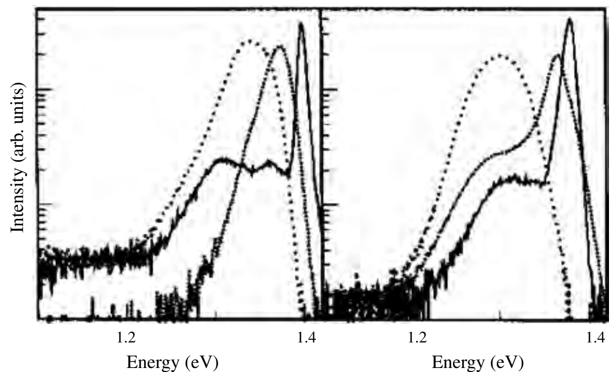

Figure 13. Photoluminescence spectra of InAs QDs grown on (511)B and (311)B substrates with different coverages measured at $T = 2$ K with an excitation power density of 20 W/cm^2. three-dimensional growth mode takes place and the QD size seems not to change appreciably across the SK transition. Thus the island nucleation on high index planes seems to proceed through a direct nucleation of QDs with a well defined size and aspect ratio rather than through the formation of quasi three-dimensional islands as shown for the (100) growth in [104].

The relationships between the QD optical properties and morphology are discussed in [116], comparing the features of PL spectra measured on several tens of MBE samples grown in different laboratories and under different growth conditions. This analysis was stimulated by the observation that PL spectra of QDs grown with the same coverage L are characterized by spectral bands with different peak energies E_p and lineshapes. The peak energy of the PL bands E_p measured at low temperature as a function of the thickness of the deposited layer L for a number of InAs/GaAs QD samples is reported in Figure 14 from [116]. The authors highlight an excellent agreement between their results (Fig. 14) and literature data, thus proving that the (E_p, L) plane is intrinsically divided into the three regions shown in Figure 14.

The interpretation of these data is as follows. The energy of the PL emissions of samples with L lower than about 1.5 MLs (region I) shows a weak linear dependence on L (about 40 meV/ML) and is some tens of meV lower that the WL recombination. The emission in this region can be attributed to the three-dimensional precursors of QDs, that is, lens-shaped structures with a quite low aspect ratio. These emissions are seen only in samples grown at low temperature (420 °C). For L values around the critical thickness L_c, namely in the 1.5–2.0 MLs range (region II), E_p shows a strong dependence on L (about 600 meV/ML). In this region QDs develop and their aspect ratios and E_p are intermediate between those of precursors and those of well developed QDs. The high slope of the E_p on L dependence can be attributed to the change in the dimension and shape of QDs. Finally, at L values larger than about 2 MLs, samples grown in different conditions give rise to independent sets of emission energies, with the result that discrete values of energy can be observed at a given L value. The rate of change of E_p with L decreases to the value observed in region I. As suggested by morphological high resolution cross-sectional transmission electron microscopy characterization, a different lateral faceting seem to characterize the QDs in the samples connected with the different lines in region III.

Obviously, the size also influences the energy of the QD excited states. The dependence of the energy of the QD excited states on the QD size has been analyzed in InGaAs/GaAs samples [103]. The dependence of the resonance energy (determined by the PLE and RPL spectra and attributed to excited state transitions) on the energy of the QD ground state allows the authors to evidence the combined role of quantum size and quantum shape effects in determining the energy of QD excited states.

The QD morphology can also be modified by a suitable choice of the GaAs substrate orientation. An early study of strained InGaAs epilayers grown on non-(100)-oriented substrates showed that this is a promising method for the self-aggregation of nanostructures [117]. Indeed the self-organization of InGaAs QDs on different GaAs surfaces intermediate between (100) and (111) has been subsequently demonstrated and the PL of these QDs has been studied [118–120].

A careful analysis of the QD self-assembling process in these QD systems has shown that the island assembling critical thickness in InAs QDs is affected in a controlled way by the substrate orientation. The determination of the onset of the island nucleation via PL measurements in samples grown on (100), (311)B, and (511)B oriented substrates is reported in [121]. In this paper it is shown that the critical coverage on the (311)B surface is larger than that on the (511)B substrate, which in turn is larger than that on the (100) surface. In [121] it is concluded that the driving force of the critical thickness dependence on the substrate orientation is the reduction of the in-island strain relaxation in high Miller index substrates. Furthermore, modifications of the internal energy induced by island shape and faceting seem to be less relevant than strain relaxation effects [121].

