In additional to the fabrication of device prototypes, EBDWL, with its recent improvements in repeatability and throughput of shaped EBL tools, has also been recognized as a feasible method for the low-volume production of ASICs and other special devices, for example hard disk heads.

As described in Section 5.2.1.5, forward scattering into the resist can be reduced by increasing the acceleration voltage of the electrons. While this approach causes a

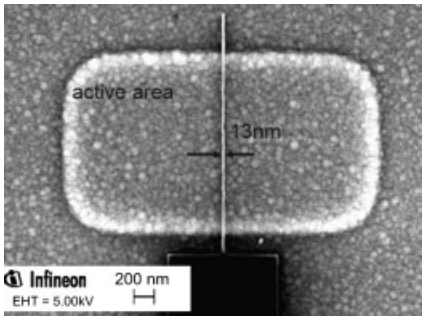

Figure 5.29 Nanoscale planar MOSFET demonstrator. A gate with a 13 nm linewidth prepared using direct-write electron beam lithography (EBDWL) [33].

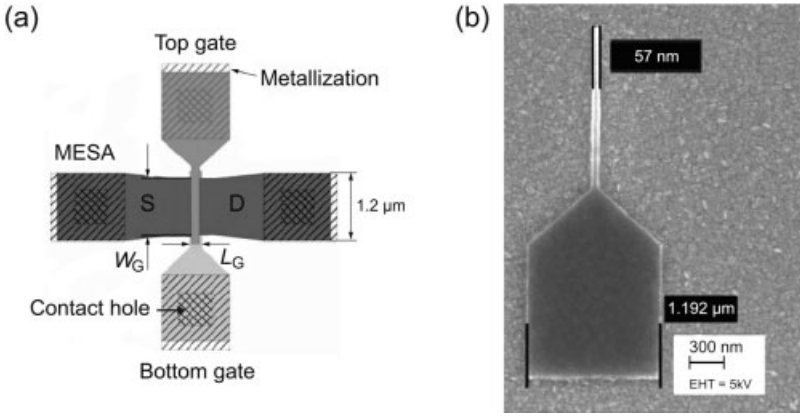

Figure 5.30 Nanoscale planar double gate transistor. (a) Top view of the design. (b) Scanning electron microscopy image of the first fabricated structure: bottom gate (produced by EBDWL) [42].

significant increase of the scattering within the substrate, and also heats up the substrate, in the case of silicon wafers this problem is less pronounced due to silicon's high thermal conductivity. As distortions of the wafer can be rectified by electrostatic chucks with wafer backside cooling, modern direct-writing tools employ an acceleration voltage of up to 100 kV.

Aside from the electron beam writer, specialized post-exposure processing equipment is required for reliable EBDWL. Similar to photomask fabrication, CA resists are employed, for which the PEB is a critical process step, requiring a temperature uniformity of <0.1 K within the resist plane of the wafer. However, because of the high thermal conductivity of silicon wafers, such uniformity is less difficult to achieve than with photomasks. As with photomask fabrication, the post-exposure processing equipment is preferably connected directly to the electron beam writer, enabling the PEB and development to be conducted immediately after exposure.

The fabrication of integrated circuits, either completely with EBL or with mix-and-match lithography, poses some significant challenges in integrating the required

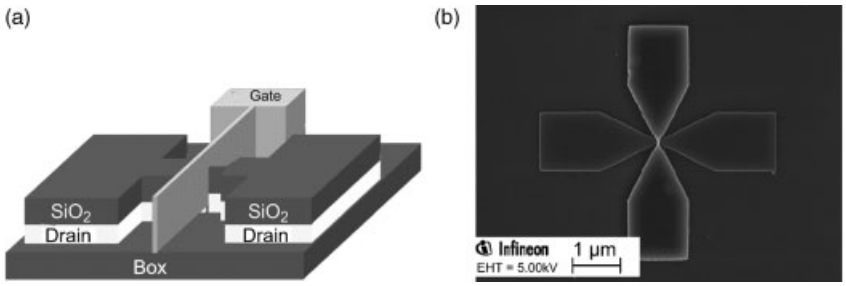

Figure 5.31 FinFET. (a) The design model [43]. (b) Scanning electron microscopy image of the actual device: with 50 nm gate (produced by EBDWL) [44].

process steps, and especially when aligning the different layers of patterned functional films. These challenges – and the methods used to overcome them – are discussed in Section 5.2.4.

5.2.3.3 Maskless Lithography

Considerable effort has been made towards making EBL available for volume production. The initial approach had been to implement either separate multiple electron optical columns [46] or separate multiple electron beams [47], to achieve massively parallel EBDWL. However, as the adequate calibration of either multiple columns or beams is a very challenging task, the suggestion was made to mimic optical lithography by introducing a transmission mask and projection optics with electromagnetic lenses to direct the electrons, which led in time to the development of electron projection lithography (EPL). In parallel, the use of a 1 : 1 transmission mask was also investigated, which led to the development of proximity electron lithography (PEL). As mentioned in Section 5.1, EPL was removed from the ITRS in 2004 due to significant difficulties with fabrication and application of the EPL transmission masks. PEL was subsequently removed in 2005, although its re-emergence cannot be ruled out completely. Whilst EPL and PEL are currently dormant, the advances made in electron optics have been significant, and hence the idea was conceived to devise electron projection and proximity techniques without the use of a mask – hence the term maskless lithography (ML2). As the current ML2 techniques are, loosely, derivatives of EPL and PEL, the details of both processes are explained in the following sections.

EPL: Principles and Limitations The transmission mask for EPL is a 4 : 1 stencil mask, a thin membrane through which holes are etched for the transmission of electrons. The stencil masks are themselves prepared using EBL, utilizing similar processes as for photomasks (see Section 5.2.3.1). Due to the instability of the membrane, fabrication has proven very challenging. In addition, a stencil mask absorbs electrons where there are no holes, thus causing the mask to undergo considerable heating, which then leads to distortions. Two concepts were devised to overcome this problem:

- SCALPEL (SCattering with Angular Limitation Projection Electron-beam Lithography) employed a scattering mask made from an extremely thin membrane (<150 nm) of low-atomic-number material (e.g., silicon nitride), through which the electrons can pass. The development of SCALPEL has been stopped, mainly because even the smallest deviation in mask membrane thickness resulted in intolerable intensity variations on the wafer. The main principles of SCALPEL are detailed in Ref. [48].
- PREVAIL (PRojection Exposure with Variable Axis Immersion Lenses) employed a stencil mask with a thick membrane (1–2 μm), thereby scattering the electrons to unexposed spots. This concept is quite similar to the vector-shaped beam strategy presented in Section 5.2.1.4, but instead of a simple shape a quadratic portion of the stencil mask was printed onto the wafer. The development of PREVAIL has also been stopped, mainly because even today it is not possible to make a 4 : 1 stencil

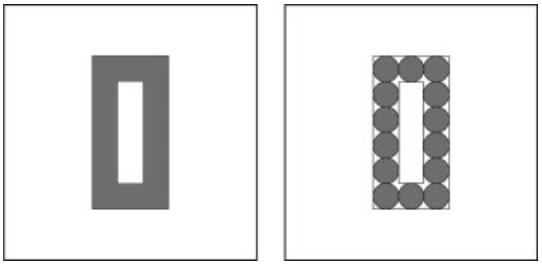

Figure 5.32 Electron projection lithography: the "donut problem".

mask covering an exposure field equal to that of an optical stepper with 26×26 mm, and therefore several masks must be stitched together to expose a single chip. Moreover, a stencil mask encounters the so-called "donut problem": the pattern shape shown in Figure 5.32 can only be made by two exposures with two complementary stencil masks, since on a stencil mask for a single exposure the center would fall out. For IPL, single stencil masks for fourfold exposure have been developed to circumvent this problem, as detailed in Section 5.3.2.1. The principle of PREVAIL is described in Ref. [49].

The electron optical columns for EPL experience a peculiar aberration in addition to the electron optical imperfections described in Section 5.2.1.2, namely the charge effects resulting from the electric charges of the electrons. Charge effects can be separated into a global charge effect, which influences any individual electron when traveling within an electron beam; this can be viewed as a continuous negative charge, with a charge density ρ. The single electron is within an electrostatic potential as of:

$$\nabla^2 \Phi = -\frac{\rho}{\varepsilon_0} \tag{5.18}$$

This electrostatic potential acts as an extended diverging lens. The global charge effect can, in principle, be compensated for by a suitable electron lens [50].

This is not the case for the stochastic charge effect, which is especially pronounced in a crossover, for example at demagnification, where all electrons interact within a small space. The stochastic charge effect leads not only to a beam blur but also to a beam energy spread, which in turn leads to chromatic aberrations. Global and stochastic charge effects are illustrated in Figure 5.33.

PEL: Principles and Limitations The transmission mask for PEL is a 1 : 1 stencil mask, and electrons are used for the proximity printing of this mask to the wafer. Initially, PEL employed 10 keV electrons, but currently low-energy electron-beam proximity lithography (LEEPL) [51], which utilizes low-energy electrons of 2 keV, is the PEL technique of choice.

The principle of LEEPL is shown in Figure 5.34. A single electron beam is generated in an electron beam column, and the mask is scanned. The low-energy electrons minimize the proximity effect, but forward scattering degrades the resolution.

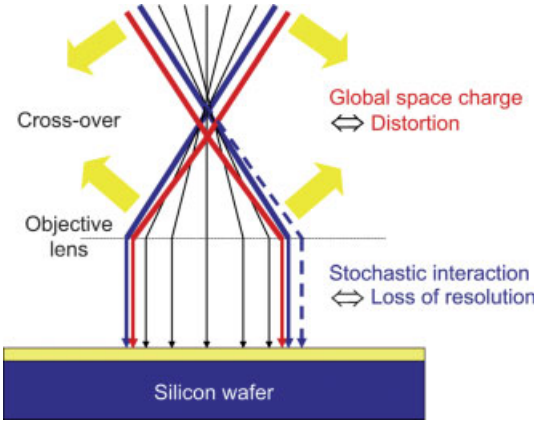

Figure 5.33 Electron projection space charge effects.

As the range of 2 keV electrons in the resist is <150 nm, the resist thickness for LEEPL is limited to 100 nm. In order to achieve the required aspect ratios, BLR [52] processes, which initially were developed for extending DUV lithography towards smaller features, must be applied (see Figure 5.35). Currently, LEEPL is not included in the ITRS as it has encountered several problems. For example, as this is a proximity technique, the distance between the stencil mask and the wafer is very small, usually <50 μm. Therefore, any distortion of the mask or wafer, or the presence of particles, would severely compromise the exposure. Furthermore, the implementation of bi-layer electron resist processes is not yet satisfactory. One positive development

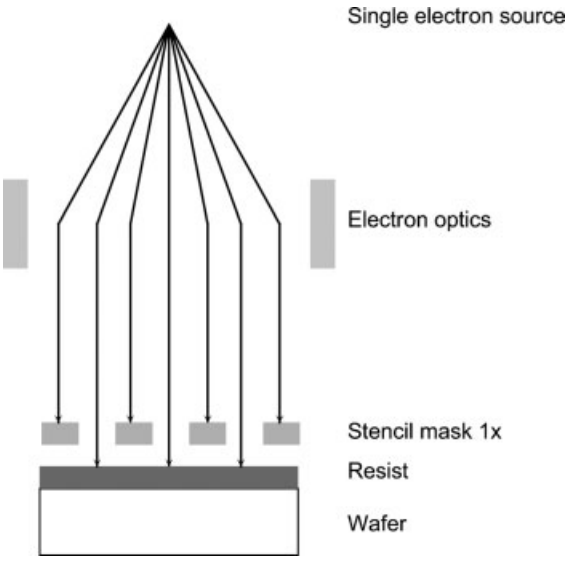

Figure 5.34 Proximity electron lithography techniques: LEEPL.

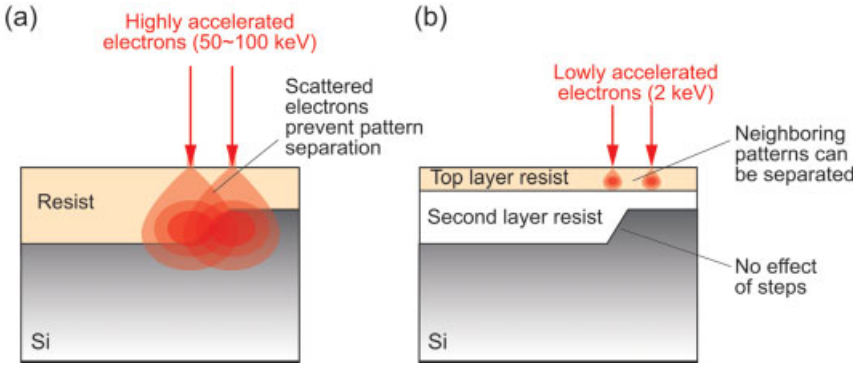

Figure 5.35 Comparison of single-layer (a) and bi-layer (b) resist processes [51].

however has been that, recently, stencil masks with a 26×26 mm exposure field could be prepared.

Projection Maskless Lithography Projection ML2 (PML2) [53] can be seen as the ML2 equivalent of EPL. Here, a single electron beam is split into multiple beams, with imaging being accomplished by a programmable aperture plate system (APS) [54, 55]. A range of innovative technologies was introduced to overcome the specific problems of both electron beam direct write and multiple beam application. The column of the demonstration system is shown in Figure 5.36 [53]. This employs a single electron source, therefore avoiding the control problems with multiple sources. The primary electron beam has a low acceleration voltage of $U = 5$ kV, and is widened by condenser optics to fully cover the APS. Because of the low energy of the electrons, the APS cover plate experiences no significant thermal expansion problems. Subsequently, hundreds of thousands of separate electron beams emerge from the APS,

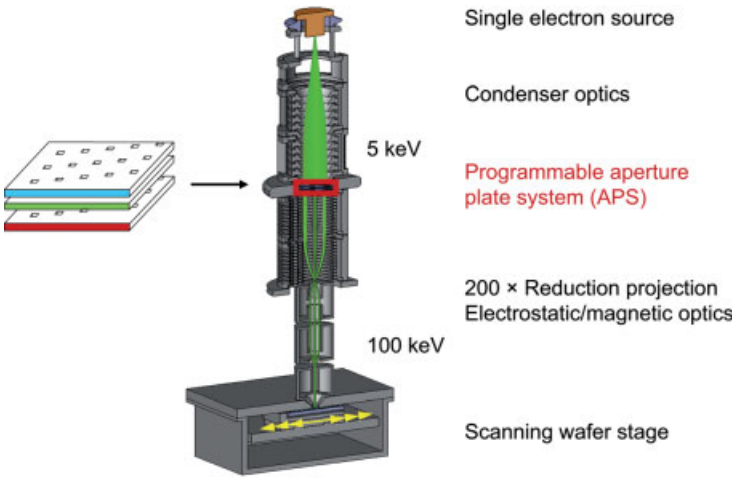

Figure 5.36 Schematic diagram of the PML2 multi-electron-beam column demonstrator [53, 54].

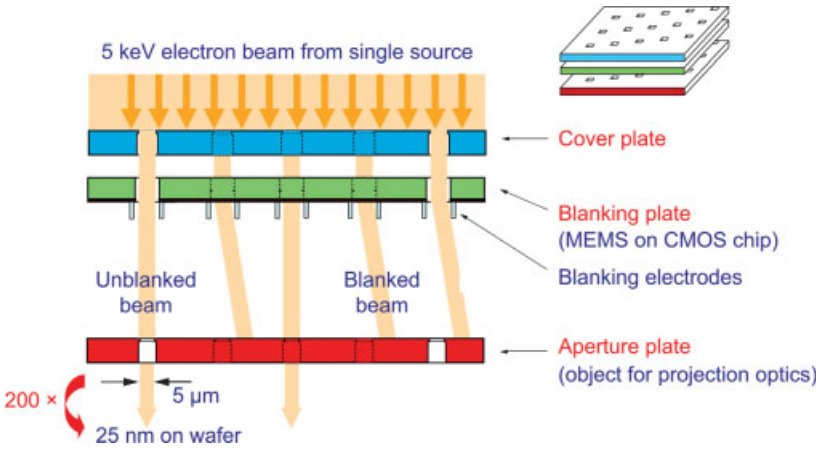

Figure 5.37 Schematic diagram of the multi-electron-beam modulator (APS) [53–55].

and are accelerated by $U = 100\,\text{kV}$, which results in a very high contrast when imaging on the wafer.

The APS, which is shown in detail in Figure 5.37 [53–55], consists of a cover, blanking, and aperture plate. The blanking plate employs MEMS-based structured electrodes for each of the transmission holes, which deflect the electron beam to strike the aperture plate and provide opaque features on the wafer. The diameter of each transmission hole is 5 µm. By using a two-stage electron optics, a reduction of ×200 is achieved, leading to a beam size of 25 nm on the wafer. Currently, the exposure area of the APS is $100 \times 100\,\mu\text{m}$.

With this exposure area, patterns on the wafer are written in stripes as shown in Figure 5.38 [53]. As discussed in Section 5.2.1, this may potentially lead to butting errors but, due to the small stripe size of $<300\,\mu\text{m}$ compared to current vector shaped-beam tools, no difficulties are expected.

The major challenge for PML2 is certainly to provide the required data transmission rate to the APS control electronics. A proof-of-concept (POC) tool was intended

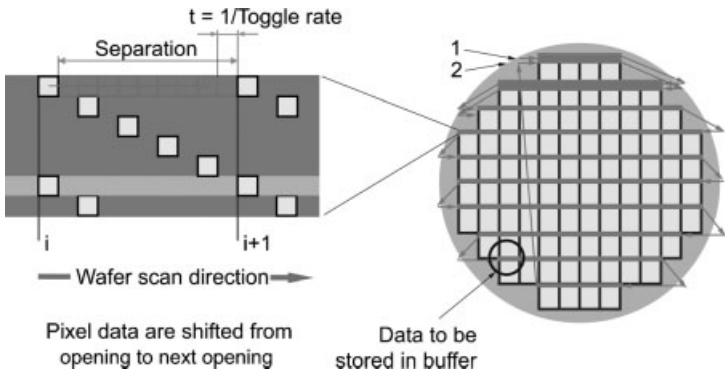

Figure 5.38 The writing strategy of a multi-electron beam system [53, 54].

within the MEDEA+ "CMOS logic 0.1 μm" project [56], for which a data transmission rate of 36 Gbit s^{-1} was demonstrated, scalable by channel count. A throughput of approximately 0.1 of a 300-mm wafer per hour was intended with this POC tool, although commercial tools should expose up to five 300-mm wafers per hour. However, this is still a small throughput compared to optical lithography steppers, with typical exposure throughputs of >100 wafers per hour. Nonetheless, this would be a great leap from EBDWL, which accomplishes much less than 0.1 wafer per hour in 65-nm patterning. Another issue is that the ×200 reduction requires all electrons to cross in a single region, thus leading to global and stochastic space charge effects, which potentially limit the throughput for the 22-nm node to less than one wafer per hour. To address this problem, an innovative PML2 scheme, with a throughput potential of up to 20 wafers per hour for the 32 and 22-nm nodes, is currently being investigated within the Radical Innovation MAskless NAnolithography (RIMANA) project [57].

Proximity Maskless Lithography Proximity ML2 (Mapper) [58] can be seen as the ML2 equivalent of LEEPL. Within Mapper, low-energy electrons of 5 keV are used, and the multiple electron beams are generated by splitting a single electron beam that originates from a single electron source. The multiple beams are then separately focused within an electrostatic lens array. The electron beams are arranged in such a way that they form a rectangular slit with a width of 26 mm, the same width as a field in current optical steppers. During exposure, the beams are deflected over 2 μm perpendicular to the wafer stage movement. With one scan of the wafer a full field of 26 × 33 mm can be exposed. During simultaneous scanning of the wafer, and deflection of the electron beams, these beams are switched on and off by light signals, one for each beam. The light signals are generated in a data system that contains the chip patterns in a bitmap format. The column of the proof-of-lithography (POL) tool, implementing 110 electron beams, is shown in Figure 5.39 [58]. A commercial tool would most likely implement 13 000 electron beams, so the bitmap would be divided over 13 000 data channels and streamed to the electron beams at up to 10 GHz, thus enabling a throughput of ten 300-mm wafers per hour.

As with LEEPL, the major challenges for Mapper are the problems arising with the proximity of the exposure, and the resist process. Additionally, as Mapper imple-

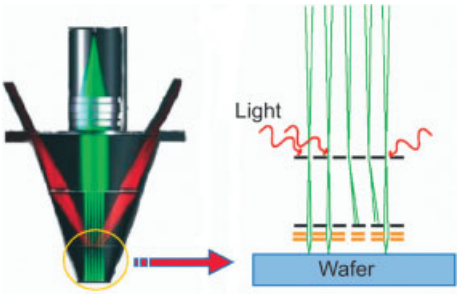

Figure 5.39 Schematic of the Mapper multi-electron-column demonstrator [58].

ments an electrostatic lens array within a <50 µm distance to the wafer, it is still unclear how the cleanliness of this array can be maintained during wafer throughput.

Overall, as ML2 techniques may provide the performance and throughput advantages of EPL and PEL, whilst avoiding the problems arising from mask fabrication and application, they should have the potential to rival optical lithography [59].

5.2.3.4 Imprint Templates

Nanoimprint lithography (NIL), considered to be a lithography method with the potential to rival optical lithography, is a technique where a patterned template is pressed onto a substrate coated with resist [60]. Currently, photoactivated NIL (PNIL), which uses a monomer resist with low viscosity, is considered to show the highest potential for volume production. The template, which must be constructed from a transparent material such as fused silica, is pressed onto the sample, after which a polymerization reaction is induced in the resist by applying UV light (thus, the technique is also called UV-NIL), and the template is removed.

Whilst NIL in itself does not involve exposure with photons or charged particles, the patterned template must be fabricated first, similar to a photomask for optical lithography. The templates are prepared by electron beam lithography, using similar processes as for photomasks (see Section 5.2.3.1). As the template is reproduced without demagnification, and therefore requires the same feature size as the pattern on the wafer, both fabrication and application still pose certain challenges. Currently, efforts are under way to utilize photomask fabrication methods for making PNIL templates [61]. As mentioned above, the templates must be transparent to UV light, and therefore fused silica photomask blanks may be used for template making. An overview of the template process flow is shown in Figure 5.40: in a first lithography step, the template is structured by EBL (first write). In a second lithography step, the pedestal required for imprint is made (second level write). Further details of the template process flow are presented in Refs. [62, 63].

When using photomask fabrication methods, currently four imprint templates are structured on a single photomask blank, as shown in Figure 5.41a and b. The photomask blank is then diced into separate templates (Figure 5.41c). As the dicing introduces contamination and mechanical strain, a modified fabrication approach must be developed before NIL can be employed in volume production. The size standard for templates resembles the exposure field of current optical lithography steppers (Figure 5.41d).

Complete details of the NIL imprint processes are described in Chapter 7 of this volume.

5.2.4 Integration

Although EBL is widely used in research because of its flexibility and high resolution, its low throughput and complex maintenance requirements of electron beam writing tools have limited the use of EBDWL in volume production. However, continuous improvements have led to the development of reliable tools with shaped beam writing

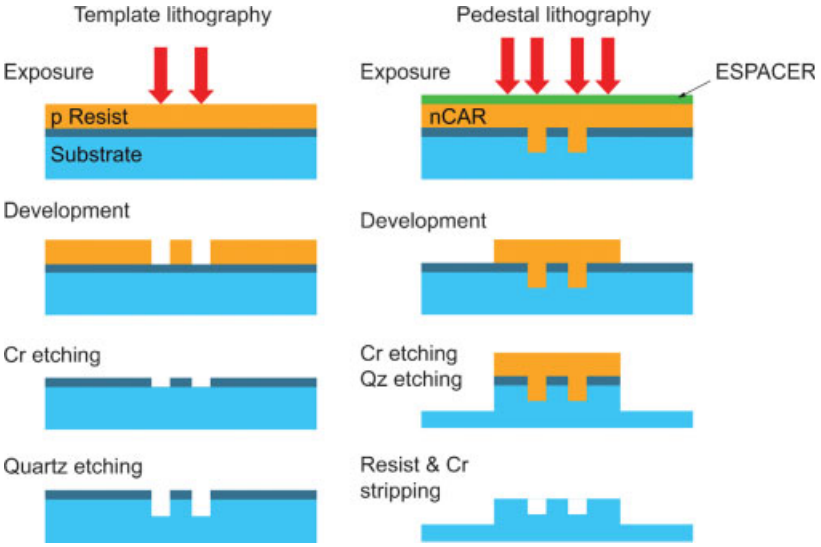

Figure 5.40 An overview of the fabrication process for two-dimensional templates [62, 63].

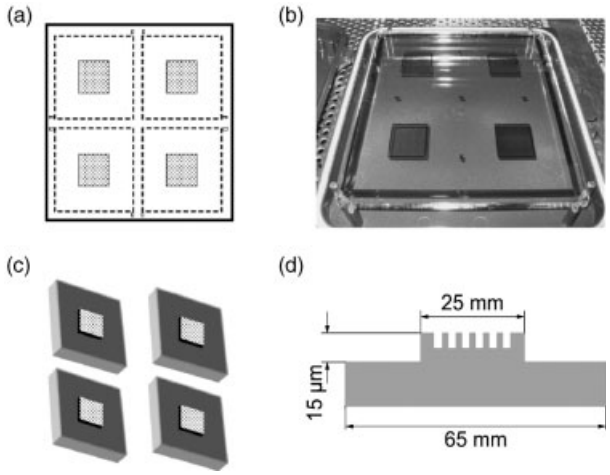

Figure 5.41 Application of photomask fabrication methods for template making [64].

strategy, which fulfill the requirements of the current 65 nm node fabrication which, according to the ITRS, are 65 nm dense lines, 45 nm isolated lines, 90 nm contact holes, and an overlay accuracy of <25 nm [16]. Yet, while the required resolution and repeatability has been achieved through developments in tools and CA resists, the overlay accuracy has long posed a major challenge.

Integrated circuits consist of several functional layers, for example metallizations and barriers, which must be fabricated sequentially. In optical lithography, each layer is patterned by a suitably made photomask. When using EBL, two scenarios can occur:

- Either all layers are made by EBL, which is the case for making device prototypes [65]
- Just one critical layer, for example the gates, are made by EBL, and all other layers are made by optical lithography.

The use of mixed EBL and optical lithography in volume production is referred to as "mix-and-match" lithography production [66], or hybrid lithography [67] if a single resist is utilized as both electron resist and photoresist.

In order to ensure that all subsequent layers are exactly matched, aligning techniques are used in optical lithography. One widely used alignment method in wafer steppers is through-the-lens alignment, where an alignment mark on the wafer is projected onto an alignment mark on the photomask, and a comparison is made. However, this approach is not possible with EBL tools; rather, two types of EBL alignment mark are currently used. The first option is to employ marks made from a film of high-atomic-weight material. This type of mark can be detected by secondary electron emission, but the method may lead to contamination issues and it is, therefore, mostly used only for back-end processing [68]. The second option is to create trenches as marks (see Figure 5.42), which are then scanned. This EBL alignment strategy has been used successfully in creating 65 nm node integrated circuits with hybrid lithography [69].

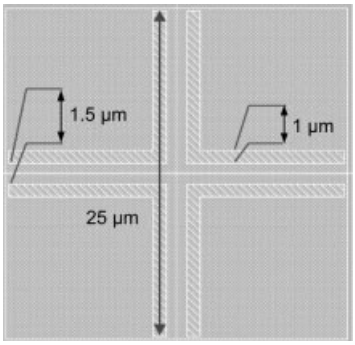

Figure 5.42 Trench alignment mark for EBDWL of a 25 × 25 µm integrated circuit [69].

5.3 Ion Beam Lithography

5.3.1 Introduction

Ion beam lithography (IBL) either utilizes ions to induce a chemical reaction in an ion resist for pattern formation, or can directly structure a functional film such as a metallization or barrier layer. When using ion resists, the wavelength of accelerated

ions is even smaller than that of electrons, because of their higher mass. For example, the mass of H^+ is 2000-times the mass of an electron, and therefore a calculation analogous to that in Section 5.2.1 yields:

$$\lambda = \frac{h}{\sqrt{2mQU}} \tag{5.19}$$

which, with an acceleration voltage of $U = 100\,\text{kV}$, gives $\lambda = 0.0001\,\text{nm}$.

Simple IBL tools use ion optics to focus ions from a source into a beam with a Gaussian energy distribution; therefore, they are referred to as focused ion beam (FIB) tools. The functional principle is analogous to the Gaussian EBL tools introduced in Section 5.2.1. A significant difference is that, because of the much higher mass of ions, a deflection is more difficult to achieve.

5.3.1.1 Ion Sources

IBL tools utilize volume ion sources [70], which consist of an ionizing region, where a plasma is formed, and an extraction region, where an electric field extracts the ions and accelerates them to form a beam. As with the thermal electron sources discussed in Section 5.2.1.1, the maximum current density j which can be obtained for an acceleration voltage V and an acceleration distance d is:

$$j = \frac{1}{9\pi d^2}\sqrt{\frac{2Q}{m}}V^{\frac{3}{2}} \tag{5.20}$$

5.3.1.2 Ion Optics

Ion optics function in a very similar manner to electron optics (see Section 5.2.1.2). The general trajectory representation as Equation 5.13 remains valid, when the electron charge e is replaced by the appropriate ion charge Q. However, there is an important difference with the design of ion optical columns: while magnetic lenses are used in electron optics, because of their lower aberrations compared to electrostatic lenses [70], in ion optics only electrostatic lenses can be used because, unlike magnetic fields, electric fields focus independently of the charge to mass ratio (see Section 5.2.1.2).

5.3.1.3 Patterning

The initial idea behind using IBL instead of EBL for fabricating integrated circuits was that ions scatter very little in solids. Unlike with EBL, there is no significant proximity effect, and therefore IBL can deliver very high resolution and contrast. Advances in EBL technology (especially proximity effect corrections), together with the fact that because of their high mass, ions are likely to damage functional films or doped areas on the substrate, EBL is the currently established technology for direct-write methods.

5.3.2 Applications

Although IBL is not used for integrated circuit fabrication, it is being applied and continuously improved for the direct-structuring of functional films in the

fabrication of special devices, such as nano-electromechanical systems (NEMS), nanophotonics, nanomagnetics, and molecular nanotechnology devices. Direct-structuring is also currently being investigated for the fabrication of imprint templates for NIL.

5.3.2.1 **Direct-Structuring Lithography**

Focused ion beam (FIB) tools can be used to create patterns in functional films, such as metallizations, or barriers on wafers directly, which is referred to as ion direct-structuring (IDS) lithography. The ions, when striking the functional film, cause the material to sputter, such that IDS is also known as *ion milling*. Another possibility is the local deposition of a functional film, with ions inducing the decomposition of a process gas at the surface of the wafer.

One major application of FIB tools is the repair of photomasks for optical lithography. As noted above (see Section 5.2.3.1), photomask quality is of utmost importance for yield. However, if due to a problem in the manufacturing process a part of the opaque film is sticking where it should have been removed, it can be sputtered away (see Figure 5.43) [71] or, if part of the opaque film is damaged, then it can be partially redeposited (see Figure 5.44) [71].

For some applications it is also reasonable to employ techniques initially developed for IPL, which introduced a transmission mask and projection optics with electromagnetic lenses to direct ions. This derivative of IPL is called ion projection direct structuring (IPDS). As mentioned in Section 5.1, IPL was removed from the ITRS in 2004 due to significant problems with fabrication and the application of the transmission masks.

IPL requires the use of stencil masks (see Section 5.2.3.3), because ions cannot pass through membrane masks, even with the thinnest imaginable membrane. However, a stencil mask absorbs the ions where there are no holes, and the resultant heating of the mask leads to its distortion. Further, with stencil masks it is not possible to make all required patterns with a single exposure, and so sets of complementary masks are required (see Section 5.2.3.3). Although initially these issues appear to make IPL impractical, studies to rectify the situation are ongoing. For example, thermal radiation cooling could be utilized to solve the heating problem,

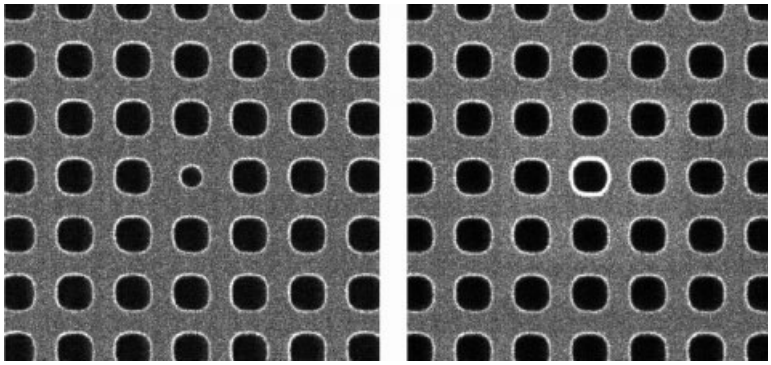

Figure 5.43 Opaque film defect: the repair of an undersized contact hole [71].

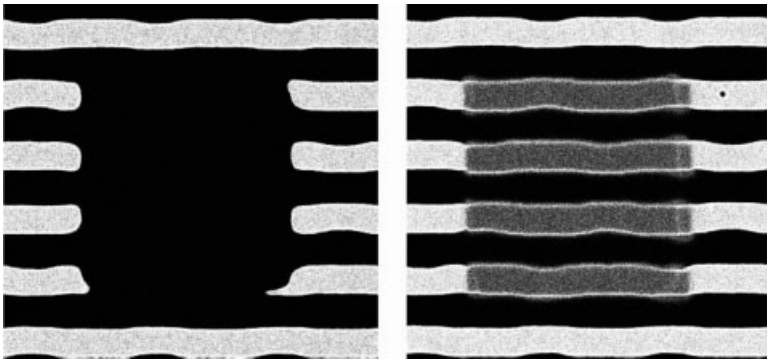

Figure 5.44 Pattern copy: the repair of missing lines [71].

while single stencil masks with fourfold exposure could enable complex patterns, but require half-sized features [54]. A comprehensive discussion of IPL, in addition to the details of a proposed IPL system, are presented in Refs. [54, 72].

IPDS can, for example, be applied to structure magnetic media for high-density data storage in a single exposure by inter-mixing the films of a multilayer structure [73]. For such an application a single stencil mask is sufficient [74].

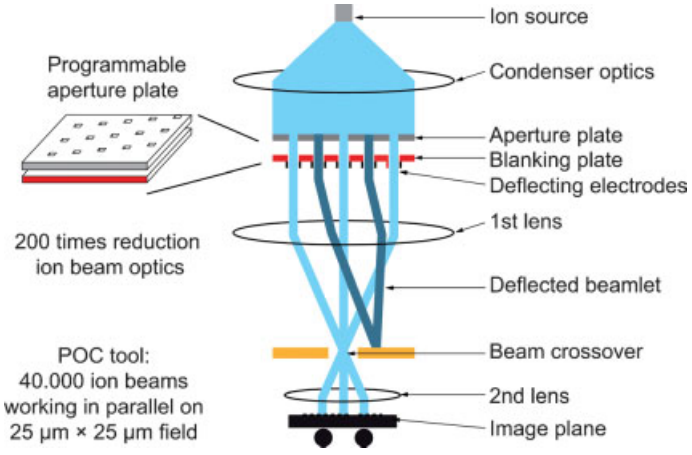

Figure 5.45 Schematic of multi-ion-beam column demonstrator [53, 75].

Considerable effort has also been made towards developing IPDS for volume production. The most-often investigated approach is to use the technique for multiple EBL (see Section 5.2.3.3), to split a broad ion beam into multiple beams, and to image with a programmable APS. This multiple ion beam projection maskless patterning (PMLP) technique is currently being developed within the project CHARPAN (CHARged PArticle Nanotech) [53, 75], and the column of the demonstration system used is shown schematically in Figure 5.45 [53, 75].

A possible multi-ion-beam tool resulting from CHARPAN would have a wide range of applications. In addition to IPDS, several other ion-beam-induced patterning

processes, such as beam-assisted etching, deposition, polishing, nanometer-resolved ion implantation, and ion-beam-induced mixing, are possible. All of these processes are considered to be fundamental for the fabrication of emerging nanoscale devices.

5.3.2.2 Imprint Templates

As discussed in Section 5.2.3, NIL requires the use of templates which are currently fabricated by EBL. However, this method requires a full process sequence similar to photomask making, such as resist coating, exposure, development, and etch to be applied to a blank. The use of a FIB tool enables direct-structuring of the chromium film on the blank, by sputtering.

Whilst FIB tools, compared to state-of-the-art EBDWL tools, lack the throughput required for sensible template fabrication, a reliable multi-ion-beam tool would clearly take over from EBL, and consequently the resistless fabrication of templates has been included within the CHARPAN project.

5.4 Conclusions

The continuous improvement of EBL has always placed it one step ahead of the most advanced optical lithography in integrated circuit fabrication. Although mask fabrication for optical lithography is still its principal application, EBL has become a time- and cost-effective technique for early device and technology development. Further, with mask costs currently showing huge increases, EBL represents a viable option for small-volume production, despite its comparatively low throughput. Additionally, even in medium-volume production, EBL is employed for writing critical layers within mix-and-match and hybrid lithography. Because of ever-increasing device complexity, applying EBDWL, using shaped-beam writing tools in combination with advanced CA resists, is mandatory. In parallel, efforts are being continued in the investigation of parallel electron beam writing systems (ML2), which show the potential almost to match the throughput of optical lithography, and thus may in time complement or even replace the latter process for high-volume production.

In contrast, in its current form, IBL is not applicable for integrated circuit fabrication, although further improvements in FIB tools towards IPDS, as well as the development of parallel ion beam writing systems (PMLP), may lead to its feasible application.

Integrated circuit fabrication aside, both EBL and IBL techniques are currently being used and continuously improved for the fabrication of special devices in low volume, such as nano-electromechanical systems, nanophotonics, nanomagnetics, and molecular nanotechnology devices.

Extreme Ultraviolet Lithography

Klaus Bergmann, Larissa Juschkin, and Reinhart Poprawe

6.1
Introduction

6.1.1
General Aspects

The ongoing reduction of structure sizes in semiconductor devices such as memory chips or microprocessors means that conventional optical lithography is reaching its physical and technological limits. This technology makes use of the demagnified imaging of structures on a mask onto a photo resist. Currently, optical lithography utilizes deep ultraviolet (DUV) light at 193 nm and a high numerical aperture (NA) optical system consisting of transmitting lenses. Generally, the achievable resolution at wafer level (RES) and the depth of focus (DOF) can be expressed by the Rayleigh formulas:

$$\mathrm{RES} = k_1 \frac{\lambda}{\mathrm{NA}}, \quad \mathrm{DOF} = k_2 \frac{\lambda}{(\mathrm{NA})^2} \tag{6.1}$$

Here, λ is the wavelength, NA is the numerical aperture ($=n \sin\alpha$, where n is the index of refraction of the medium between the wafer and the last optical element, and α is the half-opening angle of the beam), and k_1 and k_2 are process-dependent constants with values typically of approximately 0.5. Today, the best resolution is in the region of 60–65 nm, operating at a wavelength of 193 nm, a NA of 0.93, and a k_1-value of 0.31 [1]. Currently, the semiconductor industry is investigating all the possibilities for further reducing the structure size offered by Equation 6.1. That is to say, by reducing the wavelength, increasing the NA above unity, and operating with lower k_1-values. In this way, ASML – one of the leading stepper manufacturers – has successfully demonstrated a water-based immersion system with NA = 1.20 and $k_1 = 0.28$ for printing 45-nm structures. Another strategy is that of *double patterning*, where two masks are imaged successively onto the wafer, which permits a smaller k_1-value of 0.2. However, structure sizes below 32 nm are considered only to be achievable with a large reduction of the wavelength into the extreme ultraviolet

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

(EUV) range. A reduction from 193 to 13.5 nm in EUV lithography relieves the situation with the process constants and the numerical aperture. Thus, 16 nm is expected to be printable with a NA of 0.35 and k_1 equal to 0.41 [1].

According to the current roadmap for semiconductors [2], EUV lithography will be introduced into the production process at the 45 nm node during the year 2011, together with improved 193 nm technologies. In moving towards ever smaller features below 22 nm and approaching the physical limits of silicon-based chips, EUV seems to be the only photon-based solution from today's point of view [1].

The step from DUV to EUV, however, implies a variety of technological changes compared to the conventional technology. Operating in the EUV range requires that all components are held in a vacuum in order to avoid absorption in an ambient gas. EUV radiation has the strongest interaction with matter – that is, the highest cross-section for absorption. Typical penetration depths of EUV radiation into solids are in the range of a few hundreds of nanometers. The optical system and the mask to be imaged onto the wafer consist of reflecting multilayer mirrors, and the source is no longer a UV laser but rather an incoherent plasma source emitting isotropically with a wavelength around 13.5 nm. The technology still requires further development before reaching industrial maturity, which is expected to be achieved by about 2010.

A simple discussion of Equation 6.1 allows an estimation to be made of the required wavelength region aiming at a resolution of, for example, better than 70 nm and a depth of focus of more than several hundreds of nanometers. This consideration leads to a wavelength below 20 nm. Multilayer-based mirrors with a high normal incidence reflectivity at a wavelength of about 13 nm are currently available, and the semiconductor industry has fixed the wavelength to 13.5 nm as a standard to maintain lithium-based plasmas as an option, which have a strong line emission at this wavelength. With our current knowledge of all components, such as mirror reflectivity, sensitivity of the resist, parameters of the optical system and the desired wafer throughput, it is possible to specify the requirements for the source, which can be considered as the least known component of the system. Although a solution for the final concept has not yet been found, some early examples of source and system specifications have been identified, for example in Refs. [3, 4]. In addition, the actual requirements are updated continuously, taking into account new aspects and increasing knowledge [5].

The present chapter provides an overview of the system architecture of an EUV scanner, together with the demands made on each component, namely the light source, optical components for beam propagation and imaging, masks and resists. The current status of development and future challenges are also addressed.

6.1.2 System Architecture

A variety of EUV lithography systems have been installed during the past few years in order to test the whole chain, beginning at the source and ending at the wafer level or using simpler, high-NA systems with small imaging fields for printing fine structures [4, 6, 7]. The principle of an EUV scanner will be explained with the example of

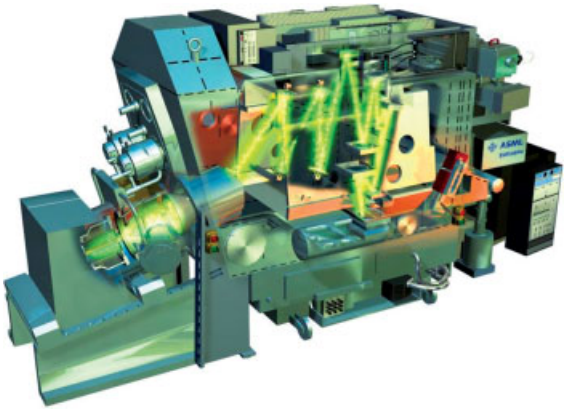

Figure 6.1 Schematic view of the ASML alpha demo tool, the first full-field scanner for extreme ultraviolet (EUV) lithography. The collector and source are not shown clearly; the beam propagation at the respective location of the source collector module is shown on the left.

the ASML alpha demo tool demonstrator, which can be regarded as the latest development and which is close to the future lithography tool with respect to design. A schematic of the alpha demo tool is shown in Figure 6.1 (taken from Ref. [8]). Using a collector – preferably a Wolter-type nested shell collector – the light of a plasma source is focused into the so-called *intermediate focus* as the second focal point of the collector (Figure 6.1 shows only the beam propagation from the source and the collector to the second focus, but not the hardware itself). The light is fed into the illuminator, which consists of a set of spherical multilayer mirrors and is used to produce a banana-shaped illumination of the mask (the top optical element in Figure 6.1). Another set of mirrors is used to image this field onto the wafer (the bottom optical element in Figure 6.1), with a typical magnification of 0.25. Wafer and mask are moved continuously to scan the whole mask and to transfer the structures onto a wafer of typically 300 mm diameter. In contrast to conventional DUV scanners, all of the components are contained inside a vacuum in order to achieve a high optical transmission for the EUV light. The etendue of the current optical system is around 3.3 mm^2 sr, which leads directly to a specification for the source size [9]. The optical system is able to use all the light from a spatially extended plasma source of around 1.6 mm in length along the optical axis and 1 mm in diameter in the radial direction, which is emitted into the solid angle of the collector. The plasma source is operated in a pulsed mode, ultimately requiring repetition rates of 7–10 kHz to guarantee a sufficiently homogeneous illumination of the resist. There are requirements on all components of the scanner – that is, the source, collector, optical system and components, masks, resist and on the system itself, concerning, for example, vacuum conditions and contamination issues. Today, the source is regarded as the most critical component, although this might also be due to the fact that other

components were developed prior to of the plasma source, and consequently less experience is available with this component.

The wafer throughput is furthermore dependent on the mechanical properties of the mask and the wafer handling system. According to Ref. [10], a simplified wafer throughput model can be formulated:

$$\begin{aligned} T &= T_{\text{scan}} N + T_{\text{oh}} \\ &= N(t_{\text{acc}} + t_{\text{settle}} + t_{\text{exp}} + t_{\text{settle}} + t_{\text{dec}}) + T_{\text{oh}} \\ &= N\left[\frac{2P}{a_{\text{w}} WR} + 2t_{\text{settle}} + \frac{(L+H)WR}{P}\right] + T_{\text{oh}} \end{aligned} \tag{6.2}$$

where T_{scan} is the scanning time per field, N is the number of fields per wafer, T_{oh} is the overhead time (wafer exchange, wafer alignment, ...), t_{acc} (t_{dec}) is the acceleration (deceleration) time, t_{exp} is the field exposure time, t_{settle} is the stage settling time after acceleration and before deceleration, P is the EUV intensity on wafer, a_{w} is the acceleration of the wafer stage, $W(H)$ is the field width (arc height + slit width) of the banana-shaped field, L is the field height, and R is the sensitivity of the resist. With this model the wafer throughput as a function of the reticle stage acceleration has been estimated for different illumination power levels ranging from 160 to 640 mW on the wafer [5]. The higher dose leads to a higher throughput only if the acceleration is increased; for example, an 80 wafers per hour throughput can only be achieved for the 640 mW, if the acceleration is more than 1.5 G. In the 160 mW case, a lower acceleration is required. With higher acceleration values and higher power levels at the wafer throughput is, of course, higher. These numbers are based on a $R = 5\ \text{mJ cm}^{-2}$ resist, a stage settling time of 25 ms, an overhead time of 11.5 s, a field size of 25×25 mm, a number of 89 fields, and an exposure slit of $2 \times 25\ \text{mm}^2$.

The first results have been obtained with the alpha demo tool, and the possibility of full-field imaging has been successfully proven. An example of different printed lines of 50 nm down to 35 nm and the corresponding line edge roughness (LER) using a resist of $18\ \text{mJ cm}^{-2}$ sensitivity, is shown in Figure 6.2. Full-field imaging

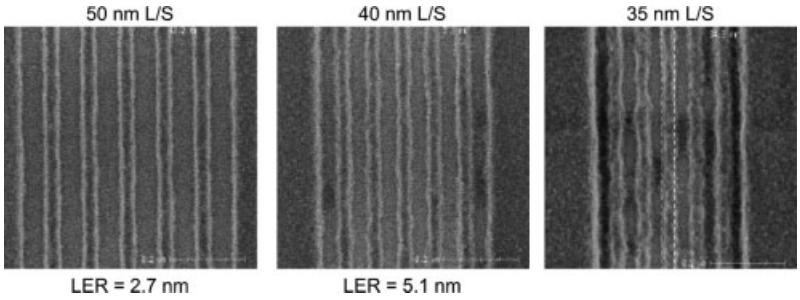

Figure 6.2 First results obtained with the ASML alpha demo tool of printed lines and spaces with resolution down to 35 nm and the respective LERs. The sensitivity of the resist was $\sim 18\ \text{mJ cm}^{-2}$.

over more than 20 mm slit height at the wafer level with a depth of focus of more than 240 nm has been demonstrated experimentally [6, 8].

6.2 The Components of EUV Lithography

6.2.1 Light Sources

According to Ref. [5], some of the requirements for the source and lifetime of the system for a production tool are as follows:

• Central wavelength (nm)	13.5
• Usable bandwidth (nm)	0.27
• Throughput (wafers h^{-1})	100
• EUV power at IF (W)	>115
• Repetition rate (kHz)	7–10
• Collector lifetime (months)	12
• Source electrode lifetime (months)	12
• Projection optics lifetime (h)	30 000
• Etendue of source output (mm^2 sr)	<3.3
• Spectral purity (% of EUV)	to be determined

The use of a multilayer mirror system (see Section 6.2.3) restricts the usable bandwidth to 2% around 13.5 or 0.27 nm, which is termed *inband radiation*. The throughput model is based on a 5 mJ cm^{-2} sensitivity of the resist, which has not yet been achieved (as discussed below). A less-sensitive resist would lead to higher source power specifications. The incoherent plasma source emits not only light but also debris in the form of particles, at least from the EUV-emitting plasma, irrespective of the source concept. Thus, some type of debris mitigation element is required between the source and collector appropriate to the actual source design. Typical collector half-opening angles range up to 70–80°. The total overall efficiency of the collector and the debris mitigation system can be estimated as around 20% of all the inband light emitted in the hemisphere of 2πsr [12], assuming a transmission of the debris mitigation system of 50%. This requires an inband emission of the source of at least 600 W/(2% b.w. 2πsr). Reasonable conversion efficiencies in the range of, at maximum, a few percent of the input energy for usable EUV radiation require a power input in the range of several tens of kilowatts. This imposes strict thermal demands, especially for the cooling of the debris mitigation system and the collector, which is the closest optical element to the source.

The multilayer mirrors have a finite transmission in the DUV range of 130 to 400 nm, which means that the emission from the source should not be too great within this wavelength region, as the resists are also sensitive in the DUV. The final

specification is still under consideration and is, for example, dependent on progress in spectral purity filters with minimum losses for EUV radiation.

6.2.1.1 Plasmas as EUV Radiators

Extreme ultraviolet radiation sources can be divided into thermal and non-thermal emitters. Non-thermal emitters are X-ray tubes or synchrotron radiation sources, where the radiation is generated by deflecting charged particles. Thermal emitters, based on the generation of hot plasmas, are a cost-effective and compact solution for EUV lithography. Generally, for thermal emitters matter is heated up to a high temperature, T, where the limit of the emission of light can be described by Planck's law of radiation:

$$B_\lambda(T) = \frac{2hc^2}{\lambda^2}\left(e^{\frac{hc}{k_B T_\lambda}} - 1\right)^{-1} \tag{6.3}$$

with speed of light, c, Planck's constant, h, and Boltzmann constant, k_B. For a black-body radiator, the temperature and the wavelength of maximum emission are related by Wien's law, which is derived from Equation 6.3:

$$\lambda_{max} T = 250\,\text{nm eV} \tag{6.4}$$

By aiming at a wavelength of $\lambda = 13.5$ nm, we obtain a temperature of around $T = 20$ eV (1 eV = 11 605 K). Such a high temperature is associated with matter in the plasma state. Usually, the emission of a plasma does not reach the Planck limit over the whole wavelength range, but only in individual strong emission lines of highly charged ions. Furthermore, for real plasmas the optimum emission is achieved at somewhat higher temperatures, depending on a variety of conditions, as discussed elsewhere [13]. The emission spectrum is characteristic of the respective element. Typical candidates discussed for EUV lithography are hydrogen-like lithium ions; that is, twofold ionized lithium with a strong single emission line at 13.5 nm, or tin and xenon as broadband emitters around 13.5 nm. In the case of xenon, the radiation around 13.5 nm arises from a transition of 10-fold ionized ions. For tin, the spectral efficiency is better compared to xenon (see Figure 6.3). With tin, more ionization levels exhibit transitions around 13.5 nm, leading to a more pronounced emission in the spectral range of interest.

Two concepts are pursued for generating such plasmas: laser-induced plasmas and discharge-produced plasmas. With laser-induced plasmas a pulsed laser beam is focused onto the target to be heated up. In the other case, the energy is taken from a pulsed electrical discharge. Many reports have been made concerning the different concepts, and discussing their special advantages and drawbacks [11]. In the next subsection, attention will be focused on the physical fundamentals of laser-induced and discharge-produced plasmas.

Irrespective of the individual concept, such plasmas are not only a source of light but also of debris consisting of fast ions and neutrals, clusters, droplets, and also heat. Sophisticated strategies are required to protect the optical system against this debris in order to avoid the deposition of matter onto the optics surface, or sputtering.

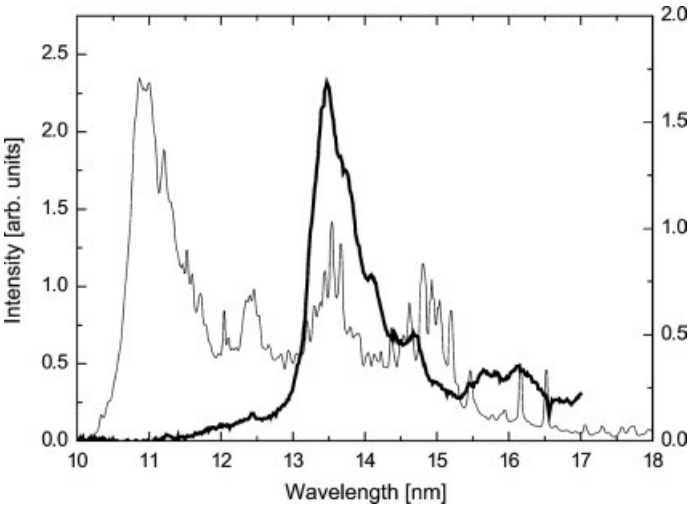

Figure 6.3 Typical emission spectra in the EUV for tin- and xenon-based gas discharge plasma sources. In the case of tin (bold line), the laser-induced plasma appears similar, whereas for xenon the laser-induced emission spectrum is smoother due to overlapping emission lines. The transitions of tin around 13.5 nm are iso-electronic to those of xenon around 11.0 nm.

6.2.1.2 **Laser-Induced Plasmas**

Hitting a target that is either solid, liquid or gaseous with a high-intensity laser beam leads to a plasma, where the laser energy is converted to thermal energy by inverse bremsstrahlung as the dominant process. Electrons are accelerated in the electrical field of the laser and transfer their energy to the ions. The laser energy is coupled to the plasma in a region where the plasma has the critical density, n_{crit}, which is dependent on the laser wavelength, λ_{laser} (ε_0 is the permittivity of free space, m_e the electron mass, e the electron charge, and ω_{laser} the laser frequency, that equals the plasma frequency at the critical density):

$$n_{crit} = \frac{\varepsilon_0 m_e \omega_{laser}^2}{e^2} = 1.11 \times 10^{21}\ \mathrm{cm}^{-3} \left(\frac{\mu m}{\lambda_{laser}}\right) \tag{6.5}$$

The temperature of the resulting plasma roughly scales with the laser intensity, I_{Laser}, according to $T_e \sim I_{Laser}^{4/9}$ [14, 15]. For a Nd:YAG laser with $\lambda_{laser} = 1.064\,\mu m$, the electron temperature, T_e, can be estimated as described in Ref. [16]:

$$T_e = 2.85 \times 10^{-4}\ \mathrm{eV} (I_{Laser}/(W/\mathrm{cm}^2))^{\frac{4}{9}} \tag{6.6}$$

Thus, in order to achieve an electron temperature of around 30 eV a laser intensity of $2 \times 10^{11}\ \mathrm{W\,cm^{-2}}$ is required, which is also observed experimentally as an optimum laser intensity [17, 18]. Typical pulse durations of a laser-induced plasma are in the range of nanoseconds or even less. The spatial extension of the EUV-emitting region is below 100 μm; thus, the etendue requirement of $<3.3\ \mathrm{mm^2\,sr}$ is easily fulfilled with

this type of plasma. Maximum conversion efficiencies of 5%/(2πsr 2% b.w.) for solid tin targets have been reported in the literature [18]. The conversion efficiency is defined as the ratio of usable inband EUV radiation into 2πsr to the incident laser light energy. In order to meet the source power requirement of 115 W in the intermediate focus, an average laser power of more than 5 kW is required, assuming an optimistic efficiency of 50% for the collector and the debris mitigation system. Obtaining high-power pulsed lasers at this level is an issue in current research and development activities. Different laser concepts are under discussion, such as pulsed CO_2 lasers or solid-state diode pumped laser, as reported elsewhere [19, 20, 22, 24]. However, it has not yet been shown that laser-induced plasmas can operate continuously on this power level. Further details on laser-induced plasma are available elsewhere [21, 23].

Besides the availability of the laser itself, the target is still an issue. Currently, different target concepts are under discussion, such as mass-limited targets to reduce debris production to a minimum level, and gaseous or droplets targets from frozen liquids or gases [18]. Most of the effort is currently being expended on tin-based targets, which have the highest expected conversion efficiencies.

6.2.1.3 Gas Discharge Plasmas

Producing the hot plasma by an electrical discharge is another well known method for the generation of light. For EUV-emitting plasmas, a pulsed electrical current is fed into an electrode system, which is filled with the working gas to be heated up at a neutral gas pressure of several tens of Pa. In a simplified concept, the current can be assumed to flow through a plasma cylinder, which is compressed by the self-magnetic field of the current to a high density of up to typically $n_e \sim 10^{19}\,\mathrm{cm}^{-3}$. The plasmas also experience ohmic heating, finally resulting in a dense and hot plasma column of several tens of eV electron temperature, and with a typical diameter of several hundreds of micrometers and a length in the range of few millimeters. The necessary current, I_o, can be approximated by assuming a Bennet equilibrium of the magnetic force and the plasma pressure [25]:

$$\frac{\mu_0}{8\pi^2}\frac{I_0^2}{r_p^2} = (n_i + n_e)k_B T_e \tag{6.7}$$

where μ_0 is the magnetic field constant, r_p is the radius of the compressed plasma column, and n_i and n_e are the electron and ion density, respectively. The term $r_p^2 \cdot (n_i + n_e)$ can be expressed by the starting radius, a, of the neutral gas column and the neutral gas pressure, p, by pa^2 [26]. As an example, for a xenon plasma with 10-fold ionized ions ($\langle Z\rangle = 10$, $n_e = \langle Z\rangle\ n_i$) and a desired electron temperature of 35 eV, a current of 8 kA results, which is also characteristic of the devices under investigation. This pulsed current is usually produced in a fast discharge of a charged capacity, C, which is connected in a low-inductive manner to the electrode system. Typical values for the inductance of the system are around 10 nH and few 100–1000 nF for the capacity. Stored pulse energies are in the range from 1 to 10 J.

A variety of different concepts exist for discharge-based plasmas, which differ mainly in the special geometry of the electrode system and the ignition of the plasma. For further information the reader is referred to numerous other reports [11, 27, 28].

6.2.1.4 Source Concepts and Current Status

During recent years, many industrial laboratories have increased their efforts into the development of sources for EUV lithography, and consequently a variety of concepts of either laser-induced plasmas or gas-discharge plasmas have been investigated, or are currently under investigation. An excellent overview of the current "players" and of the technological progress made can be found in Refs. [11, 27, 29]. An overview of the current status and progress, compared to the year 2000, for different concepts such as the hollow-cathode-triggered pinch plasma [30, 31], the plasma focus [32], different Z-pinch-like concepts [33–36] and laser-induced plasma [37], is shown in Figure 6.4 (from Ref. [28]). Of note, it is clear that rapid progress is being made, and that more powerful sources will be available in the near future. The overview in Figure 6.4 refers only to source power and repetition rate, which is of course not sufficient to assess a certain concept. For example, the source powers achieved do not generally refer to continuous operation but rather to short-term operations ranging down to a few seconds. Furthermore, other specifications such as the plasma source size or the lifetime must also be considered more closely. Often, only the best values are presented and the current status for the simultaneous achievement of specifications is difficult to identify.

One promising concept, which is also used in the ASML alpha demo tool described above, is the Philips laser-triggered vacuum arc [39] (Figure 6.5). This concept makes use of two electrodes, which rotate in a liquid tin bath to continuously re-cover the electrode surface. The system set-up is illustrated schematically in Figure 6.6. Both

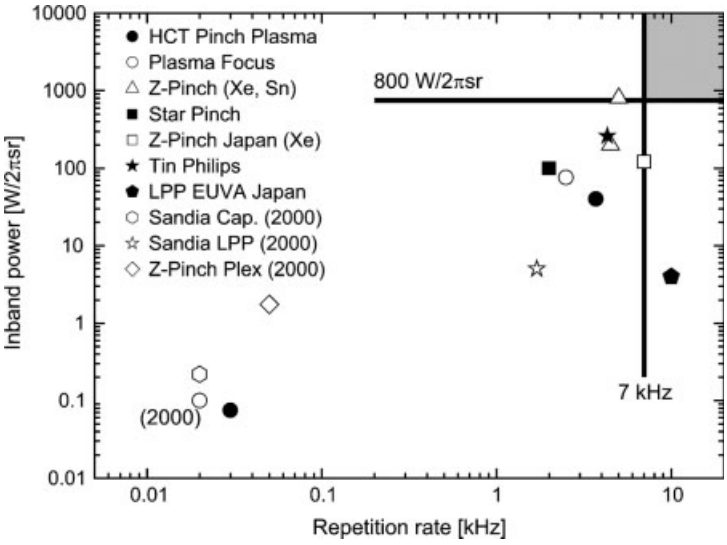

Figure 6.4 Currently achievable radiation power at 13.5 nm into 2% spectral bandwidth for different source concepts, and the corresponding repetition rates. Some data from 2000, taken from Ref. [38], are also shown to illustrate the rapid progress in source power.

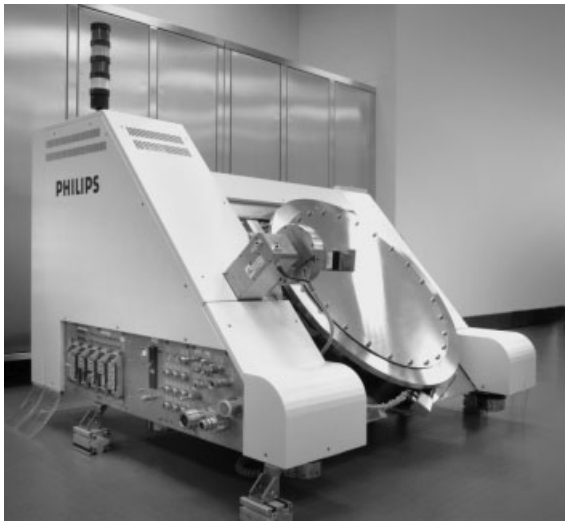

Figure 6.5 The Philips NovaTin EUV source based on the vacuum arc concept, which is used in ASMLs alpha demo tool.

electrodes are connected to a charged capacity, whereupon a laser pulse is used to evaporate a certain amount of tin, which also closes the electrical circuit in the gap between the two electrodes. The rapid discharge of the capacity heats up the tin plasma, which is used as an emitter of EUV radiation. Conversion efficiencies of up to 2.5%/(2πsr 2% b.w.) have been reported for this concept, with an average power of up to 300 W/(2πsr 2% b.w.) [40]. This is not too far away from the final specification for the source power. This concept has advantages with respect to cooling due to the rotating electrodes and electrode lifetime arising from covering the electrode surface with liquid tin and liquid metal cooling. However, a large amount of tin is also produced and emitted towards the collector. Thus, sophisticated means for debris

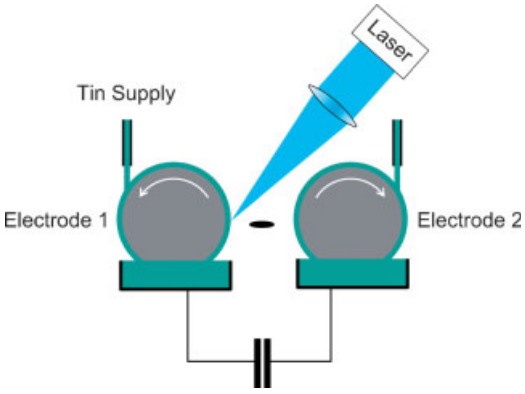

Figure 6.6 Scheme of the working principle of Philips NovaTin EUV source, based on the vacuum arc concept.

mitigation and cleaning strategies are required to guarantee a sufficient lifetime of the optical system. Recently, collector integration with a lifetime of more than 500 Gshots was successfully demonstrated using such a tin source [39]. Details of the collector design and the debris mitigation system are provided in the following section.

6.2.2 Collectors and Debris Mitigation

The currently preferred technical solution for collecting the light of the isotropically emitting plasma is the nested Wolter-type multi-shell collector [41]. A single collector shell consists of a hyperboloid and an ellipsoidal shell with identical focal points. The source is located within this common focal point, and is focused into the other focal point (intermediate focus), where the collector, although not an imaging element, leads to a "magnification" of the source by a factor of about 10 in the intermediate focus. The first optical element is about 50–100 cm behind this second focus. This type of collector allows light to be collected over a relatively large opening angle with a moderate gracing incidence angle at the reflecting surface, which is of particular importance for high reflectivity in the EUV. Such gracing incidence optics usually have a ruthenium coating with large reflectivity up to angles of $\sim 20^\circ$, which is typical of applications in EUV lithography. An example of a multi-shell collector which is used for modeling light distribution after the intermediate focus at the first optical element of the illuminator is shown in Figure 6.7. A collection angle of more than 80° half-opening angle with a total efficiency, including the finite reflectivity of the ruthenium coating, of more than $40\%/(2\pi\text{sr})$ is reported from the collector supplier [12].

Figure 6.8 shows the theoretical angular-dependent reflectivity of a ruthenium coating for different surface roughnesses, σ, and the typical range of operation for the collector. It should be noted that two reflections occur for the hyperboloid and the

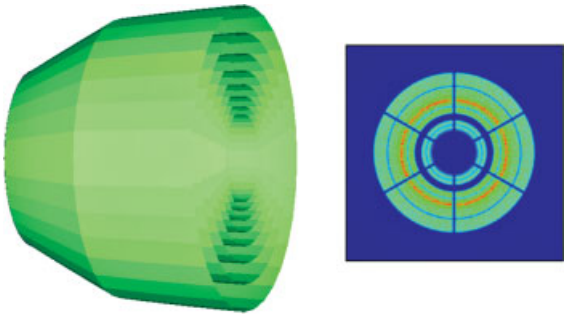

Figure 6.7 Schematic diagram of a Wolter-type nested shell collector with eight shells, as used in a ray-tracing calculation. This collector has opening angles between 11° and 45° corresponding to a collected solid angle of 1.7 sr or 27% of 2πsr. The right-hand diagram shows a simulated distribution in the far field for a spherical source of 50 μm FWHM.

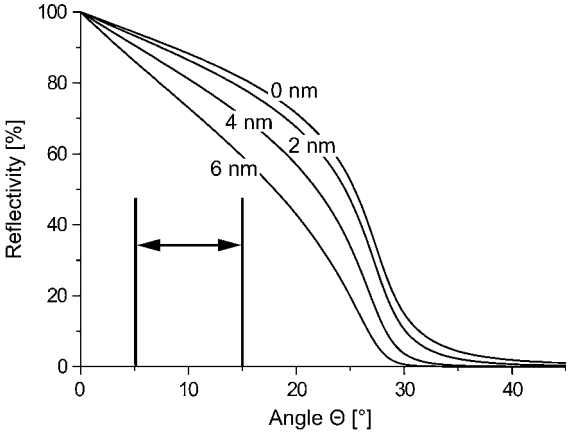

Figure 6.8 Calculated grazing incidence reflectivity of ruthenium for different roughness values, according to the CXRO database. The typical angle range for a multi-shell grazing incidence collector is also indicated. For collectors to be used in EUV lithography, the roughness is below 1 nm, leading to a reflectivity close to the theoretical limit.

ellipsoid. The data points are based on the atomic data for the refractive index published by CXRO [42]. The state of the art at the collector manufacturers – for example, Zeiss or Media Lario – involves surface roughness below 1 nm and chemically clean surfaces based on a physical vapor deposition (PVD) coating technology. Thus, the transmissions of the collectors are close to the theoretical limit. In addition, there is no longer any difficulty in fabricating substrates for the shells with diameters of several tens of centimeters.

Figure 6.7 also shows a typical light distribution for an eight-shell collector and a point source in a plane after the intermediate focus; this indicates the contributions of the different shells and the shadow of the mechanical support structure for the shells. Usually, the collector is located at a distance of only a few tens of centimeters from the plasma, which is also a thermal source in the 10 kW range. Cooling of the collector is achieved by using water-cooled lines around each collector shell. Results relating to the cooling capabilities are reported in Ref. [43], with a temperature increase of less than 1° when operated in the vicinity of a high-power source. Currently, research is going on in order to clarify whether this approach is sufficient, or whether more sophisticated cooling strategies must be applied, including for example a homogeneous temperature increase of the shell surfaces.

Another option is to have a normal-incidence collector based on a Schwarzschild design, with two spherical, multilayer coated mirrors. Some possible solutions to this problem are presented in Refs. [44–46].

As the closest optical element to the source, the collector experiences most of the heat load and debris emitted from the source. Consequently, overcoming the problems of a limited collector lifetime represents some of the major issues in current EUV lithography development activities. Today, such investigations are

under way not only in industry but also at various academic institutes, all of which have encountered this problem [47, 48]. Within the present chapter, the details of various debris mitigation schemes, and the results obtained, are restricted to the activities at Philips, whose clear aim is to integrate the above-mentioned tin-based gas discharge source.

The minimum number of particles necessary for the effective generation of an EUV-emitting pinch plasma is about 10^{15} atoms per pulse. These particles can be assumed to be emitted into 4πsr, partly redeposited onto the electrodes, and also emitted towards the optical system. For a 1-hour operation at 5 kHz this will require approximately 3.5 g of tin. Such an amount is clearly excessive, assuming that this will be deposited on the collector surface, where even a few nanometers' thickness is unacceptable due to the reduced reflectivity of a tin-coated surface. Hence, both the deposition of material and sputtering of the optical coating by the emitted particles must be avoided. The particles are emitted in the form of fast ions with energies exceeding at least 10 keV, as neutrals, and also as droplets from the wet electrode surfaces. One highly effective method of stopping and removing particles is the so-called "foil trap concept", which is described in more detail in Ref. [48]. The process, which is shown schematically in Figure 6.9, includes a system of lamellas located between the source and the collector. The foil trap is operated in combination with a buffer gas, usually argon with high transmission in the EUV. The emitted particles are deflected and finally stopped by the ambient argon atoms, and then stick to the walls of the foil trap. In the case of tin, the foil trap is heated above the tin melting point in order to avoid an accumulation of tin in the system of the lamellas. Using only this technique, a collector lifetime of more than 10^9 shots has been reported for an operation with a tin-based discharge source [39]. However, the foil trap concept does not permit complete suppression of the emission of particles towards the collector, and consequently for longer operating times a deposition of tin on the

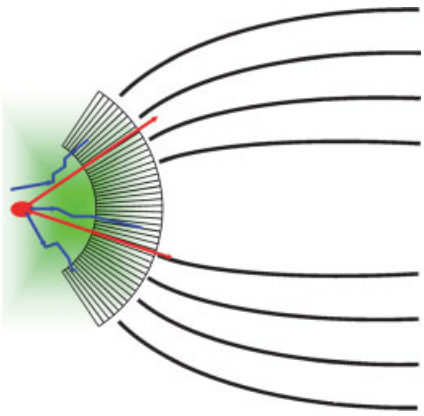

Figure 6.9 Schematic diagram of a foil trap system including buffer gas to protect the multi-shell collector against debris from the source. The foil trap has a high optical transmission, while the particles are efficiently stopped.

nanometer scale would be expected. In an attempt to overcome this problem several cleaning strategies for the collector have been proposed. One possibility would be to flood the collector chamber with a halogen gas, such as chlorine or iodine; the gas reacts with the tin to form volatile tin halides, which can be pumped away, while the ruthenium coating is unaffected. Using this technique permitted the complete recovery of a tin-coated ruthenium surface [49].

6.2.3 Multilayer Optics

For EUV radiation, the index of refraction is close to unity, and the absorption in matter is relatively high. A high reflectivity at surfaces is only achieved for incidence angles of the light of typically below 20°. This feature is, for example, exploited with gracing incidence optics as presented above. A high reflectivity for normal incidence is only achieved with multilayer systems, as shown schematically in Figure 6.10. Such multilayer systems consist of alternating layers of so-called "spacer material" and "absorber material", which have different indices of refraction and are thus reflective at their boundaries. Part of the incident light is reflected at each layer boundary, and the superimposed beam exhibits a high intensity. A well-known example, which is also used in EUV lithography, is a system consisting of silicon and molybdenum with high peak reflectivity around a central wavelength of 13–14 nm. A transmission electron microscopy (TEM) image of a real mirror is also shown in Figure 6.10. The

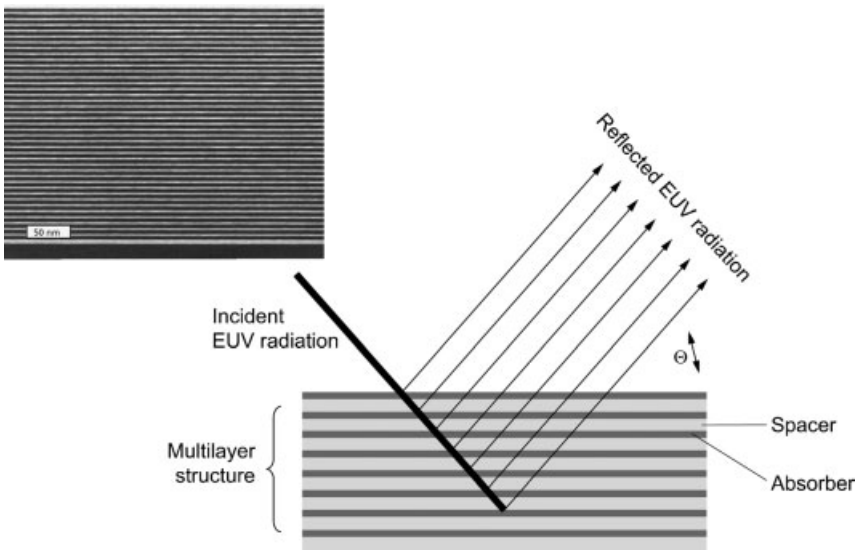

Figure 6.10 Schematic diagram of a multilayer mirror consisting of spacer (e.g., silicon) and absorber (e.g., molybdenum), where a high reflectivity is achieved by superimposing all rays reflected at the boundaries. A transmission electron microscopy image of a real Mo/Si system is shown in the top left section of the figure.

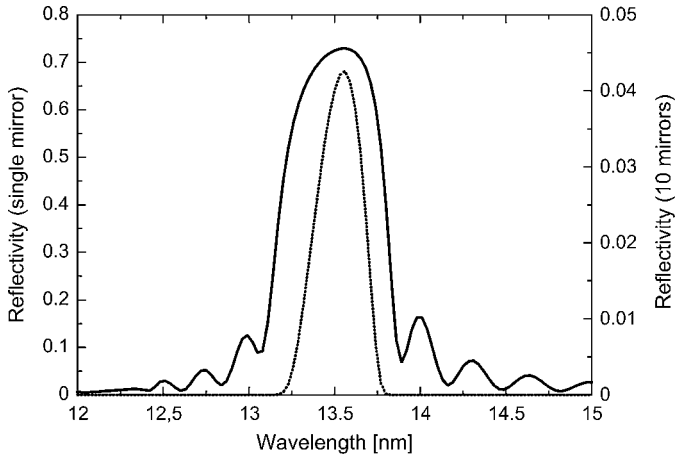

Figure 6.11 Wavelength-dependent reflectivity (solid line) of an ideal Mo/Si multilayer mirror according to the CXRO database, and the resulting reflectivity of a 10-mirror system (dotted line).

center wavelength of the maximum reflectivity of such a system can be expressed in terms of the total thickness, d, of a bi-layer, the incident angle, θ, ($\theta = 90^\circ$ corresponds to normal incidence) and a material constant δ' by the Bragg equation:

$$m\lambda = 2d \sin\theta \sqrt{1 - \delta'/\sin^2\theta} \tag{6.8}$$

where δ' is the weighted material constant for both elements with a complex index of refraction, $n = 1 - \delta + i\beta$. By using the atomic data of the CXRO database [43], Figure 6.11 shows the reflectivity of an ideal Mo/Si multilayer system with zero roughness and no intermixing of the layers with a peak reflectivity of more than 70%. Values of approximately 70% are also achieved for real mirrors. A multilayer reflectivity close to this maximum is achieved at different locations. In order for systems to be used in an EUVL scanner, some losses occur due to the capping layers necessary for avoiding contamination, or additional layers for improving the thermal stability of the multilayer system. Figure 6.11 also shows, graphically, the transmission of a corresponding system of ten multilayer mirrors, which are typically used in EUV lithography. The overall transmission is only 4%, as the theoretical limit and the bandwidth decrease to below 0.3 nm FWHM. This is also the main reason for the restriction to only 0.27 nm or 2% of the 13.5-nm bandwidth, as discussed for the source specifications.

A variety of activities have been developed to improve the multilayer coatings to be used in EUV lithography systems with respect, for example, to increasing the reflectivity or achieving better thermal stability. In order to achieve a higher reflectivity and better thermal stability, additional layers of boron carbide (B_4C) are introduced to reduce the interdiffusion of silicon and molybdenum at their boundaries [50]. This diffusion leads effectively to a higher surface roughness, and thus to a

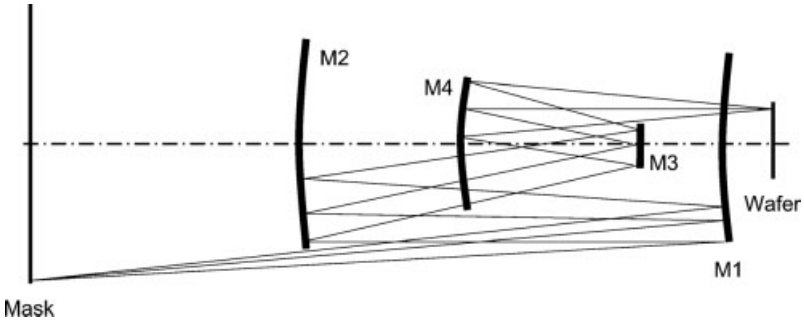

Figure 6.12 Schematic drawing of the projection optics of the ETS, consisting of four multilayer-coated reflective mirrors.

reduction in reflectivity. Furthermore, pure silicon molybdenum interfaces tend to be unstable and show even higher diffusion for temperatures above 100 °C. Here, ruthenium inter-layers are discussed as an alternative to boron carbide for increasing thermal stability [51]. Such protective layers are of special interest if multilayer coated components are to be used as collectors, as these must be heated for debris mitigation purposes [52]. Other activities are aimed at an improved coverage of the multilayer coating to protect against contamination or oxidation or at the suppression of the deep UV (100–200 nm) reflectivity in comparison to the EUV reflectivity. The latter strategy is one of several such approaches, including special thin filters for the deep UV, which are intended to fulfill the specification of spectral purity at the resist [53].

An imaging system for an EUV scanner consists of a number of multilayer-coated reflective mirrors. The design and specifications are discussed here as examples of the optical system of the Engineering Test Stand (ETS), which was the first full-field imaging system based on a plasma source. Details of the optical system can be found in Ref. [54]. A schematic of the projection optics consisting of four mirrors with NA = 0.1, a magnification of 0.25 and a resolution of 100 nm, is shown in Figures 6.12 and 6.13. Mirrors M1 and M3 are convex, while M2 and M4 are concave. The beam propagates off-axis, as indicated in Figure 6.13. In this special case, the mirror

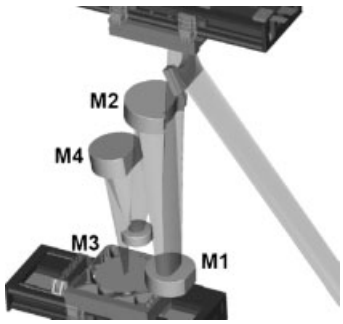

Figure 6.13 A three-dimensional view of the ETS projection optics system.

diameters are 165 mm for M1, 209 mm for M2, 104 mm for M3, and 170 mm for M4. The corresponding radii are −3055 mm for M1, +1088 mm for M2, −389 mm for M3, and +504 mm for M4 [55], where "+" indicates a concave and "−" a convex surface. Usually, a system of several mirrors is chosen in order to have sufficient degrees of freedom for the correction of aberrations and other imaging errors.

Typical diameters of the mirrors reach 200 mm for the ETS system, and even more for other optical systems. In order to meet the imaging specifications, the root mean square (RMS) figure error and the roughness must be below a certain level. The surface specifications will be discussed in more detail. Usually, the surface topology is described by a function $z(x, y)$. For simplicity, the following discussion and definitions are for the one-dimensional case $z(x)$. The extension to two dimensions is described elsewhere [56].

The average of the surface height is defined:

$$\bar{z} = \lim_{L\to\infty} \frac{1}{L} \int_{-L/2}^{L/2} z(x)dx \tag{6.9}$$

with L being the spatial extension under consideration of the surface. The surface roughness, σ, is given by:

$$\sigma^2 = \lim_{L\to\infty} \frac{1}{L} \int_{-L/2}^{L/2} (z(x) - \bar{z})^2 dx \tag{6.10}$$

It is useful to discuss the Fourier transform of the surface in terms of the spatial frequency, f_x:

$$Z(f_x, L) = \int_{-L/2}^{L/2} z(x) e^{-2\pi i f_x} dx \tag{6.11}$$

The power spectral density (PSD) function is often used for characterization of a surface, which can also be directly measured in scatterometry [56] and can be related to the Fourier transform $Z(f_x, L)$:

$$\mathrm{PSD}(f_x) = \lim_{L\to\infty} \frac{1}{L} |Z(f_x, L)|^2 \tag{6.12}$$

As defined in Equation 6.10, the roughness is the integral over all spatial frequencies of the PSD function. Often, different regions are defined in the specifications depending on the respective frequency interval $f_{\min}$ to $f_{\max}$

$$\sigma^2_{\Delta f} = 2 \int_{f_{\min}}^{f_{\max}} \mathrm{PSD}(f_x) df_x \tag{6.13}$$

The surface figure error corresponds to frequencies typically ranging from the inverse aperture to 1 mm^{-1}. This type of error is responsible for aberrations. The

roughness in the mid-spatial frequency range (MSFR), from $1\,mm^{-1}$ to $1\,\mu m^{-1}$, determines flare and contrast. The high spatial frequency range (HSFR) includes all frequencies above $1\,\mu m^{-1}$. The HSFR roughness influences the EUV reflectivity; for the ETS optical system, a surface figure roughness of <0.25 nm RMS, a MSFR roughness of <0.2 nm RMS, and a HSFR roughness of <0.2 nm RMS are specified. The specifications for the Zeiss projection optics system for the ASML alpha demo tool are similar [57]. Here, the figure error should be <0.2 nm RMS, and the MSFR and the HSFR roughnesses should be between 0.1 and 0.2 nm RMS. Different analysis methods for determining the PSD function show that these specifications are fulfilled [57], which is also confirmed by the successful printing of small structures with diffraction-limited resolution.

6.2.4 Masks

In contrast to conventional DUV lithography, masks are also based on multilayer-coated reflective mirrors. A cross-section of a mask is shown schematically in Figure 6.14. The mask blank is defined as that part including the substrate and a protective layer of, for example, SiO_2 necessary for the patterning process. The structures to be imaged onto the wafer are written onto the surface using an absorber layer of typically 100 nm thickness. The preferred absorber materials are Cr, TaN, Al or W. However, as the mask is imaged, there are additional specifications in comparison to the multilayer mirrors for the optical system [58, 59], and these will be addressed in the following.

The substrate must have a low thermal expansion coefficient (CTE) of typically less than 5 ppb K^{-1}, as approximately 40% of the incident EUV light is absorbed and heats up the mask. A low thermal expansion is required in order to avoid any magnification correction between the changing of a wafer, and also to minimize image placement distortion due to thermal expansion of the mask. With respect to multilayer optics, the roughness specification is divided into high spatial frequency roughness (HSFR) and mid-spatial frequency roughness (MSFR). HSFR ($\lambda_{spatial} < 1\,\mu m$) should be

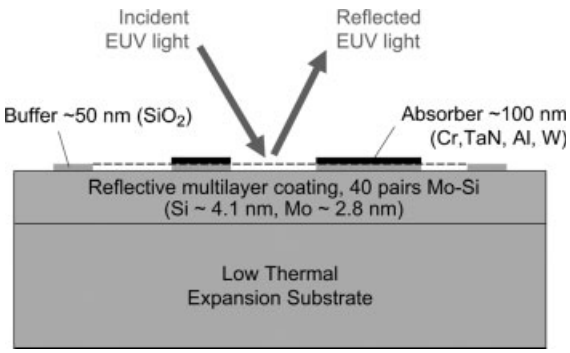

Figure 6.14 A cross-section of a mask to be used in EUV lithography.

below 0.10–0.15 nm (RMS) in order to reduce the losses due to scattering of light out of the entrance pupil of the optical system. In order to reduce the small angle scattering and image speckles, MSFR (1 μm $< \lambda_{spatial} <$ 10 μm) should also be below 0.1–0.2 nm (RMS). A peak reflectivity of more than 67% with a centroid wavelength uniformity across the mask of below 0.03 nm is required.

Another specification refers to the defect density of below 0.003 defects cm^{-2} for defects larger than 30 nm. This is the most challenging demand for the masks, and is one of the most critical issues in EUV lithography. As EUV light has a strong interaction with matter, and thus a short penetration depth of typically <100 nm, defects on the masks have a much higher probability of being printed, in contrast to other wavelengths as in the UV region. Thus, special care must be taken to reduce the defects on the masks to a level of 0.003 per cm^2 or, in other words, to less than a few defects per mask.

Many different categories of defect have been defined, and many activities are required simply to reduce the number on masks, mask blanks and the substrate by cleaning and repair techniques [60], detecting printable defects [61] and simulation of their influence on the picture at the wafer level [62]. Although defects on the substrate will be buried after the multilayer coating is applied, the various types of defect may lead to phase errors of the reflected light. Once such defect has been localized the absorber structure can be appropriately aligned to cover these defect and thus reduce its influence. The influence of defects (particles) on the mask depends on their size. If they are sufficiently small, they are not seen in the de-magnified image on the wafer; hence, only defects larger than 20–30 nm are of interest. The influence of defect size on image is discussed in Ref. [62].

In order to obtain an impression of the current status, the defect densities achieved on mask blanks are taken from Ref. [1]. For defects larger than 120 nm the density is 0.03 defects cm^{-2}, while for >60 nm a density of 0.3 defects cm^{-2} is achieved, this being more than two orders away from the final specification. As yet, no appropriate metrology is available for smaller defects.

6.2.5 Resist

The use of higher photon energies and the printing of ever-smaller features requires the development of a new generation of photo resists compared to those currently used in DUV lithography. According to the International Roadmap for Semiconductors (ITRS), a resist thickness of between 40 and 80 nm is required for EUV, while the line edge roughness (LER) and the critical dimension control (resolution) should be below 1 nm (3σ) [63, 64]. It should be noted that these specifications have near-atomic-scale resolution, which is not achievable with sufficiently high sensitivity when using the resists and concepts currently available. To ensure a certain wafer throughput, the resist sensitivity – that is, the number of photons or energy per unit area required to convert the resist molecules into solvable components – should be in the range of a few mJ cm^{-2}. The required thickness of less than 80 nm is lower than for DUV resists because of the short absorption length for EUV radiation in

polymers. To ensure an approximately homogeneous illumination as a function of the penetration depth, the permissible resist thickness is limited to these values below 100 nm. This also implies a loss of usable photons by having a rather large portion of transmitted light.

There is a trade-off between high sensitivity, low LER and high resolution, which means that improving one feature will lead to a worsening of the other features. This fact, and the special challenges involved in applications for EUV lithography, are discussed in more detail below.

Conventional lithography makes use of a chemically amplified resist (CAR). An incident photon releases a H^+ ion (acid), which serves as a catalyst to react with other molecules to form solvable components, volatile products and another acid to trigger this reaction again. This mechanism is used to increase the sensitivity of the resist, but has an impact on the achievable resolution and LER. The processes are shown schematically in Figure 6.15. The amplification of soluble production by the acids is accompanied by a diffusion process into the unexposed regions. This diffusion process takes place during the post-exposure baking process, as indicated in Figure 6.15, and is determined by the diffusion constant, D, and the duration of the process, t_f. The higher the diffusion, the more sensitive is the resist, but the achievable resolution decreases. In order to quantify this dependence, a one-dimensional exposure with a sinusoidal modulation of photo acids with pitch, p, is considered for simplicity. A measure of the achievable resolution is the modulation transfer function (MTF_{diff}) of this initial distribution altered by the diffusion process [65, 66]:

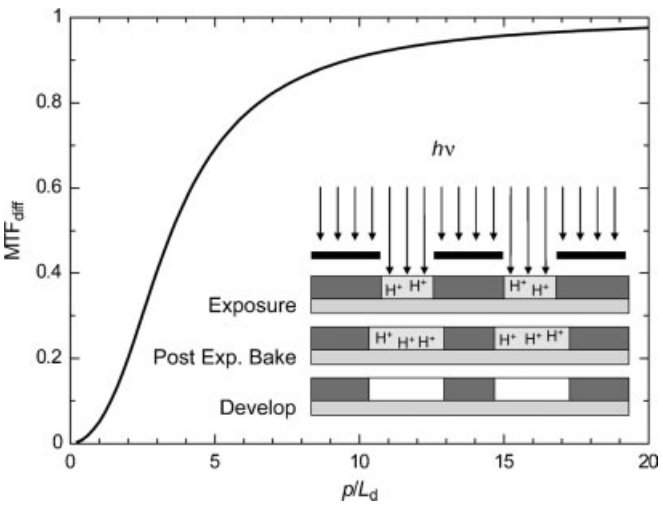

Figure 6.15 Modulation transfer function (MTF) for a sinusoidal exposure of lines and spaces with pitch, p, as a function of diffusion length and a schematic drawing of the exposure, post-exposure baking and developing process of a chemically amplified resist.

$$\mathrm{MTF}_{\mathrm{diff}} = \frac{p^2}{4\pi^2 D t_{\mathrm{f}}} \left\{ 1 - e^{\frac{4\pi^2 D t_{\mathrm{f}}}{p^2}} \right\} \tag{6.14}$$

The respective diffusion length, L_{d}, is defined by ${L_{\mathrm{d}}}^2 = 2Dt_{\mathrm{f}}$. The modulation transfer function is shown as a function of the ratio p/L_{d} in Figure 6.15, where $\mathrm{MTF}_{\mathrm{diff}} = 1$ implies no change of the initial distribution. For example, if a deterioration to 70% is accepted, the diffusion length should not exceed a value of $0.2p$. This limitation of the diffusion length also implies a limitation in resist sensitivity. It should be noted that, with decreasing pitch, the absolute value of the diffusion length must also decrease, which therefore means less sensitivity in the transition from DUV to EUV.

Another parameter describing the quality of a resist is the LER, which is distinct from the achievable resolution in terms of the above discussion. Generally, the LER is dependent on the spatial distribution of solvable components after exposure with a number density, A. The LER is given by the ratio of the standard deviation of this density and its gradient, leading to $\mathrm{LER} \propto \sigma_{\mathrm{A}}/\nabla A$. For a sufficiently low number of photons, both parameters are determined by the incident number of photons. Here, a variation due to the Poisson statistic (shot noise) of the absorbed photons and, in the case of CA resist, the number of produced acids also comes into play. In general, the standard deviation, σ_{N}, of the number of photons, N, in a certain volume is proportional to $\sqrt{N}$, while $A \propto N$. Consequently, the LER scales as $\mathrm{LER} \propto 1/\sqrt{N}$ or $1/\sqrt{E}$, where E is the incident dose. For a chemically amplified resist, the volume – which is relevant to the estimation of the number of photons – is the diffusion sphere. Thus, for a low diffusion length the LER is proportional to ${L_{\mathrm{d}}}^{-3/2}$ when the dose is kept constant. With increasing diffusion length and lower variation due to photon statistics, the diffusion process and the MTF become dominant. The scaling of LER with the diffusion length can be expressed [66]:

$$\mathrm{LER} \propto \left(\frac{1}{L_{\mathrm{d}}}\right)^{3/2} / \mathrm{MTF}_{\mathrm{diff}}\left(\frac{L_{\mathrm{d}}}{p}\right) \tag{6.15}$$

The LER scaling factor according to Equation 6.15 is shown in Figure 6.16 as a function of the diffusion length relative to the pitch. Two regions can be distinguished: for $L_{\mathrm{d}}/p < 0.33$, the scaling is dominated by the photon statistics, whereas for $L_{\mathrm{d}}/p > 0.33$ region the acid diffusion process is relevant for the LER. These two scaling regions are also observed experimentally [66].

The absolute value of LER is still dependent on the resist sensitivity or the necessary dose, which leads to the scaling with $1/\sqrt{E}$. This is illustrated in Figure 6.17, which shows the LER achieved for resists of different sensitivity [67]. The estimated shot noise limit is also indicated. The theoretical limit has clearly not yet been achieved, as the experimental data are slightly higher compared to this limit.

A number of other parameters, such as resist thickness, molecular size or outgassing, are also relevant to use in EUV lithography (see discussion in Ref. [65]). In summary, it is somewhat challenging to meet the specifications for a chemically amplified resist for use in EUV lithography, and in fact such a resist does not yet exist. In terms of LER and resolution, the specifications may be achieved with a

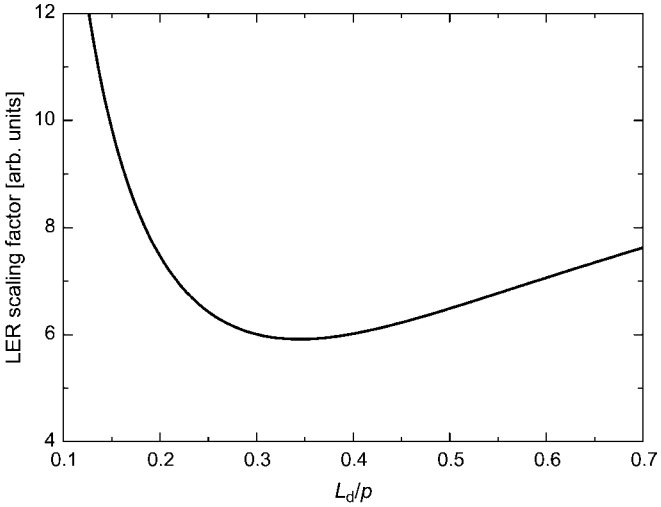

Figure 6.16 Line edge roughness (LER) of a resist with fixed sensitivity as a function of the diffusion length relative to the pitch.

non-chemically amplifying resist. One example is polymethyl methacrylate (PMMA), although this has a rather low sensitivity (in the range of 50–100 mJ cm^{-2}), and is therefore not acceptable for EUV lithography. Some printed lines down to 17.5 nm half pitch [68] are illustrated in Figure 6.18; the smallest currently achieved structure size is a half pitch of 12.5 nm [69].

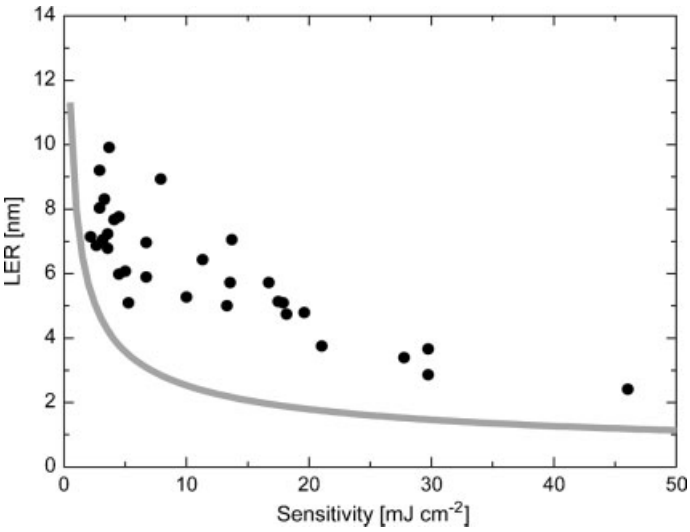

Figure 6.17 Experimentally determined line edge roughness (LER) as a function of sensitivity for different resists. The line gives an estimation of the shot noise limit, which has not yet been achieved.

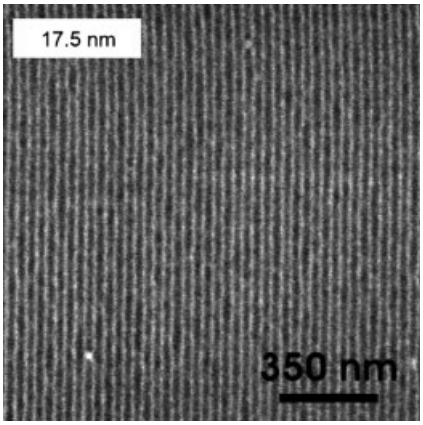

Figure 6.18 Printed lines and spaces with a non-chemically amplified resist (polymethyl methacrylate), with a half-pitch down of 17.5 nm.

Finally, it is illustrative to discuss the role of shot noise simply by estimating the number of photons involved in the exposure process. The incident number of photons per unit area, I, can be rewritten in terms of the necessary dose, E, and the wavelength, λ, of the photons:

$$I = 5.0 \times 10^{-2} \frac{N_{\mathrm{Ph}}}{\mathrm{nm}^2} \frac{\lambda}{\mathrm{nm}} E \frac{\mathrm{cm}^2}{\mathrm{mJ}} \tag{6.16}$$

In the transition from DUV with 193 nm to EUV at 13.5 nm, the reduced wavelength alone leads to a more serious influence of the photon statistics. For EUV radiation and an envisioned resist sensitivity of $E = 5\,\mathrm{mJ\,cm^{-2}}$, we obtain $3.4\,\mathrm{Ph\,nm^{-2}}$. With regards to the specifications of LER and CD control below 1 nm, it is clear that shot noise becomes a limiting factor in EUV lithography. This not only requires the development of new resist materials, but also implies that many research investigations will be necessary over the next few years.

6.3 Outlook

Intensive research and development activities conducted during the past decade have shown that EUV lithography has the potential to provide a solution for the high-volume manufacture of semiconductor devices. Moreover, the technique has the potential to decrease structure sizes to 11 nm, into the range of the physical limits of silicon-based semiconductor technology. Several machines have been installed to demonstrate the capability of printing small structures using EUV radiation; most notably, the ASML alpha demo tool exhibits the full architecture with respect to the optical system, wafer and mask handling for a scanning operation and full-field imaging. The diffraction-limited printing of small structures down to 29 nm was also

successfully demonstrated, though major efforts are still needed to meet the requirements of the components and to drive the technology to its theoretical limits in different areas. These challenges extend not only to the source power but also to the simultaneous high reliability and long lifetime of the source, and this is valid for both laser-induced and discharge-based plasmas. Further issues here include debris mitigation in order to increase the collector lifetime, collector thermal issues, and increase the opening angle. Additional studies are also required on the lifetime and contamination of the optical system by oxygen and hydrocarbons under EUV radiation, on defect-free masks, and on resists with a sufficiently high sensitivity at high resolution and low LER.

Despite the final specifications not having yet been met for several components, progress is nonetheless being made in all fields. For example, activities during the past few years have led to plasma sources which emit inband radiation into the hemisphere on a power level of several hundred watts – close to final specification that in the past was believed to be the most critical issue in EUVL. Major progress is also being achieved in improving the lifetime of both the source and the collector, using sophisticated debris mitigation techniques. In fact, a collector lifetime of more than 1 Gshot has recently been demonstrated, operating with a tin-emitting plasma source, and an ultimate lifetime of 100 Gshot seems feasible.

Non-Optical Lithography

Clivia M. Sotomayor Torres and Jouni Ahopelto

7.1
Introduction

In the quest to use nanofabrication methods to exploit the know-how and potentials of nanotechnology, one major roadblock is the high cost factor which characterizes high-resolution fabrication technologies such as electron beam lithography (EBL) and extreme ultraviolet (EUV) lithography. The need to circumvent these problems of cost has inspired research and development in alternative nanofabrication, also referred to as "emerging" or "bottom-up" approaches. Hence, it is within this context that the status and prospects of nanoimprint lithography (NIL) are presented in this chapter.

Nanofabrication needs are highly diverse, not only in the materials used but also in the range of applications. Within the physical sciences, the drive is to realize nanostructures in order to produce artificial electronic, photonic, plasmonic or phononic crystals. This, in turn, depends on an ability to realize periodic or quasi-periodic arrays of nanostructures, on the one hand to meet the stringent demands of periodicity, order and critical dimensions to obtain the desired dispersion relation and, on the other hand, to identify a reproducible, cost-effective and reliable way in which such materials may be fabricated, using a suitable form of nanopatterning.