Another powerful tool in order to manipulate the QD morphology and, in turn, the QD energy levels is the rapid thermal annealing (RTA) technique [122–125]. During the RTA treatment the QD material undergoes to a thermal annealing in argon atmosphere for few tens of seconds and for temperature ranging from 700 to 950 °C [124, 126]. The presence of group III vacancies in the InGaAs/GaAs QD material should stimulate [127], under RTA, interdiffusion of the In and Ga atoms at the interface between the QD and the barrier [126]. This should result in a change in the

QD composition, thus reducing the confining potential and an effective increase in the dot size [126]. The study of the morphological modifications of the QDs after RTA has been performed mainly by PL measurements, a well established method for the characterization of the interdiffusion effects in nanostructures [128, 129]. As expected (Fig. 15) an increasing blueshift in the QD emission, caused by a change in the QD composition, and a narrowing QD PL line, due to a larger mean size of the QDs, is observed for increasing RTA temperature [123, 124, 126].

4.1.4. Optical Anisotropy

Although quantum dots are often referred to as artificial atoms, their geometrical shape is quite often characterized by a much stronger confinement along some peculiar crystallographic directions. This morphological in-plane anisotropy of the QDs can be directly monitored by analyzing the polarization properties of the PL emission both from the top and from the edge of the samples.

A clear indication of optical anisotropy in QD emission has been reported in [130] where natural QDs, formed by large interface fluctuations in GaAs/AlGaAs quantum wells, are studied. A scanning tunnel microscope (STM) analysis shows that these islands are asymmetric with an elongated shape along the [−110] crystal axis. As a consequence of this reduction of symmetry, the PL spectra are polarized. A discussion of the origin of the observed polarization behavior is reported in [130].

The presence of optical anisotropy is of the utmost relevance also for laser application. In [131] anisotropic self-assembled $In_{0.5}Ga_{0.5}As/Al_{0.25}Ga_{0.75}As$ QDs, whose PL spectra show optical polarization, are used to control the polarization mode of a QD vertical cavity self-emitting laser.

QDs with very large morphological asymmetry can be growth on (N11) oriented substrates. InAs quantum dashes have been grown on GaAs (211)B substrates by increasing the growth temperature [132]. Arrow-like InAs QDs have been obtained by growth on (311)A GaAs substrates. The peculiar shape of the (311)A InAs QDs is determined by the properties of the reconstruction of the surface on which nanostructures are grown. The (311)A surface reconstruction, at typical MBE growth temperatures, discussed in detail in [133–135], gives rise to a corrugated surface with channels running along the [$\bar{2}$33] direction.

The shape of MBE InAs QDs grown on the (311)A oriented surface reflects this peculiar reconstruction. The STM analysis (Fig. 16) of QDs grown with 1.8 ML of InAs on (311)A and (100) substrates placed side by side provides evidence of a marked shape differences. The QDs grown on (100) oriented substrates have a shape ranging from round domes to square based pyramids, whereas the (311)A QDs display an arrow-head-like faceted shape. The arrow orientation points along the [$\bar{2}$33] direction, which is related to the (311)A surface reconstruction.

The QDs grown on two faces have comparable PL efficiency and a strict mutual relationship is observed between the QD shape and their optical response [136]. In particular, no PL polarization anisotropy was observed on the (100) grown sample. On the contrary, on the (311)A sample the maximum intensity was observed with a Polaroid analyzer parallel to the [$\bar{2}$33] direction, the same direction of the arrow QD tips (see Fig. 16). The polarization ratio ρ (i.e., the fraction of light polarized along [$\bar{2}$33]) was

$$\rho = \frac{I_{[\bar{2}33]} - I_{[01\bar{1}]}}{I_{[\bar{2}33]} + I_{[01\bar{1}]}} = 0.13 \pm 0.02 \tag{10}$$

where $I_{[\bar{2}33]}$ and $I_{[01\bar{1}]}$ are the integrated PL intensities along the two orthogonal directions [$\bar{2}$33] and [01$\bar{1}$], respectively. An explanation of the observed polarization anisotropy has been proposed taking into account the nonspherical QD shape as well as of the degeneracy of the valence bands in bulk III/V semiconductors [137].

It should be mentioned that the polarization anisotropy of QD emission is connected to asymmetries in the hole confining potential introduced or by anisotropic shapes [136, 137] or by quadrupolar piezoelectric effects (see Section 3.2.1) [52]. Symmetric QDs show isotropic oscillator strength [137].

Lowering the symmetry of the QD leads to a substantial mixing between "light-hole" (LH) and "heavy-hole" (HH) states, hence to a polarization asymmetry of the oscillator strength.

An interesting study addressing the polarization properties of the interband optical dipole transition in InAs/GaAs QDs is reported in [138]. The reported results show, in fact, that a moderate LH–HH mixing characterizes the ground hole state.

4.1.5. Photoluminescence Thermal Quenching

The temperature dependence of the QD PL shows some complex characteristics. In fact, an unusual temperature dependence of the integrated intensity, the energy of the maximum, and the width of the PL bands has been reported in InAs/GaAs QDs by several groups [139–144]. In particular, the peak energy of the PL bands exhibits a sigmoidal behavior and, at low temperature, the PL band linewidth decreases with increasing temperature. Such features cannot be explained using the rate equation models commonly adopted to describe the temperature dependence of the PL in confined structures, even if one introduces two activation energies to account for the temperature quenching of the PL bands. For instance, in [110] it is reported that the temperature dependence of the PL integrated intensity of InAs/GaAs/$Al_xGa_{1-x}As$ QDs with different Al mole fractions x cannot be described simply in terms of an Arrhenius plot with one or more activation energies. Moreover, the general description in terms of a carrier thermal evaporation from the QD ground state is complicated by the presence of the WL connecting the QDs. The use of a simple thermal escape model has been questioned and the critical role of the carrier capture and relaxation, as well as of their dependence on temperature, in determining the QD radiative recombination efficiency has been pointed out [115]. In particular, a detailed study of the temperature dependence of the PL decay measured at different wavelengths across the PL band is reported in [144]. The results strongly suggest that excitons or carriers, thermally activated from the QD states to the WL states, move in the WL and finally are recaptured into other QDs. During this process carriers or excitons in QDs with higher transition energy are effectively promoted to the WL states, whereas the population of lower energy QDs tends to increase, due to retrapping. The experimental temperature dependence of the PL decay times is well explained quantitatively in terms of a rate equation model which considers the effects of both carrier emission and retrapping [144].

Recently, a steady-state thermal model for the temperature dependence of the PL spectra in InAs/GaAs QDs has been introduced which takes into account all the most important mechanisms invoked for explaining the peculiar evolution of the InAs QD PL band with temperature, namely, carrier thermal escape and retrapping, QD inhomogeneous broadening, random population of the QD ground states, lack of direct coupling between different QDs, saturation effects, and increasing carrier thermalization for increasing temperature [145]. The model is based on a system of rate equations connecting the main components of the system: the QD states, the wetting layer states, and the GaAs barrier states.

The model accurately fits the integrated intensity dependence on temperature, well reproduces the redshift of the peak position, and reasonably describes the full width at half maximum (FWHM) temperature dependence, as shown in Figure 17. The substantial agreement between model simulations and experimental data suggests a description of the carrier quenching process in QDs in terms of thermal excitation of correlated e–h pairs from the QD to the WL state, which acts as a transit channel to other QDs or to quenching states inside and/or outside the GaAs barrier. The non monotonic dependence on T of the linewidth and peak energy is accounted for in terms of an increasing carrier thermalization within the QD disordered system and in the WL.

A general conclusion that can be drawn from the T-dependence of the QD PL is that the QD interconnection via the WL has a strong influence on the InAs/GaAs QD optical properties [139, 140]. In particular, following the model presented in [145], the carrier escape toward the WL is mainly responsible for the thermal quenching of the InAs/GaAs QD emission. The possibility to control the electronic levels of the WL is therefore of the utmost relevance for the optimization of QD structures toward device applications at room temperature.