Nanopatterning covers a wide range of methods from top-down approaches, as well as bottom-up approaches (for discussions, see Chapters 5, 6, 8 and 9 of this volume). In fact, the needs for lithography are found in several fields:

- In nano-CMOS (complementary metal-oxide semiconductor) for example, to produce pattern gates of lengths down to a few nanometers in order to reach the technology nodes of the semiconductor industry roadmap [1], whilst at the same time complying with the most strict lithography demands.
- In (nano)photonics, a field in which – in addition to packaging – the cost of fabrication of III-V semiconductor optoelectronic devices containing nanostructures in the form of photonic crystals, is prohibitive.

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

- In nanobiotechnology, to fabricate a variety of sensors and lab-on-a-chip platforms based on micro- and nano-fluidics.
- In organic opto- and nano-electronics, where the lifetime issue of the organic materials is compounded with that of a cost-effective volume production with lateral resolution down to a few hundreds of nanometers for electrodes and pixels.
- In micro electro-mechanical systems (MEMS) and nano electro-mechanical systems (NEMS), where the fabrication of resonators, cantilevers and many other structures with and without direct interface to Si-based electronics, requires the control of 3-D nanofabrication with minimum damage to the underlying electronic platform.

Moreover, nanopatterning methods act as enabling technologies to facilitate the progress of research in chemistry, such as the realization of nanoelectrodes to monitor electric activity; in biology, to connect electrically to cells; in physics, to realize nanostructures commensurate with the De Broglie wavelength of a given excitation; in material sciences, through research on novel nanostructured artificial materials; and also in several other engineering disciplines.

In 2003, the state of the art covering most bottom-up emerging nanopatterning methods was collected in Ref. [2] under the title *Alternative Lithography: unleashing the potentials of Nanotechnology*. Of these methods, probably the most advanced is polymer molding or nanoimprint lithography [3]. Other emerging bottom-up methods are those based on scanning probes [4, 5], self assembly (see Chapters 9 and 10 in this volume), micro-contact printing or soft-lithography [6, 7] and stenciling [8], as well as atom lithography [9] and bio-inspired lithography [10].

In this chapter, attention is focused primarily on NIL as an example of non-optical lithographies, as it covers the 1 μm to few nanometer lateral resolution range. Here, the basic principles of this method are described, the state of the art is reviewed, and the main scientific and engineering issues are addressed.

7.2 Nanoimprint Lithography

7.2.1 The Nanoimprint Process

Historically, NIL has been preceded by some remarkable events. In the twelfth century, metal type printing techniques were developed in Korea; for example, in 1234 the "Kogumsangjong-yemun" (Prescribed Ritual Text of Past and Present) appeared, while in 1450 Gutenberg introduced his press and printed 300 issues of the two-volume Bible. Somewhat strangely, an extensive time lapse then occurred until the early twentieth century, when the first vinyl records were produced by using hot embossing [11]. The next major step occurred during the 1970s, when compact discs were fabricated by injection molding.

The term "nanoimprint lithography" was most likely used for the first time by Stephen Y. Chou, when referring to patterning of the surface of a polymer film or resist with lateral feature sizes below 10 nm [3]. Previously, within a larger lateral size range, the method was referred to as "hot embossing". At about the same time, Jan Haisma reported the molding of a monomer in a vacuum contact printer and subsequent curing by UV radiation, which was known as "mold-assisted lithography" [12]. The first comprehensive review of these two approaches appeared in 2000 [13], but since then several excellent reviews of NIL have been produced [14, 15]. During recent years these methods have developed further and have become to be known as "thermal nanoimprint lithography" and "UV-nanoimprint lithography" (UV-NIL), respectively.

The question must be asked, however, what is NIL? Nanoimprint lithography is basically a polymer surface-structuring method which functions by making a polymer flow into the recesses of a hard stamp in a cycle involving temperature and pressure. In order to nanoimprint a surface, three basic components are required: (i) a stamp with suitable feature sizes; (ii) a material to be printed; and (iii) the equipment for printing with adequate control of temperature, pressure and control of parallelism of the stamp and substrate. The NIL process is illustrated schematically in Figure 7.1. In essence, the process consists of pressing the solid stamp using a pressure in the range of about 50 to 100 bar, against a thin polymer film. This takes place when the polymer is held some 90–100 °C above its glass transition temperature (T_g), in a time scale of few minutes, during which time the polymer can flow to fill in the volume delimited by the surface topology of the stamp. The stamp is detached from the printed substrate after cooling both it and the substrate. The cycle, which is illustrated graphically in Figure 7.2, involves time, temperature, and pressure. Here, we have the main issues of NIL: polymer flow and rheology. Although these points have been addressed from the materials point of view in Refs. [16, 17], they remain a serious challenge for feature sizes below 20 nm. These aspects will be discussed in the following sections.

In UV-NIL the thermal cycle is replaced by curing the molded polymer by UV light through a transparent stamp. This requires different polymer properties, as will be discussed in the next section.

7.2.2 Polymers for Nanoimprint Lithography

The polymers used in NIL play a critical role. A comparison of the 10 most-often used polymers (resists) used in thermal NIL is provided in Ref. [15]. The resists determine both the quality of printing and the throughput. Quality is achieved via the thickness uniformity of the spin-coated film, the strong adhesion to the substrate, and the weak adhesion to the stamp. Throughput is achieved via the duration of the printing cycle, which in turn is determined by several time scales including:

- the time needed to reach the printing temperature (the higher the T_g, the longer the cycle, unless there is a pre-heating stage)

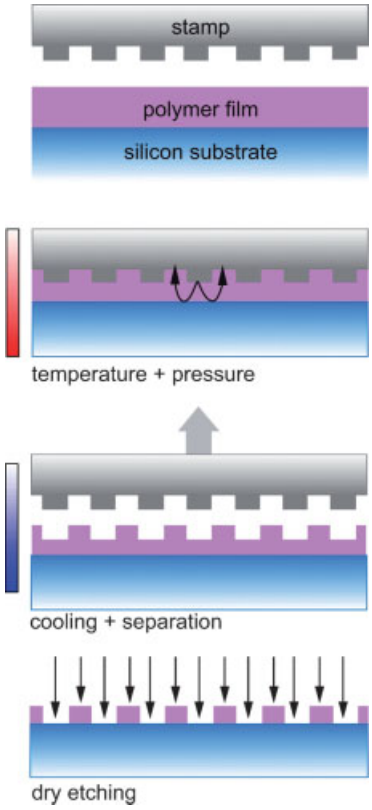

Figure 7.1 Schematics of the thermal nanoimprint concept. Top to bottom: The polymer layer on a solid substrate is heated to a temperature above the glass transition temperature (T_g). The stamp and polymer layer are brought into contact. Pressure is applied to start the polymer flow into the cavities of the stamp. The sample and stamp are cooled down for demolding or separation at a temperature below T_g. The residual polymer layer is removed, typically by dry etching. The end result is a patterned polymer layer on a substrate.

- the hold time for optimum flow at the printing temperature (the more viscous the polymer, the longer the hold time)
- the time needed for cooling and demolding.

Different criteria must be met for thermal NIL and for UV-NIL [18]. For thermal NIL, the polymer is used as a thin film of a few hundred nanometers thickness which is spin-coated onto the support substrate. The key properties are of a thermodynamic nature, and therefore these polymers are of the thermoplastic and thermosetting varieties with varying molecular weights, chemical structures, and rheological and mechanical behaviors. The dependence of the viscosity of a thermoplastic polymer as a function of temperature is shown graphically in Figure 7.3, and illustrates the region where thermal NIL takes place. The mechanical behaviors of polymers in different temperature regimes, in relation to the molecular mobility, are listed in Table 7.1.

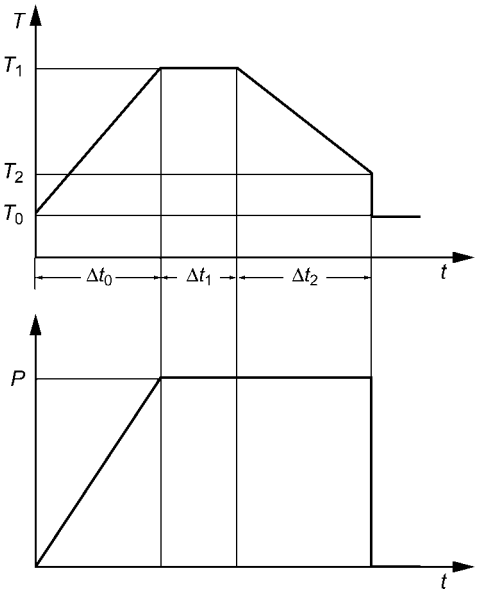

Figure 7.2 Temperature and pressure cycles as a function of time in the thermal NIL process. Typical parameters used for thermoplastic polymers are: Printing temperature T_1 (°C) = 185; demolding temperature T_2 (°C) = 95; printing pressure P (bar) = 30; time to reach printing temperature allowing polymer to go from solid to viscous regime Δt_0(s) = 60; molding time Δt_1 (s) = 60; cooling time Δt_2 (s) = 160.

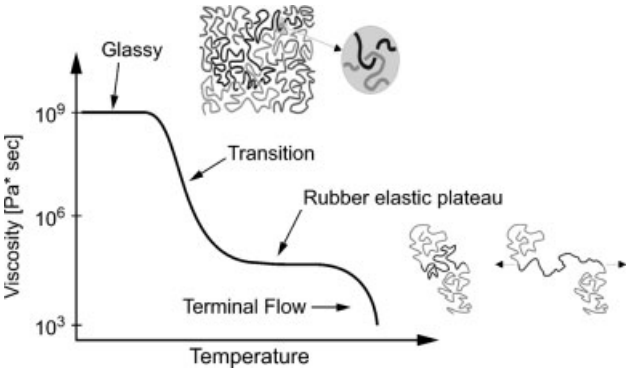

Figure 7.3 Typical dependence of a polymer viscosity on temperature. At room temperature, the polymer is in its solid (glassy, brittle) state. As the temperature increases the short-chain segments become disentangled and the polymer rapidly undergoes a transition from its solid to a rubbery state, changing its viscosity by several orders of magnitude around the glass transition temperature, T_g. Further temperature increases lead to disentanglement of the long polymer chains and resulting in a terminal flow of the viscous melt. Printing takes place in the region where the flow is optimum for filling of the stamp cavities, depending on the molecular weight and stamp design.

Table. 7.1 Relationship between molecular mobility and mechanical behavior of polymers in different temperature regimes.

Temperature regime		$T_{subtransition}$	T_g	T_{flow}
State	Glassy	Rubber elastic	Plastic	
Mechanical appearance	Brittle	Hard elastic, rigid	Rubber elastic	Viscoelastic
Young's modulus ($N\,mm^{-2}$)	about 3000	about 1000	about 1	Too small to measure
Molecular mobility	Molecular conformation completely fixed.	Molecular conformation largely fixed. Occasional change in molecular positions of side groups and chain segments.	Entanglement and physical junction zones prevent movement of entire macromolecules. Entropy-elastic change of molecular position of chain segments. Micro-Brownian motion. Creep, no plastic flow.	No restricted rotation around single bonds. Whole macromolecules change their positions gliding past each other. Plastic flow. Macro-Brownian motion.
Effect of stress	Energy-driven elastic distortions.	Energy-driven elastic distortions.	Entropy-driven elastic distortion. Besides temperature, the deformation rate affects the mechanical behavior.	Pseudoplasticity, shear thinning.
Suitability for printing			Imprinting is possible, but will have memory effects.	Best printing temperature range.

[a] Adapted from Ref. [19]; reproduced with permission.

One of the polymer strategies used to reduce the printing temperature and to improve thermal stability has been to cure prepolymers (special precursors of crosslinked polymers). Here, the term "curing" refers to the photochemical (UV)- or thermal-induced crosslinking of macromolecules to generate a spatial macromolecular network. The prepolymers are low-molecular-weight products, with a low T_g, which are soluble and contain functional groups for further polymerization. Thus, lower printing temperatures of about 100 °C can be used. Curing can take place during the printing time, or thereafter, with the thermal stability enhancement arising from the crosslinking process of the macromolecules.

Polymers for UV-NIL must be suitable for liquid resist processing; that is, they are characterized by a lower viscosity than the polymers for thermal NIL. Naturally, they must also be UV-curable over short time scales [19]. The characteristics of these polymers after printing for their direct use, as in polymer optics or microfluidics, or as a mask for subsequent pattern transfer, by means of dry etching, demand high mechanical, thermal and temporal stability. In photonic applications, stability in

terms of optical properties, such as refractive index, is also essential. Recently, micro resist technology GmbH [20] has developed a whole range of polymers for thermal and UV-NIL (for a discussion, see Ref. [21]). Moreover, tailoring the polymer properties to increase the control of critical dimensions remains an area where, although rapid progress has recently been made [18, 19, 21], further research investigations are still required. The importance of this research may be appreciated especially in a one-to-one filling of the stamp cavities, thereby making the printed polymer features resilient to residual layer removal. Moreover, polymer engineering is also a determinant in larger throughputs, in terms of shorter times for the curing and pressure cycles.

In recent years several reports detailing mechanical studies of thermal NIL have been made, and the interested reader is referred to the data of Hirai [22], the review of Schift and Kristensen [15], and to a recent review of the research on the simple viscous squeeze flow theory [23].

7.2.3 Variations of NIL Methods

To date, four main variations of the NIL process have been developed, and these are briefly described below.

7.2.3.1 Single-Step NIL

This is the most commonly used method to print a polymer in one temperature–pressure cycle, and has been extended to the printing of 150-mm [24] and 200-mm wafers [25]. A scanning electron microscopy (SEM) image of an array of lines of 200 nm width printed over a 200-mm silicon wafer is shown in Figure 7.4. Although one-step thermal NIL can be performed using regular laboratory-scale equipment, commercially available tools include, among others, those of OBDUCAT [26] and EVG [28], which are available in Asia and the Americas. Thermal expansion may cause distortions in the imprinted pattern and to avoid this, strategies for room-temperature NIL have been investigated [28, 29].

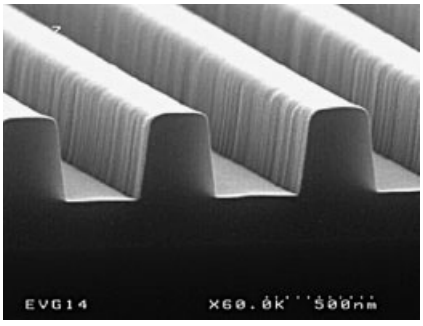

Figure 7.4 A scanning electron microscopy image of 200-nm lines printed in polymer on a 200-mm wafer [25].

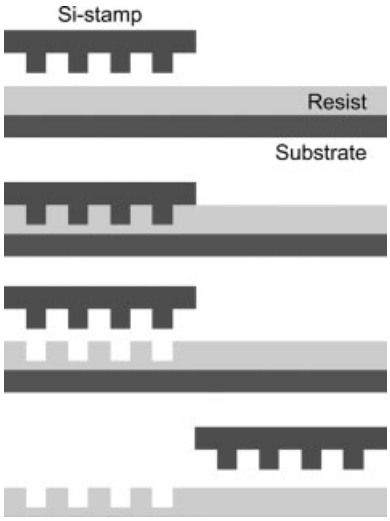

Figure 7.5 The step-and-stamp imprinting lithography process shown schematically. The substrate is patterned in a sequential process by stepping and imprinting across the surface. During the process, the substrate temperature is kept below the glass transition temperature of the resist polymer, while the temperature of the stamp is cycled up and down, above and below the glass transition temperature [30].

7.2.3.2 **Step-and-Stamp Imprint Lithography**

Step-and-stamp imprint lithography (SSIL) is a sequential process, pioneered by Tomi Haatainen and Jouni Ahopelto [30], and is depicted schematically in Figure 7.5. Basically, the system employs thermal NIL and uses a small stamp to print, step and print again, in order to nanostructure the desired area. Initially, SSIL was developed using a commercially available flip-chip bonder, but a dedicated wafer-scale tool from SUSS MicroTec is now available for SSIL [31]. One advantage of SSIL is its capability to achieve a high overlay accuracy, which makes it possible to pattern several consecutive layers or to mix and match with other lithography techniques [32]. An example of a full-patterned wafer is shown in Figure 7.6.

7.2.3.3 **Step-and-Flash Imprint Lithography**

Step-and-flash imprint lithography (SFIL) is also a sequential process, and uses UV radiation instead of temperature to generate relief patterns with line widths below 100 nm. Like NIL, SFIL does not use projection optics but, unlike NIL, it functions at room temperature. SFIL, which is depicted schematically in Figure 7.7, was pioneered by the team of Grant Wilson in the USA [33, 34], with an initial target of meeting the needs of front-end CMOS process fabrication. One of its attractive features is the ability to print over already patterned surfaces. Molecular Imprints Inc. has developed a range of tools for SFIL [35]. As with UV-NIL, SFIL requires transparent stamps

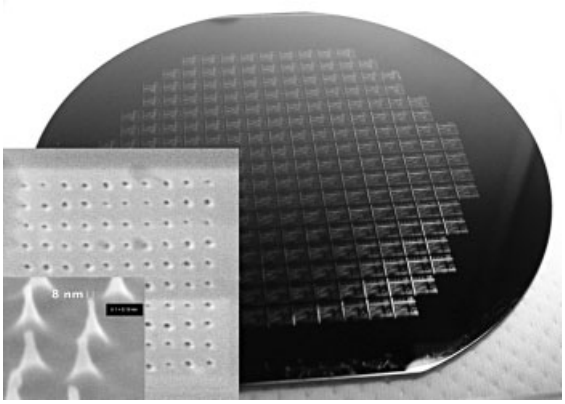

Figure 7.6 A full 100-mm wafer patterned by SSIL, consisting of a matrix of more than 200 imprints into mr-I 7030 resist. The inset shows scanning electron microscopy images of a silicon stamp with sub-10-nm pillars, together with the corresponding imprint.

(usually quartz), the fabrication of which is at present less straightforward than for thermal NIL.

7.2.3.4 **Roll-to-Roll Printing**

This is an advanced sequential method stemming from production method used in, for example, the newspaper industry. Roll-to-roll nanoimprinting is a versatile method that can be combined with other continuous printing techniques, as shown schematically in Figure 7.8. Its extension to 100-nm lateral resolution has been reported [36]. Recent developments suggest that roll-to-roll nanoimprinting is the closest to an industrial technology for organic opto- and nano-electronics, as well as for lab-on-chip device fabrication. The challenge is to fabricate the round stamps; that is, the printing rolls with nanometer-scale features. Moreover, due to the nature of the continuous process, some restrictions may arise in applications requiring multilevel patterning with high alignment accuracy between the layers. Examples of the feature size that can be obtained with a laboratory-scale roll-to-roll printer are shown in Figure 7.9.

7.2.4 **Stamps**

Stamps for NIL have been extensively discussed in Ref. [15]. The main considerations from the materials aspect include:

- Hardness (e.g., typically from 500 to thousands of kg mm^{-2}), which determines the stamp lifetime and the way in which it wears out.

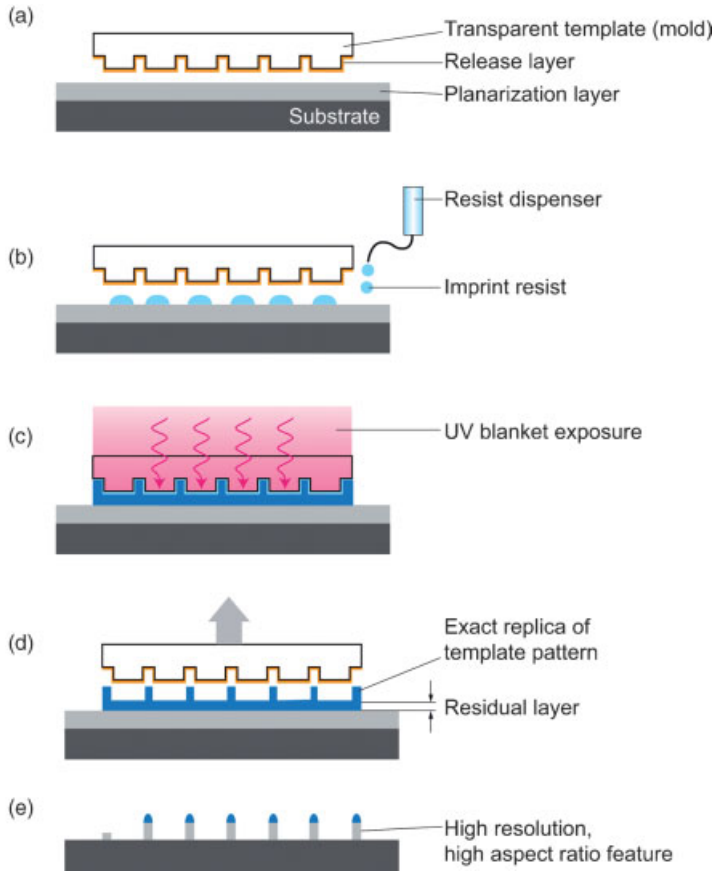

Figure 7.7 Schematics of the step-and-flash imprint lithography (SFIL) process. (a) The pre-planarized substrate and treated stamp are oriented parallel to each other. (b) Drops of UV-curable, low-viscosity imprint resist are dispensed on specified places. (c) The stamp is lowered to fill the patterns and the imprint fluid is polymerized (cured) with UV light at room temperature and low pressure. (d) The stamp is separated from the imprinted substrate. (e) A halogen breakthrough etch to remove the residual layer is performed, followed by an oxygen reactive ion etch [35].

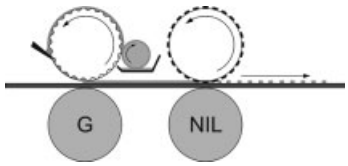

Figure 7.8 The advanced roll-to-roll nanoimprinting process, shown schematically. The gravure unit on the left (G) spreads a film of the conducting polymer on the web. This is followed by patterning of the film, using the nanoimprinting unit (NIL) on the right. The combining of different techniques allows the fabrication of complex layered structures in a single pass [36].

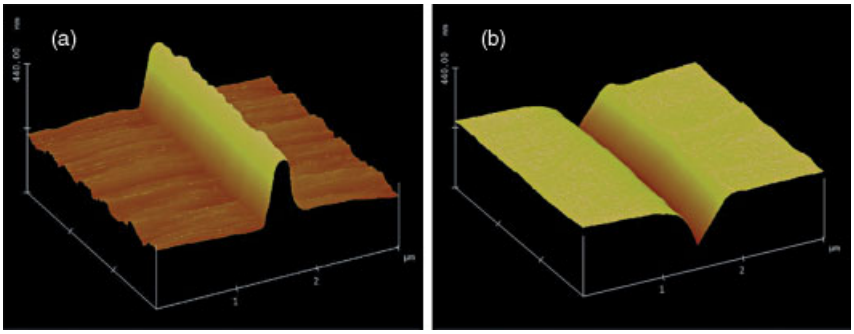

Figure 7.9 (a) Atomic force microscopy (AFM) image of a 100 nm-wide and 170 nm-high ridge on an electroplated roll-to-roll nanoimprinting stamp. (b) AFM image of a trench imprinted into cellulose acetate using the stamp shown in (a). The process temperature is 110 °C and the printing speed 1 m min^{-1}. There was no significant difference between the results obtained at speeds ranging from 0.1 to 5 m min^{-1}.

- Thermal expansion coefficient (e.g., typically from 0.6 to 3×10^{-6} K^{-1}), as well as Poisson's ratio (e.g., typically from 0.1 to 3.0), which will have a strong impact on distortion while demolding.
- Surface smoothness (e.g., better than 0.2 nm), as a rough surface will require large demolding forces and may lead to stronger than needed adhesion.
- Young's modulus (e.g., typically from 70 to hundreds of GPa), which in turn will control possible stamp bending. The latter effect may lead to uneven residual layer thickness, and thus compromise critical dimensions.
- Thermal conductivity (e.g., typically from 6 to hundreds of Wm^{-1} K^{-1}), which determines the duration of the heating and cooling cycles.

With regards to fabrication, the parameters to be considered include the minimum lateral feature size or resolution, the aspect ratio (feature lateral size: feature height), the homogeneity of the feature height across the stamp, as well as depth homogeneity, sidewall roughness, and inclination. For thermal NIL, stamps are usually fabricated in silicon by using EBL and reactive ion etching for the highest resolution and versatility. Unfortunately, these procedures are rather expensive, so that strategies for lower-cost replication have been developed, such as SSIL, the use of a master stamp and a (negative) first-generation replica using NIL or a (positive) second-generation replica, again using NIL. Replication while maintaining a resolution of 100 nm or better requires electroplating to replicate the original in metal. Current developments in the replication of a master stamp in thermosetting polymers show great promise, as they are expected greatly to reduce the cost of stamp replication [37]. As nanoimprint is a 1-to-1 replication technology, it is essential that the stamp has the correct feature sizes required on the wafer, thus emphasizing the need for quality stamps.

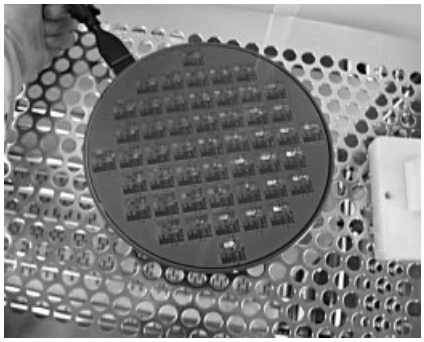

Figure 7.10 Optical image of a 200-mm silicon stamp fabricated by electron beam lithography [25].

In the past, stamps have been realized for wafer-scale thermal NIL (see Figure 7.10). In addition, electron-beam-written silicon stamps for thermal NIL are commercially available from NILTechnology [38], and an example is shown in Figure 7.11.

In recent years, the adhesion between the stamp and the printed polymer film has been the subject of significant research effort in thermal NIL. Here, the main issue is to ensure that the interfacial energy between the stamp and the polymer film to be printed is smaller than the respective interfacial energy between the substrate and the polymer film [39]. However, based on the materials commonly used, this matching is not sufficient for easy detachment, in which the frozen strain also plays a role. The normal practice here in order to facilitate demolding and to prolong the stamp

Table. 7.2 Surface energies of common materials used in nanoimprint lithography.

Material	Surface energy (mN m^{-1})
PMMA	41.1
PS	40.7
PTFE	15.6
–CF3 and –CF2	15–17
Silicon surface	20–26

Values are taken from Reference [39].

lifetime, is to coat the stamp with an anti-adhesive layer to minimize the interfacial energy and, therefore, the adhesion. Values of the surface energies of materials commonly used in the NIL process are listed in Table 7.2. These data show that a fluorinated compound can dramatically reduce the surface energy and minimize adhesion while demolding a stamp from the printed polymer.

For both UV-NIL and SFIL, UV-transparent stamps are required, and these are typically constructed from quartz. Although, the fabrication of quartz stamps for high resolution has not yet been standardized, various efforts have been made to use photomask fabrication methods to prepare stamps or templates for UV-NIL [40]. A schematic overview of the stamp fabrication process is shown in Figure 7.12. In a first lithography step, the stamp is structured using EBL (first level writing), while in a second lithography step the pedestal requirement for imprint is made (second level

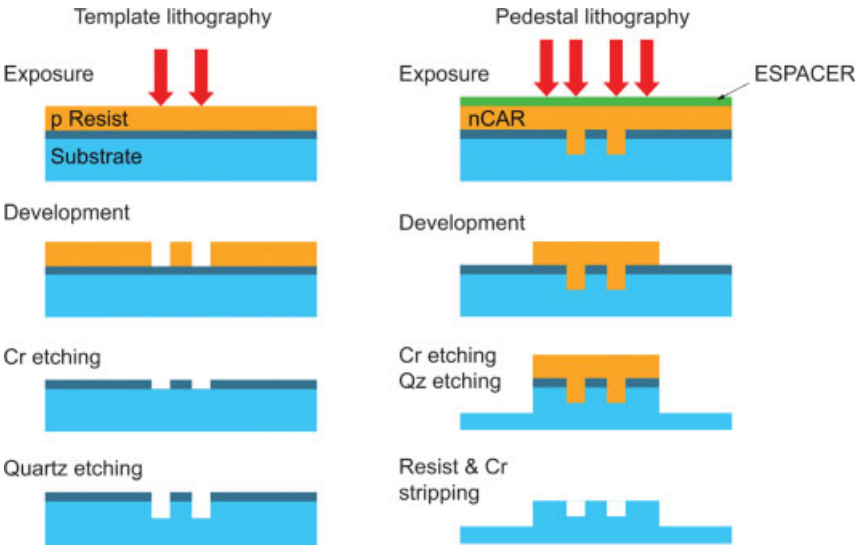

Figure 7.12 Schematics of the fabrication process of two-dimensional stamps for step-and- stamp and or step-and-flash UV-NIL [41, 42].

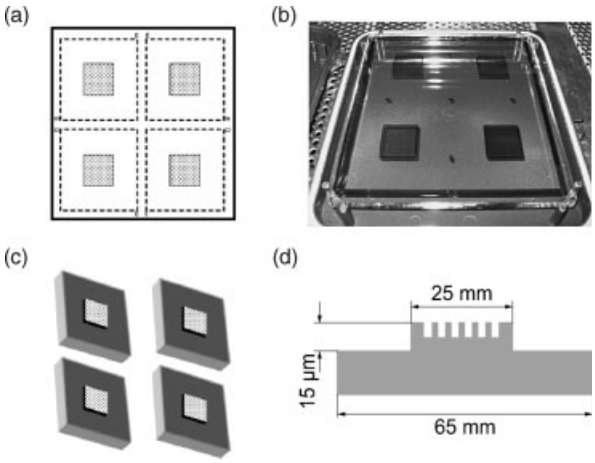

Figure 7.13 Photomask fabrication methods for UV-NIL stamp fabrication [43].

writing). Further details on the process flow for UV-NIL stamps can be found in Refs. [41, 42]. By using photomask fabrication methods, four imprint stamps or templates may be structured on a single photomask blank (see Figure 7.13a and b). The photomask blank is then diced into separate stamps (Figure 7.13c). As dicing introduces some contamination and mechanical strains, a modified fabrication process must be introduced before step-and-repeat- and step-and-flash- UV-NIL can be employed in volume production. The size standard for stamps resembles the exposure field of current optical lithography steppers (see Figure 7.13d).

Recently, stamps for 3-D structuring tests of several layers of functional films using UV-NIL targeting the back-end CMOS processes have been developed, using stamps similar to that shown schematically in Figure 7.13d.

The fabrication of stamps with high-resolution features for roll-to-roll nanoimprinting is more complicated because patterning of the curved surfaces is not straightforward. One possibility way to overcome this is to make a bendable shim that is wrapped around the printing roll. Such bendable large area stamps can be fabricated by electroplating, and exploiting SSIL in large-area pattering has been shown to reduce the fabrication time remarkably [44]. A 100 mm-diameter bendable Ni stamp is shown in Figure 7.14; this figure also shows that sub-100-nm features can be easily reproduced by using an electroplating process.

The details of stamps used for 3-D printing are discussed later in the chapter.

7.2.5
Residual Layer and Critical Dimensions

Most of the processes described above yield a nanostructured polymer layer (as shown schematically in Figure 7.1), with a residual layer under the features of the stamp. If the desired nanostructured surface is the polymer itself, with no material

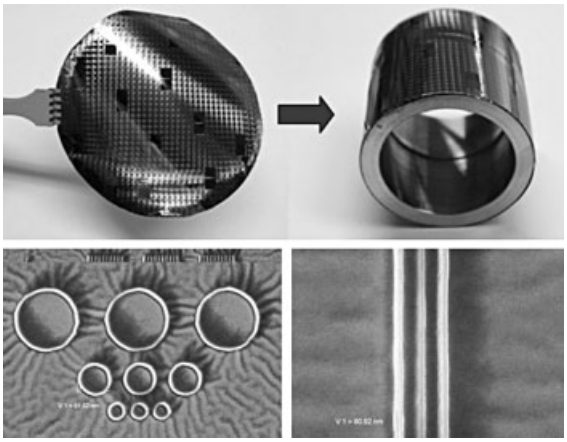

Figure 7.14 (a) An electroplated, bendable 100 mm-diameter Ni shim. The thickness of the shim is 70 μm. The roll-to-roll stamp is made by wrapping the shim around a stainless steel roll. (b) Scanning electron microscopy images of various 80 nm-wide features on an electroplated Ni shim patterned by SSIL. The surface metal layer on the stamp is TiW.

between the features, then the residual layer must be removed. The same applies [44] if the patterned polymer or resist is to be used directly as a mask for pattern transfer into the substrate by, for example, reactive ion etching, or if a metal lift-off step will be needed that will result in a metal mask for further pattern transfer [45]. An etching step of the printed polymer, whether to remove the residual layer or to be used as a mask, necessarily results in the feature sizes experiencing change. This was shown in the variation in the width of printed Aharonov–Bohm ring leads following removal of the residual layer by etching, and after metal lift-off. The leads increased by 15 nm in width from the targeted width of 500 nm, taken over an average of 20 samples [32]. This means that, in order to control the critical dimensions of the printed features, the residual layer thickness uniformity must also be controlled, as its removal leads to a size fluctuation of the resulting nanostructures. Significant efforts have been made to develop non-destructive metrology for nanoimprinted polymers. One of the most salient approaches is to use scatterometry as applied to NIL [46], in order to determine both the feature height and residual layer thickness. Being based on the principles of ellipsometry, a laser spot is used, which is scanned over the region of interest. An example of this is shown in Figure 7.15 (right panel), with a cross-sectional SEM image of the printed ridges and the corresponding scatterometry data and curve fitting. The left panel of Figure 7.15 depicts an optical reflection image of a printed wafer, showing the thickness variation of the residual layer across the wafer [47]. An *in-situ* and non-destructive method was demonstrated by adding chromophores to the printed polymer and using their emission as an indicator of stamp deterioration (such as missing features), mirrored in the printed fields. Although the resolution of this method was poor, it did at least demonstrate the feasibility of the in-line monitoring of printed arrays of nanostructures [48].

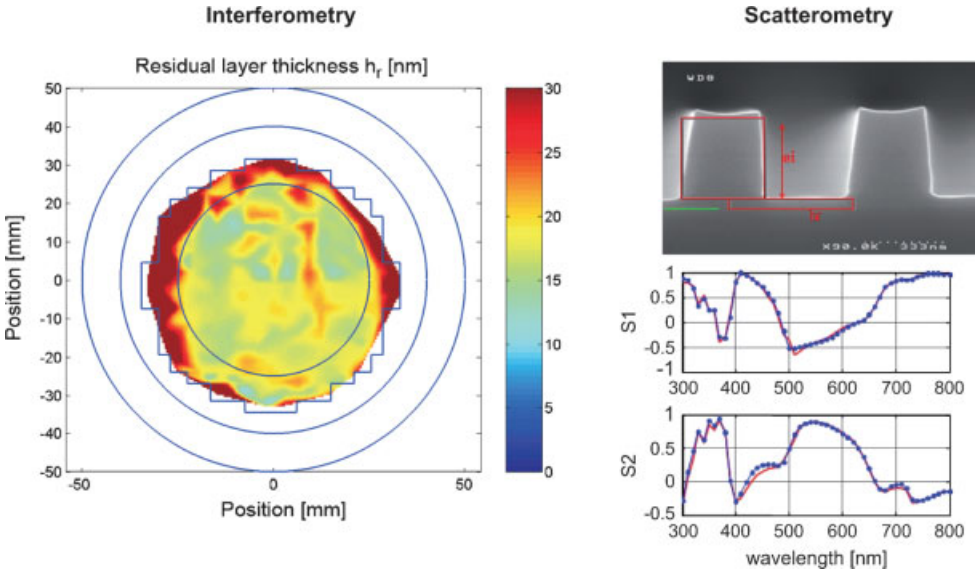

Figure 7.15 Two approaches to metrology. Left: Optical imaging of the contrast resulting from variations of the residual layer thickness over a 100-mm wafer, showing a good uniformity over most of the wafer, except at the edges [47]. Right: The upper image is a cross-section micrograph showing the feature height and residual layer thickness; the lower images show experiments and fit of a scatterometry spectrum recorded on a printed sample, from which the residual layer as well as the feature size can be obtained [46].

Control of the residual layer is necessary due to a need to fill in completely the stamp cavities, whilst achieving as thin and as uniform a residual layer as possible. This is a non-trivial issue which depends not only on nanometer-scale polymer rheology but also on the stamp and substrate deformation.

The polymer challenge in thermal NIL is basically four-fold: (i) to obtain complete filling of the cavities or to ensure a one-to-one transfer; (ii) to obtain as thin a residual layer as possible to control critical dimensions; (iii) to ensure that the printed features do not relax mechanically; and (iv) to achieve a reasonable throughput.

A typical curve of the dependence of viscosity on temperature (e.g., Figure 7.3) shows that T_g occurs in a regime where the viscosity is changing by several orders of magnitude. This poses a non-negligible challenge to understanding polymer flow in the context of NIL. Initially, the polymer flow has been approximated to that of a Newtonian fluid in the gap between two parallel disks of radius R (as discussed in Ref. [49]). The discussion of Ref. [49], which is summarized below, is probably the most complete account to date covering the simple case and providing an insight into the scope of the problem. By using the Stefan equation for the quasi steady-state solution (this is a simplified version of the non-stationary Navier–Stokes equation), the force is found to be proportional to the viscosity, the fourth power of the disk radius, the speed of the disks coming together, and inversely proportional to the cube of the initial layer thickness. In other words, a huge force is needed for a fast fluid

motion in thin films over large distances. There are two basic considerations to this point:

- The force has only a linear dependency on viscosity, which changes by orders of magnitude when the temperature is in the vicinity of T_g.
- Although a Newtonian fluid, or a fluid in the limit of small shear rates, the viscosity does not depend on the shear rate. However, at moderate or high shear rates, a non-linear flow can lead to a decrease in viscosity by several orders of magnitude. The effect of this on the NIL process would be seen as a reduction either in the pressure needed or in the processing time.

The question is, therefore, what are the contributions to the force from pressure and shear stress of the fluid motion? Clearly, pressure is related to the contact area of the stamp and the fluid (polymer above T_g), whereas the shear stress is related to the flow velocity, which in turn depends on the distances over which the fluid must be transported, and therefore on the particular stamp design. At any given time, the condition of continuity and the conservation of momentum of an incompressible liquid requires that the velocity must increase with radial distance, which would result in a parabolic velocity profile in the z-direction. The velocity would be least at the interface with the disk walls, and greatest in the middle of the gap. To this, the inversely proportional cubic dependence on liquid layer thickness must be added. The calculated values of viscosity and transport thickness tend to agree with the observed experimental values for polymethyl methacrylate (PMMA) and, rather simplistically, some basic trends can be obtained:

- Thermal NIL works best for smallest features (sub-100 nm) which are close together and in which a local flow takes place, allowing easy and reliable filling of the stamp cavities.
- Conversely, large features (>10 μm) separated by large distances require a large displacement of material, and larger forces.

Here, the force–displacement curve results reviewed in Ref. [23] are highly illuminating, as a more complete model requires the consideration of several flow fields arising from the different shapes, depths, and separation of cavities in the stamp. Schift and Heyderman carried out a thorough analysis in this respect in the linear micrometer regime [50].

In the linear regime, the temperature dependence of the viscosity is viewed as a thermally activated process [49, 50], following a formalism of amorphous polymers and remaining within the limit of small shear rates. Such a non-linear regime is substantially more complex, and is basically exemplified by shear thinning and extrudate swelling. Hoffmann suggested that shear thinning, with its inherent shear rate-dependent viscosity, may influence the thermal NIL process, especially for small features [49].

A key remaining issue is the understanding of how the stored deformation energy depends on the rate at which the temperature and pressure are applied and released,

and to what degree these influence the mechanical stability of the printed polymer features in time scales of weeks, months, and years.

In practice, on order to gain an understanding of the filling dynamics of a stamp cavity under the combined effects of squeezing flow, polymer rheology, surface tension and contact angle in typical NIL experiments, full fluid–solid interaction models based on the continuum approach have been devised [51, 52]. In these, both the fluid bed and the solid stamp are represented and a continuity of displacement and pressure is applied at the interface. As these are based on finite elements, there are almost no limits to the choice of the materials' constitutive behaviour, and these clearly reflect the effects of stamp anisotropy and the shear thinning behavior of the polymer. In particular, they are especially efficient at predicting the shape of the polymer in partially filled cavities.

Coarse grain methods have proven powerful in computing the residual layer thickness of the embossing process [53]. Based on the Stokes equation, they solve the simple squeeze flow equation for Newtonian fluids and embossed areas of up to

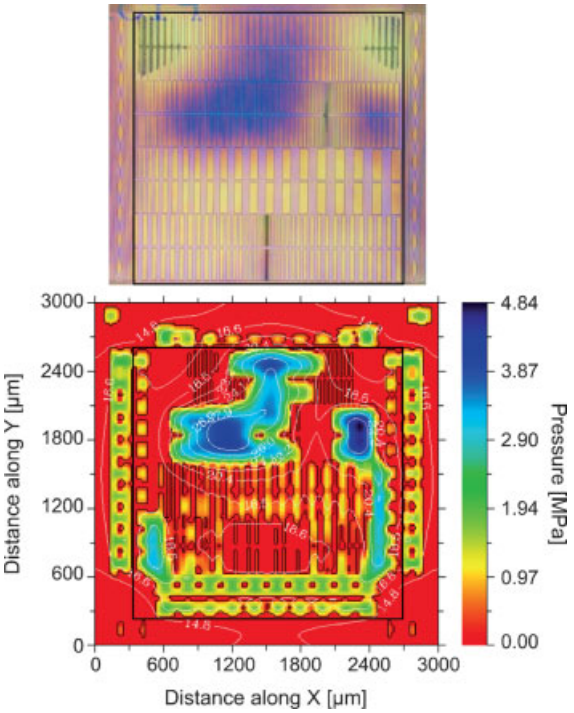

Figure 7.16 Experimental (top) and simulated (bottom) residual layer thickness. The colors correspond to different thicknesses, as observed in an optical microscope. The self-consistent coarse-grain model considers that the stamp is flexible; thus, the resulting contour lines are the variation with respect to the imposed average residual layer thickness. (Illustration courtesy of D.-A. Mendels and S. Zaitsev.).

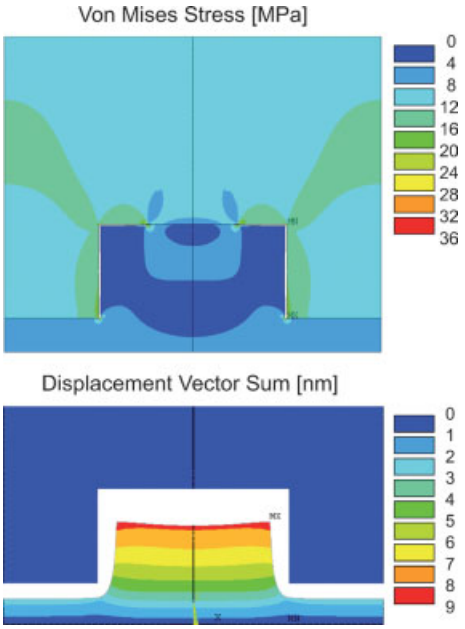

Figure 7.17 Upper: Von Mises stress and stamp/polymer interfacial separation during cool-down of a $200 \times 100\,nm^2$ single polymer cavity obtained by embossing, with a poor interfacial adhesion. Lower: Residual displacement and shape of the same structure after stamp removal in the case of high interfacial adhesion. (Illustration courtesy of D.-A. Mendels.)

several square millimeters within a matter of minutes. Here, the calculation is based on the determination of a homogenized depth which is representative of the average pressure applied to the area. The quantitative agreement has proven excellent, and is generally acceptable when the polymer layer is embossed well above T_g [54]. Freezing of the embossed structures through the T_g has also been modeled [55, 56], and has provided precious insight into the build-up of internal stresses prior to stamp release and of the polymer–stamp interface. It has also been possible to simulate the demolding process, and thus the final shape of the embossed structures, both after stamp release and after relaxation for a given period of time [57]. Two examples of the models described in this section are shown in Figures 7.16 and 7.17.

7.2.6 Towards 3-D Nanoimprinting

One special aspect of NIL and SFIL is their ability to pattern in three dimensions compared to other lithographies. Several applications require this ability, from MEMS to photonic crystals, including a myriad of sensors. One of the first demonstrations of 3-D patterning by NIL was the realization of a T-gate for microwave transistors with a footprint of 40 nm by a single-step NIL and metal lift-off [58]. SFIL

also showed its 3-D pattering ability in the fabrication of multitiered structures, maintaining a high aspect ratio [59].

If metal lift-off is to be avoided, then 3-D NIL requires 3-D stamps. These are produced by gray-scale lithography with sub-100 nm resolution, but are limited in depth and volume production due to the sequential nature of EBL [60]. One recent variation of this approach consisted of using inorganic resists and low-acceleration electron-beam writing, thus allowing the control of the depth to tens of nanometers [61].

A combination method which was based on focused ion beam and isotropic wet etching has been demonstrated by Tormen *et al.* [62], and resulted in tightly controlled 3-D profiles in the range from 10 nm to 100 μm.

Within the microelectronics industry, one of the main expectations from NIL was its application as a lithography method in the dual damascene process for back-end CMOS fabrication [1], and this process is still undergoing testing today.

Bao *et al.* showed that it is possible to print over non-flat surfaces using polymers with different mechanical properties using thermal NIL and polymers with progressively lower T_g-values for each subsequent layer [63]. This meant that a different polymer must be used for each layer. In order to overcome this situation, several other variations and combinations of methods based on NIL have been developed. One such development is that of reversed contact ultraviolet nanoimprint lithography (RUVNIL) [64], which combines the advantages of both reverse nanoimprint lithography (RNIL) and contact ultraviolet (UV) lithography. In this process, a UV crosslinkable polymer and a thermoplastic polymer are spin-coated onto a patterned

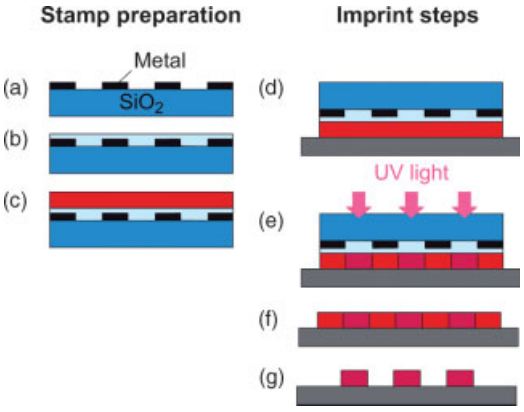

Figure 7.18 Schematics of the reverse contact UV NIL (RUVNIL) process. Left panel: Steps to prepare a stamp. (a) A hybrid mask of SiO_2 with metal feature; (b) a thermoplastic polymer, for example, mr-I 7030, is spin coated; (c) a UV crosslinkable polymer, for example, mr-I 6000 is spin-coated. Right panel: Steps to obtain nanostructures by this method. (d) Reverse imprinting on a Si substrate is carried out; (e) the silicon substrate is heated to heat the polymer above T_g, and pressure is applied; (f) the polymer is cooled down and exposed to UV light; (g) the stamp is separated from the substrate; (h) the exposed polymer layer is developed in acetone, resulting in a polymer pattern with no residual layer. The fabrication time per printed layer is just under 2 min [64].

hybrid metal–quartz stamp. The thin polymer films are then transferred from the stamp to the substrate by contact at a suitable temperature and pressure, after which the whole assembly is exposed to UV light. Following separation of the stamp and substrate, the unexposed polymer areas are rinsed away with a suitable developer, leaving behind the negative features of the original stamp. The process is shown schematically in Figure 7.18.

By using the same UV-curable polymer for each layer, 3-D nanostructures have been obtained (Figure 7.19). This technique offers a unique advantage over reverse-contact NIL and thermal NIL, as no residual layer is obtained by controlling the UV light exposure. This avoids the normal post-imprinting etching step, and therefore results in a much better control of the critical dimensions. Another interesting feature here is that it is not necessary to treat the stamp with an anti-adhesive coating.

Three-dimensional UV-NIL can be potentially used in the fabrication of modern integrated circuits, which employ several layers of copper interconnects, separated by an interlayer dielectric (ILD) and connected by copper vias (Figure 7.20). An imprintable and curable UV-ILD material is deposited on an existing interconnect layer (Figure 7.20a), this material having been structured by a 3-dimensional

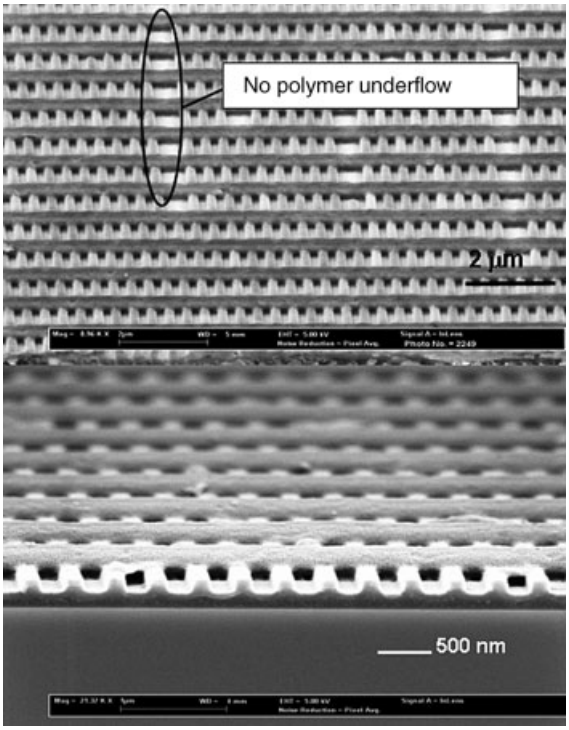

Figure 7.19 RUVNIL prints showing two layers printed without leaving a residual layer, and avoiding polymer overflow of the second layer [64].

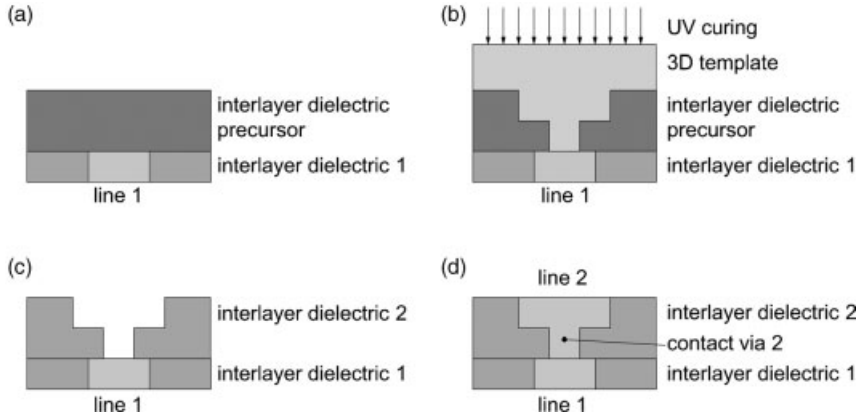

Figure 7.20 Schematics of direct-printing of interconnect layers using a three-dimensional stamp. (Illustration courtesy of L. Berger.)

stamp (Figure 7.20b). After UV-curing, the materials resembles a structured ILD (Figure 7.20c), which is then filled with copper to form two layers of vias and interconnects (Figure 7.20d).

7.2.7 The State of the Art

A comparison of the methods discussed to date, in addition to some relevant data, are displayed in Table 7.3. This information forms part of the studies of the European integrated project "Emerging Nanopatterning Methods (NaPa)" [65], which is exploring several non-optical lithographic methods with the purpose of gathering a library of processes that employ some of these newly emerging patterning technologies.

7.3 Discussion

Nanoimprint lithography, as an example of non-optical lithographies, has proven to be a versatile patterning method in several fields of application where a rather rapid development has been demonstrated, in addition to sole pattern transfer, notably in the areas of optics [66] (some of them at 200 mm wafer scale [67]) and microfluidics [68]. The versatility of NIL opens new possibilities for the nanostructure of various types of functional material, such as conducting polymers [69], light-emitting polymers [70], polymers loaded with nanocrystals [71], and biocompatible polymers [72]. An example of photonic applications is shown in Figure 7.21, which depicts a printed two-dimensional photonic crystal in polymer. The patterning of functionalized materials may be difficult when using traditional methods such as optical or electron beam

Table. 7.3 Comparison of the different printing techniques.

Technique	Smallest/largest features in same print	Min pitch (nm)	Largest wafer printed (mm)	Overlay Accuracy (nm)*	T align, T print, T release, T cycle	No. of times stamp used	Materials
NIL	5 nm[a]/N/A	14	200[b]	500	Minutes, 10 s, Min, 10–15 min	>50[c]	Various
SSIL[d]	8 nm min features. 50 nm/5 μm on same stamp	50	200	<250	Full cycle 2.5 min with, 20 s without full auto-collimation.	1000	mr-I 8000, mr-I 7000
SFIL[e]	25 nm[f]/μm	50[f]	300[g,h,m] stamp size: ~26×26 mm^2	50[i] (about 20[i])	20 wafers/h[j]	800[g]	Various NILTM105, AMONIL, PAK 01
UV-NIL[k]	9 nm/100 μm[l]	12[m]	200[n]	about 20[o]	20 s/step[p] three wafers/h[q]	>1000[r]	MRT07xp, PAK01, AMONIL1, AMONIL2, NXR, Laromer
Soft UV-NIL	25 nm/20 μm[s]	150[t]	200	1–50 μm[u]	4–5 min; about 12 wafers/hr[v]	>50[w]	AMONIL1, NXR-Mod, Laromer

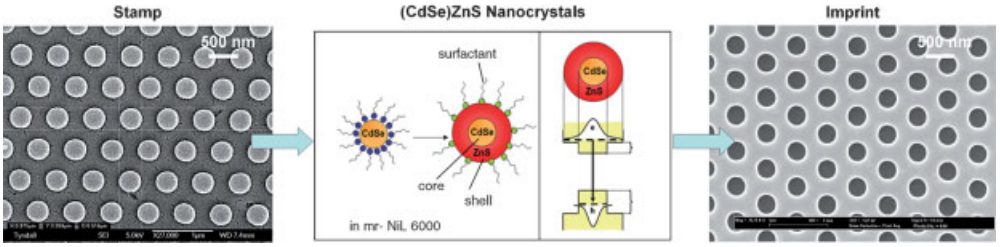

Figure 7.21 Two-dimensional photonic crystals printed in a polymer containing semiconductor quantum dots to control the spontaneous emission. This single-step imprint resulted in a 200% increase of the emission efficiency [71].

lithography, because it may not be possible to incorporate photosensitive components without degrading the functionality; alternatively, the materials may not tolerate the chemical processes associated with these pattern-transfer technologies. As described above, NIL requires only a fairly moderate temperature cycle in order to mediate the patterning process.

One exciting extension of NIL is the potential for patterning curved, 3-D surfaces, and this is yet to be exploited both in research and commercial applications. Somewhat surprisingly, it has been the lack of straightforward ways to provide curved surfaces that has hindered progress in this area. Nonetheless, NIL provides a simple means of realizing various types of curved 3-D surface which, of course, require the fabrication of a master stamp. This ability can be used, for example, in optics [72], cell cultivation [73], and plasmonics [74, 75]. The possibility of aligning to already existing patterns in SSIL and SFIL allows the use of mix-and-match approaches and the combination of more than one technique to build up multifunctional structures. The promise of low-cost and high-throughput uses of NIL in nanofabrication may be fulfilled by the roll-to-roll type of continuous approaches. During the late 1990s, the tools used for nanoimprinting were mainly commercial presses with heating units, but some time later tools based on modified optical mask aligners emerged, both for thermal and UV NIL. Today, several commercially available machines are dedicated to the nanoimprinting processes. The development of materials intended for NIL has also witnessed similar progress since the late 1990s, with not only methods but also instruments and software for non-destructive characterization and metrology having been introduced [46]. Clearly, whilst NIL is becoming a mature and capable technology for nanofabrication, its prospective roles are reaching even further, and have been included among the top ten technologies considered capable of "changing the world" [76]. This situation is reflected in the dissemination of information pertaining to NIL, with the numbers of published reports increasing at breath-taking pace, along with numerous conferences and discussion sessions of microfabrication and nanofabrication systems dedicated to nanoimprinting.

Despite these many advances, much remains to be understood and achieved. One such example is the need to pin down design rules based on an understanding of non-linear processes in viscous flow. If NIL is to improve its throughput, then by necessity faster processes will have to be partly non-linear and undergo concomitant modeling

challenges. Here, the impact will be upon stamp layout, and on the design rules. With regards to critical dimensions, those applications with a strict control of periodicity and smoothness of features will serve as the "acid test" for NIL. For example, if NIL is to be used as a mask-making method for the transfer of 2-D photonic crystal patterns into a high-refractive index material then, in addition to alignment, the "disorder" must be controlled to better than a few nanometers after pattern transfer – that is, after reactive ion etching. Although these critical dimensions are more relaxed in lower-refractive index photonic crystals, such as those printed directly in polymers [71], the verticality of the side walls is still of paramount importance. While the current resolution of NIL is already of a few nanometers, such demands will need to be even more stringent in order to fabricate hypersonic phononic crystals and nanoplasmonic structures, where the relevant wavelengths are of the order of only a few nanometers.

The versatility of the printable polymers, the resolution of NIL and the ability to realize 3-D structures open further possibilities. One such advance is the use of 3-D templates or scaffolds to provide not only the support but also input and output contacts for supramolecular structures. To be successful, this has two requirements: first, the feature sizes must be commensurate, and the structured polymer surface site-selectively functionalized. Whilst the complete proof of concept is still missing, some degree of progress has been made towards spatially selective functionalization by means of NIL, chemical functionalization and lift-off, and this has resulted in electrical contacts to 150 nm-wide arrays of polypyrrole nanowires [76]. The second requirement is in the use of 3-D nanostructures, beyond the face-centered cubic (fcc) and cubic symmetries, the properties of which can be modified by subsequent surface treatment, while preserving the symmetry. Modifications may include coating with oxides, and also removal of the polymer template, followed by subsequent infilling with another material. In this way, an artificial 3-D superlattice may be realized, thereby providing a periodic or quasi-periodic arrangement for electronic and or optical excitations.

7.4 Conclusions

In this chapter we have reviewed some of the key developments of NIL, as a non-optical lithography method, paying particular attention to the schematics of the process, and discussing: (i) materials issues and their impact on the process; (ii) the variations of NIL (among which roll-to-roll appears particularly promising for volume production); (iii) stamp design, both in terms of robustness and adhesion; (iv) the issue of residual layer thickness and its impact on critical dimensions; and (v) finally briefly reviewing the latest progress in 3-D NIL. In addition, we have discussed the importance of understanding polymer flow as an enabling knowledge to optimize stamp design, and thereby throughput. When discussing 3-D NIL, the scope for further progress was outlined as to date this is largely unexplored.

NIL has been said to have short-term prospects in back-end CMOS fabrication processes, but more so in the fabrication of photonic structures and circuits, with a

proviso in case of photonic crystals where stringent tolerances are still to be met. On the other hand, applications in less-demanding areas, such as gene chips for diagnostic screening, appear to have a very bright future.

Acknowledgments

he authors gratefully acknowledge the support of the EC-funded project NaPa (Contract no. NMP4-CT-2003-500120) and of Science Foundation Ireland (Grant No. 02/IN.1/172). They are also grateful to A. Kristensen, H. Schift, M. Tormen, T. Haatainen, P. Majander, T. Mäkelä, N. Kehagias, V. Reboud, M. Zelsmann, F. Reuther, D.-A. Mendels and many other colleagues of the NaPa project for fruitful discussions and joint investigations over the years. Note: The content of this work is the sole responsibility of the authors. Part of the sections on stamps (Photomasks) and on 3-D stamps for integrated electronic circuits were kindly provided by L. Berger.

8
Nanomanipulation with the Atomic Force Microscope

Ari Requicha

8.1
Introduction

The Scanning Probe Microscope (SPM) provides a direct window into the nanoscale world, and is one of the primary tools that are making possible the current development of nanoscience and nanoengineering. The first type of SPM was the Scanning Tunneling Microscope (STM), invented at the IBM Zürich laboratory by Binnig and Rohrer [1], who received the Nobel Prize for it only a few years later (1986). The STM provided for the first time the ability to image individual atoms and small molecules, and it is still widely used, especially to study the physics of metals and semiconductors. Much of the STM work is conducted in ultra high vacuum (UHV) and often at low temperatures. The STM main drawback is the need for conductive samples, which rules out many of its potential applications in biology and other important areas.

The next instrument to be developed in the SPM family was the Atomic Force Microscope (AFM), sometimes also called Scanning Force Microscope [2]. The AFM has become the most popular type of SPM because, unlike the STM, it can be used with non-conductive samples, and therefore has broad applicability. Today, there are many other types of SPMs. All of these instruments scan a surface with a sharp tip (with apex radius on the order of a few nm), placed very close to the surface (sometimes at distances $\sim$1 nm), and measure the interaction between tip and surface. For example, STMs measure the tunneling current between tip and sample, and AFMs measure interatomic forces – see Section 8.2 below for a lengthier discussion of SPM principles.

It was noticed from the beginnings of SPM work that scanning a sample with the tip often modified the sample. This was initially considered undesirable, but researchers soon recognized that the ability to modify a surface could be exploited for nanolithography and nanomanipulation. In SPM nanolithography one writes

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

lines and other structures directly on a surface by using the SPM tip. A well-known technique is called local oxidation, first demonstrated by passing an STM tip in air over a surface of hydrogen-passivated silicon [3]. Other materials can be used, as well as a conductive AFM tip in lieu of an STM [4]. Another STM method involves removing atoms from a silicon surface by applying voltage pulses to the tip [5]. Lines as narrow as a silicon dimer have been produced by this method. Lithography by material deposition, as opposed to material removal, has also been demonstrated in early work. For example, in [6] atomic-level structures of germanium were deposited on a Ge surface in UHV by pulsing the voltage on an STM tip, whereas in [7] gold clusters were deposited on a gold surface also by applying voltage pulses to the STM tip, but in air and at room temperature. Many other SPM nanolithography approaches have been demonstrated – see [8] for a survey of early work.

More recently, several other SPM nanolithographic techniques have been developed. Some examples follow. Dip Pen Nanolithography [9] involves depositing material on a surface much like one writes with a pen on paper. A pen (the AFM tip) is inked by dipping it into a reservoir containing the material to be deposited, and then it is moved to the desired locations on the sample. As the tip approaches the sample, a capillary meniscus is formed, which drives the material onto the sample. Other approaches are discussed for example in [10–15]. For a recent review see [16].

Nanomanipulation is defined in this chapter as the motion of nanoscale objects from one position to another on a sample under external control. Precise, high-resolution nanolithography shares with nanomanipulation the need for accurately positioning the tip on the sample. This is a challenging issue, which we will discuss later in this article.

Given the atomic resolution achieved by SPM imaging, one would expect also that atoms might be moved individually. This is indeed the case, and it was demonstrated in the early 1990s [17]. At the IBM Almadén laboratory, Eigler's group has been able to precisely position xenon atoms on a nickel surface, platinum atoms on platinum, carbon monoxide molecules on platinum [18], iron on copper [19], and so on, by using a sliding, or dragging process. The tip is brought sufficiently close to an adsorbed atom for the attractive forces to prevail over the resistance to lateral motion. The tip then moves over the surface, and the atom moves along with it. Tip withdrawal leaves the atom in its new position.

Eigler also has succeded in transferring to and from an STM tip xenon atoms on platinum and nickel, platinum on platinum, and benzene molecules. This was done by approaching the atoms or molecules with the tip until contact (or near contact) was established. In addition, xenon atoms on nickel were transferred to the tip by applying a voltage pulse to the tip. All of Eigler's work cited above has been done in ultra high vacuum (UHV) at 4 K.

Avouris group, at the IBM Yorktown laboratory, and Aono's group in Japan have transferred silicon atoms between an STM tip and a surface in UHV at room temperature, by aplying voltage bias pulses to the tip [20, 21].

Atomic manipulation with SPMs continues to be studied today and is providing new insights into nanoscience. For example, in the late 1990s, Rieder's group in Berlin conducted a series of experiments in which they showed that xenon atoms can be pushed and pulled across a copper surface, in UHV and at low temperature, and that the tunnel current during the motion has distinct signatures that correspond to the pushing and pulling modes [22]. As an example of very recent work, a NIST group has shown that a cobalt atom can be moved on a copper surface by exciting it electronically with and STM tip in UHV and at low temperature [23].

Molecules have been arranged into prescribed patterns at room temperature by Gimzewski's group at IBMs Zürich laboratory (now at UCLA). They push molecules at room temperature in UHV by using an STM. They have succeeded in pushing porphyrin molecules on copper [24], and they have arranged bucky balls (i.e., C_{60}) in a linear pattern, using an atomic step in the copper substrate as a guide [25]. They approach the molecules, change the voltage and current values of the STM so as to bring the tip closer to the sample than in imaging mode, and push with the feedback on. C_{60} molecules on silicon also have been pushed with an STM in UHV at room temperature by Maruno and co-workers in Japan [26], and Beton and co-workers in the UK [27]. In Maruno's approach the STM tip is brought closer to the surface than in normal imaging mode, and then scan across a rectangular region with the feedback (essentially) turned off. This may cause probe crashes. In Beton's approach the tip also is brought close to the surface, but the scan is done with the feedback on and a high value for the tunneling current; the success rate is low.

It should be clear from this brief review, which is not meant to be exhaustive, that much work has been done in nanomanipulation and related topics. In this article our focus is on manipulation by using AFMs, in air or a liquid, of objects such as nanoparticles or nanowires, which are larger than atoms or small molecules. The remainder of the chapter is organized as follows. First we address in some detail the principles of operation of the AFM, and the spatial uncertainties associated with the instrument. Next we present various protocols for moving nanoobjects with the AFM tip and discuss research aimed at building nanoassemblies. Section 8.4 addresses systems for nanomanipulation, both interactive and automated. We draw conclusions in a final section.

Before we embark on the main discussion of this chapter, we point out that SPM manipulation is not the only way of positioning nanoobjects on a surface. A variety of other approaches has been reported in the literature, using principles from optics, magnetics, electrophoresis and dielectrophoresis, which are beyond the scope of this chapter. The pros and cons of these other approaches are not fully understood. For example, optical, laser traps are normally used to move micrometer-sized particles, but they can also manipulate smaller objects. They can achieve 3-D (three-dimensional) positioning, unlike AFMs, but cannot resolve objects which are at a distance significantly below the wavelength radiation used, which is typically in the hundreds of nanometers.

8.2
Principles of Operation of the AFM

8.2.1
The Instrument and its Modes of Operation

The AFM links the macroworld inhabited by users, computers and displays to the nanoworld of the sample by using a microscopic *cantilever* that reacts to the interatomic forces between its sharp *tip* and the sample. Cantilevers are typically built from silicon or silicon nitride by using MEMS (microelectromechanical systems) mass fabrication techniques. They have typical dimensions on the order of $100 \times 20 \times 5$ μm. Tips are built at one of the ends of the cantilevers and are usually pyramidal or conical with apex diameters on the order of 10–50 nm. The tip apex has dimensions comparable to those of the sample's features and can interact with them effectively.

Figure 8.1 shows diagramatically the interaction between atoms in the tip and in the sample. The main forces involved are the long-range electrostatic force (if the tip or sample are charged), the relatively short-range van der Waals force, the capillary force (when working in ambient air, which always contains some humidity), and the repulsive force that arises when contact is established [28]. The cantilever bends under the action of these forces, and its deflection is usually measured by an optical system, as shown in Figure 8.2. Laser light bounces off the back of the cantilever, opposite to the tip, and is collected in the two halves of a photodetector. In the AFM jargon, the electrical signals output from the two photodetector halves are called A and B, and the diferential signal is called A–B. For zero deflection and a calibrated instrument, the differential signal from the detector is also zero, and in general A–B is approximately proportional to the cantilever deflection. The force between tip and sample is simply the product of the measured deflection and the cantilever's spring constant k, which can be determined in several ways [29].

Relative motion between the tip and the sample is accomplished by means of a *scanner,* which consists of piezoelectric actuators capable of imparting x, y, z displacements to the tip or, more commonly, to the sample. (We assume that the sample is on the x, y horizontal plane, and the tip is approximately aligned with the z axis.) Piezo drives react quickly and are very precise, but require high voltages on the order of 100–200 V, and have a small range of motion. They also are highly nonlinear, as we will discuss later.

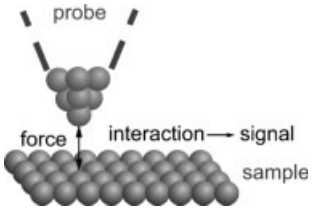

Figure 8.1 Tip sample atomic interactions.

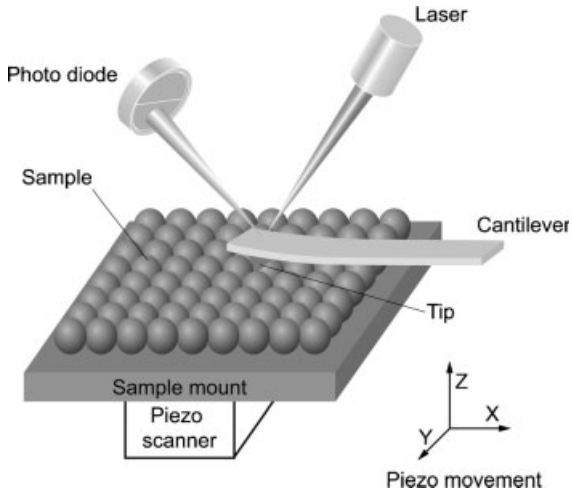

Figure 8.2 Optical detection of cantilever deflection.

In *contact mode* operation, the tip first moves in z until it contacts the sample and a desired value of the tip-sample force, called the *force setpoint*, is achieved. Then it scans the sample by moving in x, y in a raster fashion, while moving also in z under feedback control to maintain a constant force. The feedback circuitry is driven by the deviation (or error) between the (scaled) photodetector signal A–B and the force setpoint. Suppose that the tip moves in straight line along the x direction, at a constant y. When it encounters a change of height Δz of the sample, the scanner must move the sample by the same Δz in the z direction to maintain the contact force (i.e., cantilever deflection). Therefore, the amount of motion of the scanner in z at point x gives us exactly the height of the surface $z(x)$, usually called the *topography* of the surface. Now we move the tip back to the beginning of the line, increment y by Δy and scan again in the x direction. If we do this for a large number of y values we obtain a series of *line scans* that closely approximate the surface of the sample $z(x, y)$. In this example, x is called the *fast scan* direction, and y the *slow scan* direction. In practice, line scan signals are sampled (perhaps after some time-averaging) and discretized, and the output signal becomes a series of values $z(x_i, y_j)$, often called *pixel* values, since the output is a digital image. These images are normally displayed by encoding the height values z as intensities. Of course, other display options are also available, such as perspective images that provide a better feel for the three-dimensional structure of the sample, and so on. A typical AFM image contains 256×256 pixels. For this resolution and a square scan of size 1×1 μm, pixels are $\sim 4 \times 4$ nm, which is a rather large size. Therefore, very small scan sizes are necessary for precise operations.

In contact mode, essentially, the tip is pushed against the sample and dragged across it. This may damage the sample and the tip, and may dislodge nanoobjects from the surface on which they are deposited, thereby making it impossible to image them. An alternative mode of AFM operation that avoids the drawbacks of contact

mode and is kinder to the tip and sample is the *dynamic* mode, also known by other designations such as non-contact, tapping, intermitent-contact, AC, and oscillatory. Here the cantilever is vibrated at a frequency near its resonant frequency, which is typically on the order of 100–300KHz in air and 1–30KHz in water. The vibration is usually generated by a dedicated piezo drive installed at the base of the cantilever. The piezo moves the cantilever endpoint opposite to the tip up and down at a frequency near resonance, and the vibration is mechanically amplified by the cantilever, resulting in a much larger amplitude of oscillation at the tip. Alternatively, the cantilever can be coated with a magnetic material and oscillated by means of an external electromagnet. This is usually called *MAC* mode (for magnetic AC), and does not require operation near the resonance frequency since it does not rely on mechanical amplification.

The amplitude of the vibration at the output of the photodetector is computed, typically by a lock-in amplifier or an analog or digital demodulation technique, and compared with an amplitude setpoint A_{set}. Feedback circuitry drive the z piezo and adjust the vertical displacement to keep the amplitude constant – see Figure 8.3.

The principles of dynamic mode operation may be explained by approximating the vibrating tip with a harmonic oscillator in a nonlinear force field, as follows. Suppose initially that the tip is at some distance z_0 to the sample, with a force $F(z_0)$ between tip and sample. Then, the following equation of motion must be satisfied:

$$m\ddot{z}_0 + c\dot{z}_0 + kz_0 = F(z_0),$$

where m is the effective mass, c is the damping coefficient, k is the spring constant, and the dots denote derivatives with respect to time. Now, consider deviations from this point that are small compared to the tip-sample distance. Denote by z the

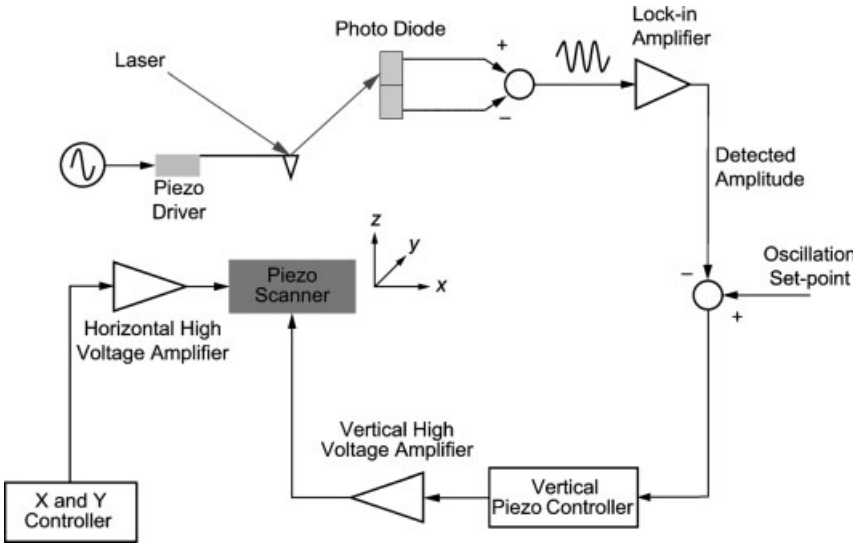

Figure 8.3 Schematic of AFM dynamic mode system.

deviation from the value z_0. The equation of motion may now be written as

$$m(\ddot{z}_0 + \ddot{z}) + c(\dot{z}_0 + \dot{z}) + k(z_0 + z) = F(z_0 + z).$$

Subtracting the two previous equations, expanding F in Taylor series and keeping only the first term yields

$$m\ddot{z} + c\dot{z} + kz = zF'(z_0),$$

where F' denotes the derivative of F with respect to z. This equation may be written as

$$m\ddot{z} + c\dot{z} + k'z = 0,$$

where

$$k' = k - F'(z_0).$$

This means that small deviations of the cantilever satisfy the equations of motion of a simple harmonic oscillator with a spring constant k', which depends on the actual spring constant of the cantilever and the gradient of the tip-sample force at the equilibrium point. Therefore, the resonance frequency changes from its initial value to

$$\varpi'_0 = \sqrt{k'/m}.$$

When the cantilever is at a large distance from the sample, the interaction forces between the two are negligible, the cantilever has a resonance frequency f_{res} corresponding to its spring constant k, and has a resonance curve (amplitude *vs.* frequency) as shown by the red curve in Figure 8.4.

Suppose now that we drive the cantilever at a frequency f_{drive}, which generally is near f_{res}. If the tip is sufficiently far from the sample for the interation force to be negligible, $F = 0$, the cantilever oscillates with the frequency f_{drive} and an amplitude A_{free} that we can read directly from the resonance curve. This is called the *free amplitude*. Now we specify an amplitude setpoint, smaller than A_{free}. For the cantilever to oscillate at this amplitude, the resonance curve must shift as shown by the blue curve in the figure. Therefore, the feedback system must move the

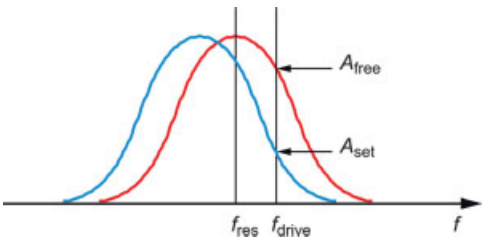

Figure 8.4 Amplitude *vs.* frequency curves when the cantilever is at a large distance from the sample (thick) and when the distance is smaller so that there is significant interaction and a concomitant shift of resonance frequency (thin).

cantilever closer to the sample until the force gradient is such that the spring constant and corresponding resonant frequency shift appropriately. We see that the DC, or average, position of the cantilever is controlled in a rather indirect manner, via the f_{drive}, A_{free}, and A_{set} parameters. (The free amplitude essentially scales the resonance curve.) A_{set} is usually specified as a percentage of A_{free}. Typical values of A_{set} are on the order of 80%. Lower setpoints imply large damping, which means that a considerable amount of the cantilever's oscillation energy is being transferred to the sample. In essence, we are tapping hard on the sample, and this is usually undesirable.

The theory just presented is simple and provides an intuitive understanding of the dynamic mode operation. Unfortunately, it is predicated on a linearization about an operating point, and is valid only for small oscillation amplitudes. Usually, however, the AFM is operated with a setpoint that implies a relatively large amplitude and causes the tip to hit ("tap" on) the surface of the sample at the lower part of each oscillation cycle. The actual behavior of the cantilever when tapping is involved is rather complicated – see for example [30, 31]. But in normal imaging conditions the oscillation amplitude varies approximately linearly with the DC tip position, as shown in Figure 8.5. Note that such A-d (amplitude-distance) curves vary from cantilever to cantilever and depend on several parameters.

The feedback circuitry in dynamic mode maintain a constant amplitude, and therefore a constant distance to the sample. (Here we are assuming that the sample is of a homogeneous material, or at least that the tip-sample forces do not vary over the sample's extent.) Scanning the tip over the sample in dynamic mode produces a topographic image of the sample. There are other modes of AFM operation, but the two discussed above are the most common and important.

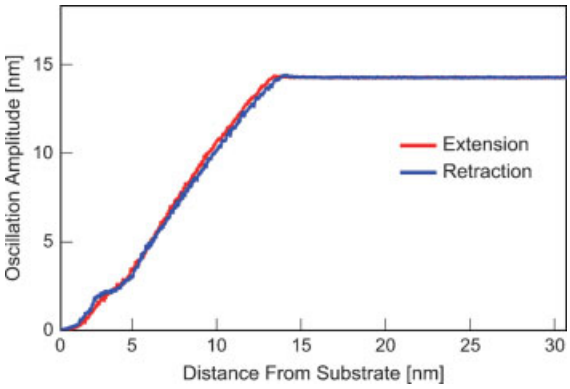

Figure 8.5 Experimental amplitude-distance curve obtained with the MFP-3D AFM (Asylum Research). Cantilever resonance frequency 240.654KHz, drive frequency 240.556KHz, spring constant ~25 N/m, free amplitude 14.2 nm. The zero point for the distance from the surface was inferred by extrapolating the A-d curve to the zero amplitude point.

More information on AFM theory and practice are available for example in [32–34].

8.2.2 Spatial Uncertainties

Let us now turn our attention to the sources of positional errors in AFM operation. These give rise to spatial uncertainty and are important for accurate imaging and especially for nanomanipulation. User intervention is normally used to compensate for spatial uncertainties in nanomanipulation, but extensive user interaction is slow and labor intensive, and therefore is severely limited in the complexity of structures it can construct. Automatic operation is highly desirable but cannot be accomplished without compensating for spatial uncertainties, as we will show below. Compensation techniques are described later in this chapter, in Section 8.4.2.

We noted earlier that the output of a line scan along the x direction is the topography $z(x)$. In the actual implementation this is not quite true. If no error compensation is used, the output is $V_z(V_x)$, where V_z and V_x are the voltages applied to the z and x piezos. In an ideal situation these voltages would be linearly related to the piezo extensions, and the signals $V_z(V_x)$ and $z(x)$ would coincide modulo scale factors. But in practice they don't.

There are many nonlinearities involved. Some of these are normally taken into account by AFM vendors' hardware and software, for example, non-linearities in the voltage-extension relationship for the piezos, coupling between the different axes of motion, and so on. The most pernicious are drift, creep and hysteresis. As far as we know, at the time of this writing (2006), drift is not adequately compensated for in any commercial instrument, and creep and hysteresis are negligible only in top of the line AFMs that have feedback control for the x, y directions, and whose controller noise r.m.s. is under 1 nm. The vast majority of AFMs in use today either have no x, y feedback or have noise levels on their feedback circuitry that are too large for precise lithography and manipulation. Open-loop operation with a small scan size (e.g., 1×1 μm) is preferable for nanomanipulation operations with such instruments.

Drift is caused by changes of temperature in an instrument made from several materials with different coefficients of expansion. At the very low temperatures often used for atomic manipulation the effects are negligible, but at room temperature they can be quite large. Figure 8.6 shows four AFM images of gold nanoparticles with 15 nm diameters, taken at successive times, 8 min apart. The particles appear to be moving, but in reality they are fixed on the substrate surface. The piezos are driven by the same voltage signals in all the panels of the figure, and have the same extensions, but the position of the tip relative to the sample is the sum of the piezo extension and the drift, and therefore changes with time. Experimental observations in our lab indicate that drift is a translation with speeds on the order of 0.01–0.1 nm/s. The drift velocity remains approximately constant for several minutes, and then appears to change randomly to another value.

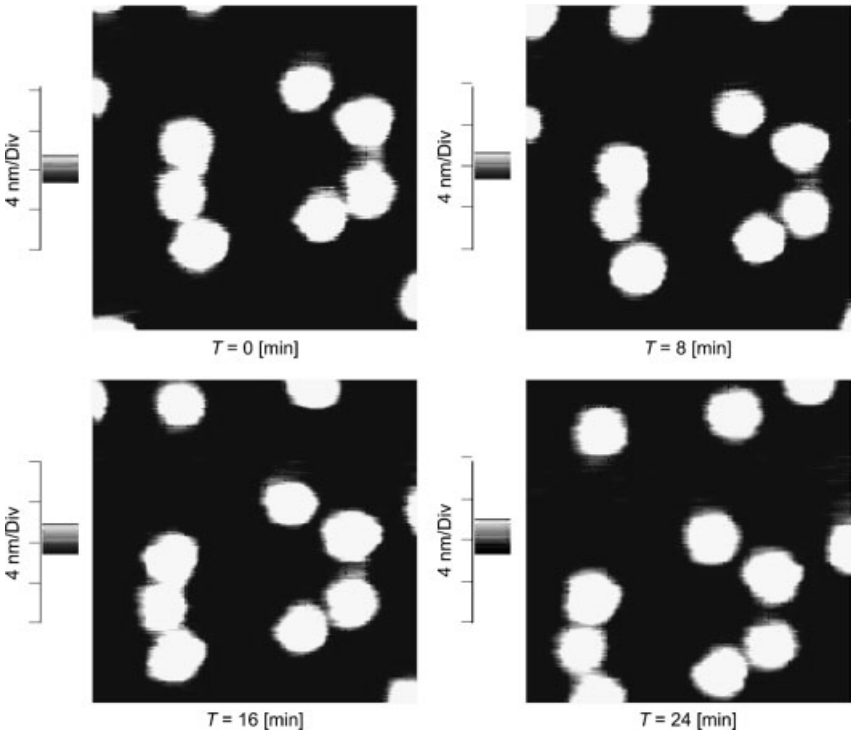

Figure 8.6 Successive images taken at 8 min intervals showing the effects of thermal drift. Gold nanoparticles with nominal diameter 15 nm on mica coated with poly-L-lysine, 1Hz scan rate, Autoprobe CP-R AFM (Veeco). Reproduced with kind permission from [71].

Suppose now that we were trying to manipulate a large set of nanoparticles similar to those in Figure 8.6, and that the manipulation operations would take a total time of 1 hour. Assuming an average drift velocity of 0.05 nm/s, the total drift after 1 hour would be 180 nm. If we relied on the original images and did not compensate for drift, it is clear that as time went by we would completely miss most of the 15 nm particles.

After drift, creep is another major source of spatial uncertainty in AFMs. A piezo actuator commanded to move by a certain distance first responds very quickly and moves by ~70–90% of the commanded distance, and then slowly "creeps" to the final position – see Figure 8.7. Creep is especially noticeable for large motions. Successive images of the (nominally) same area taken after a large tip displacement show an apparent motion of the features in the area. The effects of creep can last several minutes and are sufficiently large to foil manipulation attempts, especially for small particles with dimensions on the order of 10 nm. Creep can be avoided by waiting for several minutes after any large tip motion, but this is obviously a very inefficient approach.

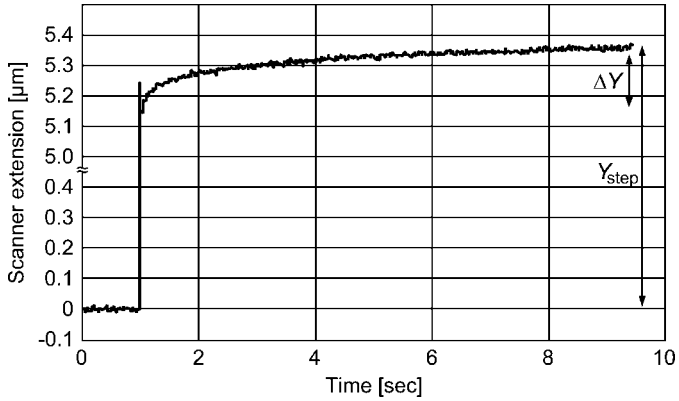

Figure 8.7 Experimental curve showing a scanner response to a 5.4 µm step function. Reproduced with kind permission from [95].

Hysteresis is also present in piezo actuators and has non-negligible effects – see Figure 8.8. Hysteresis is a nonlinear process with memory. The extension of a piezo depends not only on the currently applied voltage, but also on past extremal values.

Finally, the images of the features that appear in a topography scan differ from the actual physical features in the sample because of tip effects. The tip functions as a low-pass filter, and broadens the images. To a first approximation, the image's lateral dimensions of a feature equal the true dimensions plus the tip diameter. Algorithms are known for combating this effect [35]. Note that the vertical dimensions of a feature's image are not affected by the tip's dimensions.

Compensation of spatial uncertainties due to drift, creep and hysteresis in AFMs will be discussed later, in Section 8.4.2, in the context of automated nano-manipulation.

8.3
Nanomanipulation: Principles and Approaches

8.3.1
LMR Nanomanipulation by Pushing

Here we discuss the approach to nanomanipulation that has been under development at USCs Laboratory for Molecular Robotics (LMR) over the last decade. It was first presented at the fourth International Conference on Nanometer-Scale Science and Technology, Beijing, P.R. China, September 8–12, 1996, and later reported in a string of papers [36–41]. Other approaches are considered in the next subsection.

We begin by preparing a sample with nanoparticles or other structures to be manipulated. A typical sample consists of a mica surface coated with poly-L-lysine, on which we deposit Au nanoparticles. The coating is needed because freshly cleaved mica is negatively charged, and so are the nanoparticles; the poly-L-lysine attaches to the mica and offers a positively-charged surface to the nanoparticles. We have also used other surfaces such as (oxidized) silicon, glass and ITO (indium tin oxide), other coatings such as silane layers [42], other particles such as latex, silver or CdSe, and rods or wires of various kinds. We typically manipulate particles with diameters between 5 and 30 nm, but have occasionally moved particles as small as 2 nm and as large as 100 nm. In all cases the structures to be moved are weakly attached to the underlying surfaces and cannot be imaged by contact mode AFM. We image them in dynamic mode, apply a flattening procedure to remove any potential surface tilt, and then proceed with the manipulation. The bulk of our experiments have been conducted in ambient air at room temperature and without humidity control, but we also have demonstrated manipulation in a liquid environment [43]. We use stiff cantilevers, with spring constants >10 N/m.

The nanomanipulation process is very simple. We move in a straight line with an oscillating tip towards the center of a particle and, before reaching the particle, turn off the z feedback. We turn the feedback on when we reach the desired end of the particle trajectory. With the feedback off, the tip does not move up to keep constant distance to the sample when it encounters a nanoparticle. Rather, it hits the particle and pushes it. We use the same dynamic AFM parameters for pushing as for imaging, but sometimes we force the tip to approach the surface by applying directly a command to move by Δz immediately after turning off the feedback.

Figure 8.9 shows experimental data acquired during a pushing operation for a 15 nm Au particle on mica. The two vertical dashed lines indicate the points where the feedback is turned off and on. The top trace (A) is simply the topography signal acquired by a single line scan in dynamic mode. The next trace (B) is the topography signal during the push. The topography signal is flat while the feedback is off because the tip does not move up and down to follow the sample topography. Observe that as soon as the feedback is turned back on we immediately get a non-null topography signal that indicates that the tip was somewhat below the top of the particle at the end

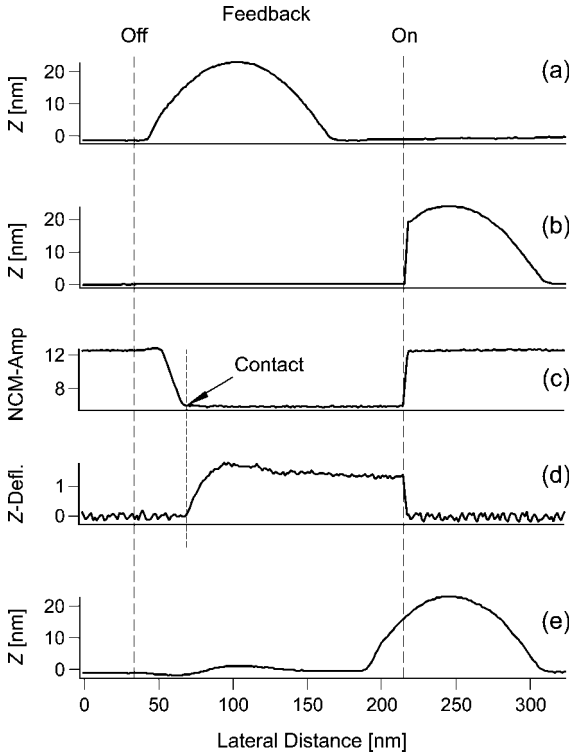

Figure 8.9 Data acquired during a manipulation operation. (a) Dynamic-mode single line scan image of the particle before manipulation. (b) Topography signal during the push. (c) Vibration amplitude during the push. (d) Average position of the antilever during the push. (e) Image of the particle after the manipulation. AutoProbe AFM, 15 nm Au particles on mica with poly-L-lysine, cantilevers with (nominal) spring constant 13 N/m. Reproduced with kind permission from [37].

of the manipulation. We conclude from these data that the tip is pushing the particle forward rather than dragging it behind itself.

Trace C shows the amplitude of the vibration during the manipulation. The amplitude is constant at the setpoint value when the feedback is on, but it decreases as the tip approaches the particle with the feedback off, and eventually reaches zero and stays at zero for the reminder of the push. At the same time that the amplitude decreases, the average (DC) value of the cantilever deflection increases and then reaches an approximately constant level – trace D in the figure. Finally, trace E is a single line scan after the push.

We interpret the data in Figure 8.9 as follows. When the tip approaches the particle with the feedback off, it starts to exchange energy with the particle and the vibration amplitude decreases, much like in standard A-d curves (see Section 8.2.1). When the vibration goes to zero, the tip touches the particle, and remains in contact with it until the feedback is turned on. While the tip contacts the particle the cantilever starts to

"climb" the particle, and the DC deflection increases. When enough force is exerted on the particle for it to overcome the surface adhesion forces, the particle moves, and the deflection (and hence the force) remains approximately constant. Our experiments reveal that there is a deflection (or force) threshold above which the particle moves.

For successful pushing, the trajectory has to pass close to the center of the particle. Here the spatial uncertainties discussed in Section 8.2.2 are a major source of problems. We address these problems in the interactive version of our Probe Control Software (PCS) as follows. The user draws a line over the image and instructs the AFM to scan along that line and output the corresponding topography signal. The user moves the line over (or perhaps near) the particle to be pushed until he or she detects the maximum height of the particle – see Figure 8.10. This indicates that the line is going through the center of the particle. Usually this is several nm away from the apparent center because of drift and other spatial uncertainties. After the center is found, the user sets two points along the trajectory for turning the feedback off and on, and instructs the AFM to proceed with the push. The result can be assessed immediately by looking at the single line scan after the push – see trace E in Figure 8.9.

The amplitude and deflection signals – see traces C and D in Figure 8.9 – are useful to assess whether a pushing operation is proceeding normally. For example, we have observed experimentally that when we "loose" a particle (i.e., when it does not move as far as specified) the deflection drops to zero prematurely. In principle, one could monitor the amplitude and deflection signals while pushing and, for example, stop and locate the particle when the signals are not as expected. In practice, however, this may require substantial modifications to the controller, if decisions are to be made automatically based on this information while the manipulation operation is taking place.

How reliably can particles be moved by the LMR aproach? Figure 8.11 attempts to answer this question. Observe that operations in which the commanded motion is below 50 nm are very successful, whereas for distances ~80 nm the actual and

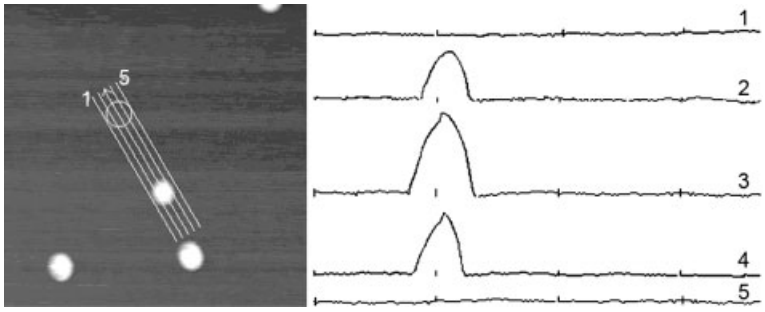

Figure 8.10 Interactive search for the center of a particle with single line scans. Line 3 has the largest peak and is chosen as trajectory for the pushing operation. Reproduced with kind permission from [36].

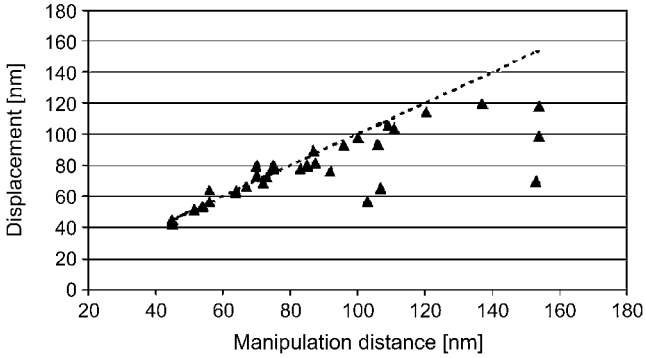

Figure 8.11 Reliability plot, showing the actual distance a particle moved as a function of the commanded manipulation distance. AutoProbe CP-R, 15 nm Au particles on mica, interactive pushing. The dashed line corresponds to perfect pushing, with equal actual and commanded displacements. Reproduced with kind permission from [90].

desired displacements of the particles begin to differ considerably. The reasons why pushing over large distances is unsuccessful are not fully understood.

8.3.2 Other Approaches

At the LMR we have experimented with several other approaches to pushing nanoparticles. We had occasional success with all of these approaches, but did not achieve reproducible, controlled manipulation. The reliability of these protocols has been until now much lower than that of the standard method discussed in the previous subsection. Here is a short description of these various protocols. They all begin with imaging in dynamic mode and finding a particle's center interactively, as discussed earlier.

- As the tip approaches the particle, instead of turning the feedback off and on, change the amplitude setpoint so that the tip gets closer to the surface.
- Move towards the particle while tapping hard on the substrate and then turn the feedback off an on. This appears to induce a "lateral push", in which the cantilever deflection does not increase as in the standard pushing protocol of the previous subsection.
- Approach the particle while moving in a zig–zag pattern, in a direction normal to the desired trajectory and with the feedback off. This appears to simulate pushing with a linear edge rather than a round tip, and has been reported in [44, 45].

The first published reports that demonstrated manipulation of nanoparticles with the AFM came from Purdue University in the US [46] and the University of Lund in

Sweden [47]. The Purdue group pushed 10–20 nm gold clusters on graphite or WSe_2 substrates with an AFM, in a nitrogen environment at room temperature [46]. They image with non-contact AFM, but then stop the cantilever oscillation, approach the substrate until contact, disable the feedback, and push. Samuelson's group at the University of Lund succeeded in pushing galium arsenide (GaAs) nanoparticles of sizes in the order of 30 nm on a GaAs substrate at room temperature in air [47]. They use an AFM in non-contact mode, approach the particles, disable the z feedback and push. This is the protocol investigated in detail later on by the LMR, and discussed in the previous subsection. Essentially the same protocol is used in [48] to push Ag nanoparticles. They observe that the vibration amplitude decreases as the particle is approached, and then essentially vanishes during pushing, which agrees with the findings in our own laboratory.

Lieber's group at Harvard has moved nanocrystals of molybdenium oxide (MoO_3) on a molybdenium disulfite (MoS_2) surface in a nitrogen environment by using a series of contact AFM scans with large force setpoints [49]. The nanoManipulator group at the University of North Carolina at Chapel Hill moves particles by increasing the contact force, under user control through a haptic device [50]. Sitti's group reports manipulation of Au-coated latex particles with nominal diameters 242 and 484 nm on a Si substrate with accuracies on the order of 20–30 nm [51]. First, they move the tip until it contacts the surface, and then move it horizontally to a point near the particle, and up by a predetermined amount. Next, they move against the particle using feedback to maintain either constant height or constant force on the particle. In constant-height pushing, the force signal exhibits several characteristic signatures that may be interpreted as signifying that the particle is sliding, rolling or rotating. Constant-force pushing is equivalent to contact-mode manipulation. Xi's group at Michigan State University has demonstrated pushing of latex nanoparticles with 110 nm diameters on a polycarbonate surface by two methods [52]. The first consists of scanning in contact mode with a high force. The second disables the feedback and moves the tip open loop along a computed trajectory based on a model of the surface acquired by a previous scan. This requires an accurate model of the surface.

Theil Hansen and coworkers moved Fe particles on a GaAs substrate by approaching a particle in dynamic mode, switching to contact mode and pushing with the feedback on [53]. This has the advantage that the pushing force can be controlled by the AFM. However, switching modes is a non-trivial operation that can cause damaging transients. (In the AutoProbe CP-R AFM that we use routinely for nanomanipulation at LMR, such a switch is not allowed by the vendor's software.) Furthermore, switching from tapping to contact mode implies that the tip in contact mode does not touch the same point of the surface it was tapping on, because the cantilever normally is not horizontal – see Figure 8.12.

The LMR and related protocols are essentially "open-loop", because it is virtually impossible to incorporate the force sensed by the cantilever into a feedback loop during actuation for commercial AFMs. For example, in the AutoProbe CP-R we are completely "blind" during a pushing operation. We can

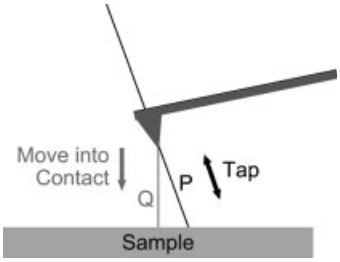

Figure 8.12 A cantilever is initially tapping on a sample at point P. When the AFM is switched into contact mode and the vibration stops, the tip must approach the sample to maintain contact. However, the contact will be at point Q, not P.

record the force (deflection) signal while pushing, but cannot do anything with it until the motion stops. To do otherwise would require a major change to the controller. On the other hand, it is not difficult to make the force signal available for visualization in interactive pushing, and several research groups have reported such capabilities. By developing their own controllers, Sitti and co-workers have been able to use the force signal during pushing, primarily to determine when an operation should be stopped because it is not going to succeed. When the tip-particle force drops to zero the particle is no longer being pushed. One should stop the motion, locate the particle and schedule a new operation to deliver it to its target position.

The AFM is both an imaging device and a manipulator but not both simultaneously. For example, it would be useful to see a particle while it is being pushed, but this cannot be done solely with an AFM. An interesting approach that provides real-time visualization consists of operating the AFM within the chamber of a Scanning Electron Microscope (SEM), or sometimes a Transmission Electron Microscope (TEM). The motion of the tip can then be monitored by the electron microscope and known techniques for visual feedback developed at larger spatial scales can be deployed [54].