This objective has be pursued by different approaches. In particular, it has been recently demonstrated experimentally by means of PL measurements of self-assembled $In_{0.5}Ga_{0.5}As/Al_xGa_{1-x}As$ QD structures grown by atomic layer MBE that the energy separation between the fundamental QD state and the WL electronic levels can be tuned by increasing the barrier bandgap [146]. The energy separation between 0D and 2D levels strongly increases with the Al content, due to the larger penetration into the barrier of the wavefunctions of the WL states with respect to the QD states, and thus the confinement effect related to the increase of the barrier potential is larger for the 2D-WL levels. Furthermore, the use of ternary alloys for both the QD

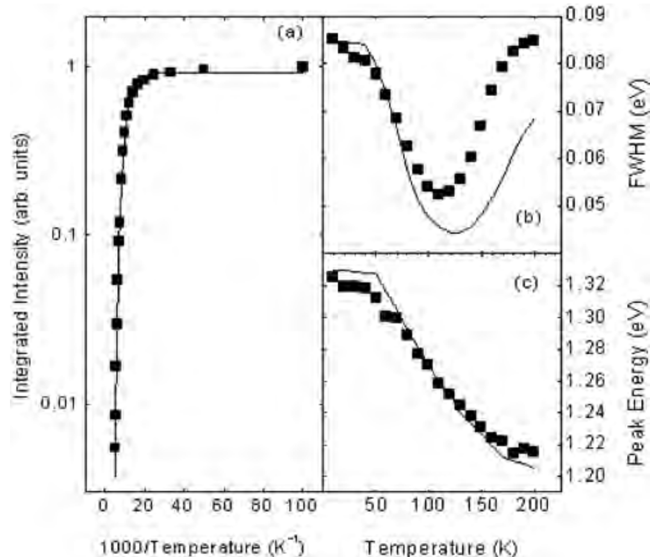

Figure 17. Integrated intensity (a), FWHM (b) and peak position (c) of the PL band of InAs/GaAs QDs vs temperature. The full lines are calculated following the model discussed in [145].

layers and barrier layers allows one to separately tune the QD and the WL emission energies [146]. An alternative way to control independently the energy of the WL states and of the QD states has been proposed: InGaAs QDs have been grown on an AlInAs WL whose energy is matched to the GaAs barrier and embedded in a GaAs matrix [147]. In this system the energy of the WL, increased with respect to the conventional InGaAs/GaAs structures, reduces the thermal carrier redistribution processes, as shown by the temperature dependence of the PL spectra. A strong reduction of the PL thermal quenching has been found when increasing the energy separation between QD and WL electronic levels [110–112, 146, 147].

4.1.6. Piezoelectric Effect in InAs Quantum Dots

The zinc blende III–V semiconductors are piezoelectric because of the lack of inversion symmetry. As a consequence a built-in piezoelectric field, due to the shear strain, can be present. In (001) QD structures the shear strain at the QD edges gives rise to a quadrupolar piezoelectric charge distribution which reduces the QD symmetry [35]. As discussed in Section 4.1.4, this has a quite small effect on the ground state energy transition. On the other side, the piezoelectric field forces the electron states to prefer the [110] direction and the holes to be more attracted toward the [$1\bar{1}0$] directions. This reduces the overlap between the electron and hole states, leading to an intrinsic dipole moment [52, 68].

Piezoelectric effects are relevant also in enhancing the interaction with longitudinal optical (LO) phonons. The polar exciton–LO phonon coupling strength, described by the Huang–Rhys factor S, is dependent on the difference between the probability densities of the electron and hole. In the case of self-assembled QDs, a strong difference between the electron and hole wavefunctions is expected. The charge separation between electron and holes, driven by the piezoelectric potential in the QD, provides an intrinsic way of enhancing polar exciton–phonon coupling [148, 149]. This has been demonstrated in [148] where low energy sidebands of the main exciton recombination peak in InAs/GaAs QDs have been observed. These sidebands, attributed to phonon-assisted exciton recombinations, allow the determination of the Huang–Rhys factor S, which is about 5 times larger than in bulk InAs, thus proving the enhancement of the polar-exciton–LO-phonon interaction in QDs. It should be remarked that the determined value of the Huang–Rhys factor ($S = 0.012$) in InAs/GaAs QDs nicely agrees with the theoretically predicted value. Finally, it is reported that the experimental S values in InAs/GaAs QDs exhibit a clear trend as a function of the QD emission energy: samples emitting at high energy are characterized by high S values, whereas in samples emitting at low energy the S values decrease with the emission energy [150].

Much stronger piezoelectric effects are expected on QDs grown on ($N11$) oriented GaAs substrates where a dipolar distribution of the piezoelectric charges is predicted [151]. Whereas piezoelectric effects in InGaAs/GaAs quantum wells grown on ($N11$) substrates have been largely investigated, leading to a well-established understanding of the problem [152, 153], only very recently has this problem been investigated in QDs. The reverse quantum confined stark (QCS) effect has been evidenced in a series of ($N11$) InAs/GaAs QDs by means of CW PL measurements [154], the direct QCS effect has been investigated by means of photocurrent spectroscopy in a (311)B InGaAs/GaAs QD [155], and finally, the dynamic QCS effect has been analyzed by means of time-resolved PL [156].

The first evidence of piezoelectric effects in ($N11$) QDs was reported in [154]. The PL band of QDs grown on ($N11$) oriented substrates ($N = 2, 3$, and 5) with the two A and B terminations shifts toward the blue for increasing the excitation power density [154]. The blueshift (Fig. 18) shows a clear dependence on $1/N$ with a marked asymmetry about the (100) orientation, being larger on the A faces than on the B faces. The PL integrated intensity of these QDs measured at $T = 2$ K and low excitation power density shows a reduction for large values of $1/N$. Also in this case an asymmetry is found between A and B terminations: the PL efficiency of ($N11$)A samples drops by more than two orders of magnitude when the coverage and thus the QD size is increased, while on the ($N11$)B side the PL intensity reduction is definitely less pronounced.

This phenomenology can be interpreted in the light of the strain induced piezoelectric field, whose presence is expected in self-assembled QDs grown on ($N11$) GaAs substrates. The injection of photogenerated carriers produces a reduction of the internal field and then the QD PL band

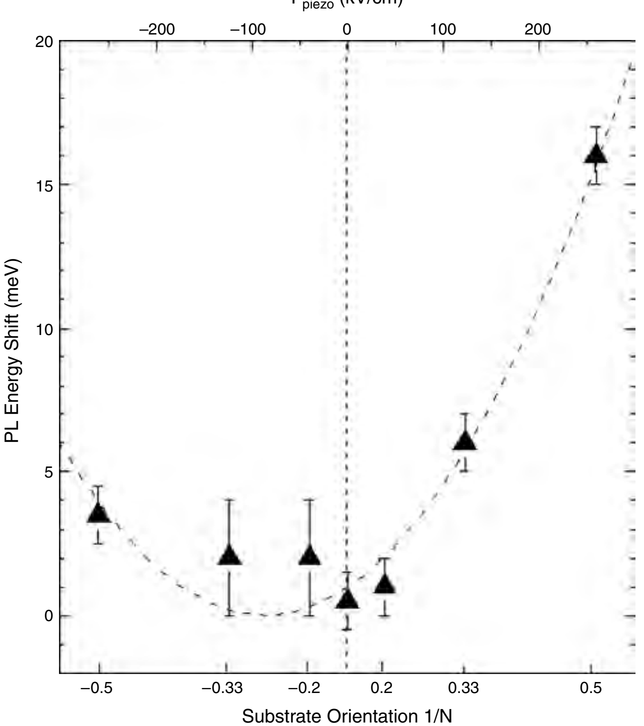

Figure 18. Maximum PL blueshift induced by the increase in the exciting intensity as a function of the substrate orientation. The markers indicate different InAs coverages: 1.4 (squares), 1.8 (triangles), 2.3 (stars), and 3.8 MLs (circles). Reprinted with permission from [151], S. Sanguinetti et al., *Microelectron. J.* 33, 583 (2002). Elsevier Scicence.

shifts toward the blue (photoinduced reverse QCS shift) for increasing the excitation power density. The observed dependence of the PL blueshift on the substrate orientation agrees with the expected QCS shift due to the built-in piezoelectric fields in InAs (N11) QDs. Finally, the asymmetry with respect to A or B termination can be explained by assuming that in the (N11) QDs a permanent dipole similar to the (100) case is present [157]. Confirmation of this picture has been found by time-resolved investigation (Section 4.2.6).