The AFM-SEM approach was pioneered by Sato's group for microscopic objects [55, 56], and has been used successfully by several groups [50, 57–59]. In some of this work an AFM cantilever is used as an end effector for a specially-built micromanipulator. Working inside an SEM has its drawbacks: electron microscopes are expensive instruments, they are less precise than AFMs, require more elaborate sample preparation, and normally operate in a vacuum environment, which precludes their use for certain applications, for example, in biology.

All of the work on AFM nanomanipulation discussed above involves essentially pushing objects on a flat surface. Pushing nanoparticles over steps [37] and onto other particles [60] has been demonstrated by our group, but this is a very rudimentary 3-D capability. More sophisticated 3-D tasks would be feasible if there was the equivalent of a macroscopic "pick-and-place" operation for nanoparticles. (Pick-and-place is possible with atoms and small molecules, as noted in the

Introduction.) We know of only one report in which nanoparticles are controllably picked up by the AFM tip and then deposited elsewhere [61]. They succeed in picking up Si nanocrystals deposited by silane CVD (chemical vapor deposition) on a Si surface. They place the tip in contact with the particle and apply successive voltage pulses of opposite polarity to the AFM tip. The tip is then moved to a target location, lowered until there is contact with the surface, and again a series of pulses is applied. This work requires a dry atmosphere and the experiments were performed in a nitrogen environment. The process appears to have limited reproducibility. Diaz and co-workers report a pick-and-place process that uses redox reactions on the tip to pick up and deposit particles, but they only demonstrate it for large, micrometer scale particles [10]. Note that it is not difficult to pick up a nanoobject with a tip, even by just using van der Waals forces. What is very hard to do is to controllably release the object at a target location.

8.3.3
Manipulation and Assembly of Nanostructures

The majority of the experimental work on nanomanipulation has been conducted with nanoparticles. These are simple but interesting nanobjects because many types of them are available (metalic, semiconducting, magnetic, etc.), they often are monodisperse (i.e., have the same size), they can be smaller and more uniform than structures made by other means such as electron-beam lithography, and can be arranged into arbitrary patterns by nanomanipulation. Patterns of nanoparticles may be useful in themselves, or they may serve as templates for constructing other structures [62]. We present examples of both below.

Figure 8.13 illustrates the use of particle patterns to store digital information. The particles are located at the nodes of a uniform grid. We interpret the presence of a particle at a node as a digital "1" and its absence as a "0". Each row of particles represents an ASCII character. From top to bottom, this structure encodes the characters "LMR". These are 15 nm Au nanoparticles, and the internode distance along a row or column is $\sim$100 nm, which corresponds to a density of 10 Gbit/cm^2. This is considerably higher than the current compact disk (CD) density. By using smaller particles and closer spacing, higher densities are achievable. In addition, this structure is editable, simply by moving the particles.

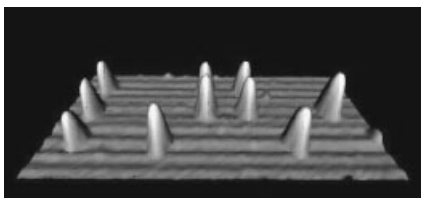

Figure 8.13 The ASCII characters "LMR" encoded in the positions of 15 nm Au nanoparticles on mica.

Nanoparticle patterns can also be used as a resist, as shown by research at the University of Konstanz, Germany [63]. They started with a self-assembled regular pattern and deposited material so as to fill the space between the particles. By etching the particles away, they obtained the complement of the original pattern. In a similar vein, a Japanese/English group used regular nanoparticle patterns as templates in a process that involves both etching and growth [64]. They deposited nanoparticles on a Si substrate and then etched the Si. As the substrate was etched away, reaction products condensated around the nanoparticles and formed regular patterns of pillars with diameters on the order of a few nm. Similar results were obtained in [65]. Another use of Au nanoparticles as a mask is reported in [66], where they demonstrate that the particles can serve as an anti-oxidation mask to prevent the AFM-tip induced oxidation of a modified Si surface. Subsequent etching produces Si nanopillars. In all of these cases, it should be possible to perform similar operations for arbitrary patterns constructed by nanomanipulation. Nanoparticle manipulation may also be an effective way to build templates or molds, for example for imprinting techniques that construct a large number of structures in a parallel fashion by pressing a template against a substrate [67]. Nanoparticle-based templates can be more uniform and have smaller features than those built by other means such as electron-beam lithography. Applications to template or mold making, however, have not yet been demonstrated.

Nanoparticle manipulation with the AFM has been used to build prototype structures for several nanodevices such as single-electron transistors [44, 68], plasmonic waveguides [69, 70], and quantum-dot cellular automata gates [71].

Most nanoparticles are approximately spherical, although some of the nanoparticles used in the research cited above (e.g., [47]) are more like "islands", and have vertical dimensions smaller than their horizontal counterparts. Structures with other shapes have also been nanomanipulated. Rods, wires and tubes have been investigated extensively. They normally require a series of pushes to reach a target position because they tend to rotate. And sometimes they deform or even break, rather than simply move on the surface. At the LMR we have manipulated Au rods with diameters ~ 10 nm and lengths ~ 70 nm deposited on a SiO_2/Si (1 1 1) substrate modified with MPMDMS (3-mercaptopropylmethyldimethoxysilane) [72]. Xi's group has demonstrated manipulation of Ag rods with diameters ~ 110 nm on a polycarbonate surface [73].

Several groups have manipulated carbon nanotubes (CNTs). Avouris and co-workers at the IBM Yorktown laboratories moved multiwall CNTs on a hydrogen-passivated Si surface by using contact mode AFM [74]. They also showed that the nanotubes can be bent and cut by the AFM tip. The nanoManipulator group in North Carolina reported rolling and sliding of CNTs on a graphite surface [75]. Other work in CNT manipulation include [57, 58, 76, 77], Roschier an co-workers [78] who built a single-electron transistor by manipulating a multiwall CNT so as to connect it to electrodes made by electron-beam lithography. Several of these groups also used the AFM tip to probe the mechanical properties of the CNTs – see for example [50, 57]. Nanowires can also be

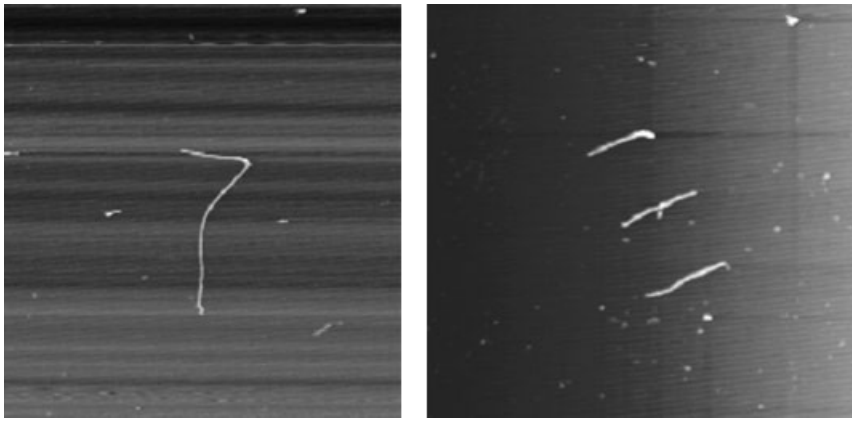

Figure 8.14 Cutting a SnO_2 nanowire and making an array with the resulting three pieces by using the AFM tip.

manipulated by the AFM. Figure 8.14 shows on the left a SnO_2 wire with a diameter of ~10 nm and a length of ~9 μm, and on the right the result of cutting the wire in two spots and then moving the three smaller wires. The manipulation was done at the LMR by using our standard protocols.

For many applications, particles and other nanoscale objects must be linked together to form a single, larger object. Linking may be accomplished by various methods: chemically, by using material deposition, sintering, and "welding". We showed that Au nanoparticles can be connected chemically by using linkers with thiol functional ends [79]. This can be done in two ways: (1) the particles are first functionalized with the di-thiols, then deposited and manipulated against one another to form the target structure, or (2) the manipulation is done first and then the thiol treatment is applied. In either case the result appears to be the same. The resulting assemblies can then be manipulated by using the same protocols, and joined to make larger assemblies. Therefore, we have demonstrated that hierarchical assembly is possible at the nanoscale [80]. Figure 8.15 shows on the left clusters of 2 and 3 particles, which were constructed by manipulating individual particles (initial configuration not shown). On the right is a ring-like structure obtained by moving the clusters on the left.

A different approach is reported in [81]: nanoparticles are manipulated to form a target structure, which is then grown by deposition of additional material. Growth is accomplished essentially by electroless deposition, by immersing the sample in a hydroxilamine seeding solution. Figure 8.16 illustrates the results. On the top left is a "wire" made by manipulating Au particles, and on the top right is a single line scan through the centerline of the structure, showing that the height of the particles is ~8 nm. On the bottom left is the structure after deposition by hydroxilamine seeding, and on the bottom right is a single line scan, which now shows a particle size of ~20 nm. The initial structure looks like a continuous wire

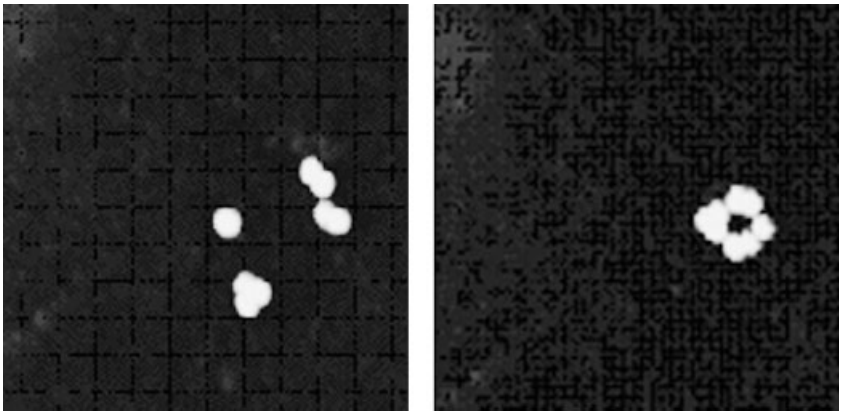

Figure 8.15 Hierarchical assembly. Thiolated 27 nm Au nanoparticles on Si coated with poly-L-lysine, 800 × 800 nm scan size. Reproduced with kind permission from [79].

in the figure but is not mechanically stable; touching it with the tip causes the structure to fall apart. In contrast, the final structure is a solid wire. One disadvantage of this method is that after the seeding the structures can no longer be moved on the substrate surface.

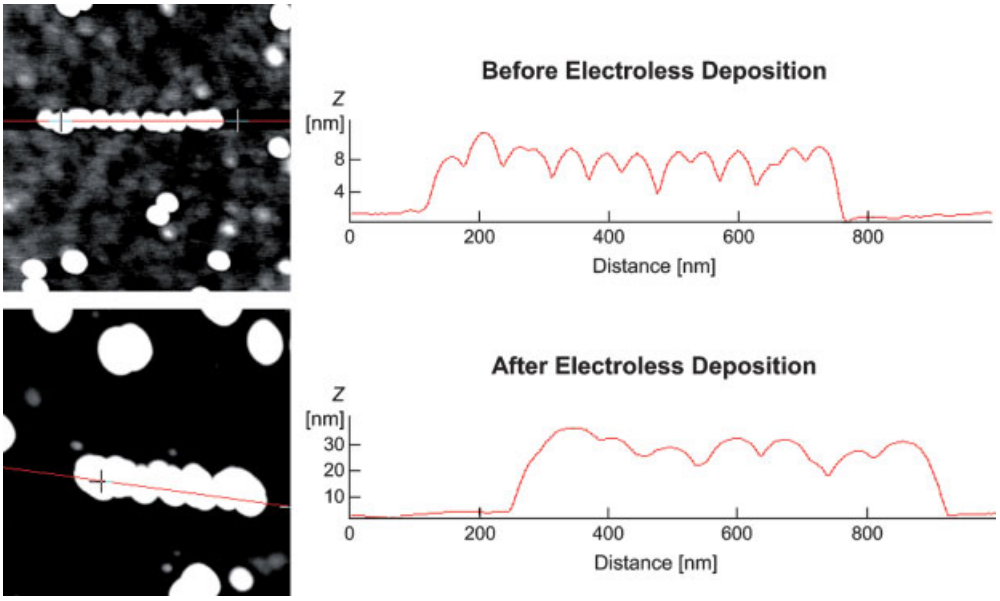

Figure 8.16 Linking nanoparticles by hydroxilamine seeding of a template built by manipulation. 8 nm Au particles on Si modified with aminopropyltrimethoxysilane (APTS). Reproduced with kind permission from [81].

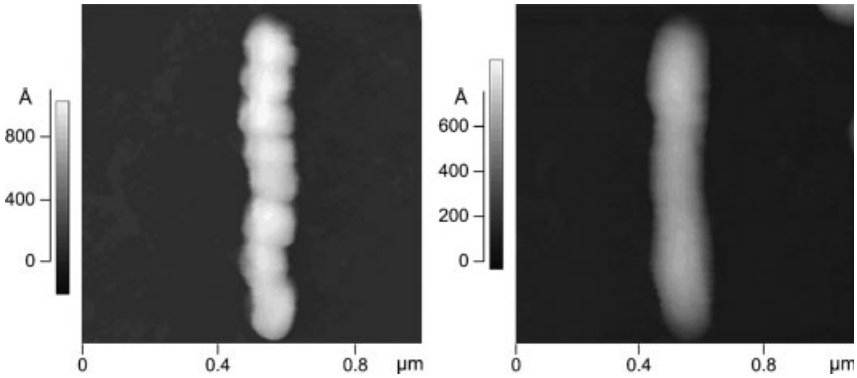

Figure 8.17 Linking nanoparticles by sintering a template built by nanomanipulation. 100 nm latex particles on Si. Reproduced with kind permission from [82].

Finally, we have demonstrated an even simpler approach to particle linking, which is based on sintering a structure after its template is built by nanomanipulation [82]. Figure 8.17 shows on the left a "wire" built by manipulation of latex particles with 100 nm diameter. On the right is the result of heating the sample at $\sim$160° for $\sim$10 min. The particles form a contiguous, solid structure. This process works very well for latex particles, but, unfortunately does not appear to be applicable to Au (and perhaps other metalic) particles.

Another interesting approach to joining nanoobjects is "welding", usually done within an SEM by using the electron beam. Contamination within the SEM chamber usually suffices to generate carbonaceous residues at the beam's target, and this can be used to link objects such as nanotubes [57, 76]. Similar approaches but using an environmental SEM and a field emission SEM are reported, respectively, in [77, 83]. Here they "solder" by inducing deposition of conductive materials with the electron beam in the presence of a source of a precursor.

8.4 Manipulation Systems

8.4.1 Interactive Systems

We discussed briefly in Section 8.3.1 the interactive manipulation capabilities of the LMR software. Ours is an unsophisticated system which provides a set of minimal capabilities a user needs to manipulate nanoobjects with the AFM. Since the beginnings of the LMR we have focused on automation – see the next subsection – and therefore did not invest resources in user interfacing.

Much more sophisticated interfaces have been developed by others. Hollis' group at the IBM Yorktown laboratory (now at Carnegie Mellon University) built an interface to an STM in which the user could drive the tip over the sample by moving a mechanical wrist [84]. The z servo signal is fed back to the wrist so that the user feels the topography of the surface as wrist vertical motions. This force, however, is not (a scaled version of) the actual force between tip and sample.

The nanoManipulator group in North Carolina has developed virtual reality user interfaces, first for STMs and then for AFMs [45, 50, 85, 86]. In the AFM interface a user can either be in imaging or manipulation mode. During imaging, the topographical data collected by the AFM is presented to the user in virtual reality, as a 3-D display. In addition, the user can feel the surface by using a haptic device, as if moving a stylus over a hard surface. Note, however, that the forces felt through the haptic device are not the cantilever-sensed forces, but rather are forces computed by standard virtual reality techniques so as to simulate the feel of a surface that approximates the measured topography of the sample. In the imaging mode, the user haptic input does not control the actual motion of the instrument, but rather the position of a virtual hand over the image of the surface. In contrast, the hand can be used to move the tip over the sample in manipulation mode. As the hand moves in virtual space and the tip moves correspondingly over the sample, the topography data generated by the AFM is used on the fly to compute a planar approximation to the surface. The user feels this approximated surface through the haptic stylus. Although the user does not feel the actual forces sensed by the cantilever, he or she can control the force applied to the sample during manipulation by using a set of knobs.

Sitti and co-workers also implement a virtual reality graphics interface, and add a one degree-of-freedom haptic device [51, 87]. Through a bilateral feedback system based on theoretical models of the forces between tip, sample and particle, the user can drive the tip over the sample by using a mouse, while at the same time feeling with the haptic device the forces experienced by the cantilever.

Xi's group has developed an augmented reality system in which cantilever forces are reflected in a haptic device [88, 89]. They develop a theoretical model for the interaction forces between tip, object and surface, and use it to compute the position of the tip based on the real-time force being measured. The visual display in a small window around the point of manipulation is updated in real-time to reflect the computed particle position. Thus, a user can follow the (computed) motion of the particle in real time during the manipulation.

8.4.2 Automated Systems

The automatic assembly of nanoobject patterns with the AFM consists of planning and executing the motions required for moving a set of objects from a given initial configuration into a goal configuration. The initial state usually corresponds to nanoobjects randomly dispersed on a surface.

As far as we know, there are only two systems today that are capable of building nanoobject patterns *automatically* by AFM nanomanipulation. One is being developed by Xi's group at Michigan State University, and the other at the LMR [73, 90]. The two systems use different planning algorithms and pushing protocols. Xi's system addresses at length the issues that arise in nanorod manipulation, and therefore is more general than ours, which focuses on nanoparticles. On the other hand, the Michigan State system has a more rudimentary drift compensator than ours, and does not compensate for creep or hysteresis, which are important for the manipulation of small objects, with dimensions $\sim$10 nm or less. The manipulation tasks demonstrated in [73] involve objects which are roughly one order of magnitude larger than those we normally manipulate, and the positional errors in the final structures shown in the figures of [73] also appear to be similarly larger than ours.

In the remainder of this section we describe the LMR automatic manipulation systems, from the top down, starting with high-level planning and ending with the system software architecture.

The input to the planner consists of a specification for a goal assembly of nanoparticles, and an initial arrangement that is obtained by imaging a physical sample with a compensated AFM (compensation is discussed below). In an initial step the planner assigns particles to target locations by using the Hungarian algorithm for bipartite matching, which is optimal [91]. It uses direct, straight-line paths if they are collision free, or indirect paths around obstacles computed by the optimal visibility algorithm [92]. Next, the planner computes a sequence of positioning paths, to connect the locations of the tip at the end of a push (determined in the previous step) and at the beginning of another push. This is done by a greedy algorithm, which sequentially selects the shortest paths. It is sub-optimal but performs well in practice. In a general case collisions between particles may arise. The planner handles collisions by exploiting the fact that all particles are assumed identical. It simulates the sequence of operations previously computed, at each step updating the state of the particle arrangement. If a collision is detected, it swaps operations, and does this recursively because solving one collision problem may generate new ones.

The planner just outlined is the second one we write. Our first planner, developed several years ago [93], was more complicated and slower, and did not perform better than the current one. However, we abandoned work on planning at that time not because of planner problems, but rather because we could not implement reliably the primitive operation assumed by the planner, which is simply to move from an initial point P to another goal point Q. The spatial uncertainties associated with the AFM – see Section 8.2.2 – were such that after a few operations we could no longer find the particles and push them without user interaction, and the task could not be completed automatically. We embarked on a research program aimed at compensation of uncertainties, and developed the compensators described briefly below. Details are available in [71, 94, 95].

The drift compensator is based on Kalman filtering, a standard technique in robotics and dynamic systems. We assume a simple (but incorrect) model for the

time evolution of the drift. The model can be used to predict future values of the drift, but these values will become increasingly wrong as time goes by, because the model is not perfect. The Kalman equations provide us with means to estimate the prediction error. When this value exceeds a threshold, drift measurements are scheduled, and the measured and predicted values are combined to produce better estimates, again by using the Kalman equations. A decade-long series of experiments indicates that the drift is accurately approximated as a translation, with a direction and speed that vary slowly. The estimated drift values obtained from the Kalman filter are added as offsets to all the motion commands of the AFM, thus compensating for this translation. Drift measurement techniques require that the AFM tip move on the sample to acquire data. Therefore, manipulation operations must be suspended when a measurement is needed. In contrast, when the filter is in prediction mode the offsets can be calculated very quickly and used to update the coordinates without interrupting the manipulation task.

Creep and hysteresis compensation is achieved through a feedforward scheme. A model for the two phenomena together is constructed as explained below, using a Prandtl-Ishlinskii operator [95]. This operator has the important property of invertibility. The inverse operator is computed and the desired trajectory is fed to the inverse system. The result is the signal required to drive the AFM piezos so as to follow the goal trajectory, assuming that the model is perfect. The model, of course, is not perfect, but experimental results show that it is sufficiently accurate for obtaining very good results – an order of magnitude decrease on the effects of creep and hysteresis has been verified experimentally. Creep is modeled by a linear term plus a superposition of exponentially decaying terms, with different time constants. Hysteresis is modeled by a superposition of operators which are essentially simple hysteresis loops. The piezo extension is the sum of the values of creep and hysteresis obtained from their models, and can be expressed in terms of a Prandtl-Ishlinskii operator. The combined model depends on several parameters, which can be estimated by analyzing the AFM topography signal for a line scan over a few particles. The line should span the entire region in which the manipulations will take place. The parameters are valid as long as the scan size of the AFM is not changed, and can be computed rapidly by running the tip back and forth a few times with the compensator on. Details may be found in [95].

Running both compensators together results in a software-compensated AFM with sufficiently low spatial uncertainties to provide a reliable implementation of the most basic robotic primitive "Move from point P to point Q" on the sample. However, this is not sufficient to reliably push particles between arbitrary points because long pushes tend to be unreliable – see Figure 8.11. Therefore, we break down any long pushing trajectory into smaller segments, currently $\sim$30 nm long. Having a reliable pushing routine, the output of the high-level planner can now be executed also with high reliability.

Now that we have discussed the high-level planner and its primitive commands, let us turn our attention to the software needed to implement the system. We found in the beginnings of the LMR, in 1994, that commercial AFM software was designed for

imaging and not suitable for manipulation. Therefore we designed and implemented a manipulation system, called Probe Control Software (PCS), running on top of the vendor-supplied Application Programming Interface (API) [36]. It was implemented on AutoProbe AFMs (Park Scientific Instruments, which later on became Thermomicroscopes and now Veeco), which to our knowledge were the only instruments sold with an available API. PCS evolved as time went by, and was the workhorse for the interactive manipulation research in our laboratory until recently. Research often moves in unpredictable ways, and we found that the ability to easily modify the software was fundamental to our experimental work. Unfortunately, the API was written for a 16-bit Windows system, which is far from being convenient to program. We concluded that we were spending too much time fighting an inhospitable programming environment and launched a re-write of the whole system, which has been "completed" recently. (We find that research software is in a permanent state of flux.)

The new system is called PyPCS, for Python PCS. It is written in C++ and Python, which is a scripting language that greatly facilitates program development. For example, new modules may be added to the system without the need to recompile and link the whole system. PyPCS has a client-server architecture. The server is written in C++ for 16-bit Windows and runs in the PC that controls the instrument. The client is written in Python, communicates with the server via standard interprocess communication primitives, and may run in the AFM PC or in any computer that is connected to it by Ethernet [96].

We conclude this section with a complete example, including planning and execution in the AFM. Figure 8.18 shows on the left panel the initial random dispersion of nanoparticles on the sample. On the right is the goal configuration (yellow crosses) plus the result of planning, with the pushing paths in red, and the positioning paths between pushes in green. The particles marked with a black

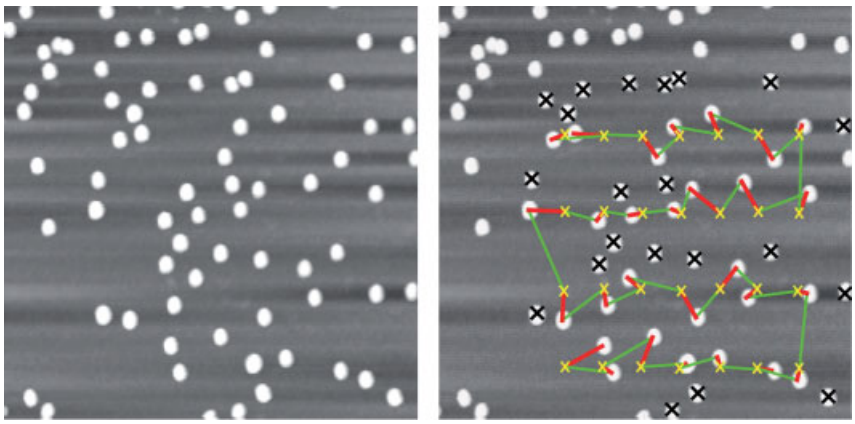

Figure 8.18 Left: Initial state. Right: Goal state (yellow) and planner output superposed on the intial image, showing pushing paths (red) and positioning paths (green). 15 nm Au particles on mica. Reproduced with kind permission from [90].

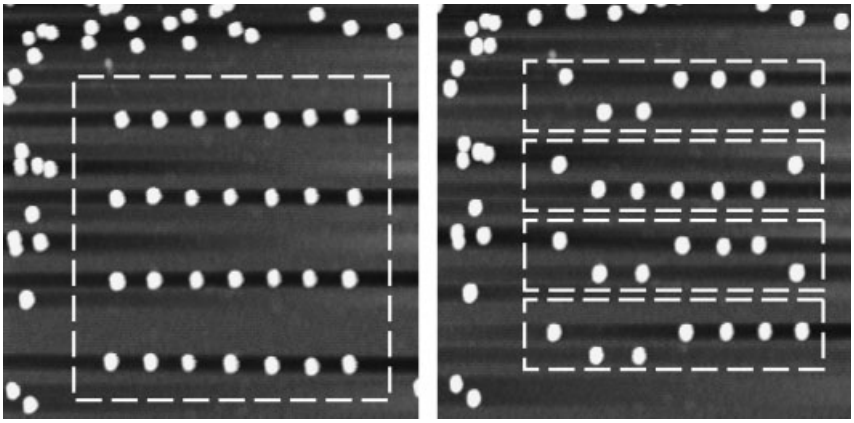

Figure 8.19 Left: Result of the execution of the plan of Figure 8.4.2.8. Right: An additional task, also planned and executed automatically. Reproduced with kind permission from [90].

cross are extraneous and should be removed from the area where the pattern is being built. (This is also done automatically.) Figure 8.19 shows on the left the result of executing the plan. On the right is the result of another similar operation also performed automatically. The pattern on the right of Figure 8.19 represents a different encoding of ASCI characters into nanoparticle positions – compare with Figure 8.13. Here a particle on the top row of each 2-row group signifies a "1" and a particle on the bottom row signifies a "0". The 4 groups of 2 rows read "NANO" in ASCI. This encoding uses twice as many particles as that of Figure 8.13 but has an interesting advantage: editing the stored data amounts simply to pushing particles up or down by a fixed amount, and could be achieved very efficiently by an AFM with a multi-tip array with spacing equal to that of the particle grid – see [97] and the discussion in the next section. The patterns shown in Figure 8.19 were built in a few minutes with the automated system. They would take at least one day of work by a skilled user if they had been built with our interactive system.

8.5 Conclusion and Outlook

Manipulation with the AFM of nanoscale objects with dimensions ~5–100 nm has been under study for over a decade, and is now routinely performed in several laboratories. Nevertheless, some basic questions remain unanswered. For example, how far off center can we hit a particle for it to be pushed reliably? How high above the surface can we strike a particle for it to move? Does the size of a particle matter? Do the shape and size of a tip matter? Why do particles fall off the desired trajectories? What is the force threshold needed to move a particle? Are there preferred directions

of motion? For a given surface, coating, nanoparticle, cantilever and environmental conditions, can we predict which operational parameters, if any, will result in reliable manipulation? And we could go on. In short, we lack a predictive understanding of the manipulation process, especially an understanding grounded on measurable parameters. However, there is enough experimental evidence on certain materials and systems for us to successfully complete non-trivial manipulation tasks, as shown in this chapter.

Nanomanipulation has been used until now for demonstrations or to prototype new devices. It is a useful prototyping tool because it can be used to build devices that cannot be made otherwise, and it greatly facilitates parametric studies. For example, the effect of spatial errors on a given device can be investigated by moving one of its constituent particles and recording the associated functional changes. The complexity of the structures built by nanomanipulation has been severely restricted by the sheer amount of labor and time needed to construct them interactively. Automated systems such as those described in this chapter are beginning to appear, and may significantly impact what can be done by nanomanipulation. It is fair to say, though, that a "killer app" has not yet been found for nanomanipulation. A high value, low volume application seems most appropriate, because, even with automated operation, nanomanipulation with the AFM is a serial and relatively slow process, not very suitable for mass production. Perhaps repair of fabrication masks and other high cost devices will be an important application in the future.

Another technical advance that may have a strong impact on nanomanipulation is the development of instruments with multiple tips. There are currently several research efforts aimed at producing multi-tip arrays, but they tend to be unusable for manipulation because they do not provide individual control of height (z) for each tip – see for example [98]. Furthermore, whereas efficient algorithms for nanolithography with multi-tip arrays are known [97, 99], manipulation tasks are inherently more difficult because of registration problems between tips and particles. The tips are normally arranged in a regular array, while the particles are initially randomly dispersed, and when a tip is positioned near a particle for pushing it, the other tips are unlikely to be in positions where they can push other particles. If this happens, a multi-tip array will be no faster than a single tip.

In summary, much has been learned about nanomanipulation with AFMs, and new automated systems are a breakthrough improvement over their traditional, interactive counterparts, but we still lack a deep, predictive understanding of the manipulation phenomena, as well as a convincing demonstration of economic viability for practical applications. Massively parallel operation by using multi-tip arrays may be he next breakthrough.

Acknowledgment and Disclaimer

The LMR work on nanotechnology was supported in part by the NSF Grants EIA-98-71775, IIS-99-87977, EIA-01-21141, DMI-02-09678 and Cooperative Agreement CCR-01-20778; and the Okawa Foundation.

I would like to thank my LMR faculty colleagues, postdocs and students, too many to mention here, who did much of the LMR work reported in this chapter and from whom I learned much over the last decade. I wish to single out the students who built the probe control software who made possible all of our work on nanomanipulation. They were Cenk Gazen, who started it all, Nick Montoya who extended and maintained PCS for a couple of years, Jon Kelly, who wrote the first version of PyPCS, Babak Mokaberi, who built the drift, creep and hysteresis compensators, Dan Arbuckle, who is the architect of the current version of PyPCS, which integrates the old PCS with Mokaberi's work, and Jaehong Yun, who did the high level planning software and, with Arbuckle, has integrated it into PyPCS.

An exhaustive bibliography on nanomanipulation and related topics is beyond the scope of this Chapter. In many cases I have attempted to cite the pioneering works on specific subjects but I may have failed to acknowledge some of them. I offer my apologies to the colleagues whom I may not have cited, or whose work I may have misinterpreted. There is simply too much research in this area for me to be able to keep up with all of it.

9
Harnessing Molecular Biology to the Self-Assembly of Molecular-Scale Electronics

Uri Sivan

9.1
Introduction

Microelectronics and biology provide two distinct paradigms for complex systems. In microelectronics, the information guiding the fabrication process is encoded into computer programs or glass masks and, based on that information, a complex circuit is imprinted in silicon in a series of chemical and physical processes. This top-to-bottom approach is guided by a supervisor whose "wisdom" is external to the circuit being built. Biology adopts an opposite strategy, whereby complex constructs are assembled from molecular-scale building blocks, based on the information encoded into the ingredients. For example, proteins are synthesized from amino acids based on the instructions coded in the genome and other proteins. The assembled objects process further molecules to form larger structures capable of executing elaborate functions, and so on. This autonomous bottom-up strategy allows, in critical bottlenecks, for an exquisite control over the molecular structure in a way which is unmatched by man-made engineering. In other cases it allows for the errors that are so critical for evolution.

The fact that man-made engineering evolved so differently from "nature engineering" deserves a separate discussion that is beyond the scope of this chapter. Here, we will only comment that the perception of nature as a type of engineering is somewhat oversimplifying. While engineering aims at meeting a predefined challenge – namely, to execute a desired function – nature evolved with no aim. Yet, the hope behind biomimetics is that concepts and tools which evolved during several billions years of evolution may find applications in engineering.

Electronics is particularly alien to biology. With the exception of short-range electron hopping in certain proteins, biology relies on ion transport rather than electrons. The electronic conductivity of biomolecules is orders of magnitude too

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

small for implementing them as useful electronic components. For instance, albeit in earlier reports, DNA has been found to be an excellent insulator [1–3]. The foreseen potential of biology in the context of electronics is, therefore, in the assembly process rather than in electronic functionality *per se*. This observation is reflected in the scientific research described below; it concerns the bioassembly of electronic materials to form devices, rather than attempts to use biomolecules as electronic components.

The term "self-assembly" is widely used to describe a variety of processes which include the self-assembly of organic molecules to form uniform monolayers on substrates. This is not the type of self-assembly under consideration in this chapter, whereby the term refers to the construction of an elaborate object, namely, the embedment of a significant amount of information into the object being built. The subject of the intimate relationship between self-assembly, information, and complexity will be revisited in Section 9.4.

The term "complex self-assembly" deserves some introductory remarks. When looking back at nature, one realizes that complex objects are typically assembled in a modular way. Most protein machines, for instance, comprise several subunits, each made of a separate protein. Each such protein is synthesized in the cell from amino acids which are in turn synthesized from atoms. This example is identified in four levels of hierarchy, namely atoms, amino acids, proteins, and machines made of several protein subunits. This hierarchal or modular assembly is an essential ingredient of complex self-assembly, the reason being that none of the modules reflects a global minimal free energy of its elementary constituents. The protein machine, for instance, does not pertain to a minimal free energy of the collection of amino acids making it, and so on.

In many instances the system is guided to a certain configuration by auxiliary molecules (enzymes, chaperones, etc.) which at times consume energy. However, in the cases of interest here, where self-assembly is governed by non-covalent interactions and relatively simple configurations, each step can be driven by a down-hill drift in free energy towards a long-lived metastable state, thus rendering the module amenable for the next assembly step. Clearly, complex electronics cannot be assembled from its elementary building blocks in a single step, and so requires modular assembly.

The next comment concerns the unavoidable errors characterizing self-assembly. In order for molecular recognition to take place, the molecules should effectively explore multiple docking configurations with other parts of the target molecule or with other molecules. The free energy landscape corresponding to the collection of all such configurations should, therefore, facilitate thermally assisted hops between local minima, corresponding to "wrong" configurations, in addition to the desired configuration. Special measures must be devised in order to produce overwhelming discrimination in favor of the desired configuration at finite time experiments. In the absence of such measures, the yield of self-assembly is intrinsically limited by the same fluctuations that facilitate molecular recognition. Over time, biology has evolved sophisticated error suppression and correction tools, and equivalent

methods will have to be developed if the self-assembly of molecular-scale electronics is to be taken seriously.

The effect of errors on modular assembly is of particular importance. As the yield in each assembly step is less than perfect, faulty modules are produced. An uncontrolled modular assembly therefore inevitably produces an exponentially larger fraction of faulty modules as the levels of hierarchy accumulate. One strategy for making useful circuits may thus rely on circuit architectures that are tolerant to faults. One such outstanding example is embodied in the Teramac machine developed at HP laboratories [4]. In the present chapter we adhere to conventional architectures requiring near-perfect circuits. The faulty modules in each step therefore need to be identified and either repaired or eliminated. Within the context of electronic circuits built by biology, the identification of faulty devices and their removal presents a remarkable challenge; that of devising a biomolecular machine that tests non-biological devices for electronic functionality, filters out non-functional devices, and then signals the system to proceed to the next assembly step. Although significant progress has been made towards the isolation of antibodies that sense the electric output presented to them by an electronic device, the discussion of electro-bio feedback loops is deferred to future publications, and focus here is on free-running assembly.

The conjecture behind the experiments described in this chapter may be summarized as follows. Simple functional devices can be assembled efficiently from electronic materials, taking advantage of the remarkable assembly tools provided by molecular biology. The realization of elaborate constructs necessitates hierarchical modular assembly, while the inevitable accumulation of errors with increasing levels of hierarchy requires error suppression and correction mechanisms, as well as biomolecular feedback switches that judge for electronic functionality and feedback to the bioassembly process.

In Section 9.2 the concept is of DNA-templated electronics [1, 5] is introduced, and expanded to include sequence-specific molecular assembly [6, 7] based on the recombinant protein, RecA. This section culminates in the bioassembly of a fully functional field effect transistor made from a carbon nanotube (CNT) [8]. While the topics of Section 9.2 rely on existing biotechnological tools, in Section 9.3 the toolbox is expanded to demonstrate how to isolate antibodies that recognize electronic materials directly [9]. The fact such antibodies can be isolated is encouraging with respect to the prospect of realizing a functional interface between molecular biology and nanoelectronics [10].

As DNA-templated electronics requires long DNA molecules with unique addresses, advantage is then taken of DNA computing to demonstrate the autonomous synthesis of DNA templates having these properties [11]. The synthesis algorithm, as outlined in Section 9.4, relies on the chemical realization of shift registers (SRs), and incorporates an error suppression scheme inspired by the redundancy codes employed in data communication. To the best of the present author's knowledge, these chemical SRs constitute the first embodiment of error suppression codes in chemical synthesis.

9.2
DNA-Templated Electronics

9.2.1
Scaffolds and Metallization

Double-stranded DNA (dsDNA) is chosen in most cases to template the assembly of molecular-scale electronics as well as other constructs of non-biological functionality. dsDNA is mechanically and chemically stable, easy to obtain at any desired sequence, and readily amenable to diverse enzymatic manipulations including restriction, digestion, replication, ligation, and recombination. In the schemes described below, dsDNA doubles as the information-carrying molecule and the physical support for the assembled electronic materials.

The assembly of DNA-templated electronics comprises two steps. First, the biological machinery is employed to construct a DNA scaffold with well-defined molecular addresses. Then, electronic functionality is instilled by the localization of electronic devices at specific addresses along the scaffold and conversion of the DNA template into a conductive network interconnecting devices to each other and to the external world.

An heuristic solution to some of the major challenges faced by molecular electronics, namely, the precise localization of a large number of molecular devices, inter-device wiring, and electrical interface between the molecular and macroscopic worlds, is depicted in Figure 9.1(a–d). The first step involves the definition of macroscopic electrodes on an inert substrate. As the electrodes are macroscopic, this process can be performed using standard photolithographic techniques (Figure 9.1a). The electrodes are provided with an identity by covering each of them

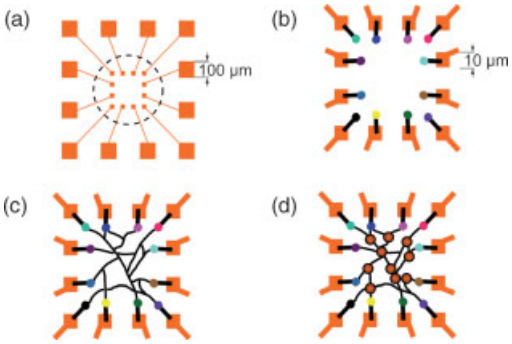

Figure 9.1 Heuristic scheme of a DNA-templated electronic circuit. (a) Gold pads are defined on an inert substrate. Panels (b–d) correspond to the circle of (a) at different stages of circuit construction. (b) Oligonucleotides of different sequences are attached to the different pads. (c) DNA network is constructed and bound to the oligonucleotides on the gold electrodes. (d) Metal clusters or molecular electronic devices are localized on the DNA network. The DNA molecules are finally converted into metallic wires, rendering the construct into a functional electronic circuit. Note that the figures are not to scale; the metallic clusters are nanometer-sized, while the electrode pads are micrometer-sized.

with a monolayer of a different short, single-stranded oligonucleotide using, for example, an ink-jet printer (Figure 9.1b). This step may still involve physical manipulations as the electrodes to be covered are macroscopic. After this step, each electrode is labeled with a monolayer of a unique oligonucleotide sequence and, hence, is able to recognize a specific complementary sequence in solution. In the third step, a network of well-defined connectivity is assembled using DNA hybridization and recombinant processes (see below). The network is then localized on the substrate using, for example hybridization of DNA molecules with the electrode-bound oligonucleotides (Figure 9.1c). The previous steps instill the formerly uniform substrate with well-defined molecular addresses based on distinct sequences of DNA molecules. This allows the subsequent positioning of functional electronic elements at molecularly accurate addresses (Figure 9.1d). At the end of this step, the network should bear functional elements at predesigned sites. However, as DNA molecules have insulating properties, the network should be functionalized (e.g., metallized) in order to render it conductive.

Now, the questions to be asked are how accurate is the topology of the assembled DNA network? Can it be inspected for structural integrity? Was the template assembled properly on the electrodes? Were the devices localized at their planned destinations? Did the devices connect electrically? Are they functional? These are just a few of the questions that must be addressed in any specific attempt to self-assemble molecular-scale electronics.

The experimental procedure used to demonstrate DNA-templated assembly and electrode attachment of a conductive silver wire [1, 5] are depicted in Figure 9.2. First, 12-base oligonucleotides, derivatized with a disulfide group at their 3′ end, were attached to the electrodes through a thiol–gold interaction. Each of the two electrodes was marked with a different oligonucleotide sequence. The electrodes were then bridged by hybridization of a 16 μm-long λ-DNA molecule containing two 12-base-long sticky ends, each of which was complementary to one of the two sequences attached to the gold electrodes.

The inset to Figure 9.3 presents a single DNA molecule bridge as observed by fluorescence microscopy. The measurements on the stretched DNA molecules indicated a resistance higher than the internal resistance of the measurement apparatus ($>10^{13}\,\Omega$). It was therefore concluded that, in order to instill electrical functionality, the DNA bridge must be coated with metal. Albeit contradicting results reported previously in the literature, it is now widely accepted that the intrinsic conductivity of DNA is indeed too small for direct application as a conducting element in a circuit [2].

The three-step silver-coating process (Figure 9.2c–e) was based on the selective localization of silver ions along the DNA molecule through Ag^+/Na^+ ion-exchange [1, 5], and the formation of complexes between the silver and the DNA bases. The silver ion-exchanged DNA was then reduced to form nanometer-sized silver aggregates bound to the DNA skeleton. These aggregates were further "developed" (much as in a standard photographic procedure) by using an acidic solution of hydroquinone and silver ions under low-light conditions [12, 13]. This solution was metastable, and spontaneous metal deposition was normally very slow,

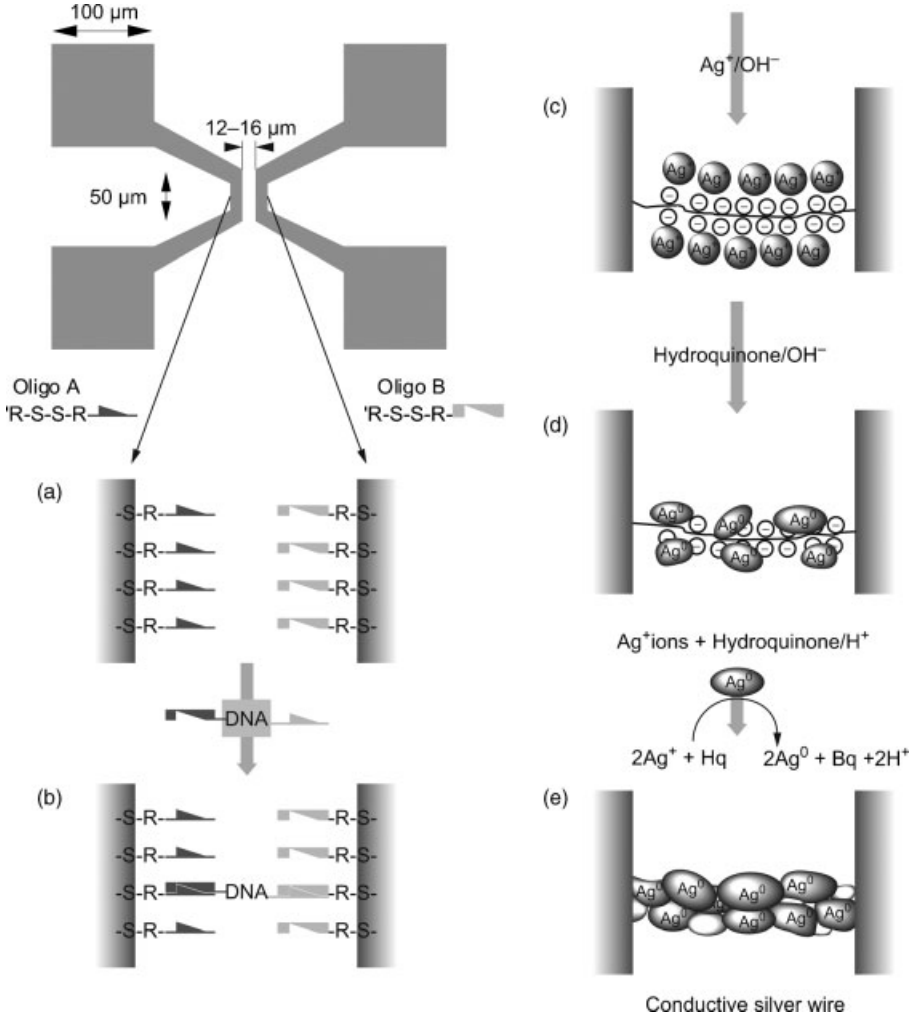

Figure 9.2 A gold pattern, 0.5 × 0.5 mm in size, was defined on a passivated glass using microelectronics techniques. The pattern comprised four bonding pads, each 100 μm in size, connected to two 50 μm-long parallel gold electrodes, 12–16 μm apart. (a) The electrodes were each wetted with a 10^{-4} μL droplet of disulfide-derivatized oligonucleotide solution of a given sequence (Oligos A and B). (b) After rinsing, the structure was covered with 100 μL of a solution of λ-DNA having two sticky ends that are complementary to Oligos A and B. A flow was applied to stretch the λ-DNA molecule between the two electrodes, allowing its hybridization. (c) The DNA bridge was loaded with silver ions by Na^+/Ag^+ ion exchange. (d) The silver ion–DNA complex was reduced using a basic hydroquinone solution to form metallic silver aggregates bound to the DNA skeleton. (e) The DNA templated wire was "developed" using an acidic solution of hydroquinone and silver ions. (Reprinted from Ref. [1]; © *Nature*, 1998.).

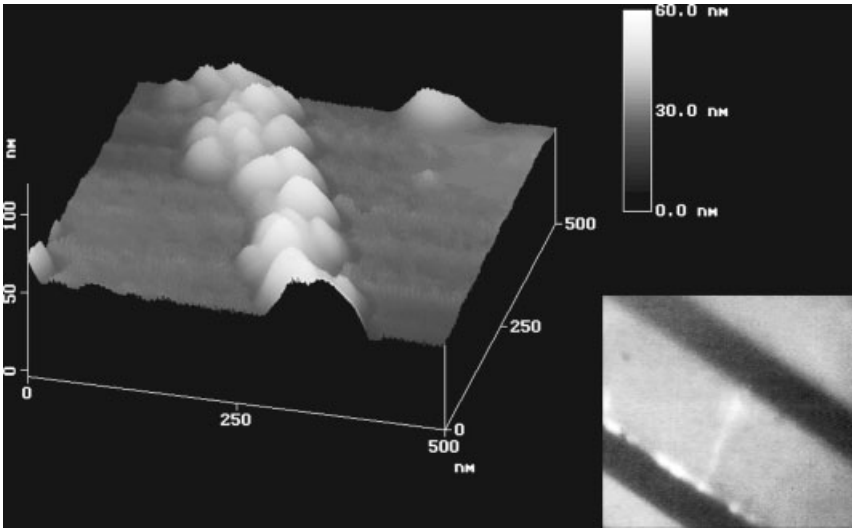

Figure 9.3 Atomic force microscopy (AFM) image of a silver wire connecting two gold electrodes 12 μm apart. Field size = 0.5 μm. Inset: Fluorescently labeled λ-DNA molecule stretched between two gold electrodes (dark strips), 16 μm apart. (Reprinted from Ref. [1]; © *Nature*, 1998.).

except on the silver aggregates attached to the DNA catalyzed the process. Under the experimental conditions, metal deposition therefore occurred only along the DNA skeleton, leaving the passivated substrate practically clean of silver. An atomic force microscopy (AFM) image of a segment of a 100 nm-wide, 12 μm-long silver wire prepared in this way is shown in Figure 9.3.

Since the publication of Ref. [1], the metallization scheme has been improved in two essential ways. First, silver has been replaced with gold [6] in the enhancing step and, after a few hours sintering at 300 °C, excellent wires were obtained. Second, the hydroquinone has been substituted for glutaraldehyde [6, 14] localized on the DNA itself. The confinement of the reducing agent to the DNA molecule suppressed non-specific metal deposition on other objects in the system, leading to much cleaner circuits. A DNA-templated gold wire is depicted in the inset of Figure 9.4, together with its current–voltage (I–V) characteristics.

Other research groups have since extended the scope of the metallization of biomolecules to proteins, amyloid fibrils, protein S-layers, microtubules, actin fibers, and even complete viral particles. Today, the choice of metals includes Pd, Pt, Au, Cu, and Co. An account of biomolecules metallization can be found in Refs. [15–20].

9.2.2
Sequence-Specific Molecular Lithography

In analogy with photolithography in conventional microelectronics, the realization of DNA-templated devices and circuits requires tools for defining circuit architectures.

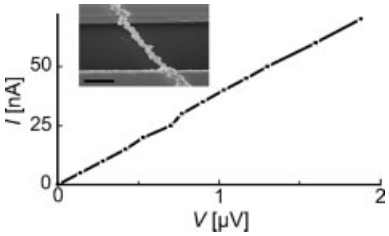

Figure 9.4 Two-terminal current–voltage (I–V) curve of a DNA-templated gold wire. The resistivity of the wire ($1.5 \times 10^{-7}\,\Omega\cdot$m) was only seven-fold higher than that of polycrystalline gold ($2.2 \times 10^{-8}\,\Omega\cdot$m). Inset: Scanning electron microscopy (SEM) image of a typical DNA-templated gold wire stretched between two electrodes deposited by electron-beam lithography. Scale bar = 1 μm. (Reprinted from Ref [6]; © 2002, American Association for the Advancement of Science.).

These include the formation of rich geometries, wire patterning at molecular resolutions, and molecularly accurate device localization. To that end, "sequence-specific molecular lithography" has been developed which enables the elaborate manipulation of dsDNA molecules, including patterning of the metal coating of DNA, the localization of labeled molecular objects at arbitrary addresses on dsDNA, and the generation of molecularly accurate stable DNA junctions [6, 8, 14].

The molecular lithography system developed at Technion utilizes homologous genetic recombination processes carried out by the RecA protein from *Escherichia coli*. The patterning information encoded in the DNA molecules replaces the masks used in conventional photolithography, while the RecA protein serves as the resist. The molecular lithography functions at high resolution over a broad range of length scales, from nanometers to many micrometers.

Homologous genetic recombination is one of several mechanisms that cells use to manipulate their DNA [21]. In this process, two parental DNA molecules which possess some sequence homology cross-over at equivalent sites. The reaction is based on protein-mediated, sequence-specific DNA–DNA interaction. Although RecA is the major protein responsible for this process in *E. coli*, it is also able to carry out the essential steps of the recombination process *in vitro*.

In the present author's procedure, RecA monomers are polymerized on a probe single-stranded DNA (ssDNA) molecule to form a nucleoprotein filament (Figure 9.5, step i). The nucleoprotein filament binds to a substrate molecule at an homologous probe–substrate location (Figure 9.5, step ii). RecA allows the addressing of an arbitrary sequence, from as few as 15 bases [22] to many thousands of bases, by the same standard reaction. This versatility presents an advantage over DNA-binding proteins which are restricted to particular DNA sequences. Moreover, unlike DNA hybridization, sequence-specific recognition can be performed on dsDNA, rather than ssDNA. Being chemically more inert and mechanically more rigid, the former provides a better substrate than the latter. The high efficiency and specificity of the recombination reaction, which evidently is essential for its biological roles, are beneficial in its utilization for molecular lithography.

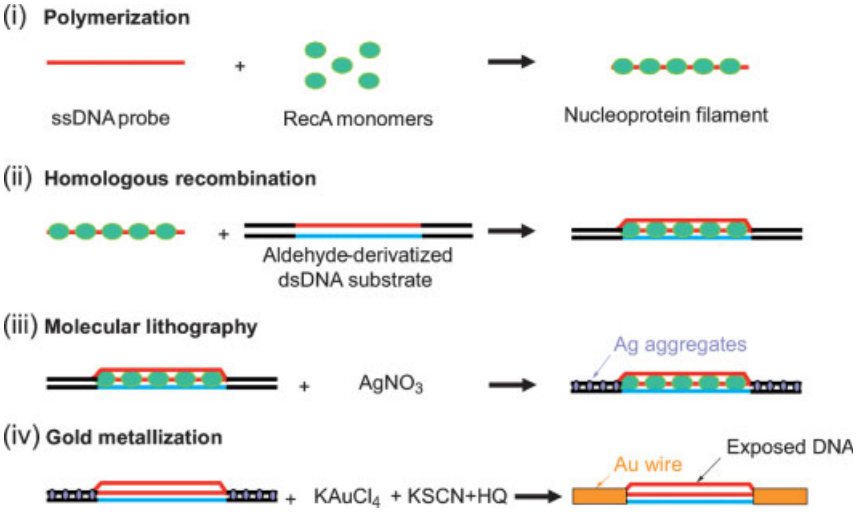

Figure 9.5 Schematics of the homologous recombination reaction and molecular lithography. (i) RecA monomers polymerize on a ssDNA probe molecule to form a nucleoprotein filament. (ii) The nucleoprotein filament binds to an aldehyde-derivatized dsDNA substrate molecule at an homologous sequence. (iii) Incubation in $AgNO_3$ solution results in the formation of silver aggregates along the substrate molecule at regions unprotected by RecA. (iv) The silver aggregates catalyze specific gold deposition on the unprotected regions. A highly conductive gold wire is formed with a gap in the protected segment. (Reprinted from Ref [6]; © 2002, American Association for the Advancement of Science.).

The application of sequence-specific molecular lithography to the definition of a patterned gold wire is outlined in Figures 9.5 and 9.6. Here, the previously described DNA metallization scheme is employed in which DNA-bound glutaraldehyde is used as a localized reducing agent [6], and the RecA is used as a sequence-specific resist. RecA monomers polymerize on a single-stranded probe DNA to form a nucleoprotein filament (Figure 9.5, step i) which locates and binds to a homologous sequence on a dsDNA molecule (Figure 9.5, step ii). Once bound, the RecA in the nucleoprotein filament acts as a sequence-specific resist, physically protecting the aldehyde-derivatized substrate DNA against silver cluster formation in the bound region (Figure 9.5, step iii). Subsequent gold metallization leads to the growth of two extended DNA-templated wires separated by the predesigned gap (Figure 9.5, step iv).

Figure 9.6 depicts images of the products of the various steps leading to a patterned gold-coated λ-DNA. Extensive AFM and scanning electron microscopy (SEM) imaging confirmed that the metallization gap was located where expected. The position and size of the insulating gap could be tailored by choosing the probe's sequence and length. The ability to pattern DNA metallization facilitates modular circuit design, and is therefore valuable for the realization of DNA-templated electronics. Insulating and conducting regions can be defined on the DNA scaffold according to the underlying sequence, thus determining the electrical connectivity in the circuit. In addition, patterning DNA metallization is useful for the integration of molecular objects into a circuit. Such objects can be localized and electrically

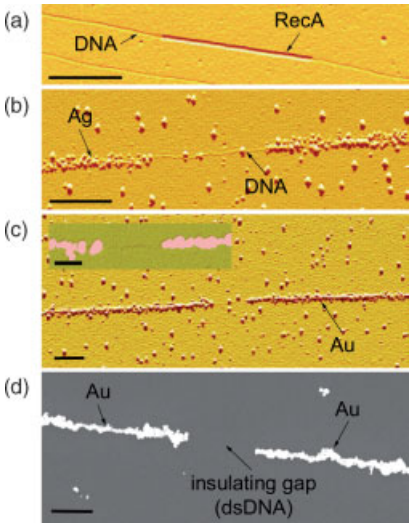

Figure 9.6 Sequence-specific molecular lithography on a single DNA molecule. (a) AFM image of a 2027-base RecA nucleoprotein filament bound to an aldehyde-derivatized λ-DNA substrate molecule. (b) AFM image of the sample after silver deposition. Note the exposed DNA at the gap between the silver-loaded sections. (c) AFM image of the sample after gold metallization. Inset: zoom on the gap. The height of the metallized sections is ~50 nm. (d) SEM image of the wire after gold metallization. All scale bars = 0.5 μm; inset to (c) = 0.25 μm. The variation in the gap length is due mainly to variability in DNA stretching on the solid support. The very low background metallization in the SEM image compared with the AFM images indicates that most of the background is insulating. (Reprinted from Ref [6]; © 2002, American Association for the Advancement of Science.).

contacted within the exposed DNA sequences present in the unmetallized gaps. Further manipulations of DNA templates including the localization of man-made objects at specific addresses along the DNA molecule, the generation of three- and four-armed junctions, and elaborate metallization patterning can be found in Refs. [6, 7, 14, 16].

9.2.3
Self-Assembly of a DNA-Templated Carbon Nanotube Field-Effect Transistor

The superb electronic properties of CNTs [23], their large aspect ratio, and their inertness with respect to the DNA metallization process, make them an ideal choice for the active elements in DNA-templated electronics. The ability to localize molecular objects at any desired address along a dsDNA molecule and to pattern sequence-specifically the DNA metallization (as described above) facilitate the incorporation of CNTs into DNA-templated functional devices, and their wiring. In the assembly of the field-effect transistor (FET), a DNA scaffold molecule provided the address for the precise localization of a semiconducting single-wall carbon nanotube (SWNT), and templated the extended wires contacting it. The localization of the SWNT relied on

homologous recombination by the RecA protein. The assembly of the SWNT–FET, which is shown schematically in Figure 9.7, employed a three-strand homologous recombination reaction between a long dsDNA molecule serving as a scaffold and a short auxiliary ssDNA. The short ssDNA molecule was synthesized so that its sequence was identical to the dsDNA at the designated location of the FET. RecA

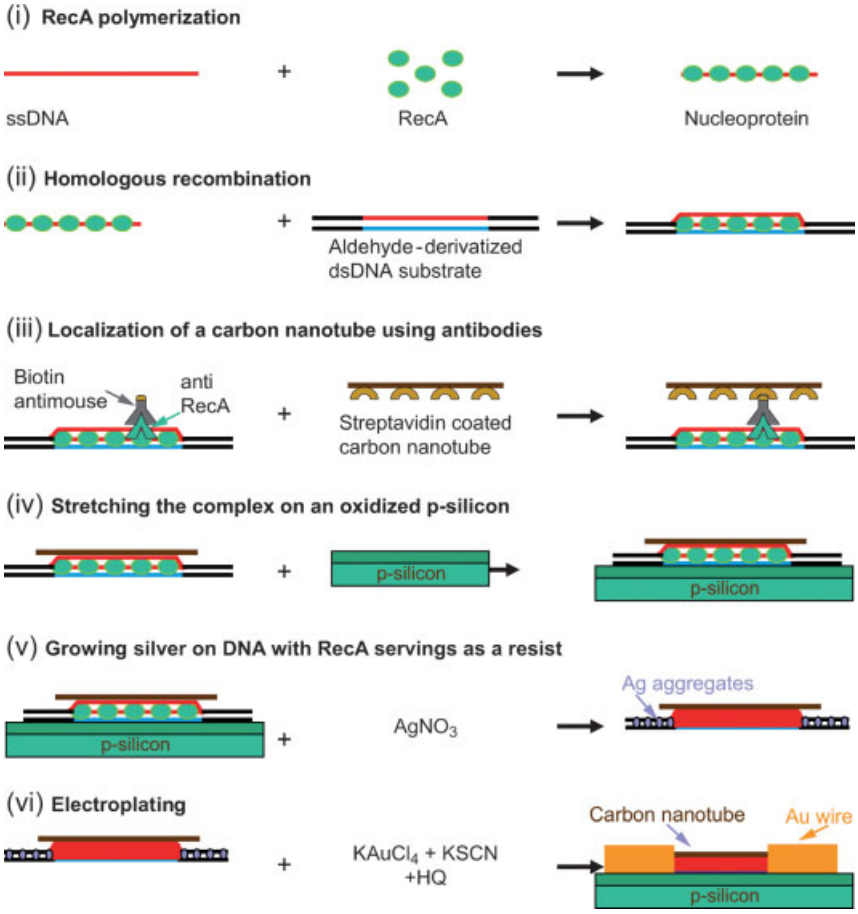

Figure 9.7 Assembly of a DNA-templated FET and wires contacting it. Steps are as follows. (i) RecA monomers polymerize on a ssDNA molecule to form a nucleoprotein filament. (ii) Homologous recombination reaction leads to binding of the nucleoprotein filament at the desired address on an aldehyde-derivatized scaffold dsDNA molecule. (iii) The DNA-bound RecA is used to localize a streptavidin-functionalized single-wall carbon nanotube (SWNT), utilizing a primary antibody to RecA and a biotin-conjugated secondary antibody. (iv) The complex is stretched on an oxidized *p*-type silicon wafer by dipping the substrate in a solution containing the complexes and pulling it out. (v) Incubation in an $AgNO_3$ solution leads to the formation of silver clusters on the segments that are unprotected by RecA. (vi) Electroless gold deposition, using the silver clusters as nucleation centers, results in the formation of two DNA-templated gold wires contacting the SWNT bound at the gap.

proteins were first polymerized on the auxiliary ssDNA molecules to form nucleoprotein filaments (Figure 9.7, step i), which were then mixed with the scaffold dsDNA molecules. The nucleoprotein filament bound to the dsDNA molecule according to the sequence homology between the ssDNA and the designated address on the dsDNA (Figure 9.7, step ii). The RecA later served to localize a SWNT at that address and to protect the covered DNA segment against metallization. A streptavidin-functionalized SWNT was guided to the desired location on the scaffold dsDNA molecule using antibodies to the bound RecA and biotin–streptavidin-specific binding (Figure 9.7, step iii). The SWNTs were solubilized in water by micellization in sodium dodecyl sulfate (SDS) [24] and functionalized with streptavidin by non-specific adsorption [25, 26].

Primary anti-RecA antibodies were reacted with the product of the homologous recombination reaction, and this resulted in specific binding of the antibodies to the RecA nucleoprotein filament. Next, biotin-conjugated secondary antibodies, having high affinity to their primary counterparts, were localized on the primary anti-RecA antibodies. Finally, the streptavidin-coated SWNTs were added, leading to their localization on the RecA via biotin–streptavidin-specific binding (Figure 9.7, step iii). The DNA/SWNT assembly was then stretched on a passivated oxidized silicon wafer. An AFM image of a SWNT bound to a RecA-coated 500-base-long ssDNA localized at the homologous site in the middle of a scaffold λ-DNA molecule is shown in Figure 9.8a. The conducting CNT can be clearly distinguished from the insulating DNA by the use of scanning conductance microscopy [27, 28]. The topographic and conductance images of the same area are depicted in Figure 9.8b and c, respectively. The evident difference between the two images identifies the SWNT on the DNA molecule. It should be noted that the CNT is aligned with the DNA, which is almost always the case due to the stiffness of the SWNT and the stretching process.

Following stretching on the substrate, the scaffold DNA molecule was metallized. The RecA, doubling as a sequence-specific resist, protected the active area of the transistor against metallization. The metallization scheme described above was employed, in which aldehyde residues, acting as reducing agents, were bound to the scaffold DNA molecules by reacting the latter with glutaraldehyde. Highly conductive metallic wires were formed by silver reduction along the exposed parts of the aldehyde-derivatized DNA (Figure 9.7, step v) and subsequent electroless gold plating using the silver clusters as nucleation centers (Figure 9.7, step vi). As the SWNT was longer than the gap dictated by the RecA, the deposited metal covered the ends of the nanotube and contacted it. A SEM image of an individual SWNT contacted by two DNA-templated gold wires is depicted in Figure 9.8d.

The extended DNA-templated gold wires were contacted by electron-beam lithography, and the device was characterized by direct electrical measurements under ambient conditions. The p-type substrate was used to gate the transistor. The electronic characteristics of the device are shown in Figure 9.9a and b. The gating polarity indicated p-type conduction of the SWNT, as is usually the case with semiconducting CNTs in air [29]. The saturation of the drain-source current for negative gate voltages indicated resistance in series with the SWNT; this

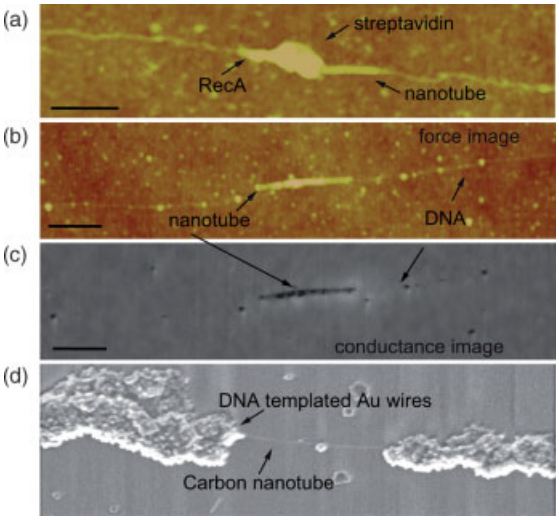

Figure 9.8 Localization of a single-wall carbon nanotube (SWNT) at a specific address on the scaffold dsDNA molecule using RecA. (a) An AFM image of a 500-base-long (~250 nm) RecA nucleoprotein filament localized at a homologous sequence on a λ-DNA scaffold molecule. Scale bar = 200 nm. (b) An AFM image of a streptavidin-coated SWNT bound to a 500-base-long nucleoprotein filament localized on a λ-DNA scaffold molecule. Scale bar = 300 nm. (c) A scanning conductance image of the same region as in (b). The conductive SWNT yields a considerable signal, whereas the insulating DNA is hardly resolved. Scale bar = 300 nm. (d) SEM image of the resulting device. The DNA-templated gold wires and the assembled nanotube are indicated by arrows. The DNA molecule itself is not resolved in this image.

resistance was attributed to the contacts between the gold wires and the SWNT as the four-terminal resistance of the DNA-templated gold wires was typically smaller than 100 Ω. Each of the different devices had somewhat different turn-off voltages.

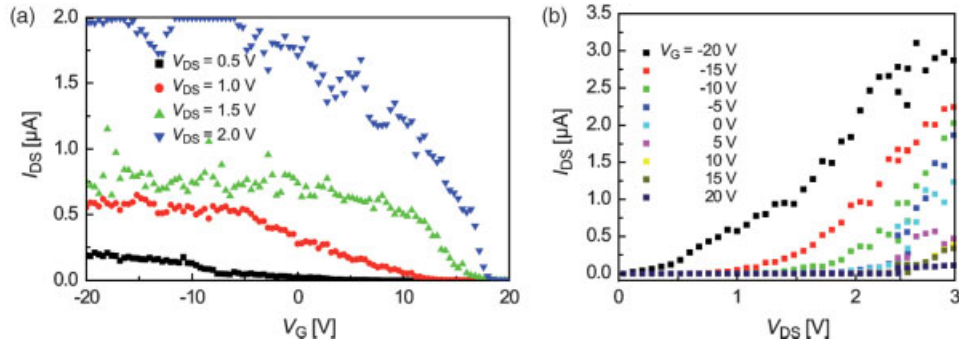

Figure 9.9 Electrical characteristics of a self-assembled *p*-type field effect transistor based on a semiconducting single wall carbon nanotube. (a) Drain-source current versus gate bias applied between the *p*-type substrate and the source electrode. (b) Same versus drain-source voltage for different gate voltages.

9.3
Recognition of Electronic Surfaces by Antibodies

The self-assembly described in Section 9.2 relies on existing biotechnological tools, but in this section the toolbox is expanded to show how to isolate antibody molecules that recognize electronic surfaces directly. As a specific example, the isolation of antibody molecules capable of discriminating between different crystalline facets of a GaAs crystal is reviewed. Beyond the potential application of such antibodies for the direct localization of molecular-scale objects at desired sites on an electronic substrate, the success in isolating these antibodies is encouraging with regards to the prospects of isolating antibodies that can "read" electrical signals presented to them by electronic devices. The latter constitute a critical milestone on the way to *functional* integration between molecular biology and nanoelectronics.

The mammalian immune system offers a vast repertoire of antibody molecules capable of binding, in selective manner, an immense number of molecules presented to the body by invading pathogens such as bacteria, viruses, and parasites. Although this repertoire has evolved to target mostly biomolecules, it may potentially contain selective binders to other targets, or it may be expanded to include such binders. Indeed, the injection into mice of cholesterol and 1,4-dinitrobenzene [30, 31] microscopic crystals, as well as C_{60} conjugated to bovine thyroglobulin [32] have resulted in the generation of antibodies against these materials by the immune system of the injected animal. Here, the scope of the system is expanded, and it is shown that human antibody libraries – specifically, single-chain Fv (scFv; [33]), which are the antibody variable binding domains – contain specific binders, capable of discriminating between different crystalline facets of a GaAs semiconductor crystal, which is an almost flat target and unfamiliar to the immune system. This selectivity is remarkable given the very simple structure of semiconductors compared with biomolecules.

By using phage display technology, the *in-vitro* isolation of scFv that bind GaAs (1 1 1A) facets almost 100-fold better than GaAs (1 0 0). is demonstrated. More generally, this finding implies that antibody molecules may find application in the assembly of nanoelectronics [1, 6, 8], in the production of templates for localizing nanoparticles [34], or for biosensors [35].

The isolation of short peptides that bind inorganic materials has been demonstrated for gold [36, 37], silver [38], silica [39], metal oxides [40, 41], minerals [42], CNTs [43], and various semiconductors [44–46]. Of these reports, Ref. [46] is particularly relevant to the present section, as the authors report the isolation of peptides (by phage display) that bind GaAs (1 0 0) preferentially to GaAs (1 1 1A) and (1 1 1B). However, all assays in Ref. [46] probed the peptides displayed on the phages rather than the free peptides. Indeed, when one of these peptides was later synthesized and applied to GaAs [47], no selectivity was found between the (1 0 0) and (1 1 0) facets (see Figure 5 in Ref. [47] and the following discussion).

As this discrepancy was difficult to comprehend, attention was towards studying the non-specific binding of M13 phages (which carried no peptides or antibodies) to GaAs (1 0 0), GaAs (1 1 1A) and GaAs (1 1 1B). As a consequence, M13

was found to bind preferentially to the (1 0 0) facet through its coat protein (Figure 1S, supplementary material to Ref. [9]). As those phages were identical to the library phages used in Ref. [46], and given the lack of selectivity displayed by the only free peptide tested thus far [47], it seemed that further experiments with free peptides would be needed in order to either confirm or disprove semiconductor facet recognition by short peptides. In contrast to Ref. [46], the present antibodies were also tested and found to be selective towards crystal orientation when detached from the phage.

The 7- and 12-mer peptides used in most *in-vitro* selections of binders to inorganic crystals are typically too short to assume a stable structure. Antibodies on the other hand, display a rigid three-dimensional (3-D) structure which is potentially essential for high-affinity selective binding [30, 31]. Moreover, the recognition site in the latter case involves six amino acid sequences grouped into three complementarity-determining regions (CDR). All together, these CDRs form a large, structured binding site spanning up to 3×3 nm. The critical role of the antibody 3-D structure for the recognition of organic crystal facets is well established [30, 31].

Another hint to the importance of rigidity for facet recognition is provided by the rigid structure characterizing antifreeze peptides that target specific ice facets [48]. It has also been shown that the stable helical structure of a 31-mer peptide catalyzing calcite crystallization is essential for inducing directed crystal growth along a preferred axis [49], possibly due to its differential binding to the various facets. Hence, structure rigidity may turn central to facet recognition by biomolecules, thereby underscoring the importance of antibody libraries as a promising source for selective binders.

Selective binding to specific crystalline facets can be directly utilized for numerous micro- and nanotechnological applications, including the positioning of nanocrystals at a well-defined orientation, governing crystal growth and forcing it to certain directions [49], and positioning nanometer-scale objects at specific sites on a substrate marked by certain crystalline facets. An application of one of these soluble antibodies to the latter task is demonstrated in Figure 9.10. By using conventional photolithography and $H_3PO_4 : H_2O_2 : H_2O$ etching, a long trench has been defined on a GaAs (1 0 0) substrate in the (1 1 0) direction (Figure 9.10a). Due to the slow etching rate of phosphoric acid in the (1 1 1A) direction, the process leads to slanted (1 1 1A) side walls and a flat (1 0 0) trench floor (Figure 9.10a). A SEM image of a cut across the trench, and proving that the slanted walls are indeed tilted in the (1 1 1A) direction (54.7° relative to the (1 0 0) direction), is depicted in Figure 9.10b. When the isolated scFv antibodies are applied to the GaAs substrate they attach themselves selectively to the (1 1 1A) slopes.

In order to image the bound antibody molecules, they were targeted with anti-human secondary antibodies conjugated to a fluorescent dye, Alexa Fluor. As shown in Figure 9.10c, fluorescence is limited solely to the (1 1 1A) slopes with practically no background signal coming from the (1 0 0) surfaces. Control experiments depleted of the scFv fragments exclude possible artifacts such as the natural fluorescence of the (1 1 1A) facets, selective binding of the fluorescent dye, or secondary antibodies to that facet.

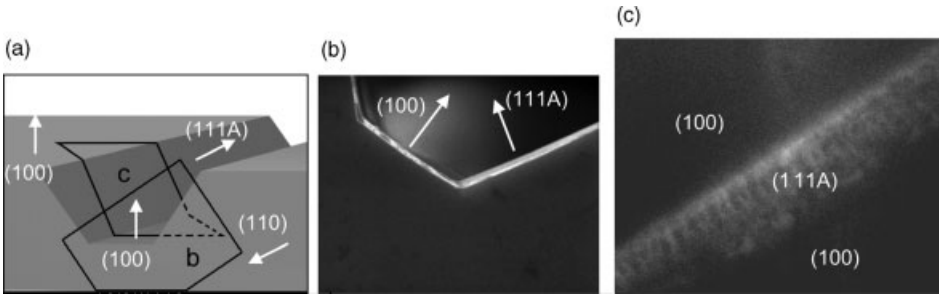

Figure 9.10 (a) Diagrams of the etched trench labeled with the various crystalline facets. The black frames correspond to the views depicted in panels (b) and (c). (b) SEM image of a cut across the trench. (c) Fluorescence image of the trench viewed from the top. Fluorescence is confined to the (1 1 1A) slopes, proving selective binding of the scFv fragments to that facet. Note the negligible binding of antibody molecules to the (1 0 0) facets. (Reprinted from Ref. [9]; © 2006, American Chemical Society.).

The images in Figure 9.10 prove that the selected scFv antibody molecules recognize and bind selectively GaAs (1 1 1A) as opposed to GaAs (1 0 0). As such, they can be used to localize practically any microscopic object on (1 1 1A) surfaces, with negligible attachment to other crystalline facets. The isolation of such binders using phage display technology, and the quantification of their selectivity, is described in the following section.

The Ronit1 scFv antibody phage library [50] used in the present study, is a phagemid library [51] comprising 2×10^9 different human semi-synthetic single-chain Fv fragments, where *in-vivo*-formed CDR loops were shuffled combinatorially onto germline-derived human variable region framework regions of the heavy (V_H) and light (V_L) domains.

To select scFv binders to GaAs (1 1 1A), approximately 10^{11} phages ($\approx$100 copies of each library clone) were applied to the semiconductor crystal (panning step). After washing the unbound phages, the bound units were recovered by rinsing the sample in an alkaline solution. The recovered viruses were then quantified by infecting bacteria and plating dilution series on Petri dishes. The amplified sublibrary was applied again to the target crystal facet, and so on. Typically, three to four panning rounds were required to isolate excellent binders to the target. As is evident from Figure 9.11, the number of bound phages retrieved from the semiconductor grew 300-fold when panning was repeated three times. For comparison, the non-specific binding of identical phages (M13) carrying no scFv fragments remained low throughout the selection process. It was found experimentally that blocking with milk was essential to prevent the non-specific binding of phages to the GaAs targets. Interestingly, as shown in the supplementary material to Ref. [9], in the absence of blocking against non-specific binding (a step missing in Ref. [46]), the non-specific binding of phages through their coat protein to GaAs (1 0 0) was larger than to GaAs (1 1 1A). The data in Figure 9.11 prove the selection of increasingly better binders to GaAs (1 1 1A), but provide no indication of selectivity with respect to GaAs (1 0 0).

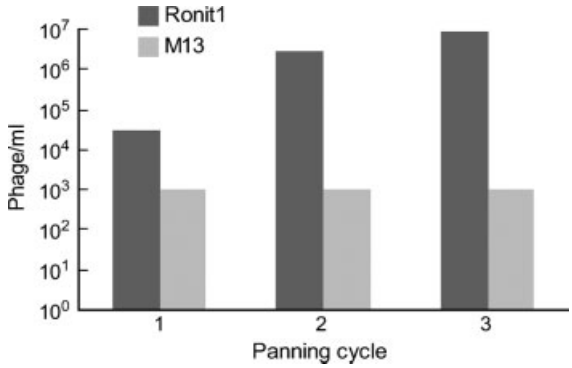

Figure 9.11 Enrichment of anti-GaAs (1 1 1A) phages carrying scFv fragments versus panning cycle. Phage concentration has been deduced by counting colonies of *E. coli* bacteria infected with different dilutions of the phages recovered after each cycle. The monotonic increase in binding of phages carrying scFv (Ronit1) is contrasted with the much weaker, non-specific binding of similar phages lacking the scFv antibody. The value of the latter (1000 phages mL^{-1}) sets an experimental upper limit on their binding; the actual values are likely to be smaller. (Reprinted from Ref. [9]; © 2006, American Chemical Society.).

Indeed, as indicated by the two left-hand columns of Figure 9.12, application of the polyclonal population of binders selected on GaAs (1 1 1A) to GaAs (1 0 0) shows similar binding to the latter crystalline facet. Hence, the process described above produced good, but non-selective, binders.

Preferential binding to a given crystalline facet was achieved by a slight modification of the process. The phages recovered from the first panning on GaAs (1 1 1A)

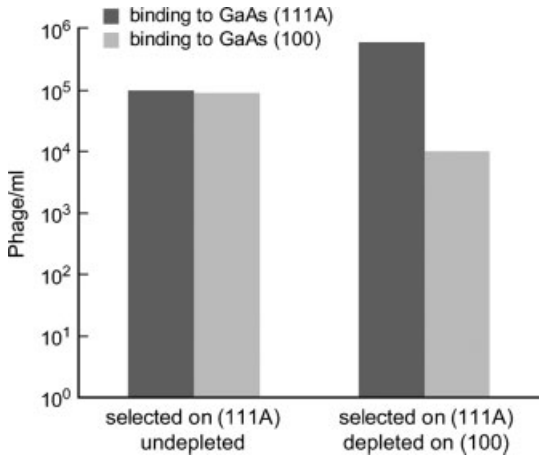

Figure 9.12 Density of recovered binders to GaAs (1 1 1A) after three panning cycles. The two right-hand (or left-hand) columns correspond to selection on GaAs (1 1 1A) with (or without) depletion on GaAs (1 0 0). (Reprinted from Ref. [9]; © 2006, American Chemical Society.).

were amplified in *E. coli* and then applied to GaAs (1 0 0). However, this time the *unbound* phages were collected and applied in a second panning step to GaAs (1 1 1A). As evident from the two right-hand columns of Figure 9.12, the "depletion" step on GaAs (1 0 0) is enriched for specific phage clones that both bind GaAs (1 1 1A) and lack binding to GaAs (1 0 0). On this occasion, binding of the selected phages to the (1 1 1A) facet was almost 100-fold higher than to the (1 0 0) facet. This depletion step, which was crucial to the present case, was missing in Ref. [46].

The polyclonal population of selected phages contains different scFv fragments, each characterized by different affinity and selectivity to the two crystalline facets. In order to correlate specificity with sequence, the binding selectivity of the individual clones was next analyzed. Monoclonal binders were isolated by infecting *E. coli* bacteria with the sublibrary and plating them on solid agar. As each bacterium can be infected by a single phage, all bacteria within a given colony carry DNA coding for the same scFv fragment. Infection of the colony with helper phages resulted in the release of phages displaying the same scFv on their PIII coat proteins. The isolated monoclonal phages were then analyzed with ELISA against GaAs (1 1 1A) and (1 0 0). The sequences of the light (V_L) and heavy (V_H) CDRs of ten monoclonal binders that were identified by the ELISA assay can be found in Ref. [9] and its supplementary material, together with a discussion of their main features.

Figures 9.11 and 9.12 correspond to the scFv fragments displayed on phage particles. For practical applications (such as that demonstrated in Figure 9.10) it is preferable to have soluble monoclonal scFv fragments detached from the phage coat proteins. The results of the ELISA assays of the scFv fragment of Figure 9.10, in its soluble form, are presented in Figure 9.13.

In Figure 9.13, bars 1–6 correspond to the six ELISA assays on GaAs (1 1 1A) and GaAs (1 0 0) pieces, each of 4×4 mm. After washing the substrates, the bound antibodies were reacted with anti-human horseradish peroxidase (HRP), and the binding was quantified by adding tetramethylbenzidine (TMB) as a colorimetric substrate, and reading the resulting optical density (OD) at 450 nm. Bars 7–9

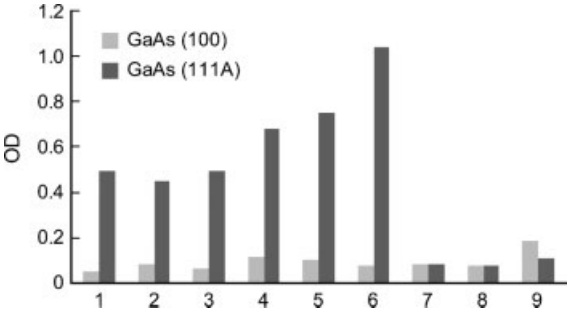

Figure 9.13 Bars 1–6 display the results of six comparative ELISA assays of the scFv molecule (detached from the phage) on GaAs (1 1 1A) and GaAs (1 0 0) substrates. The optical density (OD) reflects the number of bound molecules in arbitrary units. Bars 7–9 display the results of three control experiments (see text), and can be used to estimate the background signal (ca. 0.1 OD) coming from sources, other than selective binding of the scFv to the semiconductor substrates. (Reprinted from Ref. [9]; © 2006, American Chemical Society.).

provided the following controls. Bars 7 quantified the non-specific binding of the secondary anti-human HRP to the ELISA plate in the absence of the EB scFv and semiconductor substrates. Bars 8 corresponded to the non-specific binding of the scFv to the plate, and bars 9 to non-specific binding of the secondary antibodies to the semiconductor substrates.

The background ELISA signal, depicted by bars 7–9, accounts for most of the GaAs (1 0 0) signal in columns 1–6. When subtracting this background from columns 1 to 6, a remarkable preference is found to GaAs (1 1 1A) compared with (1 0 0). Interestingly, the binding of the secondary antibody to GaAs (1 0 0) was almost twice as large compared to its binding to GaAs (1 1 1A), in opposition to the selectivity of the isolated scFv fragments. Overall, the data in Figure 9.13 prove that the isolated scFv preserves its selectivity also when detached from the phage.

Little is known of the interaction between biomolecules and inorganic surfaces, let alone the recognition of such surfaces by antibody molecules. The GaAs surface is modified by surface reconstruction, oxidation, and possibly other chemical reactions. Moreover, it displays atomic steps and possibly surface defects. It is therefore difficult to estimate how much of the underlying crystalline order manifests itself in the recognition process. Unfortunately, as no experimental tools capable of determining these parameters with atomic resolution exist at present, the recognition mechanism is unclear, except for the accumulating indications of the importance of structural rigidity (as discussed in the introduction to this section). The discrimination between the two crystalline facets may reflect the different underlying crystalline structures, they may stem from the different surface chemistries of the two facets, or they may result from global properties such as atom density and different electronegativity. The latter factor has been found to be important for the differential binding of short peptides to different semiconductors [47]. The abundance of positively charged amino acids in the heavy chain of CDR1 and CDR3 and the light chain of CDR1 may indicate an affinity to the exposed gallium atoms. The negatively charged amino acid in CDR3 V_L (missing in anti-gold scFv isolated from the same library) combined with the positively charged CDR3 V_H may match the polar nature of GaAs.

The recognition of man-made materials by antibodies opens new opportunities for a *functional* interface between biology and nanotechnology, far beyond what was has been exercised to date.

9.4
Molecular Shift-Registers and their Use as Autonomous DNA Synthesizers [11]

9.4.1
Molecular Shift-Registers

The DNA-templated assembly of elaborate circuits requires distinct dsDNA molecules with non-recurring sequences. For the assembly of periodic structures, such as memories, a segment of non-recurring sequences should be replicated to form a periodic molecule, and the synthesis of such molecules presents a remarkable

challenge to biotechnology. The two existing strategies for generating long molecules, namely PCR [52] and ligase assembly [53], utilize synthetic oligonucleotides which together span (with overlap) the full length of the desired molecule. Hence, when following any of these strategies, the assembly of an N-base long molecule with distinct p-long segments requires $O(N/p)$ oligonucleotides. These approaches therefore quickly become impractical when a rich variety of distinct molecules or addresses along a given molecule are needed for the construction of an elaborate template for molecular electronics [1, 5]. Motivated by the concept of DNA-templated electronics, the present author and colleagues were therefore forced to invent an exponentially more economic synthesis strategy based on the chemical realization of molecular SRs. The dramatic reduction in synthesis effort by SRs is facilitated by exploiting a novel concept in DNA synthesis; a sliding overlapping reading frame. Rather than the fixed frame that directs segment ligation or polymerization in the two schemes listed above or in hairpin-based DNA logic [54, 55] and programmed mutagenesis [56], the SRs utilize a previously synthesized sequence to dictate synthesis of the next bases. The automaton is an example of DNA computing where the result of the computation (tape) is a useful molecule.

An autonomous binary p-shift register (p-SR) is a computing machine with 2^p internal states represented by an array of p cells (Figure 9.14a), each occupying one bit, $x_i\,\{i = 1 \ldots p\}$. In each step a binary function, $f(x_1, x_2, \ldots x_p)$, is computed and its value is inserted into cell p. Simultaneously, x_j is shifted to cell $j-1$; $\{j = 2 \ldots p\}$. On printing x_1 to a tape, a long periodic binary sequence is generated. Electronic SRs are utilized in many applications including secure communication, small signal recovery, and sequence generation [57]. Here, it is shown that molecular SRs can be realized and utilized for the autonomous synthesis of DNA molecules the sequence of which is uniquely determined by a chemical embodiment of the function $f(x_1, x_2, \ldots x_p)$.

Consider a 3-SR with $x_{n+1} = f(x_{n-2}, x_{n-1}, x_n) = x_{n-2} \oplus x_n$ ($\oplus \equiv$ XOR) and an initial setting (seed) $x_1, x_2, x_3 = 001$. Repetitive application of f generates the sequence 001110100111010.... The sequence is periodic with a period seven and any of the seven $L \geq 3$ bit long consecutive strings in a period is different from the rest. In general, it is well known [57] that for any p, a SR can be found a with a linear feedback function [58], $f = \sum_{i=1}^{p} \alpha_i x_i; \alpha_i \in \{0, 1\}$ (the sum is mod 2), that generates a sequence

of maximal period $2^p - 1$ bits with no repetition of strings of lengths $L \geq p$ within a period. Such SRs are termed "maximal linear SRs" as they generate all possible permutations of a p-long sequence except the zero string [59]. Functions, f, can always be found such that the number of non-vanishing α_i is smaller than p (in the example above, $\alpha_2 = 0$). Consequently, $2^p - 1$ different addresses can be generated by an exponentially smaller truth table and, hence, as shown below, by an exponentially smaller synthesis effort compared with direct synthesis of all addresses.

We now show how to implement an autonomous molecular SR using DNA. Imagine a DNA molecule for which the Watson–Crick rules are that 1 binds exclusively to its complementary bit, $\bar{1}$, but not to 1, 0 or $\bar{0}$. Similarly, 0 binds to $\bar{0}$ but not to 0, $\bar{1}$, or 1. We translate the function $f(x_1, x_2, x_3) = x_1 \oplus x_3$ to an equivalent truth table (left three columns in Figure 9.14b) and embody it by the mixture of the seven [59] possible four-bit rule strands, $(\bar{x}_1, \bar{x}_2, \bar{x}_3, (\overline{x_1 \oplus x_3}))$, listed in the right-hand column of Figure 9.14b.

The SR sequence is generated by thermally cycling a mixture containing the seven rule strands, a "seed" strand (e.g., the strand 001), and a polymerase. For simplicity, it is assumed that the rule strands are synthesized with ddDNA at their 3′ end and are therefore not elongated in the process. Each cycle comprises annealing, extension, and melting steps. In the first annealing step, some of the first, $\bar{0}\bar{0}\bar{1}\bar{1}$, rule strands bind to seed molecules, leaving an $\bar{1}$ overhang (Figure 9.15, steps i and ii) which is readily copied by the polymerase in the extension step (Figure 9.15, step iii). Next (Figure 9.15, step iv), the temperature is raised to 95 °C and the rule strand dissociates from the elongated seed (tape). In the second annealing step, a $\bar{0}\bar{1}\bar{1}\bar{1}$ rule strand binds to the tape (Figure 9.15, step v), leaving again an $\bar{1}$ overhang which is readily copied by the polymerase (Figure 9.15, step vi). At each additional cycle (Figure 9.15, steps vii–x) some

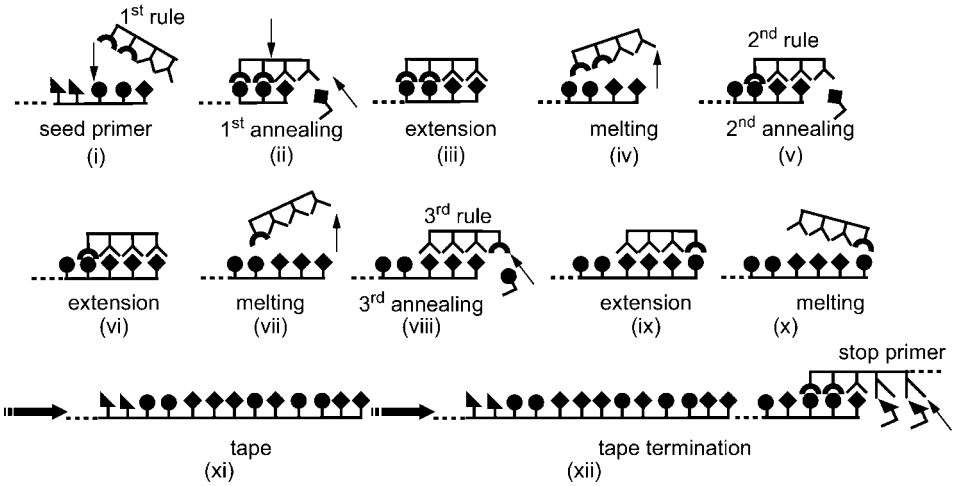

Figure 9.15 The principle of the shift register. ◆ ◠ ● ◠ represent 1, $\bar{1}$, 0, $\bar{0}$, respectively. ◣ ◥ represent sequences other than 0 or 1 and their complementary sequences, respectively. (Reprinted from Ref. [11]; © 2006, American Physics Society.).

of the tape molecules are elongated by one bit according to the rule $x_{n+1} = x_n \oplus x_{n-2}$. Elongation is terminated by addition of excess stop primers that intercept the tape molecules as soon as the latter display a desired tail (001 in the example of Figure 9.15 step xii). The polymerase then copies the stop primer and adds its alien sequence to the tape, which is unrecognizable by any rule strand. As a result, elongation terminates. The 5′ seed and 3′ stop primers tails are later used for PCR amplification of the tape. Elongation is guided by a sliding reading frame where all, except the first, shifted bits from the previous reading frame plus a single new bit provide the current reading frame. The sliding frame is the crux of our concept, as it facilitates exponentially smaller synthesis effort compared with any of the previous, fixed-frame approaches.

It should be noted that rule strands are not consumed during synthesis; rather, they only serve as enzymes to direct the reaction. Thus, synthesis in flow may be envisioned, where the rule strands are attached in synthesis order to subsequent segments of a tube or a column. While the reactants flow through the tube the correct sequence is generated, and this strategy is advantageous to straightforward synthesis in a DNA synthesizer as faulty strands are not recognized (and hence not elongated) by rule strands. Clearly, errors are doomed to be short.

Now, an actual demonstration of the concept may be described. In the first implementation each bit is realized by a sequence of three nucleotides, 5′TGC for "0" and 5′GCT for "1". These sequences were chosen as they minimize errors due to one and two base shifts in the annealing step. The demonstration starts with the three-bit maximal SR as discussed above. Such SR requires seven 4-bit (3-bit rules plus one function bit) strands (Figure 9.14b), but in order to suppress synthesis errors longer, redundant 6-bit rules (5-bit rules plus one function bit) are employed. Error suppression by redundancy is discussed in Section 9.4.2. The seven 6-bit rule strands [60] used in the synthesis comprise, $3'\bar{0}0\bar{1}\bar{1}\bar{1}\bar{0}$, $3'\bar{0}\bar{1}\bar{1}\bar{1}0\bar{1}$, $3'\bar{1}\bar{1}\bar{1}0\bar{1}0$, $3'\bar{1}\bar{1}0\bar{1}0\bar{0}$, $3'\bar{1}0\bar{1}0\bar{0}\bar{1}$, $3'\bar{0}\bar{1}0\bar{0}\bar{1}\bar{1}$, $3'\bar{1}\bar{0}\bar{0}\bar{1}\bar{1}\bar{1}$. The complementary bits, $\bar{0}$ and $\bar{1}$, correspond to 3′ACG and 3′CGA, respectively. The rule strands are synthesized with three nucleotides only (G, C, A) in order to prevent their extension by polymerase ("poor man's ddDNA"). The 2/3 GC content gives [61] $\Delta G \approx 8.5 \div 10.5\, k_B T$ free energy per bit (stacking included) which in a 5-bit realization of a 3-bit SR translates ideally to suppression of the error rate by a factor proportional to $\exp(-3\Delta G/k_B T) \leq \exp(-25.5)$ (see Section 9.4.2). The seed strand comprises a 5′ tail followed by a 5-bit sequence [62], 5′GCATGCGCCCGTCAGGCG00111. The tail is later used to amplify the SR sequence by PCR. The seed, the rule strands, and three nucleotides (dGTP, dCTP, dTTP) are mixed together and subjected to 45 thermal cycles [63], after which a stop primer, $3'\bar{0}1\bar{0}\bar{0}1$GACGTC, is added in 10-fold excess compared with each rule strand. During an additional five to ten cycles the tape molecules are further elongated until in some cycle their last five bits read 01001. At that point a stop primer binds to the tape and its complementary sequence is added to the tape by the polymerase. The elongation now terminates as the sequence added by the stop primer is alien to all rule strands. The absence of dATP guarantees single strand synthesis. The expected synthesized sequences read

$$\underset{\text{seed primer}}{5'\text{GCATGCGCCCGTCAGGCG00111}}\,(0100111)_n \mapsto \underset{\text{complementary to stop primer}}{01001\text{CTGCAG}} \quad \text{with } n = 0, 1, \ldots \tag{9.1}$$

Finally, the elongation products are PCR amplified with two primers, identical to the first 19 nucleotides of the seed (5′GCATGCGCCCGTCAGGCGT) and to the last 19 nucleotides of the stop primer (5′CTGCAGAGCGCAGCAAGCG).

The resulting PCR products, when run against a standard ruler in a polyacrylamide gel, are depicted in Figure 9.16a. Four bands corresponding to Equation 9.1 with $n = 0, 1, 2, 3$ are clearly resolved. Sequencing of the four bands with a primer identical to the first 19 nucleotides on the 5′ end of the seed primer proves the bands identification with the respective n values in Equation 9.1. The high fidelity of the automaton is reflected in the perfect matching of the sequencing with Equation 9.1, and the absence of any unexpected bands.

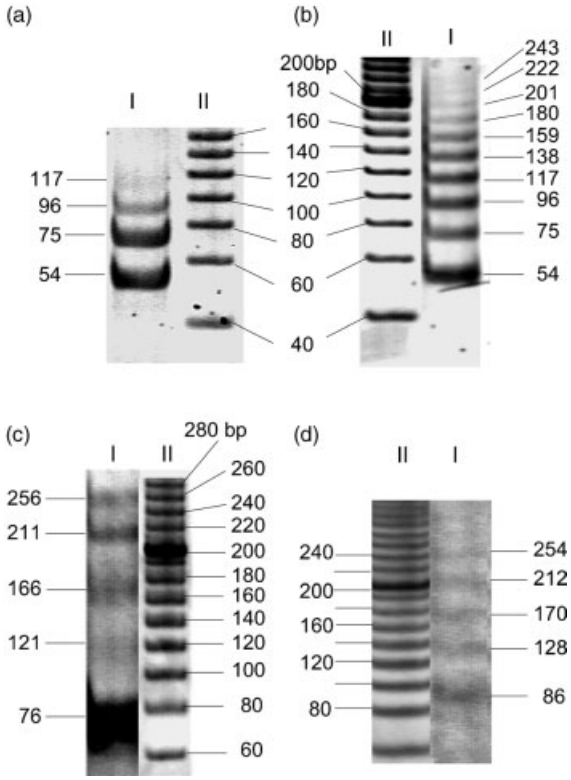

Figure 9.16 (a) Lane I, product after 45 elongation cycles, five cycles with stop primer, and PCR amplification. The four bands correspond to Eq. 9.1 with $n = 0, 1, 2, 3$, namely 54, 75, 96, and 117 base-long sequences. Lane II, ruler. (b) Lane I, same as (a), but with 100 elongation cycles followed by filtering out short sequences (Microcon YM-10; Millipore Corporation, Bedford, MA, USA). Ten bands corresponding to Eq. 9.1 with $n = 0, 1, 2, 3, 4, 5, 6, 7, 8, 9$ are resolved. Lane II, ruler. (c) Four -shift register with 45 bp periodicity realized with 7-bit rule strands; 2 h reaction time at a constant temperature of 72 °C. Lane I, shift register product. The five resolved bands are indicated. Lane II, ruler. (d) Same as (c) for partial 3-shift register with four-letter alphabet. The period comprises 14 bits (42 bp). (Reprinted from Ref. [11]; © 2006, American Physics Society.).

As shown in Figure 9.16b, after 100 elongation cycles it was possible to resolve 10 bands, $n = 0 - 9$, corresponding to 54, 75, 96, 117, 138, 159, 180, 201, 222, and 243 base-long sequences. The automaton thus synthesizes at least 204 bases at a remarkable fidelity. The $n = 9$ sequence comprises 10 periods, each of 21 bases, with exactly one repetition of each 3-bit (or longer) address per period. Direct sequencing of the bands confirmed the results up to $n = 6$. The small material quantities in the higher bands were insufficient for reliable sequencing. As PCR amplification favors shorter sequences, the relative band brightness cannot be taken as a measure for synthesis efficiency of molecules with different n-values.

The synthesis of longer period molecules, as well as of non-binary sequences, is demonstrated in Figure 9.16c and d, and details can be found in Ref. [11]. The synthesis of the last two examples was held in a thermal ratchet mode at a fixed temperature [11].

9.4.2
Error Suppression and Analogy Between Synthesis and Communication Theory

As emphasized in the introduction, errors are intrinsic to molecular assembly. Thus, the invention of error correction and suppression codes is critical for the realization of complex structures. Since the introduction of DNA computing by Adleman [53], the intimate relationship between self-assembly and computation has been slowly revealed. At this point, it may be beneficial to highlight another intriguing link between self-assembly and an engineering concept, this time "communication theory". This link draws an analogy between the synthesis of the long DNA molecule by the SR apparatus and the decoding of a long message transmitted over noisy lines. The addition of a wrong DNA base in synthesis is equivalent in that analogy to the assignment of a wrong value to a bit read in a message. This analogy has far-reaching consequences, as it suggests that some of the powerful strategies developed for suppressing and correcting errors in communication may be adapted to chemical synthesis. One such principle, the addition of degenerate bits to a message, is implemented in the synthesis of DNA molecules by the SRs.