4.1.7. Electronic Coupling Effects in Multilayer Quantum Dots

A key aspect in the technological applications of self-assembled QDs is connected to the achievement of both high spatial density and good size uniformity of the nanostructures. Actually, the state-of-the-art of QD lasers is represented by multilayer structures, where layers of self-assembled QDs are grown in close sequence. As discussed in Section 2.1.1, multilayer depositions of InAs separated by thin GaAs spacers result in the formation of stacked, vertically aligned, InAs QD columns.

Spectroscopic evidence of the interdot coupling is shown in Figure 19 where PL peak energies and Full width at half maximum (FWHM) as a function of the number of vertically stacked InAs/GaAs QDs layers are reported [40]. The band of the single layer sample is broad, reflecting a large QD size variation. Increasing the number of QD layers, the peak energy of the PL band shifts to lower energies and the FWHM decreases. The reduction of the PL band broadening is clear evidence of the reduction of the spread in QD size distribution. The stacking of QD layers produces a relevant ordering in the QD size due to the fact that the QD nucleation is driven by the strain of the buried layer. Thus the spontaneous vertical ordering of QDs in multilayer structures is very important also for controlling the QD size distribution. Nevertheless, more evidence is reported in

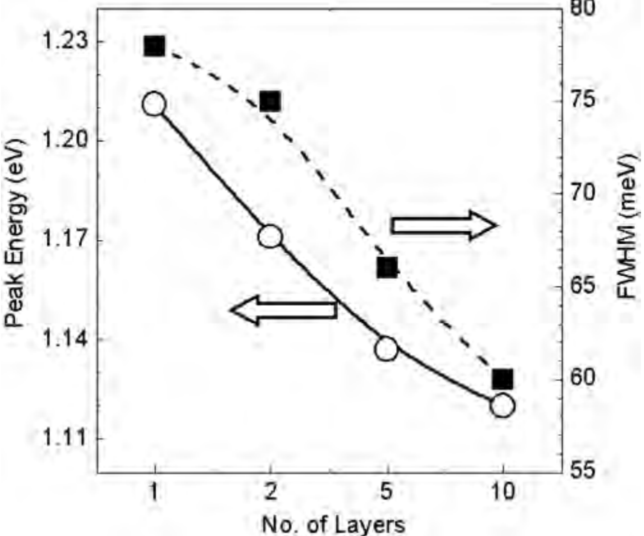

Figure 19. Low temperature photoluminescence peak position (circles) and FWHM (squares) as a function of the number of vertically stacked QD layers. The lines are guides for the eye. Data taken from [40].

[158] leading to the conclusion that in the InAs/GaAs system the stacking of QD layers determines a deterioration of the GaAs barrier. In fact, increasing the number of layers and decreasing the interlayer spacing induce a decrease of the carrier transfer efficiency from the GaAs to the QDs. Efficient nonradiative quenching channels of the QD emission have also been observed. This deterioration of the GaAs interdot layers should be connected with the strain accumulated in the structure [158].

The spectral shift of the QD PL shown in Figure 19 has been interpreted in terms of carrier delocalization induced by the vertical electronic coupling of QDs in columns. This reduces the ground state confinement energy of each dot column since the carrier wavefunction is spread over many QD sites. The coupling between adjacent QDs leads to the splitting of the levels [85, 86] and eventually minibands can open in a QD superlattice [87]. The interplay of Coulomb correction and carrier delocalization complicates the analysis of the optical transition of stacked QDs. In [159] it has been shown that the different delocalization of electrons and holes can also produce a blueshift of the PL from vertically aligned QDs due to the reduction of the e–h Coulomb interaction. A more detailed analysis with analogous results is reported in [160], where the low temperature PL of vertically aligned InAs/GaAs QD structures with 10 layers and spacers varying between 7.7 and 12.5 nm at steps of 0.2 nm is measured.