The first stage is to classify any possible synthesis errors. At each annealing step, rule strands other than the correct ones may bind to the tape and affect the SR operation. These events may be divided into two groups: benign, and error. The benign events include all cases where rule strands bind to the tape either with no overhang or with a 2-bit overhang with the correct sequence. In the first case, the particular tape molecule remains idle throughout the cycle, whereas in the latter case it grows by two correct bits. Errors, on the other hand, are generated mostly by annealing of the wrong rule strand, shifted one bit to the right, to form a 2-bit overhang with the wrong sequence. It is easy to verify that, since the maximal register sequence contains all p-bit permutations, an error is manifested in a partial deletion of a period. The same fact guarantees that the tape is always "legal", namely it is available for elongation in the next cycle.

A SR is conveniently represented by a path on a corresponding de Bruijn graph [57], where the nodes depict all distinct internal states and the directed edges connecting them are labeled by the rules, notably by a string comprising the predecessor state plus a function bit. When a p-SR is realized with $p+1$ long rule strands, a maximal linear SR sequence passes exactly once through all nodes, except the zero node. A de Bruijn graph for a 3-SR is depicted in Figure 9.17, with arrows indicating the walk guided by Equation 9.1.

Although an elongation error corresponds to skipping some nodes, synthesis can always proceed as the rule strands recognize all nodes. When a p-SR is realized with rule strands of length $p'+1$; $p'>p$, as is the case here, the sequence passes exactly once through a subset of nodes in the much larger graph corresponding to p'-SRs. In the SR of Figure 9.16a and b, for instance, the 6-bit long rules correspond to a partial walk on de Bruijn graph of order 5 rather than 3. Two types of errors may then occur – a skip to a node in the sequence, or a skip to an alien node. In the first case, synthesis proceeds with partial deletion of the sequence. In the second case, the new node is not recognized by any rule strand and synthesis halts until that node is connected again to the SR sequence by an additional error. In both cases, each additional bit in the rule strands increases the Hamming distance for an error by at least 1 and, hence, suppresses the synthesis error rate by $\sim\exp(-\Delta G/k_BT)$. Optimization of the alphabet minimizes one- and two-base shift errors. Errors other than shifts, including hairpins, require further analysis.

The formation of an unwarranted 2-bit overhang can be minimized with respect to the desired 1-bit overhang by optimizing the temperature. Optimally, the error

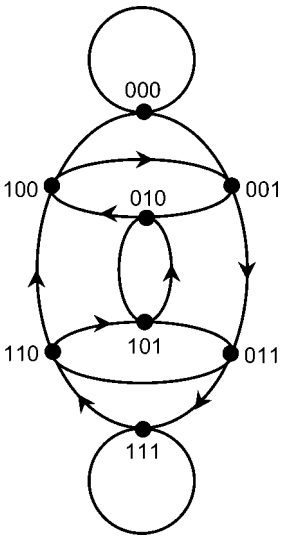

Figure 9.17 de Bruijn graph for a 3-shift register. The maximal path defined by Equation 9.1 corresponds to a walk on the graph (start from node 001 and follow the arrowheads).

rate (the ratio between incorrect and correct annealing) can be reduced in this way to $\approx\exp(-\Delta G/k_BT)$, where ΔG is the corresponding free energy per bit. The error rate may be systematically suppressed by using longer rule strands to generate the same sequence. By using de Bruijn graphs it can optimally be shown that each extra bit can reduce the error rate by an additional factor of $\approx\exp(-\Delta G/k_BT)$. This is the reason for the 6-bit long rule strands used in the realization of the 3-SR. The two extra bits are meant to suppress synthesis errors.

To the best of the present author's knowledge, this is the first incorporation of a redundancy code in chemical synthesis. The analogy drawn between chemical synthesis and transmission of messages over noisy lines suggests further applications of communication theory to chemical synthesis.

9.5 Future Perspectives

In Sections 9.2 to 9.4, a novel concept was outlined, namely the harnessing of the remarkable assembly strategies and tools of molecular biology to the self-assembly of molecular-scale electronics. Central issues such as instilling biomolecules with electrical conductance, molecular lithography for patterning metallization and localizing devices on DNA templates, the direct recognition of electronically relevant man-made objects by biomolecules, and the economic synthesis of DNA molecules characterized by non-recurring sequences have now been resolved to a point where the formidable challenge of complex self-assembly can be faced with confidence. However, harnessing the power of bioassembly presented here to the realization even of simple circuits requires more than mere optimization of the tools developed to date. As argued above, complex self-assembly will require a hierarchical, modular approach and, hence, the development of molecular switches that test for electronic functionality and feed back on the bioassembly process. Such switches will involve a functional interface between molecular biology and electronics, namely the ability of biomolecules to read electronic signals presented to them by the assembled devices and circuits, and then to effect the assembly process based on those findings. Only then can a full merging of biology and electronics be achieved.

Acknowledgments

The concepts and tools described in this chapter have been developed over the past decade by a significant group of researchers at Technion – Israel Institute of Technology. The author is especially grateful to Erez Braun, Kinneret Keren, Yoram Reiter, Arbel Artzi, Stav Zeitzev, Ilya Baskin, and Doron Lipson, whose contributions were immeasurable. Different areas of the research were funded by the Israeli Science Foundation, Bikura, the fifth EU program, the German Israeli DIP, the Rosenbloom family, and the Russell Berrie Nanotechnology Institute.

Formation of Nanostructures by Self-Assembly

Melanie Homberger, Silvia Karthäuser, Ulrich Simon, and Bert Voigtländer

10.1
Introduction

The increasing demand for high-density electronic devices has triggered – and continues to trigger – the development of new nanofabrication methods. Two conceptually different strategies are applied for the fabrication of nanostructures, namely: (i) the *top-down* strategy; and (ii) the *bottom-up* strategy.

The *top-down* approaches utilize lithographical methods to fabricate nanostructures starting from the bulk materials (see Chapters 5, 6, and 7), whereas in the *bottom-up* approaches nanostructures are built up from atoms, molecules, or nanoscale sub-units. The *top-down* methods enable the generation of a large variety of defined structures, but these are limited by the resolution of current lithography techniques. The *bottom-up* methods offer the opportunity to fabricate structures even in the single-digit nanometer range, but they suffer from the fact that it is still a great challenge to direct the functional sub-units into desired structures. One extreme approach in this context is the utilization of a scanning probe microscope for building up nanostructures atom by atom at low temperatures (see Chapter 9). However, although this approach is ultimate in terms of the size of the nanostructures, it is a very slow and sophisticated method. Compared to this method, processes based on self-organization or self-assembly have the key advantage that they enable the formation of billions of nanostructures with control over size, shape, and composition in a fast and parallel fashion. Due to entropic effects during the formation of nanostructures by self-assembly, defects are expected always to be present, and fault-tolerant architectures are required to cope with this problem. The combination of the self-assembly of atoms, molecules and nanoscale subunits could lead to well-ordered functional nanostructures. For example, inorganic nanostructures, generated by the self-assembly of atoms via epitaxial growth, may serve as templates for the selective adsorption of functional molecules, which themselves display "anchor-points" at which size-selected clusters could be attached, altogether leading to highly ordered functional nanostructures with applications in molecular electronics. One critical

ISBN: 978-3-527-31738-7

factor determining the benefits of this approach for electronic systems will be the surface-selective SAM formation – that is, the selective assembly of functional molecules on special device patterns forming an ordered array. In this context, in the following chapter attention is focused on the formation of nanostructures by self-assembly via epitaxial growth, the self-assembly of molecules, and the formation and self-assembly of nanoscale subunits. Basic physical principles and selected examples will be presented.

10.2 Self-Assembly by Epitaxial Growth

One approach for the fabrication of nanostructures is *epitaxial growth*. Such growth usually occurs under kinetic conditions, so that the sizes can be tuned down to the single-digit nanometer range by choosing appropriate growth conditions. However, size uniformity is the greatest challenge here. If the growth is taking place under (near) equilibrium conditions, then the size distribution of the nanostructures may be narrow, but is provided by the material system and cannot be varied easily. The formation of islands, wires and rods will be presented as examples of nanostructures grown by epitaxy. Subsequently, the growth of nanostructures on template substrates structured by step arrays or underlying dislocation networks will be considered. The combination of self-organized growth with lithography ("hybrid methods") allows the self-assembled nanostructures to be aligned relative to predefined patterns. It is possible that such inorganic nanostructured templates may be used in the future for the selective formation of molecular layers.

10.2.1 Physical Principles of Self-Organized Epitaxial Growth

10.2.1.1 Epitaxial Growth Techniques

The main methods used for semiconductor epitaxial growth are chemical vapor deposition (CVD) [1] and molecular beam epitaxy (MBE) [2, 3]. In CVD, growth gases containing compounds of the elements to be deposited are introduced into the growth chamber. When the gas molecules hit the substrate surface, they decompose (partially) and the gaseous products desorb from the surface. Different chemical reactions taking place at the surface, or even in the gas phase, lead to a quite complex nature of the fundamental processes of epitaxial growth in CVD. Molecular beam epitaxy is conceptually simpler; here, the elements to be deposited are heated in evaporators until they evaporate, whereupon the beam of the atoms hits the surface and the atoms diffuse over the surface and finally bind at surface lattice sites (Figure 10.1).

In spite of the fact that the MBE growth is, in principle, much easier than the CVD growth, there are still many different fundamental processes occurring during epitaxial growth by MBE [4]. Part of these are illustrated schematically in Figure 10.1. Atoms from the molecular beam arrive at the surface of the crystalline substrate (a)

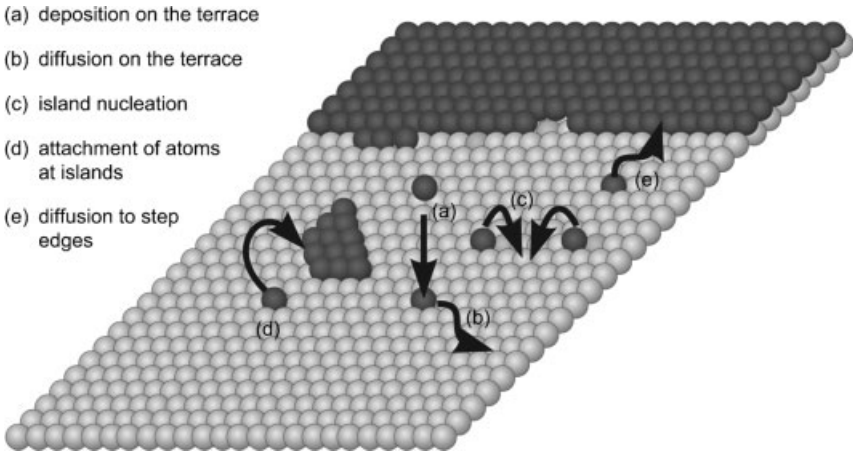

Figure 10.1 Scheme of different fundamental processes occurring during epitaxial growth, leading to a self-organization of two-dimensional islands.

and may diffuse over the surface when the activation energy for diffusion is overcome (b). When two atoms (or sometimes also more than two atoms) meet, they form a nucleus for a stable island (c). Such a nucleus may grow to a stable two-dimensional (2-D) island by attachment of further diffusing adatoms (d). The nucleus for which the probabilities to grow or decay are equal is called the *critical nucleus* [5]. Nuclei which are larger than the critical nucleus are termed stable 2-D islands, while nuclei smaller than the critical nucleus are called subcritical nuclei or *embryos*. Another process is the diffusion and attachment at pre-existing steps if the diffusion length is sufficient (e).

10.2.1.2 Kinetically Limited Growth in Homoepitaxy

In kinetically limited growth the system is governed by energetic barriers such as barriers for the diffusion of adatoms and barriers for incorporation of atoms into the crystal, and additionally by outer conditions such as the growth rate. The 2-D islands (which are one atomic layer high) represent the simplest example of the self-assembled growth of nanostructures. In the following section it will be shown how the density and size of these islands can be controlled by the kinetic parameters temperature and growth rate. First, the deposition temperature influences the island density strongly, as shown by the comparison of Figure 10.2a and b. The island density as function of temperature follows an Arrhenius law: $n \sim \exp(E_{\mathrm{act}}/kT)$, where E_{act} is an effective activation energy consisting of a diffusion energy and binding energy component, having values around 1 eV in the case of semiconductors [5]. The temperature is one important parameter of growth kinetics, and the deposition rate is another. It has been found that the island density (n) scales with the deposition rate (F) in the form of a power law $n \sim F^{\alpha}$, with a scaling exponent α. Combining the temperature and the rate dependence results in the following scaling law: $n \sim F^{\alpha}$

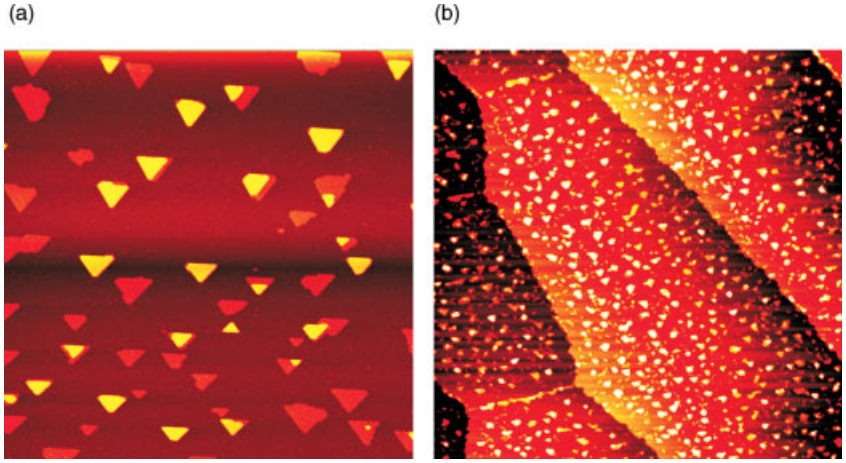

Figure 10.2 Scanning tunneling microscope images after the growth of 0.2 atomic layers of silicon on a Si(1 1 1) surface. The islands have triangular shape due to the symmetry of the substrate, and have a height of one atomic layer (orange) or two atomic layers (yellow). The island density depends on the temperature, as can be seen by comparison of growth at high temperatures of 770 K (a) to growth at a lower temperature 610 K (b). Both images have a size of 350 nm.

$\exp(E_{\mathrm{act}}/kT)$ [5], which shows that the island density can be controlled over a wide range by adjusting the kinetic growth parameters of temperature and growth rate. The average island distance is simply the square root of the inverse of the island density $L = 1/\sqrt{n}$.

Although the nucleation of the islands is a random process, the distribution of the island sizes is centered around a mean value (Figure 10.3). This arises due to a saturation of the island nucleation, as will be explained in the following. During the early stage of growth (nucleation regime), the islands nucleate randomly on the surface and the distance between them decreases. If the distance between the islands is equal to the mean distance that an adatom travels before a nucleation event happens, then the incorporation of adatoms in existing islands becomes a more probable event than the nucleation of new islands; hence, a "capture zone" forms around each island. Adatoms deposited in this capture zone attach to the corresponding island. Without this effect the distribution of island sizes would be even broader. The nucleation of further islands is suppressed beyond a certain coverage (growth regime), and the average island size can be controlled by the deposited amount. The island size distributions for two different temperatures are shown in Figure 10.3, where it can be seen that the peak in the island size distribution scales towards larger sizes with higher temperatures. For very small islands, the surface reconstruction can also modify the island size distribution [4]. In the kinetic growth regime the island density of 2-D islands can be controlled by the kinetic parameters temperature and deposition rate, while the size distribution is quite broad due to the stochastic nature of the nucleation of the islands.

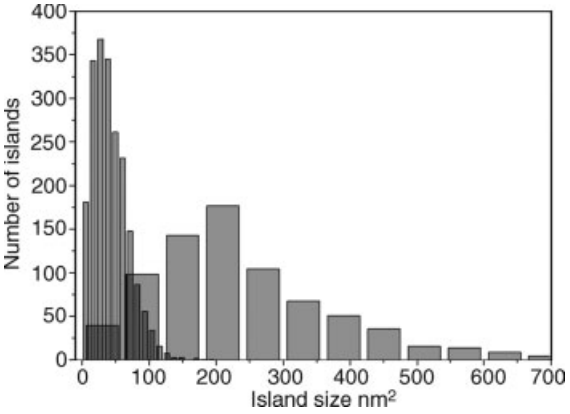

Figure 10.3 Island size distribution for two-dimensional Si islands on Si(1 1 1). The width of the distribution is of the order of the average size of the islands. Two distributions for two different temperatures are displayed. The narrow bins (peak at small island sizes) correspond to deposition at 610 K. The distribution with the wide bins peak at larger island sizes) corresponds to deposition at 710 K.

10.2.1.3 **Thermodynamically Stable Nanostructures**

If nanosized islands were to be thermodynamically stable, their size distribution could be narrow. A thermodynamically stable island size means that the energy (per atom) has a minimum for this stable size. For configurations with larger or smaller islands, the energy (per atom) would be higher, and therefore it only necessary to approach thermodynamic equilibrium in order to obtain a very narrow island size distribution. One way to achieve thermodynamic equilibrium is to heat a sample with different island sizes present and then to wait until equilibrium has established. The equilibrium configuration will be established by material transport between the islands, as the atoms will detach from islands with higher energy and attach to islands with a lower energy (per atom). However, as will be shown below, in the simplest case (considering only a surface or edge energy term) the thermodynamically stable island size is infinitely large. This behavior is not of any use for the formation of nanostructures with a narrow size distribution, and corresponds to the well-known Ostwald ripening. Only if additional terms in the energy are important (e.g., strain energy) will the energy per particle show a minimum for a finite particle size, while a narrow size distribution can be expected under equilibrium conditions.

In order to describe material transport in a system with a variable number of atoms, the chemical potential is used; this is the change of the energy (of an island) when the number of particles changes $\mu = \mathrm{d}E/\mathrm{d}N$. During the equilibration process atoms detach from islands where the chemical potential is highest, and attach to islands with a lower chemical potential. This lowers the total energy of the system, and consequently the material transport between different islands is governed by the chemical potential. A simple example is the chemical potential of quadratic 2-D islands of dimension L (Figure 10.4a). The energy difference between different-sized islands

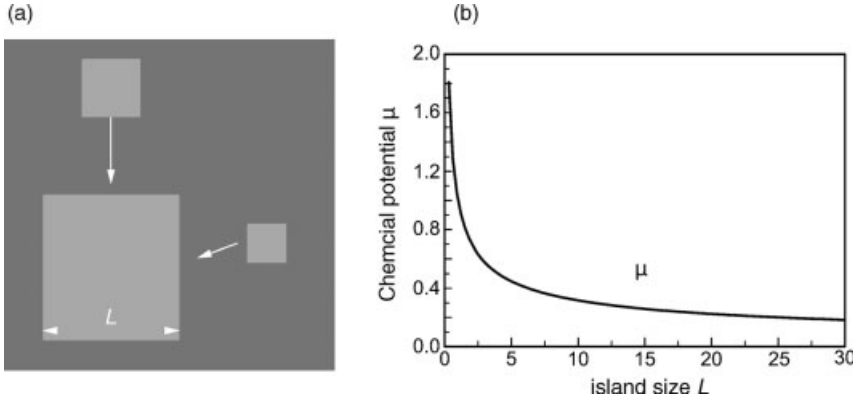

Figure 10.4 (a) Coarsening of a large island at the expense of small islands. (b) The chemical potential of an island.

comes from the edge energy (β is the edge energy per length). The energy of an island is $E = E_{\text{edge}} = 4\,L\beta$. The number of atoms in an island (N) depends on the dimension L, as $N = L^2/\omega$, with ω being the area per atom. The chemical potential is then

$$\mu = \frac{dE}{dN} = \frac{2\omega\beta}{L} \sim \frac{1}{L} \tag{10.1}$$

Since μ is decreasing for larger islands, infinite size islands have the lowest chemical potential (Figure 10.4b), which means that the stable island is infinitely large. In this case, the equilibration does not result in a stable finite island size; equilibration in this model by material transport between islands is also referred to as *coarsening* because it results in the shrinkage of small islands and a growth (coarsening) of large islands (Ostwald ripening).

An infinitely large stable island size is the result for homoepitaxial growth, taking into account only the edge energy. However, the situation becomes different when elastic stress is also taken into account, as it occurs in heteroepitaxy where two different materials grow onto each other. Here, stress is induced by the different lattice constants of the substrate material and the material of the islands. The elastic effect of strained 2-D islands can be approximated by that of a surface-stress domain – that is, the surface stress at the area of the island is different from that at the rest of the surface (Figure 10.5). The strain energy of a quadratic surface-stress domain can be calculated using the elastic theory as $E_{\text{strain}} = 2LC\ln L$ [6]. Adding the step edge energy results in a total energy of a strained island:

$$E = E_{\text{edge}} + E_{\text{strain}} = 2L[2\beta - C'\ln L] \tag{10.2}$$

This results in the following chemical potential:

$$\mu = \omega\left[\frac{2\beta - C'}{L} - \frac{C'}{L}\ln L\right] \tag{10.3}$$

which is illustrated in Figure 10.5. In this case, the chemical potential has a minimum at the size $L_{\min} = \exp(2\beta/C')$, which would mean that during coarsening the islands

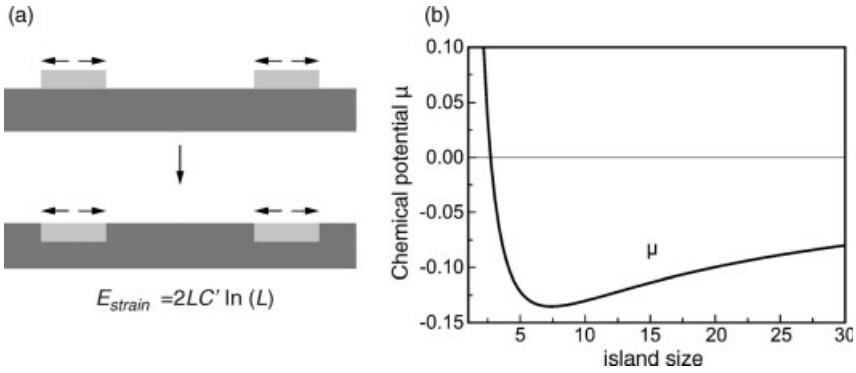

Figure 10.5 (a) The elastic stress induced by two-dimensional islands with a different lattice constant than the substrate can be approximated by surface stress domains. (b) Chemical potential of an island with an energy component due to elastic strain included.

would approach this size. Larger islands would dissolve and smaller islands grow until all islands have the size $L_{\min}$, that is, the lowest chemical potential, and this would result in a very narrow size distribution. Unfortunately, step energies are only very poorly known, so that it is not possible to predict a reliable number for the equilibrium island size. An experimental realization of thermodynamically stable islands has not yet been confirmed, apart from surface reconstructions with a relatively large unit cell.

If the formation of nanostructures in equilibrium is compared to the formation of nanostructures by growth kinetics, the following advantages and disadvantages occur. Nanostructures grown under equilibrium conditions have (under specific conditions) the advantage of a narrow size distribution around the optimum size. However, a disadvantage is that the size is determined by the material parameters (strain energy and step edge energy for instance), and cannot be tuned freely. The size and density of nanostructures formed under kinetic conditions can be tuned easily by variations of the growth parameters such as growth rate and temperature. On the other hand, the size uniformity of the islands grown under kinetic conditions is relatively poor.

10.2.1.4 **Nanostructure Formation in Heteroepitaxial Growth**

Semiconductor nanostructures can be fabricated by self-organization using heteroepitaxial growth, which is the growth of a material B on a substrate of different material A. In heteroepitaxial growth, the lattice constants of the two materials are often different. The lattice mismatch for the two most commonly used material systems, Si/Ge and GaAs/InAs, is 4.2% and 7%, respectively (shown schematically in Figure 10.6a). This lattice mismatch leads to a build-up of elastic stress in the initial 2-D growth in heteroepitaxy. In the case of Ge heteroepitaxy on Si, the Ge is confined to the smaller lattice constant of the Si substrate – that is, the Ge is strained to the Si lattice constant (Figure 10.6b). One way to relax this stress is via the formation of three-dimensional (3-D) Ge islands, in which only the bottom of the islands is

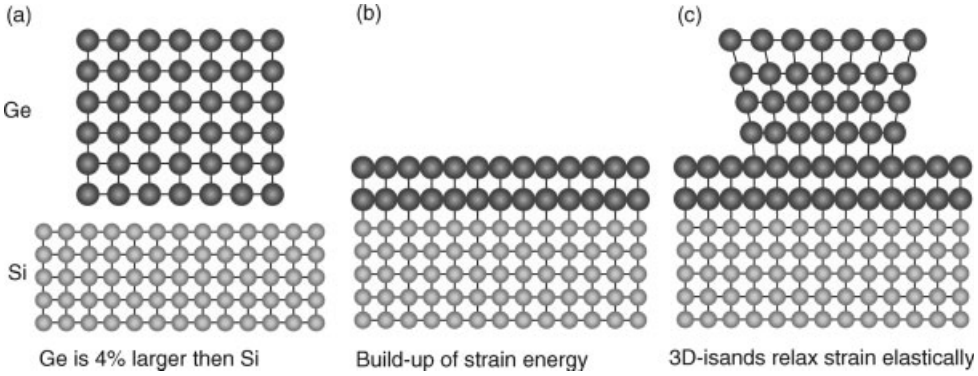

Figure 10.6 (a) Schematic representation of Si and Ge crystals with different lattice constants. (b) Build-up of elastic strain energy during 2-D growth with Ge confined to the Si lattice constant, and (c) elastic relaxation by the formation of 3-D islands (Stranski–Krastanov growth). In the upper part of the 3-D island the lattice constant relaxes towards the Ge bulk constant. The usual form of the 3-D islands is a pyramid, and not like that shown in this schematic.

confined to the substrate lattice constant. In the upper part of the 3-D island the lattice constant can relax to the Ge bulk lattice constant and reduce the stress energy in this way (Figure 10.6c). This growth mode, which is characterized by the formation of a 2-D wetting layer and the subsequent growth of (partially relaxed) 3-D islands, is referred to as the Stranski–Krastanov growth mode, some examples are which are described shown in Section 10.2.2.

The driving force for the formation of self-organized nanoislands in heteroepitaxial growth is the build-up of elastic strain energy in the stressed 2-D layer. As a reaction to this, a partial stress relaxation by the formation of 3-D islands can lower the free energy of the system. The process of island formation close to equilibrium is a trade-off between elastic relaxation by the formation of 3-D islands, which lowers the energy of the system, and an increase of the surface area, which increases the energy.

In a simple model, where the islands are cubes with the length x, the additional surface energy for a film in an island morphology (compared to a strained film) is proportional to the island length squared (x^2). The gained elastic relaxation energy compared to that of a flat film is, in the simplest assumption, proportional to the volume of the island (x^3). For the same total volume in the film, the energy difference between the 3-D island morphology and the flat morphology is

$$\Delta E = E_{\text{surf}} - E_{\text{relax}} = C\gamma x^2 - C'\varepsilon^2 x^3 \tag{10.4}$$

where γ is the surface energy, ε is the lattice mismatch, and C and C' are constants. The contributions of E_{surf}, E_{relax} and the total energy difference between the 3-D island morphology and a flat film are shown in Figure 10.7, as a function of the island size x. For small sizes of the 3-D islands, the 3-D island morphology is unfavorable up until the point where the absolute value of the gained elastic relaxation energy ($\sim x^3$) becomes larger than the cost of the surface energy ($\sim x^2$). For islands larger than a

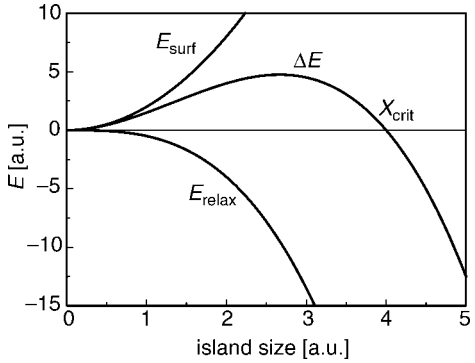

Figure 10.7 Energy difference between a film of flat 2-D morphology and a film morphology consisting of 3-D islands. The total energy difference and the contributions surface energy difference and relaxation energy are plotted.

critical island size, x_{crit}, the formation of 3-D islands is energetically preferred over the 2-D film morphology. While this simple model shows the basic driving forces for the 2-D to 3-D transition, it contains several simplifications. For example, in this simple model the island morphology is assumed as being cuboid, which does not correspond to the experimentally observed island shapes. Further, the simple model contains only energetic considerations of two final states. Kinetic effects, such as the required material transport necessary during the 2-D and 3-D transition are not considered.

Apart from the formation of 3-D islands, there is another process which can partially relax the stress of a strained 2-D layer, namely the introduction of misfit dislocations. This corresponds to the removal of one lattice plane of a compressively strained 2-D layer. If a lattice plane is removed in regular distances in the 2-D layer, then a misfit dislocation network forms. Depending on the growth parameters of temperature and growth rate, the self-organized growth can either be close to equilibrium or in the kinetically limited regime. At close to equilibrium (i.e., at high growth temperatures or low deposition rates), the occurring morphology (strained layer, 3-D islands, or a film with dislocations) is determined only by the energies of the particular configurations, and the morphology with the lowest energy will be formed. If the growth is kinetically limited, then the activation barriers are important. For instance, an initially flat strained layer can transform to a morphology with 3-D islands or to a film with dislocations. Yet, what actually happens depends on the kinetics of the growth process – that is, on the activation energy for the formation of 3-D islands compared to the activation energy for the introduction of misfit dislocations.

10.2.2 Semiconductor Nanoislands and Nanowires

10.2.2.1 Stranski–Krastanov Growth of Nanoislands

Stranski–Krastanov growth occurs, for example, in InGaAs/GaAs growth [7]. An example of InAs nanoislands grown on a GaAs substrate is shown in the transmission

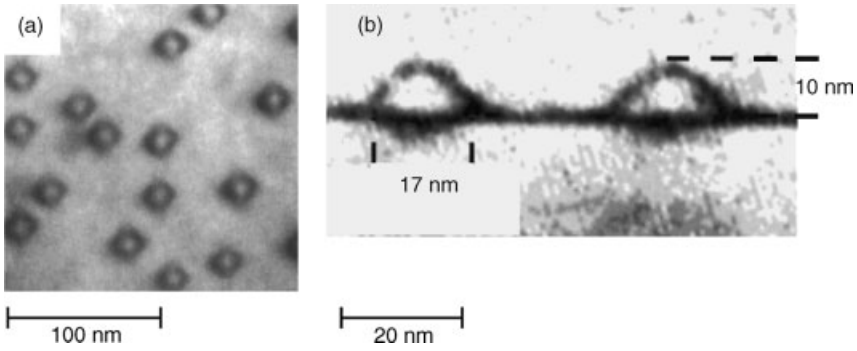

Figure 10.8 InAs nanoislands grown on a GaAs surface. (a) As imaged by plan-view transmission electron microscopy (TEM); (b) cross-sectional view with TEM [7].

electron microscopy (TEM) image in Figure 10.8. The GaAs islands were grown by MBE at a growth temperature of 775 K, and the density of the islands was 4.5×10^{10} cm^{-2}, with an average lateral size of 17.5 ± 0.5 nm. The challenges in the growth ofthese semiconductor islands are to grow islands of desired size and density, and with a high size uniformity. As in the case of the 2-D islands, a higher growth temperature generally leads to the formation of larger islands, while a higher growth rate leads to the formation of smaller islands. The size of the islands increases with coverage; often, the density of the islands saturates during an early stage of the growth. These are general trends which may depend on the material system and the particular deposition technique. In some cases (self-limiting growth), the size of the islands saturates while the density increases with coverage, and this type of growth mode leads to a high size uniformity of the islands. The size uniformity achieved in self-assembled growth of semiconductor islands may be as small as a small percent. The confinement of charge carriers in all three directions gives rise to atomic-like energy levels. Quantum dot lasers operating at room temperature have now been realized [8]. The islands grown on a flat substrate are usually not ordered laterally due to the random nature of the nucleation process. In the following section, it will be shown how nucleation at specific sites can be achieved.

10.2.2.2 Lateral Positioning of Nanoislands by Growth on Templates

An example of ordered nucleation at a prestructured substrate is shown in Figure 10.9a [9], where Ge islands nucleate above dislocation lines. However, when a SiGe film is grown on a Si(0 0 1) substrate, dislocations form at the interface between the SiGe film and the substrate. The driving force for the formation of dislocations is the relief of elastic strain, which arises due to the different lattice constants between the Si substrate and a Ge/Si film on this substrate. During annealing, the dislocations form a relatively regular network, due to a repulsive elastic interaction between the dislocations. The preferred nucleation of Ge islands above the dislocation lines (Figure 10.9a) can be explained by local stress relaxation above the dislocation lines providing a lattice constant closer to the Ge one. The nucleation does not occur

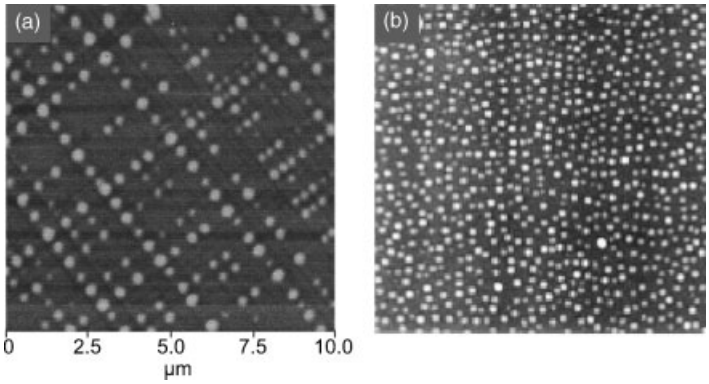

Figure 10.9 (a) Ordered nucleation of Ge islands on a template which is pre-structured by an underlying network of dislocations. (b) Germanium islands grown on a substrate without dislocations [9]. Image sizes 7 μm.

randomly at the surface, but rather occurs simultaneously at sites which have the same structure. This leads to a more narrow size distribution than that for the growth on unstructured Si(0 0 1) substrates (Figure 10.9b).

10.2.2.3 **Silicide Nanowires**

If the crystal structure of the deposited material is different from that of the substrate, then effects related to the anisotropic match of both crystal structures may appear. If the overlayer material has a crystal structure which is closely lattice-matched to the substrate along one major crystallographic axis, but has a significant lattice-mismatch along the perpendicular axis, this should allow unrestricted growth of the epitaxial crystal in the first direction but limit the width in the other direction. Such a strategy has been applied to grow silicide nanowires [10]. Here, the substrate is a Si(1 0 0) surface (Si has diamond crystal structure), and by deposition of Er and subsequent annealing, $ErSi_2$-oriented crystallites with a hexagonal AlB_2-type crystal structure were formed on the Si substrate. The [0 0 0 1] axis of the $ErSi_2$ was oriented along a $[\bar{1}\,1\,0]$ axis of the Si(0 0 1) substrate, and the $[1\,1\,\bar{2}\,0]$ of the $ErSi_2$ was oriented along the perpendicular [1 1 0] axis, with lattice mismatches of $+6.5\%$ and -1.3%, respectively; this almost satisfies the proposed growth conditions for nanowires. $ErSi_2$ nanowires grown on the Si(1 0 0) surface are shown in Figure 10.10. The $ErSi_2$ nanowires align along one of the two perpendicular $<1\,1\,0>$ Si directions, which are the small mismatch directions. In these directions the crystal can grow without much build-up of stress, while the width of the $ErSi_2$ nanowire is $\sim$4 nm, the height $\sim$0.8 nm, and the length is several hundred nanometers. Such self-assembled arrays of nanowires may also be used as conductors for defect-tolerant nanocircuits, or as a template for further nanofabrication.

10.2.2.4 **Monolayer-Thick Wires at Step Edges**

Monolayer-high surface steps can be used to fabricate Ge nanowires using step-flow growth. Here, pre-existing step edges on the Si(1 1 1) surface are used as templates for

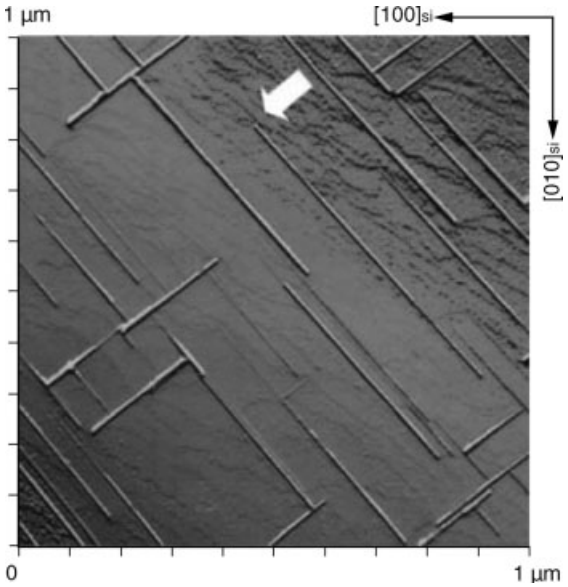

Figure 10.10 Scanning tunneling microscopy (STM) topograph showing $ErSi_2$ nanowires grown on a flat Si(0 0 1) substrate. The long direction of the nanowires is the one with the low lattice mismatch (1.3%), while the lattice mismatch in the perpendicular direction is 6.5%.

the growth of 2-D Ge wires at the step edges. When the diffusion of the deposited atoms is sufficient to reach the step edges, the deposited atoms are incorporated exclusively at the step edges, and the growth proceeds by a homogeneous advancement of the steps (step flow growth mode [4]. If small amounts of Ge are deposited, then the steps will advance only a few nanometers and narrow Ge wires can be grown.

One key issue for the controlled fabrication of nanostructures consisting of different materials is a method of characterization which can distinguish between the different materials on the nanoscale. If the surface is terminated with a monolayer of Bi, it is possible to distinguish between Si and Ge [11]. Figure 10.11a shows a scanning tunneling microscopy (STM) image after repeated alternating deposition of 0.15 atomic layers of Ge and Si, respectively. Due to the step-flow growth, the Ge and Si wires are formed at the advancing step edge. Whilst both elements can be easily distinguished by the apparent heights in the STM images, it transpired that the height measured by the STM was higher in areas consisting of Ge (red stripes) than in areas consisting of Si (yellow stripes). The apparent height of the Ge areas was $\sim$0.1 nm higher than that of the Si wires (Figure 10.11b), and the cross-section of a 3.3 nm-wide Ge nanowire was seen to contain only approximately 20 atoms (Figure 10.11c). The apparent height difference arises due to an atomic layer of Bi which is deposited initially and always floats on top of the growing layer. The different widths of the wires can easily be achieved by depositing different amounts of Ge and Si.

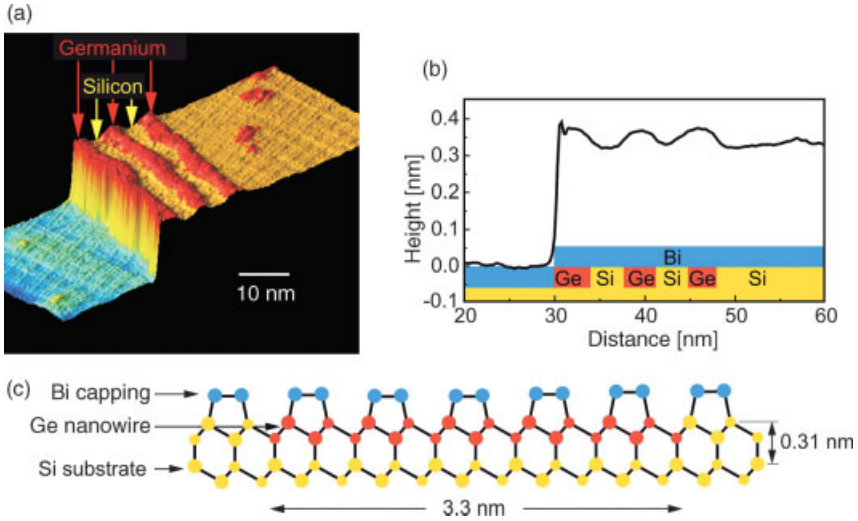

Figure 10.11 (a) STM image of 2-D Ge/Si nanowires grown by step-flow at a pre-existing step edge on a Si(1 1 1) substrate. The Si wires (yellow) and Ge wires (red) can be distinguished by different apparent heights. (b) A cross-section across the nanowires. (c) The atomic structure of a Ge wire on the Si substrate capped by Bi. The cross-section of the Ge wire contains only approximately 20 Ge atoms [11].

10.2.3
Hybrid Methods: The Combination of Lithography and Self-Organized Growth

In hybrid methods, self-organization is combined with lithographic patterning to form nanostructures on a smaller scale than are accessible by lithography. Most importantly, the hybrid methods provide a direct contact of nanostructures formed by self-organization to mesoscopic lithographically patterned structures. The self-organized growth of Ge islands in oxide holes is shown in Figure 10.12a–d. The starting surface is a silicon substrate with a thin oxide layer at the surface, and electron lithography is used to remove the oxide and form holes of a diameter of 0.5 μm where the bare Si surface is exposed [12]. The self-organized growth of Ge leads to the formation of Ge islands which may be smaller than the size scale of the electron beam lithography (EBL). The gas-phase growth of Ge is selective; that is, Ge will only grow on Si areas (inside the holes in the oxide), and not on the oxide itself. Figure 10.12 illustrates the nucleation of Ge islands in the holes in the oxide for different growth temperatures. At lower temperatures, the island density is so large that several islands nucleate in one oxide hole. However, if the temperature is increased, ultimately only one Ge island is able to nucleate in each oxide hole, and the size of the Ge island is smaller than the lithographically defined oxide hole. However, as seen in Figure 10.12d, the position of the Ge island inside the oxide hole is not defined but is rather randomly distributed within the oxide hole. Due to the fact that

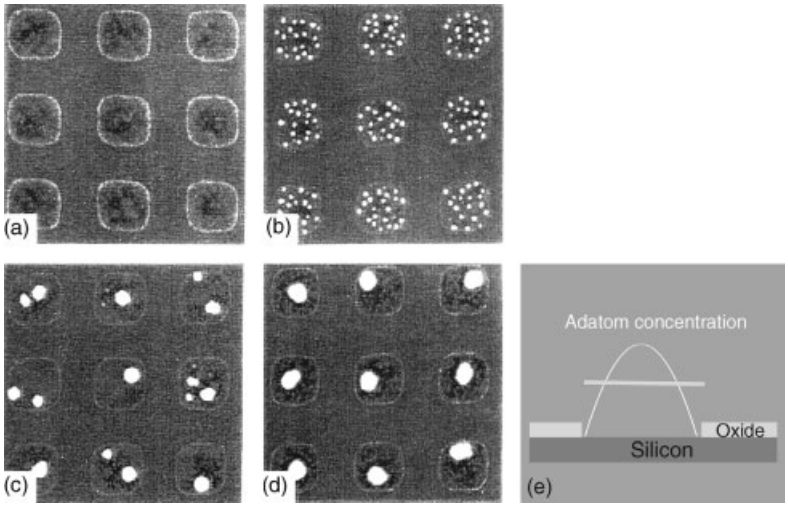

Figure 10.12 (a–d) Growth of Ge islands inside holes on an oxidized Si substrate [12]. (e) Adatom density in an oxide hole for those cases where the hole edges are sinks of adatoms (parabolic line), or for the case when the edges are not sinks for adatoms (horizontal line).

the Ge does not grow on the oxide, the edges of the oxide hole cannot serve as sinks for deposited Ge atoms, and therefore the Ge adatom concentration is homogeneous across the hole and nucleation of the Ge island is random within the oxide hole. If the edges of the hole were to serve as sinks for Ge atoms (e.g., if the edges of the hole were to consist of Si), then the adatom density would have a maximum at the center of the hole and the nucleation of Ge islands would occur preferentially at the center of the oxide holes (Figure 10.12e).

10.2.4
Inorganic Nanostructures as Templates for Molecular Layers

Several of the nanostructures discussed here can potentially be used as templates for the selective formation of molecular structures onto specific areas of the inorganic nanostructures generated by the self-assembly of atoms via epitaxial growth. The importance of the inorganic substrate for the formation of molecular layers, which is discussed in detail in the following section, is manifold. The role of the inorganic nanostructured template for the molecular self-assembly may be to steer the adsorption process kinetically, and to direct the molecules towards predefined adsorption sites. The first steps in this direction have been taken recently. Initially, special substrate surfaces were selected in accordance with their ability to adsorb molecules. For example, substrates with only weak adsorption properties are useful for molecular assemblies with weak intermolecular interactions, because such substrates allow for the necessary reorganization of molecules. In addition, it is

necessary that the interatomic distances at the substrate surface correspond to the dimensions of molecular structure elements. One example of such an substrate, which allows for a weak adsorption of polycyclic aromatic compounds is the Ag/Si(1 1 1)-$\sqrt{3}\times\sqrt{3}$R30° surface (Figure 10.13a). This surface is described by the honeycomb-chain-trimer model, in which each surface Si atom is bound to one Ag atom. This structure is derived from a Si(1 1 1) bulk termination by removing the top half of the first bilayer of Si atoms, forming trimers from the remaining Si atoms, and then adding a full monolayer of Ag atoms in positions slightly distorted from the regular triangular lattice (Figure 10.13a). An STM image of this structure is shown in Figure 10.13b. In this empty states image (+1.6 V sample bias), the bright protrusions correspond to the center of three Ag atoms (Ag trimers indicated by A in Figure 10.13b), and the minima in this image, indicated by B, correspond to the Si trimers). In the following, for simplicity, this surface is represented by a hexagonal network also indicated in Figure 10.13a. A supramolecular 2-D honeycomb network,

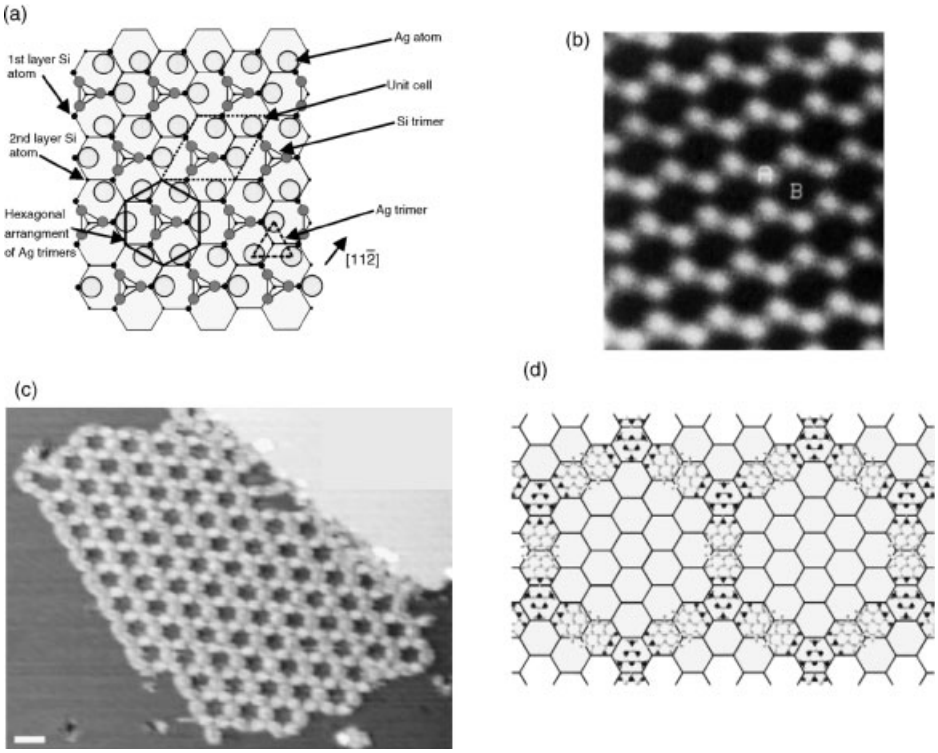

Figure 10.13 (a) Schematic showing the honeycomb-chain-trimer model for the Ag/Si (1 1 1)-$\sqrt{3}\times\sqrt{3}$R30° reconstruction [14]. STM image (empty states, +1.6 V sample bias) of the Ag/Si(1 1 1)-$\sqrt{3}\times\sqrt{3}$R30° substrate surface. The bright protrusions correspond to the center of three Ag atoms (image size 3 nm) [15]. (c) STM image of the hexagonal molecular network (see also Section 10.3.3) [13]. Scale bar = 3 nm. (d) Schematic diagram showing the registry of the molecular network with the underlying Ag/Si (1 1 1)-$\sqrt{3}\times\sqrt{3}$R30° surface reconstruction shown as hexagons.

with a larger periodicity (five times that of the Ag/Si(1 1 1)-$\sqrt{3} \times \sqrt{3}$R30° lattice constant; see Figure 10.13d) has been created by the assembly of two types of molecule on the Ag-terminated silicon surface [13]. This hexagonal molecular network is shown in Figure 10.13c, and is discussed in detail in Section 10.3.3. The registry of the molecules with respect to the underlying silver-terminated Si surface has been determined, and is shown schematically in Figure 10.13d. The calculated melamine–melamine separation has a near-commensurability with the surface lattice, showing the importance of the underlying inorganic template for the formation of the supramolecular structure.

In the future, the selective bonding of molecular species to inorganic template structures, which would enable site direction, will also represent a major challenge for the successful combination of inorganic templates and molecular structures.

10.3 Molecular Self-Assembly

Self-assembly is a bottom-up technique that uses the self-organization capabilities of molecular building blocks – that is, the ability to rearrange continuously until a complete ordered monolayer of molecules is formed – to assemble desired nanostructures. As a result of the self-assembly process, the molecular constituents form an ordered structure with a minimum global energy on well-defined, atomically flat surfaces. The term "molecular self-assembly" is reserved for the adsorption of molecular constituents onto surfaces and the spontaneous organization into regular arrangements. If only non-covalent interactions are used to direct the molecular constituents into the resulting surface pattern, these structures are termed "supramolecular" (supramolecular chemistry = the chemistry of the intermolecular non-covalent bond [16]). On the other hand, the term "self-assembled monolayer" (SAM) is reserved, according to Whitesides [17], for a 2-D film with the thickness of one molecule that is attached to a solid surface through covalent bonds.

The surface properties of metals, metal oxides or semiconductors can be changed in a desired way by the adsorption of SAMs onto these materials. Therefrom, a number of useful applications result, such as: (i) the modification of adhesion and wetting control [18]; (ii) an increase in corrosion resistance [19]; or (iii) the development of heterogeneous chiral catalysts [20]. By exploiting the chemical properties of the organic molecules used, additional functionalities can be created, and consequently the development of chemical sensors [21] and chemical force microscopy [22], the site-selective adsorption of nanoscale subunits (see also Section 10.4.2), or the fabrication of electronic devices [23, 24], is possible. Additionally, SAMs themselves are nanostructures with nanoscale dimensions useful in nanolithography [25]. Supramolecular surface patterns on the other hand can be used to create nanocavities, to provide well-defined reaction spaces, and they may also control host–guest chemistry or steer heterogeneous catalysis [26]. Further details of the present state of molecular self-assembly on planar substrates are provided in a series of reviews [20, 26–30].

10.3.1
Attaching Molecules to Surfaces

Bare surfaces of metals and metal oxides tend to adsorb organic materials because the adsorbates lower the free energy of the interface between the respective material and the ambient environment. The character of the chemical bond between the adsorbed molecules and the metal surface determines the interfacial electronic contact and the strength of the geometric fixation. Two main groups of links between molecules and solids can be distinguished: (i) covalent bonds, which result from the overlap of partially occupied orbitals of interacting atoms; and (ii) non-covalent bonds, which are based on the electrical properties of the interacting atoms or molecules.

Planar molecules with extended π-systems have been found to physisorb onto surfaces, such as highly oriented pyrolytic graphite (HOPG), Au(1 1 1), Cu(1 1 0), in a flat-lying geometry. This allows functional groups at the molecular periphery to approach each other easily and to build up intermolecular interactions, predominantly comprising hydrogen bonds and metal–ligand interactions. If the molecules are sufficiently mobile to diffuse on the surface, then the intermolecular interactions will guide the adsorbed molecules into 2-D supramolecular systems. Then, by adjusting the molecular backbone size and the position or number of the functional "recognition groups", complex supramolecular nanostructures can be designed [31].

Covalent bonds are established, if there is a significant overlap of the electron densities of the molecules and the metal, and this will result in a strong electronic and structural coupling. The spontaneous formation of SAMs on substrates through covalent bonds requires organic molecules with a chemical functionality or "headgroup" and a specific affinity for a selected substrate. There exists a number of headgroups, which bind to specific substrates forming directed covalent links. One frequently used covalent link is the bond between a thiol group on the molecular site and a noble metal substrate. Here, gold is favorable due to its proper non-oxidizing surface, although thiol or selenol bonds are also possible to Ag, Pt, Cu, Hg, Ge, Ni, and even semiconductor surfaces. The reason for the great success of the S–Au bond is its good stability at ambient temperature, and the ease of reorganization to form an ordered array. Both are elementary requirements for the building up of a self-assembled monolayer.

Besides the prominent thiolates, other functional molecules, such as alcohols (ROH) or acids, have been demonstrated to form organized monolayers on metals or metal oxide surfaces, such as Al_2O_3, TiO_2, ZrO_2, or HfO_2. SAMs of alkylchlorosilanes ($RSiCl_3^-$) and other silane derivatives require hydroxylated surfaces as substrates for their formation. The driving force for this self-assembly is the *in-situ* formation of polysiloxane, which is connected to surface silanol groups (−SiOH) via robust Si−O−Si bridges [32]. Substrates on which these monolayers have successfully been prepared include silicon oxide, aluminum oxide, quartz, glass, and mica.

During the past few years, significant advances have been made by coupling alkenes and alkines onto Si and Si−H surfaces. The covalent coupling of vinyl compounds on H-terminated silicon yields very stable Si−C covalent bonds [33], and recently a method for the direct assembly of aryl groups on silicon and gallium

arsenide using aryl diazonium salts has also been developed. There is a spontaneous ejection of N_2 and direct carbon–silicon formation [34], but the C−Si bonds are so strong that a facile reconstruction in order to form a highly ordered SAM is implausible.

10.3.1.1 Preparation of Substrates

For the deposition of a SAM, a 2-D film with a thickness of one molecule, a high-quality surface with a very low surface roughness is required. Depending on any further use of the SAM, the quality of the surface must be adapted. For example, if the SAMs are applied as etch resists, protection layers, chemical sensors or model surfaces for biological studies, then polycrystalline films will mostly suffice as substrates. In contrast, if the properties of the SAMs themselves are to be studied in detail, such as their organization, structure or electronic properties, then oriented single crystalline surfaces are required as substrates.

Planar substrates for SAMs are either thin films or single crystals of metals, semiconductors, or metal oxides. Thin films can be grown on silicon wafers, glass, single crystals or mica by CVD, physical vapor deposition (PVD), electrodeposition, or electroless deposition. Metal films on glass or silicon are polycrystalline and composed of grains that can range in size from 10 to 1000 nm.

As pseudo "single crystals", thin films of metals on freshly cleaved mica are commonly used. Gold films grow epitaxially with a strongly oriented (1 1 1) texture on the (1 0 0) surface of mica. The films are usually prepared by thermal evaporation of gold at rates of 0.1–0.2 nm s^{-1} onto a heated (400–650 °C) sample [35]. By using an optimized two-step process, a surface roughness down to 0.4 nm over areas of 5×5 μm can be achieved [36]. Surfaces with almost comparable roughness can be created by a method known as "template stripping" [37]. Here, a glass slide or a silicon wafer is glued to the exposed surface of a gold film on mica, and subsequently the gold film is peeled from the mica to expose the surface that had been in direct contact with the mica. Typically, these methods result ultimately in surface roughnesses of 1 nm over areas of 200×200 nm^2. For fundamental studies of SAMs by ultra-high vacuum (UHV) methods, single-crystal metal substrates provide the highest quality with respect to surface roughness, orientation, and cleanliness. These substrates result in densely packed SAMs of the highest order.

10.3.1.2 Preparation of Self-Assembled Monolayers

In principle, there are two possibilities of preparing SAMs, namely deposition from solution, and deposition from the vapor phase. For deposition from solution, a clean, freshly prepared substrate is immersed into a highly diluted solution of the corresponding organic molecules. After only a few minutes of immersion, a dense molecular monolayer is built; however, to ensure that the film reaches equilibrium the substrates are kept in solution for several hours to allow reorganization (Figure 10.14). In particular, the structure of the adsorbate determines the highest achievable density of the SAM on a given surface, or whether a SAM can be formed at all. The other parameters, such as solvent, temperature, concentration and immersion time, should be chosen adequately to achieve the best possible result. The

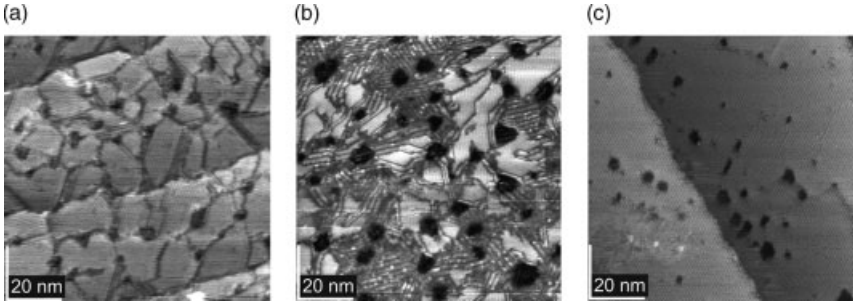

Figure 10.14 (a) Dodecanethiol SAM grown from solution. (b) SAM grown from solution. A 6.5-h annealing step at 78 °C in solution leads to a partial desorption of the dodecanethiol molecules, and results in the striped lying-down phase of alkanethiols [38]. (c) SAM grown from vapor phase. The domains extend over the whole gold terrace.

advantages of this method are the simplicity of the equipment and the ease of preparation.

In the case of alkanethiols on Au(1 1 1), the annealing procedure at elevated temperatures to increase the quality of the films has been studied extensively. Annealing the SAMs in a diluted solution of their molecules for short periods at 80 °C often results in a reduction in the number of vacancy islands, and an enlargement of the domain sizes due to *Ostwald ripening*. This behavior is explained by an intralayer diffusion of monovacancies towards larger holes, which grow at the expense of smaller holes. Furthermore, some vacancy islands diffuse towards the gold step edges and annihilate there, which explains the decrease in area occupied by the vacancy islands. In addition, the conformational defects in the SAMs decrease, and this will result in a higher order.

In the case of gas-phase deposition, UHV systems with base pressures in the range of 10^{-5} to 10^{-7} mbar are used. The amount of deposited molecules is controlled by the pressure, the temperature and the time. Vapor deposition has the advantage that absolutely clean surfaces can be used, a good control of the amount of deposited molecules is possible, and the SAM can be transferred to an analyzing tool without breaking the vacuum. By applying this method, submonolayers and highly ordered monolayers of extreme size can be created (Figure 10.14).

10.3.1.3 **Preparation of Mixed Self-Assembled Monolayers**

Mixed SAMs – that is, SAMs built up from different organic molecules and showing a well-defined structure – can be created in several ways; however, the two most widely used approaches will be described here.

The first method is coadsorption from solutions containing mixtures of selected organic molecules, and results in mixtures of molecular structures (Figure 10.15). This process allows the formation of SAMs with widely varying compositions and physical properties [39, 40].

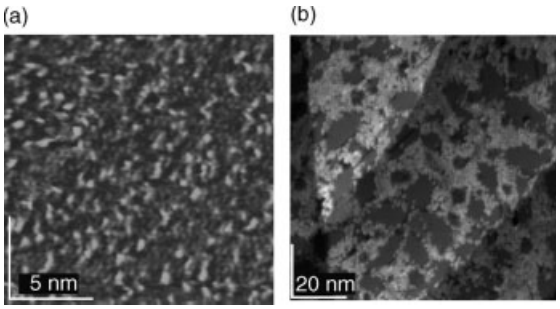

Figure 10.15 Scanning tunneling microscopy images of mixed monolayers. (a) By coadsorption of 11-mercaptoundecanoloctanethiol (=1:3) from solution [40]. (b) By insertion of a biphenylbutanethiol derivate into a closely packed SAM of dodecanethiol on Au(1 1 1). The film shows separate domains of the biphenylbutanethiol derivate (which appear higher) and dodecanethiol [43].

The second method is a two-step deposition process which begins with a full coverage monolayer of one organic species, which is used as the host matrix [41–43]. In a second step, the substrate covered with this host-matrix is immersed into the solution of an organic molecule of interest. Insertion of this "guest-molecule" takes place preferentially at defect sites such as pin holes or domain boundaries in the host matrix. The rate-determining step is the replacement of host molecules by guest-molecules. Depending on the immersion time, domains of inserted molecules, bundles or even single guest molecules can be identified in the resulting mixed monolayer (Figure 10.15). A well-ordered surrounding matrix can be used as the reference system for the analysis of the structural and electrical properties of the inserted molecules. This matrix-isolation method, in combination with scanning probe microscopy (SPM) techniques, is suitable for investigating series of organic molecules in order to determine new physical properties.

10.3.2 Structure of Self-Assembled Monolayers

The structure of SAMs is widely studied using spectroscopic methods including optical ellipsometry, reflectance absorption infrared spectroscopy (RAIRS), X-ray photoelectron spectroscopy (XPS), low-energy electron diffraction (LEED), and high-resolution electron energy loss spectroscopy (HREELS). In particular, the development of near edge X-ray absorption fine structure spectroscopy (NEXAFS) has led to new insights into the structure of SAMs. In addition, an increased understanding of the SAM structures has been achieved by the development and intense use of high-resolution topographic methods such as SPM.

During the self-assembly of organic molecules on planar substrates, complex hierarchical structures are formed involving multiple energy scales and multiple degrees of freedom (Figure 10.16). The geometric arrangement of organic molecules

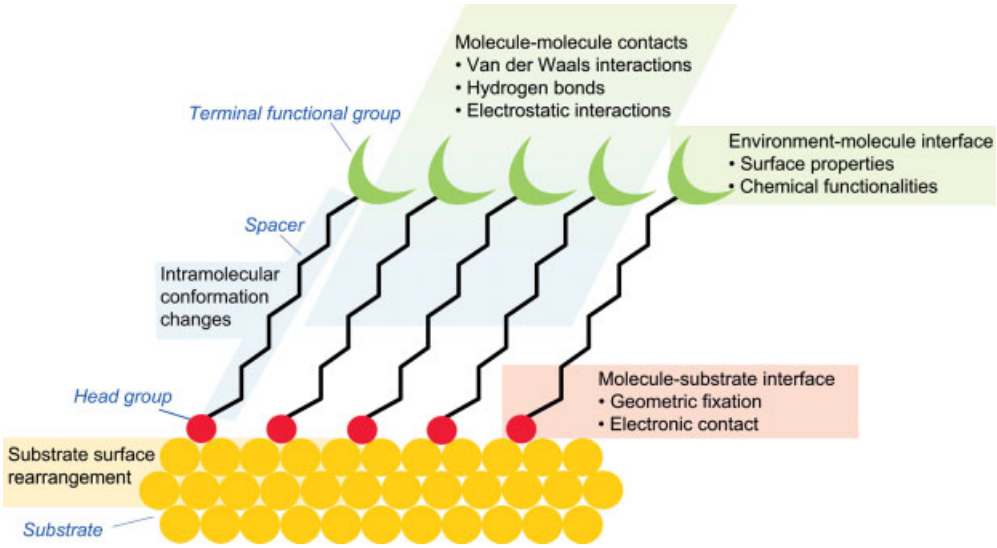

Figure 10.16 A schematic diagram of a SAM, with the characteristic features highlighted.

on a surface is determined in a first level of organization by the footprint of the molecule, the nearest-neighbor distances between the metal atoms at the surface, and the chemical bond formation of the molecules with the surface. The resulting 2-D density of the molecules on the surface may not correspond to the density that the same molecules can attain in crystalline form. In order to minimize the free energy of the organic layer, the molecules perform intramolecular conformation changes such as bond stretches, angle bends, or torsions, which in turn maximize the lateral interactions (e.g., van der Waals interactions, hydrogen bonds, or electrostatic interactions) in a second level of organization. The surface rearrangement of the substrate corresponds to a third level of organization. The balance of these forces determines the specific molecular arrangement, while the driving force is the minimization of the global energy.

10.3.2.1 Organothiols on Metals

The most studied – and probably best understood – SAM is the full-coverage phase of alkanethiols (R−SH) on Au(1 1 1) surfaces. The adsorbing species on the gold surface is the thiolate (RS^-), while the hydrogen atoms are desorbed in form of H_2 molecules with the gold surface acting as catalyst. The thus-formed Au–S bond that anchors the SAM is a strong homolytic bond with a strength on the order of approximately 200 kJ mol^{-1}. The alkanethiols are stabilized by van der Waals interactions between adjacent molecules. These dipole–dipole interactions are proportional to the alkyl chain length (~4.0 kJ mol^{-1} of stabilization to the SAM for each methylene group), and are responsible for the degree of order in the SAM.

A number of studies of alkanethiolate monolayers on gold have shown that the formed structure is commensurate with the sulfur atoms occupying every sixth

hollow site on the Au(1 1 1) surface. The symmetry of the alkanethiolates is hexagonal with a $(\sqrt{3}\times\sqrt{3})$ R30° structure relative to the underlying Au(1 1 1) substrate, a S−S spacing of 0.4995 nm, and a calculated area per molecule of 0.216 nm^2. The alkanethiols are tilted ∼30° off the surface normal, and the hydrocarbon backbones are in all-*trans* configuration. Additionally, the alkanethiolates on Au(1 1 1) surfaces exhibit a c(4×2) superlattice which is characterized by a systematic arrangement of molecules showing a distinct height difference (Figure 10.17) [44]. The height differences in STM images are believed to be due to different conformations of the molecules.

Highly ordered SAMs can easily be built up from alkanethiols, although their structure is affected directly by the addition of any sterically demanding top-end group. The size and the chemical properties (e.g., high polarity) of additionally introduced surface functionalities may reduce the monolayer order.

10.3.2.2 **Carboxylates on Copper**

Compared to the extensive studies of organothiols on gold surfaces, very few investigations have been undertaken to study the self-assembly process of carboxylic acids on metal surfaces. The carboxyl group is known to be an anchoring group for the chemical bonding to metal surfaces. During the adsorption process of simple carboxylic acids the acid group is deprotonated into the carboxylate functionality, resulting in an upright adsorption configuration onto copper or nickel surfaces, as are observed for formic, acetic, and thiophene carboxylic acids [20]. The oxygen atoms in

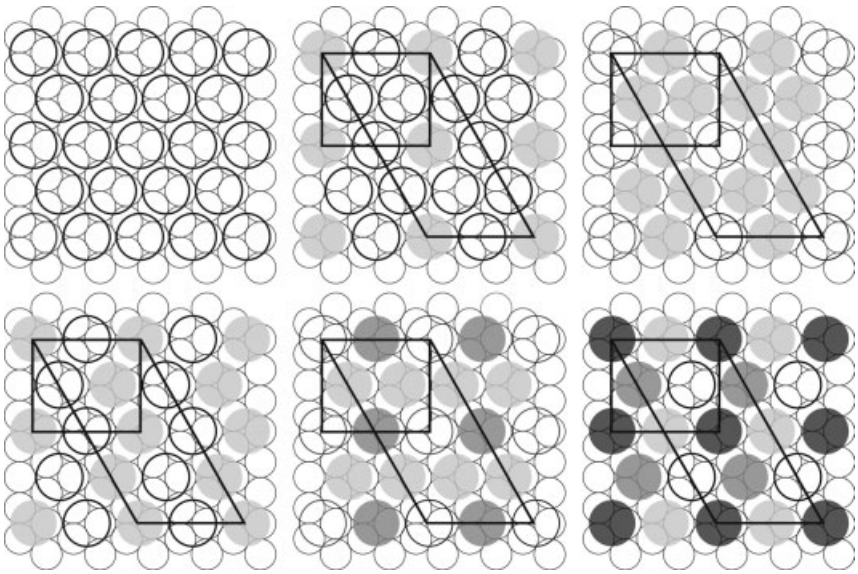

Figure 10.17 Schematic diagram of different phases for the superstructure of alkanethiols on Au(1 1 1) with the $(3\times2\sqrt{3})$ and the c(4×2) superlattice unit cell outlined [44].

the carboxylate group are equidistant to the surface and form a rigid adsorption geometry.

More recently, tartaric acid adsorbed onto copper or nickel surfaces [20] has attracted interest because of a possible use in chiral technology. It is the aim of this technology to establish enantioselective catalytic methods to produce pure enantiomeric forms of materials such as pharmaceuticals and flavors. One way to create heterogeneous chiral catalysts is to adsorb chiral organic molecules at metal surfaces in order to introduce asymmetry. Tartaric acid has two chiral centers, and is therefore of potential interest as chiral modifier; indeed, recently it has been used successfully to stereodirect hydrogenation reactions with a yield of >90% of one enantiomer.

The self-assembly process of *R,R*-tartaric acid on Cu(1 1 0) under varying coverage and temperature conditions leads to a variety of different structures. Due to the two carboxylic acid functionalities, *R,R*-tartaric acid can adsorb in the monotartrate, the bitartrate, or the dimer form. It can be seen from Figure 10.18 that the bitartrate and the dimer–monomer assembly have no symmetry elements and create a chiral surface which is non-superimposable on its mirror image. This is a result of the inherent chirality of the *R,R*-tartaric acid molecules and their two-point bonding at the surface, which uniquely dictates the position of all its functional groups. Subsequently, the intermolecular interactions control the placement of the neighboring molecules. Due to the chirality of the adsorbates the lateral interactions are anisotropic and lead to organized chiral structures.

10.3.3
Supramolecular Nanostructures

Highly ordered 2-D supramolecular nanostructures can be created by using the MBE technique, or at the solid–liquid interface from solution [31] by tuning the molecular backbone size and controlling the supramolecular binding. This approach is based, in principle, on the concepts of supramolecular chemistry directing 3-D structures [16], but in the case of 2-D structures the influence of the substrate must also be taken into account [26].

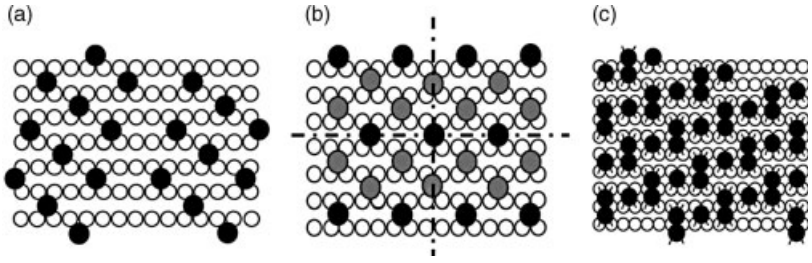

Figure 10.18 Adsorbate templates on Cu(1 1 0) surfaces created by (a) bitartrate (organizational chirality), (b) monotartrate (two symmetry planes), and (c) dimer–monomer assembly (organizational chirality) [20].

A supramolecular 2-D honeycomb network has been created by the assembly of two types of molecule on a silver-terminated silicon surface (this was discussed earlier, in Section 10.2.5) [13]. In the first step, a submonolayer of perylene tetra-carboxylic di-imide (PTCDI) was deposited by sublimation under UHV. Subsequently, melamine (1,3,5-triazine-2,4,6-triamine) was deposited while the sample was annealed at ~100 °C. The substrate allows a free diffusion of the molecules, and this makes formation of the supramolecular network possible. Furthermore, the compatibility of the molecular geometries results in three hydrogen bonds per melamine–PTCDI pair, an intentionally strong heteromolecular hydrogen bonding. In the 2-D honeycomb network the melamine molecules form three-fold connection sites, while the linear PTCDI molecules are used as one-dimensional linkers (Figure 10.19). This ordered array of pores can serve as traps for the co-location of several large molecules. By subliming C_{60} onto the hexagonal network, heptameric C_{60} clusters with a compact hexagonal arrangement are formed within the pores and are clearly stabilized by the PTCDI–melamine network.

The pronounced effect of the substrate in the self-assembly process of 2-D supramolecular structures becomes obvious, when prochiral molecules are used. Upon adsorption, these molecules lose their freedom of rotation and, in consequence, their symmetry and become chiral. Recently, the thermally induced switching of such prochiral molecules between different enantiomeric forms on the surface has been studied [45]. The molecule under investigation was a multiple-substituted phenylenethynylene oligomer (Figure 10.20a). The molecules align into rows and

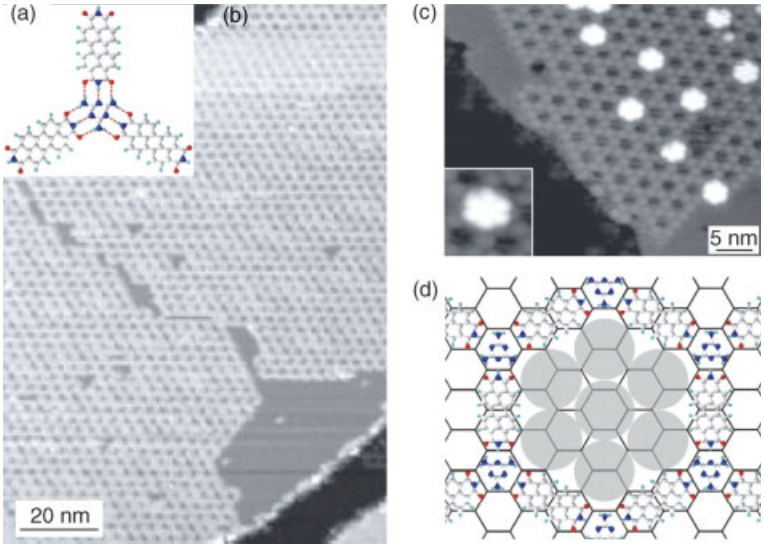

Figure 10.19 (a) Trigonal motif built by perylene tetracarboxylic di-imide and melamine. (b) STM image of a large-area PTCDI–melamine network. (c) STM image of C_{60} heptamers trapped in the pores of the PTCDI–melamine network. (d) Schematic diagram of C_{60} heptamer [13].

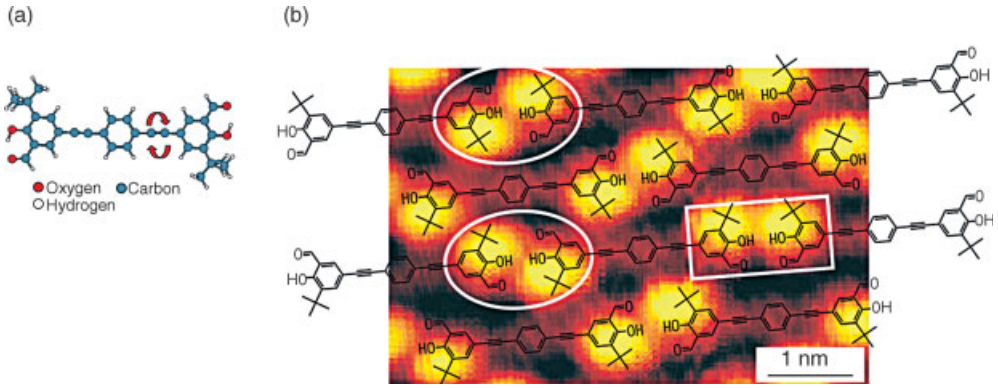

Figure 10.20 (a) The chemical structure of the investigated molecule. (b) A schematic model of the brick-wall adsorption structure superimposed on an STM image [45].

form a brick-wall structure on the Au(1 1 1) surface. The bright protrusions in the STM image (Figure 10.20b) may be attributed to *tert*-butyl groups at both ends of the molecules; the positions of these groups with respect to the molecular backbone identifies the enantiomeric form of the molecule. Two chiral enantiomers (LL and RR) and one achiral meso-form (LR/RL) of this molecule exist. The molecules are not completely stereochemically fixed by the substrate, but change between different surface conformers. An intermolecular *trans* configuration of the headgroups of two adjacent molecules has been found to exhibit the lowest potential energy ($\Delta \sim 4\,\mathrm{kJ\,mol^{-1}}$).

Supramolecular structures built by strong metal–ligand interactions are of high stability, and the incorporated metal centers offer additional functionalities. A system which forms a variety of 2-D surface-supported networks is based on iron (Fe) and aromatic dicarboxylic acids in different relative concentrations on copper surfaces. Mononuclear metal–carboxylate clusters are obtained from one Fe center per four tricarboxylic acid (TCA) molecules on Cu(1 0 0) surfaces [46]. The ($Fe(TPA)_4$) complexes form large, highly ordered arrays which are thought to be stabilized by substrate templating and weak hydrogen bonds between neighboring complexes (Figure 10.21a). From this a perfect arrangement of the Fe ions results, which cannot be achieved by using top-down methods.

A completely different network is obtained when two Fe atoms per three dicarboxylic acid (DCA) molecules are deposited onto the Cu(1 0 0) surface. The resulting array can be described as a ladder structure forming a regular array of nanocavities [26] (Figure 10.21b). The ladders are formed by metal–ligand interactions, while the connections between the ladders are formed by hydrogen bonds. If one Fe atom is deposited per linker molecule, a fully interconnected metal–ligand 2-D network results [47] (Figure 10.21c). By using DCAs of different length as linker molecules between the Fe centers, the size of the resulting nanocavities in the network can be tuned.

10.3.4 Applications of Self-Assembled Monolayers

10.3.4.1 Surface Modifications

One potential application for SAMs is the modification of surfaces in order to change the surface properties for special applications. For example, polar surfaces can be created by the adsorption of SAMs with terminal groups such as cyano (C≡N). These polar surfaces are useful for the investigation of dipole–dipole interactions in surface adhesion. On the other hand, SAMs with terminal OH groups can vary wetting behaviors, and are used in investigations to study the importance of H-bonding in surface phenomena. Additionally, surface OH and COOH groups – and especially acid chlorides – are very useful groups for chemical transformations. For example, reacting the acid chloride with a carboxylic acid-terminated thiol provides the corresponding thioester. The control of surface reactions opens up the way to chemical sensors [21], and is the basis of chemical force microscopy [22].

10.3.4.2 Adsorption of Nanocomponents

Mixed SAMs containing two or more constituent molecules can be used as test systems to study the interactions of surfaces with bioorganic nanocomponents (proteins, carbohydrates, antibodies). Usually, the SAM contains alkanethiols with a surface terminal group of interest (e.g., suitable for hydrophobic or hydrophilic interactions) and an alkanethiol with a reactive site for linking to a biological ligand. SAMs make it possible to generate surfaces with anchored biomolecules that remain biologically active and in their native conformations.

Additionally, it is possible to use the specific chemical binding properties of SAM surface groups to direct nanocomponents into desired structures. This approach has been used extensively to form selected assemblies of nanoparticles, and opens up a pathway to a variety of different structures (this subject is discussed in detail in Section 10.4.2). Another example of the fabrication of desired structures due to the binding properties of SAMs is the directed assembly of carbon nanotubes (CNTs). Recently, a method was developed which is based on the observation that CNTs are

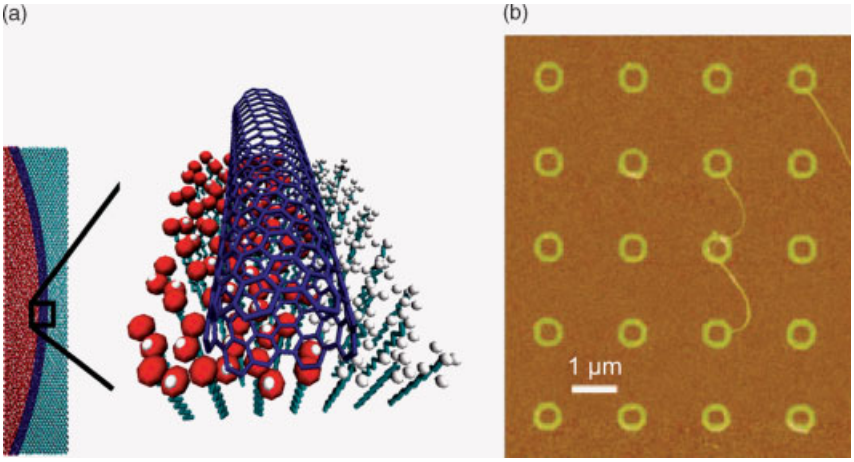

Figure 10.22 (a) Schematic diagram of the directed assembly process. (b) AFM tapping mode topographic image of carbon nanotubes assembled into rings [48].

strongly attracted to COOH-terminated SAMs or to the boundary between COOH- and CH_3-terminated SAMs. By using nanopatterned "affinity templates", desired structures of CNTs can be formed (Figure 10.22). Useful methods for the generation of appropriate templates include dip-pen nanolithography (see Chapter 8) and micro- or nano-contact printing [48].

10.3.4.3 Steps to Nanoelectronic Devices

Molecular electronics requires several structural elements such as wires, diodes, switches, and transistors in order to build up nanodevices. In the studies conducted by Weiss and colleagues [24], conjugated oligophenylene ethynylenes (OPE) have been investigated, which possess potentially interesting features, including negative differential resistance (NDR) (increased resistance with increasing driving voltage), bistable conductance states, and controlled switching under an applied electric field. Single OPEs have been studied in a 2-D isolation matrix of host SAMs of dodecanethiolate on a gold electrode. As a result, series of surface images (Figure 10.23) showed the conductance switching due to conformational changes of the OPE molecules with a low rate, if the surrounding matrix was well ordered. Conversely, when the surrounding matrix was poorly ordered, the inserted molecules switched more often [24]. The switching of OPE molecules can only be observed in arrays of small bundles of molecules. Therefore, it is assumed that the forming and breaking off of hydrogen bonds between adjacent molecules – and the consequent twisting of the molecule, which prevents conjugation of the π-orbitals of the molecular backbone – is responsible for the two conduction states. Such a device, constituted by a switching molecule attached to a bottom electrode and a conductive tip, represents a simple form of a memory.

According to Avriam and Ratner in 1974 [49], the working principle of a molecular diode should be based on two separated electron–donor and electron–acceptor

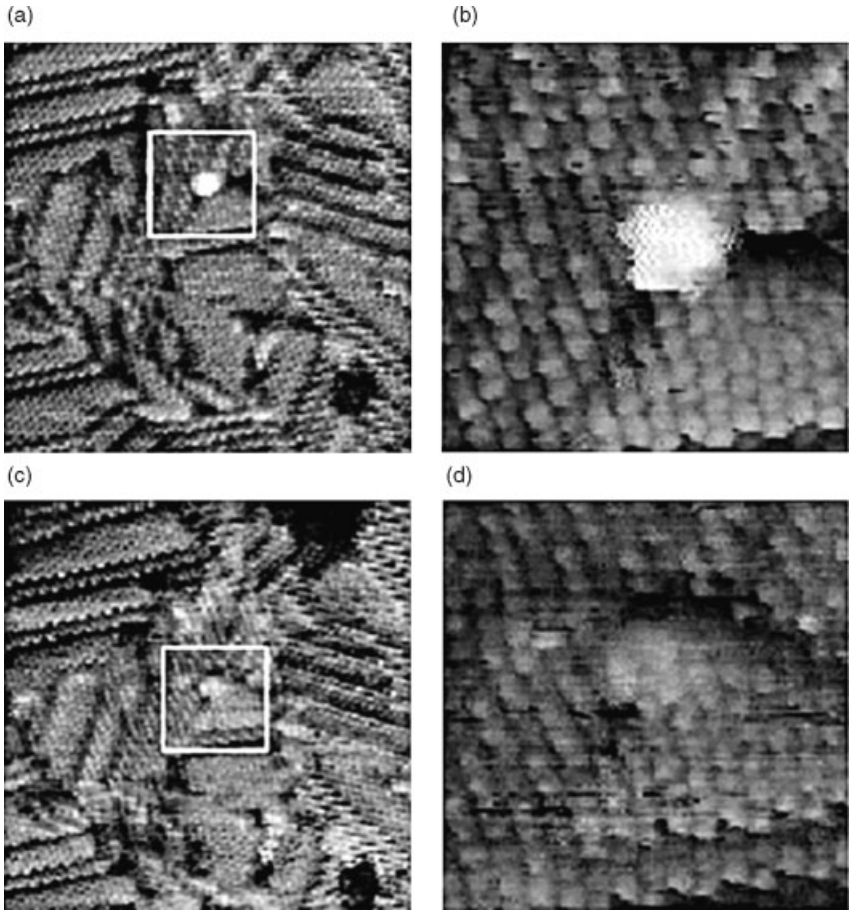

Figure 10.23 Topographic STM images of a molecular switch (OPE) inserted in a dodecanethiol SAM [24]. (a) A 20×20 nm image of the molecule in the ON state; (b) a 5×5 nm image of the same area; (c) 20×20 nm; and (d) 5×5 nm images of the same area, with the molecule in the OFF state.

π-systems (see Chapter 24). However, in recent years asymmetric electron transmission through symmetrical molecules has been also observed by SPM investigations on the molecular level [50]. Diode behavior is possible for symmetric molecules, if they are connected asymmetrically to the electrodes – that is, with two different molecule–electrode spacings, or if asymmetric electrodes are used. A further development of this idea leads to the assumption, that engineering the frontier orbitals of the molecule in the asymmetric junction should make it possible to control the orientation of the diode – that is, whether an alignment of the cathode to the LUMO of the molecule or of the anode to the HOMO is achieved at lower bias. If, additionally, the frontier orbitals of the molecule can be changed reversibly by an electrical pulse, then an optical pulse

or a chemical reaction a transistor would result. An example of such a molecular transistor device based on a supramolecular assembly is given by Rabe and coworkers [51], who used a hexa-peri-hexabenzocoronene (HBC) derivative with six electron-accepting anthraquinones (AQs) symmetrically attached to the HBC, and has the function of an electron donor. The resulting HBC–AQ_6 molecules (Figure 10.24a) were investigated at the HOPG/solution interface, where they form monolayers with an ordered structure. The identification of the conjugated HBC cores and the attached AQ molecules, as well as the recording of the current–voltage (I–V) curves through HBC cores, AQs and alkyl chains was possible by using STM/scanning tunneling spectroscopy (STS).

In a next step, the frontier orbitals of the HBC–AQ_6 molecules were intentionally changed in order to vary the electron transmission properties of the HBC cores. This was achieved by the addition of 9,10-dimethoxyanthracene (DMA) to the solution. DMA is an electron donor which is known to build a charge-transfer complex with AQ. It is remarkable that two different I–V curves through the HBC core are observed, depending on whether or not charge-transfer complexes are coadsorbed next to HBC.

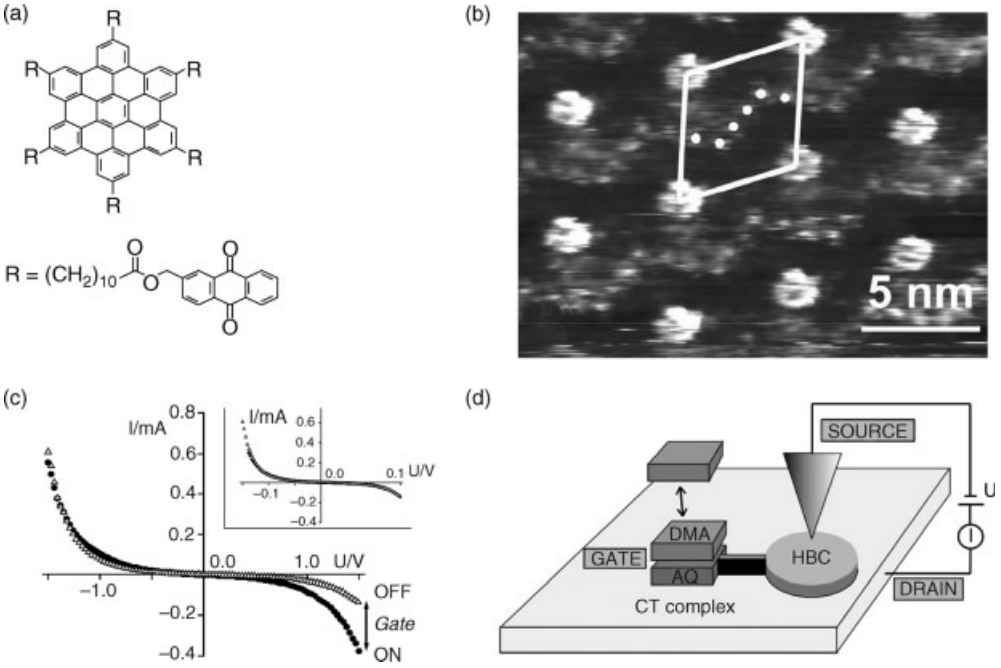

Figure 10.24 (a) Chemical formula of hexa-peri-hexabenzocoronene (HBC) decorated with six anthraquinone (AQ) functions. (b) STM current image of HBC–AQ_6 molecules with coadsorbed charge-transfer (CT) complexes. (c) Current–voltage (I–V) relationships through HBC cores in domains where the charge-transfer complexes are adsorbed, or where no charge-transfer complexes were present. (d) Schematic of a prototypical single-molecule chemical field effect transistor (CFET) [51].

This set-up can be regarded as a "single-molecule chemical field-effect transistor", as the change in the I–V relationship results from the chemical formation/solution of a charge-transfer complex (= gate) which alters the electron transmittance through the covalently attached HBC (= channel) (Figure 10.24). Despite the fact, that the gates cannot be addressed selectively and the device structure changes simultaneously with the electron transmission properties, this approach is a major step towards monomolecular electronics with a complete transistor integrated into one molecule.

10.4 Preparation and Self-Assembly of Metal Nanoparticles

In addition to the previously discussed two nanofabrication methods of epitaxial growth and molecular self-assembly, metal nanoparticles also play an important role in the context of nanofabrication. The extraordinary size-dependent electronic, magnetic and optical properties [52] of nanoparticles have triggered many fascinating ideas for potential applications in breakthrough future technologies, including sensors, medical diagnostics, catalysis, and nanoelectronics. Therefore the preparation and the question of how to assemble metal nanoparticles remain objectives of great interest. The major challenges that are still to be overcome in this context are, on the one hand, the preparation of (ideally) monodisperse metal nanoparticles with simultaneous control over size, shape and composition; and on the other hand, the controlled assembly. Much effort has been expended in attempts to prepare metal nanoparticles of different sizes and shapes, to assemble them into three, two or even one dimensions, and to study and to understand their physical properties. The results of these investigations form the fundamental knowledge for potential applications in nanotechnology. Some of these synthetic routes and self-assembly patterns are outlined in the following paragraphs.

10.4.1 Preparation of Metal Nanoparticles

Generally, metal nanoparticles are prepared by the reduction of a soluble metal salt via suitable reducing agents, or via electrochemically [53–55] or physically assisted methods (e.g., thermolysis [56], sonochemistry [57], photochemistry [58]), or directly via the decomposition of labile zero-valent organometallic complexes. In all cases the synthesis must be performed in the presence of surfactants, which form SAMs on the nanoparticles surfaces (see also Section 10.3) and thus stabilize the formed nanoparticles. The stabilizing effects of the surfactants refer to: (i) steric effects, meaning stabilization due to the required space of the ligand shell; and (ii) electrostatic effects, implying stabilization due to coulombic repulsion between the particles. Furthermore, the surfactants influence the size, shape, and the physical properties and assembly patterns of the nanoparticles. In recent years, many excellent reviews have been produced providing detailed overviews on the preparation techniques, properties and surfactant influences [59–63]. In this context it should be mentioned that,

because of the protecting SAM on the surface, ligand-stabilized nanoparticles are also sometimes denoted as monolayer-protected clusters (MPCs). However, in comparison to SAMs on planar surfaces, the structures of the SAMs on the nanoparticles surfaces differ greatly due to the surface curvature [64].

Important – and already more or less standardized – examples of the preparation of non-stoichiometrically composed metal nanoparticles via the reduction of a metal salt with a suitable reducing agent include the route of Turkevich *et al.* [65] and that of Brust *et al.* [66, 67]. Turkevich and colleagues were the first to introduce a standardized method for the preparation of gold nanoparticles with diameters ranging from 14.5 ± 1.4 nm to 24 ± 2.9 nm, via the reduction of $HAuCl_4$ with sodium citrate in water. Thereby, the nanoparticle size can be controlled by variation of the ratio $HAuCl_4$/sodium citrate. This route is often applied due to the fact that citrate-stabilized gold nanoparticles can simply be surface-modified because of a weak electrostatically bound, and thus easily exchangeable, citrate ligand. Brust *et al.* utilized sodium borohydride as a reducing agent, and took advantage of the high binding affinity of thiols to gold; this enabled the preparation of relatively stable nanoparticles that could be precipitated, redissolved, analyzed chromatographically, and further surface-modified without any apparent change in properties. This high stability represents an important property in terms of controlling nanoparticle assembly.

A recently published report described the surfactant-free synthesis of gold nanoparticles [68]. This approach is especially interesting in terms of the preparation of small gold nanoparticles with narrow dispersity, protected by ligands carrying functional groups that are typically not stable towards reducing agents. In this method, a solution of $HAuCl_4$ in diethyleneglycol dimethyl ether (diglyme) is reduced by a solution of sodium naphthalenide in diglyme to yield weakly solvent-molecule-protected gold nanoparticles. In the first step, these formed nanoparticles are further stabilized and functionalized simply by the addition of various ligands (1-dodecanethiol, dodecaneamine, oleylamine and triphenylphosphine sulfide). The size of the nanoparticles can be tuned within the range of 1.9 to 5.2 nm, with dispersities of 15–20% depending on the volume of the added reduction solution and the time between addition of the reduction solution and the ligand molecule solution.

Magnetic nanoparticles, such as cobalt or iron nanoparticles, are typically prepared via the decomposition of a zero-valent organometallic precursor, for example carbonyl metal complexes. One example is the synthesis of monodisperse ($\pm$ one atomic layer) Co and Fe nanoparticles with sizes of approximately 6 nm via thermal decomposition of the respective carbonyl compounds ($Fe(CO)_5$, $Co_2(CO)_9$) under an inert atmosphere [69]. In this way the nanoparticle size can be controlled by adjusting the temperature and the metal precursor:surfactant ratio. For example, higher temperatures and higher metal precursor:surfactant ratios produce larger nanoparticles. An additional control parameter is the ratio of the surfactants tributyl phosphine and oleic acid, both of which bind to the nanoparticle surface. Tributyl phosphine binds weakly, allowing rapid growth, while oleic acid binds tightly and favors slow growth to produce smaller particles. As might be expected, iron

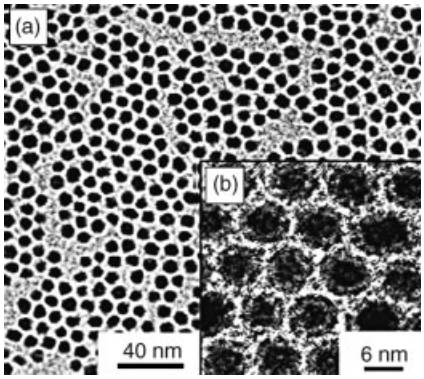

Figure 10.25 (a) TEM image of an ensemble of 6-nm iron nanoparticles. (b) At higher magnification, the surface oxide layer is clearly visible. (Illustration reprinted from Ref. [69], with kind permission.).

nanoparticles show great sensitivity towards oxidation in air; even a short contact of the nanoparticle surface with air resulted in the formation of an Fe_3O_4 layer with a thickness of approximately 2 nm (Figure 10.25).

The thermal decomposition of metal carbonyl complexes for the preparation of nanoparticles or nanostructured materials can also be achieved by treatment with ultrasound. Treatment of a liquid with ultrasound causes the formation, growth and implosive collapse of bubbles in the liquid, and this in turn generates a localized hot-spot [70]. As an example, amorphous Fe/Co nanoparticles are prepared by the sonolysis of $Fe(CO)_5$ and $Co(NO)(CO)_3$ in decanediphenylmethane at 293–300 K under an argon atmosphere, to produce pyrophoric amorphous Fe/Co alloy nanoparticles. Annealing of these particles in an argon atmosphere at 600 °C leads to growth of the Fe/Co particles, and this finally yields air-stable nanocrystalline Fe/Co particles due to carbon coating on the surface [70].

While the above-mentioned examples were all non-stoichiometrically composed gold nanoparticles, one famous example of a stoichiometrically composed gold nanoparticle – and thus great control over size-dependent properties – is the so-called *Schmid cluster* $[Au_{55}(PPh_3)_{12}Cl_6]$, which was introduced in 1981 [71]. The cluster is prepared by the reduction of $Au(PPh_3)Cl$ with *in-situ*-formed B_2H_6 in warm benzene. The relevance of this cluster refers to its quantum size behavior and to the fact that it can be regarded as a prototype of a metallic quantum dot [72, 73]. The defined stoichiometric composition of $Au_{55}(PPh_3)_{12}Cl_6$ is based on the so-called "full-shell cluster principle", whereby the cluster is seen as a cut-out of the metal lattice of the bulk metal. This implies that the cluster consists of a metal nucleus surrounded by shells of close-packed metal atoms, so that each shell has $10n^2 + 2$ atoms (n = number of shells) [59, 74]. Further examples in this context are $[Pt_{309}phen^*_{36}O_{30}]$ (four-shell cluster) and $[Pd_{561}phen_{36}O_{200}]$ (five-shell cluster) (phen* = bathophenanthroline; phen = 1,10-phenanthroline) [75–77].

10.4.2 Assembly of Metal Nanoparticles

As mentioned above, the unique physical properties of metal nanoparticles with diameters of between one and several tens of nanometers make them promising building blocks for the construction of functional nanostructures. Furthermore, it was found that assemblies of nanoparticles show physical properties that are situated between those of an isolated cluster and the bulk material; this in turn would lead to a new class of materials, the properties of which are affected by the nanostructure itself. Arrays of nanoparticles exhibit delocalized electron states that depend on the strength of the electronic coupling between the neighboring nanoparticles, whereby the electronic coupling depends on the particle size, including the particle size distribution, the particle spacing, the packing symmetry and the nature and the covering density of the stabilizing surfactant [78, 79]. Thus, major efforts are under way to organize nanoparticles into one to three dimensions in order to investigate electronic, magnetic and optical coupling phenomena within such assemblies, and even to utilize these coupling effects for the set-up of novel nanoelectronic, diagnostic, or nanomechanical devices [80].

The assembly principle to achieve large ordered arrangements of nanoparticles is the self-organization of ligand-protected nanoparticles due to weak ionic or van der Waals interactions, or due to strong covalent bond formation via respective functional ligand-protected nanoparticles. Some examples of building up 1-D to 3-D nanoparticle arrangements via self-organization are presented in the following sections.

10.4.2.1 Three-Dimensional Assemblies

The easiest achievable construction scheme is the self-assembly into three dimensions which, when occurring spontaneously, is in principle *crystallization*. For example, $Au_{55}(PPh_3)_{12}Cl_6$ crystallizes from dichloromethane solution if the solvent is evaporated, yielding small hexagonal microcrystals. Such a microcrystal obtained in this way is shown in Figure 10.26 [81].

The self-assembly of FePt nanocubes (see also Section 10.3.1) during controlled evaporation of the solvent from a hexane dispersion leads to (1 0 0) textured arrays. This assembly is energetically favored, as it gives the maximum van der Waals interaction energy arising from face-to-face interactions in a short distance of the cube assembly. The interparticle distance is approximately 4–5 nm, which is close to the simple thickness of the surfactant layer (2–2.5 nm, the length of oleate or oleylamine). Interestingly, thermal annealing induces an internal particles structure change and transforms the nanocube assembly from superparamagnetic to ferromagnetic. The study cited here is an example of the influence of particle shape on the assembly scheme.

Co, Ni, and Fe nanoparticles self-assemble from solution to form close-packed nanoparticle arrays on a variety of substrates if the dispersing solvent is evaporated. A TEM image of such a hexagonal superlattice with rows of 8-nm mt-fcc Co nanoparticles aligning to form facets is shown in Figure 10.27. Such 3-D magnetic

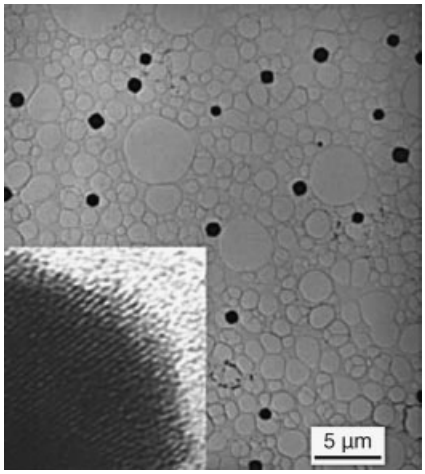

Figure 10.26 TEM image of typical microcrystals of $Au_{55}(PPh_3)_{12}Cl_6$ formed on the grid from dichloromethane solution. The inset shows a high-resolution TEM image of a $Au_{55}(PPh_3)_{12}Cl_6$ microcrystal. (Illustration reprinted from Ref. [81], with kind permission.).

nanoparticle arrays provide important models by which collective interparticle interactions may be explored [69].