4.1.8. Photoluminescence of Single Quantum Dots

The main part of the experimental results published on PL of QDs refers to large ensembles of nanostructures. Indeed the large areal dot density, together with the relatively low spatial resolution of the conventional optical techniques, usually makes a huge number of QDs contribute to the optical spectrum. Of consequence, large inhomogeneously broadened bands characterize, even at low temperature, the PL spectra. The bands usually display a Gaussian shape, thus showing that the broadening is due to statistical fluctuations of the QD size around a mean value determined by the growth conditions (coverage, growth temperature, etc.). The best results refer to PL bands whose FWHM is of the order of few tens of meV. We could mention a FWHM of about 15 meV obtained in a InAs/GaAs heterostructure grown on a (511)A oriented substrate [119] and FWHM of 22 meV in InGaAs/GaAs DE grown structures [49].

Such a large width of the PL bands limits in a significant way the potentialities of the QD applications and, furthermore, partially masks the intrinsic properties of QDs, sometimes making their study complex. An example where the discrete nature of the transitions contributing to the large inhomogeneous band is evidenced is reported in Figure 20. The measurements have been performed on MBE grown self aggregated $In_{0.5}Ga_{0.5}As/GaAs$ structure using a conventional, broad area, PL or a confocal micro-PL apparatus capable of micrometer spatial resolution. The broad area PL spectrum displays the typical Gaussian shape, with a FWHM of about 50 meV; reducing the diameter of the spot via micro-PL measurements, the spectrum is resolved in a series of narrow lines (Fig. 20), whose FWHM is about 40–60 μeV [100].

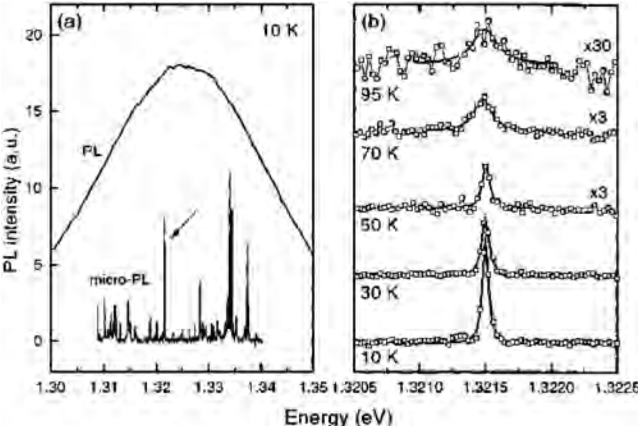

Figure 20. (a) Photoluminescence and microphotoluminescence spectra of InGaAs/GaAs QDs. (b) A single line [marked with an arrow in (a)] measured at different temperatures. The spectra have been vertically displaced for clarity and horizontally shifted for $T > 10$ K to compensate the change in bandgap. Reprinted with permission from [100], K. Leosson et al., *Phys. Status Solidi B* 221, 49 (2000). © 2000, Wiley Science.

These interesting results have stimulated an intense activity aimed at developing experimental techniques for the measurement of the optical properties of a small number of QDs or of a single QD. In particular, the development of near-field spectroscopy (see, e.g. [102]) has allowed the spectroscopic study of single QDs.

A typical example of low temperature PL spectra of a single self-assembled GaAs/$Al_{0.3}Ga_{0.7}As$ QD for different excitation intensities is shown in Figure 21. At the lowest excitation intensity, a single narrow spectral line, whose linewidth is limited by the spectral resolution of the apparatus (0.7 meV), is observed. Increasing the excitation intensity, weak lines appear some meV below the narrow line. Higher energy lines may appear some tens of meV above the first line [81] and can be attributed to the excited states of the QDs. The low energy lines provide evidence of the existence of multiexciton complexes. In [81, 82] these attributions are supported also by the time evolution of the PL spectra and by the results of a theoretical multiexciton model. A detailed analysis of the multiexciton states of single self-assembled QDs is presented in [161, 162], where emission spectra obtained at different excitation intensities are compared with a theoretical many-body model.

The linewidth of the fundamental interband transition of single InGaAs QDs has recently been measured as a function of the temperature using a high spectral resolution apparatus obtained inserting a Michelson interferometer in the detection path of a microphotoluminescence system [101]. The very high spectral resolution obtained in this way (0.2 μeV) showed that the FWHM strongly varies from QD to QD, due to extrinsic effects connected to the electrostatic environment of QDs. The data also show that the interaction with acoustic phonons dominates at low temperature, producing a linear variation of the FWHM for $T \leq 40$ K. At higher temperature an exponential variation is observed, attributed to the interaction with optical phonons.

In [101] the temperature dependence of the homogeneous linewidth of the excited states of single InAs/GaAs QDs is also studied, evidencing an efficient acoustic phonon broadening.

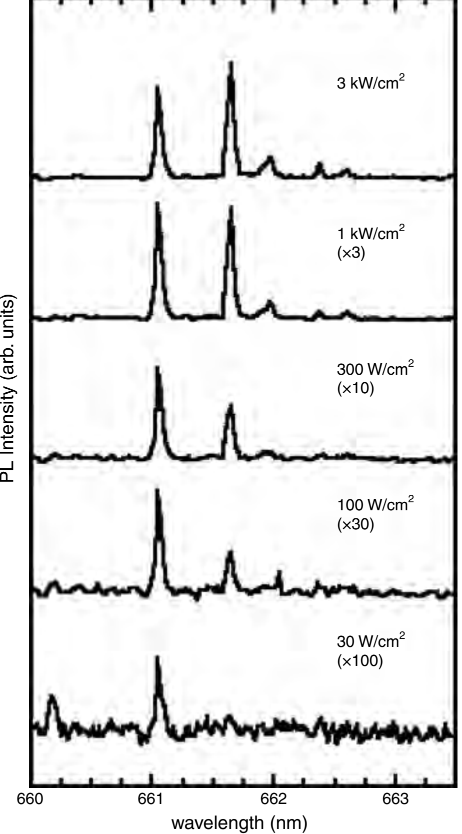

Figure 21. PL spectra of single self assembled GaAs/AlGaAs QD measured at $T = 15$ K for different excitation powers. Courtesy of T. Kuroda.

Interesting effects on single QD PL, the so-called "random telegraph noise" [163] and "spectral diffusion" [164], have been recently reported. These are assumed to be extrinsic effects, usually attributed to defects surrounding the QD and to their state of charge.

The "random telegraph noise," or blinking, consists of a QD switch among two or three levels, with a corresponding change in the PL intensity. The switching rate has a typical scale of seconds or even minutes and increases, increasing the temperature or the excitation intensity. Apparently the emission energy does not change appreciably between the on and the off state [165]. For the explanation of these data a model has been proposed involving a photoactivated defect, having two fairly long–lived configurations. In one configuration the defect captures carriers from the QD, which of consequence has a low emission efficiency. In the other configuration the carrier capture is less efficient and the QD is characterized by a high PL efficiency [163].

The "spectral diffusion" manifests itself as an inhomogeneous broadening of the PL of single QDs at low temperature, determined by the electric fields due to fluctuations in the charge distributions surrounding the dot, with an unexpected temperature behavior [164]. In InP/GaInP QDs the single QD band at low temperature is characterized by a FWHM of some meV; increasing the temperature the band

abruptly changes, switching into several narrow lines and then, at even higher temperatures, to a single sharp peak of very narrow width. The interpretation of these data, as discussed in [164], is as follows. The sharp line in the high temperature spectra is due to the unperturbed fundamental transition of the OD and the broadening of this emission at low temperature is attributed to the interaction of the QD electron and hole states with charges trapped or released by the sites surrounding the QD, leading to fluctuations in the charge configuration. The mode of QD emission depends on the position of the Fermi level determining the charge of these sites. The presence of spectral diffusion effects may not allow one to measure the QD homogeneous broadening using single QD PL. This problem can be overcome by using four-wave mixing techniques [99].

4.1.9. External Applied Fields

The spectroscopic techniques permitting the study of single QDs have opened great opportunities for the analysis of the effect of external fields on the electronic states of zero-dimensional structures.