Covalently linked gold nanoparticles can be obtained by using bifunctional ligands that are able to interconnect nanoparticles. Brust *et al*. were the first to describe the formation of gold nanoparticle networks by using dithiol molecules as ligands [82]. Their method involved the preparation of gold nanoparticles in a two-phase liquid–liquid system [83], whereby dithiols rather than monothiols were used. The use of dithiols leads directly to the formation of an insoluble precipitate of dithiol crosslinked clusters. The existence of self-assembled nanoparticles is deduced from TEM images (Figure 10.28).

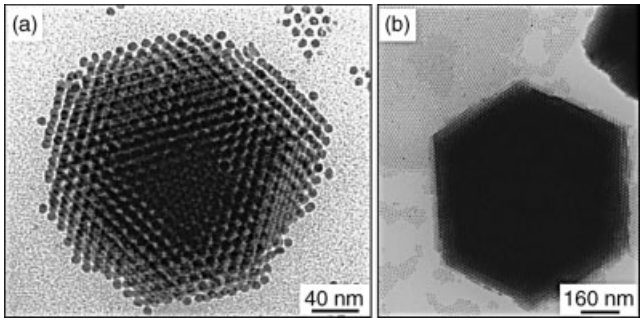

Figure 10.27 (a) TEM image of a hexagonal superlattice grown from 8-nm mt-fcc Co NPs. (b) Lower-magnification image of large hexagons formed in the sample. (Illustration reprinted from Ref. [69], with kind permission.).

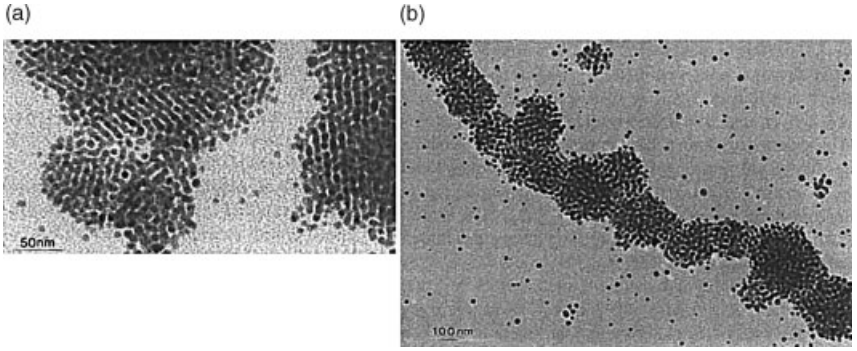

Figure 10.28 (a) TEM image of 8-nm gold nanoparticles crosslinked with 1,9-nonanedithiol, showing the parallel alignment of adjacent particles. (b) TEM image of 8-nm gold nanoparticles crosslinked with 1,9-nonanedithiol, showing a self-assembled string of "superclusters", which is a typical feature of these preparations. (Illustration reprinted from Ref. [82], with kind permission.).

The influence of the ligand, the type, and the linker length on charge-transport properties in metal nanoparticle assemblies has been studied for a variety of cases. For example, the insertion of bifunctional amines into the 3-D arrangement of $Pd_{561}phen_{36}O_{200}$ clusters yields an increased interparticle spacing compared to the closed sphere packing obtained from solution. The increased interparticle spacing is reflected in an increase of the activation energy of the electron transport through the material [84]. The influence of ligand type was recently discussed for the case of Au_{55}-cluster arrangements by Simon and Schmid [85]. When comparing the charge-transport properties of networks of Au_{55}-clusters interconnected by either weak ionic interaction or by covalent bond formation between bifunctional ligands, it transpired that both types showed characteristically different charge-transport properties. The non-covalently interconnected cluster systems showed a continuous increase of activation energy for the charge transport with increasing interparticle distance, whereas the covalently linked cluster systems showed a decrease in activation energy, to significantly lower values [85].

10.4.2.2 Two-Dimensional Assemblies: The Formation of Monolayers

In general, the assembly of nanoparticles into two dimensions is achieved by binding the metal nanoparticles onto a substrate surface. Thus, in order to direct the assembly into a defined pattern, the key point is the existence of functional groups on the substrate surface which enable a specific interaction between the nanoparticle and the surface. These interactions may be either weak electrostatic forces or weaker van der Waals forces; alternatively, covalent bonds may be formed between the monolayer-protected nanoparticle and the substrate surface. The weak interactions have the advantage that they allow a reasonable mobility on the surface, and so enable ordering due to self-organization. Covalent bond formation has the advantage of building

more stable and durable arrays. However, in order to enable electrostatic or covalent interactions, the substrate surface must be adequately modified (see also Section 10.2). The formation of 2-D gold nanoparticle arrays is presented in the following examples.

One example of a 2-D assembly due to electrostatic interactions is the assembly of hydrophilic $Au_{55}(Ph_2PC_6H_4SO_3H)_{12}Cl_6$-clusters on a poly-(ethyleneimine)-coated TEM-grid, as reported by Schmid and coworkers [86]. The driving force for the deposition of colloids on the surface is the acid–base interaction between the $-SO_3H$ group of the ligand and the NH-group of the imine. This procedure leads to a close packing which can be visualized by using TEM (Figure 10.29).

A recently published example for the controlled assembly of gold nanoparticles into two dimensions, and which utilizes electrostatic forces, is the assembly of citrate-protected gold nanoparticles on carbon surfaces [87]. The key point here is that the carbon surfaces are electrochemically modified with primary amines (*n*-hexylamine, tetraethylene glycol diamine). This electrochemical surface modification method allows the number of amine functionalities on the surface to be controlled, and in turn allows control to be exerted on the density of the nanoparticle assembly.

Another example, which is within the context with the electrical characterization of 2-D arrays of gold nanoparticles, is the electrostatic adsorption of 15-nm gold nanoparticles on 3-aminopropyltrimethoxysilane (APTS)-modified silicon substrates. Thereby, the particles are deposited from an aqueous solution (pH 5) to yield a densely packed monolayer of gold colloids with an average density of

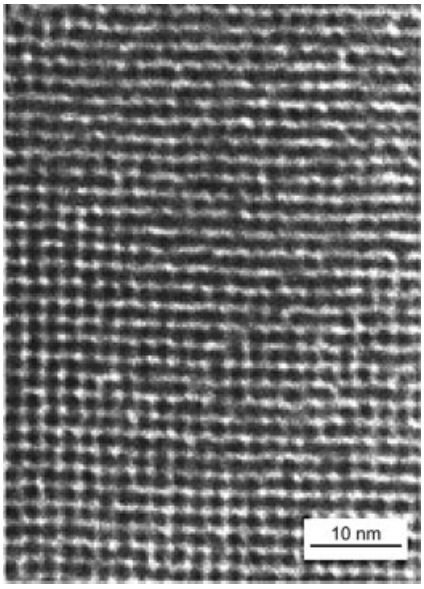

Figure 10.29 $Au_{55}(PPh_3)_{12}Cl_6$-clusters fixed on a PEI-coated grid, as imaged with TEM. (Illustration reprinted from Ref. [86], with kind permission.).

approximately 1500 particles per μm^2 (Figure 10.30) [88]. The average interparticle spacing is adjusted by the thickness of the citrate shell.

SAMs based on the covalent attachment of nanoparticles were presented by Schmid and coworkers, who described the formation of 2-D arrangements of ligand-stabilized gold clusters and gold colloids on various inorganic conducting and insulating surfaces [89]. For this purpose, oxidized silicon as well as quartz glass surfaces were treated with (3-mercaptopropyl) trimethoxysilane to generate monolayers of the SH-functionalized silane. When dipped into an aqueous solution of 13-nm gold colloids, stable covalent S–Au bonds were formed, thus fixing the colloids in a highly disordered arrangement. The coating of the surface was visualized using AFM.

Microcontact printing (μCP) is also used to create nanoparticle surface assemblies based on covalent forces, and with predefined positions of the nanoparticles within these arrays. A recent example of μCP use was the chemically directed assembly of monolayer-protected gold nanoparticles on lithographically generated patterns [90]. Here, gold surfaces patterned with mercaptohexadecanoic acid (MHA) were prepared using μCP and dip-pen nanolithography. A diamine molecule was used to link the mercaptoundecanoid acid-coated gold nanoparticles onto the MHA-defined patterns. Sonication was then used to remove the non-specifically absorbed nanoparticles, and the nanoparticle assembly was proven by using AFM, with height increases of 2–6 nm with respect to the preformed MHA SAM (Figure 10.31).

10.4.2.3 **One-Dimensional Assemblies**

The 1-D assembly of nanoparticles remains a major challenge, as 1-D (or at least quasi-1-D) assemblies require appropriate nanoparticle surface modification, appropriate templates, or special techniques (including special substrate modifications, e.g., AFM-based methods).

One recently published example is the spontaneous quasi-1-D arrangement of spherical Au nanoparticles protected by a liquid crystal ligand (the 4′-(12-mercapto-

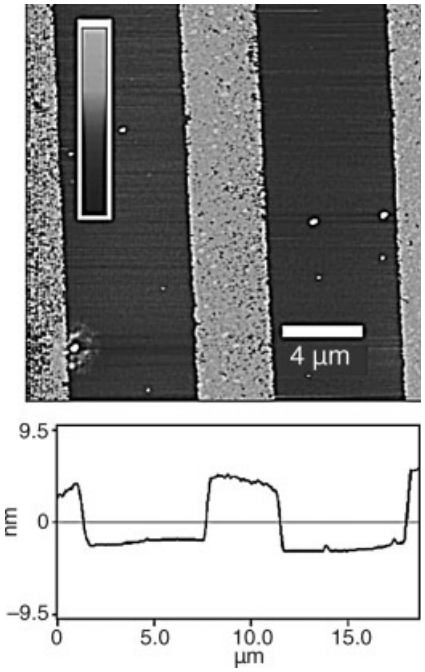

Figure 10.31 Contact mode AFM height image (top image) and average height profile (bottom image) of gold nanoparticles chemically directed onto mercaptohexadecanoic acid (MHA) features patterned by microcontact printing (µCP). The lines show an average height of 6.5 nm (the average height profile is shown at the bottom of the figure), and a 6 nm increase over the feature height after nanoparticle assembly. The inset shows the height scale bar of 20 nm). (Illustration reprinted from Ref. [90], with kind permission.).

dodecyloxy)biphenyl-4-carbonitrile). Thereby, gold nanoparticles protected by a ligand consisting of a liquid crystal mesogen unit and an alkane thiol unit spontaneously ordered themselves just by a simple thermal treatment, without the sue of any templates. The length of the arrangement was 1 to 60 nm, and the inter-array distance was approximately 7 nm (Figure 10.32) [91].

Another approach that utilizes covalent forces is the chemically directed assembly of gold nanoparticles on a thiol-patterned silicon surface [92]. The patterning of the silicon surface is predefined using AFM, and achieved via *chemical force microscopy* [22]. The process is as follows. A silicon surface is modified with a monolayer of 3,5-dimethoxy-α,α-dimethylbenzyloxycarbonyl (DZZ)-protected thiol (DZZ is a photocleavable group typically used in organic synthesis and lithography). It transpired that the application of a voltage between an AFM tip and a selected location on the monolayer yielded deprotection (Figure 10.33), and consequently it was possible to "write" a thiol-end-group pattern into the given monolayer. Following treatment with a 10-nm citrate-stabilized gold nanoparticle solution, the particles were chemisorbed via thiol–gold bond formation. In this way, single lines of gold nanoparticles can be produced, even with a defined particle separation (Figure 10.34) [92].

10.5 Conclusions

In this chapter, we have discussed the basic principles and selected examples of the formation of nanostructures via the self-assembly of atoms by epitaxial growth, of molecules, and of metal clusters. The examples presented have provided an impressive demonstration that these methods represent powerful tools for the controlled preparation of highly ordered nanostructures. In future, a combination of the three methods should represent the next key step towards building up well-defined functional nanostructures with suitable properties for applications in molecular electronics. Moreover, besides the applications of self-assembled structures discussed here, such nanoscale structures are of growing interest in the development of new sensors and catalysts. Inorganic substrates with epitaxially grown nanostructures display suitable starting points for the site-selective attachment of molecules, and such molecules may serve as intelligent adhesives for the binding of nanoscale subunits. The future goal of fabrication of complex functional nanoscale structures will be achieved only by employing a hierarchical self-assembly approach, using different scales and materials.

Flash-Type Memories

Thomas Mikolajick

11.1
Introduction

The trend towards mobile electronic devices drives an increasing demand for non-volatile memories [1]. In 2007, the market for NAND Flash memories approached the size of the dynamic random access memory (DRAM) market with regards to bit volume, and continues to grow. The hierarchy of today's non-volatile memories is illustrated schematically in Figure 11.1. From this, with the technologies available today, a trade-off between cost and flexibility must be made.

At the low end of flexibility there is the read-only memory (ROM), which can only be programmed during production, but delivers the lowest cost per bit. In a practical application the most important feature today is the *electrical rewritability*. The electrical erasable and electrical programmable ROM allows for this reprogrammability on a Byte level. To achieve this, each memory cell must be constructed from two transistors – the storage transistor and a select device – but this leads to a large cell size. The electrical programmable memory (EPROM), on the other hand, consists of only one memory transistor, but does not allow an electrical erase. The Flash-type memory combines the small cell size of the EPROM with the electrical erasability of the EEPROM simply by allowing the erase operation not on a Byte level but only on large blocks of 16 kB to 1 MB (see Figure 11.2). At the high end of flexibility there is a memory that allows random access-like operation as in DRAMs or static random access memories (SRAMs), and is non-volatile. Today, this non-volatile RAM can only be realized by the combination of DRAM or SRAM [2] with EEPROM or Flash, or by ferroelectric RAMs [3].

Today's standalone Flash memories can be divided into memories for code applications and for data applications. In the code application, the memory must allow a fast random access to enable real-time code execution. In the data application, the focus is on highest density and fast program and erase throughput. The implications of this difference on the array architecture and cell construction will be explained in Sections 11.3.2 and 11.3.3. Additionally a number of applications

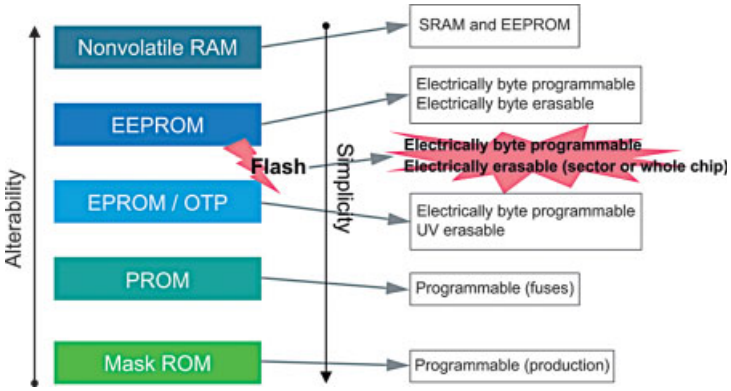

Figure 11.1 Hierarchy of today's non-volatile memory devices. With the available technologies a trade-off between simplicity (reflecting cost) and alterability exists. Flash memories that are programmable on a single byte or page level and erasable on large blocks have evolved as the best compromise for many mobile applications, such as cell phones.

such as "smart cards" call for Flash memory embedded into a high-performance logic circuit [4]. In the embedded Flash segment the density is typically much lower than in standalone memories. Therefore, the focus lies on easy integration into the standard complementary metal oxide–semiconductor (CMOS) flow and low design circuit overhead for the memory module. The requirements, however, are dependent on the actual application, which in turn leads to the development of a large number of different concepts for embedded Flash memories. In the standalone segment of the market, in contrast, one mainstream solution for code and one mainstream solution for data Flash memories have evolved.

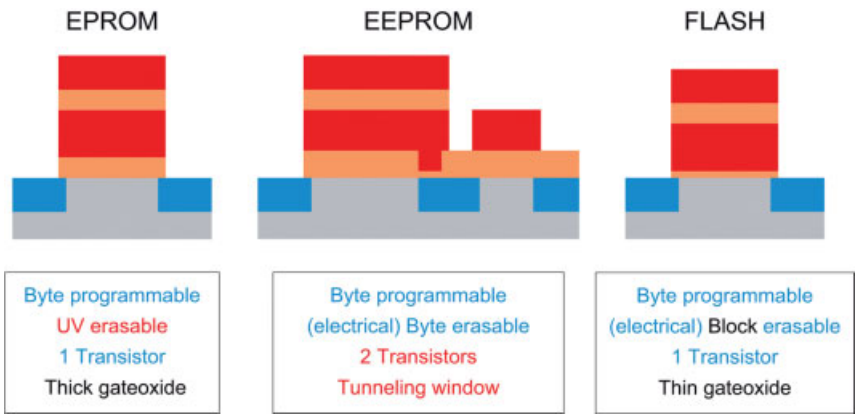

Figure 11.2 A comparison of floating-gate-based EPROM, EEROM and Flash memory cells. By sacrificing on the erase flexibility, a Flash memory cell can be realized with one transistor only.

At the heart of every non-volatile memory today there is either a floating-gate or a charge-trapping transistor, both of which were invented in 1967 [5, 6]. Due to the low oxide quality that was available during the late 1960s, a floating-gate transistor with good retention was difficult to achieve, and charge trapping was therefore very successful until the 1980s. However, with the improvement of oxides, the FAMOS cell [7], which is based on a floating gate that is programmed by avalanche injection and constructed similar to the cell shown at the left of Figure 11.2, was successfully introduced in 1971 for EPROM-type memories. Early EEPROM memories were based on charge-trapping devices using a trigate cell [8]. In 1980, the FLOTOX cell [9] (which is similar to the cell shown in the center of Figure 11.2) was demonstrated and became the mainstream for EEPROM memories. The first Flash memory was introduced at IEDM in 1985 [10], and in 1988 the ETOX cell [11] – which today is the mainstream for NOR-type memories – was proposed. Finally, NAND Flash [12] – the standard for data Flash memories – was first reported at the 1988 VLSI Technology Symposium. In 1987, charge trapping was revived by introducing a cell programmed by hot electrons and erased by hot holes [13]. This allowed the solution of the basic retention issue of charge-trapping devices, and in 1999 it was first demonstrated that this concept could be used to store two physically separated bits in one memory cell, thus reducing the effective cell size below the lithographic limit [14].

11.2
Basics of Flash Memories

In order to integrate a Flash memory into a product, two basic elements are required. First, a memory cell that can perform the program, erase and read operation with the required parameters is necessary. A generic charge storage memory cell, illustrating the program, erase and read operation, is shown in Figure 11.3. To build a large memory, these memory cells must be connected into memory arrays, with the final memory parameters being governed by the combination of memory cell and array architecture.

11.2.1
Programming and Erase Mechanisms

In programming and erase, the charge must be transferred to and from the charge storage layer, overcoming the large potential barrier of the bottom or tunneling dielectric. In principle, two different mechanisms are possible (see Figure 11.4). In the *hot carrier injection mode*, the energy of the carriers is heated up to a level which is sufficient to overcome the barrier. In the *tunneling mode* a large voltage is applied to the barrier in order to reduce its effective width. Variants of both effects are used in different type of Flash concepts. The ways in which several combinations of these effects are realized in Flash concepts are listed in Table 11.1, and the most important concepts will be explained in Section 11.3. Details of other concepts may be found in the references listed in Table 11.1. At this point it should be noted that in Table 11.1

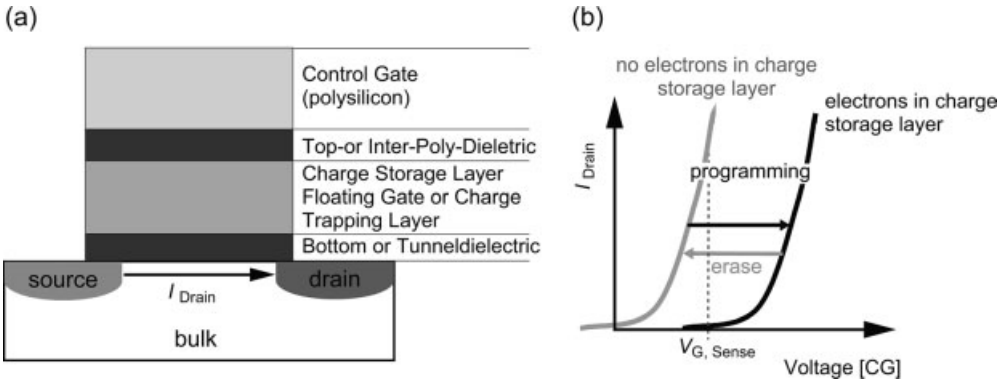

Figure 11.3 Generic charge storage memory cell (a) and basic cell operation (b). The charge storage layer, which can be either a floating gate (Section 11.3) or a charge-trapping layer (Section 11.4) is separated from both the control gate as well as the transistor channel by an insulator. By placing electrons or holes inside of the charge storage layer, the threshold voltage of the transistor can be controlled leading to a significant difference in drain current at a given gate voltage.

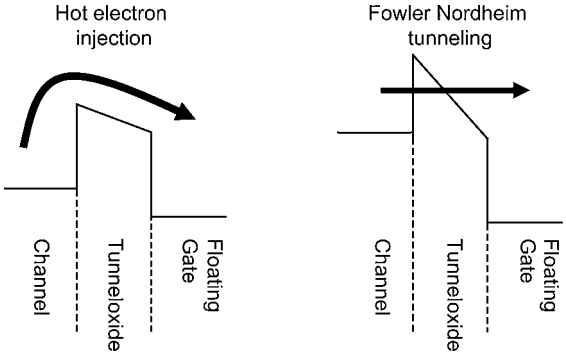

Figure 11.4 Two ways to overcome the silicon/silicon dioxide barrier. In the hot electron injection, carriers are accelerated until they have enough energy to surmount the barrier. In Fowler–Nordheim tunneling, a large electric field is applied to the barrier, leading to a reduction of the effective thickness of the barrier.

and the remainder of this chapter, the operation performed on a byte, word or page level is called "programming" and the operation performed on a block level is called "erase".

11.2.1.1 **Hot Carrier Injection**

In channel hot electron programming, the electrons are accelerated until they have enough energy to surmount the barrier between silicon and silicon dioxide. For electrons this barrier is about 3.1 eV [18], whilst for holes the silicon bandgap must be

Table 11.1 Combination of program and erase mechanisms used in different Flash cell concepts.

Erase	Programming		Hot Electrons	Hot Electrons with secondary impact ionization	Source Side Injection	Hot Holes (BBT)	Fowler Nordheim Tunneling		
							from channel	from Drain	from Source and Drain
Fowler	to Source	ETOX till 0.18 µm [11]	CHISEL [19]						
Nordheim	to Drain			HMOS [21]		AND [32] DINOR [16]	FLOTOX [9]	HiCR [17]	
Tunneling	to Channel	ETOX below 0.18 µm [15]		AG-AND [44]	PHINES [88]	NAND [12] UCP [34] SONOS [70]			
	to Poly	Triple Poly Split gate [31]		Field Enhancing Tunneling Injector [47, 48]	PHINES [89]				
Hot Holes (BBT)		NROM [14], TwinFlash [78], MirrorBit [76]		Twin MONOS [85, 86]					

added, resulting in a barrier of 4.2 eV. To achieve this energy, a high field must be generated in the channel by applying a sufficiently high drain voltage. Additionally, a gate voltage that attracts the generated carriers must be applied. This method has the advantage of microsecond programming speed for a single bit, as well as the fact that it is a three-terminal operation making the disturb optimization easy in a NOR-type architecture. On the other hand, the mechanism has the problem of being very ineffective, as typically approximately 10^5 to 10^6 channel electrons are needed to inject one electron into the storage layer. This leads to a current consumption which is in the range of 100 μA per cell. The consequence is a limited parallelism of cells during programming, and therefore a limited programming throughput.

In order to reduce both the programming current as well as the drain voltage required during programming, two alternative approaches are possible (see Figure 11.5). First, it is possible to apply a bulk voltage during programming, and in this case the field between drain and bulk is increased. As hot electrons at the drain side will lead to electron hole pair creation by impact ionization, the generated holes can be accelerated to the bulk and thereby create a second impact ionization. The so-generated tertiary electrons again may be accelerated towards the charge storage layer. By using this approach the drain voltage can be reduced below 3 V and the current can also be significantly reduced [19]. However, care must be taken to maintain the benefit when scaling down the channel length [20].

Another approach is to use a so-called "split gate transistor", where the channel region is divided into two serial regions with individual gates. The storage layer is present only below one of the two gates. The gate voltage at the gate close to the source is chosen at a value slightly above the threshold voltage, which limits the current flowing trough the channel. The voltage of the second gate is set to a high enough voltage to accelerate the carriers into the charge storage layer. By doing this, a high

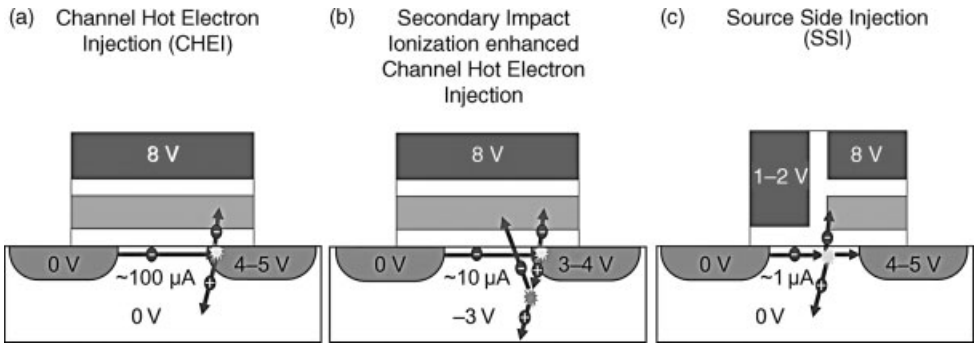

Figure 11.5 Channel hot carrier injection mechanisms. In the classical channel hot electron injection, the injection is mainly by primary channel electrons or secondary electrons (a). With applied back bias, the injection current is significantly increased by the carriers additionally generated during the secondary impact ionization event (b). In source side injection mode the channel current is limited by a second control gate and the field for hot carrier generation is decoupled from the field that attracts the carriers to the storage layer (c). This enhances the efficiency by about 2 orders of magnitude.

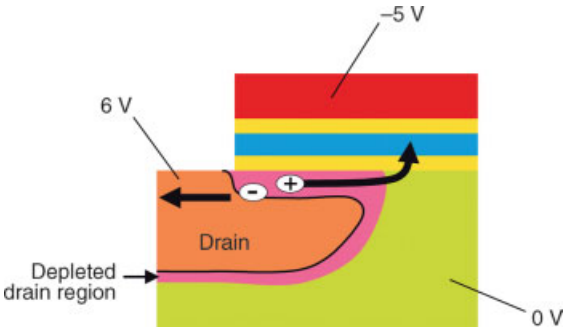

Figure 11.6 Generation of hot holes by band to band tunneling. The band bending in the highly doped region of the n^+ junction leads to generation of carriers by band to band tunneling. The carriers are heated by the lateral electrical field and attracted to the storage layer via the vertical electrical field.

field is created at the region between the two gates, such that the electrons will become hot in that area of the device. As the carriers are injected at a location close to the source, this method is referred to as "source side injection" (SSI) [21]. The channel current can be reduced to the single μA range. Due to the necessity of a second gate electrode, however, there is a cell size drawback and a circuit overhead associated with this source side injection.

Besides channel hot electron generation, carriers generated by band to band tunneling [27] may also be used for programming and erase. In this case, band-to-band tunneling in the drain junction is induced by applying a high drain potential while the gate is turned off. The so-generated carriers are accelerated towards the channel by the electrical field, collecting enough energy to surmount the potential barrier. This is illustrated in Figure 11.6 for the case of hot hole generation in a n-channel device. A modified version uses a highly doped buried layer to generate the band-to-band tunneling [28].

11.2.1.2 Fowler–NordheimTunneling

In Fowler–Nordheim (FN) tunneling, a high electric filed applied to the barrier creates a trapezoidal barrier which significantly reduced the effective barrier for the carriers (see Figure 11.4). The current can be calculated according to the well-known equation [29]:

$$I_G = A_{\mathrm{FN}} E_{\mathrm{ox}}^2 \exp\left(-\frac{B_{\mathrm{FN}}}{E_{\mathrm{ox}}}\right) \tag{11.1}$$

where E_{ox} is the electrical field in the oxide and A_{FN} and B_{FN} are material-specific constants. If a dielectric charge-trapping layer is used for charge storage, the material stack relevant for the tunneling will also depend on the applied field [33]. For low fields, the carriers must tunnel through part of the trapping layer in addition to the tunneling dielectric. For higher fields and very thin layers, direct tunneling is

dominant. Finally, for high fields the FN tunneling [as given by Equation 11.1] is the most important mechanism.

Until now, we have been considering charge transfer between the transistor channel and the charge storage layer. However, by using tunneling the charge can also be transferred to the gate electrode [30] or to a specially designed erase gate [31]. In this case the modified properties of the tunneling barrier created on a polysilicon electrode, as well as field enhancement by poly tips, must be taken into account in the FN tunneling current.

11.2.1.3 **Array Architecture**

When combining memory cells to a memory array, different versions are possible. The straightforward way is to connect the gate of every memory cell to a wordline, the drain of every memory cell to the bitline, and to connect all the sources of the memory cells to ground. By using this construction all n cells on one bitline are connected in parallel to each other. As this resembles the n-channel portion of a n-input NOR gate, this architecture is referred to as NOR, or more precisely common ground NOR. Other types of NOR architecture will be discussed later in this section. In contrast, it is also possible to connect the cells on the bitline in a serial connection, leading to a NAND-type array. In practical applications the number of cells in series must be limited to keep the read current on an acceptable level; therefore, typically 32 cells are placed between two select transistors and the so-constructed NAND strings are connected to the bitline in a similar manner as the individual cells in the standard NOR arrangement. When comparing NAND and NOR architectures, it is clear that the random access time is much faster in the NOR-type array, as every cell is directly accessed by a bitline. In the NAND architecture, in contrast, the serial connection of cells results in a high resistance through which the current must flow to the bitline. The result is a much lower read current – and therefore a much slower random access. On the other hand, the NAND arrangement has a distinct size advantage, as the contacts are shared between all cells of the string, whereas one contact for every two cells is necessary in common ground NOR.

The program and erase mechanism used in the cell also has an impact on the possible array architecture. For a cell programmed by channel hot electron injection, the common ground NOR arrangement is an ideal fit, as the necessary voltages can be precisely applied to the cell, thus minimizing any disturbance to other cells. For other injection mechanisms, or to minimize the cell size, the common ground NOR architecture may be modified. An overview of the possible array architectures is shown in Figure 11.7. In NOR, as well as the above-mentioned common ground NOR architecture, a separate source line may also be used for every bitline; such as array is commonly known as an AND [32] array. Although the most compact realization uses buried bitlines, some versions with metal bitlines are also used [34] if access time has to be minimized rather than cell size. Finally, in such an array each pair of neighboring bit line and source line can be combined to one line. Since here the ground is defined only by the operation of the array, this architecture is referred to as a "virtual ground NOR array" [35]. This has the advantage of a very small cell size (similar to NAND), and also enables a symmetrical operation of the cell, which is essential in multi bit operation (see Section 11.4.2).

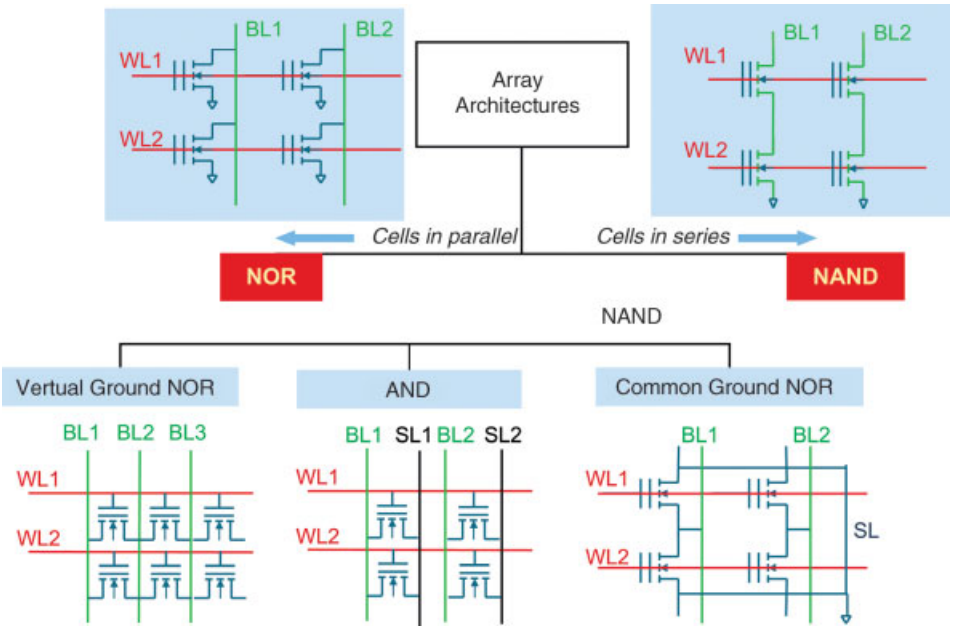

Figure 11.7 Architectures for Flash memory arrays. In principle, it is possible to connect the cells on one bitline in parallel leading to the NOR-type array and in series leading to the NAND-type array. For NOR-type arrays, many different variants have been proposed, whereas for NAND there is only one mainstream solution.

11.3 Floating-Gate Flash Concepts

11.3.1 The Floating-Gate Transistor

In essence, every flash cell is a metal oxide silicon (MOS) transistor with the charge storage layer placed in between the control gate and the channel. The drain current I_D of a MOS transistor can be expressed by the set of Equation 11.2 [36]

$$\begin{aligned} I_D &= \beta\left((V_G - V_T)V_D - \frac{V_D^2}{2}\right) && \text{for} \quad V_G - V_T > V_D > 0 \\ I_D &= \frac{\beta}{2}(V_G - V_T)^2 && \text{for} \quad 0 < V_G - V_T \leq V_D \\ I_D &= 0 && \text{for} \quad V_G - V_T < 0 \end{aligned} \tag{11.2}$$

where V_G is the gate voltage, V_D is the drain voltage, V_T is the threshold voltage, and β is the transconductance. β and V_T are given by Equation 11.3:

$$\beta = \frac{W}{L} C_{IS} \mu$$
$$V_T = \Phi_{MS} - 2\phi - \frac{Q_S}{C_{IS}} - \frac{Q_{IS}}{C_{IS}} \tag{11.3}$$

where W and L are the channel width and channel length of the device, C_{IS} is the total capacitance of the gate insulator, μ is the channel mobility, Φ_{MS} is the workfunction difference between the gate electrode and the channel, ϕ_B is the Fermi potential, Q_S is the charge in the depletion layer, and Q_{IS} is the total charge in the insulator normalized to the silicon/insulator interface. In principle, the stored charge in a non-volatile memory cell can be modeled by the insulator charge Q_{IS}. For a charge-trapping device (as introduced in Section 11.4) this holds true, without further modifications.

In the floating-gate device, however, the gate controlling the device is the floating gate (FG) where, from the outside world, only the control gate (CG) can be accessed. Therefore, the gate potential V_G in Equation 11.2 can only be controlled according to the capacitive coupling of the floating gate to the external terminals. The capacitive coupling of the floating gate to the external accessible terminals is illustrated schematically in Figure 11.8; from this figure, under the assumption that the bulk and source of the device are grounded, Equation 11.4 can readily be deduced giving the floating-gate voltage V_{FG} as a function of the gate and drain voltage.

$$V_{FG} = \alpha_G (V_{CG} + f V_D)$$
$$f = \frac{\alpha_D}{\alpha_G} = \frac{C_D}{C_C} \tag{11.4}$$

In Equation 11.4 α_G and α_D are the gate-coupling and the drain-coupling coefficients, which are a function of the respective capacitances according to Equation 11.5:

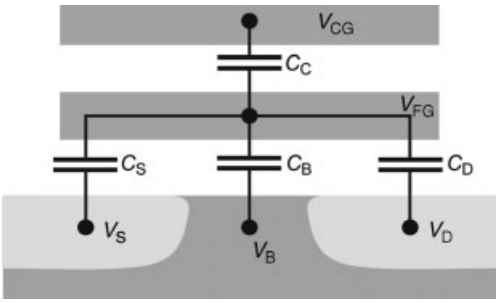

Figure 11.8 Schematic drawing of a floating-gate cell, illustrating the capacitive coupling of the floating gate to the external accessible terminals.

$$\begin{aligned} \text{gate coupling}: \quad \alpha_G &= \frac{C_C}{C_T} \\ \text{gate coupling}: \quad \alpha_D &= \frac{C_D}{C_T} \end{aligned} \tag{11.5}$$

$C_T = C_C + C_S + C_B + C_D$ is the total capacitance, where the individual capacitance are defined in Figure 11.8. By substituting Equation 11.4 into Equations 11.2 and 11.1 and rearranging, the threshold voltage with respect to the control gate is obtained

$$V_{T,CG} = \frac{V_{T,FG}}{\alpha_G} - \frac{\alpha_D}{\alpha_G} V_D - \frac{Q_{FG}}{C_C}. \tag{11.6}$$

The CG threshold voltage is a function of the floating-gate threshold voltage, the charge in the floating gate, and also a function of the applied drain voltage. This means that the threshold voltage is lowered when the drain voltage is increase or, in other words, the device can be turned on by the drain terminal. This effect must be considered when designing floating-gate memory arrays.

11.3.2 NOR Flash

Whilst, in Section 11.2.2 it was shown that a significant number of variants of different NOR-type concepts exist, this section will focus on the mainstream NOR concept. This uses a common ground NOR architecture (see Figure 11.7) in combination with the so-called EPROM tunnel oxide (ETOX) cell. The ETOX cell is, in principle, a stacked gate cell (see Figure 11.2, right and Figure 11.3a) that is programmed using channel hot electrons, and is erased using FN tunneling. In older generations the erasing was carried out towards the source terminal of the device, but as this calls for a large underdiffusion of the source junction under the gate in newer generations it was replaced by tunneling towards the channel.

The cell layout and cross-sections through a cell fabricated in 90-nm technology is illustrated in Figure 11.9. It can be seen that the wordline (WL) pitch is larger than the bitline (BL) pitch, as the channel length cannot be scaled to the minimum feature size using channel hot electron programming and the contact that must be placed in between two cells. The source line, in contrast, is fabricated self- aligned to the word line. The BL pitch on the other side is close to twice the minimum feature size, which is accomplished by self-aligning the bottom part of the floating gate to the shallow trench isolation (STI) and using an unlanded contact. Note that the top part of the floating gate is overlapping the STI, leading to a floating gate space below the minimum feature size. This, in combination with the portion of the control gate that is between the floating gate, provides more area to increase the gate coupling coefficient (see Figure 11.9).

The voltages applied to the terminals for programming, erasing and reading the cell are listed in Table 11.2. Programming is carried out using channel hot electron injection; optionally, the efficiency may be improved by applying a low bulk voltage.

Another important aspect that must be considered in the operation of every flash memory array are *disturbs*. These can cause an unwanted change of the cell content.

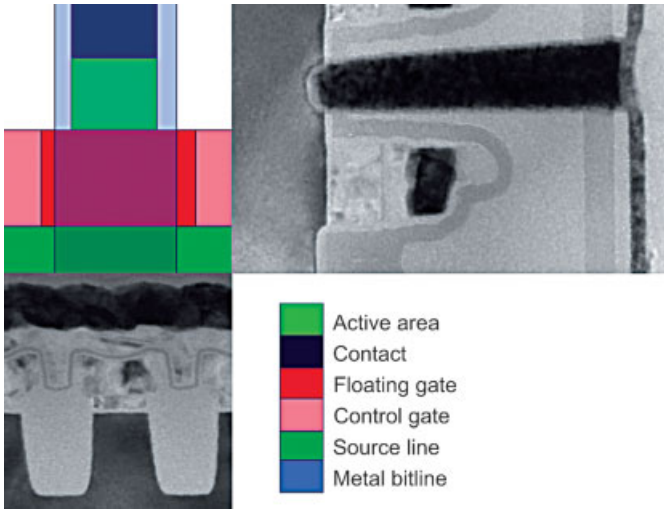

Figure 11.9 Layout and cross-sections of an ETOX-type Flash memory cell. The scanning electron microscopy cross-sections are taken from a 90-nm technology [37].

Table 11.2 Voltage conditions in read, program and erase for a typical ETOX-type cell.

	Gate	**Drain**	**Bulk**
Read	4 V	<1 V	0 V
Program	7 to 10 V	3 to 6 V	0 to −1.5 V (optional)
Erase	−6 to −8 V	float	6 to 8 V

A read disturb is caused by the fact that, for very low drain voltages, there is a probability of hot carriers being injected into the floating gate. Additionally, during read the applied gate voltage may cause FN tunneling into the floating gate. Both of these effects give rise to an unwanted programming of a cell during read. During programming, all cells connected to the same bitline are seeing a drain disturb, while all cells connected to the same wordline are seeing a gate disturb (see Figure 11.10). In

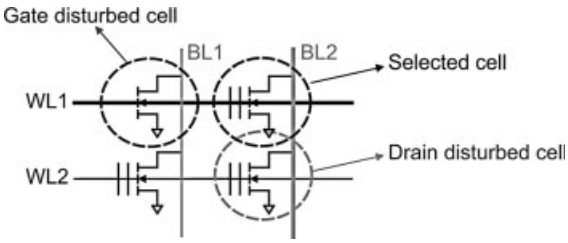

Figure 11.10 Gate and drain disturb in a common ground NOR-type Flash memory array.

erase, the disturb can be eliminated in flash-type memories by physically separating the erase sectors from each other.

11.3.3 NAND Flash

In NAND, only one concept exists, as illustrated in Figure 11.7. As with the NOR-type memory, the cell is a stacked gate but, due to the serial connection of cells, hot electron programming is not practical. The cells are therefore programmed and erased by FN tunneling between channel and floating gate. A schematic overview of a typical NAND string, including cell cross-sections taken from a 60-nm cell, is shown in Figure 11.11 [38]. Today, 32 cells are connected between two selects; this number has increased from eight cells via 16 cells, and may increase to 64 cells in the future [59]. The ground select connects the string to a sourceline, while the bitline select connects each string to a metal bitline.

In the wordline direction the cell resembles the ETOX cell described earlier. In the bitline direction, the cell is much denser due to a lack of contacts, as well as the channel length which can be scaled down to the minimum feature size due to the fact that the cell only has to isolate very low voltages. This becomes clear from Figure 11.12, where the main operations – read, write and erase – are explained in more detail. Erase is achieved simply by applying a sufficiently high voltage for FN tunneling to the well and applying 0 V to all the wordlines in the sector that must be erased, while leaving the wordlines of the non-erased sectors floating.

In the read operation a voltage higher than the highest V_T of a programmed cell must be applied to all the non-selected wordlines. In the erased state, the threshold voltage of the cells is chosen to be negative. Therefore, 0 V can be used on the wordlines that must be read. If a voltage of about 1 V is applied to the bitline, the selected cell will conduct if it is in the erased state and will be below threshold in the programmed state. For writing, a voltage high enough for FN tunneling (e.g., 15–20 V) is applied to the selected wordline. The channel of the selected cell is set to 0 V by applying 0 V to the selected bitline, turning the bitline selector on, and applying a high enough voltage to all the other wordlines; this will allow all other cells in the string to be turned on.

Care must be taken to avoid programming of the cells on the same wordlines. In early NAND Flash implementations a voltage of about 7 V was applied to the unselected bitlines and transferred to the channel of the cells on the selected wordline [39]. This, however, had two significant drawbacks. First, the junctions of the cells had to withstand the high voltage applied to the unselected bitlines, which restricts the scalability of the cell. Second, all the unselected bitlines had to be charged to a high voltage during programming. When the supply voltage was reduced from 5 to 3.3 V a new solution was implemented [40]. In that solution the bitline selects of the unselected wordlines are switched off by applying V_{DD} to the unselected bitlines. The channel of the inhibited cell will then raise its potential by capacitive coupling via the tunnel oxide capacitance C_{Tunnel} and the ONO capacitance C_{ONO} to the high voltage applied to the wordline. A high voltage applied to the passing wordlines will

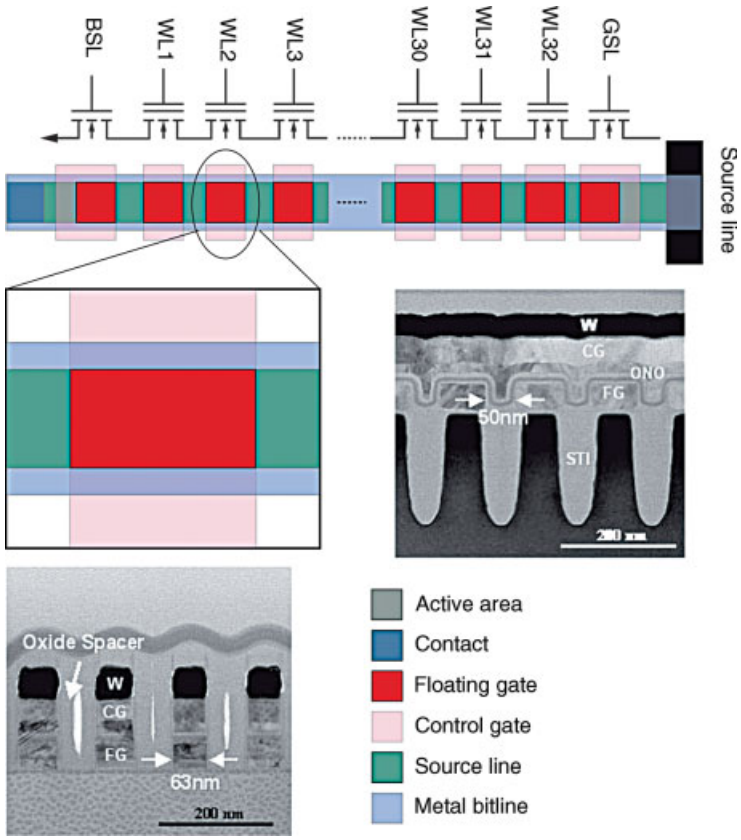

Figure 11.11 Layout and cross-sections of a string of NAND memory cells. In today's technologies, 32 cells are placed between a ground select and a bitline select. The ground select connects the string to a ground line, that in turn connects all strings to ground. The bitline select connects every string to a metal bitline via a bitline contact. The cross-sections are taken from a 60-nm technology [38].

further help to raise the channel potential in the disturbed cell. Now, the programming voltage and the voltage applied to the passing wordlines must be optimized to minimize the disturb effect. Examples for 120 and 90 nm Technology generations can be found in Ref. [41].

A large number of floating-gate concepts other than standard NOR or NAND have been proposed, and some of these are – or were – in production. Good overviews can be found in Refs. [42, 43]. Embedded flash memories have somewhat different requirements than standalone memories. Normally, much smaller memory densities are required than in standalone memories, and therefore the cell size is not as important but rather the size of the complete memory module including charge pumps, decoding, and so on must be minimized. This results in a high incentive to minimize the voltage requirements. Besides, every application focuses on different

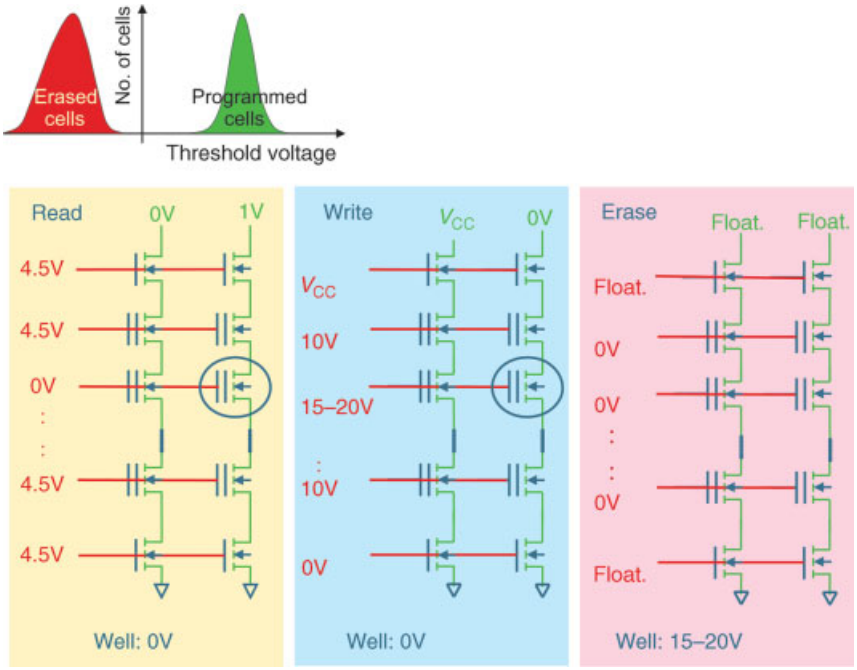

Figure 11.12 Read, write and erase operations of a NAND memory array.

requirements such as very fast random access, high endurance, high reliability, or low power, and therefore a large number of concepts coexist. In general, the ETOX is a good fit to many requirements, as long as the power consumption during programming can be tolerated. Among the large number of different concepts (some of these are referred to in Table 11.1) the field-enhancing tunneling injector cell [45, 47] is very popular and has been adopted by many foundries. Here, source side injection is used for the programming.

11.3.4 Reliability Aspects of Floating-Gate Flash

Every charge-based non-volatile memory inherently faces two reliability challenges. The first challenge is that the stored charge may be lost or charge may be gained during storage, leading to a loss of information; this phenomenon is referred to as *retention loss*. The second challenge is that the memory cell will degrade during repeated programming and erase cycles. Therefore, the endurance that a memory cell can achieve is a decisive quality criterion. Figure 11.13 illustrates how these basic properties manifest themselves in a 90 nm NAND Flash memory cell [46]. As program and erase cycling degrades the properties of the memory cell, the retention properties will also be affected by the precycling.

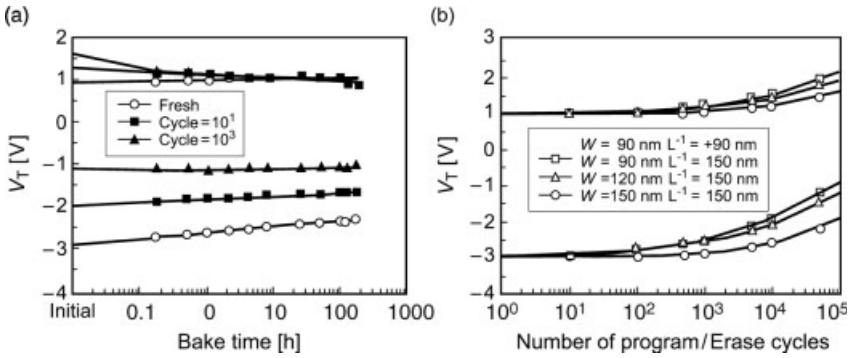

Figure 11.13 Retention (a) and endurance (b) characteristics of a 90-nm NAND Flash memory cell [49]. The dependence on precycling is shown for the retention characteristics, while the influence of device geometry is illustrated for the endurance curve.

In floating-gate memories, two specific effects must be mastered. The first is an effect that causes an abnormal erase behavior, leading occasionally to a much faster erase in some cells (see Figure 11.14a). As this effect is erratic in nature and affects single bits rather than the whole population, this phenomenon is called *erratic bit* [47]. The second phenomenon is also statistical in nature, in that during storage some cells may lose charge much faster than the main population. This effect occurs at lower temperatures, disappears at high storage temperatures, and becomes more pronounced after cycling (Figure 11.14b and c). This second effect is referred to as *anomalous SILC* or *moving bit effect*. Erratic bits are attributed to hole trapping in the bottom oxide. A small probability exists that clusters of three or more trapped holes exist. The overlap of the electrical field of the trapped holes leads to a strong increase in tunneling current [48], and thus to a much faster erase. The anomalous SILC or moving bit is explained by charge loss via neutral traps that are generated while cycling the cell. As a percolation path of such traps must exist for a charge loss to occur, the phenomenon is a strong function of oxide thickness, with thicker tunneling oxides showing much lower moving bit rates than their thinner counterparts [49].

11.3.5 Scaling of Floating-Gate Flash

The most severe issue in scaling down floating-gate devices is the non-scalability of the tunnel oxide and the inter poly dielectric. In order to achieve non-volatile retention, the tunneling dielectric must be at least 6 nm thick [50], although in practical memories thickness of 8–10 nm are used, based on the concrete reliability specification. This margin allows the covering of extrinsic effects such as moving bits. Scaling of the oxide-nitride-oxide (ONO) layer used as the interpoly dielectric is limited to an electrical effective thickness of about 13 nm due to retention and V_t stability constraints [51].

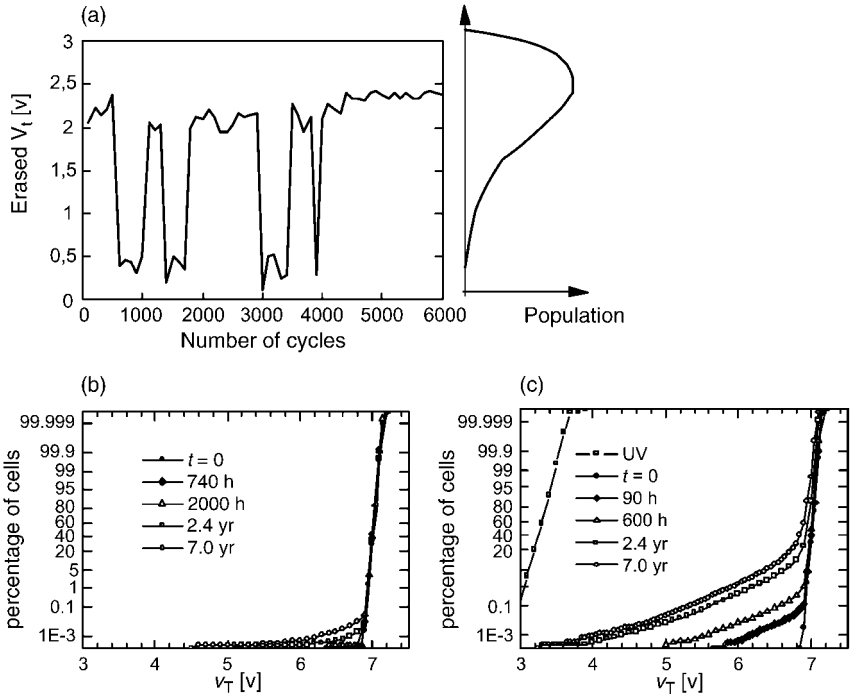

Figure 11.14 Specific reliability phenomena in floating gate memory cells [50]. Erratic bits (a) occasionally have a much faster erase than the majority of the population. Some bits show a pronounced low-temperature retention loss which is much higher after cycling (c: after 10 k cycles) than before cycling (b: after 10 cycles).

Further scaling of the tunneling oxide can only be obtained by radically re-engineering the tunnel barrier. Materials with a higher dielectric constant (e.g., HfO_2, ZrO_2) that are currently investigated for logic transistors can help. Crested barriers [52] could further improve the basic memory cell by increasing the ratio between the on and off current, leading to much faster write times as well as lower programming voltages. The principle of such an approach is shown schematically in Figure 11.15. The triangular shape of the barrier maintains the maximum barrier height if no voltage is applied (retention case), but drastically reduces the effective barrier in case of an applied voltage (programming or erase case). As a crested barrier is not achievable with those materials that have the required barrier heights, a staircase approximation using three layers with different band offsets, as well as different dielectric constants, is a reasonable approach. In the optimum structure the center layer would have a high band offset and a high dielectric constant, while the surrounding layer has lower band offset as well as a lower dielectric constant (Figure 11.15c). In most materials, however, a high band offset is correlated with a low dielectric constant and vice versa, making the optimum choice very difficult. A stack consisting of $Si_3N_4/Al_2O_3/Si_3N_4$ could be a reasonable and producible

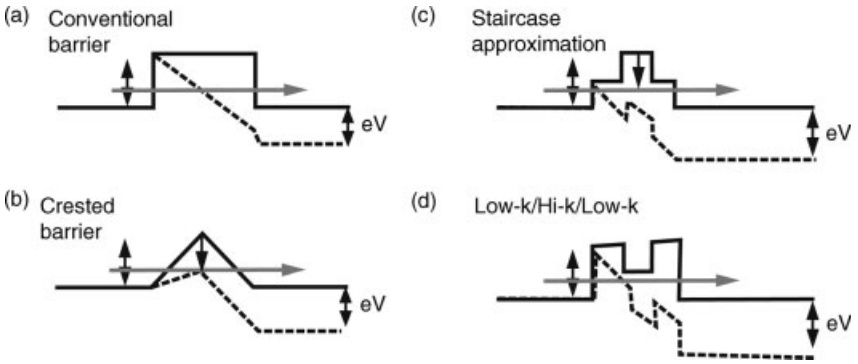

Figure 11.15 Different approaches to re-engineer the tunneling barrier of a floating-gate memory cell. (a) Conventional barrier; (b) ideal crested barrier; (c) staircase approximation of a crested barrier; (d) hi-k barrier sandwiched in between two low-k layers.

compromise [53]. An alternative – and perhaps better – manufacturing approach would be to sandwich a hi-k layer in between two low-k layers [54], and encouraging data have recently been demonstrated by using such an approach [55].

The non-scalability of the inter-poly dielectric thickness will eventually lead to a situation where the control gate will not fit into the space between two floating gates (Figure 11.16a). With the conventional ONO dielectrics this would lead to a situation where the control gate to floating gate coupling is significantly degraded [56]. To compensate for this, a high-k coupling dielectric is required, which has a k-value high enough to achieve the coupling only via the top of the floating gate (Figure 11.16b). Typical materials are very similar to those used for gate dielectrics, including HfO_2 and Hf/Al micro laminates [57].

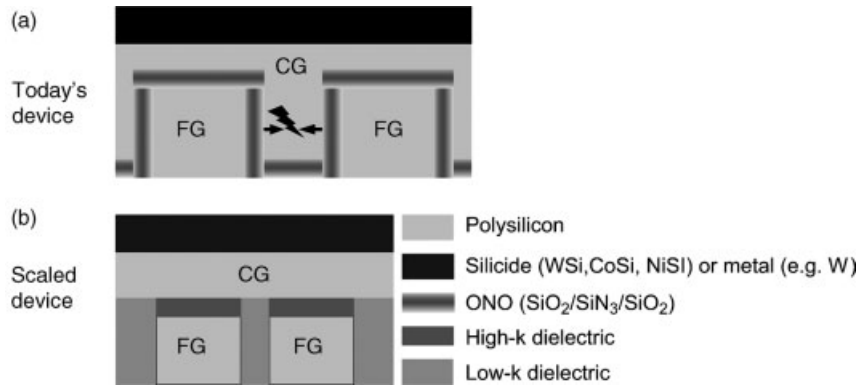

Figure 11.16 Possible scaling path for floating-gate memory cells. (a) Today's device architecture. (b) A scaled device using high-k inter-poly dielectrics as well as low-k dielectrics between floating gates. CG, control gate; FG, floating gate.

The reduced spacing between floating gates will also lead to higher capacitive coupling between floating gates, and result in severe crosstalk between cells [55]. This calls for a material with a lower dielectric constant between the floating gates, as shown in Figure 11.16b. This must also be implemented in the area between the word lines. Replacement of the silicon nitride spacer of the cell transistor with a silicon dioxide spacer (as shown in Ref. [58]) may help to significantly reduce the effect, but in the long term real low-k materials will be necessary. The recently demonstrated air gaps between the floating gates may represent an ultimate solution [59].

Although the scaling challenges presented so far are valid for all types of floating-gate flash memory devices, in the NOR-type architecture two more limitations must be considered [60]. First, a contact is required for every two cells, and this results in a significant area overhead. The overhead can be minimized by using a contact that is self-aligned to the control gate [61], or by using a virtual ground NOR array rather than a common ground NOR array [62]. The second limitation is that the channel length scaling is limited by the high voltages required during channel hot electron programming. However, a vertical device may be required to overcome this issue [63].

Instead of reducing the feature size, the cost reduction and density increase of a flash memory can also be achieved by increasing the number of bits stored on the same surface area, rather than reducing the size of a physical cell. As the charge storage is analogue in nature, more than two levels can be stored on one floating gate. To code n bits, 2^n levels are required. Figure 11.17 illustrates the corresponding V_T distributions for both NOR and NAND devices. For NOR devices, the multi-level approach was introduced to the market back in 1997 [64], and today in NAND devices

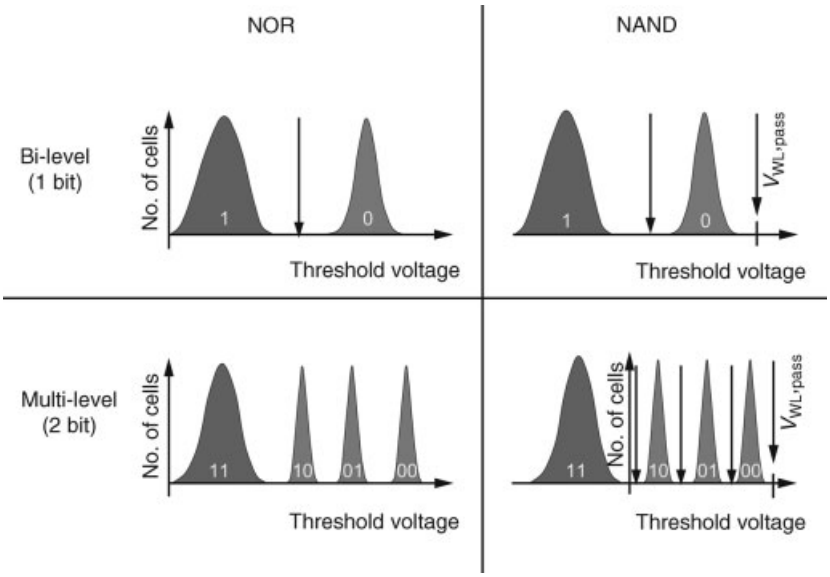

Figure 11.17 Multi level storage. The V_T distributions of a 1-bit and a 2-bit cell are compared for NOR as well as NAND Flash memories.

multi-level is also becoming increasingly popular as cost reduction is the most important aspect in data storage [65]. In the long term, the three-dimensional stacking of memory cells may also be an option; an example of this, namely the vertical integration of a NAND string, was demonstrated in Ref. [66].

11.4 Charge-Trapping Flash

Instead of using a floating gate to store the charge, an insulator with a high density of traps – a so-called *charge-trapping layer* – may also be used. Although this approach enjoyed some success during the 1970s and 1980s for EPROM and EEPROM memories [67, 68], in Flash memories the floating gate, in its ETOX and NAND versions, became dominant during the 1990s. The charge-trapping concept has some interesting advantages over floating-gate devices. As the charge is highly localized, no capacitive coupling effects (as described in Section 11.3.1) need to be considered. The cell can be described by Equations 11.2 and 11.3 with the storage charge included in Q_{IS}, which means that there is no drain turn on effect. The localization of charge also makes the cell less sensitive to any local defects responsible for erratic and moving bits in floating-gate cells. The coupling between cells is also much less pronounced. A few years ago the localization was utilized to store two physically separated bits in the same memory cell to create a multi-bit cell [69] (see Section 11.4.2), and this led to a revival of charge-trapping devices in the Flash world.

11.4.1 SONOS

Today, charge-trapping devices typically use a stack consisting of a polysilicon control gate electrode, a silicon dioxide topoxide, a silicon nitride storage layer, and a silicon dioxide bottom oxide placed on top of the active silicon. This stack (see Figure 11.18, left side) is referred to as a SONOS structure. Figure 11.18 also illustrates the programming and erase operation of such a structure using tunneling. During the programming and erasing operation, electrons or holes can be injected into or ejected out of the nitride storage layer. In programming, it is mainly electron injection from the silicon channel over the bottom oxide barrier into the nitride that takes place. Generally, for very long programming times and high V_T shifts, the hole injection from the control gate becomes significant and reduces any further programming. In the initial phase of the erase, the tunneling of electrons from traps via the nitride conduction band into the channel region is the dominant process, but this is increasingly being replaced by hole tunneling from the channel to the nitride as the erase progresses [70]. The erase process will result in less-negative charge in the trapping layer, leading to a reduction of the trapping layers potential. Therefore, the field over the bottom oxide is reduced and the field over the top oxide is increased, leading to an onset of electron tunneling from the gate to the trapping layer and a

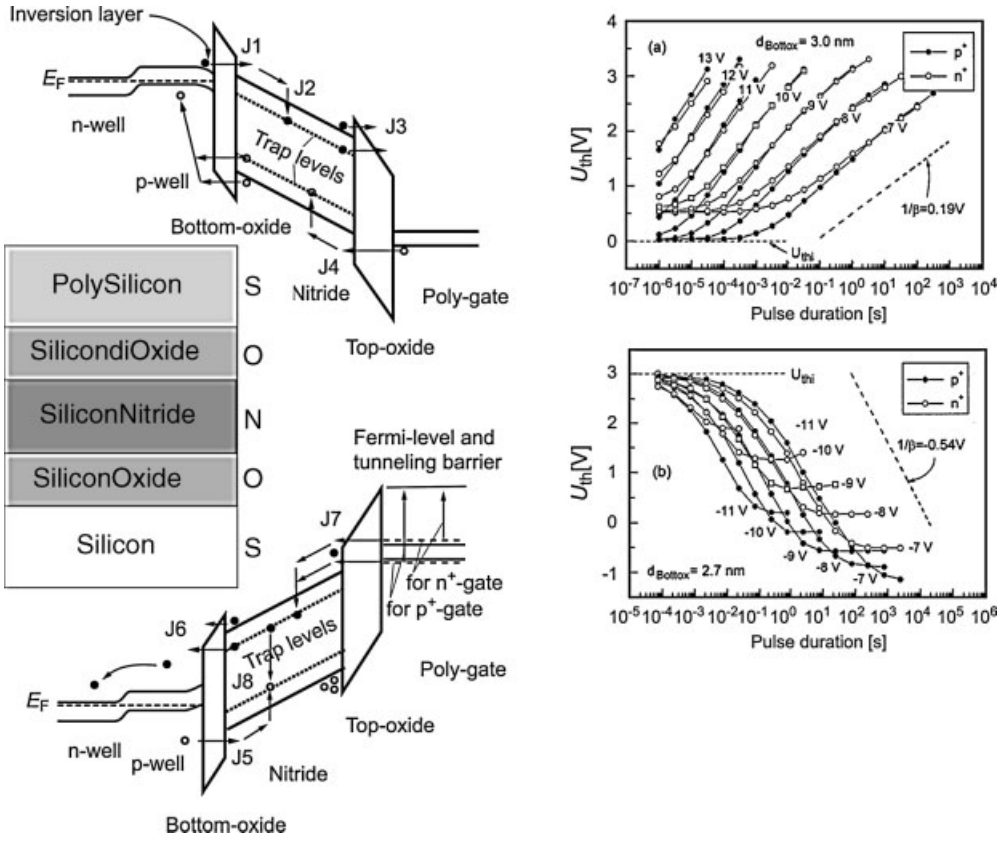

Figure 11.18 Programming (top row) and erase (bottom row) operation of a SONOS-type structure illustrated in the band diagram and a V_T over time characteristic [70]. During erase, the field over the bottom oxide will gradually decrease, while the field over the top oxide will increase; this will lead to a steady state and therefore to a saturation effect. The asymmetry of the two interfaces makes the saturation occur at higher V_T levels for higher gate voltages.

reduction of hole tunneling from the channel to the trapping layer. Finally, a steady state of the two processes – and therefore a saturation of the erase – will occur.

Due to the asymmetry of the two interfaces, the increase in erase voltage will lead to a strong increase in the injection from the gate, and hence to an even higher saturation level. This can be seen in the lower right-hand graph in Figure 11.18. In order to increase the erase speed, it is possible to increase the field over the bottom oxide, to reduce the field over the top oxide, or to increase the barrier for electrons at the control gate–top oxide interface. Although the simplest choice is to reduce the bottom oxide thickness, which will lead to a significantly increased field over the bottom oxide, it will also degrade the retention properties. For many years, therefore, the SONOS development was caught in the trade-off between bad retention and slow erase.

The increase in the barrier for electron injection from the gate electrode is very effective, as can be seen in Figure 11.18 (lower right), where n^+ doped gates and p^+ doped gates are compared. However, this alone is insufficient to achieve an erase performance that will be fast enough for a data Flash memory, yet still be secure after 10 years of retention. The field over the top oxide can be reduced by replacing the silicon dioxide with a high-k material such as Al_2O_3 [71]. Indeed, recently the combination of an Al_2O_3 topoxide and a high-workfunction TaN gate electrode was implemented in order to achieve NAND Flash-compatible performance on a 63 nm demonstrator using a bottom oxide as thick as 4 nm [72]. The structure used was referred to as a TANOS (Tantalum-nitride/Silicon-nitride/Silicon-dioxide/Silicon). The cross-section of the used stack, as well as the erase curves demonstrating a memory window of 5 V, are shown in Figure 11.19. This device represents a very promising candidate for NAND Flash memories with sub-40 nm ground rules.

11.4.2
Multi-Bit Charge Trapping

If the localized charge storage properties of a charge-trapping layer are combined with the localized injection by channel hot electrons, then the stored charge can be

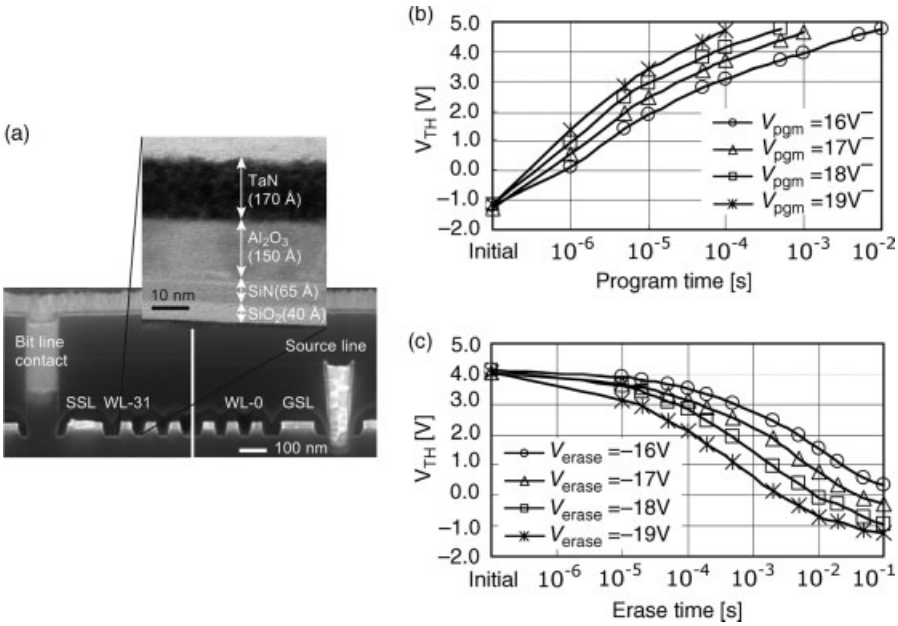

Figure 11.19 NAND Flash demonstrator using a TANOS cell on 63-nm ground rules [72]. The cross-section (a) shows the similarity to a floating-gate NAND. Program and erase performance is good enough to achieve 5 V memory window using a 4 nm-thick bottom oxide which ensures non-volatile retention.

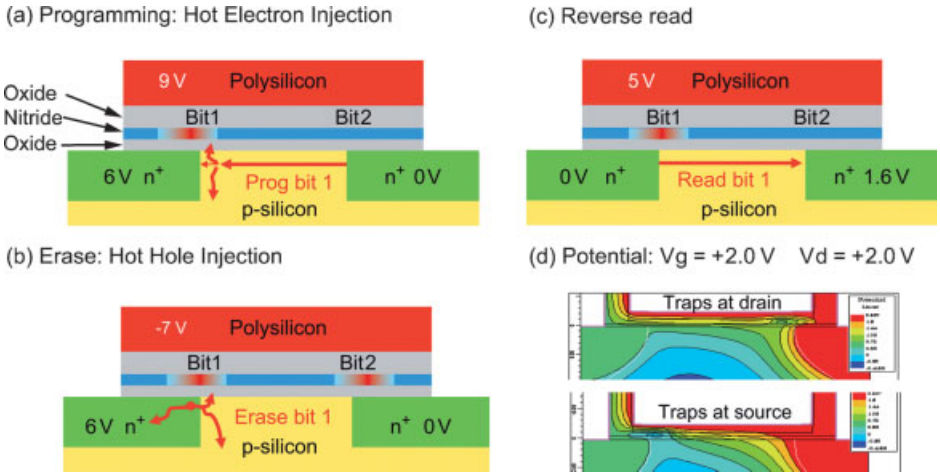

Figure 11.20 Multi-bit charge trapping memory cell. To inject charge self-aligned to the drain junction, programming is done by channel hot electron injection (a). Hot hole erase (b) enables the use of a thick bottom oxide. In reverse read (c), the charge of the second bit in the same cell is screened by applying a sufficiently high drain potential, while the role of drain and source are interchanged as compared to the programming conditions. The potential diagrams (d) show how the potential of the region below the charge is controlled by the drain potential rather than the stored charge if the drain potential is high. In (d), in red = high potential; blue = low potential.

placed in very narrow region which is self-aligned to the drain junction of the device. By interchanging the source and drain of such a device, two physically separated bits can be stored (see Figure 11.20a and Ref. [69]). In order to read the bits separately from one another, the source and drain must be interchanged compared to the programming conditions, and a drain voltage large enough to punch through the region below the charge above the drain region used in read must be applied (Figure 11.20c and d). As the charge is localized in a region close to the drain junction during programming, hot holes generated by band-to-band tunneling can be used for erase to compensate the stored charge (Figure 11.20b; see also Figure 11.7 and Ref. [13]). This allows for a sufficiently thick bottom oxide layer so as to avoid vertical charge loss and circumvent the erase saturation issue described in Section 11.4.1.

This device is implemented under different trade names such as NROM [13], MirrorBIT [73], NBit [74] and Twin Flash [75], both in code and data Flash products.

In order to operate the multi-bit charge-trapping cell described above, it is essential to have an architecture where no difference between bitlines and sourceline exists. The virtual ground NOR array (see Figure 11.7) therefore is the natural choice. This can be constructed by the structuring of a ONO layer, implanting the bitlines through the openings, growing an oxide for isolation, and finally forming the wordlines perpendicular to the bitlines. This method was used in the first-generation systems (see Figure 11.21a), but it has the drawback of a high thermal budget that must be applied to the bitline implants.

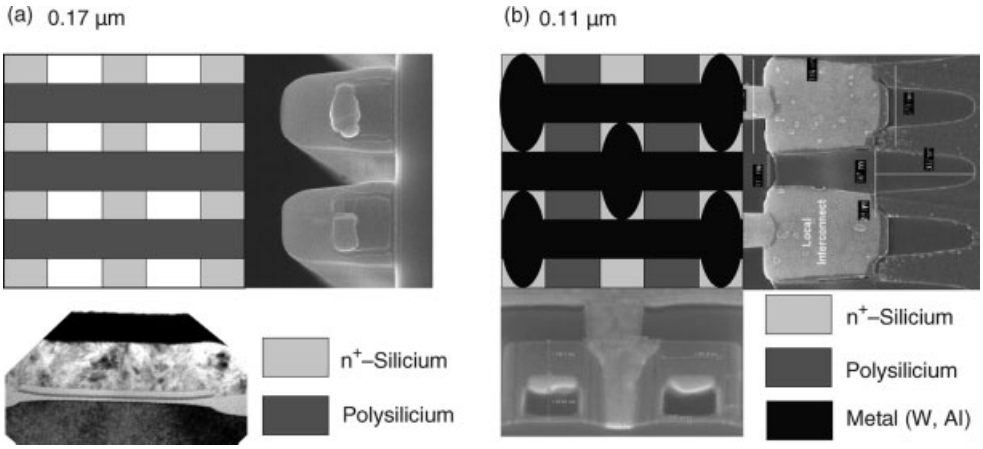

Figure 11.21 Multi-bit charge-trapping memory cells. In the 0.17 µm generation a buried bitline with crossing wordlines was used [79]. A more advanced version uses a device that resembles a standard MOS transistor [80, 81]. To end up with a virtual ground NOR architecture, a local interconnect must connect two neighboring devices over an isolation region. This local interconnect is then connected to the metal bitline.

Although the multi-bit charge-trapping type of memory cell has all the advantages described in Section 11.4.1, plus the inherent two bit per cell operation, there remain two challenges that must be considered. First, the unique mechanism of localized charge storage makes an understanding of the reliability-governing factors more complex. On an empirical basis, all effects that are necessary to create a reliable product are well understood and under control [76]. The physical basis for the observed results, however, remains the subject of debate among the scientific community. In principle, two effects may occur: First, the injection of hot holes during erase may damage the bottom oxide, leading to traps that can cause a vertical loss of the stored electrons [77]. Second, due to the fact that in programming and erase two localized mechanisms are used that will not be totally aligned to each other, a dipole will be created. This dipole may lead to lateral charge movement and therefore a change in V_T. In practice, however, both mechanisms may be involved, leading to a well-behaved and predictably reliable unit [78].

A number of modifications of the above-described multi-bit charge-trapping cell have been reported. For example, by adding an assist gate programming can be carried out using source side injection, which significantly reduces the cell current during programming. Examples of multi-bit charge-trapping cells using source side injection may be found in Refs. [82–84]. Another interesting variant is created by programming the cell with hot holes rather than hot electrons. In that case, the erase may be performed by FN tunneling either to the channel or to the gate [85, 86]. This concept, which is referred to as PHINES (programming by hot-hole injection nitride electron storage), has one main drawback in that programming of the second bit on

the same junction must be avoided. However, the same basic cell can also be used in a NAND-type architecture [87].

11.4.3
Scaling of Charge-Trapping Flash

When further scaling down the planar type of SONOS cell, the cell properties will suffer from low gate control, low read current, and a small number of electrons. In principle, the options of tailoring the tunneling barrier described for floating-gate device scaling can also be applied to the bottom oxide of a charge-trapping cell. Charge trapping, however, also enables another scaling path, by utilizing a FinFET device [88]. In principle, this could also be achieved with a floating-gate device, but two problems are encountered: First, the stack of tunnel oxide, floating gate and interpoly dielectric is too thick to fit the space between two neighboring cells; and second, the high coupling of the floating gate to the channel in a FinFET device will cause a deterioration in the gate coupling ratio [see Equation 11.2]. In a charge-trapping device the implementation of a FinFET device is straightforward; the general concept, as well as the excellent programming and erase curves that may be achieved with devices as short as 20 nm [89], are illustrated in Figure 11.22.

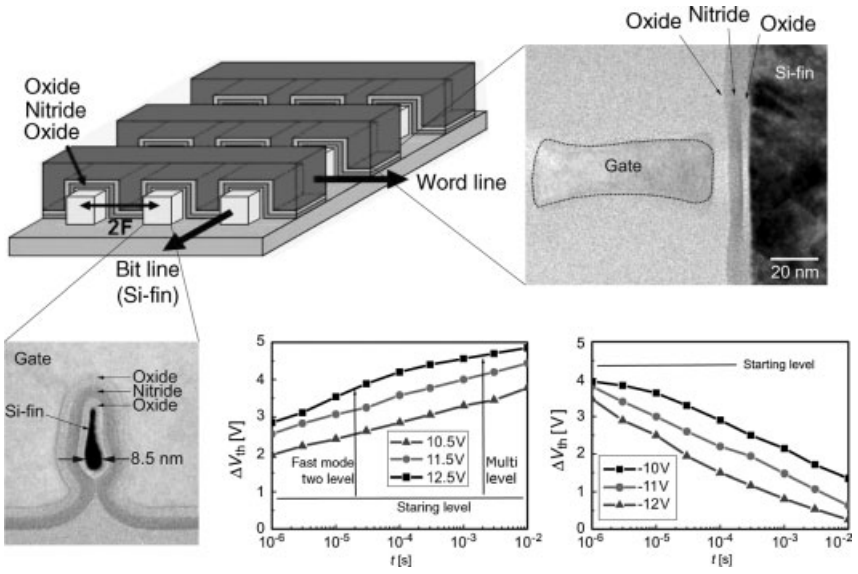

Figure 11.22 FinFET-based charge-trapping NAND [89]. The SEM images show cross-sections of a fabricated device with a channel length of 20 nm and a fin width below 10 nm. The programming and erase characteristics demonstrate a memory window of more than 4 V with fast program and erase.

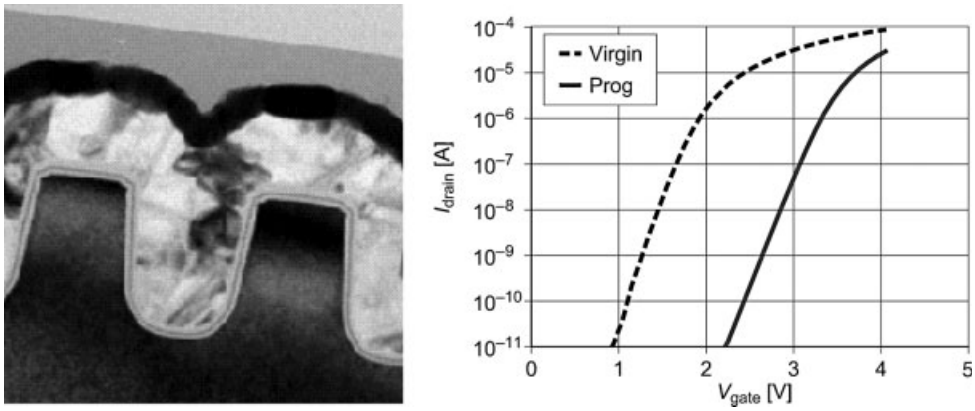

Figure 11.23 U-shaped multi-bit charge-trapping cell [93]. The U-shaped channel allows the surface area usage to be reduced, without any reduction of the effective channel length. The current–voltage (I–V) curves demonstrate the excellent separation of the two bits. Virgin = unprogrammed; Prog = programmed.

In order to further increase the memory density, a 3-D NAND-type memory would be very beneficial. Although the straightforward approach here would be to use thin-film transistors, charge trapping is again the favored solution, as it is much easier to integrate in a stacked manner compared to a floating-gate device. The first results of a thin-film transistor-based charge-trapping memory cell have recently been published by Walker and colleagues [90].

For the multi-bit charge-trapping memory cell it is essential to scale down the channel length, and indeed some excellent cell properties have been demonstrated down to 60 nm generation with the type of cell shown in Figure 11.21b [75, 81]. For further scaling down, a cell which uses structured nitride areas to store the charge was proposed. This has the advantage of controlling the cross-talk between bits, as well as being able to us thinner gate dielectrics between the ONO layers [91, 92]. A more radical approach that utilizes the third dimension by adopting a U-shaped device [93] is shown in Figure 11.23. Another approach to increase the storage density and reduce the area usage per bit is to combine the multi-bit concept with a multi-level approach. As a result, with four levels on each side of the cell (a total of eight levels), 4 bits can be stored [94], whereas by comparison a floating-gate cell requires 16 levels to store 4 bits (see Section 11.3.5).

11.5
Nanocrystal Flash Memories

In addition to floating gates and charge-trapping layers, nanocrystals are also currently under investigation for future use as flash devices [95]. A typical

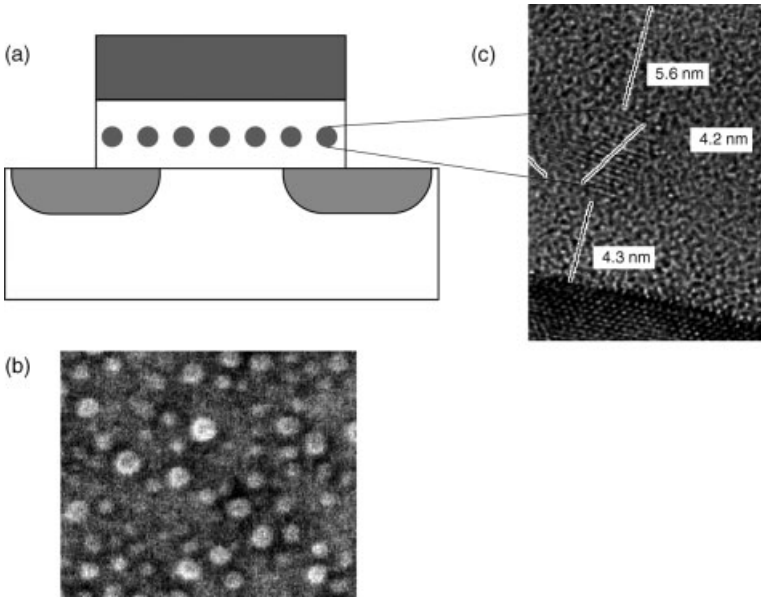

Figure 11.24 Silicon nanocrystal Flash cell. (a) Conducting nanocrystals are embedded into the gate dielectrics of a MOS device. The SEM images show (b) a top view and (c) a cross-section of a typical silicon nanocrystal layer [99].

nanocrystal device is illustrated schematically in Figure 11.24, whereby small conductive crystals with a diameter of about 2–5 nm are embedded into a silicon dioxide layer. Most of these investigations have been conducted on silicon nanocrystals, although germanium [96] or metal [97, 98] nanocrystals have also been studied. As with charge-trapping devices, nanocrystal devices are much more robust with respect to local defects in the bottom oxide layer. They also show the unwanted erase saturation that is observed in SONOS. However, in the case of silicon nanocrystals there are two identical interfaces/barriers between the control electrode and topoxide, as well as between the nanocrystal and bottom oxide. Hence, a higher voltage will not lead to an even higher erase saturation level, and the erase can be accelerated to the appropriate level by using a higher erase voltage [100].

Nanocrystal devices can be programmed and erased either by tunneling [101] or by hot electron/hot hole injection [102]. In the latter case, as with charge-trapping memories, a multi-bit device can be realized, whereas in the former version nanocrystals may be candidates for future NAND-type memories. Although the erase saturation is somewhat relaxed, the trade-off between fast program and erase and sufficient non-volatile retention is a key issue for nanocrystal devices which are programmed and erased using tunneling. One way to improve the retention is to use a self-aligned double stack of nanocrystals [103]; in this way, by utilizing the coulomb blockade effect and quantum confinement, the retention can be improved if

a small nanocrystal embedded into a thin oxide layer is placed below the larger nanocrystal which actually carries the stored charge.

In most cases, either a low-pressure chemical vapor deposition (LPCVD) from SiH_4 [104] or ion-implantation with subsequent thermal treatment [105] are used to fabricate nanocrystals. Although other techniques have shown promise [106], LPCVD and ion implantation are the easiest procedures for integration into a standard CMOS process. In both cases, the nanocrystal formation is a statistical process leading to controllability issues in scaled down devices [107]. Methods for controlled fabrication of nanocrystal size and distance by using templates or self-organization would, therefore, significantly improve the outcome [108]. When further scaling down the nanocrystal device, this path may in time lead to a single-electron memory [109].

11.6 Summary and Outlook

The trend towards mobile electronic devices has created – and continues to create – a rapidly increasing demand for non-volatile memories. Today, Flash memories represent the best solution for most of these applications, where coded Flash applications are typically covered by NOR Flash devices and data Flash applications by NAND Flash devices. Currently, the floating-gate transistor is seen as the "workhorse" of those cell devices used in many of today's technologies. Indeed, floating-gate technology shows a scaling potential for further generations if innovations such as high-k coupling dielectrics or low-k isolation oxides can be mastered. By contrast, charge-trapping devices are possibly due to make a return, with multi-bit charge-trapping having recently emerged in a number of applications. In fact, a modified version of the classical SONOS device, programmed and erased by tunneling, may replace the floating-gate transistor in future generations of NAND Flash. Nanocrystals represent another option to replace the floating gate, although at present the challenges that they face seem much more severe than for the charge-trapping case. However, in the long term this development may lead to a single-electron device.

Unfortunately, flash-type memories based on charge storage in either floating gates or charge-trapping layers still suffer from important drawbacks, including limited endurance, slow write/erase, and no direct overwrite. Hence, for many years research groups have sought new storage mechanisms that could supply a non-volatile memory without such shortcomings. To achieve this goal, new materials with innovative switching effects must be integrated into the CMOS flow [110, 111]. Although these technologies are beyond the scope of this chapter, it is important to note that although they may have distinct advantages over Flash memories, and indeed some have now reached the production stage (see Chapters 13–16), the scaling of Flash memories has to date been much more successful. Such scaling possibilities provide Flash with a major competitive advantage in terms of system cost.

Dynamic Random Access Memory

Fumio Horiguchi

12.1
DRAM Basic Operation

Dynamic random access memories (DRAMs) use the charge stored in a capacitor to represent binary digital data values. They are called "dynamic" because the stored charge leaks away after several seconds, even with power continuously applied. Therefore, the cells must be read and refreshed at periodic intervals. Despite this complex operating principle, their advantages of small cell size and high density have made DRAMs the most widely used semiconductor memories in commercial applications. In 1970, the three-transistor cell used for the 1 kbit DRAM was first reported [1], and the one-transistor (1T-1C) cell became standard use in 4 kbit DRAMs [2]. During the following years, the density of DRAMs increased exponentially, with rapid improvement to the cell design, its supporting circuit technologies, and fine patterning techniques.

The equivalent circuit of the 1T-1C DRAM cell is shown in Figure 12.1. The array transistor acts as a switch and is addressed by the word line (WL), which controls the gate. The storage capacitor, C_S, represents the charge storage element containing the information and is connected to the bit line, BL, via the array transistor. When the array transistor switch is closed, the voltage level $+V_{DD}/2$ or $-V_{DD}/2$ is applied to C_S via the bit line. The corresponding charge on C_S represents the binary information, "1" or "0". After this write pulse, the capacitor is disconnected by opening the array transistor switch.

The memory state is read by turning on the array transistor and sensing the charge on the capacitor via the bit line, which is precharged to $V_{DD}/2$ (where V_{DD} is the power supply voltage). The cell charge is redistributed between the cell capacitance, C_S, and the bit line capacitance, C_B, leading to a voltage change in the bit line. This voltage change is detected by the sense amplifier in the bit line and amplified to drive the input/output lines. Because a read pulse destroys the charge state of the capacitor, it must be followed by a rewrite pulse to maintain the stored information. The plate, PL, is kept at $V_{DD}/2$ to reduce the electric voltage stress on the capacitor dielectric, which is charged to $+V_{DD}/2$ or $-V_{DD}/2$ instead of being discharged to 0 V and charged to the full power supply voltage, V_{DD}.

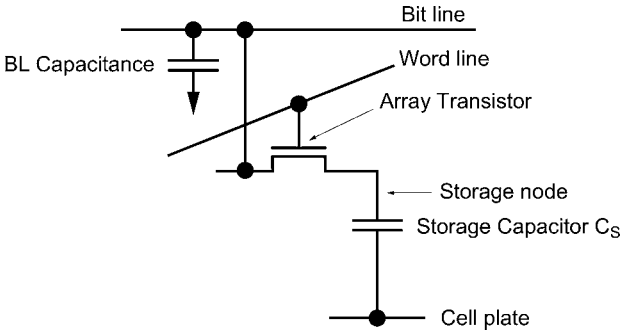

Figure 12.1 DRAM memory cell equivalent circuit. See text for details.

DRAM has required almost constant storage capacitance (more than 40 fF, i.e., 4×10^{-14} F) among the generations, despite the scaling to smaller cell sizes, and this is the reason for the requirement of three-dimensional (3-D) structures such as trench or stacked capacitor. A trench capacitor uses the inner surface of a Si hole to store charge, while a stacked capacitor uses a poly Si capacitor above the array transistor and bit line (see Figure 12.2).

12.2 Advanced DRAM Technology Requirements

Historically, the cost of DRAM has been forced to decrease to retain its share in the huge and competitive market for high-density memory. This has resulted in a

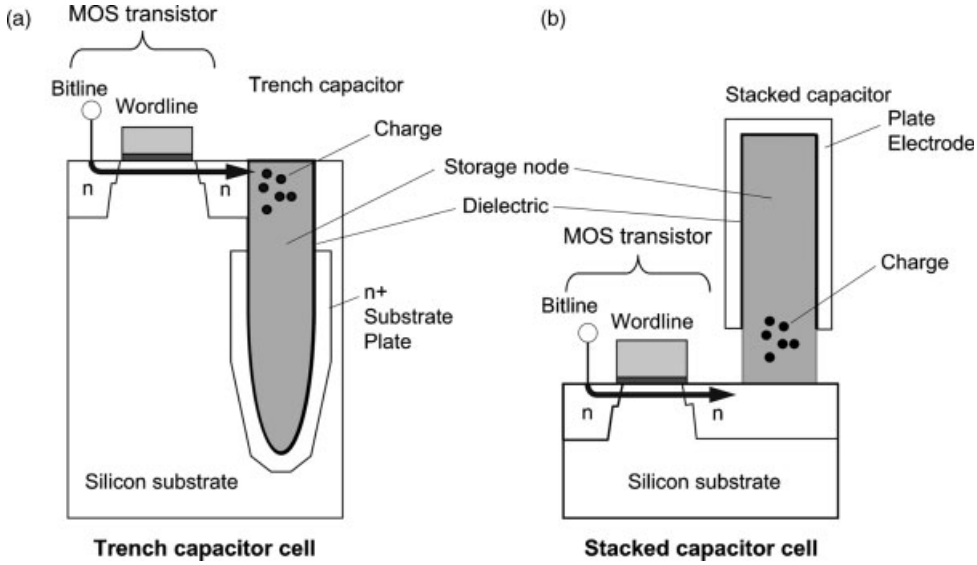

Figure 12.2 Conventional DRAM cells.

Table 12.1 Technology requirements for a DRAM memory cell.

Cell area	Smaller cell area $<8\,F^2$
Storage capacitor	>40 fF, low leakage $<1\times10^{-16}$ A
Array transistor	High drivability; low leakage current ($<1\times10^{-16}$ A)
Bit line contact	Self-aligned to the word line
Storage node contact	Self-aligned to the word line (and trench capacitor or bit line)

decrease in DRAM cell size because the chip cost is directly related to the cell area. Thus, every part of the cell is required to be as small as possible, and the cell size must be less than or equal to $8\,F^2$ (where F is the feature size). A summary of the technological requirements for a DRAM memory cell is provided in Table 12.1. The most critical part in the cell shrinkage is the capacitor; thus, a 3-D structure such as a trench or stacked capacitor has been adopted to retain sufficient capacitor area within a limited space.

As the DRAM cell size shrinks to sub-100 nm, it becomes critically important to realize a sufficient on-off-current ratio in the array transistor. In general, the scaling approach implies that the transistor sizes L and W, the gate oxide thickness T_{ox}, the supply voltage, and the threshold voltage V_{th} should be reduced by a factor of $1/k$ (k: scale factor), and that channel doping should be increased by a factor of k in order to sustain or improve the transistor performance. In a DRAM cell, the charge must be stored in storage capacitors; therefore, an extremely low off-current in the array transistor is required for data retention. Thus, V_{th} should be made as small as possible to decrease the channel leakage current, and the supply voltage should be minimized so that sufficient charge can be written into the capacitor. Gate oxide thickness must also be reduced to maintain a sufficient breakdown voltage for the gate dielectrics. All this means that the array transistor cannot be scaled down in a conventional manner. On the other hand, a sufficient on-current in the array transistor is required for fast writing characteristics. This suggests a short L and large W, but scaling difficulties prevent the reduction of L and the cell size limits W. Thus, maintaining sufficient on-current in the array transistor is difficult and, moreover, increasing channel doping degrades the channel mobility, which further decreases the on-current in the array transistor.

In view of these considerations, a different structural approach for array transistors in DRAMs is necessary.

12.3 Capacitor Technologies

The first generation of DRAMs used a planar storage capacitor for memories of up to 1 Mbit. However, from the 4 Mbit generation onwards, trench or stacked capacitors were used for maintaining the same storage capacitance within a limited cell area. A comparison between the stacked capacitor cell and the trench capacitor cell is shown

Table 12.2 Stacked versus trench cells.

	Stacked	Trench
Complexity of capacitor formation	×	×
Decrement of memory cell parasitics	○	△
Shrinkability of memory cell	△	○
Compatibility with logic process integration	△	○
Compatibility with logic device characteristics	○	◎
Compatibility with logic layout design rules	△	◎
Additional mask steps: @130 nm node		6–9

in Table 12.2. The differences arise mainly from the transistor formation process compared with the capacitor formation process. The array transistor in a stacked capacitor is formed before the capacitor; thus, the transistor source/drain junctions can easily be extended after the stacked capacitor is fabricated by a thermal process, which results in a degradation in transistor performance. Figures 12.2 to 12.4 show

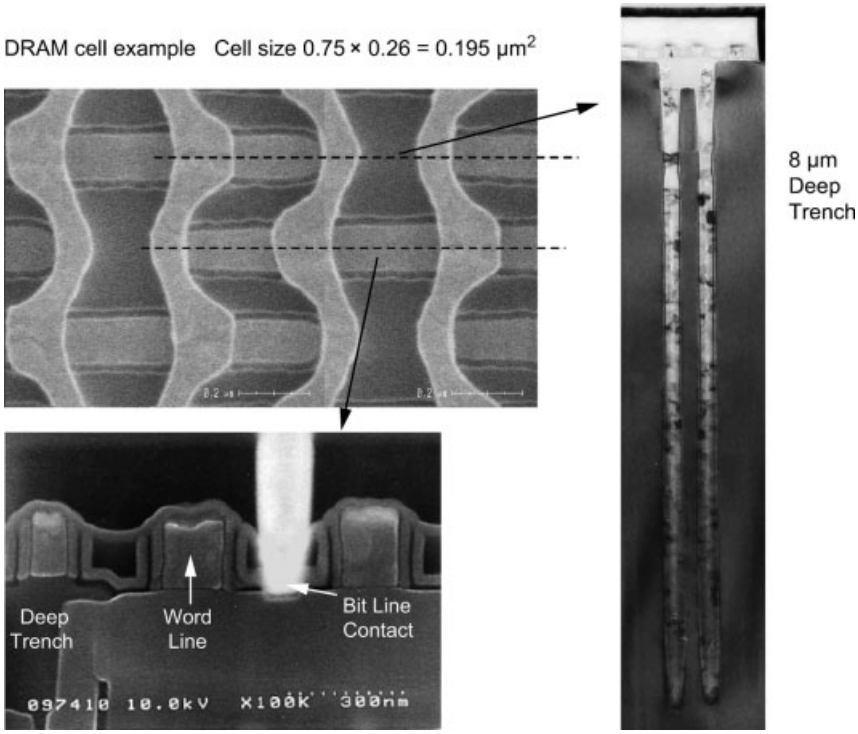

Figure 12.3 Trench capacitor cell. This has a 8 μm-deep trench capacitor and a sidewall storage-node contact for enough storage capacitance and small contact within a small area. (After Yamada, VLSI Tech. Short Course 2003 and Ref. [3]).

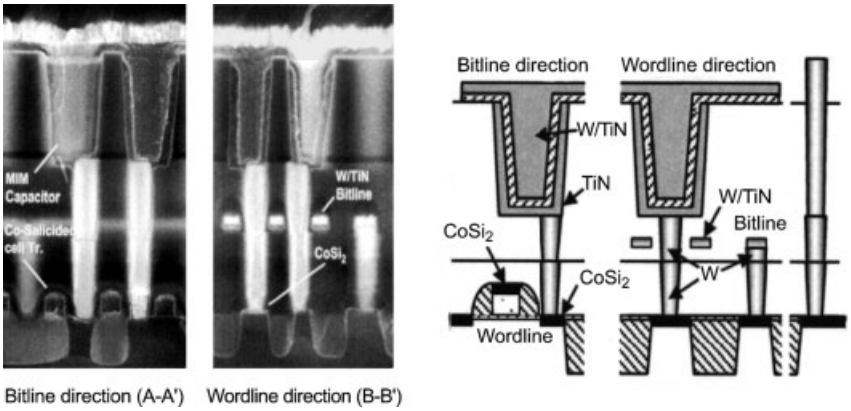

Figure 12.4 Stacked capacitor cell. This has a high-aspect-ratio storage node over the bit line and word line. The capacitor is composed of two electrodes and nitride-oxide or high-k dielectrics [4].

examples of trench and stacked capacitor cells, where each cell has high-aspect-ratio storage nodes under (trench) and over (stacked) the array transistor [3, 4].

Figure 12.5 shows the relationship between C_S and the trench diameter. C_S becomes smaller than 40 fF for a design rule of less than 90 nm because of the smaller capacitor area. To overcome the capacitor area reduction, hemispherical grains (HSG) [5, 6] can be used to enhance the surface area of the storage node in a deep trench cell (see Figure 12.6). HSG technology is an approach more typically used in the stacked capacitor cell. Another technique to enhance the capacitance is to use "high-k" dielectric materials such as Al_2O_3 or Ta_2O_5, where k denotes the dielectric permittivity. An example of a trench capacitor with a high-k Al_2O_3 dielectric is shown in Figure 12.7 [7]. The capacitance is increased by more than 30% compared with the standard nitride-oxide (NO) dielectric, which must be scaled to 1–2 nm thickness in a typical 65-nm process. As capacitor dielectrics are scaled, the leakage current increases (1.2 nm SiO_2 consists of only five atomic layers). Consequently, high-k dielectrics have been

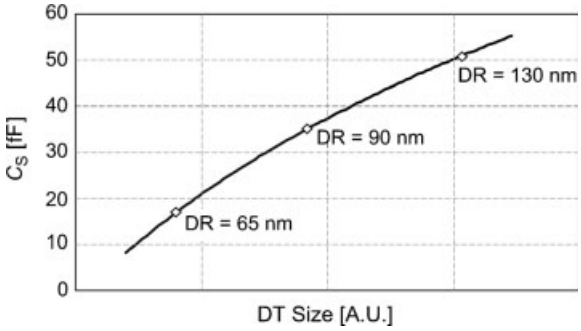

Figure 12.5 The relationship between capacitance (C_S) and trench diameter (DT).

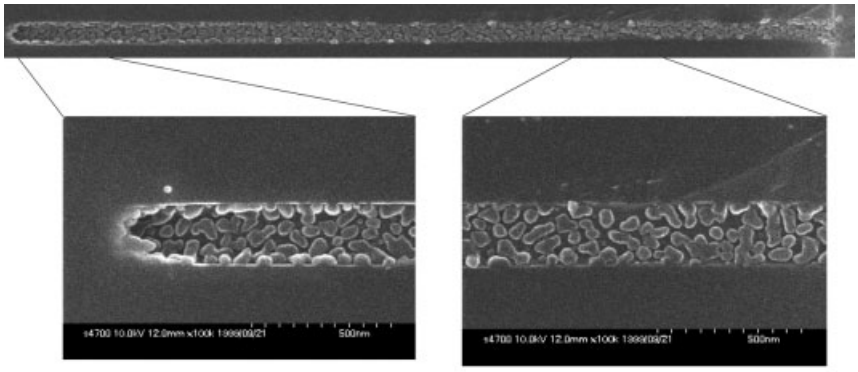

Figure 12.6 Trench capacitor with hemispherical grains (HSG).

proposed as alternatives for capacitor dielectrics to address the leakage problem. The most common high-k capacitor dielectrics used for gate dielectrics are Al_2O_3, Ta_2O_5 and hafnium-based dielectrics (e.g., HfO_2, HfSixOy). However, high-k gate dielectrics are not compatible with the polysilicon gate electrodes commonly used in today's integrated circuit technology. Their combination leads to threshold voltage uncontrollability and on-current reduction. Thus, metal gate electrodes with appropriate work functions must be used. Despite this, the implementation of high-k

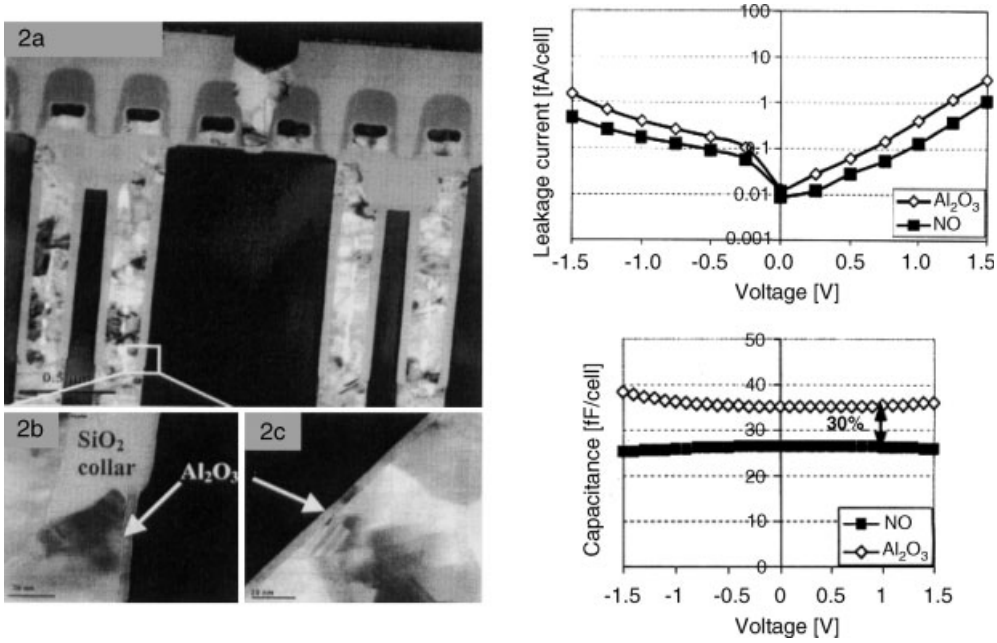

Figure 12.7 Trench capacitor with a high-k dielectric (Al_2O_3).

dielectrics and metal gate electrodes into complementary metal oxide–semiconductor (CMOS) technology is difficult, and involves many technical issues such as deposition methods, dielectrics reliability, charge trapping and interface quality. For capacitor dielectrics, it is much easier to implement high-k dielectrics because the threshold voltage shift induced by the charge trapping and the interface quality do not affect the capacitor characteristics compared with their effect on gate dielectrics. Thus, Al_2O_3 or Ta_2O_5 have been used as capacitor high-k dielectrics for a few DRAM products. For future DRAMs, high-k dielectrics will most likely be used not only for capacitor dielectrics but also for peripheral transistor gate dielectrics to overcome scaling problems.

12.4
Array Transistor Technologies

The recess-channel-array transistor (RCAT) [8] is used to reduce the electrical field near the drain to achieve a long data retention time in a stacked capacitor cell. Figure 12.8 shows the RCAT structure, which increases the effective gate length of the array transistor and mitigates the short-channel effect without increasing area.

Usually, channel doping enhances the electric field near the drain and degrades data retention characteristics because of the increased drain leakage current. To overcome this effect, the RCAT is used to reduce the electric field by separating the channel from the drain using an engraved channel region. This is effective in reducing the electric field and short-channel effects; however, the longer channel results in a small on-current in the array transistor. Thus, the RCAT is not suitable for high-speed writing.

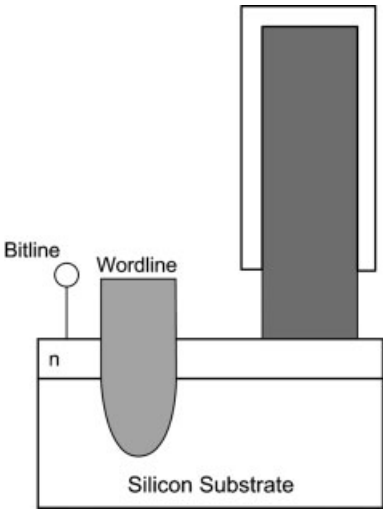

Figure 12.8 The recess-channel-array transistor (RCAT).

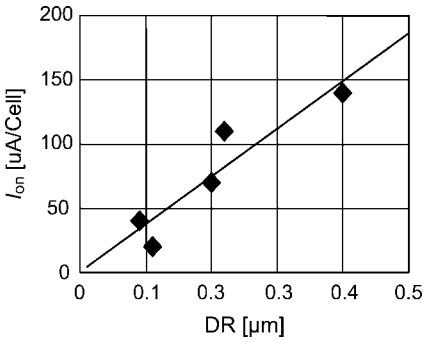

Figure 12.9 On-current (I_{on}) trend of array transistors.

The RCAT can be used down to around the 50 nm node, but below this another 3-D approach will be needed to satisfy the requirement of current drivability and to reduce the short-channel effect.

Figure 12.9 shows the on-current (I_{on}) trend of array transistors. The I_{on} decreases with transistor size in accordance with the design rule scaling; this in turn increases the signal delay in data sensing on the bit line (see Figure 12.10), in the case of reading a "1". When I_{on} is small, the signal appears on the bit line with a delay and approaches the "1" target level slowly.

To overcome these constraints in the array field-effect transistor (FET), a trench isolated transistor using sidewall gates (TIS) or a fin-array-FET can be adopted to improve the transistor performance, as in the case of silicon-on-insulator (SOI) transistors [9–12]. Figure 12.11 shows a "bird's-eye view" of a TIS-array FET where the TIS gate structure, which consists of a top gate and a sidewall gate enables a high on-current and a low off-current simultaneously because of the double-gate structure and high gate controllability. Figure 12.12 shows the T_{fin} (the width of the fin) dependence of the minimum gate length (L_g). A thinner T_{fin} would be expected to result in a marked reduction of off-current, which means that the TIS gate structure is very suitable for array transistors.

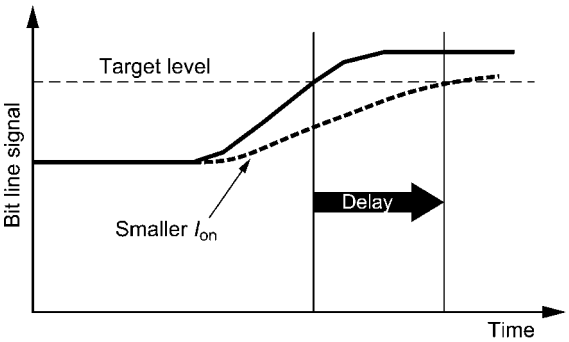

Figure 12.10 Signal delay by the smaller I_{on} current.

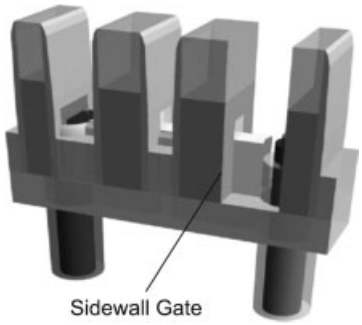

Figure 12.11 TIS/Fin array field-effect transistor (FET) DRAM.

In the TIS structure, the fin substrate is fully depleted and the double side gates contribute to the potential of each side channel. The subthreshold swing of the TIS transistor is smaller than that of the conventional planar transistor because of the strong effect of the sidewall gates. Thus, a small gate voltage difference can rapidly change the drain current from a small off-current to a large on-current. Moreover, the constant threshold voltage characteristics without a back-gate bias effect contribute to the large on-off-current ratio.

A more advanced array transistor is the *vertical transistor*, in which the source, gate and drain are arranged vertically. There are two types of vertical transistors. One uses the inner sidewall of the trench hole, while the other uses the outer sidewall of a silicon pillar for the channel. The former is suitable for trench capacitor cells [13], while the latter is known as a surrounding gate transistor (SGT) [14, 15]. The gate electrode of the SGT surrounds a pillar of silicon, and the gate length of the SGT is

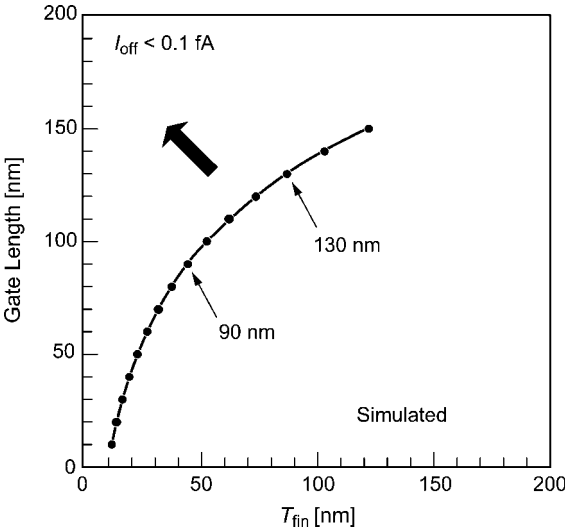

Figure 12.12 The dependence of fin width (T_{fin}) on minimum gate length (L_g).

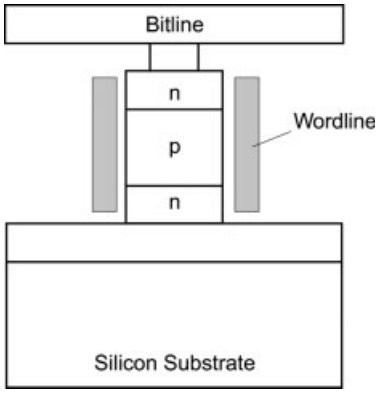

Figure 12.13 A surrounding gate transistor. The gate electrode of SGT surrounds a silicon pillar, with the gate length being adjusted by the pillar height.

adjusted by the pillar height, as shown in Figure 12.13. Therefore, the SGT has the merits of short-channel-effect immunity and superior current drivability resulting from the excellent gate controllability.

Planar array transistors cannot easily be scaled down (as noted above), and the TIS has good on-off-current ratio characteristics. The vertical transistor is different from the planar type in that the channel length is defined by the depth of the hole or the height of the pillar. Thus, the gate length is free from the minimum design rule and the cell area limitations, and can be selected to be sufficiently large so as to avoid the short-channel effect. Similar to the trench-type capacitor, the vertical transistor and the capacitor are formed in the same hole, and this contributes to the small cell size of less than $6\,F^2$. In the SGT cell, it is more difficult to form the capacitor and array transistor, although it has ideal array transistor characteristics. The SGT substrate is fully depleted and the surrounding gate contributes to the potential of the pillar surface channel. The subthreshold swing of the SGT cell is smaller than that of the conventional planar transistor and the TIS because of the stronger effect of the surrounding gate. Also, surrounding gate structures contribute to the large width of the transistor by using the entire perimeter of the pillar. Thus, a large on-off-current ratio can be attained without a back-gate bias effect, and the SGT can be used for $4\,F^2$ small-cell-size DRAMs.

DRAM scaling will continue to enable the integration of many advanced technologies in view of the huge size of the DRAM market. Thus, these advanced technologies will be used in future-generation DRAMs.

For the array transistor, the TIS/fin type structure is expected to be adopted using p^+ poly for obtaining a suitable threshold voltage with low channel doping. For the capacitor, a high-k dielectric (e.g., barium strontium titanate, BST) may be used in future DRAMs. For the peripheral transistor, mobility enhancement technologies such as the use of SiGe or a linear strain technique and high-k gate dielectrics will be adopted to achieve large driveability for a high-speed operation. A $4\,F^2$ cell layout is

predicted to be introduced to obtain higher-density DRAMs, and during this generation, new structures such as the SGT will be adopted.

12.5
Capacitorless DRAM (Floating Body Cell)

The difficulties of DRAM integration are mainly attributable to the necessity for constant capacitance, even when the cell size is reduced. For this reason, the integration of capacitors is very complicated for trench or stacked capacitors. The floating body cell (FBC) is a new concept of a DRAM without a capacitor. Because the cell is composed of one transistor, the FBC has a simple and compact structure.

Figure 12.14 shows the principle of the FBC, which involves the storage of the signal charge in the body of the cell transistor. To write "1", V_{WL} is biased to 1.5 V and V_{BL} to 2 V, so that the body potential (V_{body}) is increased by the holes that accumulate by impact ionization. To write "0", V_{WL} is biased to 1.5 V and V_{BL} to -1.5 V, so that V_{body} is decreased by ejecting holes from the body. The body potential difference (ΔV_{body}) is stored by setting V_{WL} to -1.5 V and V_{BL} to 0 V. In order to read the stored data, V_{BL} is biased to 0.2 V and V_{WL} is swept up to a certain level, while the bit line current (I_{read}) is measured. The I_{read}–V_{WL} characteristics are shown in Figure 12.15. The threshold voltage difference between a "0" cell and a "1" cell (ΔV_T), which is an index of the data reading margin, is about 0.32 V. In order to increase ΔV_T or ΔI_{read}, C_S (the body capacitance for data storage) plays an important role, because the ΔV_{body} of the hold state is reduced by WL-body and BL-body capacitance coupling. A back gate is used to enable charge accumulation in the body [16–18], and also to increase C_S, which stabilizes the body potential. The structure of the FBC has a modified double-gate configuration. A transmission electron microscopy cross-section of a fully depleted FBC, with thin SOI and BOX layers, is shown in Figure 12.16.

The body capacitance is small compared to the standard DRAM capacitor, typically by two orders of magnitude. However, the leakage current of the FBC storage node is small because of the small p–n junction area, which is located only at the channel-side

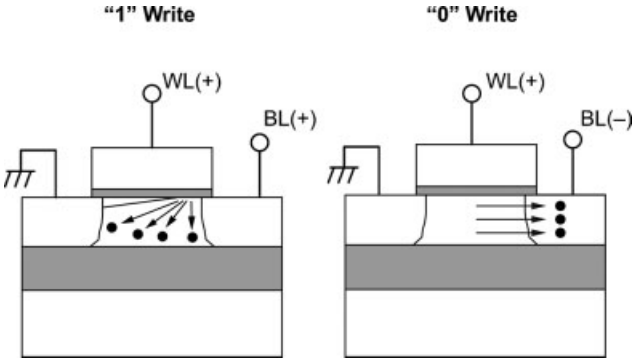

Figure 12.14 The write operation of the floating body cell (FBC). See text for details.

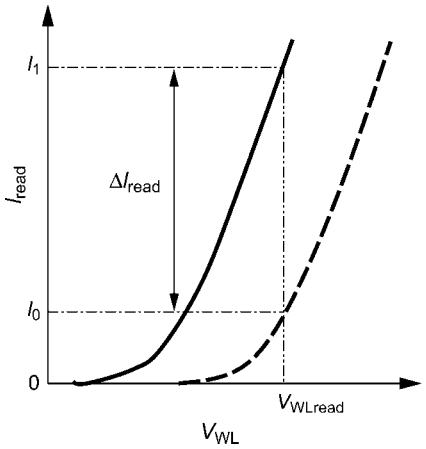

Figure 12.15 The read operation of the floating body cell (FBC). See text for details.

edges of the source and drain. Thus, the retention time of the FBC is reduced slightly compared to the standard DRAM. As a consequence, and because of the short retention time, the FBC is suitable for high-performance embedded DRAM applications rather than low-power applications.

The SOI structure has been widely used for high-performance applications, particularly game processors, and is expected to be used in the embedded DRAM for on-processor caches. An FBC using a SOI substrate can easily be used for these applications with the same compatibility as the SOI substrate. As the FBC is composed of one transistor and has no capacitor, it is scalable down to the 32 nm node. Details of this structure are provided in Ref. [17]. An image of an FBC with 128 Mb DRAM, along with the chip features, is shown in Figure 12.17. The FBC, which has dimensions of 7.6×8.5 mm, contains all of the necessary circuits (including internal voltage generators) and operates using a single 3.3 V power supply [18].

Figure 12.17 Floating body cell (FBC) 128 Mb DRAM and its features.

12.6 Summary

Today, while the demand for DRAM remains greater than for any other type of memory, the capacity of DRAM is continually increasing such that variations are now becoming available for both low-power and high-speed applications. Because of the scaling limitations, the TIS/fin array-transistor is expected to be used in future-generation DRAMs, with more advanced DRAMs – such as vertical transistors such as the SGT – most likely being used for DRAMs with a smaller cell size. In addition, the capacitorless DRAM – the FBC – shows great promise as a candidate for next-generation embedded DRAMs offering both high density and high speed. Clearly, the use of 3-D structures should help to overcome the scaling problems likely to be encountered in future-generation memories.

Ferroelectric Random Access Memory

Soon Oh Park, Byoung Jae Bae, Dong Chul Yoo, and U-In Chung

13.1
An Introduction to FRAM

An ideal non-volatile memory should possess the required characteristics such as high density (high scalability and compact cell size), high reliability (excellent retention and endurance), low cost, and high performance (random access, high read/write speed, and low power consumption) [1, 2]. Although Si-based Flash memory with high density and low cost is the leading non-volatile memory, it cannot basically meet the needs of high endurance and performance characteristics. Therefore, new concepts for non-volatile memory such as FRAM (Ferroelectric RAM), PRAM (Phase change RAM), MRAM (Magnetoresistive RAM), and RRAM (Resistive RAM) have been demonstrated as strong candidates for an ideal non-volatile memory.

Among these emerging memories, PRAM uses phase-change material as a storage element, and shows high scalability and compact cell size owing to its simple cell structure [3]. However, it has disadvantages such as long crystallization time, high power consumption for phase-change switching, and low endurance performance. MRAM uses magnetic material for data storage and shows excellent high speed and good reliability performance, but it requires a large cell area to make a unit cell [4]. Recently emerged RRAM uses resistive switching material as a storage element, but its technology is not yet matured [5]. Finally, FRAM uses ferroelectric materials as a storage element and has been a strong candidate to a universal memory since the late 1980s [6–8]. Because of its similar structure and operation scheme to DRAM (Dynamic RAM) and additional non-volatility, FRAM has been developed as a universal memory for one-chip solution. The operation scheme, reliability of ferroelectric capacitor, and the technology of high-density FRAM for a universal memory will be introduced in the following sections.

ISBN: 978-3-527-31738-7

13.1.1
1T1C and 2T2C-Type FRAM

The operation and architecture of capacitor-type FRAM is almost identical to that of dynamic random access memory (DRAM). It should be noted that every cell has its own separate plate line in capacitor-type FRAM, whereas DRAM uses common plate-line in the level of a half V_{dd}. Necessarily, a ferroelectric capacitor replaces the linear capacitor in a metal-insulator-metal (MIM) storage element.

A schematic view of the two-transistor–two-capacitor (2T2C) -type FRAM and the one-transistor–one-capacitor (1T1C) -type FRAM [9] are shown in Figure 13.1. In the 2T-2C type, the switching and non-switching charges of two adjacent ferroelectric capacitors are used as data "1" or "0" charges, which have a large sensing window and uniform cell operation. However, the cell area is too large to be used for high-density ferroelectric devices because two capacitors can store only a single bit. On the other hand, the 1T1C type provides an advantage of small cell area because single capacitor stores single bits. However, the sensing margin of the 1T1C type is reduced as a half of that of 2T2C type by setting a reference level in the middle of data "1" and "0". The sensing margin might be further reduced due to the variation of reference ferroelectric capacitors. Nevertheless, the 1T1C type is used as the cell structure due to its small cell size in most high-density ferroelectric devices.

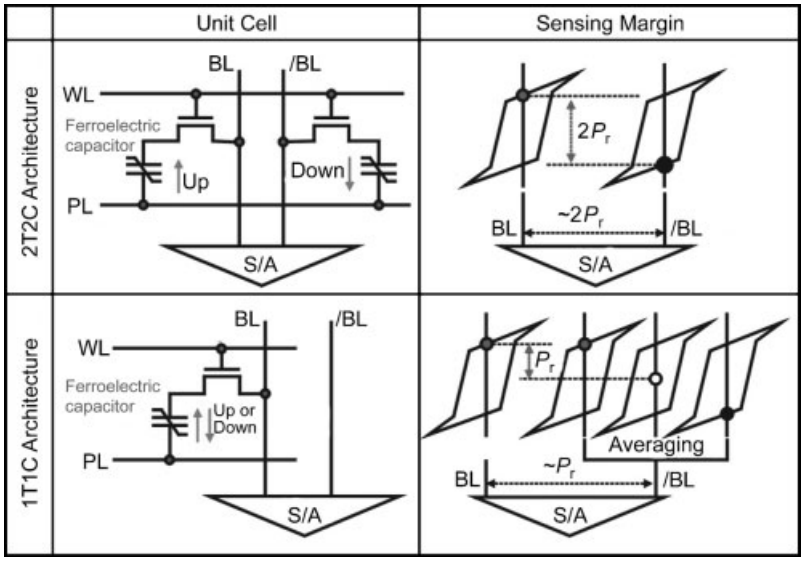

Figure 13.1 Comparison of 2T2C and 1T1C FRAM architectures in respect of cell size and sensing margin.

13.1.2
Cell Operation and Sensing Scheme of Capacitor-Type FRAM

Figure 13.2 illustrates the writing operation of 1T1C-type FRAM. Figure 13.2a is the schematic of 1T1C FRAM which is composed of the word line (WL), bit line (BL), and plate line (PL). Figure 13.2b shows the charges preserved in the hysteresis curve, while Figures 13.2c and d show the timing diagrams of writing data "1" and "0". To write "1" into the memory cell, the BL is raised to V_{pp} and PL is kept as ground (GND). The polarization directions are from PL to BL and the $-P_r$ value is preserved. To write "0", the BL is kept as GND and the PL is kept high as V_{pp}. Thus, the opposite direction of the polarization is generated and $+P_r$ value is preserved.

Figure 13.3 illustrates the reading operation of 1T1C-type FRAM [10]. A read access begins by precharging the BL to GND, after which the PL is raised to V_{pp}. This establishes serial two capacitors consisting of C_s and C_{BL} between the PL and the GND, where C_s is the capacitance of ferroelectric storage element and C_{BL} is the parasitic capacitance of BL. Therefore, the V_{pp} is divided into V_f and V_{BL} between C_s and C_{BL} according to their relative capacitance. Depending on the data stored, the voltage developed on the ferroelectric capacitor and BL can be approximated as follows:

$$V_f = C_{BL} \times V_{PP}/(C_s + C_{BL}) \tag{13.1}$$

$$V_{BL}(\text{Data"1"}) = dQ_{sw}/(C_{sw} + C_{BL}) \tag{13.2}$$

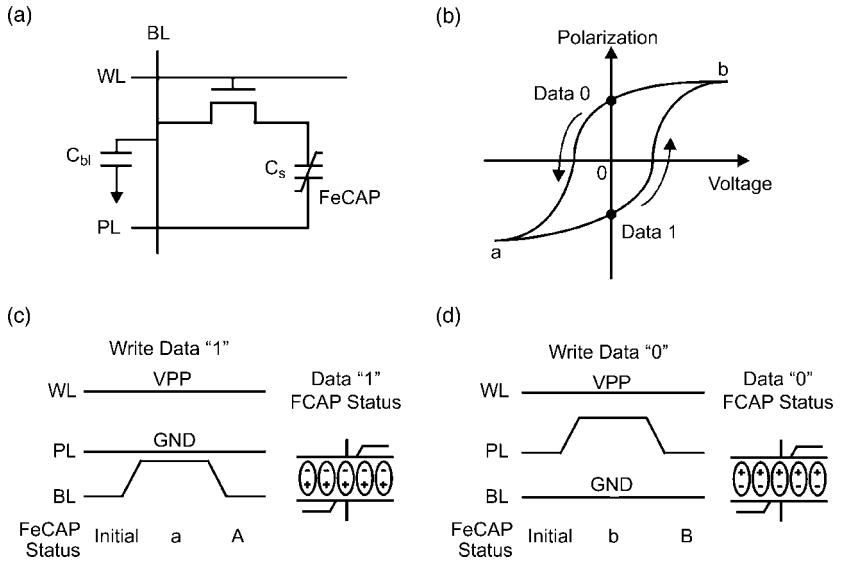

Figure 13.2 The writing operation of 1T1C-type FRAM. (a) Schematic of 1T1C FRAM which is composed of word line (WL), bit line (BL), and plate line (PL). (b) Charges preserved in hysteresis curve. (c,d) Timing diagrams of (c) writing data "1" and (d) writing data "0".

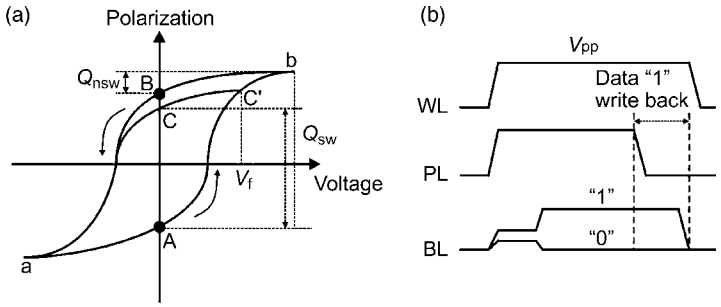

Figure 13.3 Schematic illustration of read operation procedures in 1T1C FRAM.

$$V_{BL}\,(\text{Data“0”}) = dQ_{nsw}/(C_{nsw} + C_{BL}) \tag{13.3}$$

In general, the voltage developed in the BL is too small to sense charge differences. Therefore, a sensing amplifier should be used in order to drive the BL to full V_{pp} if the data is "1", or to 0 V if the data is "0". The structure of the sensing amplifier of capacitor-type FRAM includes the cross-coupled latch sense amplifier of DRAM. It can be classified to a folded bit line and an open bit line according to the cell array, as shown in Table 13.1 and Figure 13.4 [11]. The open bit-line scheme is applicable to 1T1C structure, and the folded bit-line scheme can be applied to both 1T1C and 2T2C structures.

Table 13.1 Comparison of FRAM sense amplifier types.

	Sense amplifier	Realization	Noise immunity	Sensibility
Folded bit-line	1 ea/2 BL	Easy layout	Same noise environment	Good
Open bit-line	1 ea/1 BL	Difficult layout	Different noise environment	Not good

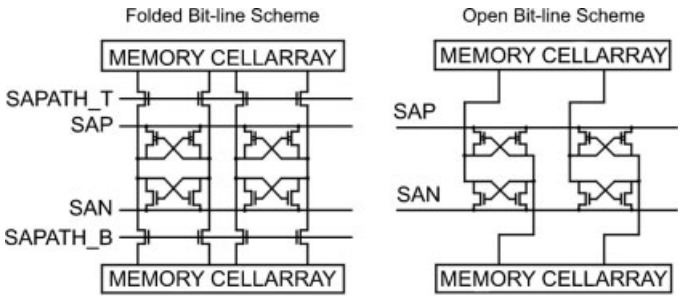

Figure 13.4 Schematic diagrams of FRAM sense amplification.

13.2
Ferroelectric Capacitors

Similar to the DRAM device, the capacitor technology concerning ferroelectrics serves as a guideline to the development of FRAM devices. In this regard, the material characteristics and reliability of typical ferroelectric capacitors will be considered in this section.

13.2.1
Ferroelectric Oxides

Representative ferroelectric materials for complementary metal oxide–semiconductor (CMOS) integration can be divided to two groups, including perovskite-structured (PZT and $BiFeO_3$) and Bi-layer structured (SBT, BLT, and BTO) materials. The characteristics of these are summarized in Table 13.2 [12, 13]. The crystal structure of PZT can be either tetragonal or rhombohedral according to the Zr/Ti composition ratio below Curie temperature. In SBT, two $SrTaO_3$ perovskite blocks and one $(Bi_2O_2)^{2+}$ layer constitute one unit cell, as shown Figure 13.5b. In BLT, La atoms are partially substituted to Bi atom in $Bi_4Ti_3O_{12}$ (BTO) crystal which is composed of three TiO_6 octahedra and one $(Bi_2O_2)^{2+}$ layer leading the wanted crystal structure. These differences of unit cell structure largely determine the characteristics of corresponding ferroelectrics. Therefore, the typical properties of PZT, SBT and BLT can be compared from this point of view.

First, the remanent polarization value (P_r) determines the sensing margin between data "0" and "1" (the larger $2P_r$, the better sensing-margin), while the coercive voltage (V_c) or coercive field (E_c) decides the operating voltage in an FRAM device (the smaller V_c, the better operation voltage). PZT shows large P_r and E_c values because of strong interactions between neighboring perovskite unit cells. In contrast, SBT and BLT request the anisotropic growth along the a-b axis to attain direct interactions between the neighboring perovskite unit cells toward electrical field direction. The smaller P_r and E_c values of SBT, compared to PZT, tend to increase by Nb doping.

Table 13.2 The features of typical ferroelectrics used for FRAM.

Ferroelectrics	$Pb(Zr,Ti)O_3$ (PZT)	$SrBi_2Ta_2O_9$ (SBT)	$(Bi,La)_4Ti_3O_{12}$ (BLT)
P_r [$\mu C\ cm^{-2}$]	10–40	5–10	10–15
E_c [$Kv\ cm^{-1}$]	50–70	30–50	30–50
Endurance	Poor on Pt electrode Good on oxide electrode	Good on Pt electrode	Good on Pt electrode
Crystallization temperature [°C]	450–650	650–800	650–750
Curie temperature [°C]	~400	~400	~400

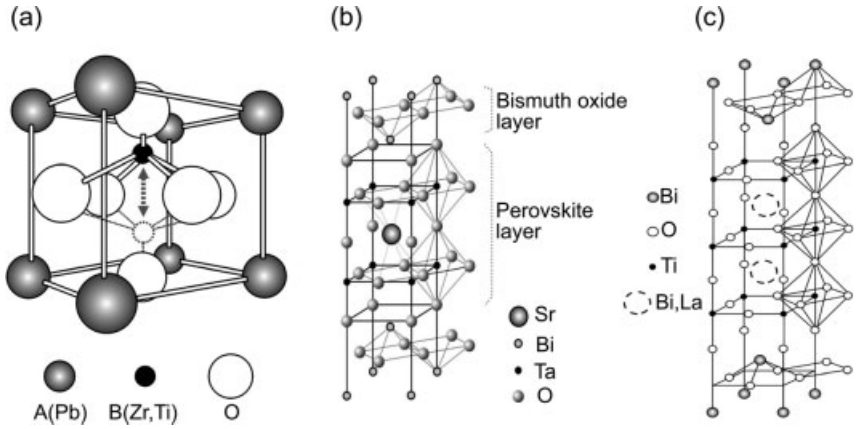

Figure 13.5 The crystal structures of ferroelectric (a) PZT, (b) SBT, and (c) BLT.

Ferroelectric films must attain a crystallized perovskite structure in order to show the polarization behavior. Therefore, the plentiful oxygen atmosphere and high substrate temperature in order to crystallize ferroelectric oxide lead to the demand for a noble metal electrode and oxidation barrier to achieve CMOS integration. In a stacked FRAM cell with COB (capacitor over bit-line) structure, the capacitor is located directly on the top of the MOSFET drain, which requires the low-temperature process to realize high-density CMOS integration. In this respect, the lower crystallization temperature of PZT than that of SBT and BLT is advantageous for the fabrication of future high-density FRAM.

To date, PZT has long been the leading material considered for ferroelectric memories, and has been superior to SBT and BLT. The higher P_r value and lower process temperature of PZT can act as strong merits for the fabrication of high-density COB cells in CMOS integration. On the other hand, lead-free SBT and BLT can be considered for environmentally friendly FRAMs. Recently renewed multiferroic $BiFeO_3$ exhibits both ferroelectric and magnetic properties, but it is unclear whether this is useful for memory application, or not [14]. In particular, the proper ferroelectrics for CMOS integration should be chosen by serious consideration for the degradation induced by hydrogen, plasma, stress, and heat in the succeeding integration processes [15].

13.2.2 Fatigue

"Fatigue" is a term describing the fact that the remanent polarization becomes small when a ferroelectric film experiences numerous polarization reversals. When PZT on Pt electrodes suffers from reading/writing cycles over 1E5 cycles, the P_r value shows a conspicuous reduction, which limits the repeated use of a memory. A few reports about non-fatigue phenomena of Pt/PZT/Pt capacitors should be regarded with great care because this type of behavior can be observed when the applied voltage is less

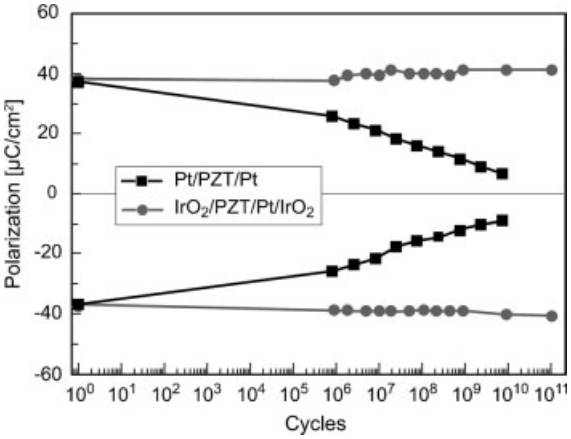

Figure 13.6 Fatigue properties of PZT and an IrO_2 electrode.

than $V_{(90\%)}$. Fatigue behavior is strongly related to the generation of oxygen vacancy by the repeated cycles, which induces dipole-pinning electrons for charge-neutrality; this is why oxygen vacancies are the only mobile ionic species in the lattice even at the room temperature on the basis of defect chemistry model. However, the fatigue problems of PZT can be almost solved at present by the use of conducting oxide electrodes (e.g., IrO_2, RuO_2, $SrRuO_3$, $CaRuO_3$, $LaNiO_3$, and LSCO), ensuring no degradation of the P_r value even up to 1E12 cycles. Figure 13.6 shows a comparison of fatigue properties in PZT capacitor with Pt and IrO_2 electrodes [16]. This improvement of fatigue property can be explained by the fact that oxygen in the IrO_2 electrodes reduces oxygen vacancies, which prevents fatigue degradation reducing the dipole-pinning effect. As Ir is stably converted into IrO_2 under oxygen at ambient temperature, the fatigue problem can be remarkably enhanced in the case of using an IrO_2 oxide electrode.

In contrast to the PZT film, an SBT film does not show the fatigue phenomenon up to 1E13 switching cycles, even if Pt electrodes are used. It was speculated that the $(Bi_2O_2)^{2+}$ interlayer can compensate the produced oxygen vacancy. However, similar Bi-layer structured BTO shows fatigue problems on a Pt electrode, which suggests that the simple charge-compensation role of the $(Bi_2O_2)^{2+}$ layers is not sufficient to make the fatigue-free films. This reduction in polarization could be much alleviated by using La-doped BTO (so-called BLT). Accordingly, the limited switching cycles of dipoles are no longer a serious problem for any ferroelectric materials, as shown in Figure 13.7 [13, 14].

13.2.3 Retention

Polarization retention is the ability of poled ferroelectric capacitors to preserve the poled state over time (generally 10 years into the future at 85 °C). The retention property represents an important reliability issue for non-volatile ferroelectrics

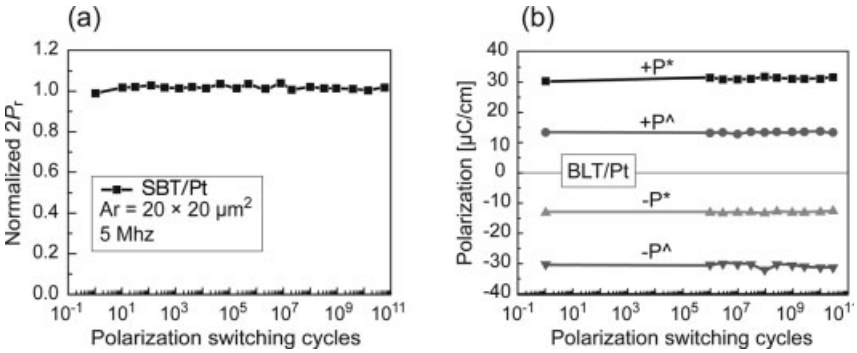

Figure 13.7 Fatigue properties of (a) SBT and (b) BLT film on Pt electrode. The symbols are indicated in Figure 13.9.

memories. Most commonly, the retention of ferroelectrics can be classified into the same-state and opposite-state retention.

The same-state retention, which is closely related to aging, represents the loss of polarizability when one first writes the datum of "0" or "1" in a capacitor with electrical pulses, and reads the datum again after long period without changing the initial status. Therefore, the same-state retention failure can occur when the relaxation component in the opposite-polarity state increases at the expense of the relaxation component in the stored polarity state. The stored polarity status can be stabilized by the use of ferroelectrics with "high" Curie temperature, after which the same-state retention loss can be improved from the viewpoint of thermodynamics. For instance, $BaTiO_3$ is not applicable for non-volatile FRAM because of its low Curie temperature (~140 °C), although this can be raised to 500 °C by imposing biaxial compressive strain.

The opposite-state retention, which is closely related to imprint, represents the loss of polarizability when one first writes the datum of "0" or "1" in a capacitor with electrical pulses and reads the "changed" datum again. In words, the same-state retention is a longstanding problem of the read-only memory (ROM), while the opposite-state retention is that of the random-access memory (RAM), because information must be modifiable (as shown in Figure 13.8) [17].

The opposite-state retention failure occurs when a capacitor, which has aged considerably in one state, is switched to the opposite state. In this case, the capacitor behaves as if it would prefer to remain in the original state. The charge defects are activated by thermal energy and redistributed by the polarization field. Therefore, the resulting internal field causes a lower energy barrier and invokes polarization back-switching during the delay time, as shown in Figure 13.9 [18]. Accordingly, the opposite-state retention can be solved by minimizing the space charges, which results from defects inside the ferroelectrics, domain wall motion, or defects near the electrode-ferroelectric interfaces.

The thickness scaling of ferroelectric films is indispensable when pursuing a low switching voltage, making this suitable for integrated electronics applications. However, to date, thinner ferroelectric films have shown serious degradation of

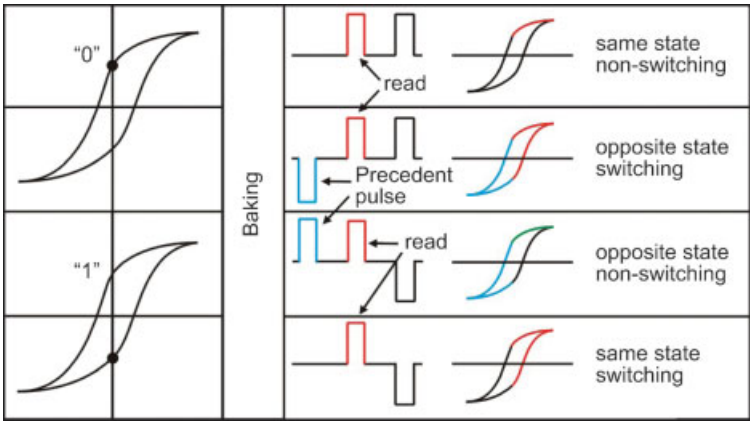

Figure 13.8 Retention pulse sequence.

opposite-state retention compared to same-state in cumulative studies. Consequently, during the past few years much attention has been focused on the failure mechanism of the opposite-state retention. In order to solve the opposite-state retention failure problem, it is necessary to utilize frequently used technologies such as seeding, metalorganic chemical vapor deposition (MOCVD), and perovskite oxide electrode in the case of PZT ferroelectrics. Thus, these technologies will be reviewed briefly in the following sections.

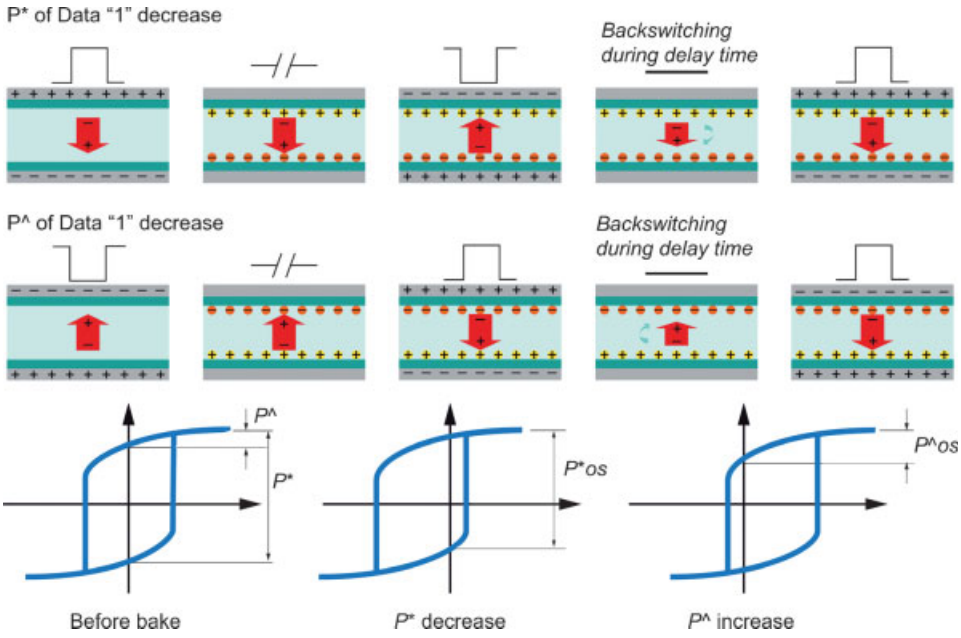

Figure 13.9 Retention failure mechanism.

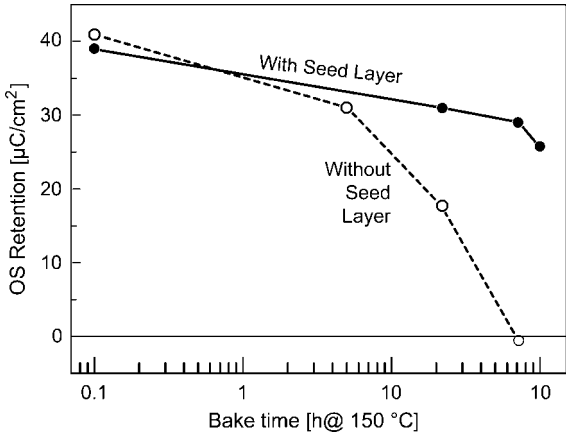

Figure 13.10 Improved opposite-state retention by the use of $PbTiO_3$ seed layer.

13.2.3.1 Crystallinity of PZT Film

Frequently, the perovskite-structured PZT phase can be generated by utilizing nucleation and the grain growth process from the pyrochlore phase. Because the nucleation process is strongly dependent on the substrates, an appropriate seed layer can supply nucleation sites in order to decrease activation energy for crystallization of the perovskite phase. A $PbTiO_3$ seed layer is very effective for supplying a high density of nuclei in the initial stage of deposition, because the crystallization temperature (350∼680 °C) is lower than that of PZT (>650 °C). The succeeding PZT film shows a much enhanced crystallinity and preferred orientation, and thereby exhibits improved retention result (see Figure 13.10 [19, 20]. For this purpose, an optimum thickness of $PbTiO_3$ is essential because a thinner $PbTiO_3$ layer cannot play a sufficient role for the seed layer, while a thicker one may cause adverse effects on the electrical properties of the overall film. A $PbTiO_3$ seed layer is helpful in the initial stage of film growth, but still constitutes a portion of the ferroelectric films. Therefore, the use of a perovskite oxide electrode as a seed layer may provide a better means of preparing reliable ultrathin ferroelectric films, because the seed layer belongs to the electrode and not to the ferroelectrics.

13.2.3.2 The MOCVD Deposition Process

Most current FRAM cells below 64 Mb density are based on a planar capacitor stack. In CMOS integration, it is commonplace to use either chemical solution deposition (CSD) or a sputtering technique for the deposition of planar films, and chemical vapor deposition (CVD) for a conformal deposition, based largely on an economics viewpoint. Somewhat ironically, however, such common sense has caused a "dribbling" (slow movement, low amplitude) of technological developments in this field. For example, the current deposition method used for "planar" PZT films is mostly based on an "MOCVD process" in order to pursue the excellent opposite-state retention properties [21]. The comparative retention of a PZT film deposited by CSD

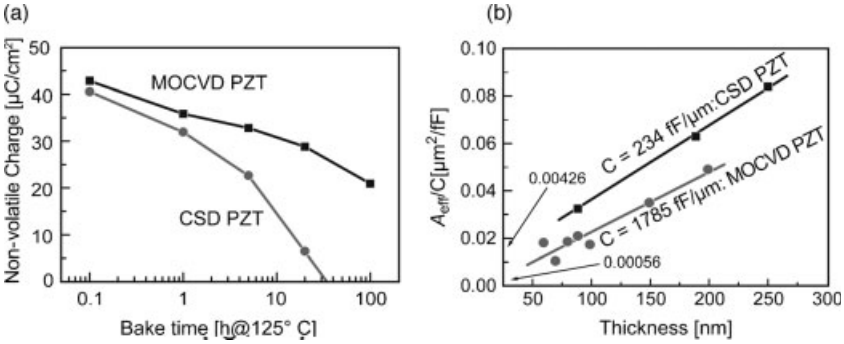

Figure 13.11 Improved opposite-state retention by using the metalorganic chemical vapor deposition (MOCVD) deposition process.

and MOCVD method is shown in Figure 13.11, where the MOCVD PZT film shows superior retention properties to those of CSD films due to the low defect density in ferroelectrics and/or interfaces. It may be speculated that an as-crystallized PZT film on an Ir electrode can be obtained by using the MOCVD process, such that the non-switching layer at the interface between the electrode and ferroelectrics is thinner, without the formation of Pt_3Pb alloys.

13.2.3.3 **Perovskite Oxide Electrode**

Most ferroelectric materials have a perovskite crystal structure, as outlined in the previous section. Therefore, if a conducting oxide electrode having a perovskite structure is use, then ferroelectric properties such as reliability can be greatly improved due to the reduction of any non-ferroelectric dead layer at the interface between the ferroelectrics and electrodes. Such remarkable improvement of retention properties by using an $SrRuO_3$ electrode with a perovskite structure is illustrated in Figure 13.12 [22].

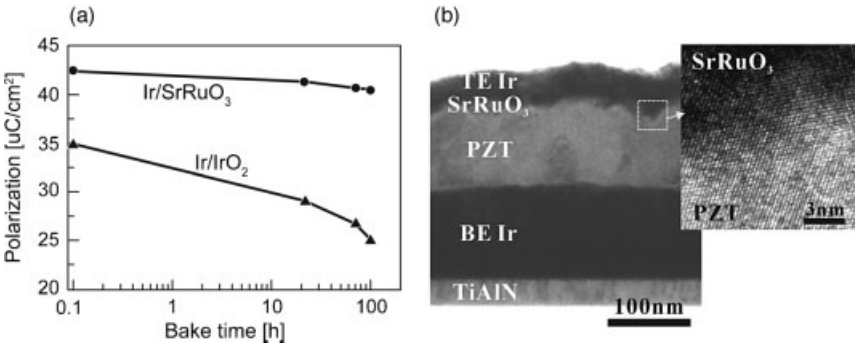

Figure 13.12 (a) Retention properties of a PZT capacitor with $Ir/SrRuO_3$ and Ir/IrO_2 electrodes. (b) Transmission electron microscopy image of the interface between $SrRuO_3$ and PZT films.

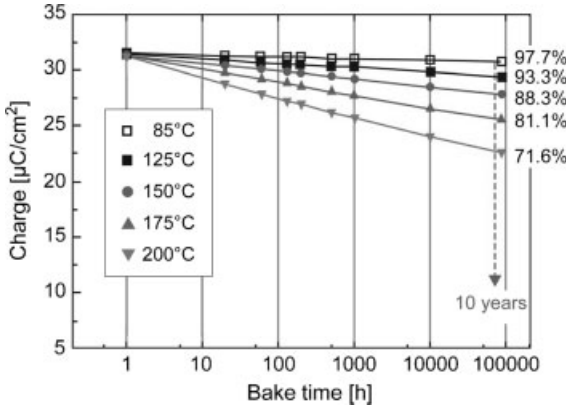

Figure 13.13 The ultrahighly reliable properties of the FRAM device.

During recent years, although perovskite oxide electrodes such as $SrRuO_3$, $LaNiO_3$ and $CaRuO_3$ have undergone intense investigation, the problems of high leakage currents – which inevitably are induced by high defect densities in the oxide electrode – remain to be overcome.

Recently, the successful development of an ultrahighly reliable FRAM device has been reported, and the retention properties of this fully integrated device, at different temperatures, are illustrated graphically in Figure 13.13 [23]. Based on these findings, the FRAM device could be expected to maintain >80% of any initial charge, even after 10 years at 175 °C.

13.3
Cell Structures

A vertical scanning electron microscopy image of the FRAM cell structure is shown in Figure 13.14 [24]. The cell is composed of a cell transistor, capacitor, buried contact, bit line, word line, and plate line. The cell structure can be divided into the CUB (capacitor under bit line) and COB (capacitor over bit line) structures, the merits and demerits of which are considered in the following section.

13.3.1
CUB Structure

In the CUB cell structure, the ferroelectric capacitor is formed beside the cell transistor, as shown in Figure 13.15 [25]. This requires a large cell area compared to the COB cell structure, in which the ferroelectric capacitor is formed over the cell transistor. The CUB scheme has no thermal budget limitations on the ferroelectric film deposition, and the subsequent anneal process for crystallization of the ferroelectric film, because the ferroelectric capacitor formation processes (including stack deposition and dry etching) are completed before the metallization process is

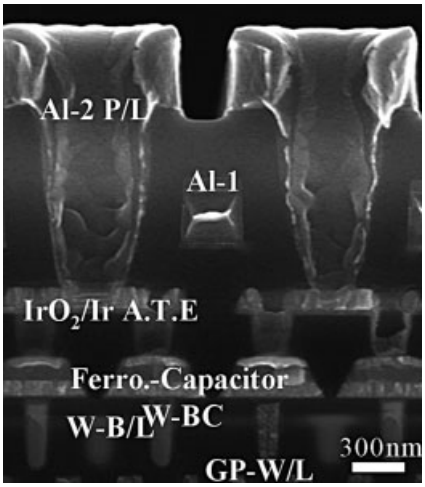

Figure 13.14 A vertical scanning electron microscopy image of the FRAM cell.

carried out. Due to technical difficulties in realizing a ferroelectric film with low thermal budget processes, and of identifying a suitable oxidation barrier metal which is stable above 600 °C, the early FRAMs were developed with a CUB cell structure, thereby sacrificing cell size efficiency.

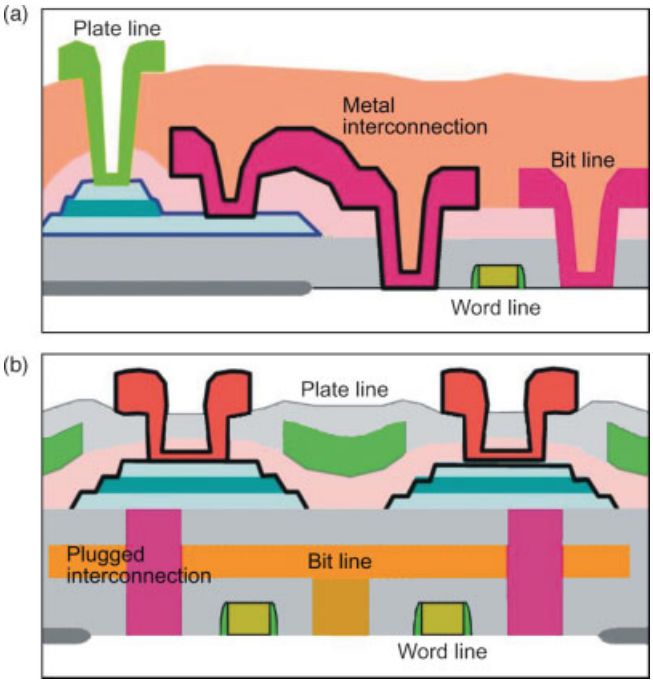

Figure 13.15 Schematic diagram of (a) capacitor under bit line (CUB) and (b) capacitor over bit line (COB) cell structures.

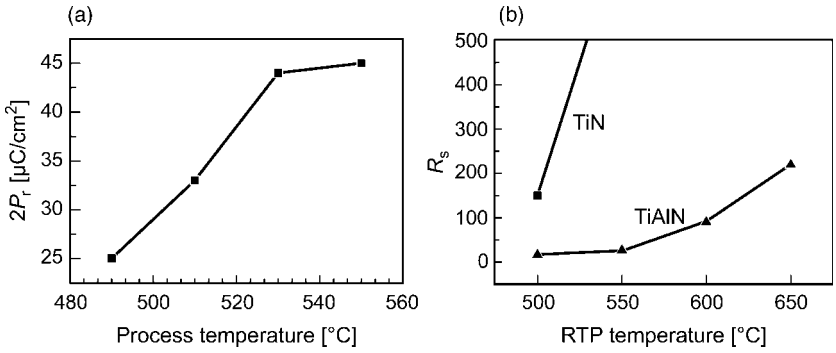

Figure 13.16 (a) $2P_r$ variation versus MOCVD process temperature and (b) comparison with oxidation resistance of TiAlN and TiN.

13.3.2
COB Structure

In the COB cell structure, the ferroelectric capacitor is formed over the bit line. Thus, the realization of a COB cell structure requires both a new buried contact (BC) plug and new metal technologies for the oxidation barrier. A stable contact between the BC plug and the bottom electrode must be provided when the ferroelectric capacitor has been processed at a high temperature of 600 °C or above [26]. As shown in Figure 13.16a, a high-temperature process is essential to obtain a sufficient polarization value in an MOCVD PZT process [27]. In order to prevent oxidation of the BC plug, various oxidation-barrier metals have been widely investigated; among these, a TiAlN film proved successful in preventing oxidation of the BC plug. The oxidation resistance properties of TiAlN and TiN thin films, as a function of temperature, are illustrated graphically in Figure 13.16b.

As mentioned above, as the COB structure is more beneficial with regards to high-density integration than are CUB structures, an increasing proportion of FRAM devices are today adopting the COB structure.

13.4
High-Density FRAM

In this section, the current status of planar capacitor technology, together with the technical issues involved in the development of 3-D capacitors for high-density FRAM device application, will be discussed.

13.4.1
Area Scaling

In order to achieve a high-density FRAM, the cell size must be scaled down as much as possible. Unfortunately, however, there exists a scaling limit because the

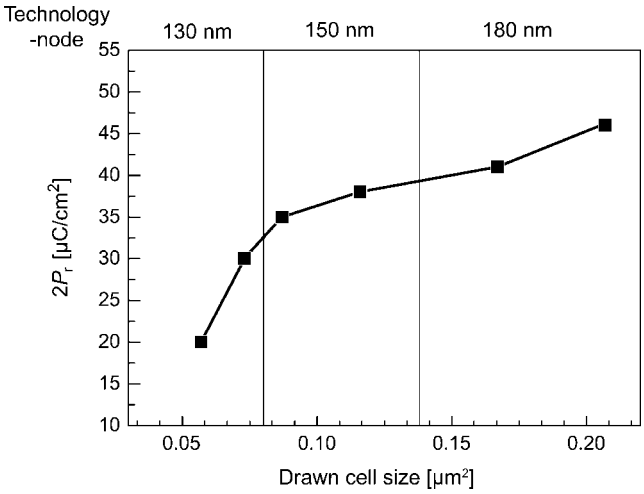

Figure 13.17 Polarization decay as a scale-down of the drawn cell size.

polarization value ($2P_r$) decreases in proportion to the cell size, such that etching damage on the capacitor becomes increasingly critical. The data in Figure 13.17 show that the polarization decays as the drawn cell size decreases. With a planar capacitor structure, although the polarization degradation is negligible down to the 150-nm technology node, the polarization value decreases rapidly below that level. This effect is mainly caused by the difference between the drawn area and the effective area, and indicates that the etched slope is no longer steep enough to provide both a designed top-electrode area and sufficient spacing between adjacent bottom electrodes at the 130-nm technology node. Therefore, in order to increase the effective capacitor area below the critical cell size, both thickness scaling and the high-etched slope of the capacitor stack should be guaranteed.

In order to maximize effective capacitor area, the most important technology is to achieve the high-etched slope of the capacitors, but this is difficult because both top and bottom electrodes are usually noble metals, and the noble metal etch process has remained an unanswered question since the initial stages of FRAM development. Even until quite recently, the limitation of the capacitor etched slope was about 60∼65°, mainly owing to the loss of hard-mask from the sputtering condition of the noble metal etch. This lower capacitor slope can lead to a decrease in capacitor area of the top electrodes, or to a short circuit between the cap-to cap at the bottom electrode. However, based on some experimental findings (see Figure 13.18), new technology has been successfully developed in order to obtain a high-etched slope of about 80∼85° [28]. This new etching scheme was tested at high temperature with chlorine and fluorine chemistry, and a dual hard mask (oxide and metal). As a result, the noble metal was successfully etched with a high slope by improving the reactivity between the noble metal and etch gases, and by increasing the process temperature and reinforcing the robustness of the hard-mask.

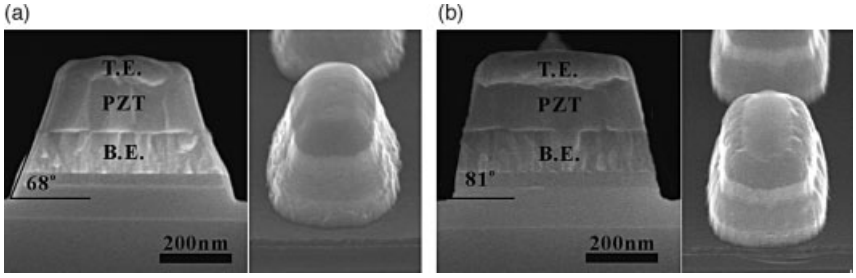

Figure 13.18 Scanning electron microscopy image showing the improvement of capacitor etch slope. (a) Normal cap etch condition; (b) enhanced cap etch condition.

13.4.2
Voltage Scaling

With the advent of the "mobile" era, low-voltage operation has become increasingly important in the reduction of power consumption. In the case of FRAM devices, the operation voltage is directly related to the thickness of the ferroelectric film; hence, the latter dimension should be minimized for low voltage application. As shown in Figure 13.19a, a PZT capacitor prepared by the CSD process shows a drastic degradation of ferroelectric properties below 100nm thickness. This is clearly a critical problem which must be solved in the case of high-density FRAM devices. As described above, both ferroelectric properties and reliability are greatly improved when the PZT films are prepared with MOCVD process; thus, even an 80 nm-thick PZT film prepared in this way demonstrates highly reliable ferroelectric properties [29] (Figure 13.19b).

It is difficult to prevent ferroelectric degradation at the interface between electrodes and ferroelectric material, even when the MOCVD process is employed. However, if perovskite oxide electrodes are used, the dead layer effect at the interface may be remarkably reduced. Recently, it has been reported that a high reliability can be achieved even with a 50 nm-thick PZT capacitor [30]. The charge-to-voltage (Q–V)

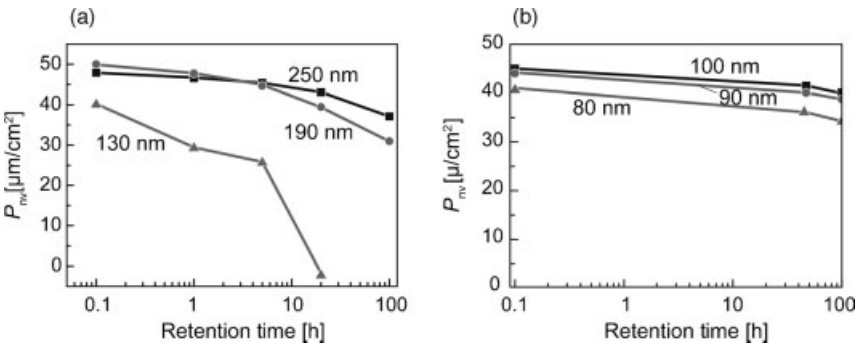

Figure 13.19 Retention properties as PZT thickness is scaled down. (a) CSD-processed PZT; (b) MOCVD-processed PZT.

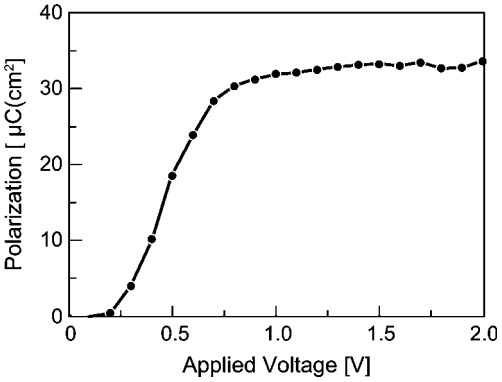

Figure 13.20 Charge–voltage (*Q*–*V*) diagram of 50 nm-thick PZT capacitor.

diagram of such as capacitor is illustrated graphically in Figure 13.20, with the capacitor being fully polarized well below an operation voltage of 1 V.

With thinner PZT films, however, several problems persist, including roughness and high leakage current. In order to overcome these difficulties, a chemical mechanical polishing (CMP) process has been introduced for PZT films. As the increase in leakage current for thin PZT film depends mainly on the surface roughness, a CMP process for PZT films can greatly reduce the leakage current [31]. The atomic force microscopy (AFM) findings and ferroelectric properties for PZT films, with or without the CMP process, are shown in Figure 13.21.

13.4.3 3-D Capacitor Structure

13.4.3.1 Limitation of Planar Capacitor

Today, many technical challenges remain to be solved for high-density planar capacitor structured FRAMs, including the limitation of capacitor stack thickness, the noble metal etch process, and thin PZT degradation. In addition, an optimum cell size is clearly required for a sufficient sensing window in FRAM devices (Figure 13.22) [32].

It can be seen from Figure 13.22 that it is difficult to achieve the 200 mV sensing margin which is required in 1T1C cell structure with sub-130 nm design rules. From this point of view, even if a thin capacitor stack and a high-etch slope were to be realized in the planar capacitor structure, it would appear difficult to embody a high-density FRAM device in excess of 256 Mb. Therefore, in order to overcome this limitation, FRAM development should ideally be pursued with a 3-D capacitor structure similar to the present-day DRAM.

13.4.3.2 Demonstration of a 3-D Capacitor

As mentioned above, the requirement for a 3-D capacitor structure is inevitable for high-density FRAM development, and the structure – together with the necessary technologies to develop a 3-D FRAM cell – are shown schematically in Figure 13.23 [33].

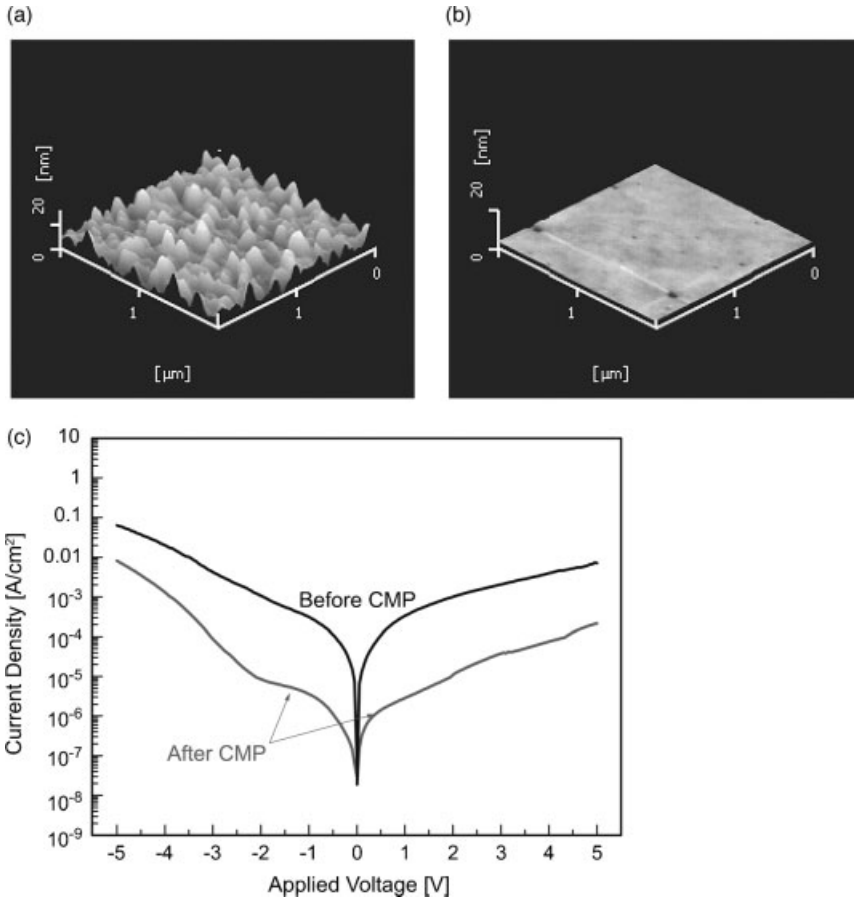

Figure 13.21 (a,b) Atomic force microscopy images and (c) leakage current characteristics of PZT films before and after CMP processing.

A prototype 3-D capacitor has recently been demonstrated, and a TEM image representing a 3-D PZT capacitor is shown in Figure 13.24. Although some pyrochlores remained in the trench capacitor, the columnar grains were well established at the side-wall of trench, with optimized deposition condition.

Figure 13.25 illustrates, graphically, the ferroelectric properties with different-sized trench structures. The polarization–voltage characteristics of a planar capacitor and trench capacitors are shown in Figure 13.25a. Under 2.1 V external bias, and an electric field of $350\,\mathrm{kV\,cm^{-1}}$, these capacitors produced no current leakage and showed quite good hysteretic behavior compared to their planar counterpart. The remnant polarization ($2P_r$) plotted against the external maximum voltage is shown in Figure 13.25b; these data showed that $2P_r$ is very similar to that for the planar capacitor in the case of a 0.32 μm trench-diameter 3-D capacitor. However, a 0.25 μm trench-diameter capacitor showed a $2P_r$ value of $19\,\mu\mathrm{C\,cm^{-2}}$ under an external

maximum voltage of 2.1 V, which was 80% of the $2P_r$ values in either planar or 0.32 μm trench-diameter cases. This difference may be derived from an incomplete extension of the columnar grains on the 0.25 μm trench side-wall. Based on these findings, it is quite possible that the side-wall PZT film has the same ferroelectric properties as the planar PZT film.

In order to realize Giga-bit FRAMs with a 3-D capacitor, it has been necessary to develop the atomic layer deposition (ALD) process for the PZT and electrode material. As shown in Figure 13.23, the thickness of the ferroelectric material should be less than 50 nm because the bottom/top electrode and ferroelectric films may be formed inside a trench of 200 nm diameter. This means that the ferroelectric properties of sub-50 nm-thick PZT capacitors should be obtained for 3-D capacitor research. In addition, a step coverage of the PZT film becomes important as the aspect ratio of the capacitor increases. Because the PZT film should have a uniform composition at the bottom and side-wall, the ALD method is regarded as the best choice among other deposition methods, such as PVD and CVD. Although ALD for PZT has been investigated by many research groups, process optimization is still required. Moreover, both noble electrode metals and ferroelectric materials may be prepared using ALD. Recently, although iridium was successfully deposited using ALD, additional improvements of properties should also be investigated. In contrast, a CMP technology for noble metal electrodes may need to be introduced in order to separate each capacitor within this structure. Although noble metal CMP has not yet been achieved, it is currently undergoing extensive investigation.

Unfortunately, as of today several technical difficulties, including the reliability of the 3-D capacitor, have not been fully solved. Nonetheless, the activities of many research groups have provided much promise for 3-D FRAM development. It follows that, if some of the above-mentioned problems are solved in the near future, then the Giga-bit FRAM era will be well and truly opened.

13.5
Summary and Conclusions

FRAM technology, which has been undergoing continuous development since the early 1990s, has been used to target a universal memory in the semiconductor industry. Although reliability – notably endurance and retention – was initially a major challenge, recent findings have shown that this is no longer a key issue for FRAM devices. Rather, it is scalability which has become an important issue, following the development of 64 Mb FRAM through material and cell structural innovations. At this density, FRAM may be applied to low-density embedded memory (e.g., a smartcard), based on the demands of non-volatility, rapid access, high read/write endurance, low-power operation, and high security level. In order to produce high-density FRAM devices for use in major applications, a conventional planar-type capacitor technology is insufficient for further cell size scaling. Rather, breakthrough technologies such as the 3-D capacitor must be developed in order for the FRAM device to serve as an ideal, non-volatile memory in the future.

Magnetoresistive Random Access Memory

Michael C. Gaidis

14.1
Magnetoresistive Random Access Memory (MRAM)

Through the merging of magnetics (spin) and electronics, the burgeoning field of "spintronics" has created MRAM memory with characteristics of non-volatility, high density, high endurance, radiation hardness, high-speed operation, and inexpensive complementary metal oxide–semiconductor (CMOS) integration. While MRAM is unique in combining all of the above qualities, it is not necessarily the best memory technology for any single characteristic. For example, SRAM is faster, flash is more dense, and DRAM is less expensive. Stand-alone memories are generally valued for one particular characteristic: speed, density, or economy. MRAM therefore faces difficult odds in competing against the aforementioned memories in a stand-alone application. However, embedded memory for application-specific integrated circuits or microprocessor caching often demands flexibility over narrow performance optimization. This is where MRAM excels: it can be called the "handyman of memories" for its ability to flexibly perform a variety of tasks at a relatively low cost [1]. Whilst one may hire a specialist to rewire the entire electrical circuitry of a house, or install entirely new plumbing, a handyman with a flexible toolbox is a much more reasonable option for repairing a single electrical outlet or a leaky sink. Moreover, the handyman may be able to repair a defective electrical circuit discovered while in the process of repairing leaky plumbing!

A semiconductor fabrication facility that has MRAM in its toolbox is more likely to tailor circuit designs to a customer's individual needs for optimal performance at reasonable cost. The ways in which the characteristics of MRAM compare to those of other embedded memory technologies at the relatively conservative 180 nm node are listed in Table 14.1. In the remainder of this chapter, the state of the art in MRAM technology will be reviewed: how it works; how its memory circuits are designed; how it is fabricated; the potential pitfalls; and an outlook for future use of MRAM as devices are scaled smaller.

Table 14.1 Embedded memory comparison at the 180 nm node.

Parameter		eSRAM	eDRAM	eFlash	eMRAM
Size	Cell area (μm^2)	3.7	0.6	0.5	1.2
Size	Array efficiency	65%	40%	30%	40%
Cost	Additional process	0	20% (4 msk)	25% (8 msk)	20% (3 msk)
Speed	Read access	3.3 ns	13 ns	13 ns	15 ns
Speed	Write cycle	3.4 ns	20 ns	5000 ns	15 ns
Power	Data retention	400 µA	5000 µA	0	0
Power	Active read	15 pC b^{-1}	5.4 pC b^{-1}	28 pC b^{-1}	6.3 pC b^{-1}
Power	Active write	15 pC b^{-1}	5.4 pC b^{-1}	31 000 pC b^{-1}	44 pC b^{-1}
Endurance	Write	Unlimited	Unlimited	1e5 cycles	Unlimited
Rad Hard	—	Average	Poor	Average	Excellent

The shaded cells indicate where MRAM has a distinct advantage. Relative comparisons should hold through scaling to the 65 nm node [2].

14.2 Basic MRAM

MRAM (magnetoresistive RAM) differs from earlier incarnations of magnetic memory (magnetic RAM) in that MRAM tightly couples electronic readout with magnetic storage in a compact device structure. During the early second half of the twentieth century, the most widely used RAM was a type of magnetic RAM called *ferrite core memory*. These memories utilized tiny ferrite rings threaded by multiple wires used to generate fields to write or to sense the switching of the magnetic polarity in the rings [3]. Highly valued for its speed, reliability, and radiation hardness, approximately 400 kB of this core memory was used in early IBM model AP-101B computers on the space shuttle. However, with the advent of compact, reliable, and inexpensive semiconductor memory, the 1 mm^2 cell size of the core memory could no longer compete, and in 1990 the space shuttle converted to battery-backed semiconductor memory with around 1 MB capacity [4].

In order for magnetic memory to compete again in the RAM arena, miniaturization on the scale of semiconductor integrated circuitry had to be implemented. This was stimulated by the discovery in 1988 of giant magnetoresistance (GMR) structures which provided an elegant means of coupling a magnetic storage (spin) state with an electronic readout, thereby creating the field of spintronics [5]. Spintronics relies on the phenomenon wherein electrons in certain ferromagnetic materials will align their spins with the magnetization in the ferromagnet. In essence, this is a result of a greater electron density of states at the Fermi level for electrons with spin aligned parallel to the magnetization in the ferromagnet. The passing of a current along two ferromagnetic films in close proximity allows the transport of the electrons to be influenced by adjusting the relative orientation of the two films' magnetization. As shown in Figure 14.1, although for parallel orientation, electrons are less likely to suffer resistive spin-flip scattering events, for antiparallel orientation they will exhibit a stronger preference for scattering and thus an increase in resistance will be

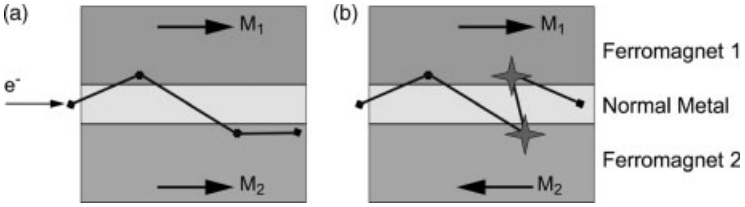

Figure 14.1 Illustration of the giant magnetoresistance (GMR) principle. For parallel alignment (a) of magnetizations M1 and M2, electron flow is subject to fewer resistive spin-flip scattering events than for antiparallel alignment (b).

apparent. The different resistance values for the high resistance state (R_{high}) and the low resistance state (R_{low}) can be used to define a magnetoresistance ratio (MR) as in Equation 14.1:

$$MR = \frac{(R_{\text{high}} - R_{\text{low}})}{R_{\text{low}}} \tag{14.1}$$

Typically, MR values for GMR devices are in the range of 5–10% for room-temperature operation.

By choosing different coercive fields for the two ferromagnets, it is possible to create a so-called *spin-valve* MRAM structure with a configuration similar to that shown in Figure 14.1. For example, ferromagnet 1 can be chosen to have a high coercivity, thus fixing its magnetization in a certain direction. Ferromagnet 2 can be chosen with a lower coercivity, allowing its magnetization direction to fluctuate. For a magnetic field sensor such as used in disk drive read heads, small changes in the magnetization angle of ferromagnet 2 induced by an external magnetic field can be sensed as changes in the resistance of the spin valve. Because the spin-valve sensitivity to external fields can be substantially better than inductive pickup, such devices have enabled dramatic shrinkage of the bit size in modern hard drives. An alternative use for the spin-valve structure is found if it is designed to utilize just two well-defined magnetization states of ferromagnet 2 (e.g., parallel or antiparallel to ferromagnet 1). Such spin-valve designs serve as a binary memory device, and have found application in rad-hard non-volatile memories as large as 1 Mb [6]. The drawbacks of this type of memory are:

- a relatively low magnetoresistance, providing only low signal amplitudes and thus longer read times
- a low device resistance, making for difficult integration with resistive CMOS transistor channels
- in-plane device formation which is more difficult to scale to small dimensions than devices formed perpendicular to the plane.

Solutions to these problems can all be found in the magnetic tunnel junction (MTJ) MRAM. The MTJ structure is similar to the GMR spin-valve in that it uses the property of electron spins aligning with the magnetic moment inside a ferromagnet. However, instead of passing current in-plane through a normal metal between

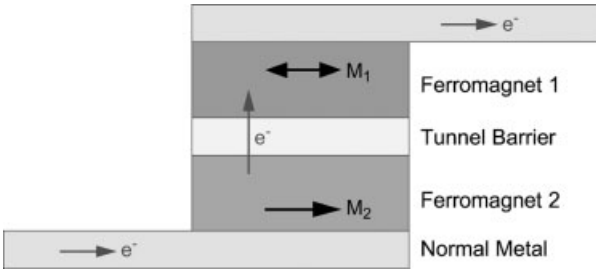

Figure 14.2 A simple magnetic tunnel junction structure. Ferromagnet 2 acts as an electron spin polarizer, and ferromagnet 1 as an electron spin filter, with magnetization either parallel or anti-parallel to the magnetization of ferromagnet 2. Parallel magnetizations generally result in a lower device resistance than anti-parallel magnetizations.

ferromagnets, the MTJ passes current perpendicular to the plane, through an insulating barrier separating two ferromagnets. An MTJ structure in its simplest form is shown in Figure 14.2. Here, one can envision the electric current impinging first on a ferromagnet which acts as a spin polarizer, then passing through the tunnel barrier and into a second ferromagnet which acts as a spin filter. The separation of polarizing and filtering functions is enabled by the physical thickness of the tunnel barrier, noting that the tunneling process preserves electron spin. The tunneling conductance will be proportional to the product of electron densities of states on each side of the barrier, and in general for ferromagnets there will be a larger density of states near the Fermi level for electrons polarized parallel to the magnetization of the ferromagnet as opposed to electrons polarized antiparallel. For polarizer and filter magnetizations aligned in the same direction, the density of states for spin-polarized electrons is large on both sides of the barrier, and the conductance of the structure is relatively high. For anti-parallel alignment of the polarizer and filter, the density of states available for spin-polarized electrons to tunnel into is somewhat reduced, and the conductance of the structure is relatively low. Proposed around 1974 [7], the first demonstrations of MTJs used Fe/Ge/Co multilayer stacks, but only showed appreciable MR (14%) at 4 K temperatures [8]. It was not until 1995 that improvements in materials processing techniques and the use of robust aluminum oxide tunnel barriers began to show reasonably large MR (18%) for MTJ devices at room temperature [9]. This breakthrough brought about huge investments from numerous companies, and ushered in a new era in the field of spintronics.

14.3 MTJ MRAM

The structure illustrated in Figure 14.2 can store binary information in the direction of magnetization within ferromagnet 1 (the “free layer”), provided that the magneti-

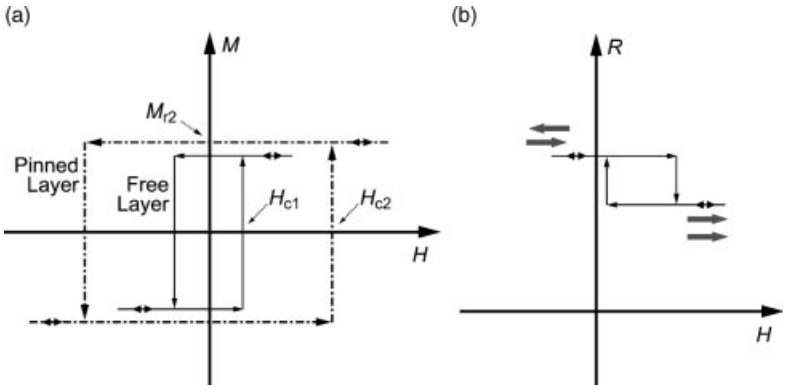

Figure 14.3 (a) Representative hysteresis curves of magnetization M versus applied field H, for a soft ferromagnet free layer and for a hard ferromagnet pinned layer in isolation. The coercive field H_{c2} is chosen large enough to keep the orientation of the pinned layer from switching while the free layer is being switched. M_{r2} represents the remanence from the pinned layer at zero applied field. (b) Resultant hysteresis of the MTJ resistance shown as a function of applied magnetic field. Due to the remanent magnetization from the pinned layer, the resistance loop is offset from the zero-applied field, and (as shown) can even result in but a single stable resistance at zero-applied field. The double arrows represent the magnetization state of the MTJ structure (anti-parallel or parallel).

zation within ferromagnet 2 (the "pinned layer") remains fixed in a predetermined direction. An asymmetry induced in the structure from device shape or intrinsic magnetic anisotropy can stabilize preferred orientations for the free layer to be one of either parallel to or anti-parallel to the pinned layer, thus maximizing the MR. A straightforward way to enable switching in the free layer without switching of the pinned layer is through the use of a material with a low coercive field H_c for the free layer, and a material with a high H_c for the pinned layer. This technique is illustrated in Figure 14.3a, with the hysteresis loops of a soft (low-H_c) free layer and a hard (high-H_c) pinned layer in isolation (i.e., not in the integrated MTJ stack structure). For operation at applied magnetic fields within the bounds set by H_c of the pinned layer, only the free layer will switch direction of magnetization. The hysteresis curve for the free layer demonstrates the necessary memory effect when the applied field is reduced to zero.

With the integrated multilayer structure of Figure 14.2, however, the hysteresis curves of the free and pinned layers in isolation are not straightforward predictors of the resistance states of the MTJ device. Because the pinned layer will maintain a remanence in a zero-applied field, there will be an offset imparted to the hysteresis loop of the free layer. (Note that there will be a similar offset of the pinned layer hysteresis loop imparted by the free layer's remanence, but for large enough H_{c2} there will be no effect on the device operation.) The effect of the pinned layer remanence on the magnetoresistive hysteresis loop R versus the applied field is illustrated graphically in Figure 14.3b. For a large remanence M_{r2}, the loop may shift so much that there is no longer a bistable memory for zero applied field. In principle, such an offset in memory product chips could be compensated by an external field

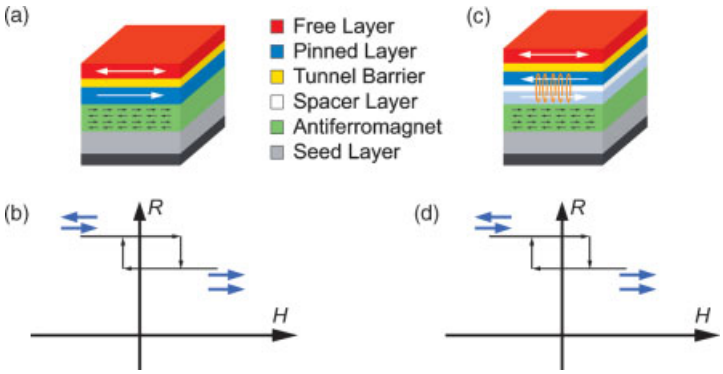

Figure 14.4 (a) Antiferromagnet-pinned reference layer structure with corresponding *R* versus *H* hysteresis loop (b). Also shown (c) is a flux-closed antiferromagnet-pinned reference layer structure with corresponding *R* versus *H* hysteresis loop (d) [2].

applied from a permanent magnet incorporated into the chip packaging. This is somewhat impractical, however, due both to packaging cost and to stringent requirements of across-chip uniformity.

Fortunately, clever manipulation of film properties has driven the evolution of several generations of MTJ structures, overcoming issues such as the offset field described above. Two such advances are illustrated in Figure 14.4. In Figure 14.4a, an antiferromagnet is exchange coupled to the pinned layer, thus providing a much larger effective coercive field for the pinned, or "reference" side of the tunnel junction [10]. With exceptional care to maintain a clean, smooth interface between the antiferromagnet and the pinned layer above it, one can obtain the strong exchange coupling between these films that is necessary to resist field switching. At least 1–1.5 nm of ferromagnetic pinned layer must still remain in the stack to act as an electron spin polarizer, but when coupled to the antiferromagnet it can be extremely well pinned even if the ferromagnet has a low H_c. By removing the need for a high-H_c ferromagnet in the pinned layer, this structure allows some additional flexibility in the choice of ferromagnet pinned layer material. One can optimize for maximum electron spin polarization for best magnetoresistance, and choose film qualities for low remanence and thus a lesser offset of the *R* versus *H* hysteresis curve. Correspondingly, Figure 14.4b illustrates a representative improvement in offset, for comparison with Figure 14.3b from the simpler stack structure.

Although there is much benefit in using the simple antiferromagnet (AF)-pinned structure of Figure 14.4a, best device operation often calls for reducing the *R* versus *H* hysteresis offset to an even smaller value. In this case, the flux-closed AF-pinned structure shown in Figure 14.4c can be tailored to give arbitrarily small offset fields. Here, a synthetic antiferromagnet (SAF) is formed from two ferromagnets separated by a thin spacer layer. For common spacer layers of 0.6–1.0 nm of Ru, one can obtain a strong antiparallel coupling between the two ferromagnets [11]. For reasonable

external fields, this coupling forces them to be antiparallel, and thus the thicknesses of the two ferromagnets can be balanced such that the external magnetic flux is negligible. The pinning of one of these ferromagnet layers with an antiferromagnet gives a high effective H_c while at the same time causing negligible offset to the R versus H hysteresis loop (Figure 14.4d).

Flux-closing the reference layer ferromagnet works remarkably well in practice, particularly with recent advances in materials deposition tooling which enable tight control over film thicknesses for multilayer film structures covering entire 200- to 300-mm wafers [13]. A cross-section transmission electron microscopy (TEM) image of such a flux-closed reference layer MTJ stack is shown in Figure 14.5. Some interesting features of the magnetics-related elements can be discerned from the TEM image, and these are discussed below.

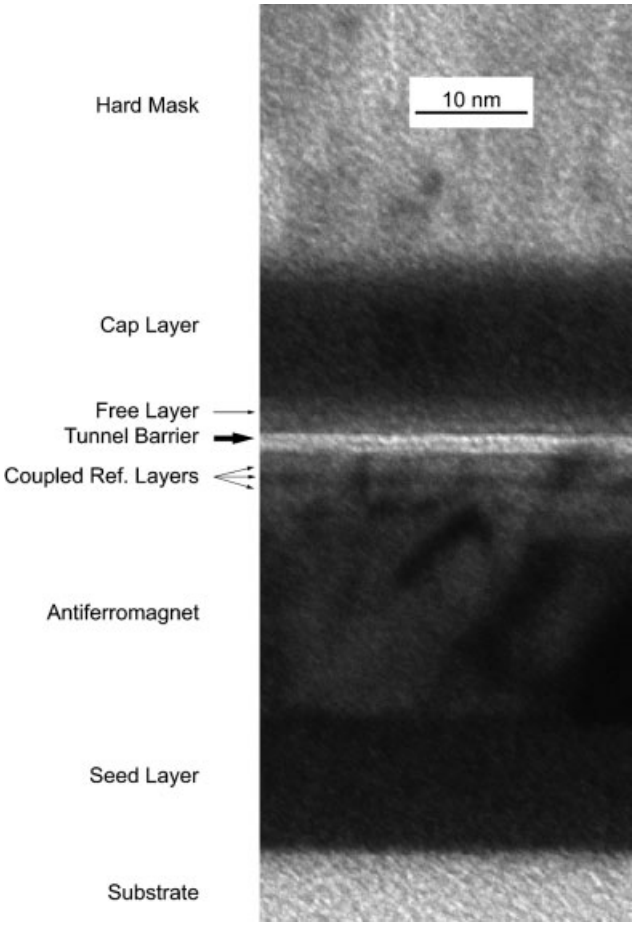

Figure 14.5 A transmission electron microscopy high-resolution, cross-sectional image of a MTJ stack with flux-closed, antiferromagnet-pinned reference layers.

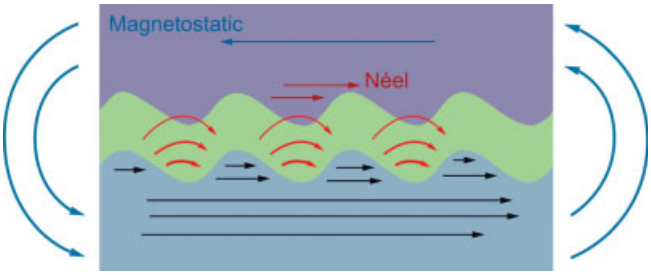

Figure 14.6 A schematic description of Néel coupling and how it relates to magnetostatic coupling. The rough-topped bottom film represents the pinned layer of Figure 14.4. Although exaggerated in the figure for clarity, an actual roughness greater than one atomic monolayer is cause for concern. The green intermediate layer represents the tunnel barrier, and the layer above is the free layer. Black arrows in the bottom film represent the internal magnetization of the pinned layer but, due to the rough surface, the magnetic poles are uncompensated in the region of the tunnel barrier. The resultant field from these poles creates a Néel field which favors parallel orientation of the free and pinned layers. The magnetostatic demagnetization field from the ends of the pinned layer favors antiparallel orientation of the free and pinned layers, but as this is non-local, it is less important in breaking the symmetry of devices with multiple layers [12].

14.3.1 Antiferromagnet

The antiferromagnet, which is generally a polycrystalline material such as FeMn, PtMn, or IrMn, is chosen and grown with several characteristics in mind:

- The interface roughness of the antiferromagnet must be sufficiently small that Néel coupling can be neglected (Figure 14.6), ensuring a smooth, pinhole-free tunnel barrier.
- The pinning strength must be large compared to the fields used to switch the free layer between its binary memory states.
- The blocking temperature of the antiferromagnet must be in a suitable range. In order to obtain an ideal pinning of the ferromagnet reference layer, the antiferromagnet/ferromagnet bilayer must be annealed above the blocking temperature T_B at which the exchange coupling between the films is zero. An applied magnetic field fixes the orientation of the ferromagnet, and then the bilayer is cooled. During cooling, the surface magnetization of the antiferromagnet aligns with the field-imposed ferromagnet magnetization. After cooling and removal of the field, exchange coupling across this interface keeps the ferromagnet pinned. Here, an antiferromagnet must be chosen with a blocking temperature T_B below approximately 300 °C in order to minimize material diffusion and tunnel barrier degradation. In addition, T_B must be sufficiently above the device operating temperatures, around 125 °C.
- The antiferromagnet must be able to withstand process temperatures of the ensuing circuit integration. Roughly, this translates into saying that the compo-

nents of the antiferromagnet should not dissociate and diffuse out of the layer for process temperatures below about 250 °C.

14.3.2 Reference Layer

The reference layer closest to the tunnel barrier must act as an effective spin polarizer, and so it must be of thickness at least of order the electron spin-flip scattering length. This implies that 1–1.5 nm is the minimum thickness of the layer closest to the tunnel barrier. For best flux closure and minimal offset to the free layer, the reference layer adjacent to the antiferromagnet will be of a similar thickness, although a perfect zero free-layer offset may dictate small differences in the thicknesses. An upper limit to the thickness is set by the additional surface roughening and resultant Néel coupling that thicker films will generate. Reference layer materials are chosen for their best spin polarization properties and compatibility with device-processing techniques (e.g., minimal corrosion and thermal stability). Films of CoFe of the order of 2 nm thickness are typically used, separated by the 0.6- to 1.0-nm exchange-coupling Ru layer.

14.3.3 Tunnel Barrier

Aside from the requirement of reasonable magnetoresistive properties, the tunnel barrier is chosen primarily for robustness. It must be extremely thin to ensure that spin polarization is maintained during electron transit across the barrier, and the barrier must be able to survive under billions of cycles of electrical bias during its lifetime, without developing pinholes or any substantial shift in resistance. Aluminum oxide has proven an extremely suitable candidate for such tunnel barriers, and is known to offer reasonable magnetoresistance for suitable magnetic pinned and free layers. Recent developments in tunnel barrier engineering show that magnesium oxide tunnel barriers can offer MR near 500% at room temperature, although MgO-barrier devices have not yet proven to serve as robust, manufacturable layers in large arrays with good magnetic switching characteristics [14]. Aluminum oxide barrier devices can display MR near 100%, but trade-offs in the choice of magnetic materials for best switching characteristics, and in the choice of operating point for best CMOS integration, generally result in an MR less than 50%. Such MR is suitable for maintaining distinct resistance groupings of millions of devices in modern MRAM arrays, and increasing the MR is advantageous primarily in that it can reduce the necessary signal integration time to read the state of a device. Such a reduction is not a terribly strong driver at this time, as the array read time is set as much by the circuit overhead as by the device signal-to-noise ratio. Increasing the MR to 500% would likely result in only a 10–20% reduction in read duration. One area in which MgO barriers may soon establish a strong foothold is in the formation of highly transparent tunnel barriers. As device sizes shrink, the lower resistance–area product afforded by MgO will enable the best match to CMOS drive transistors, and thus the highest

speed of operation. Today, even more highly transparent tunnel barriers are under development for a class of devices using electron spin current to switch the device state.

14.3.4 Free Layer

The free layer shown in the TEM is reasonably thin, rather like the underlying pinned layers. However, it does have a minimum thickness limit set by the spin filtering characteristics: for a thickness less than the approximate electron spin-flip scattering length, the magnetoresistance will begin to drop, and this again sets the thickness at around 1.5 nm or more. Thicker free layers require additional energy to switch, and so are undesirable for low-power operation. Of critical importance in the characteristics of the free layer is the need for well-defined magnetic states and well-behaved magnetic switching. As one cannot tailor the read or write circuitry to every individual device in megabit arrays of MRAM devices, it is critical that each device behave very much like all others in the array. Ill-defined magnetization states such as vortices, S-shapes, C-shapes, and multiple domains will add variability to the resistance measured by the circuitry, because electron spin polarization filtering may not be strictly parallel or antiparallel to the spin polarization imparted by the pinned layer. In addition, sensitivity of the film switching behavior to tunnel barrier and cap materials, or to device edge roughness or chemistry, can impart variability to the write operation of the individual bits in megabit arrays. NiFe alloys are preferred for good magnetic behavior with reasonable corrosion resistance. The addition of Co or Fe to the NiFe, or dusting with Co or Fe between the tunnel barrier and NiFe layer, can help to adjust the magnetic anisotropy and improve the MR. Layer thicknesses are typically in the 2- to 6-nm range for best low-power operation with good switching characteristics.

Several additional non-magnetic elements are visible in the TEM image, and these are discussed below.

14.3.5 Substrate

An ultra-smooth substrate is required as the starting point for smooth, uniform, and reliable tunnel barriers. Rough interfaces also result in increased Néel coupling, which is detrimental to device performance. Representative materials for the substrate are thermally oxidized silicon, or chemical-mechanical planarized (CMP) polished dielectrics such as silicon nitride, silicon oxide, or silicon carbide.

14.3.6 Seed Layer

An appropriate seed layer is required to obtain good growth conditions for the antiferromagnet, both to ensure a smooth top surface and to ensure good magnetic

pinning strength. Given the high stress in some of the films in the MTJ stack, this seed layer is also critical for ensuring good adhesion to the substrate. It may be formed from tantalum nitride or permalloy (NiFe), for example.

14.3.7
Cap Layer

The proper choice of a cap layer is necessary to protect the free layer during further device fabrication processing. It is essential as a barrier or "getter" for contaminants, keeping the free layer clean and magnetically well behaved. Often-used materials for this layer include ruthenium, tantalum, and aluminum. The choice of this material may also depend on its effect on the magnetic behavior of the free layer: certain cap materials can discourage smooth switching between free layer states, and can result in substantial "dead layers" which must be compensated for by a thicker free layer.

14.3.8
Hard Mask

A hard mask (as opposed to a "soft" photoresist mask) is used to enable patterning of the MTJ with industry-standard etch techniques. It also eases integration with the surrounding circuitry by providing a contact layer to connect the MTJ to wiring levels above. The hard mask material is largely chosen for its compatibility with subsequent processing in the fabrication route, and can be chosen from any number of metallic or dielectric materials.

The processing of MTJ structures to integrate them with CMOS circuitry is discussed in greater detail later in the chapter.

14.4
MRAM Cell Structure and Circuit Design

14.4.1
Writing the Bits

The mechanism for switching the state of the free layer in MRAM lends itself well to an array layout with a conventional planar semiconductor design and fabrication. A typical rectangular MTJ array layout, with word lines (WLs) arrayed beneath the devices and bit lines (BLs) arrayed atop the devices, is illustrated in Figure 14.7. Current driven along the WLs or BLs generates a magnetic field which imparts a torque on the magnetization of the device. In normal operation, the superposition of properly-sized "write" fields from both WL and BL will enable a switching event to occur in the free layer of the device at the intersection of the two lines. The write fields are chosen small enough so as not to exceed the coercivity of the pinned layer. Potential pitfalls from this scheme include write errors from half-selected devices (i.e., those subjected to only a WL or a BL field, but not both) and, worse, write errors

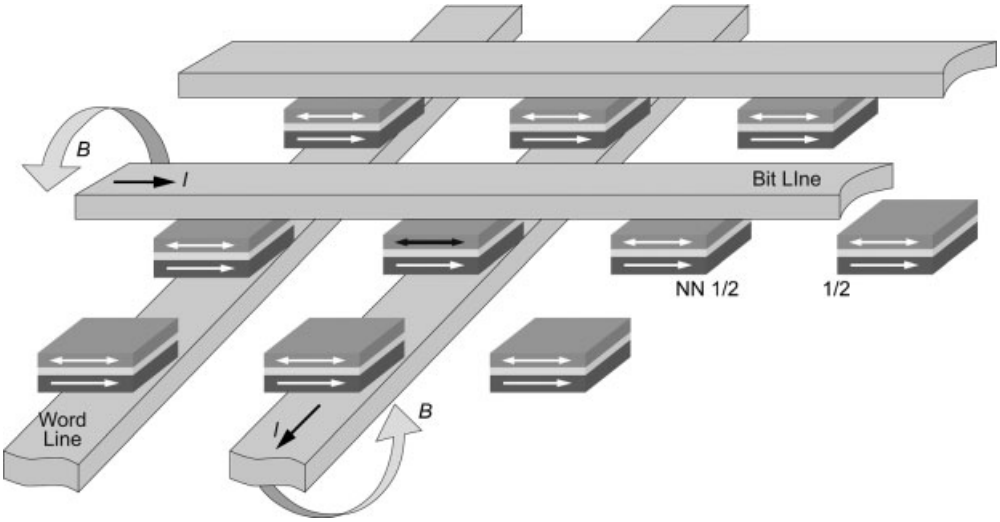

Figure 14.7 Schematic representation of a rectangular array of MTJ devices, with bit line and word line circuitry for writing the bits. Current-generated magnetic fields (B) from a given bit line and word line are sufficient only to switch the device at the intersection of the two wires. Write errors are typically worse for devices in the half-select state (MTJs labeled "1/2" in the figure), where a word line or a bit line is active, but not both. The situation is even worse for near-neighbor half-selected devices ("NN1/2" in the figure) where, for example, the device is in the column adjacent to the active word line, but is half-selected by the active bit line.

from near-neighbor half-selected devices (those subjected to a half-select field, but only one row or column away from another active line).

The diagrams in Figure 14.8 provide more details about the superposition of magnetic fields used to switch the active device. With the flux-closed antiferromagnet-pinned reference layer structure (see Figure 14.4c) forming the MTJ, the single-layer free layer is switched with characteristics first described by Stoner and Wohlfarth [15]. A simple case is that of an elliptical-shaped MTJ with shape anisotropy defining an easy axis (the major axis of the ellipse) and a hard axis (the minor axis of the ellipse). To switch the magnetization, a hard-axis field is applied to tilt the free layer magnetization away from the easy axis energy minimum, and an easy-axis field is applied to "set" the magnetization of the device in the desired easy-axis direction – parallel or antiparallel to the pinned layer. With this Stoner–Wohlfarth (S-W) switching, relatively small operating margins are illustrated by the closeness of the green and pink dots to the S–W boundary in Figure 14.8b. In addition to accounting for spreads in the switching characteristics between devices, one must also budget in extra operating window for thermal activation errors and the disturb effects of half-selects and near-neighbor field interaction. Circuit designers will try to tailor the operating window for at least 10 years of error-free operation. Without use of error-correction techniques, one generally aims for operating margins to keep the activation energy for a bit error to greater than 60 $k_B T$, where k_B is the Boltzmann constant and T is the temperature. This imposes extremely tight requirements on how uniform the array

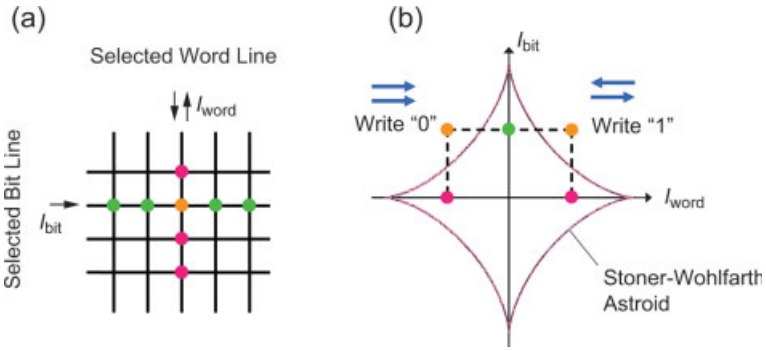

Figure 14.8 (a) Top-down schematic view of an MTJ array with rows and columns of bit lines and word lines with fields superposed to switch the device represented by a orange dot. Devices shown as green and pink dots are half-selected devices. Those green and pink devices adjacent to the orange device are near-neighbor half-selected devices. (b) A graph showing necessary bit line and word line current values needed to switch a desired device. The colored dots on the plot correspond to the devices represented by colored dots in Figure 14.8a. For suitable choice of word line and bit line currents, one can ensure switching of the desired device without switching half-selected devices.

must be in terms of switching, described in equation form by the array quality factor (AQF):

$$\mathrm{AQF} = \frac{H_{\mathrm{sw}}}{\sigma_{\mathrm{Hsw}}} \tag{14.2}$$

Here, H_{sw} is the average switching field of the devices and σ_{Hsw} is the standard deviation of the switching field distribution of all elements in the array. In rough terms, the AQF must be larger than about 30 in order to ensure a lifetime of 10 years, although some relief can be gained through the use of error correction techniques.

Toggle MRAM was invented to circumvent the difficulties faced by S–W MRAM in terms of the operating margin for half-selected bits [16]. As illustrated in Figure 14.9a, the structure has taken the flux-closed antiferromagnet-pinned reference layer structure (see Figure 14.4c) a step further by also flux-closing the ferromagnetic free layer. This is achieved by depositing a spacer layer atop the free layer ferromagnet, followed by a second ferromagnet. The spacer can be chosen (as in the pinned layer) to enhance antiparallel coupling, or the spacer can be chosen with zero or even with some parallel coupling characteristics to decrease the write field needed to switch the bit. The magnetizations of the two ferromagnets in the free layer will point in opposite directions, and their balance and proximity will flux-close the layers so there is little field seen emanating from the structure at a distance. The write operation of this toggle-mode structure is illustrated in Figure 14.9b. Noting the colors assigned to represent the magnetization of the free layers in Figure 14.9a (green for the top layer, red for the bottom layer), the plots at the top of Figure 14.9b show the relative orientation of the two magnetizations. Note that the initial state is such that the magnetization of the MTJ has easy (preferred) axis at 45° to the word and bit lines, rather than be aligned parallel to one of them as in S–W MRAM.

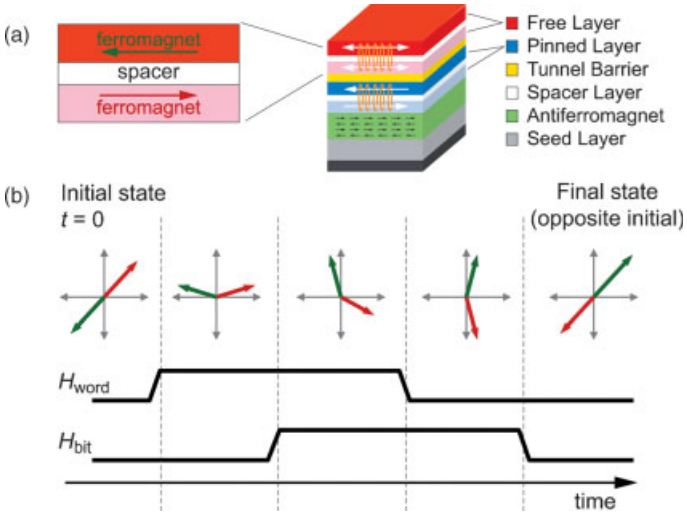

Figure 14.9 (a) Structure of the toggle-mode MTJ stack. (b) Time evolution of the free layer switching. See text for details.

Figure 14.9b illustrates the need for staggered timing of WL and BL write-field pulses. To switch the state of the free layers, a magnetic field is first applied from the WL along the positive y-direction. This magnetic field cants the magnetizations of both free layers as they try to align to the field. The antiparallel nature of the magnetic coupling between the free layers prevents the magnetizations from both fully lining up with the applied word field, as long as the field is not too large to overwhelm this antiparallel state. When the magnetizations are canted sufficiently, there is a net magnetic moment to the free layers, and this moment can be grabbed like a handle by the field now imparted by the BL. The BL applies a field in the positive x-direction, and the net moment of the two free layers follows this BL field. The WL field is then shut off, and the net moment continues to rotate around towards the applied BL field. As the BL field is shut off, the free layer magnetizations relax into their energetically favorable antiparallel configuration, but now with magnetizations exactly opposite to those at the start.

The name "toggle-mode device" is derived from the characteristic that cycling the WLs and BLs in this manner will always switch the state of the device. To set a bit in a particular state, a read operation must be performed to determine if a write "toggle" operation is required. Aside from this drawback, and the additional complexity of the magnetic stack, there are several advantages to the toggle-mode structure:

- As alluded to above, the write operating margins can be substantially larger than for devices with S–W switching. Rather than a S–W astroid boundary, the toggle-mode devices exhibit an L-shaped boundary that does not approach the WL or BL axes. The potential for half-select errors is dramatically reduced, and the requirement on AQF is approximately halved.

- In principle, shape anisotropy is not required to ensure that the bit has only two preferred states for binary memory. One can utilize the intrinsic anisotropy of the ferromagnetic free layers to define two such states. This allows the use of circular MTJ devices for the smallest memory cell size.
- The flux-closed nature of the free layers greatly reduces dipole fields emanating from the free layer. Such fields can affect the energetics of nearby devices, resulting in variability of switching characteristics, depending on the states of such devices. Thus, with flux-closed free layers, nearby devices can be packed in closer proximity for improved scaling.

14.4.2 Reading the Bits

The array structure illustrated in Figure 14.7 is often termed a "cross-point cell" (XPC) structure. More specifically, XPC refers to the case where the MTJ devices are located at the cross-points of the BLs and WLs, and are directly connected to the BLs and WLs above and below the MTJ stack. This structure offers an extremely high packing density for the lowest cost memory. The write mechanism is reasonably straightforward as described above, as long as the MTJ resistance is not so low that it shunts the write currents. More troublesome is that the read mechanism suffers from a reduced signal-to-noise ratio in this XPC structure. In order to read the resistance state of a XPC bit, a bias is applied between a desired BL and WL, and the resistance measured. However, due to the interconnected nature of the XPC structure, not only the resistance of the cross-point device is measured – there are parallel contributions of resistance from many other devices along "sneak paths" that include traversing additional sections of BL and WL. Due to the resulting loss of signal, the device must be read much more slowly to allow for integration to improve the signal-to-noise ratio. Device read times can be substantially longer for such XPC structures, making this type of memory far less desirable than one which can be read as fast as DRAM, for example.

The solution to the problem of sneak paths is to insert an isolation mechanism which ensures that read currents will only traverse a single MTJ device. For example, this can be achieved by placing a diode in series with each MTJ. Although this seems simple when drawn as a circuit schematic on paper, it is actually more straightforward to place a field effect transistor (FET) in series with each MTJ, and assign a second WL to control the read operation. The "FET cell" circuit structure is shown schematically in Figure 14.10, with separate WLs for the write and read operations. The BL is used for both read and write operations.

Figure 14.11 illustrates the implementation of the circuit structure shown in Figure 14.10, suitable for a densely packed array of MTJs. Structural additions to standard CMOS circuitry include:

- the via contact VJ between the bit line and the top of the MTJ stack
- the MTJ device

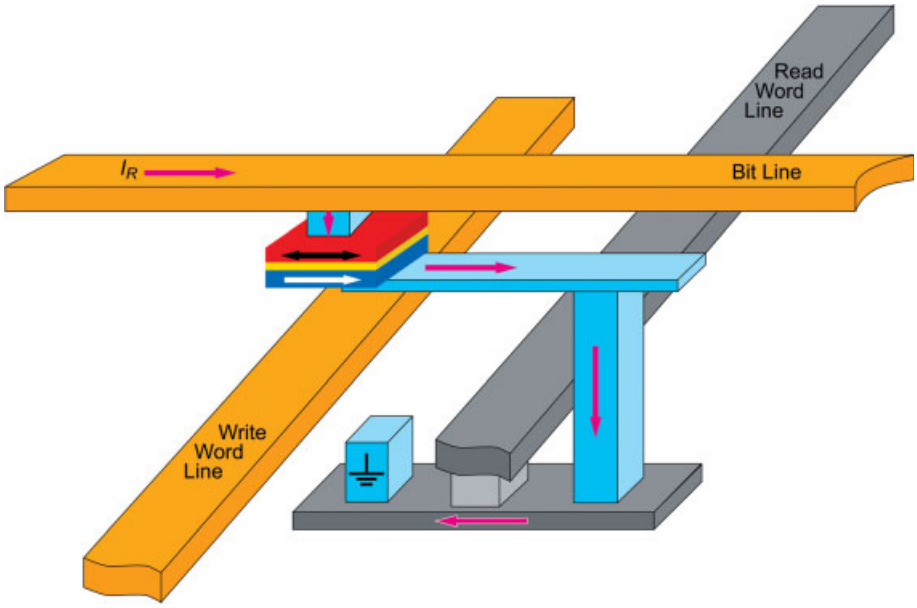

Figure 14.10 Field-effect transistor (FET) cell circuit topology, showing individual word lines for reading and for writing. A FET located in the silicon beneath the MTJ is used to switch on only the device being read, thus preventing leakage of read currents (purple arrows) through nearby MTJ devices. Additional conductor elements in this structure (compared to Figure 14.7) include a contact between the bit line and the top of the MTJ, a local metal strap (MA) connecting the base of the MTJ with a via chain that connects to the underlying FET.

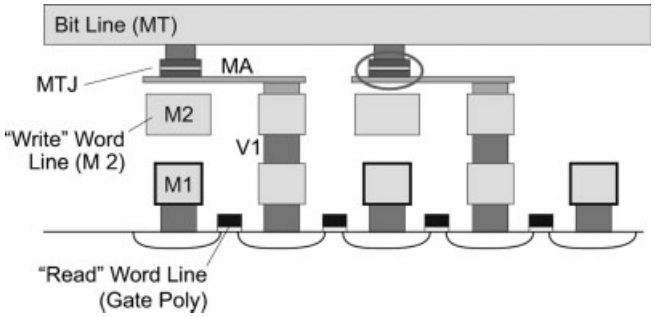

Figure 14.11 A cross-section of the FET cell topology, with two adjacent cells shown atop the silicon CMOS front-end of line (FEOL) structure. The oval encloses the critical components for MRAM implementation. As cell size is determined primarily by the MTJ and via chain above the via V1, two FETs can be used for each MTJ in order to achieve lower resistance and some redundancy. Thus, the FET gates on either side of a V1 via chain will be connected to the same "read" word line. Wires formed in the first level of metallization (M1) (outlined in bold) form a grid at a reference potential. M2 denotes the second level of metallization. The reader is referred to Ref. [17] for further details on such structures.

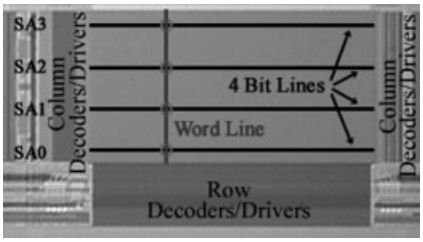

Figure 14.12 Photograph of a 128 Kb subarray, showing locations of the sense amplifiers (SA), the row and column decoders and drivers, and the concurrent activation of four bit lines with one word line for a ×4 organization of the block. A single MTJ cell is indicated by a circle at the intersection of a word line (WL) and bit line (BL).

- the local metal strap (MA) between the bottom of the MTJ stack and the via to M2
- the via VA between the MA strap and the M2 wiring, which serves to isolate the MTJ from the write WL while providing connection to the underlying FET structure for reading.

A slightly higher packing density may be achieved with a mirror-cell design, where adjacent bits mirror each other. The simple unmirrored design of Figure 14.11 is preferable to minimize any across-array non-uniformity due to inter-level misalignment and inter-cell magnetic interference. Megabit and larger MRAM memories are formed from multiple subarrays, with size determined largely by the resistance of the BLs and WLs. There is a desire always to keep applied voltage low, for CMOS compatibility and best array efficiency. The required current to generate the necessary MTJ switching fields then sets a maximum length on the BL or WL, depending on the resistive voltage drop. Bootstrapped write drivers can be used to allow smaller write drivers with improved write current control [18]. A 16 Mb MRAM under development at IBM utilizes 128 Kb subarrays (see Figure 14.12), with 512 WLs and 256 BLs of active memory elements.

The read operation is performed with sense amplifiers that compare the desired bit to a reference cell. The reference cell uses two adjacent MTJs fixed in opposite states in a configuration that acts like an ideal mid-point reference between the R_{high} and the R_{low} states [18]. Four BLs are activated in a given cycle, and are uniformly spaced along the height of the array to reduce magnetic interference between activated BLs during the write operation, and to minimize distance from the activated BLs to the sense amplifiers during a read operation. Additional reference BLs are located within the array, with one set shared by sense amplifiers 0 and 1, and one set shared by sense amplifiers 2 and 3.

The array driving circuitry for MRAM memories is commonly standardized to an asynchronous SRAM-like interface for easy interchangeability in battery-backed SRAM applications. The IBM 16 Mb chip uses a ×16 architecture that is prevalent in mobile and handheld applications with packaging intended for simple direct replacement of SRAM chips. As shown in Figure 14.13, the 16 Mb chip measures 79 mm^2 with individual memory cells of 1.42 μm^2, for an array efficiency of almost

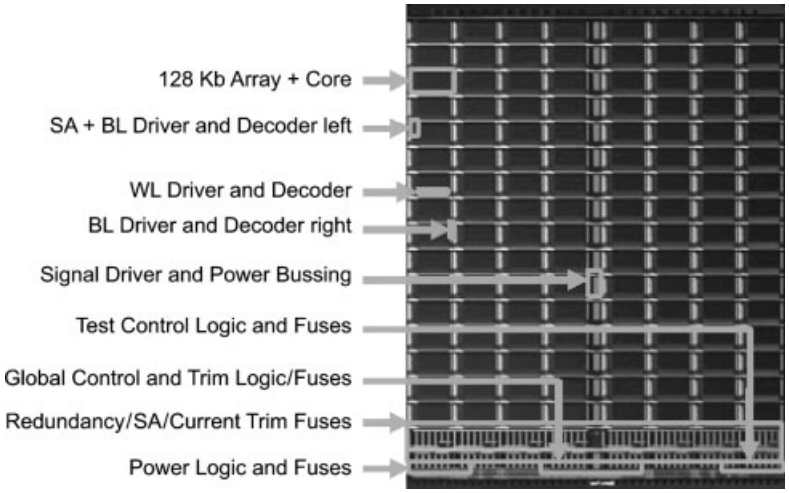

Figure 14.13 A photograph of the 16 Mb MRAM chip, showing locations of 128 Kb array cores (eight columns of 16 rows) and support circuitry [18].

30%. The array efficiency may be improved by using more metal layers and by eliminating some of the developmental test mode structures used in this chip. A reduction of the standby current for power-critical applications is achieved through the extensive use of high threshold, long-channel FET devices and careful grounding of inactive terminals in the arrays and in the write driver devices [18].

Redundant elements are included in the chip to allow the correction of defective array elements. Such redundancy is implemented with fuse latches and address comparators in a manner consistent with industry-standard memory products. The CMOS base technology is quite mature, so the focus of the redundancy is on the MRAM features. Single-cell failures or partial WL failures (from MRAM reference cell defects) are considered the most likely defects. The redundancy architecture favors replacement of WLs to capture the partial WL fails from MRAM reference cell defects. Redundancy domains are implemented at a high level in the block hierarchy so as to span several blocks and be capable of effectively fixing any random defects [18].

14.4.3 MRAM Processing Technology and Integration

The implementation of MRAM hinges on complex magnetic film stacks and several critical steps in back-end-of-line (BEOL) processing. Cell size is presently limited by the size of the MTJ devices and driving wires, and older, mature CMOS front-end-of-line (FEOL) technology can be used without limiting performance. Fabrication of the FET-cell circuit, from the CMOS FEOL through the MRAM BEOL, can encompass several hundred process steps, resulting in the fully functional structure shown in Figure 14.14. The MRAM-critical portion of the circuit is a relatively small part of the entire configuration. After the last standard CMOS step (the M2 wire completion),

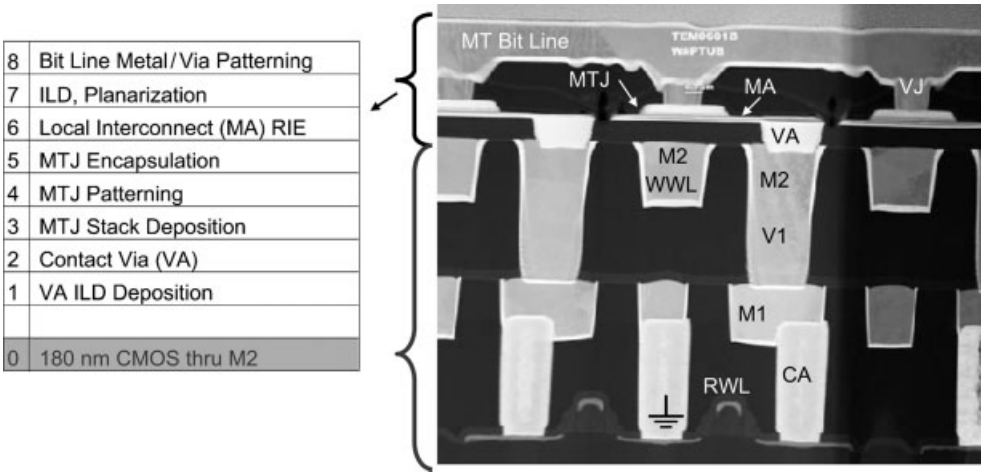

Figure 14.14 Cross-section of a product cell, showing the integration of MRAM with CMOS, and the process steps used for the MRAM-specific layers. ILD is the interlayer dielectric.

there remains the need to pattern the shallow vias, the MTJs, the local interconnects, and at least one level of wiring with contact to MTJs and the functional circuitry below. Even for simple functional circuits, five or more photomask levels are required to complete the MRAM-centric portion of the structure.

14.4.3.1 Process Steps

In conjunction with the steps outlined in Figure 14.14, below is a discussion of the important considerations for the process steps in the fabrication of the MRAM-specific levels.

1. *VA contact via and ILD:* The VA via provides a path for read current to flow from the local (MA) metal strap down through a via chain to the underlying read transistor. The most critical aspect of this module is that it must form a substrate which is sufficiently smooth for good magnetic stack growth.

2. *Magnetic film stack deposition:* Arguably the most essential technological advance in enabling MTJ MRAM was the development of tooling for the large-area deposition of extremely uniform films with well-controlled thickness. Such tooling has proven suitable for the deposition of magnetic, spacer, and tunnel barrier films with sub-Ångström uniformity across 200 mm and even 300 mm wafers [13]. The critical aluminum oxide tunnel barrier is generally formed by depositing a thin aluminum layer, followed by exposure to an oxidizing plasma [19].

3. *Tunnel junction patterning:* A commonly used and straightforward approach to patterning the MTJs is with the use of a conducting hard mask. This is later utilized as a self-aligned stud bridging the conductive MT wiring to the active magnetic films in the device. A thick hard mask, however, introduces additional

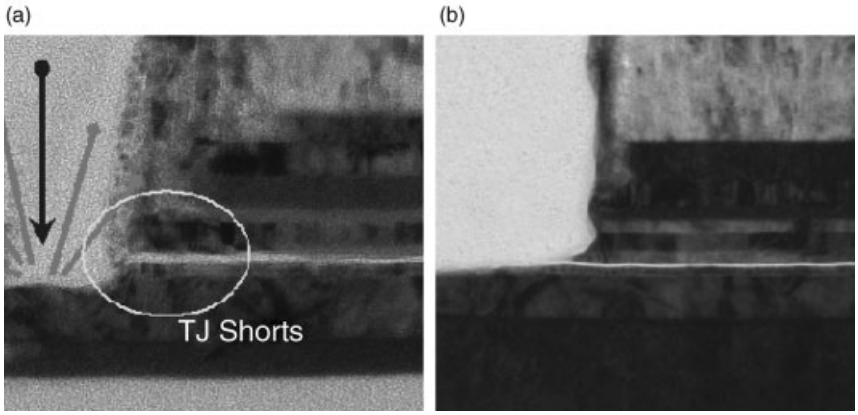

Figure 14.15 (a) Transmission electron microscopy image of the edge of a MTJ after etching to define the free magnetic layers. The etch has progressed to a depth just past the oxide tunnel barrier (the lightest contrast film in the stack). The dark arrow represents incoming sputtering ions; the lighter lines represent the path of atoms sputtered from the surface of the device being etched, many of which result in redeposits on vertical device surfaces. The consequences of sputter-etch redeposits on the sidewall of a MTJ device can be seen as a short-circuited tunnel barrier and a poorly defined edge with thick redeposits. (b) Improvements in the etch conditions can result in a much cleaner sidewall and the elimination of residues that would short-circuit the tunnel junction.

difficulties in that it can shadow the etch being used to pattern the magnetic devices. Such shadowing can add an element of variability into the size of the devices, and may also result in metal redeposits on the sidewall of the device structure. As illustrated in Figure 14.15, sidewall redeposits are particularly troublesome for commonly used MRAM stack materials because the materials do not readily form volatile RIE byproducts that provide some isotropic character to the etch. Directional physical sputtering is the main mechanism for etching of the stack materials [20]. Because the difficulties in etching the magnetic stack materials often outweigh the benefits of a simpler process integration scheme, it is often preferable to use a thinner hard mask for less etch shadowing, and an additional via level (VJ in Figure 14.14) to connect the top of the MTJ with the bit line wiring.

4. *MTJ encapsulation:* Silicon nitride and similar compounds are desirable for their adhesion to the MA and MTJ metal surfaces, and for strong interfacial bonds that inhibit migration of metal atoms along the dielectric/metal interfaces. Such metal migration is one well-documented cause of MTJ thermal degradation, and can limit processing temperatures in patterned MTJ devices to below 300 °C [21]. The use of tetra-ethyl-orthosilicate (TEOS) as a precursor in the deposition of silicon oxide films [22] is known to offer the benefits of a relatively inert depositing species which can readily diffuse into spaces adjacent to high-aspect ratio structures, even at temperatures below 250 °C.

5. *MA patterning:* For suitable thickness of seed and reference layers, the series resistance of layers remaining after MTJ etch is small enough to impart negligible

dilution of the MTJ MR signal. This simplifies the processing, as a dedicated film need not be created for the MA strap, and the reference or seed layers of the magnetic stack can perform double duty. As in the MTJ etch, the MA etch may be subject to the problem of non-volatile etch byproducts redepositing along the hard mask sidewalls.

6. *ILD deposition and planarization and wiring:* After the MA metal strap has been patterned, an interlayer dielectric is deposited in which to house the counter-electrode wiring layers VJ and MT. The counterelectrode wiring is formed with well-established semiconductor-industry Damascene techniques.

As alluded to in Figure 14.11, the MRAM-specific elements form but a small portion of the entire integrated circuit. For rapid characterization of these MRAM-specific elements, there is no need to perform a fully CMOS-integrated wafer build; rather, it is sufficient to perform a subset of the process integration steps to focus only on the critical magnetics issues [23].

14.5 MRAM Reliability

One of the strong selling points of MRAM is its reliability: write endurance is expected to be essentially infinite, the magnetics are intrinsically rad-hard, and its non-volatile memory storage can eliminate soft errors in many applications. As in any new technology struggling for successful commercialization, there are certain aspects of the new technology that are unproven and require demonstration of reliability. Areas of potential reliability risk include [24].

14.5.1 Electromigration

Electromigration in the write WLs and BLs, resulting from high write current density. Current pulses of 10 mA are typical for conservative wire cross-sections of 0.2 μm^2, corresponding to a current density of 5 MA cm^{-2}. This alone represents a serious challenge to the reliability in the array, and can potentially be worsened by local disruptions to the quality and thickness of wire material. The VJ vias of Figure 14.14, or direct connection between the BL and the MTJ hard mask in the thick hard mask integration scheme discussed above, can impact the BL wiring electromigration resistance.

Electromigration issues can potentially be improved through the use of bidirectional switching currents, which fit neatly into toggle-mode MRAM operation, but cost in terms of array efficiency. One promising method for reducing electromigration stress is through the use of ferromagnetic liners in a U-shape around the BLs and write WL. These liners serve to focus the magnetic field onto the MTJs in the desired row or column, and can increase the effective field by as much as a factor of 2 for a given current [25]. The use of ferromagnetic liners around the BL is illustrated in

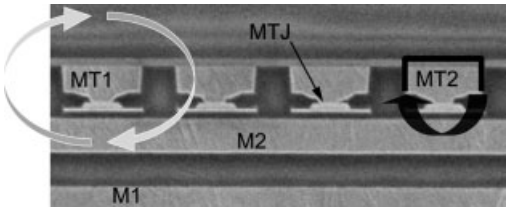

Figure 14.16 A cross-sectional image of a product array, from a viewpoint perpendicular to that of Figure 14.14. The arrows around bit line wire MT1 suggest the magnetic field configuration generated by a current through wire MT1; it is loosely contained, with only moderate magnitude at the MTJ free layers. Conversely, the wire MT2 exhibits an enhanced field magnitude due to its localization by the ferromagnetic film (lines) surrounding the copper MT2 wire.

Figure 14.16. Similar, but inverted, structures can be formed around the write WL (M2 in Figure 14.16) to enhance the field from that wire. The potential reduction in necessary current to obtain a required switching field can dramatically reduce electromigration issues. Not only do ferromagnetic liners offer potential reduction in current density, but they also improve electromigration performance relative to conventional copper processes. By reducing the interface diffusion of copper atoms, ferromagnetic cladding on the top surface of the MT wire enhances electromigration reliability to an extent similar to that seen in the industry by advanced Ta/TaN or CoWP capping processes [26].

One added benefit of the ferromagnetic liner field focusing is the reduction of any near-neighbor disturb effects. Because the field is better focused on devices along the desired WL and BL, adjacent devices are less likely to be switched by near-neighbor fields, or the combination of near-neighbor fields and thermal activation.

14.5.2
Tunnel Barrier Dielectrics

These are subject to reliability concerns because of the extremely thin nature of the barrier and related susceptibility to pinholes or dielectric breakdown. Aluminum oxide tunnel barriers have so far proven quite robust. Time-dependent dielectric breakdown (TDDB) and time-dependent resistance drift (TDRD) have been examined in 4 Mb arrays and found to exceed requirements for a 10-year lifetime [27]. The voltage stresses on the tunnel barrier are relatively modest, as the read operation takes place at 100–300 mV because the MR is higher for a lower voltage. The write operation is performed with one side of the MTJ floating, so there is no significant voltage stress on the MTJ during the higher-power write pulse.

14.5.3
BEOL Thermal Budget

The BEOL thermal budget for MRAM devices ($<$250–300 °C) is significantly lower than for conventional semiconductor fabrication processes ($\sim$400 °C), in order to

prevent degradation to the MTJs. This can affect the intrinsic quality of dielectrics being used in the BEOL, and can also worsen seam and void formation around the topographical features being encapsulated. A low thermal budget also prevents the use of certain post-processing passivation anneals, and packaging materials and processes. The move to lead-free solder with increased solder reflow temperatures represents a further challenge for MRAM.

14.5.4
Film Adhesion

This is a serious concern with the multiple new materials being introduced into the integrated process. The novel etch and passivation techniques being used also may leave behind poorly adherent layers which cannot be subjected to harsh wet cleans without MTJ exposure and degradation. Delamination risks must be mitigated through specially developed dry and wet cleans, the use of materials with tuned stress, and the choice of materials with compatible thermal expansion.

14.6
The Future of MRAM

As of July, 2006, MRAM products such as the 4 Mb memory shown in Figure 14.17 have been available from Freescale Semiconductor [28]. The market space targeted by Freescale includes networking, security, data storage, gaming, and printer data logging and configuration storage. From a customer viewpoint, this product means fewer part counts, a higher level of performance, higher reliability, greater environmental friendliness, and a lower cost solution than their current approaches, such as battery-backed SRAM.

Progressing downwards from the available 180 nm technology, future generations of MRAM are expected to utilize the same magnetic infrastructure with only evolutionary improvements, to below the 90 nm node. However, constraining the scaling are the following concerns:

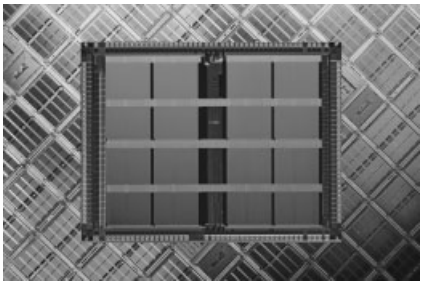

Figure 14.17 Photograph of a MR2A16A 4 Mb MRAM chip atop a wafer filled with such chips, presently available from Freescale semiconductor. (Illustration courtesy of G. Grynkewich and Freescale Semiconductor.).

- *Near-neighbor interactions:* When packing devices closer together, magnetic fields emanating from a given device can affect the switching behavior of devices nearby, and this can also be dependent on the given device's free layer state. In addition, the write wires for switching a given device will perturb neighboring devices to a greater extent as the latter come closer. It remains unclear how well these effects can be suppressed with the use of flux-closed MTJ layers and ferromagnetic cladding of write wires. Additional techniques such as enhanced-permeability dielectric (EPD) encapsulating films may be required to overcome these problems [29].
- *Increased switching fields:* As devices are scaled to smaller volumes, the anisotropy field must be increased to compensate and maintain activation energy greater than 60 $k_B T$ [30]. Write fields will scale to be of similar magnitude to the anisotropy field, and will increase superlinearly with inverse device size. As with the MTJs, the write wires must scale to a smaller footprint, making it more difficult to accommodate the increasing switching fields. In addition, ferromagnetic cladding of the wires becomes less effective because of the bending energy of the flux inside the cladding as the wire corner radius sharpens. EPD device encapsulations will help in this regard.
- *Device-to-device variability:* Process-induced line-edge roughness will become a more substantial fraction of the total device width, so that edge irregularities may become more effective at pinning the domains so they do not switch smoothly. The total device area and aspect ratio will also exhibit larger spreads, both from line-edge roughness and from variability in lithography. A reduced aspect ratio for tighter packing density will also decrease AQF, as the anisotropy field is more sensitive to shape for devices with a smaller aspect ratio [30].

Each of these concerns is not a fundamental limitation, but rather a practical limitation that can most likely be overcome with sufficient – albeit perhaps prohibitively expensive – investment in materials development and processing techniques. Hard physical limits do not appear to set in until superparamagnetism becomes important – that is, for device sizes below 20 nm [30], a dimension substantially below the limits suggested by the aforementioned practical issues.

Even with the practical limits to scaling conventional MRAM, one can expect to see revolutionary modifications to standard MRAM cell such that MRAM will be available with far greater densities, lower cost, and faster operation. Beyond the scope of this chapter are the impressive developments and exciting new proposals in the areas of:

- thermally assisted MRAM for reduced power requirements [31]
- spin-momentum transfer (SMT) MRAM for scaling to advanced process nodes and extremely small active memory devices [32]
- domain-wall memory for very high density serial storage [33]
- embedded MRAM as a replacement for embedded flash and low-density on-chip SRAM, for high-performance microprocessor cache memory and other ASIC applications [34].

In summary, this chapter has provided an overview of the rapid developments in MRAM technology over the past decade. Many major hurdles for MRAM product development have been surmounted in the face of funding limits set by competition with the huge silicon industry. Now that MRAM devices have grasped a toe-hold in the marketplace, new applications will be identified and MRAM development will proceed at an even faster pace over the next decade. Perhaps soon we will again see magnetic RAM in spacecraft!

Acknowledgments

The author would like to thank: W.J. Gallagher for the figures and editorial assistance; IBMs Materials Research Laboratory (MRL) for process development and fabrication; P. Rice, T. Topuria, E. Delenia, and B. Herbst for the TEM imaging; J. DeBrosse, T. Maffitt, C. Jessen, R. Robertazzi, E. O'Sullivan, D.W. Abraham, E. Joseph, J. Nowak, Y. Lu, S. Kanakasabapathy, P. Trouilloud, D. Worledge, S. Assefa, G. Wright, B. Hughes, S.S.P. Parkin, C. Tyberg, S.L. Brown, J.J. Connolly, R. Allen, E. Galligan for various contributions; and M. Lofaro for the advances in CMP. It is also acknowledged that the studies summarized here were supported in part by the Defense Microelectronics Activity (DMEA) and built on prior investigations conducted with Infineon (now Qimonda) within the MRAM Development Alliance, and also on earlier MRAM studies at IBM that were supported in part by DARPA.

15
Phase-Change Memories

Andrea L. Lacaita and Dirk J. Wouters

15.1
Introduction

15.1.1
The Non-Volatile Memory Market, Flash Memory Scaling, and the Need for New Memories

During the past decade, the impressive growth of the market for portable systems has been sustained by the availability of successful semiconductor non-volatile memory (NVM) technologies, the key driver being the Flash memories. In the past 15 years, the scaling trend of these charge-based memories has been straightforward. The cell density of NOR Flash, which is adopted for code storage, has doubled every one to two years, following Moore's law; the memory cell size is 10–12 F^2, where F is the technology feature size. The NAND Flash, which is optimized for sequential data storage, has been aggressively scaled and, nowadays, has a cell size of about 4.5 F^2. However, further scaling of both NOR and NAND Flash is projected to slow down, due mainly to the tunnel oxide (NOR), which cannot be further thinned down without impairing data retention, and to electrostatic interactions between adjacent cells (NAND).

Moreover, as the scaling proceeds, the number of electrons stored on the floating gate and present in the device channel decreases. As few electrons are involved, effects such as the random telegraph noise arising from trapping processes are expected to cause threshold instabilities and reading errors [1], while the requirements on retention become even more challenging. At the 32 nm node, the maximum acceptable leakage over a 10-year period will be less than 10 electrons per cell [2]. All of these difficulties, arising from the fundamental limitation of the charge storage concept, are calling for novel approaches to non-volatile storage at the nanoscale.

In recent years a number of different alternative memory concepts have been explored. Most notably, memories based on switchable resistors are considered

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

promising; among these, the phase-change memory (PCM) technology is attracting growing interest.

15.1.2 PCM Memories

PCM-based memory devices were first proposed by J.F. Dewald and S.R. Ovshinsky who, during the 1960s, reported the observation of a reversible memory switching in chalcogenide materials [3, 4]. Chalcogenides are semiconducting glasses made from the elements of Group VI of the Periodic Table, such as sulfur, selenium and tellurium, and many of these demonstrate the desired material properties for possible use in PCM applications. Two different chalcogenide material systems may be discriminated, based on their switching properties [5]:

- *Threshold-switching* in so-called "stable" glasses that show negative differential resistance and a bistable behavior, requiring a minimum "holding voltage" to sustain the high-conductive state. The typical materials are three-dimensionally cross-linked chalcogenide alloy glasses.
- *Memory-switching* in "structure reversible films" that may form crystalline conductive paths. A typical composition is $Te_{81}Ge_{15}X_4$ close to the Ge-Te binary eutectic, with X being an element from Group V or VI (e.g., Sb). The latter materials also show threshold switching to initiate the high conduction in the glass state, followed by an amorphous to crystalline phase transition which stabilizes the high-conductive state.

A non-volatile and reprogrammable phase-change (256 bit) memory array based on chalcogenide materials originally was reported by R.G. Neale, D.L. Nelson and Gordon E. Moore as far back as 1970 [6]. In these memories the memory element is basically a resistor made from a chalcogenide material and, depending on whether the chalcogenide layer is amorphous or crystalline, the device resistance would be either high (RESET state) or low (SET state) [7]. Programming of the phase state is carried out by current-induced Joule heating: either the material is heated above the melting temperature, followed by fast quenching in the amorphous state; or the element is heated to a high temperature below the melting point, allowing crystallization of the amorphous material. However, the operation characteristics of these memories were still poor (e.g., 25 V, 250 mA, 5 μs for programming in the RESET state). Indeed, such a high programming power requirement led to the suggestion that these prototype memories should be called "Read-Mostly Memory".

Chalcogenide phase-change materials were instead successfully adopted in xerography, where the photoconductive properties of arsenic-selenide (As-Se) were exploited, and in optical recording, spurred on by the development of Ge-Te glasses capable of undergoing rapid crystalline-amorphous phase transformations [8, 9]. In particular, rewriteable optical media (e.g., CDs, DVDs) became a huge field of application. In the case of CDs, the selective crystallization/amorphization is induced

by an external laser beam and not by Joule heating, while the binary information is read out by exploiting the change in optical reflectivity between the amorphous and the crystalline state, rather than the difference in electrical resistivity.

The advancements in the materials used for optical disks, coupled with significant technology scaling and a better understanding of the fundamental electrical device operation, eventually triggered the development of solid-state memory technology, which led initially to the Ovonic Unified Memory (OUM™) concept based on the use of the $Ge_2Sb_2Te_5$ chalcogenide compound [10, 11]. Since early 2000, the different semiconductor industries have considered the exploitation of the same concept for large-sized, solid-state memories [12–14]. Phase-change memories are known by different names. For example, the former OUM name was superseded by the terms PCM and phase-change RAM (PRAM). Today, PCM are considered promising candidates eventually to become the mainstream non-volatile technology, this being due to their large cycling endurance [15, 16], fast program and access times, and extended scalability [17, 18].

15.2
Basic Operation of the Phase-Change Memory Cell

15.2.1
Memory Element and Basic Switching Characteristics

The vertical OUM PCM memory element in the so-called Lance-like structure is shown schematically in Figure 15.1. The active phase-change material ($Ge_2Sb_2Te_5$; GST) is sandwiched between a top metal contact and a resistive bottom electrode (also called the heater). The programming current flows vertically from the bottom

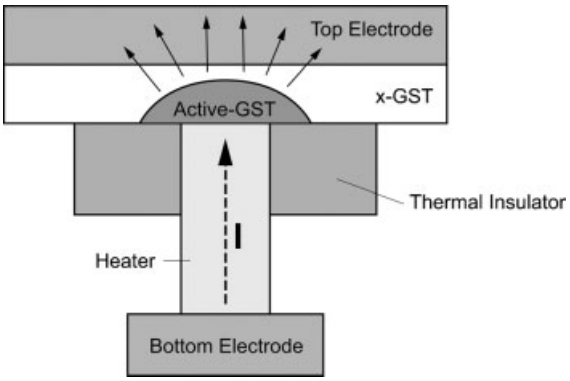

Figure 15.1 Schematic of the OUM™ vertical phase-change memory element. Due to the typical bias polarity, current flows vertically from the bottom electrode through the heater, through the $Ge_2Sb_2Te_5$ (GST) layer and to the top electrode. The current concentration near the (narrow) heater/GST contact results in local heating of the GST in a semispherical volume where the amorphous/crystalline phase change occurs. Amorphization of this region stops the low-resistive current path and results in an overall large resistance.

electrode through the heater, through the GST layer and to the top electrode. The current concentration near the (narrow) heater/GST contact results in a local heating of the GST in a semi-spherical volume where the amorphous/crystalline phase change occurs. Amorphization of this area stops the low-resistive current path and results in an overall large resistance.

The thermal and electrical switching characteristics of a vertical OUM PCM memory element are shown in Figure 15.2, with temperature evolution in the GST region above the heater contact in response to current pulses shown graphically in Figure 15.2a [12]. In order to form the amorphous phase, a 50- to 100-ns current pulse heats up the region until GST reaches its melting temperature (620 °C). The subsequent swift cooling, along the falling edge of the current pulse, freezes the undercooled molten material into a disordered, amorphous phase below the glass transition temperature. In order to recover the crystalline phase, Joule heating from another current pulse, with a lower amplitude (resulting in temperatures above the crystallization temperature but below the melting temperature), is used to speed-up the spontaneous amorphous-to-crystalline transition: the crystalline phase builds up in about 100 ns by a combination of nucleation and growth processes.

The typical current–voltage (*I*–*V*) curve of a cell for both states is shown in Figure 15.2b [19]. As the electrical resistivity of the two phases differs by orders of magnitude, at low bias, the resistance of the two memory states ranges from few kΩ (low resistance = *ON* or *SET state*) to some MΩ (high resistance = *OFF* or *RESET state*). Reading is accomplished by biasing the cell and sensing the current flowing through it; for example, a few hundreds of millivolts across the cell in the SET state generates 50–100 μA. This current is able to load the bit-line capacitances

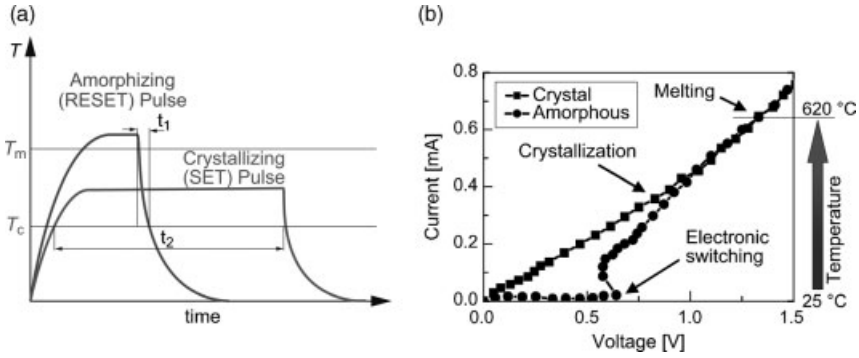

Figure 15.2 (a) Thermal-induced phase change of the material, either by melting and subsequent quenching in the amorphous phase, or by heating in the solid state inducing crystallization of the amorphous state. (Figure reproduced from Ref. [12]). (b) Current–voltage (*I*–*V*) curves for both the crystalline and amorphous states. (Figure reproduced from Ref. [19]). The high current levels required for the Joule heating can be obtained at low voltages, even for the amorphous state, on the basis of the electronic threshold switching phenomenon, which strongly increases the conductivity in the amorphous material above a certain threshold voltage.

of a memory array, making possible a reading operation in 50 ns. The same bias across the cell in the RESET state is not able to generate enough current to trigger the sensing amplifier, thus resulting in the evaluation of a "0".

It should be noted that the *I–V* curve in the high-resistance, amorphous state is quite peculiar. As the bias reaches a certain voltage (the threshold switching voltage) a "snap-back" takes place and the conductance abruptly "switches" to a high conductive state (see Figure 15.2b). The *I–V* curve of the crystalline GST does not feature threshold switching, and approaches the *I–V* of the amorphous state in the high current zone.

The occurrence of this "threshold switching" is a very important characteristic of PCM material. Indeed, without such a switching mechanism, which allows large currents to flow in the amorphous material at low voltages (~few volts), very high voltages (~100 V) would be required to switch the material to the "on" state, thus making electronic programming effectively non-practical.

The ratio of the threshold switching voltage and the thickness of the amorphous zone is usually referred to as the *critical threshold switching field*; for GST this quantity ranges between 30 and 40 V μm^{-1}. The critical threshold switching field can be taken as a guideline to compare different materials; for example, the lower the switching field the lower the switching voltage for the same thickness of the amorphous layer. However, as shown in Figure 15.3, even if the threshold voltage does scale with the memory resistance, which in turn depends on the amorphous layer thickness, the line does not cross the origin [20]. The concept of threshold switching field should, therefore, be handled with some care.

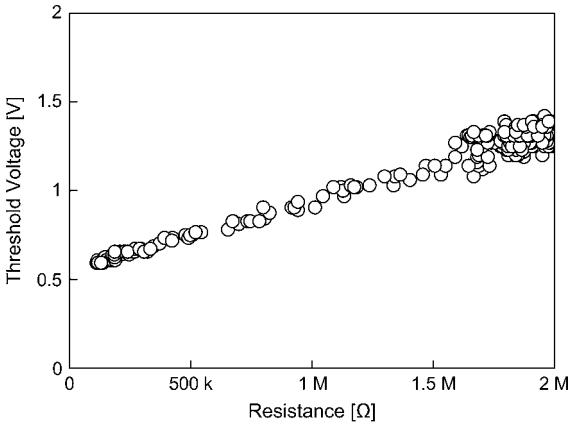

Figure 15.3 Experimental dependence of the threshold voltage on the low field resistance of the amorphous state. The threshold voltage scales with the device resistance, and therefore with the width of the amorphous zone. However, the line does not cross the origin, which highlights that a minimum voltage value of ~0.50 V, close to the holding voltage value, is required for switching to occur. (Figure adapted from Ref. [20]).

15.2.2
SET and RESET Programming Characteristics

The programming characteristic of a PCM cell [20] – that is, the dependence of the cell resistance R as a function of the programming current – is shown in Figure 15.4. The open symbols in Figure 15.4 refer to the resistance obtained when driving a cell from the RESET state. During the measurement procedure, a 100-ns programming pulse is applied and the cell resistance after programming is read at 0.2 V. Before the subsequent measurement, the cell is brought again into the initial reference RESET state by using a proper current pulse. The measurement cycle is then restarted, driving the cell with a new 100-ns programming current pulse with a different amplitude.

During this procedure, three distinct regions can be recognized:

- For programming pulses below 100 μA, the ON-state conduction is not activated and the very small current does not provide any phase change.
- In the 100 to 450 μA range, the resistance decreases following the crystallization of the amorphous GST, reaching the minimum resistance in the SET state, as denoted by R_{set}.
- Above 450 μA, the programming pulse melts some GST close to the interface with the bottom electrode, leaving it in the amorphous phase.

The solid symbols in Figure 15.4 also show the R–I characteristics obtained for the same cell, but starting from the SET state. The resistance value changes only when the current exceeds 450 μA and the chalcogenide begins to melt. The current is therefore denoted as the *melting current*, I_{melt}. From thereon the curve overlaps to the R–I of the RESET state. For programming pulses above 700 μA, the resistance of the cell reaches an almost constant value. It transpires that the PCM cell can be switched between the two SET and RESET states using current pulses of 400 and 700 μA, respectively, these pulses

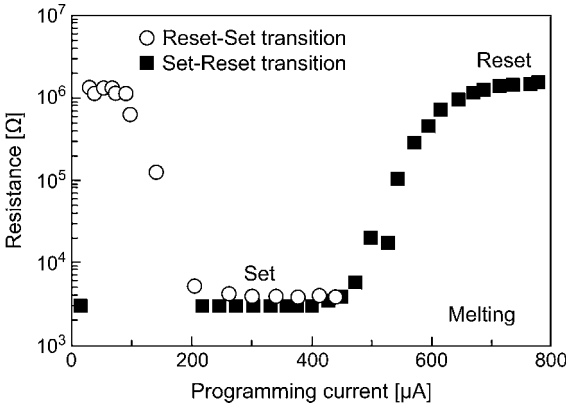

Figure 15.4 PCM programming characteristics, i.e., R as a function of the programming current I_P. Program pulses are applied to RESET cell (reset-set transition) or to a SET cell (set-reset transition). (Figure reproduced from Ref. [20]).

being independent of the initial cell state (resistance). Therefore, the cell can be rewritten with no need for any intermediate erase. The minimum current capable of bringing the cell into the full RESET state (700 μA in Figure 15.4) is denoted as reset current, I_{reset}.

The orders of magnitude difference between the cell resistance in the SET and RESET states makes the PCM memory ideally suitable for a multibit operation. In this scheme, the resistance of the cell may be set between the two extreme values, thus placing more than two levels per cell. This approach may become a viable option to further reduce the cost per bit of PCM devices.

15.3
Phase-Change Memory Materials

15.3.1
The Chalcogenide Phase-Change Materials: General Characteristics

The requirements for phase-change materials include easy glass formation during quenching from the melt, as well as congruent crystallizing compositions to avoid phase segregation during crystallization. Melting temperatures should be low to limit the switching power, whereas for non-volatility a good stability of the amorphous phase at application temperatures is required. It follows that the activation energy[1)] for crystallization of the amorphous state should be high enough to enable long data retention times. On the other hand, crystallization rates, at least at elevated temperatures, should be high enough to allow for a rapid amorphous to crystal transition, preferably in the range of a few tens of nanoseconds.[2)]

Such materials have now been under investigation for many years for their applications in DVD-RAM and DVD-R/W optical disk storage systems. Typically, metal alloys containing chalcogenide elements [by definition, elements of Group VI of the Periodic Table (O, S, Se, Te, Po)], and often referred to as "chalcogenide materials", are used. Chalcogenide elements are of interest as Se and Te compounds are easy glass-formers, because of their relatively high melt viscosities [22]. Compositions searched for are those that form a stable state in the solid phase ("polymorphic transformations"; i.e., where long-range diffusion is not required) [23].

The two typical chalcogenide material "families" used in PCM are both based on compositions of Ge, Sb and Te: (i) the pseudo-binary GeTe-Sb_2Te_3 compositions; and (ii) compositions based on the $Sb_{70}Te_{30}$ "eutectic" compound (see the Ge-Sb-Te ternary phase diagram in Figure 15.5) [24, 25].

1) The so-called "crystallization temperature" is not a uniquely defined material property, and varies depending on the time window of observation. "Activation energy" is therefore a better defined and more relevant physical parameter.

2) Recent discussions have indicated that the requirement of a rapid crystallization actually contradicts with easy glass formation, and rapid-crystallizing chalcogenides should be categorized rather as bad glass-formers based on their low glass transition to melt temperature (T_G/T_m) ratio compared to other easy glass formers such as SiO_2 [21].

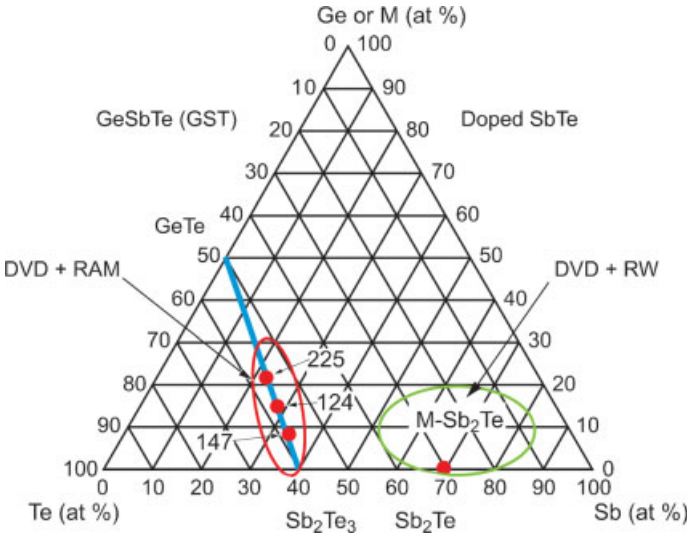

Figure 15.5 The Ge-Sb-Te (GST) ternary phase diagram, indicating the two classes of commonly used phase-change recording materials – that is, stoichiometric compositions along the GeTe-Sb_2Te_3 tie-line and compositions near the "eutectic" Sb_2Te. (Figure modified from Refs. [24, 25]).

15.3.1.1 The Pseudo-Binary GeTe-Sb_2Te_3 Compositions

The stoichiometric compositions around the GeTe and Sb_2Te_3 tie line are known as pseudo-binary compositions. These include the most widely used material $Ge_2Sb_2Te_5$, and they are used in the ovonic unified memory (OUM) [11], together with other compositions such as $Ge_1Sb_2Te_4$ [(1,2,4) material] and $Ge_1Sb_4Te_7$ [(1,4,7) material]. All of these materials are nucleation-controlled; that is, nucleation is dominant over growth [25], and are widely used in DVD-RAM applications. Along the tie line, the properties change from GeTe with high crystallization temperature (i.e., high stability) but slow crystallization speed, to Sb_2Te_3 that has a high crystallization speed but a low stability [26].

15.3.1.2 Compositions Based on the $Sb_{70}Te_{30}$ "Eutectic" Compound[3)]

These compositions are more generally indicated as doped SbTe (M-SbTe) compounds. Variants include doping with In: $In_x(Sb_{70}Te_{30})_{1-x}$, doping with Ag and In: $Ag_xIn_y(Sb_{70}Te_{30})_{1-x-y}$ (so-called "AIST"), and doping with Ge: $Ge_x(Sb_{70}Te_{30})_{1-x}$ + Sb. These materials are so-called fast-growth materials [28]: the growth starting from the crystal regions surrounding the amorphous zone is the dominant crystallization mechanism rather than nucleation of new crystals inside the amorphous. The benefits of these materials are possibly faster switching (<20 ns), a better

3 It should be noted that the $Sb_{70}Te_{30}$ "eutectic" material composition (sometimes quoted as Sb_2Te, or more exactly as $Sb_{69}Te_{31}$) is actually *not* an eutectic but an azeotropic minimum [27]; that is, it fulfills the basic requirement of a congruent crystallizing material.

high-temperature retention, and a lower threshold field for conductivity switching in the amorphous phase (10–20 V μm^{-1} instead of 30–40 V μm^{-1}). On the other hand, cycle endurance and resistance ratio would be smaller [24].

15.3.1.3 Other Material Compositions

Some other material compositions, based on selenium rather than tellurium compounds, have more recently been investigated for possible application in phase-change memories, including antimony selenide (Sb_xSe_{1-x}; main attributes, lower T_m and faster crystallization speed) [29], and indium selenide (In_2Se_3; main advantage wider resistivity range) [30].

15.3.1.4 N- or O-Doped GST

Both, nitrogen and oxygen doping of GST have been used mainly to control the resistivity of the material.

N-doping has been used successfully used to increase the crystalline GST-resistivity (from 2 to 200 mΩ·cm for N concentration from 0 to 7 atom%), and furthermore results in a smaller grain size and an increased crystallization temperature (+50 °C) [31].

O-doping of GST is reported to increase the resistance ratio (from 100 to 1000), and to improve the high-temperature retention with an increase of the activation energy from 3.6 eV to 4.4 eV [32].

15.3.2 Material Structure

15.3.2.1 Long-Range Order: Crystalline State in GST and Doped Sb-Te

GST is characterized by two different crystal structures in the crystalline state – that is, a lower temperature (higher resistivity) fcc cubic state, and a higher temperature (lower resistivity) hexagonal state (see Figure 15.6) [24]. It should be noted at this point that the temperatures at which the crystallization and phase transitions occur are not fixed but rather depend on the heating rate. In a fast phase-change operation the amorphous GST probably crystallizes in the metastable fcc phase. The existence of the two different states may however influence the long-term, low-temperature stability and eventual resistance in the SET state. However, it has been reported that, for nano-sized structures, the temperature of the fcc to hexagonal phase moves up (from ~360 °C to >450 °C for 65-nm patterns). The possible inhibition of the hexagonal state formation, together with the higher resistivity of the cubic state, may be a beneficial side effect of the scaling [34]. On the other hand, doped Sb-Te shows only one, low-resistive, hexagonal state.

15.3.2.2 Short-Range Order in Crystalline versus Amorphous State

Recent investigations have clarified the situation regarding the crystal-amorphous phase transition in these chalcogenide materials.

It has been noted [9, 35, 36] that, in contrast to the covalent semiconductors, in which amorphization does not changes the local ordering, in chalcogenide materials

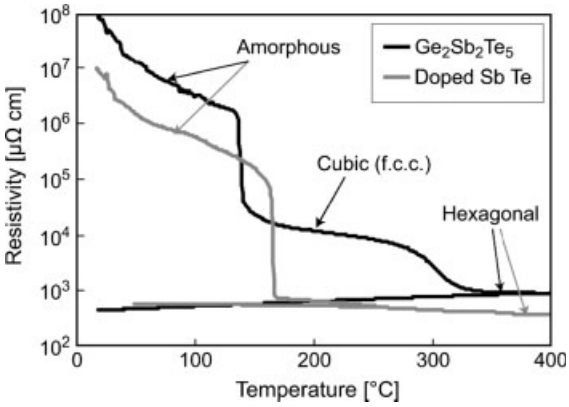

Figure 15.6 Resistive traces measured during temperature ramp of as-deposited amorphous GST and doped SbTe films, evidencing the occurrence of two different crystal states for GST but only one state for doped-SbTe. (Figure reproduced from Ref. [24]).

the amorphization induces a substantial increase in the local ordering and an important change in the resultant physical properties, such as an increased energy gap. This order–disordered transition is mainly due to a flip of the Ge atoms from an octahedral position into a tetrahedral position without rupture of strong covalent bonds (see Figure 15.7) [35]). Therefore, this class of materials is characterized by two competing structures with similar energy but different local order and different physical properties.

It is assumed that the nature of such a transformation ensures not only the large changes of physical properties (e.g., reflectivity and conductivity), but also the rapid performance and repeatable switching over millions of cycles.

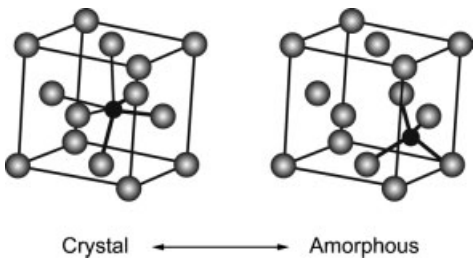

Figure 15.7 Fragments of the local structure of GST around Ge atoms in the crystallized (left) and amorphous (right) states. Upon heating the sample by a short intense pulse (above the melting point, T_m) and subsequent quenching, the Ge atoms flip from the octahedral to tetrahedral-symmetry position. Note that the stronger covalent bonds remain intact upon the umbrella-flip structural transition rendering the Ge lattice random. Exposure to light that heats the sample above the glass-transition temperature (T_g) – but below T_m – reverses the structure. (Figure reproduced from Ref. [35]).

15.3.3
Specific Properties Relevant to PCM

The majority of PCM materials investigated to date were developed for (re)writable optical discs, and existing knowledge of them, as well as experience of their reliability in products, should allow their rapid introduction into CMOS integration technology. However, their use in PC-RAM application may include various pitfalls:

- There exist certain *important operational differences* between DVD and PCM applications, that require the tuning/optimization of a number of specific material parameters for PCM that are not important for optical applications (e.g., resistivity in the on and off state, rather than reflectivity changes) (see Table 15.1). In addition, the amorphous phase should possess the particular property of threshold switching. The main material parameters for PCM applications are listed in Table 15.1.
- More importantly, however, the operating differences may have a major influence in the operation stability and repeatability. Indeed, in DVD applications, programming is achieved by laser pulse power coupling, and reading by reflectivity change. Data programming and storage relies on average material properties, such as reflectivity and absorption, that are not very sensitive to local variations. For example, they may be caused by small crystalline particles embedded in the amorphous region or vice versa, due to incomplete/inhomogeneous nucleation or amorphization. On the other hand, PCM relies on programming by Joule heating; that is, by current conduction through the device. Furthermore, the SET operation requires threshold current switching in the amorphous phase, which is a filamentary process. Also, the reading is based on a resistance (i.e., current) measurement. As the current conduction is greatly affected by the existence of local inhomogeneities, programming and reading may become highly sensitive to non-uniform/incomplete crystallization or amorphization. For example, low-resistive current paths in the incomplete amorphized state, or amorphous

Table 15.1 The major important material parameters for PCM, optimization direction, and value for GST material.

Symbol	Parameter	Optimization	GST 225 value	Reference(s)
T_m	Melting temperature	Minimal (low RESET power)	621 °C	[37]
T_c	Crystallization Temperature	Maximal (good retention)	155 °C	[37]
E_a	Activation energy	Maximal (good retention)	2.6–2.9 eV	[15, 38]
ρ_c	Resistivity crystalline state	"High" for low program current – "low" for fast read	$\sim$350 Ω μm	[18]
ρ_α	Resistivity amorphous state	High for good Resistance Ratio	$\sim$0.3 MΩ μm	[18]
E_c	Critical threshold switching field	Low for low SET program voltage	30–40 V–μm^{-1}	[24]

current-blocking regions in the incomplete crystallized state, may jeopardize proper programming or reading. In particular, the filamentary process of current switching during the SET state may induce strong inhomogeneous heating due to uncontrolled location of the filament that may results in only partial crystallization [20].

15.4
Physics and Modeling of PCM

From the basic device operation described in Section 15.2 it transpires that material-phase transitions (amorphization and crystallization dynamics) and conductance (threshold) switching mechanisms in the amorphous phase are the key processes involved in PCM. The physics of these mechanisms are outlined in greater detail below. The results of modeling studies implementing detailed microscopic descriptions of these effects have contributed greatly to an understanding of the subject, and have also supported the basis of design optimization of these devices.

15.4.1
Amorphization and Crystallization Processes

The different phase transitions of the PCM material during programming are illustrated graphically in Figure 15.8 [39]. Here, the crystalline material serves as an ideal starting point. During the programming transition from a SET to a RESET (high-resistance) state, the material is heated, begins to melt at solidus temperature,

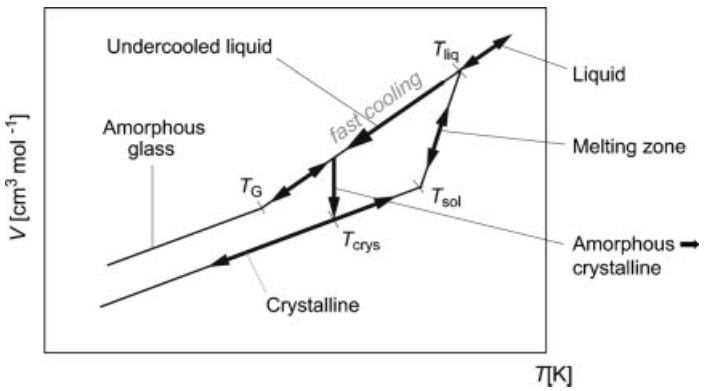

Figure 15.8 Schematic of molar volume (corresponding to 1/density) changes of phase-change material with temperature, showing the different possible phase transitions and critical temperatures. When heating a crystalline phase, melting will start at the solidus temperature T_{sol}, and will be complete at the liquidus temperature T_{liq}. Slow cooling will crystallize the material again following the same transition line; however, fast cooling results in an undercooling liquid that will be quenched in an amorphous glass below the glass transition temperature T_G. Heating the amorphous phase above T_G will result in crystallization at the crystallization temperature T_{crys}.

T_{sol}, and is completely molten at the melting temperature, T_m. When the cooling rate is higher than 10^9 K s^{-1} [40], the material does not begin to solidify at T_m, but remains an undercooled liquid. Below the glass transition temperature, T_G, the material freezes into the amorphous state.

The reverse situation is that, during the RESET to SET transition, the current pulse heats the material above T_G but below T_m, where it will begin to crystallize. There is no uniquely defined crystallization temperature, and even at relatively low temperatures (100–200 °C) crystallization may occur over long time scales (perhaps up to years). (These processes govern the basic long-term temperature retention of the RESET state, and will be discussed in Section 15.6.) For the SET programming, high-temperature rapid (<100 ns) crystallization processes are required, an understanding of which is based mainly on the general physical models for nucleation and growth. Different models have been proposed, for example by Peng *et al.* [41] and by Kelton [42], by which the temperature-dependent nucleation and growth rate can be calculated. Calculations based on these models using the different material properties of, for example GST and AIST, indeed confirm the nucleation, respectively growth-dominated crystallization mechanisms, that have been observed experimentally in these materials [43].

15.4.2
Band-Structure and Transport Model

The development of a comprehensive and quantitative framework to support the design and optimization of these devices is a challenging task. Today, PCM physics is extremely well developed, and a model should be capable of coupling a description of carrier transport in both crystalline and amorphous phases, together with the heat equation and phase-transition dynamics. The starting point here is to describe the electrical properties, thus aiming to reproduce correctly the electronic switching effect in the amorphous chalcogenide alloy.

Recently, it has been shown that the adoption of a semiconductor-like picture for both the amorphous and crystalline phases is quite effective, and may successfully account for the experimental *I*–*V* curves [33]. Moreover, this also allows the handling of simulations within the frame of codes already widely adopted by the semiconductor industries. Optical absorption data have shown that both crystalline and amorphous GST have gaps of 0.7 and 0.5 eV, respectively [33]. Moreover, there is no doubt that the carrier dynamics in the crystalline GST can be treated according to Bloch's theorem, as in a crystalline semiconductor. In contrast, investigations on amorphous compounds have demonstrated the existence of states with variable transport properties [44]. During the 1960s, it became common practice to describe these materials as shown in Figure 15.9 (left), where "mobility edges" separate fully conductive bands from the low mobility states. This picture can be easily translated in terms of a semiconductor-like framework. By assuming that low-mobility localized states behave like trapping centers, and that more conductive levels resemble delocalized states, a band structure can be defined and the amorphous GST modeled as a "very defective" crystalline semiconductor [33] (Figure 15.9, right). The material

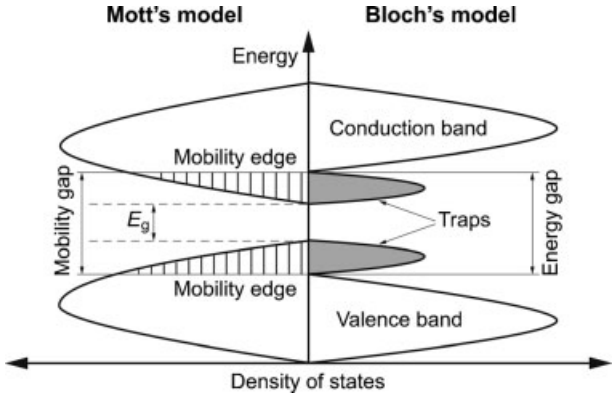

Figure 15.9 Comparison between the classical Mott and Davis's picture for the amorphous band diagram, and the scheme recently proposed by Pirovano *et al.* [33]. (Figure from Ref. [19]).

parameters, such as energy gap, trap densities and density of states for both phases, adopted in the numerical simulations, are listed in Table 15.2. It should be noted that the crystalline GST is p-type, due to a large density of vacancies (10% of the lattice sites), while the amorphous GST is characterized by a large density of donor/acceptor-like defects: the so-called Valence Alternation Pairs. This semiconductor-like picture is able to account for the peculiar conduction of the amorphous state and for the threshold switching [19].

The physics involved in the threshold switching remains a subject of debate. Since Ovshinsky first reported threshold switching [4], different models have been proposed, with many groups supporting the idea that switching is essentially a thermal effect and that the current in an amorphous layer rises above due to the creation of a hot filament [45, 46]. Later, Adler showed that the effect is not thermal (at least in thin chalcogenide films), in agreement with Ovshinsky's original picture. In their pioneering studies [47, 48], Adler and colleagues showed that a semiconductor resistor may feature switching, without any thermal effect. The condition for the threshold snap-back to occur is the presence of a carrier generation depending on

Table 15.2 Electronic parameters for both crystal and amorphous phases. (From Ref. [33]).

Property	GST crystalline	GST amorphous
E_{gap} [eV]	0.5	0.7
N_C [cm^{-3}]	2.5×10^{19}	2.5×10^{19}
N_V [cm^{-3}]	2.5×10^{19}	10^{20}
Vacancies [cm^{-3}]	5×10^{20}	—
C_3^+ [cm^{-3}]	—	10^{17}–10^{20}
C_1^- [cm^{-3}]	—	10^{17}–10^{20}
μ_n-μ_p [$cm^2 V^{-1} s^{-1}$]	0.1–23.5	5–200
F_C [$V cm^{-1}$]	3×10^5	3×10^5

field and carrier concentration (e.g., impact ionization) competing with a Shockley–Hall–Read (SHR) recombination via localized states.

The numerical model reported in Ref. [33] implements Adler's picture accounting for avalanche impact ionization in the amorphous and SHR recombination via the localized defects.

The schematic dependence of the band structure along a cross-section of a PCM device is shown in Figure 15.10, where the wide-gap region corresponds to the amorphous GST. At low bias, the quasi Fermi levels in the amorphous GST are close to their equilibrium position. As both the carrier density and their mobility is low (the average hole mobility is about $0.15\ cm^2\ V^{-1}\ s^{-1}$ [33]), the conduction regime is ohmic. By increasing the voltage, the applied field approaches the avalanche critical field of 3×10^5 [10], significantly increasing the carrier generation. The quasi Fermi levels thus split and move close to the band-edges (Figure 15.10, lower diagram). Carrier recombination mainly takes place in the region, close to the anode, where the electron Fermi level approaches the conduction band. At large bias, all defects available for recombination are full, and recombination may no longer be able to balance the exponentially rising generation rate. The system reacts by reducing the voltage drop in order to maintain the balance between recombination and generation, leading to the electronic switching. Hence, the snap-back takes place and, after switching, the GST is still amorphous but highly conductive. Generation is sustained by the large density of free carriers. According to this picture, the minimum voltage required for the switching to occur is of the order of the split between quasi Fermi levels (i.e., the

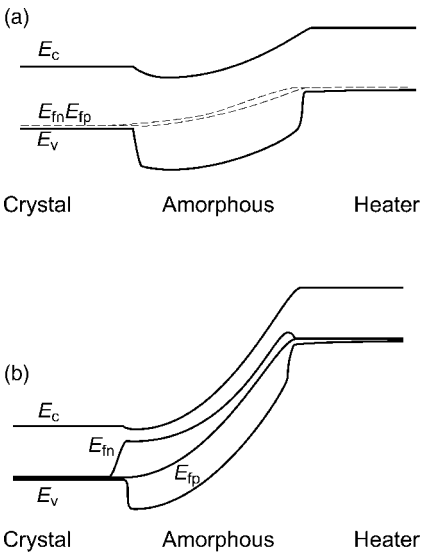

Figure 15.10 Band diagrams along the cross-section of a PCM cell in the RESET state (according to Ref. [33]). (a) At low bias, quasi-Fermi levels are close to the equilibrium value. (b) Close to threshold switching; generation by impact ionization is properly balanced by recombination though trap levels. When recombination saturates, generation finds a new stable working point reducing the voltage across the device. (Figure from Ref. [19]).

energy gap). This argument may justify why both, the holding voltage, V_H, and the asymptotic value at low R in Figure 15.2b, approaches approximately 0.5 V.

Although this picture so far has been successful in accounting for the experimental findings, it should be accepted with a degree of caution, and further investigations are needed to better assess the material properties. The quantitative description of impact ionization in these materials, as well as the role of the interfaces or of Poole–Frenkel mechanisms, deserve further investigation as many of the details still lack direct experimental verification. However, recent industrial interest in PCMs may lead to new experimental efforts and to the fabrication of devices purposely designed to test the validity of these key assumptions.

15.4.3
Modeling of the SET and RESET Switching Phenomena

The above conduction model was then coupled to heat equation and to phase-transition dynamics (nucleation and growth). When implemented in a three-dimensional (3-D) semiconductor device solver, it highlighted substantial differences in the two phase transitions [20]. The temperature maps during the SET–RESET transition, and the resulting phase distributions obtained with increasing current pulses with a plateau of 150 ns, are illustrated in Figure 15.11 [20]. In this figure, all of the pictures refer to a Lance PCM device in which a cylindrical metallic heater is in contact with the GST layer. The current flows almost uniformly across the polycrystalline GST, thus resulting in a roughly hemispherical shape of the final a-GST volume. As the programming current increases above melting, the volume left in the amorphous state increases.

On the other hand, Figure 15.12 [20] shows the calculated final phase distribution for a RESET to SET transition with programming current of 130 μA (a) and 160 μA (b) , respectively. Figure 15.12a shows that the current first sparks by electronic threshold

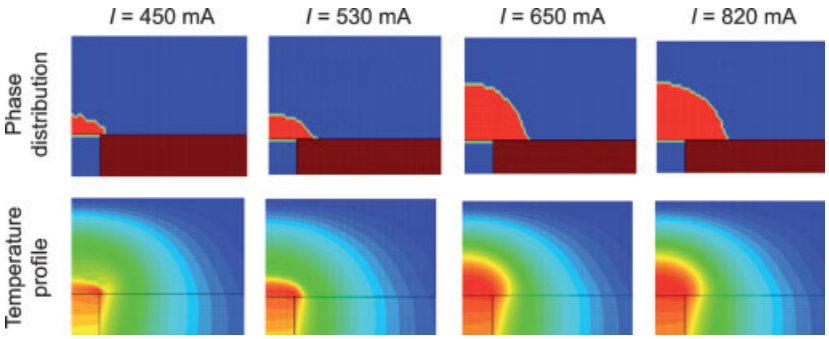

Figure 15.11 Homogeneous heating of the crystalline GTS region (blue) during SET to RESET transition (bottom row), resulting in homogeneous amorphous regions (red) at the end of a programming pulse (top row). Figures from left to right correspond to increasing the peak current value. A larger amorphous region will correspond to a higher resistance level. (Figure from Ref. [20]).

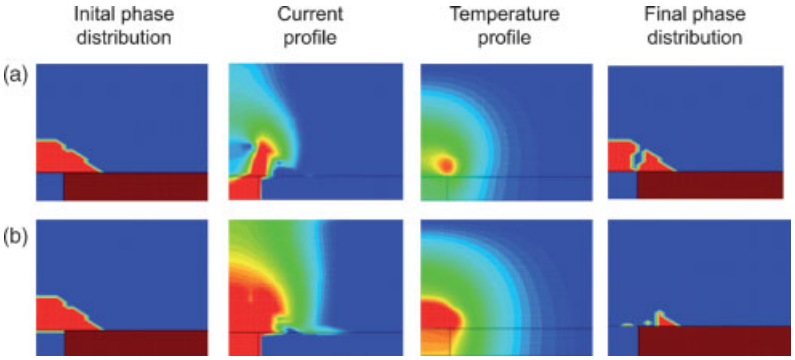

Figure 15.12 Programming operation from amorphous to crystal state (only half of the cell is shown because of cylinder-symmetry). (a) Top row: $I = 130\,\mu A$: electronic switching will occur first in the regions where the amorphous thickness is minimum. After the switching event, current spikes will increase the temperature only locally, and crystallization may only be induced in these hot zones resulting in a non-uniform final phase distribution with a major part of the amorphous zone remaining. (b) Bottom row: $I = 160\,\mu A$: only at higher voltages, eventually the hot filament extends in the whole the active area, leading to an homogenization of temperature and of the transformed volume. (Figure from Ref. [20]).

switching in the weakest a-GST region, locally triggering Joule heating and consequent crystallization processes. In case (a), the pulse amplitude/time is not sufficient to provide a complete crystalline path, and thus the active region features a residual a-GST layer causing the large measured R. In case (b), a further increase in the applied voltage eventually extends the hot filament in the whole of the active area. The initial amorphous volume has been almost completely crystallized by the programming pulse, resulting in a sufficiently low resistance. It should be noted that the localized phase transition is directly related to the details of the electronic switching mechanism, and thus can be reproduced only by a self-consistent model describing both electrothermal and phase-change dynamics.

Figures 15.11 and 15.12 also suggest that, by changing the programming pulse, the value of the cell resistance can be reliably placed in between the largest and the minimum SET value, thus opening the way to a multi-level operation. For example, four levels – each with different resistance values – might be programmed per cell, thus reducing the cost per bit.

15.4.4
Transient Behavior

V_{TH} and R are two key parameters of the memory cell. Figure 15.13 illustrates the time dependence of these parameters as measured soon after the current pulse programming the cell in the *RESET* state [19, 49]. The first fast component of the transient is referred to as *recovery*. On the longer time scale, in the so-called drift regime, the V_{TH} and R transients follow a slower power law. The recovery sets the minimum time needed after programming before reading (if the cell is read soon after being programmed in the *RESET* state, the read value might erroneously be "1").

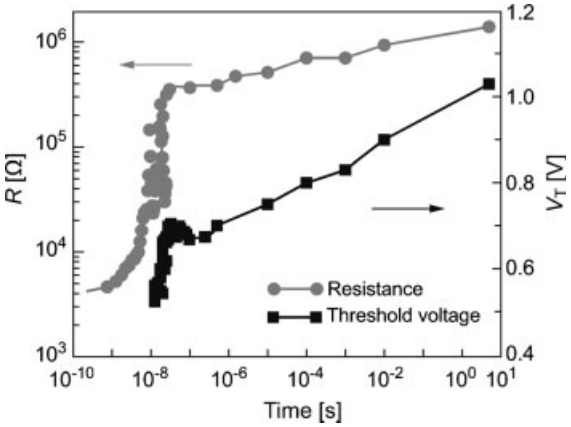

Figure 15.13 Low field resistance and threshold voltage for the amorphous phase as a function of time after reset programming operation. In about 50 ns, both low field resistance and threshold voltage are recovered, after which they continue to increase due to the drift phenomenon. (Figure from Ref. [19]).

Drift is instead a limit for multi-level operation, as the resistance of an intermediate level during ten years (3×10^8 s) might cause the bit to be erroneously decoded.

Different models have been proposed to justify these effects. Recovery is likely due to charge transients. After quenching, the newly formed amorphous region is full of trapped carriers, and some nanoseconds are required for these carriers to be released by trapping states and for the Fermi levels to recover the equilibrium value (see Figure 15.10a). During this transient stage, V_{TH} and R change from the *set* to the corresponding *RESET* values. Drift physics is more controversial, however, it having been suggested that drift might be due to mechanical stress release following the crystalline-to-amorphous phase transition. The resulting band-gap widening may reduce the mobile carrier density, thus contributing to the charge conduction. Another possible explanation links the effect to changes of the electronic states [50]. Variation of the density of states close to the band-edge already observed in other chalcogenide compounds [51] as the amorphous evolves towards to a more regular microscopic structure. In order for multi-level storage to be implemented in PCM memories, this effect should be fully understood and minimized.

15.5 PCM Integration and Cell Structures

15.5.1 PCM Cell Components

PCM elements may be organized in a memory matrix with or without adding a selection device to each phase-change element. Indeed, a raw cross-point matrix may

be conceived [52], but this would suffer read errors due to leakage through neighboring "on" elements. Moreover, as important program disturbs may occur in half-select regimes, each PCM memory cell should contain both the phase-change element and a selection device. The choice and dimensions of the selection element is determined by cell size constraints and the RESET program current. A MOSFET transistor is the most evident choice for memory integration in CMOS technology (Figure 15.14) [53]). The need for Source and Drain contacts, such a "one transistor-one resistor" (1T1R) cell would require a minimum area of 8–10 F^2 (where F is the minimum feature size of the technology). However, MOSFETs have limited current drivability, so that minimum size transistors cannot be used, and cell sizes are much larger, up to $\sim$40 F^2 in 0.18 μm technology with 0.6 mA reset current [13].

An alternative is the use of a bipolar p-n-p select device. In that case, there are still two (Base and Emittor) contacts per cell, while the Collector is a collective substate contact. As the bipolar current drivability is much higher, the overall cell size is smaller (only $\sim$10 F^2 in 0.18 μm technology with 0.6 mA reset current [13]). The trade-off is of course a more complex integration scheme for fabricating these bipolar devices in a CMOS technology, restricting this solution for stand-alone memory applications only.

In order to obtain the smallest cell area, a diode selector may be used [17], as a diode would only need one contact and can handle large currents (a self-rectifying device would be the most ideal case, so that a raw cross-array could have the same functionality with minimum cell size). However, in the diode selection regime, both bitlines and wordlines have to carry relatively high currents, leading to a partitioning of the memory as well as to larger X-decoders. Moreover, isolation is also less perfect and parasitic resistances in the full signal path are important. Both, series resistances and leakage currents, contribute to read error, while diode integration may also result in the formation of a parasitic bipolar transistor.

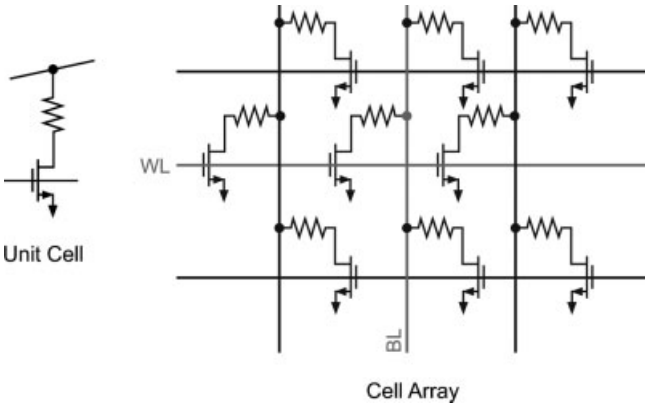

Figure 15.14 Schematic of 1T1R cell structure and memory array matrix. (Adapted from Ref. [53]).

15.5.2
Integration Aspects

Besides formation of the selection transistor, PCM fabrication requires the integration of a phase-change element in a CMOS technology. The memory element may be fabricated after the transistor processing (the so-called front-end-of-line processing; FEOL), and either before (e.g., in-between Si contacts and first metal interconnect layer) or after the first steps of the interconnect (e.g., on top of Metal 0 or Metal 1 interconnect levels). This latter scheme is the back-end-of-line or BEOL processing. A schematic state-of-the-art process flow is shown in Figure 15.15 [54, 55].

The PCM material is typically deposited by sputtering (physical vapor deposition; PVD) from a multi-element target with the desired composition. The as-deposited phase is either amorphous (for room- or low-temperature deposition), or crystalline if deposited above the crystallization temperature. In either case, due to the temperature budget of the following BEOL processing (up to 400–500 °C), the material will be fully crystallized after the integration. In a number of cell concepts, the conformal deposition of the PCM material and/or the ability to fill small pores is important [14], and these requirements would ideally call for a conformal deposition technique such as metalorganic chemical vapor deposition (MOCVD), rather than PVD. Critical elements for the integration are a good adhesion of the PCM material on the underlying substrate structure (typically a patterned metal electrode in a SiO_2 matrix), the material out-diffusion/inter-reaction/oxidation during high-temperature steps [56], and dry-etch patterning of the PCM [57, 58].

Furthermore, suitable electrode materials are needed for both the "heater" contact (where the metal will be in contact with the hot/molten PCM) and the (cold) top electrode. Material stability, low contact resistance, and good adhesion are important parameters. Poor electrode contact properties indeed have been identified as being responsible, for example, for "first fire effects" (see Section 15.6). Typical electrode materials are standard conductive barrier materials available in Si processing such as

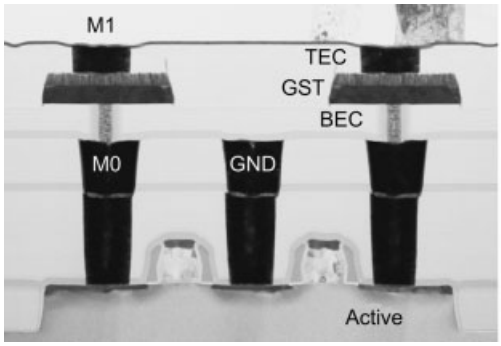

Figure 15.15 Cross-sectional scanning electron microscopy image showing the cell integration scheme (from Ref. [54]), and schematic process flow for PCM cell formation (from Ref. [55]). In this case, the PCM cell is integrated between the M0 and M1 interconnect levels.

TiN (e.g., Ref. [31]), although W is also often used [59]. The top electrode typically defines the PCM area and can be used as (part of) a hard mask during the PCM patterning.

Stability and controllability of the different process steps of the integration technology are crucial for the preparation of large-density memory arrays. The most important array characterization technique is therefore the distribution of the ON and OFF program state resistances. Tight distributions are needed to maximize the sensing window and to avoid bit errors. By process optimization, excellent distributions have been obtained on 256 Mb PCM after full integration [60].

15.5.3
PCM Cell Optimization

In the basic OUM PCM cell, the PCM and top electrode are planar layers deposited on a plug-type, bottom heater contact. That part of PCM material effectively involved in the phase switching is basically a hemispherical volume on top of the heater. To reduce the heating power (or program current), it is important to try to confine the dissipated heat as much as possible. While many different cell structures have been proposed in literature (see Figure 15.16), the optimization of heat confinement is in fact based on two simple principles: (i) by concentrating the volume where effective Joule heating takes place; and/or (ii) by improving the thermal resistance to reduce the heat loss to the surroundings.

15.5.3.1 **Concentrating the Volume of Joule Heating**

The Joule heating volume can be confined by pushing the current through a small cross-section with high current density. One obvious way to do this is to reduce the contact area of the heater contact with the PCM material, for example by minimizing the heater plug diameter (as in the small "sub-litho" contact heater cell [31]), by using only a conductive liner as heater (as in the edge-contact cell [61]), or by filling the plug with isolating dielectric material (as in the μ-trench cell [13, 62] and ring-contact heater cell [63]). The main advantage of using only the conductive liner is that at least one dimension of the heater area is controlled by the liner thickness, and not by the lithography.

Another way of confining the Joule heating volume is by structuring the PCM material to a narrow cross-section (see bottle-neck cell [64], line heater cell [24], self-heating pillar cell [65]). Finally, further improvement can be made by increasing the resistivity of the PCM material, for example by N or O doping [31, 32, 53]. In a different approach, a highly resistive TiON layer is made between the TiN electrode and the PCM material, in which layer the Joule heating will be concentrated resulting in lower program power [66]. However, such an approach may negatively influence the contact resistance to the PCM.

15.5.3.2 **Improving the Thermal Resistance**

In the so-called confined cell structure [14], the PCM is deposed in a pore etched back in the heater. This not only concentrates the Joule heating region but also surrounds a

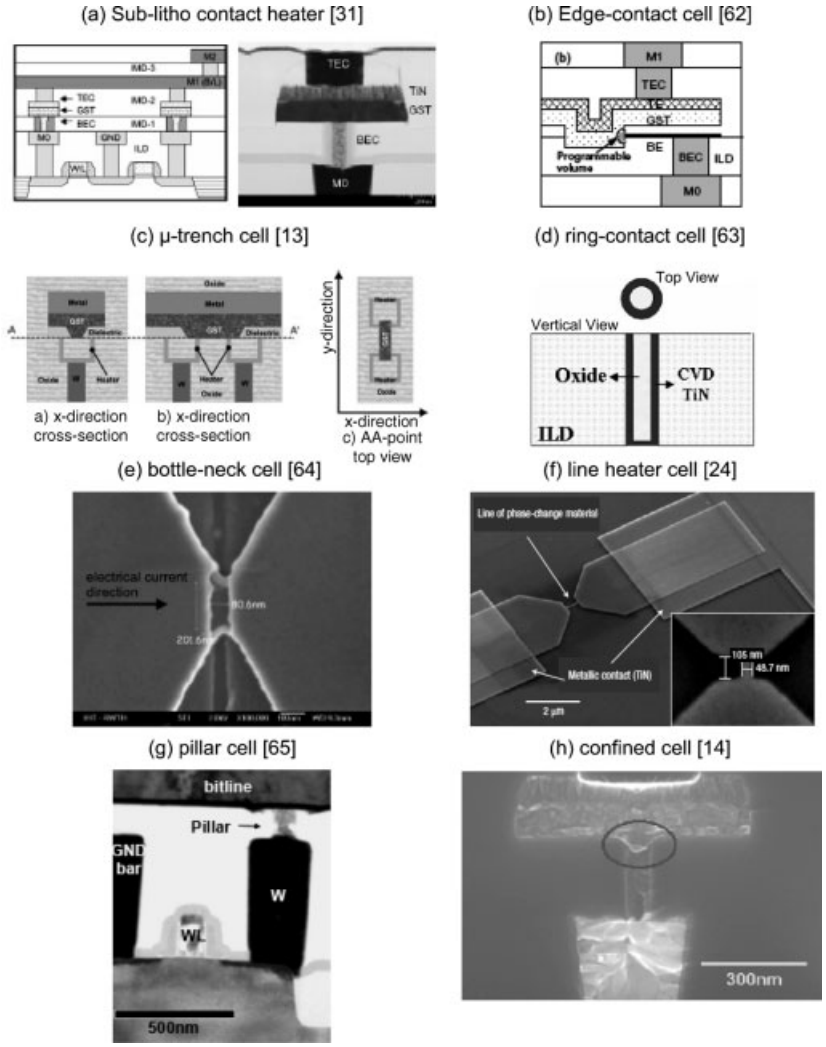

Figure 15.16 Different PCM cell structures for reducing the program power.

large part of this volume by a dielectric layer with reduced thermal conductivity. The drawback here is the topography which, ideally, would require a conformal deposition of the PCM. The alternative is to structure the PCM material, rather than the heater, leading to a plug or pillar. This approach is based on the same principle [18].

Another way to improve the thermal resistance is by increasing the PCM thickness (as this limits the heat flow to the top electrode heat sink) [14]. However, this option should be traded-off with the threshold voltage required for electronic switching during SET programming. One of the benefits of the horizontal line cell [24] is also the setting apart of the heated zone from a metal heater contact and a capping with thermal insulating dielectric.

Apart form changing only the cell structure, it is clear also that the correct material selection (use of different dielectric materials, and especially the use of porous dielectric materials) can improve the thermal heat confinement [53]. It should be noted, however, that the improved thermal isolation should not avoid the rapid quenching from the melt during RESET, otherwise the device cannot be programmed to the OFF-state.

15.6 Reliability

15.6.1 Introduction

As for any other non-volatile memory technology, reliability is one of the major concerns. The main specific reliability issues of PCM are: (i) data retention of the RESET, affected by the (limited) stability of the amorphous state; (ii) endurance, limited by the occurrence of stuck at RESET (open) or stuck at SET (short)-type defects; and (iii) program and read disturbs – that is, the stability of the amorphous phase due to repeated, though limited, thermal cycling caused by reading or programming neighboring cells.

While this section is based on reliability tests on the cell level (probing "intrinsic" reliability), for large memories the effect of reliability tests (e.g., of a temperature bake or of a large number of SET/RESET programming cycles) on the resistance distributions should also be evaluated to screen eventual "extrinsic" failures. However, until now only a few (preliminary) results on array reliability statistics have been reported [15, 67].

15.6.2 Retention for PCM: Thermal Stability

The most important requirement for a non-volatile memory is the ability to retain the stored information for a long time, the typical specification being 10 years (at a minimum of 85 °C). As the SET state is stable from a thermodynamic point of view, it has no problem of data retention. On the other hand, the RESET state, corresponding to the amorphous phase, is instead meta-stable and may crystallize following a dynamic which is heavily dependent on temperature. The retention of an amorphous state is, therefore, critical.

The retention performance of PCM technology is addressed by performing accelerated measurements at high temperatures. Figure 15.17 shows the typical failure time under isothermal conditions and with no applied bias, measured at several temperatures ranging from 150 to 200 °C [15]. The failure time is defined as the time required by a fully amorphized cell to lose the stored information. The resistance value for failure has been instead defined as the geometric average between set and reset resistances. The data clearly show an Arrhenius behavior

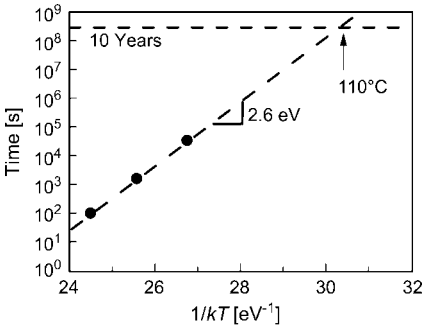

Figure 15.17 Experimental crystallization time of the RESET state as a function of temperature, shown in the Arrhenius plot [15]. A maximum temperature of 110 °C can be tolerated to guarantee 10 years' data retention.

with an activation energy of 2.6 eV, which extrapolates to a data retention capability of 10 years at 110 °C.

A wide range of activation energies have been reported. In general, quite high activation energies have been obtained from $E_a \sim 2.9$ eV for recent fully integrated cells [38] up to 3.5 eV for intrinsic material characterization of GST [17]. Even if such high activation energies are favorable for long retention, however, the physics underlying these experimental values is still not completely understood. The details of the material and integration processes apparently have a large effect, as activation energy was found to be dependent on the presence of capping layers (from a low 2.4 eV for uncapped GST to 2.7 eV for ZnS-SiO_2-capped GST [68]). Furthermore, material doping increases the activation energy (up to 4.4 eV has been reported for O-doped GST [32]).

In principle, the crystallization process during the accelerated retention tests should be described by the same theoretical models for crystal nucleation and growth as used to account for crystallization at much higher temperature (but at much shorter times) during the SET programming pulse (see Section 15.4). Although the conditions for the time window vary over many orders of magnitude (<100 ns during SET, but $>10^2$–10^3 s during retention tests), it has been shown [69] that – remarkably! – the models are indeed able accurately to describe the crystallization processes under both conditions. Moreover, the crystallization statistics also significantly impact the data retention measurements in high-temperature accelerated tests.

15.6.3 Cycling and Failure Modes

PCM cells have been shown to have an intrinsic long programming endurance – that is, up to 10^{12} SET–RESET program cycles [13, 17] (Figure 15.18), which is much superior with respect to Flash technology. In fact, cell endurance has been shown to depend heavily on the interface quality of the heater-GST system and on the possible interdiffusion between GST and adjacent materials. A non-optimized fabrication technology results in devices showing the so-called "first fire" effect [47], namely a

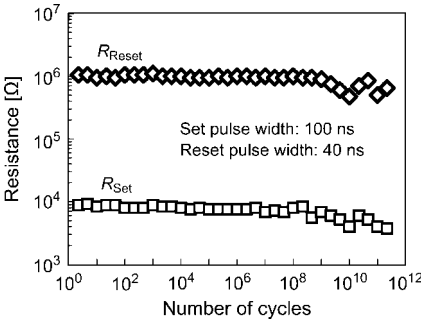

Figure 15.18 Program cycling of a PCM element. (From Ref. [13]).

higher initial programming pulse required for the first cycle of virgin devices. The same devices usually feature poor characteristics in terms of stability during cycling characterization, usually ending in a physical separation of the chalcogenide alloy from the heater (stuck at RESET).

A second failure mode has been also observed (usually called "short-mode failure" or "stuck at SET"), where the devices remain permanently in the highly conductive condition. This phenomenon requires an auxiliary physical mechanism that either forbids the phase-change transition of the GST or creates a conductive parallel path that shunts the cell electrodes. Both cases require a chemical modification of the chalcogenide alloy, suggesting that the interdiffusion of chemical species from adjacent materials plays a role. A careful definition of the materials belonging to the device active region is mandatory in order to achieve good reliability performance.

Finally, current density, as well as the high temperatures (>600 °C) reached in the active region during programming, must be considered as accelerating factors for the previously proposed failure mechanisms (i.e., poor quality interface and contamination). This explains the strong decrease in endurance as a function of the "overcurrent", or, equivalently with energy per pulse larger than required for switching [17]. The data in Figure 15.19 show that endurance at a constant programming current (~700 μA) scales inversely to the reset pulse [70]. The longer the pulse,

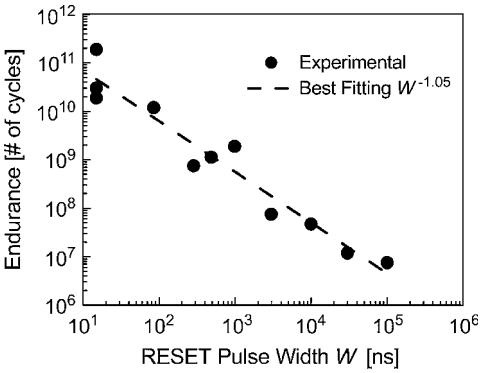

Figure 15.19 Cycling capability as function of the reset pulse window (programming energy per pulse; from Ref. [70]).

the larger the energy released per pulse, and the faster the interface degradation, while the overall energy released up to the bit failure remains almost constant.

15.6.4 Read and Program Disturbs

For most memory technologies, one important concern is the ability of the cell to retain data in the face of spurious voltage transients caused by reading and programming in the memory matrix. For PCM cells such disturbs are not directly induced by voltage pulses but rather by "thermal spikes" that can trigger the crystallization of the metastable amorphous state.

A first failure mechanism can be caused by multiple read accesses of a cell: the small current flowing through the device can induce a localized heating able to accelerate the spontaneous amorphous to crystalline transition. In a second failure mechanism, repeated programming operations on a cell can induce an unwanted heating of the adjacent bits (thermal cross-talk) that can lose the data stored.

Read disturb tests have been described in literature [15, 71], indicating that the repetitive reading of a cell in the high-resistance state with a current below 1 μA allows for a 10-year bit preservation. Such a current is one order of magnitude larger than the current flowing through the cell in standard reading conditions, thereby confirming the robustness to read-disturbs of PCM also in continuous reading, worst-case conditions. Results from program disturb tests on demonstrators have shown that cross-talk is not an issue down at the 90-nm technology node [15]. Thermal simulations, furthermore, confirm program disturb immunity up to at least the 45-nm technology node [18].

15.7 Scaling of Phase-Change Memories

A new memory technology, to be competitive with the existing Flash, must feature a small cell size combined with an excellent scalability beyond the 45-nm technology node. In this section, the scaling potential of the PCM memory is addressed. The main aspects are: (i) scaling of the thermal profiles in order to avoid thermal disturbs at shrinking cell separation; (ii) scaling of the program (RESET) current (and voltage), not only to reduce the program energy/cell, but also because it affects the cell size through the dimensions of the select transistor; and (iii) conservation of the basic material characteristics down to very small dimensions. These aspects will have a crucial impact on the scalability perspectives of PCM technology, and are still to be verified.

15.7.1 Temperature Profile Distributions

As programming of the PCM cell is based on strong heating up to high temperatures (>600 °C, above the PCM material melting point), yet on the other hand the

amorphous RESET state can become unstable at much lower temperatures (<200 °C), it is crucial for the correct operation of a PCM memory that the heating remains very localized and does not affect neighboring cells. Whilst this has been proven for current technologies down to 90 nm (see Section 15.6), it may be less evident to maintain the high temperatures localized in much further scaled technologies, beyond the 45-nm node.

As far as all the linear dimensions are reduced isotropically, the temperature distribution profile indeed does scale. This property transpires from the heat equation:

$$\kappa \cdot \nabla^2 T = g = \rho J^2 \tag{15.1}$$

where κ is the thermal conductivity and g is the heat generation per unit volume. The latter is proportional, via the electrical resistivity, ρ, to the square of the current density, J.

Let us now assume that a new device is fabricated, by shrinking all the linear dimensions by a factor α, but keeping the same boundary conditions (e.g., $T(0) = T_0$) and material properties (e.g., κ, ρ). In the new device it is:

$$\kappa \cdot \nabla'^2 T' = g' = \rho J'^2$$

Since for all the spatial coordinates it is $x' = x/\alpha$, we obtain:

$$\kappa \cdot \nabla'^2 T' = \kappa\alpha^2 \cdot \nabla^2 T' = g' = \rho J'^2$$

That is:

$$\nabla^2 T' = \rho \frac{J'^2}{\alpha^2} \tag{15.2}$$

Provided that $J' = \alpha J$, Equation 15.1 and 15.2 coincide, leading to the same temperature profile, but on a spatial scale uniformly compressed by a factor α.

It follows that if two cells in the original device, at a distance d, do not suffer from cross-talk, then in the isotropically scaled device two cells at a distance d/α will be immune to thermal disturbs. The argument holds as far as $J' = \alpha J$, which will be demonstrated in the following section.

In a more aggressive scaling scheme, only the contact area of the cell is scaled down, without changing so much the thickness of the different layers. In such an anisotropically approach, aiming to more drastically reduce the programming current, cross-talk immunity is no longer granted. However, simulations results show that, without any specific care or materials, thermal disturbs are not expected to slow down cell scaling until the 45-nm node [18].

15.7.2
Scaling of the Dissipated Power and Reset Current

The highest power and programming current is required during the RESET operation, where locally the PCM material must be heated above the melting point.

By using simplified models, the RESET power can be calculated as follows. Even if the programming current pulses last only some tens of nanoseconds, the temperature rise ΔT of the hot spot, where the PCM material eventually melts down, may be computed at steady state. This assumption holds true since the thermal transients in such a small region are characterized by a nanosecond time constant, much faster than the typical current pulse width.

At steady state, the power dissipated by Joule heating (P_J) balances the heat loss ($P_{HL} = \Delta T / R_{TH}$), where R_{TH} is the thermal resistance to the thermal sinks at room temperature (i.e., top and bottom metal layers). On the other hand, the power P_J is proportional to the current, I^2, via the electrical resistance, $P_J = R \cdot I^2$. Using this simple model, the temperature rise ΔT_M, needed to reach the melting temperature, can be written as: $\Delta T_M = P_{J,M}\, R_{TH} = R_{TH}\, R \cdot {I_M}^2$, where I_M is the melting current. It follows:

$$I_M^2 = \Delta T / (R_{TH} \cdot R) \tag{15.3}$$

In the frame of the isotropic scaling rule[4)], as the technology scales, the cell surface area decreases as F^2, but also the distances to the heat sinks decrease as F. The thermal resistance will therefore linearly increase with the scaling factor: $R_{TH} \sim \alpha$ or, equivalently, $R_{TH} \sim F^{-1}$. As for the thermal resistance, the electrical resistance of the PCM cell also increases linearly with geometry scaling ($R = \rho \cdot \text{length}/\text{Area} \sim F^{-1}$). It follows from Equation 15.3 that the melting current and the programming current, which is proportional to the latter, scales as F. The smaller the feature size, the smaller the programming current: $I_{reset} \sim F$ (or $I_{reset} \sim 1/\alpha$). Note that the current density $J = I/A$, will scale as α, as assumed above in deriving Equation 15.2 while discussing the immunity to thermal disturbs.

Although the scaling result is independent of the adopted cell architecture, this does not mean that cell architecture is not important. At a fixed technological node, the cell architecture should be optimized, by accurate design of the geometry and material engineering, to minimize the programming current and the dissipated power (examples of different cell optimizations were provided in Section 15.5).

A more aggressive reduction of the programming current may be obtained by scaling the contact area but not the other dimensions (e.g., the PCM thickness). This choice will mainly affect the thermal and electrical resistances (R and R_{TH} scale faster, i.e., $\sim F^{-2}$ instead of F^{-1}). It follows that $I_{reset} \sim F^2$ (or, $\sim 1/\alpha^2$). The scaling properties of the PCM cell are summarized in Table 15.3[18]. The more aggressive scaling will however pose some problems of manufacture, as the aspect ratio of some cell features (e.g., the thickness to cell size of the PCM material) will increase. Moreover, as discussed above, at this point thermal disturbs may begin to enter the game.

The scalability of the reset current has been addressed experimentally by measuring several test devices with different contact areas [17, 18]. An example of resulting values is given in Figure 15.20 [18]. From this figure it is clear that the reset current follows the reduction of the contact area, and values as low as 50 μA have been

4) Scaling can be indicated either by a dependence on technology feature size, F, or by a dependence on a scaling factor α, with $\alpha \sim 1/F$.

Table 15.3 Scaling rules of PCM cell. (Adapted from Ref. [18]).

	Isotropic	**Aggressive**
Parameters	Scaling factor	Scaling factor
Heater contact area A_{cell}	$1/\alpha^2$	$1/\alpha^2$
Vertical dimensions d	$1/\alpha$	1
Electrical/thermal resistances R	α	α^2
Power dissipation P_{cell}	$1/\alpha$	$1/\alpha^2$
Current I	$1/\alpha$	$1/\alpha^2$
Voltage V_{cell}	1	1
Current density J	α	1

α = scaling factor, $\alpha \sim 1/F$ with F the feature size.

achieved with a com1plete device functionality. The reset current reduction shown in Figure 15.20 can be mainly ascribed to the increase of the heater thermal resistance, R_{TH} caused by the reduction of the contact area.

Data published recently show that I_{reset} is indeed scaling in between $\sim$F and $\sim F^2$ (Figure 15.21) [19]. A scaling behavior stronger than F^2 has been indeed reported by Cho *et al.* [72]. Such a steep dependence, which is well beyond the F^2 theoretical limit, is a strong indication that other cell parameters related to the cell structure and/or material characteristic have been changed.

15.7.3
Voltage Scaling

The required program voltage is determined by the threshold for the electronic switching of the amorphous phase (SET). This voltage value scales with PCM thickness, but is also strongly material dependent; for example, the threshold field is reported to be larger for GST (225) material (threshold field $\sim$30–40 V μm^{-1}) than for the fast-growth doped SbTe materials (threshold field $\sim$14 V μm^{-1}) [24].

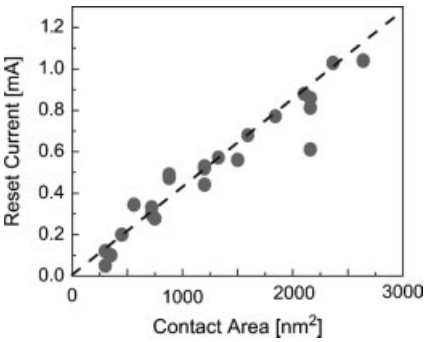

Figure 15.20 Reset current versus contact area (from Ref. [18]). Experimental values (dots), together with scaling trend line (dashed line).

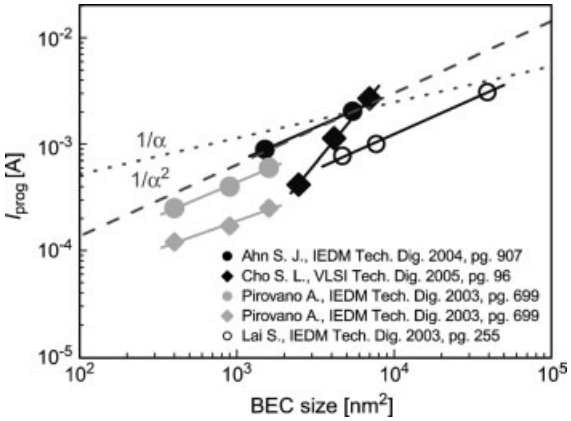

Figure 15.21 Plot of published experimental values of RESET program current versus bottom electrode contact (BEC) size, compared with the $1/\alpha$ and $1/\alpha^2$ scaling law ($\alpha =$ scaling factor, $\alpha \sim 1/F$ with F the feature size). The data are related to different cell structures. (Figure from Ref. [19]).

Furthermore, in Figure 15.3 there was shown to be a minimum value of the threshold switching voltage determined by material (bandgap) and/or contact characteristics. This is why, in Table 15.3, the voltage drop across the cell was considered not dependent on feature scaling. This limitation may pose a constraint on the maximum voltage which should be sustained by the bipolar selectors or by the gate oxide of the MOSFETs across the unselected cells of the array. Beyond the 45-nm technology node, an accurate design of the selecting device will therefore become mandatory.

15.7.4 Cell Size Scaling

In order to assess the scaling of PCM cell size, let us consider a typical MOS-select transistor PCM cell layout (Figure 15.22). The cell size can be calculated as $\sim(\mathrm{W} + 1\mathrm{F}) \times (4.5\ \mathrm{F})$, where W is the width of the access transistor. For a minimal device, $W = 1$ F, the cell size would be $\sim 9\ \mathrm{F}^2$. However, this is the ideal case as in practice, $W/L \gg 1$ to obtain the required drive current to reset the cell through the access transistor. For $W/L > 1$, splitting the gate (the so-called "dual gate concept") is favorable to minimize the cell area [13], resulting in a cell area of $\sim 6\mathrm{W} \times (1/2\ W + \mathrm{F})$.

Taking the I_{reset} values from the ITRS roadmap (predicting, in agreement with the scaling laws derived in Section 15.7.2 above, a scaling according $I_{\mathrm{reset}} \sim \alpha^{1.5}$) [73], as well as the predicted scaling of the drive current with the technology node into account, the minimum access transistor size and the corresponding PCM cell size can be predicted as a function of the technology node (Figure 15.23). From these values it transpires that, at the 45-nm node, a cell size reduction to $<15\ \mathrm{F}^2$ would become possible (with $I_{\mathrm{reset}} \sim 100\ \mu\mathrm{A}$ and $\mathrm{W} \sim 2.7$ F).

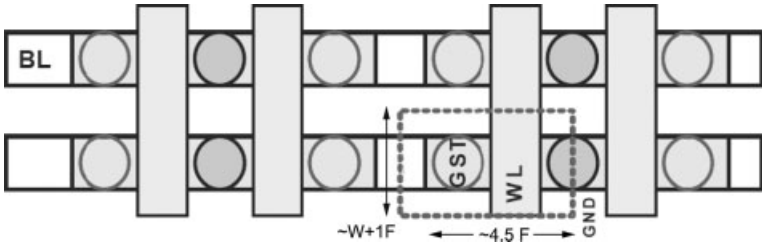

Figure 15.22 Layout schematic of PCM cell as shown in Figure 15.15. BL = bit line (M1); WL = word line (Poly-Si gate line); GND = ground connection (M0). The cell area (dashed rectangle) is approximately $(W + 1\,F)\cdot(4.5\,F)$, where W is the transistor width (in number of Fs) and F the technology feature size. (Adapted from Ref. [53]).

Further room may be obtained by using alternative solutions for ultra-scaled MOS transistors, such as ultra-thin body fully depleted on SOI or Double Gate (or FinFET). These devices are expected to have an improved driving current capability up to $2\,mA\,\mu m^{-1}$ (forecasted to be 2010) [73]. Long-term solutions may also involve the adoption of vertical MOS structures that take advantage of having only a single contact (and hence a reduced area on silicon) and an improved W (by about a factor of 3) with respect to planar solutions.

Figure 15.24 shows the projection of the PCM scaling trend. The PCM cell size will take full advantage of technology scaling, as no intrinsic limitations are expected to halt further scaling. On the other hand, both NOR and NAND scaling are expected to slow down due to scaling limitations (due to high program drain voltage for NOR and electrostatic field coupling for NAND). As a consequence, the PCM cell size will reach the NOR cell size at about the 45-nm node, and may even reach the NAND cell size at about the 32-nm node. Moreover, the memory is ideally suited to store more than two

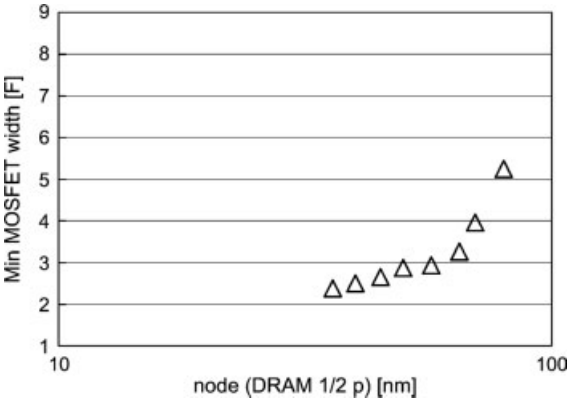

Figure 15.23 Predicted width W (in multiples of feature size F) of the PCM cell MOS select transistor required to drive the required reset current [73] as function of technology node (defined as DRAM half pitch).

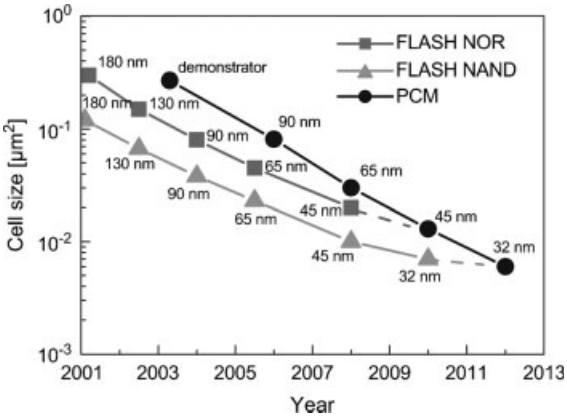

Figure 15.24 Scaling trends for NAND, NOR and PCM (with bipolar select transistor). The phase-change memory technology is expected to reach the same Flash-NAND size at the 32-nm technology feature size. (Figure from Ref. [19]).

levels per cell. This approach may become a viable option to further reduce the cost per bit of PCM devices, if reliable multi-level programming becomes feasible.

15.7.5
Scaling and Cell Performance: Figure of Merit for PCM

A low programming current can indeed be reached by tightly confining the current flow and the corresponding heat generation. However, this usually results in a high cell resistance, and there is an upper limit to the acceptable SET resistance value. The larger the resistance, the lower the cell current during the read operation, and the longer the time needed to charge the bit-line capacitance. In practice, for a read operation to occur within 50 ns the SET resistance should be kept at less than 50 kΩ (i.e., corresponding to a minimum read current in the SET state of a few μAs), but this constraint leads to a trade-off between programming current, and to the introduction of a new figure of merit, the product $R_{set} \cdot I_{melt}$, to compare different devices [19]. Figure 15.25 shows I_{melt} versus R_{set} as derived from published results, where the constant $R_{set} \cdot I_{melt}$ lines are highlighted by the dashed lines. Different cell architectures and material systems correspond to different $R_{set} \cdot I_{melt}$ values. The data clearly show the potential of PCM cells to reach programming currents of few tens of μAs.

15.7.6
Physical Limits of Scaling

To date, very few data are available regarding size effects on PCM behavior. However, from optical memory measurements, phase-change mechanisms seem scalable to at least 5 nm [74]. On the other hand, for both nanosized elements or films thinner than 20 nm, shifts in the crystallization behavior of GST (225) have been observed [75]. Yet, it is unclear if these are intrinsic effects or they are related to

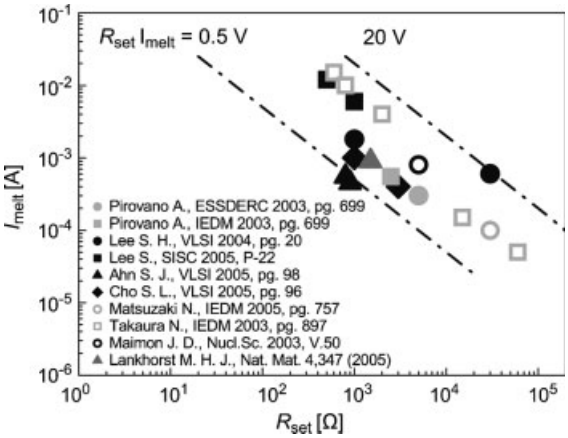

Figure 15.25 I_{melt} versus R_{set} as derived from published results. The constant $R_{set}{\cdot}I_{melt}$ lines are highlighted by the dashed lines. Different cell architectures and material systems correspond to different $R_{set}{\cdot}I_{melt}$ values, proposed as a figure of merit for PCM cells. The data clearly show the potential of PCM cells to reach programming currents of a few tens of μA. (Figure from Ref. [19]).

the preparation method (patterning damage and porosity of thinner films), or if they would inhibit phase switching. What is clear is that both the fabrication technology and behavior of nanosized PCM structures require further exploration in the near future.

15.8 Conclusions

During recent years, PCM have evolved from an interesting new concept to a viable memory technology, based on the use of improved and faster switching materials (<100 ns) and on an improved understanding of phase transformation and electronic switching processes in chalcogenide materials. PCM further shows excellent reliability properties, such as good data retention (10 years at 110 °C) and very high endurance (up to 10^{12} cycles, compared to $<10^6$ for FLASH), while the optimization of cell design has resulted in a drastic reduction of the program current (down to few hundred μA). In addition, integration technology has matured to a point where large demonstrator circuits (up to 256 Mb, in 100-nm technology) have already been built. Perhaps more importantly, the scaling potential of PCM has been assessed, and is expected to result in small cell sizes (in the range of 10 F^2 or smaller) for technologies of 45 nm and below, this being concomitant with a further reduction in program currents. For these reasons, PCM is expected eventually to replace the no-longer-scaling Flash technologies.

16
Memory Devices Based on Mass Transport in Solid Electrolytes

Michael N. Kozicki and Maria Mitkova

16.1
Introduction

As standard semiconductor nanoelectronic devices approach their scaling limits (see Chapters 00 on "FET", 11 on "Flash", and 12 on "DRAM"), concepts beyond traditional purely charge-based functionality offer additional opportunities. One such paradigm goes by the name "nanoionics". Whereas nanoelectronics involves the movement of electrons within their nanostructured settings, nanoionics concerns materials and devices that rely on ion transport and chemical change at the nanoscale. Rising interest in nanoionics has been fuelled by the wide range of demonstrated and potential applications so that the field has been equated in significance by some with nanoelectronics [1].

It is impossible to discuss nanoionics without introducing the basic principles of electrochemistry. As the name suggests, electrochemistry deals with the relationship between electricity and chemical change. In many respects, batteries are the prime example of the application of electrochemical principles; the movement of ions and the change in their oxidation state within the cell is used to release electrical energy over time. However, since ions not only carry charge but also have a significant mass, ion transport can be seen as a means to *move material* in a controlled manner. For example, a metal atom that becomes *oxidized* at one location can be moved as a cation through an electrolyte by an electric field. On receiving an electron at another location, the displaced ion is *reduced* and becomes a neutral metal atom again. In this situation, *the net change in the system is the redistribution of mass* – material is removed from one location and deposited at another using energy from an external power source. The world of electronics has benefited from such "deposition electrochemistry" for many decades. Electroplating, in which metal ions in a liquid solution are reduced to create a uniform metal film, is used in printed circuit boards and packages, and in the processes used to make copper interconnect within integrated circuits. In such cases, physical dimensions, such as electrode spacing, are typically quite large and the electric fields relatively small. The term nanoionics is

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

applied when electrochemical effects occur in materials and devices with interfaces, for example electrodes or electrochemically different material phases, that are closely spaced – perhaps by a few tens of nanometers, or less. In this size regime, the functionality of ionic systems is quite different from the macro-scale versions, but in a highly useful manner. For example, internal electric fields and ion mobilities are relatively high in nanoionic structures and this, combined with the short length scales, results in fast response times. In addition, whereas deposition electrochemistry and many batteries use liquids as ion transport media, nanoionics can take advantage of the fact that a variety of solid materials are excellent electrolytes, largely due to effects which dominate at the nanoscale. This allows nanoionic devices based on *solid electrolytes* to be more readily fabricated using techniques common to the integrated circuit industry, and also facilitates the marriage of such devices with mainstream integrated electronics. Indeed, *in-situ* changes may be controlled by the integrated electronics, leading to electronic-ionic system-on-chip (SoC) hybrids.

In this chapter, we describe the basic electrochemistry, materials science and potential applications in information technology of mass-transport devices based on solid electrolytes and nanoionic principles. The electrodeposition of even nanoscale quantities of a noble metal such as silver can produce localized *persistent* – but *reversible* – changes to macroscopic physical or chemical characteristics; such changes can be used to control behavior in applications that go well beyond purely electronic systems. Of course, electrical resistance will change radically when a low resistivity electrodeposit (e.g., in the tens of $\mu\Omega \cdot$ cm or lower) is deposited on a solid electrolyte surface which has a resistivity many orders of magnitude higher. This resistance change effect has a variety of applications in memory and logic. Here, emphasis will be placed on low-energy, non-volatile memory devices which utilize such resistance changes to store information.

16.2 Solid Electrolytes

16.2.1 Transport in Solid Electrolytes

The origins of solid-state electrochemistry can be traced back to Michael Faraday, who performed the first electrochemical experiments with Ag_2S and discovered that this material was a good ion conductor [2]. Subsequently, greater emphasis was placed on liquid electrolytes and their use in plating systems and battery cells, until the 1960s and 1970s when a significant rise in interest was noted in solid-state electrochemistry. This renewed attention was spurred in part by the development of novel batteries which had a particularly high power-to-weight ratio due to the use of solid electrolyte, mainly beta-alumina, which is an excellent conductor of sodium ions [3]. Even though these solid materials were clearly different from their liquid counterparts, many of the well-known principles developed in the field of liquid electrochemistry were found to be applicable to the solid-state systems. One major difference between most

solid and liquid ion conductors is that in solids, the moving ions are of only one polarity (cations or anions) and the opposite polarity species is fixed in the supporting medium. This has a profound effect on the types of structure that can be used for mass transport (this subject will be outlined later in the chapter). The solid electrolyte family currently includes crystalline and amorphous inorganic solids, as well as ionically conducting polymers. In general, the best solid electrolytes have high ionic but low electronic conductivity, chemical and physical compatibility with the electrodes used, thermodynamic stability over a wide temperature range, and the ability to be processed to form continuous mechanically stable thin film structures.

The mobile ions in a solid electrolyte sit in potential wells separated by low potential barriers, typically in the order of a few tenths of an electron-volt (eV), or less. The ions possess kinetic energy, governed by Boltzmann statistics, and so at finite temperature will constantly try (with around 10^{12} attempts per second) to leave their low-energy sites to occupy energetically similar sites within the structure. Thermal diffusion will result from this kinetic energy, driving ions down any existing concentration gradient until a uniform concentration is achieved. Subsequent movement of the ions produces no net flux in any particular direction. The application of an electric field to the electrolyte effectively reduces the height of the barriers along the direction of the field, and this increases the probability that an ion will hop from its current potential well to a lower energy site (see Figure 16.1) [4]. An ion current therefore results, driven by the field. It should be noted that, unlike electrons, ions in a solid are constrained to move through a confining network of narrow channels. These pathways may be a natural consequence of order in the material, as in the case of the interstitial channels present along certain directions in crystalline materials, or they may be a result of long-range disorder, as in amorphous (glassy) and/or nanoscopically porous materials. Glassy electrolytes, typically metal oxides, sulfides or selenides, are of particular interest as they can contain a wider variety of routes for cation transport than purely crystalline materials. This is a major reason for the interest in these materials – and for Group VI glasses in particular – and why they feature heavily in this chapter.

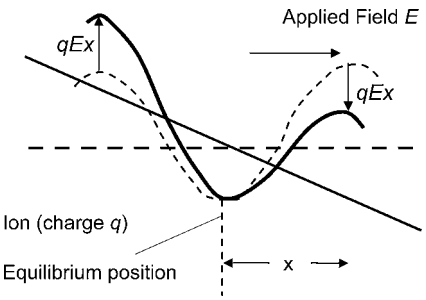

Figure 16.1 Change in the height of a potential barrier between shallow wells due to the application of an electric field. The effective barrier height is reduced by qEx, where E is the electric field and x is the barrier width.

Considering the above dependence of ion hopping on ion energy and barrier height, it should be no surprise that the expression for ion conductivity in the electrolyte is

$$\sigma = \sigma_0 \exp(-E_a/kT) \tag{16.1}$$

where k is Boltzmann's constant, T is absolute temperature, E_a is the activation energy for conduction, and the pre-exponential term σ_0 depends on several factors, including the mobile ion concentration (e.g., σ_0 is in the order of $10^4\,\Omega^{-1}\,cm^{-1}$ for >10 atom% Ag in Ge-S electrolytes [5]). As is evident from Equation 16.1, the activation energy is a major factor in determining ion conductivity. It is directly related to the structure of the host and to the existence of the conduction pathways, both of which govern the effective barrier height. Obviously, the smaller E_a is, the higher the conductivity and the better the electrolyte is. Since E_a is around 0.2–0.3 eV in Ag-saturated Ge-Se and Ge-S electrolytes, the above values lead to ion conductivities in the range 10^{-2}–$10^{-4}\,S\,cm^{-1}$. Just as with electron and hole conduction, we may also define ion conductivity as

$$\sigma = n_i q \mu \tag{16.2}$$

where n_i is the number of mobile ions per unit volume, q is the ionic charge (1.6×10^{-19} C for singly charged ions), and μ is the ion mobility. Interestingly, it is thought that n_i in high ion concentration solid electrolytes such as the Ag-Ge-S ternaries is fairly constant – around 10^{19} ions cm^{-3} [6]. This means that the ion mobilities in the solid electrolytes that are of interest to us are in the order of 10^{-2}–$10^{-4}\,cm^2\,V^{-1}\,s^{-1}$.

16.2.2 Major Inorganic Solid Electrolytes

As mentioned above, a variety of materials can act as solid electrolytes. Anion (oxide) conductors exist, such as ZrO_2, layered La_2NiO_4/La_2CuO_4 [7], or $Bi_{10}V_4MeO_{26}$, where Me is a divalent metal such as Co, Ni, Cu, or Zn [8]. However, for mass-transport devices there is a greater interest in electrolytes that conduct metallic cations as these can be used to form solid metal electrodeposits. In general, the smaller an ion is, the more mobile it should be as it will be able to slip more easily through the pathways in the solid electrolyte. This should be especially true for small-ionic radius elements such as the alkali metals (Li, Na, K). For example, Na^+ has been successfully used in beta-alumina and, to a lesser extent, in non-stoichiometric zirconophosphosilicate [9] to produce good solid ion conductors. The high conductivity in the beta-alumina compounds is a consequence of the structure which has open conduction pathways and a large number of partially occupied sites where cations can reside. Of course, Li^+ conductors in general are of great interest because of their use in high-voltage/high-power density lithium ion batteries, but highly stable Li^+ electrolytes are not easy to produce and there are not many examples of lithium solid electrolyte batteries ($Li/LiI/I_2$ is one of the few commercially available cells). Of course, the high chemical reactivity of these mobile elements makes them unsuitable for most mass transport/

solid electrolyte device applications, and so more stable alternatives must be considered.

The most widely studied solid ion conductors are those which contain silver. These tend to be less difficult to make than alkali metal ion electrolytes, and they have many desirable characteristics, including high ion mobility. Silver is especially appropriate for mass transport applications due to its nobility and ease of both reduction and oxidation. The crystalline Ag halides, principally AgI, and silver *chalcogenides* (e.g., Ag_2S, Ag_2Se, and Ag_2Te) are of particular interest as solid electrolytes. The phases of these materials that are stable at low temperature are semiconductors with moderate to low ion conductivity, but the high-temperature polymorphs (e.g., the cubic phase of Ag_2Se that is stable above 133 °C) are extremely good ion conductors [10]. The effect of this phase transition on the conductivity of AgI is shown in Figure 16.2. The Ag halides and chalcogenides possess a *bcc* structure formed by the covalently bonded halide or chalcogen atoms. An octahedral sublattice which can be occupied by Ag^+ in a multitude of ways is shown in Figure 16.3. The number of the octahedral states is typically much higher than the number of the available Ag ions, and this ensures that there are always non-occupied sites for ions to move into. This abundance of empty sites, in conjunction with the low potential barrier, results in the *superionic* nature of the materials. One other factor contributing to the high conductivity of these electrolytes is the low coordination that Ag^+ has to the immobile chalcogenide/halide sublattice (typically 2–3). This low coordination most likely plays a key role in reducing the activation energy for conduction.

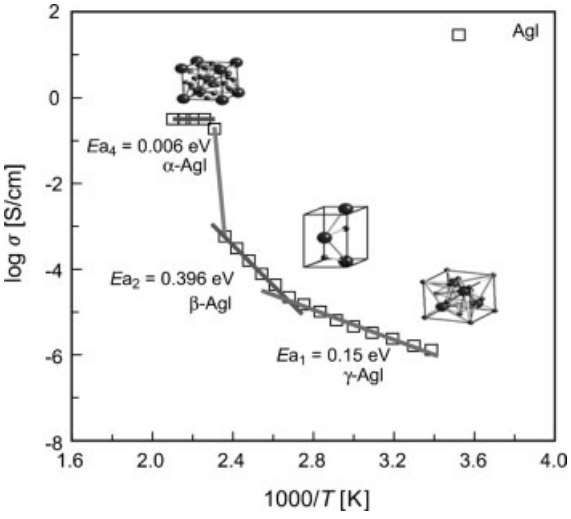

Figure 16.2 Temperature dependence of the conductivity of AgI related to its polymorph structure (Ref. [10]). The polymorph that is stable at high-temperature (denoted by α-AgI on the plot) has the highest conductivity and lowest activation energy compared with the lower temperature (β- and γ-AgI) polymorphs.

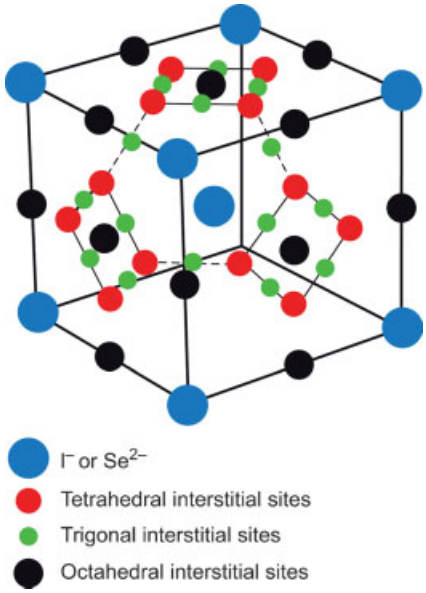

Figure 16.3 Schematic of bcc structure of Ag_2Se (or AgI) showing all possible Ag sublattices (from Ref. [10]). The large number of sites that can be occupied by cations such as Ag^+ lead to high ion mobility.

In practice, even deviations from stoichiometry, δ, as low as 1 part in 10 000 in some cases, lead to the existence of both mobile ions and conduction electrons. To illustrate this, in $\alpha Ag_{2+\delta}Se$, silver atoms are converted into silver ions and free electrons by

$$Ag_{2+\delta}Se \rightarrow (2+\delta)Ag^+ + \delta e^- + Se^{2-} \tag{16.3}$$

Both charge carriers (Ag^+ and e^-) contribute to the total conductivity, so that the material may be regarded as a *mixed conductor* [11]. Analogous effects are expected to occur in Cu-containing electrolytes (e.g., Cu_2S), although the situation will be more complex as participation of the electrons from the Cu d-orbital will result in a variety of bonding configurations. Extensive information on transport in superionic conductors is provided in a review [12]. The main issue with these binary materials is that, whereas they have been widely studied as superionic conductors, it is only their high-temperature phases that are of use in this respect, and this leads to severe practical limitations for electronic device applications.

16.2.3
Chalcogenide Glasses as Electrolytes

A chalcogenide glass is one that contains a large number of group VI or "chalcogen" atoms (S, Se, Te, and O, although oxide glasses are often treated separately from the others in the literature) [13]. These glasses have an astonishing range of physical

characteristics and as such have found a multitude of uses. They lend themselves to a variety of processing techniques, including physical vapor deposition (evaporation and sputtering), chemical vapor deposition, spin casting, as well as melt-quenching. Stable binary glasses typically involve a Group IVB or Group VB atom, such as Ge−Se or As−S, with a wide range of atomic ratios possible. The bandgap of the Group VIB glasses rises from around 1–3 eV for the tellurides, selenides and sulfides, to 5–10 eV for the oxides. The tellurides exhibit the most metallic character in their bonding, and are the "weakest" glasses as they can crystallize very readily (hence their use in so-called phase change technologies as used in re-writable CDs and DVDs), and the others exhibit an increasing glass transition temperature on moving further up the Periodic Table column, with oxides having the highest thermal stability. The non-oxide glasses usually are more rigid than organic polymers but more flexible than a typical oxide glass, and other physical properties follow the same trend. This structural flexibility of these materials offers the possibility of the formation of voids through which the ions can readily move from one equilibrium position to another and, as will be seen later, allows the formation of electrodeposits *within* the electrolyte.

The addition of Group IB elements such as Ag or Cu transforms the chalcogenide glass into an electrolyte as these metals form mobile cations within the material. The ions are associated with the non-bridging chalcogen atoms, but the bonds formed are relatively long −0.27 nm in Ag-Ge-Se and 0.25 nm in Ag-Ge-S ternaries [14]. As with any coulombic attraction, the coulombic energy is proportional to the inverse of the cation–anion distance, so long bonds lead to reduced attractive forces between the charged species. The Ge-chalcogenide glasses are therefore among the electrolytes with the lowest coulombic energies [14]. The slightly shorter $Ag^{+}-S^{-}$ bond length leads to a higher coulombic attraction, which is a factor contributing to the observed lower mobility of Ag in germanium sulfides versus selenides of the same stoichiometry. Thermal vibrations will allow partial dissociation, which results in a two-step process of defect formation followed by ion migration. The activation energy for this process depends heavily on the distance between the hopping cation and the anion located at the next nearest neighbor, as well as the height of the intervening barrier. (A discussion of the relationship between coulombic and activation energies is provided in Ref. [14] but, in addition to having low coulombic energies, the Ge-chalcogenides also have relatively low activation energies for ion transport.) In this respect, the existence of channels due to the structure of the electrolyte is critical in the ion transport process. As an example of this effect, the Ag^{+} conductivity in glassy $AgAsS_2$ is 100-fold larger than that in the crystalline counterpart due to the more "open" structure of the non-crystalline material [15].

The conductivity and activation energy for ion conduction of the ternary glasses is a strong function of the mobile ion concentration. For example, in the Ag concentration range between 0.01 and 3 atom%, the room temperature conductivity of Ag-Ge-S glass changes from 10^{-14} to about $5\times10^{-10}\,\Omega^{-1}\,cm^{-1}$, accompanied by a decline in activation energy from 0.9 to 0.65 eV. However, above a small atomic percent, both conductivity and activation energy change more rapidly as a function of Ag concentration (see Figures 16.4a and b, respectively [16]). This change in the slopes of the conductivity and activation energy curves with Ag content in both Ag-Ge-S and

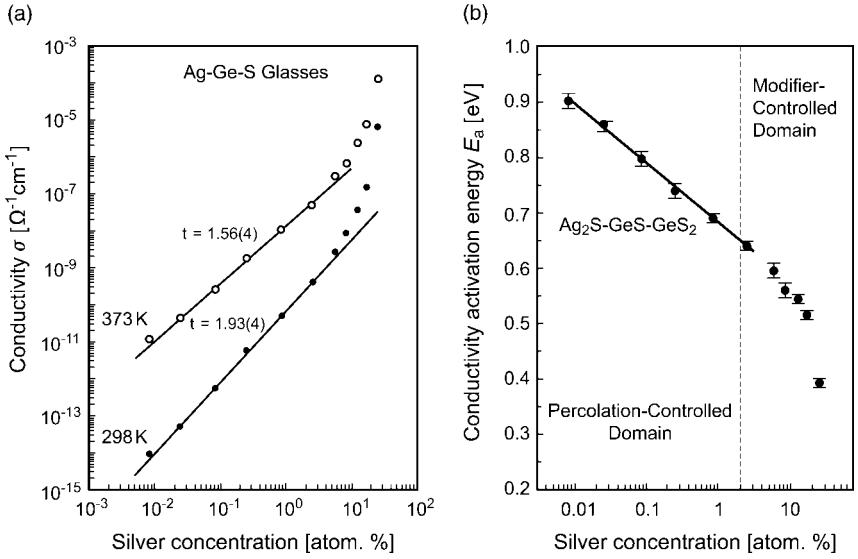

Figure 16.4 (a) Conductivity and (b) activation energy as a function of Ag concentration in Ag-Ge-S ternaries. (From Ref. [16].).

Ag-Ge-Se is a result of a transformation of the ternary material itself caused by the presence of so much silver.

16.2.4
The Nanostructure of Ternary Electrolytes

The transformation that occurs in ternary electrolytes at over a small atomic percent of metal is, by no means, subtle. Indeed, the material undergoes considerable changes in its nanostructure that have a profound effect on its macroscopic characteristics. These changes are a result of *phase separation* caused by the reaction of silver with the available chalcogen in the host to form Ag_2Se in Ag-Ge-Se and Ag_2S in Ag-Ge-S ternaries. For example, if it is assumed that the Ag has a mean coordination of 3, the composition of ternary Ag-Ge-Se glasses may be represented as

$$(Ge_xSe_{1-x})_{1-y}Ag_y = (3y/2)(Ag_2Se) + (1-3y/2)(Ge_tSe_{1-t}) \tag{16.4}$$

where t is the amount of Ge in the Ge-Se backbone $= x(1-y)/(1-3y/2)$ [17]. For a Se-rich glass such as $Ge_{0.30}Se_{0.70}$, $x = 0.30$, and $y = 0.333$ at saturation in bulk glass; hence, $t = 0.40$. This means that the material consists of Ag_2Se and $Ge_{0.40}Se_{0.60}$ (Ge_2Se_3) in the combination

$$16.7\ Ag_2Se + 10\ Ge_2Se_3 = Ag_{0.33}Ge_{0.20}Se_{0.47} \tag{16.5}$$

This electrolyte has a Ag_2Se molar fraction of 0.63 (16.7/26.7) and a Ag concentration of 33 atom% [18]. It has been determined that the dissolution of Ag into a

Se-rich base glass produces a ternary that is a combination of *separate* dispersed crystalline Ag_2Se and continuous glassy Ge-rich phases [19]. The spacing, s, between the Ag_2Se phase regions (and therefore the thickness of Ge_2Se_3 material between them) can be estimated by assuming that the crystalline regions are spherical and uniform in size and dispersion, so that

$$s = d_c(F_v^{-1/3} - 1) \tag{16.6}$$

where d_c is the average measured diameter of the crystalline Ag-rich phase and F_v is the volume fraction of this phase [20]. The volume fraction in the case of Ag_2Se in $Ag_{0.33}Ge_{0.20}Se_{0.47}$ is 0.57 (for a molar fraction of 0.63), so the average spacing between the Ag-rich regions is approximately 0.2 times their diameter. The average diameter of the Ag_2Se crystallites in Ag-diffused $Ge_{0.30}Se_{0.70}$ thin films was determined, using X-ray diffraction (XRD) techniques, to be 7.5 nm [20], which means that by Equation 16.6, they should be separated by approximately 1.5 nm of glassy Ge-rich material. This general structure has been confirmed using high-resolution transmission electron microscopy (TEM). XRD analysis was also performed on a sulfide-based ternary thin film with similar stoichiometry, $Ag_{0.31}Ge_{0.21}S_{0.48}$, with much the same results. In this case, the Ag_2S crystallites are in the order of 6.0 nm in diameter [21]. Even though the detected Ag-rich phases mainly correspond to the room-temperature polymorphs, which are not particularly good ion conductors at room temperature, the ternary is superionic at room temperature. This is not surprising as defects, interfaces, and surfaces play a considerable role in ion transport and the large surface-to-volume ratio of the crystallites within the ternary is likely to greatly enhance ion transport. In addition, it has been noted that the Ag_2Se phases that form following the solid-state diffusion of Ag into Ge-Se may be "distorted" by the effective pressure of the medium to produce high ion mobility phases [19]. The nano-inhomogeneous ternary is ideal for devices such as resistance change memory cells, as the relatively high resistivity leads to a high off-resistance in small diameter devices, although the availability of mobile ions via the dispersed Ag-rich phases means that the effective ion mobility is high.

The addition of Ag (or Cu) to the chalcogenide base glass can be achieved by diffusing the mobile metal from a thin surface film via *photodissolution*. This process utilizes light energy greater than the optical gap of the chalcogenide glass to create charged defects near the interface between the reacted and unreacted chalcogenide layers [22]. The holes created are trapped by the metal, while the electrons move into the chalcogenide film. The electric field formed by the negatively charged chalcogen atoms and positively charged metal ions is sufficient to allow the ions to overcome the energy barrier at the interface, and so the metal moves into the chalcogenide [23]. Prior to introduction of the metal, the glass consists of GeS_4 ($GeSe_4$) tetrahedra and, in the case of chalcogen-rich material, S (Se) chains. The introduced metal will readily react with the chain chalcogen and some of the tetrahedral material to form the ternary. This Ag–chalcogen reaction, which essentially nucleates on the chalcogen-rich regions within the base glass, results in the nanoscale phase-separated ternary described above [24, 25].

16.3
Electrochemistry and Mass Transport

16.3.1
Electrochemical Cells for Mass Transport

In order to move mass, it is clear that an ion current must be generated. Regardless of ion mobility in the electrolyte, a sustainable ion current will only flow if there is a source of ions at one point and a sink of ions at another; otherwise, the movement of ions away from their oppositely charged fixed partners would create an internal field (polarization) which would prevent current flow. The process of *electrodeposition*, in which cations in the electrolyte are reduced by electrons from a negative electrode (cathode), is essentially an ion sink as ions are removed from the electrolyte to become atoms. However, in the absence of an ion source, the reduction of ions at the cathode will occur at the expense of the electrolyte. The concentration of ions in the solid electrolyte will therefore decrease during electrodeposition until the electrode potential equals the applied potential and reduction will cease. Further reduction requires greater applied voltage (governed by the Nernst equation), so that the deposition process is effectively self-limiting for a moderate applied potential. It should be noted also that a depleted electrolyte could allow the subsequent thermal dissolution of an electrodeposit, which would not occur if the glass was maintained at the chemical saturation point. This has important consequences for the stability of any electrodeposit formed. It is therefore necessary to have an *oxidizable* positive electrode (anode) – one which can supply ions into the electrolyte to maintain ion concentration and overall charge neutrality. In the case of a silver ion-containing electrolyte, this oxidizable anode is merely silver or a compound or alloy containing free silver. So, the most basic mass-transport device consists of a solid electrolyte between an electron-supplying cathode and an oxidizable anode (see Figure 16.5). These devices can have both electrodes in a coplanar configuration (as in Figure 16.5a), or on opposite faces of the electrolyte (Figure 16.5b).

In such a device, the anode will oxidize when a bias is applied if the oxidation potential of the metal is greater than that of the solution. Under steady-state conditions, as current flows in the cell, the metal ions will be reduced at the cathode.

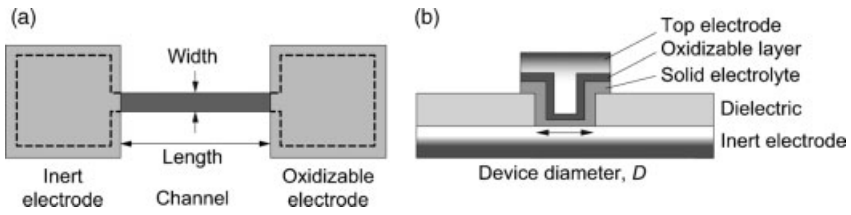

Figure 16.5 Schematic descriptions of two mass transport devices. (a) Coplanar structure that has the two electrodes on the same surface of a solid electrolyte layer. (b) Vertical structure with the solid electrolyte sandwiched between an inert electrode and an oxidizable layer which is covered by the top electrode.

For the case of silver, the reactions are:

$$\text{Anode}: \ \text{Ag} \rightarrow \text{Ag}^{+} + e^{-} \tag{16.7}$$

$$\text{Cathode}: \ \text{Ag}^{+} + e^{-} \rightarrow \text{Ag} \tag{16.8}$$

with the electrons being supplied by the external power source. The deposition of Ag metal at the cathode and partial dissolution of the Ag at the anode indicates that device operation is analogous to the reduction–oxidation electrolysis of metal from an aqueous solution and much the same rules apply, except that in this case the anions are fixed. When a bias is applied across the electrodes, silver ions migrate by the coordinated hopping mechanism (as described above) towards the cathode, under the driving force of the applied field and the concentration gradient. At the boundary layer between the electrolyte and the electrodes, a potential difference exists due to the transfer of charge and change of state associated with the electrode reactions. This potential difference leads to polarization in the region close to the phase boundary, known as the *double layer* [26]. The inner part of the double layer, consisting of ions absorbed on the electrode, is referred to as a *Helmholtz layer*, while the outer part, which extends into the electrolyte and is known to have a steep concentration gradient (over a few tens of nanometers in these systems), is called the *diffuse layer*. Electrically, the double layer very much resembles a charged capacitor, with a capacitance in the order of 10^{-14} F μm^{-2} and resistance around $10^{10}\ \Omega\ \mu m^{2}$ for a typical solid electrolyte under small applied bias [27]. An important consequence of the electric double layer is that, for the reduction–oxidation reaction to proceed, the applied potential must overcome the potential associated with the double layer. This means that no ion current will flow and no sustained electrodeposition will occur until the *concentration overpotential* is exceeded. Below this threshold voltage, the small observed steady-state current is essentially electron leakage by tunneling through the narrow double layer. Above the threshold, the ion current flows and the ions are reduced and join the cathode, effectively becoming part of its structure, both mechanically and electrically. The nature of the electrodeposits will be discussed in greater detail later in the chapter.

The intrinsic threshold is typically in the order of a few hundred millivolts. As the overpotential is governed by the ease of transfer of electrons from the cathode to the ions in the electrolyte, its precise value depends on factors such as the barrier height between the cathode material (including surface/interface states) and the electrolyte, and the bandgap/dielectric constant of the electrolyte. For example, the threshold voltage of a Ni/Ag-Ge-Se/Ag structure is in the order of 0.18 V, whereas the threshold of W/Ag-Ge-Se/Ag is around 0.25 V. Switching to a larger bandgap material, the threshold of a W/Ag-Ge-S/Ag device becomes closer to 0.45 V. The threshold has an Arrhenius dependence on temperature, with an activation energy that is in the order of a few tenths of an electron volt or less, which means that for the W/Ag-Ge-S/Ag structure, the threshold is still 0.25 V even at an operating temperature of 135 °C. Once a silver electrodeposit has formed on the cathode, the Ag metal becomes the new cathode and the threshold for further deposition of Ag is much less, typically less than half the original threshold. This reduced threshold for electrodeposition

following initiation has a profound effect on device operation, and is discussed in more detail below. Of course, long structures that have a high series resistance will require higher voltages to initiate electrodeposition, as most of the applied voltage will be dropped across the electrolyte. For example, the polarization-resistance of a 10 μm^2 electrode will be $10^9\,\Omega$, but if a 50 nm-thick 100 Ω cm Ag-Ge-Se electrolyte between anode and cathode is 10 μm wide and 100 μm long, then the series resistance will be twice this value and so at least 0.75 V will be needed to drop 0.25 V at the cathode and cause electrodeposition.

Just as in any "plating" operation, the ions nearest the electron-supplying cathode will be reduced first. However, in devices with closely spaced interfaces in which the nanoscale roughness of the electrodes is significant and the fields are relatively high, statistical non-uniformities in the ion concentration and in the electrode topography will tend to promote localized deposition or nano-nucleation rather than blanket plating. Even if multiple nuclei are formed, the one with the highest field and best ion supply will be favored for subsequent growth, extending out from the cathode as a single metallic feature. The nature of this somewhat one-dimensional growth will be discussed later in the chapter. The electrodeposition of metal on the cathode does not mean that ions entering from the oxidizable anode must travel the entire length of the structure to replace those that are reduced. As noted earlier, the ions move through the electrolyte by a *coordinated motion*; the ion closest to the reduced ion will move to the vacated negative site on the hosting material, and those upstream will do likewise, each filling the vacated site of the one downstream, until the last vacated space closest to the anode is filled by the incoming ion. So, in the initial stages, the electrodeposit is actually made up of reduced ions from the electrolyte itself; however, as each ion deposited on the growing electrodeposit corresponds to one that has been removed from the metal source, the net effect is a shift of mass from the anode toward the cathode. It should be noted that the growth process in these structures is more complex than a simple plating operation as the deposition interface is moving toward the source of the ions. As the electrodeposit is physically connected to the cathode, it can supply electrons for subsequent ion reduction; hence, the growing electrodeposit will harvest ions from the electrolyte, plating them onto its surface to extend itself outwards from the cathode. This has two consequences: (i) the growth interface continually moves out to meet the ions; and (ii) the growth closes the gap between the electrodes, thereby increasing the field. Both of these outcomes help to speed the overall growth rate of the deposit. The growth rate and electrodeposit morphology are discussed in the following section.

It should be noted that if the cathode is electrochemically inert (not oxidizable), then the electrodeposition process is reversible by switching the polarity of the applied bias. When the electrodeposit is made positive with respect to the original oxidizable electrode, it becomes the new anode and dissolves via oxidation. During dissolution of the electrodeposit, the balance is maintained by deposition of metal back onto the place where the excess metal for the electrodeposition originated. Once the electrodeposit has been completely dissolved, the process self-terminates. It is important to note that it is the *asymmetry* of the device structure that allows the deposition/dissolution process to be cycled repeatedly.

16.3.2
Electrodeposit Morphology

It is clear that the reduction of the ions results in the formation of neutral metal atoms. However, what is not so obvious is the form that the electrodeposits take, as the process depends on a number of factors and involves not only the basic principles of electrochemistry but also transport phenomena, surface science, and metallurgy [28–30]. In this section, some of the more important issues of electrodeposition and deposit morphology with the ternary solid electrolytes will be considered. This process is best illustrated in structures which support electrodeposit growth between coplanar electrodes on an electrolyte layer [31], although growth through an electrolyte film will also be considered.

In the most general case, the process of deposit formation starts with the nucleation of the new metal atom phase on the cathode, and the deposits develop with a structure that generally follows a Volmer–Weber 3-D island growth mechanism [32]. The addition of new atoms to the growing deposit occurs due to a *diffusion-limited aggregation* (DLA) mechanism [33, 34]. In this growth process, an immobile "seed" is fixed on a plane in which particles are randomly moving around. Those particles that move close enough to the seed in order to be attracted to it attach and form the aggregate. When the aggregate consists of multiple particles, growth proceeds outwards and with greater speed as the new deposits extend to capture more moving particles. Thus, the branches of the core clusters grow faster than the interior regions. The precise morphology of these elongated features depends on parameters such as the potential difference and the concentration of ions in the electrolyte [35]. At low ion concentrations and low fields, the deposition process is determined by the (non-directional) diffusion of metal ions in the electrolyte and the resulting pattern is fractal in nature; that is, it exhibits the same structure at all magnifications. For high ion concentrations and high fields, conditions common in the solid electrolyte devices, the moving ions have a stronger directional component, and *dendrite* formation occurs. Dendrites have a branched nature but tend to be more ordered than fractal aggregates and grow in a preferred axis that is largely defined by the electric field. An example of dendritic growth is shown in Figure 16.6 for a Ag electrodeposit on a Ag-saturated $Ge_{0.30}Se_{0.70}$ electrolyte between Ag electrodes. Figure 16.6a is an optical micrograph of the electrodeposit, showing its dendritic character; while Figure 16.6b is an electron micrograph of a similar deposit, showing the extreme roughness of its surface at the nanoscale.

The above model for electrodeposit evolution assumes a homogeneous electrolyte. However, since electrodeposit growth is obviously related to the presence of available Ag ions in the electrolyte surface, the content and consistency of the electrolyte will have a profound effect on electrodeposit morphology. In the case of electrolyte based on a $Ge_{0.30}Se_{0.70}$ glass, the growth of low (about 20 nm high) continuous dendritic deposits are observed on surface of the films (see Figure 16.7a). In the case of the Ge-rich glasses ($Ge_{0.40}Se_{0.60}$), the growth of isolated, tall (>100 nm) electrodeposits can be seen (Figure 16.7b) [36]. The $Ge_{0.30}Se_{0.70}$ material has the higher chalcogen content of the two, and therefore will possess greater and more uniform quantities of

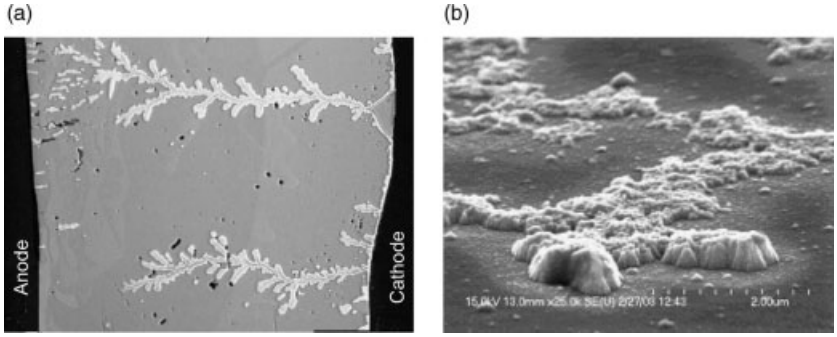

Figure 16.6 Surface electrodeposit of Ag on a Ge-Se-Ag solid electrolyte. (a) Optical micrograph of Ag dendrites. (b) Scanning electron microscopy image of the 3-D structure of the dendrites, showing the nano-roughness and large surface area. (From Ref. [31].).

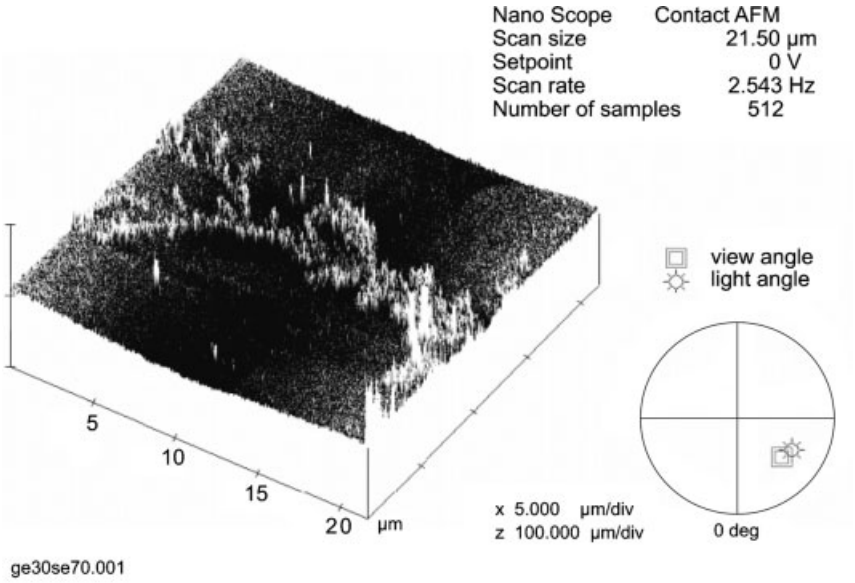
ion-supplying Ag_2Se following the addition of Ag. This leads to dendritic growth that is closer to that expected with a homogeneous material. The isolated growth on the $Ge_{0.40}Se_{0.60}$ electrolyte is a direct consequence of the greater degree of separation of the Ag-containing phases.

The alternative device configuration has the electrodes on opposite sides of a thin electrolyte film, so that the growth of the electrodeposit is forced to occur *through* rather than *on* the electrolyte. Even though the capture and reduction of ions will essentially be by the same mechanism, it is unlikely that growth inside an electrolyte film will follow the same type of evolution as surface electrodeposition. At this point in time, although our understanding of the exact mechanism of growth within these electrolytes is incomplete, it is clear that the role of the nanoscale morphology should be considered. The confining nature of the medium, with its somewhat flexible channels and voids, will distort the shape of the electrodeposit, and its nano-inhomogeneity (as discussed above) will have a profound effect on local potential and ion supply. The net result is that the electrodeposit will not necessarily appear to be fractal or dendritic in nature, instead taking a form that is governed by the shape of the glassy voids and crystalline regions in the electrolyte. An example of such distorted morphology is shown in Figure 16.8; this is an electron micrograph of an electrodeposit within a 60 nm-thick $Ag_{0.33}Ge_{0.20}Se_{0.47}$ electrolyte between a tungsten bottom electrode and a silver top electrode. This was captured by overwriting a large (5×5 μm) device to produce multiple internal electrodeposits and then using a focused ion beam (FIB) system to ion mill a hole through the electrolyte [37]. The filament appears to be around 20 nm across, but this is misleading as the feature continues to grow through ion reduction by the electron beam.

As a final comment on morphology, reversing the bias dissolves the electrodeposit as it becomes the oxidizable element in the electrochemical cell. Macroscopically, this appears to be the reverse of the growth process, with the electrodeposit dissolving backwards from its tip (or tips in the case of a more two-dimensional dendrite). On closer inspection, the deposit actually dissolves near the tip region into a string of



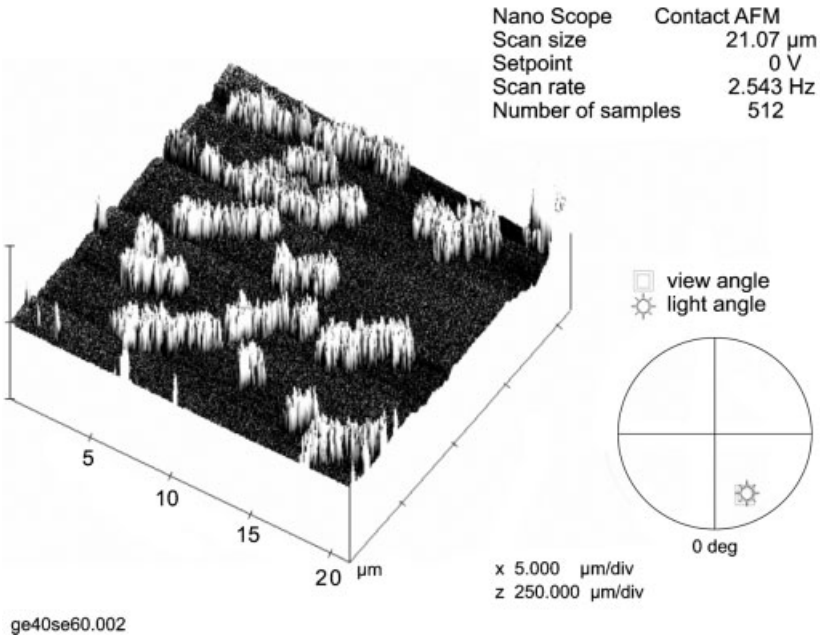


Figure 16.7 Atomic force microscopy image (3-D topographical scan) of (a) Ag electrodeposit grown on Ag-saturated $Ge_{0.30}Se_{0.70}$; the growth is continuous and the maximum electrodeposit height is a few tens of nanometers. (b) Ag electrodeposit grown on Ag-saturated $Ge_{0.40}Se_{0.60}$; the growth appears discontinuous and the maximum electrodeposit height is in the order of 100 nm. (From Ref. [36].).

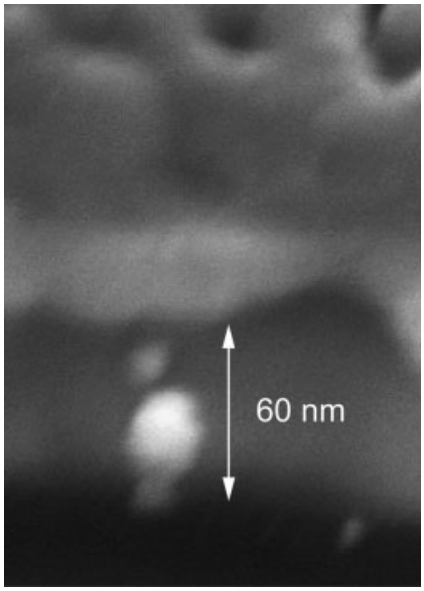

Figure 16.8 Electron micrograph of electrodeposit formation within a 60 nm-thick Ag-Ge-Se solid electrolyte observed by scanning electron microscopy following device sectioning by focused ion beam. (From Ref. [37].).

metal islands which then disappear into the electrolyte. This is a consequence of the uneven nature of the electrodeposit, created in part by the nano-morphology of the electrolyte, which allows some regions (perhaps associated with grain boundaries in the metal) to dissolve slightly faster than others.

16.3.3 Growth Rate

As in any deposition process, the growth rate of the electrodeposit, V, will depend on the ion flux per unit area, F, which corresponds to the current density, J, and the atomic density of the material being deposited, N, by

$$V = F/N = J/qN \tag{16.9}$$

The current density is given as

$$J = \sigma E \tag{16.10}$$

where E is the electric field. In large devices, the field will be relatively low, as will the current density. For example, in a 100 μm-long lateral (coplanar electrode) structure with 10 V applied, the field is $10^3\,\mathrm{V\,cm^{-1}}$. Ag-saturated ternary electrolytes such as Ag-Ge-Se have a conductivity around $10^{-2}\,\mathrm{S\,cm^{-1}}$, and so the ion current density for this field will be $10\,\mathrm{A\,cm^{-2}}$. Dividing current density by the charge on each ion (1.60×10^{-19} for Ag^+) gives the ion flux density, in this case 6.25×10^{19} ions $\mathrm{cm^{-2}\,s^{-1}}$.

Using Equation 16.9 above with the atomic density of Ag (5.86×10^{22} atoms cm^{-3}) gives a growth rate of approximately 10^{-3} cm s^{-1}, or 10 μm s^{-1}. This is a gross simplification, as the complex morphology of the electrodeposits and the moving boundary condition of the advancing electrodeposit will complicate the deposition process. However, this is the approximate average velocity that is measured in a real device for the above conditions.

The electrodeposit growth rates are much more difficult to model in devices that have a thin electrolyte layer sandwiched between two electrodes, and at this point any knowledge of the nano-morphology of the material must be invoked. The average fields in this case range from 10^5 to 10^6 V cm^{-1}, for applied voltages of a few hundred millivolts to a few volts across an electrolyte that is a few tens of nanometers thick. Local fields may be higher still, as most of the applied bias will be dropped across the high-resistance glassy areas between the lower resistivity, metal-rich nanoclusters. Taking a field of 10^6 V cm^{-1} with the conductivity given above suggests that the growth rate will be in the order of 1 cm s^{-1} or 10 nm μs^{-1}. This is much slower than the rate suggested by measured switching speeds observed in actual devices (as will be shown in the next section), so the simple approach that was appropriate for macroscale devices apparently fails at the nanoscale. This may be due to a number of factors. For example, at fields of 10^6 V cm^{-1} or more, the linear conduction equation no longer holds [38] and the mobility will be higher than in the macroscopic case. It is also likely that n_i is larger than the previously assumed 10^{19} cm^{-3}, as the overall silver concentration can be as high as 10^{22} cm^{-3} in Ag-saturated chalcogenide glass electrolytes, and more of this is likely to be mobile due to barrier lowering in materials subjected to such high fields. The overall effect is that the current densities could be sufficiently high to make the electrodeposit growth rates several orders of magnitude higher in nanoscale devices.

16.3.4
Charge, Mass, Volume, and Resistance

The atomic weight of Ag is 107.9 g mol^{-1}, and the metal has a bulk density of 10.5 g cm^{-3}. This means that each atom weighs approximately 1.79×10^{-22} g (107.9 divided by Avogadro's number, 6.022×10^{23} atoms per mol) and this, of course, is the smallest amount of mass that can be transferred using silver as the mobile ion. Each cm^3 of Ag contains 5.86×10^{22} atoms, but a more useful unit in these nanoscale systems in the nm^3; such a volume contains 58.6 atoms on average, and will weigh approximately 10^{-20} g. If this is the electrodeposited mass, then each Ag^+ ion requires one electron from the external circuit to become reduced to form the deposited atom. So, each nm^3 of Ag will require 58.6 times the charge on each electron (1.60×10^{-19} C) which is 9.37×10^{-18} C of Faradaic charge (we can also use Faraday's constant, 9.65×10^4 C mol^{-1}, to perform this calculation). This charge is merely the integral of the current over time, and so a constant current of 1 μA would supply sufficient charge in 1 μs to deposit 10^5 nm^3 or around 1 fg (10^{-15} g) of Ag. So, in this mass-transfer scheme, current and time are the control parameters for the amount of mass deposited.

The amount of charge supplied will also determine the volume of the electrodeposit. The increase in metal volume at a point on the surface of the electrolyte (or decrease in volume at the anode) could be useful in a variety of microelectromechanical applications but it is the electrical resistance of this volume that is perhaps of most interest. The resistance, R, of an electrodeposit is given by

$$R = L/\sigma_m A \tag{16.11}$$

where σ_m is the conductivity of the metal, and L and A are its length and cross-sectional area, respectively (volume is L × A). If the electrodeposited material is silver, σ_m will range from a value close to 5×10^5 S cm^{-1} (slightly higher than the bulk resistance) for features with thickness and width that are greater than a few tens of nanometers to much larger values for sub-10 nm features where surface scattering will play a considerable role. For a silver electrodeposit that is 20 μm long, 2 μm wide, and 20 nm thick (not unlike the example shown in Figure 16.7a), the resistance is about 10 Ω. This volume would take a total of 7.50×10^{-9} C to form. Note that if the underlying Ag-Ge-Se electrolyte (with conductivity 10^{-2} S cm^{-1}) was 20 μm long, 20 μm wide, and 50 nm thick, its resistance would be 2×10^7 Ω (or closer to 4×10^8 Ω for Ag-Ge-S), which is many orders of magnitude higher than that of the electrodeposit. Hence, the overall resistance of the newly formed structure is dominated by the electrodeposit. Figure 16.9 shows, graphically, the measured "on" state data from 50 nm-thick silver-doped arsenic disulfide electrolyte on a thick oxide layer on silicon substrates, patterned into channels with large silver contacts (100 × 100 μm) at the ends [39]. The "off" resistance, R_{off}, is a geometric function of the channel dimensions, following $R_{off} = L/\sigma dW + R_c$, where σ is the conductivity

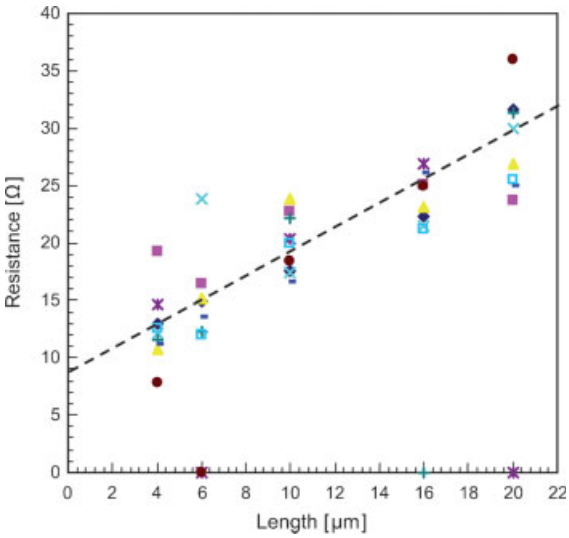

Figure 16.9 Resistance versus length for 10 μm-wide coplanar structures for a 25 mA current limit. The different symbols indicate results from different devices. (From Ref. [39].).

of the electrolyte layer (in the 10^{-3} S cm^{-1} range), d is its thickness, and W and L are width and length, respectively. R_c is the contact resistance (at zero channel length), mainly due to electrode polarization and tunneling at the measurement voltage through the polarization barrier. R_c is in the range of 10^8 to low 10^9 Ω for the electrode configuration used. A 10×10 μm ($W \times L$) device therefore exhibits an R_{off} around 1.5 GΩ. The figure shows the results from a number of 10 μm- wide devices for programming using a 5-s voltage sweep from 0.5 to 1.8 V with a 25 mA current limit. This produces a substantial surface electrodeposit with a resistance of around 1 Ω μm^{-1} of device length. The average electrodeposit contact resistance in this case is around 9 Ω.

The resistance of the electrodeposit that forms within the nanostructured electrolyte is also determined by its volume, but in this case the influence of the different phases present at the nanoscale must also be considered. As discussed above, electrodeposition in its early stages is likely to occur on the metal-rich clusters, through the glassy high resistance regions between them. This means that the initial connection through the electrolyte will essentially consist of metallic bridges between the relatively low-resistivity clusters. In the case of a link that is dominated by the conductivity of the clusters rather than that of the metal, an on-resistance in the order of 20 kΩ in a 50 nm-thick Ag-Ge-Se electrolyte would require a conducting region less than 10 nm in diameter (assuming that the conductivity of the Ag_2Se material is close to the bulk value of 10^3 S cm^{-1} [40]). In the case where the electrodeposit dominates the pathway – that is, when the electrodeposited metal volume is greater than that of the superionic crystallites in the pathway – the electrodeposit resistivity will determine the on-resistance. In this case, a 10 nm-diameter pathway will have a resistance in the order of 100 Ω. This means that the diameter of the conducting pathway will not exceed 10 nm for typical programming conditions which require on-state resistances in the order of a few kΩ to a few tens of kΩ. The small size of the conducting pathway in comparison to the device area explains why on-resistance has been observed to be independent of device diameter, whereas off-resistance increases with decreasing area [41]. An electrodeposit this small means that the entire device can be shrunk to nanoscale dimensions without compromising its operating characteristics. This has been demonstrated by the fabrication of nanoscale devices as small as 20 nm that behave much like their larger counterparts [20, 42]. The other benefit of forming a small-volume electrodeposit is that it takes little charge to do so; in an extreme case, if half the volume of a sub-10 nm-diameter, 50 nm-long conducting region was pure Ag, only a few fC of Faradaic charge would be required to form a low-resistance pathway.

As discussed above, reversing the applied bias reverses the electrodeposition process so that the electrodeposit itself becomes the oxidizable anode and is thereby dissolved. The amount of charge necessary to do this is essentially the same as that required to grow the link in the first place. However, it is not just the oxidation of the electrodeposited metal that is responsible for breaking of the link, especially in the case of a connection between the electrodes that are mostly metal rather than a chain of metallic and Ag-rich electrolytic clusters. The very narrow (and uneven) link is

susceptible to being weakened by electromigration by the current flowing through the metal. This means that the time to failure (initial breaking) of a metallic link depends partly on the current density; it can take years to break the link at a reverse current several orders of magnitude below the critical current density (around 10^7–10^8 A cm^{-2}), but the same link can be broken in less than 1 μs for a reverse current density in excess of this. In practice, for vertical structures, the critical current is typically less than the current limit used to form the link, but not less than 20% of this current. It should be noted that a forward current cannot easily be used to break the link by electromigration if the applied bias is above the threshold for electrodeposition, as any weakness (high-resistance region) in the electrodeposit will be "healed" by electrodeposition in the area due to the elevated voltage drop there. As the resistivity of the electrolyte is many orders of magnitude higher than that of the electrodeposited metal, the overall resistance of the structure rises dramatically as soon as the link is broken. The remainder of the electrodeposited metal in the now-incomplete link is dissolved electrochemically.

16.4 Memory Devices

16.4.1 Device Layout and Operation

As shown in Figure 16.5, the basic elements of a resistance change device – the solid electrolyte, the oxidizable electrode, and the inert electrode – may be configured either laterally or vertically. Whereas lateral devices may have utility in a variety of applications (e.g., microelectromechanical systems; MEMS), it is the vertical configuration that is of most interest in the context of memory devices. Vertical structures occupy the smallest possible area, which is critical for high-density memory arrays. In addition, the distance that the electrodeposit must bridge in order to switch a vertical device to its low-resistance state – a key factor in determining switching speed – is defined by the electrolyte thickness rather than by a lithographically defined gap. As the film thickness can typically be made much smaller than a lateral gap using conventional manufacturing technology, vertical structures switch faster than their lateral counterparts.

A schematic representation of how vertical solid electrolyte memory devices may be integrated in a complementary metal oxide-semiconductor (CMOS) circuit is shown in Figure 16.10. In this case, the inert electrodes are the tungsten plugs that are normally used to connect one layer of interconnect metal to another. The solid electrolyte layer is placed on top of these individual tungsten electrodes, and a common oxidizable electrode (or a bilayer of oxidizable metal and another electrode material) caps the device structures. The individual devices are defined by each tungsten plug. It should be noted that the storage elements are built in the interconnect layers above the silicon devices in a "back-end-of-line" (BEOL) process, which means that the CMOS fabrication scheme need not be changed. A further

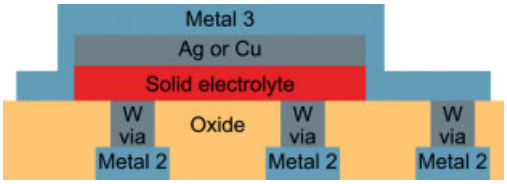

Figure 16.10 Schematic illustration of solid electrolyte device integration between two levels of metal (in this case "metal 2" and "metal 3" in a standard CMOS process. The individual devices are defined by each *W* via plug under the continuous electrolyte layer. One extra mask step is used to define which tungsten via plugs will be covered with the solid electrolyte and oxidizable metal, and which will be through connections.

advantage is that only one extra mask is required to define which tungsten plugs are covered with the device stack, and which are through-connections to the upper layers of the interconnect. This helps to reduce the cost of integration and also facilitates embedding the memory with standard logic. In order to obtain the maximum performance from the devices, each storage cell is connected through the underlying interconnect to a "select" transistor in a "one transistor-one resistor" (1T1R) cell array (Figure 16.11a). In this scheme, the transistor is used to select the cell, and an appropriate programming voltage is then applied across the device. Passive arrays, in which sneak current paths through the cells are avoided using diode elements in the array itself rather than transistors, are also possible using row and column electrodes with device structures at their intersections (Figure 16.11b). This latter approach does not allow high-speed operation but does lead to the densest array possible as there are no transistors to enlarge the total cell area.

The programming of the solid electrolyte memory devices is relatively straightforward. A forward bias (oxidizable electrode positive with respect to the inert electrode) in excess of the threshold required to initiate electrodeposition is used to write the

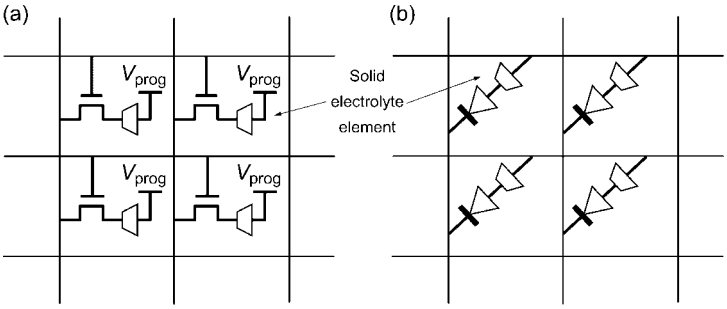

Figure 16.11 (a) Active "1T1R" array configuration. Each memory location consists of a solid electrolyte device and a transistor. V_{prog} is used to set the appropriate voltage across the device for programming. (b) Passive array configuration. Each cell has a diode to prevent "sneak paths" between rows and columns through the cells.

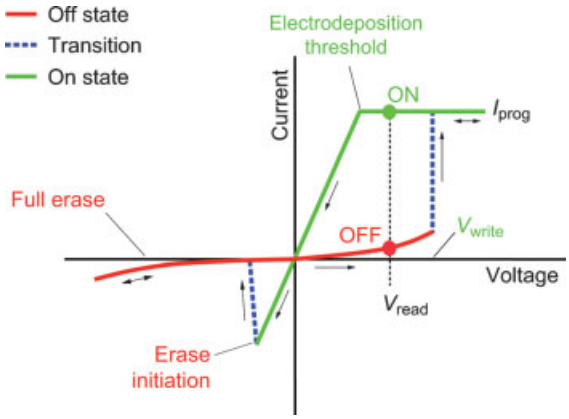

Figure 16.12 Schematic of a current–voltage plot of a solid electrolyte memory device programmed with current limit I_{prog}. The conducting pathway forms at the write voltage (V_{write}) and breaks at the erase initiation voltage/current. Further negative bias is required to fully remove the electrodeposited material and return the device to its original off state. The state of the device is read using a positive voltage below V_{write} to avoid disturbing the state.

device. A negative bias is used to erase the device. Reading the state of the device involves the application of a bias that will not "disturb" or destroy the current state. This typically means that the devices are read using a forward bias that is below the minimum required to write under normal operating conditions. This is shown schematically in Figure 16.12, which shows a current–voltage plot of a solid electrolyte memory device. Only leakage current flows in the off state, but when the conducting pathway forms at the write voltage (V_{write}), the current quickly rises to the programming current limit (I_{prog}). It should be noted that the electrodeposition continues after switching, albeit more slowly than the initial transition, until the voltage across the device reaches the minimum threshold for electrodeposition. The lower on-state resistance is preserved until the erase initiation voltage is reached, at which point the conducting pathway breaks and the device resistance goes high. Further negative bias is required to fully remove the electrodeposited material and return the device to its original off state. The device is read using a positive voltage below V_{write} and the current measured to determine the state. Note that in Figure 16.12, V_{read} has been chosen to be between the minimum voltage for electrodeposition and V_{write} (the consequences of this are discussed in Section 16.4.3). The following section provides results from a variety of fabricated devices.

16.4.2 Device Examples

To date, electrochemical switches have been fabricated using thin Cu_2S [43] and Ag_2S [44] binary chalcogenide electrolytes. The Cu_2S devices have been demonstrated in small memory arrays [45] and reconfigurable logic [46], and although the applications show promise, there is room for improvement in device performance

factors such as retention and endurance with this particular electrolyte. The studies on Ag_2S devices have concentrated on switching by the deposition and removal of small numbers of silver atoms in a nanoscale gap between electrodes. This is of major significance as it demonstrates that the electrochemical switching technique has the potential to be scaled to single atom dimensions. Various oxide-based devices have also been demonstrated [47, 48], and these show great promise as easily integrated elements. However, the lower ion mobility in these materials tends to make the devices slower than their chalcogenide counterparts. Devices based on ternary chalcogenide electrolytes, including Ag-Ge-Se, Ag-Ge-S, and Cu-Ge-S have been the most successful to date, with the silver-doped variants having been applied in sophisticated high-density memory arrays [49] and post-CMOS logic devices [50]. Ag-Ge-Te devices have also been explored [51], but these materials have a tendency to crystallize at low temperatures and so may not be the best choice for devices that must be integrated with CMOS using elevated processing temperatures.

To illustrate the operation of devices based on ternary electrolytes, the discussion will be confined here to those utilizing Ag-Ge-S and Ag-Ge-Se materials. Of these, the Ag-Ge-S electrolyte is the most compatible with BEOL processing in CMOS fabrication as it can withstand thermal steps in excess of 400 °C without any degradation of device characteristics. The sulfides possess better thermal stability as there is less change in the nanostructure at elevated temperature than in the case of selenide electrolytes [21, 52]. A typical device operation is shown in Figure 16.13a and b, which provide current–voltage and resistance–voltage plots respectively for a 240 nm-diameter W/Ag-Ge-S/Ag device with a 60 nm-thick electrolyte [53]. The voltage sweep runs from −1.0 to +1.0 to −1.0 V, and the current limit is 10 μA. As mentioned above, the write threshold for this material combination is 0.45 V, at which voltage the device

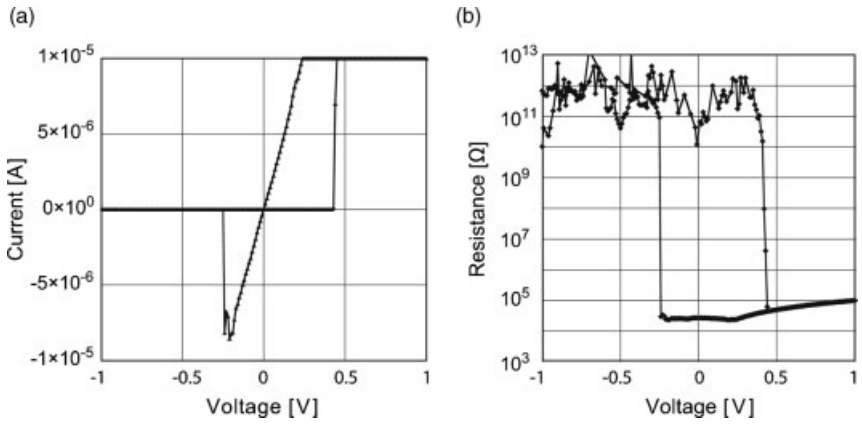

Figure 16.13 (a) Current–voltage plot of a 240 nm-diameter device with a 60 nm-thick Ag-Ge-S electrolyte using a 10 μA current limit. The device has been annealed at 300 °C. The voltage sweep is −1.0 to +1.0 to −1.0 V. (b) Resistance–voltage plot of the same device. The voltage sweep is −1.0 to +1.0 to −1.0 V. (From Ref. [52].).

switches from an off-state resistance, R_{off}, above $10^{11}\,\Omega$ to an on-state resistance, $R_{on} = 22\,k\Omega$, more than six orders of magnitude lower for the 10 μA programming current. This apparent rise in resistance following switching is caused by the current limit control in the measurement instrument. Once electrodeposition is initiated, the threshold for further electrodeposition is decreased, as indicated by the presence of a lower voltage (0.22 V) at which the current drops below the current limit on the negative-going sweep. R_{on} is determined by this voltage divided by the current limit (see below). The device transitions to a high-resistance state at −0.25 V, this being due to an initial breaking of the electrodeposited pathway by the reverse current flow. Continuing the negative sweep, the off-resistance remains above $10^{11}\,\Omega$ as the voltage is swept out to −1.0 V with a leakage current of less than 10 pA at maximum reverse bias. When considering the above characteristics, the device may be written using a voltage in excess of 0.45 V, read by applying a positive voltage that is less than 0.45 V, and erased by a bias greater than −0.25 V. These voltages are compatible with devices at the 22-nm node of the International Technology Roadmap for Semiconductors (ITRS).

Figure 16.14 illustrates the dependence of R_{on} on the programming current limit, I_{prog}, in the range 1–10 μA for a W/Ag-Ge-Se/Ag device with a 50 nm-thick electrolyte [54]. For this electrolyte/electrode combination, the write threshold is 240 mV and the electrodeposition threshold 140 mV. R_{on} is related to I_{prog} by $R_{on} = 0.14/I_{prog}$ (the solid line in the figure). This relationship between electrodeposition voltage, programming current, and on-resistance is common to all material combinations. It is explained by the fact that as long as sufficient potential difference is maintained for the situation where electrodeposition is already underway (in this case 140 mV), the reduction of silver ions will continue and the decrease in resistance of the conducting bridge will be maintained, even after it has formed. If the external current source is limited, when the resistance falls to a point where the voltage drop is no longer sufficient to support electrodeposition, the resistance lowering process ceases. The resulting resistance in ohms is therefore given approximately by the minimum potential to sustain electrodeposition in volts divided by the current limit of the external supply in amperes.

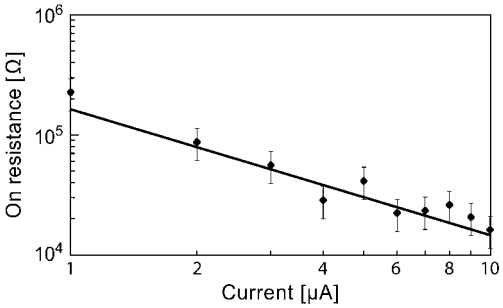

Figure 16.14 On-state resistance versus programming current for a 1 μm-diameter W/Ag-Ge-Se/Ag device. The resistance value (in Ω) is approximately 0.14 divided by the current in A (solid line). (From Ref. [54].).

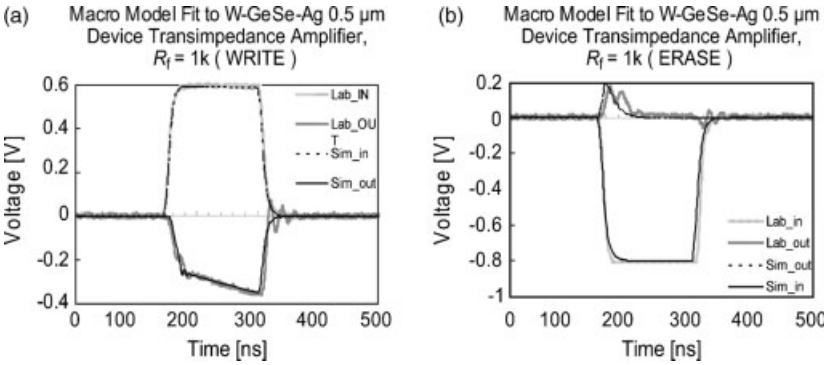

Figure 16.15 (a) Result of a 150-ns write pulse of 600 mV applied to a 500 nm W/Ag-Ge-Se/Ag device showing the output of the transimpedance measurement amplifier. The final on-resistance is 1.7 kΩ. (b) Result for a 150-ns erase pulse of −800 mV on the same device, showing the output of the transimpedance measurement amplifier. Lab_in and Lab_out are the measured input and output signals; Sim_in and Sim_out are the corresponding model generated curves. (From Ref. [55].).

The switching speed of a 500 nm-diameter W/Ag-Ge-Se/Ag device with a 50 nm-thick electrolyte is illustrated in Figure 16.15, which shows both measured and simulated device results for write (Figure 16.15a) and erase (Figure 16.15b) operations [55]. For the write, a 150-ns pulse of 600 mV was applied to the device, and the output of the transimpedance measurement amplifier shows that the device initially switches in less than 20 ns, while the resistance continues to fall more slowly, ultimately reaching an on-resistance of 1.7 kΩ at the end of the write pulse. For the erase, a 150-ns pulse of −800 mV was applied, whereupon the output of the transimpedance measurement amplifier shows that the device transitions to a high-resistance state (the start of the voltage decay in the output signal) in around 20 ns. The electrodeposit is essentially metal that has been added to a chemically saturated electrolyte, and this local supersaturation leads to high stability of the electrodeposit and excellent device retention characteristics. The results of a retention assessment test on a 2.5 µm-diameter W/Ag-Ge-S/Ag device with a 60 nm-thick electrolyte annealed at 300 °C, and programmed using a 0 to +1.0 V sweep is shown in Figure 16.16. The plot shows the off and on resistances measured using a 200 mV read voltage. The off state was in excess of 10^{11} Ω (above the limit of the measurement instrument) and remained undisturbed by the read voltage at this level for the duration of the test. The on resistance remained below 30 kΩ during the test. Following this, the device was erased using a 0 to −1.0 V sweep, and the off-state resistance measured using a 200 mV sensing voltage as before. The device remained above 10^{10} Ω beyond 10^5 s, demonstrating that the erased state was also stable. Other studies have show that both on and off states are also stable at elevated temperature, with a margin of several orders of magnitude being maintained even after 10 years at 70 °C [42]. Figure 16.17 provides an example of cycling for a 75-nm Ag-Ge-Se electrolyte device [20]. Trains of positive (write) pulses of 1.2 V in magnitude and 1.6 µs duration followed by −1.3 V negative (erase) pulses of 8.7 µs duration were

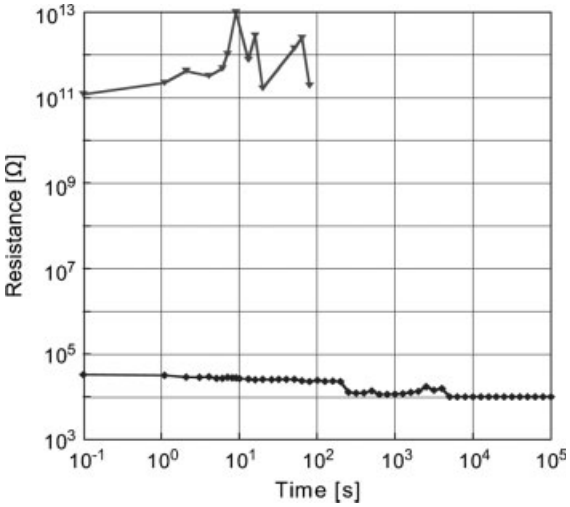

Figure 16.16 Off- (upper plot) and on-state (lower plot) resistance versus time measured using a 200 mV read voltage for a 2.5 μm W/Ag-Ge-S/Ag device programmed using a 10 μA current limit. The off-state resistance remained above $10^{11}\,\Omega$ for the duration of the test. (From Ref. [53].).

used to cycle the devices. A 10 kΩ series resistor was used to limit current flow in the on state. The results are shown in 10^9 and 10^{11} cycle ranges. The data in Figure 16.17 show that there might be a slight decrease in on current, but this is gradual enough to allow the devices to be taken well beyond 10^{11} write–erase cycles (if this decrease is maintained, there will only be a 20% decrease in on current at 10^{16} cycles).

As mentioned above in this section, oxide-based electrolytes may also be used in memory devices. Of these, Cu-WO_3 [47] and Cu-SiO_2 [48] are of particular interest as they utilize materials that are already in common use in the semiconductor industry,

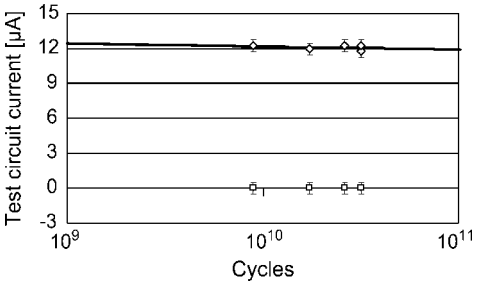

Figure 16.17 Current in the on (upper plot) and off (lower plot) state at various numbers of cycles for a 75-nm Ag-Ge-Se device. The device was cycled using trains of positive (write) pulses of 1.2 V in magnitude and 1.6 μs duration, followed by −1.3 V negative (erase) pulses of 8.7 μs duration. The solid line is a logarithmic fit to the on current data. (From Ref. [20].).

namely Cu and W for metallization and SiO_2 as a dielectric, and this will help to reduce the costs of integration. In general, the switching characteristics for both systems are very similar to those observed in metal-doped chalcogenide glasses, and that is why the same switching mechanism is assumed for the oxide-based cells, even though the material nanostructure is quite different from that found in the ternary chalcogenide electrolytes. For example, in the case of Cu-WO_3, the Cu must exist within oxide in unbound form for successful device operation [47]. For Cu-SiO_2, the best results are attained via the use of porous oxide, formed by physical vapor deposition, into which the metallic copper is introduced by thermal diffusion so that it exists in "free" form in the nano-voids in the base glass. In the case of W-(Cu/SiO_2)-Cu devices with a 12 nm-thick electrolyte, both unipolar (positive voltage for both write and erase) as well as bipolar switching has been observed [48]. Unipolar switching requires high programming currents (several hundred μA to several mA) to thermally break the electrodeposited copper connection in forward bias. Bipolar switching with a resistance ratio of 10^3 is achieved with switching voltages below 1 V and currents down to the sub-μA range. Highly stable retention characteristics beyond 10^5 s and switching speeds in the microsecond regime have been demonstrated, and the possibility of multi-bit storage exists due to the relationship between on-state resistance and programming current. These results, combined with the initial endurance testing which showed that more than 10^7 cycles were possible with these structures, indicate that this technology shows promise as a low-cost, low-energy Flash memory replacement technology.

16.4.3
Technological Challenges and Future Directions

The above results indicate that memory devices based on electrodeposition in solid electrolytes show great promise. However, although several substantial development efforts are under way, many questions remain unanswered with regards to the physics and long-term operation of this technology. The most pressing issues relate to the reliability of such devices. In any memory technology, the storage array is only as good as its weakest cell. Reduced endurance (cycling between written and erased states), poor retention, and "stuck" bits plague even the most mature memory technologies. It may be many years before the issues concerning the solid electrolyte approach are fully understood, but considerable optimism exists regarding reliability which may set this technology apart from others. For example, many technologies suffer from reduced endurance due to changes in the material system with time. In this respect, solid electrolyte devices can exhibit diminishing off-to-on-resistance ratio with cycle number if incorrect programming (overwriting and/or incomplete erase) leads to a build up of electrodeposited metal within the device structure. The convergence of the off and on states eventually leads to an inability to discriminate between them. However, it is possible electrically to "reset" the solid electrolyte using an extended or "hard" erase; this will then plate the excess material back on to the oxidizable electrode and return the electrolyte to its original composition. This ability to change material properties using electrical signals allows such corrections to be

performed in the field, and this may have a profound effect on device reliability. Another issue that can occur in written devices is the upward drift in programmed on-state resistance with time at elevated temperature. This is thought to be due to thermal diffusion of the electrodeposited metal, but it may also be a consequence of electromigration during repeated read operations. However, a read voltage that lies between the write voltage and the minimum voltage for electrodeposition will essentially repair or "refresh" a high-resistance/open on state. To illustrate this, the device characteristics shown in Figure 16.13 are revisited. If a read voltage between 0.22 and 0.45 V is used, an off/erased device will not be written, but a device that has been previously programmed will actually have its on state strengthened. This "auto-refresh" above the minimum threshold for electrodeposition is unique to electrochemical devices. It should be noted that although this effect is extremely useful, it can also lead to problems in incorrectly erased devices (those which are open circuit but still have electrodeposited material on the cathode), as these can also be written at read voltages. Clearly, under-erasing must be avoided in order to maintain high device reliability.

Attention is now turned to the scaling of solid electrolyte memory devices. This involves two points of consideration: physical scaling; and electrical scaling. Physical scaling of the types of device described in the previous section has already been demonstrated to below 22 nm, with good operational characteristics [42]. In addition, studies on the bridging of nanometer-sized gaps between a solid electrolyte and a top electrode seem to suggest that *atomic-scale* electrodeposits could be used to change the resistance of the device, and this may represent the ultimate scaling of the technology [44]. What is not known is how the "high-performance" phase-separated chalcogenide electrolytes will scale, as these contain crystallites that approach 10 nm in diameter. Clearly, further investigations are required in this area, although some are already under way. The other aspect of scaling is electrical scalability. For example, the supply voltage for highly scaled systems around the 22 nm node of the ITRS is on the order of 0.4–0.6 V. This means that, in order to avoid the use of area-, speed-, and energy-sapping charge pumps, the memory cells must be able to operate at the very low voltages at which solid electrolyte devices can function. In addition, the critical current density for 22 nm interconnect is only a few tens of μA, and the devices must also be able to operate at these current levels which, once again, is achievable by solid electrolyte devices.

The final consideration for the future relates to memory density in the Tb (10^{12} bits)/chip regime. Such high storage densities will eventually be required for high-end consumer and business electronics to replace mechanical hard drives in small-form factor, portable systems. If it is assumed that a $20 \times 20\,\mathrm{mm}^2$ chip has an extremely compact periphery such that most of the area is storage array, and a compact cell at $4\,F^2$ (where F is the half-pitch), then Tb storage would require F to be 10 nm at most. Such small wires cannot be produced using standard semiconductor fabrication technologies without significant variations, and their current carrying capacity is very small. Backing-off to $F = 22\,\mathrm{nm}$ means that multi-level cell (MLC) storage – more than one bit per physical storage cell – will be necessary to achieve Tb storage. The ability in solid electrolyte devices to control the on-resistance using the programming current allows multiple resistance levels to be stored in each cell. For

example, four discrete resistance levels leads to 2 bits of information in each cell (00, 01, 10, 11). Such MLC storage has already been demonstrated in a solid electrolyte memory array that was integrated with CMOS circuitry [56]. A combination of the above characteristics demonstrated physical scalability with low-voltage/-current/-power and MLC operation, and it would appear that solid electrolyte memory devices are a strong contender for future solid-state memory and storage.

16.5 Conclusions

Considering the characteristics described in the previous sections, devices based on mass transport in solid electrolytes appear to be appropriate for use as scalable, low-power memory elements. A reduction in resistance of several orders of magnitude is attainable in vertical devices for a write power below 1 μW, and since the on-resistance is a function of programming current, then MLC operation with simple sensing schemes is possible. The elements are non-volatile, with extrapolated retention results suggesting that the reduced resistance, with a large off-to-on ratio, will persist for well over 10 years. Even sub-100 nm devices show excellent endurance with no significant degradation to over 10^{10} cycles, and with stable operation indicated well beyond this. Both, simulated and measured data show that the devices write and erase within 20 ns, and further scaling – especially in the vertical dimension – is likely to result in even greater programming speeds. It should be noted that write times in the order of a few tens of nanoseconds mean that the write energy is less than 100 fJ, which makes solid electrolyte cells memory one of the lowest energy non-volatile technologies. The low resistivity and small size of the electrodeposits mean that the entire device can be shrunk to nanoscale dimensions, without compromising operating characteristics. This physical scalability, combined with low-voltage and low-current operation, suggests that extremely high storage densities will be possible. The other benefit of forming a small-volume electrodeposit is that it takes little charge to do so – in the order of a few fC to create an extremely stable low-resistance link. The charge required to switch a solid electrolyte element to a non-volatile state is therefore comparable to that required to program a typical dynamic random access memory cell, with the potential to further reduce this charge in future devices.

Non-Conventional Complementary Metal-Oxide-Semiconductor (CMOS) Devices

Lothar Risch

1.1
Nano-Size CMOS and Challenges

The scaling of complementary metal-oxide-semiconductor (CMOS) is key to following Moore's law for higher integration densities, faster switching times, and reduced power consumption at reduced costs. In today's research laboratories MOSFETs with minimum gate lengths below 15 nm have already been demonstrated. An example of such a small transistor is shown in Figure 1.1a, where the transmission electron microscopy (TEM) cross-section shows a functional, fully depleted silicon-on-insulator (SOI) transistor with 14 nm gate length, 20 nm spacers using a 17 nm thin silicon layer and a 1.5-nm gate dielectric. The gate has been defined with electron-beam (e-beam) lithography. For the contacts, elevated source drain regions were grown with selective Si epitaxy to lower the parasitic resistance, and a high dose of dopants was implanted into the epi layer for source and drain. In Figure 1.1b, a TEM cross-section through the fin of a SONOS memory FinFET is shown with a diameter of 8 nm, surrounded by the ONO charge-trapping dielectric. As can be seen, many critical features in Si-MOSFETs are already in the range in the range of 1 to 20 nm.

However, achieving the desired performance gain in electrical parameters from scaling will in time become very challenging, as indicated in the International Technology Roadmap for Semiconductors (ITRS) by many red brick walls [1] (see Figure 1.2).

The three main limiting factors for a performance increase are related to physical laws. Gate leakage stops SiO_2 scaling (see Figure 1.3), while source drain leakage reduction needs higher channel doping and shallower junctions. However, this increases junction capacitance, junction leakage, gate-induced drain currents, reduces carrier mobility and increases parasitic resistance. Because of this, transistors with astoundingly small gate lengths down to 5 nm have been realized [2]; although these are the smallest MOSFETs produced until now, their performance is worse than that of a 20-nm device.

When considering memories, the situation is not much different, and for mainstream DRAM and Floating Gate Flash several constraints can be foreseen. For DRAM, the storage capacitance at small cell size and a low leakage cell transistor

become a critical issue. For Floating Gate, the high drain voltages and scaling of the gate dielectric, as well as coupling to neighboring cells, are critical.

Therefore, on the way to better devices, two strategies are proposed by ITRS. The first strategy is to implement new materials as performance boosters. Among these are high-k dielectrics and metal gates, high-mobility channels and low-resistivity or

metal source drain junctions. This will lead to a remarkable improvement in the performance of transistors. The second strategy is to develop new device structures with better electrostatic control, such as fully depleted SOI and multi-gate devices. These can also be utilized in DRAMs as low leakage cell transistors, as well as in nanoscale non-volatile Flash memories.

1.2 Mobility Enhancement: SiGe, Strained Layers, Crystal Orientation

Carrier mobility enhancement of electron and holes provide the key to increase the on-currents without higher gate capacitance and without degrading the off-currents. Several methods have been developed, including SiGe heterostructures [3] with a higher hole mobility for the p-channel transistor. This is achieved by growing a thin epitaxial $Si_{1-x}Ge_x$ layer, where x is the Ge concentration, with a thickness of 5–10 nm for the channel region directly on Si (see Figure 1.4). On top of the SiGe layer a thin Si cap layer is deposited with a thickness of 3–5 nm, which is also used for the growth of the gate oxide. This forms a quantum well for the holes due to a step in the valence band of the Si/SiGe/Si heterostructure, with a depth of about 150 mV for a Ge content of 20%. The SiGe layer is under bi-axial compressive strain due to the smaller lattice constant of Si compared to SiGe (see Figure 1.4a). The mobility is enhanced because of the lower effective mass of the holes in SiGe and a split of the degenerated three-valence bands, thus reducing intervalley scattering. Compared to pure Si with a peak hole mobility of about 110 $cm^2 Vs^{-1}$, with 0.25 Ge 210 $m^2 Vs^{-1}$ have been achieved [4],

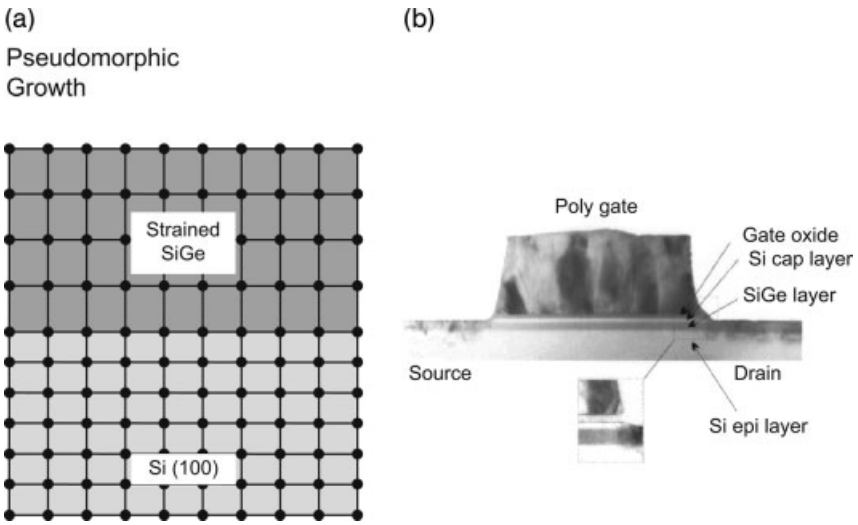

Figure 1.4 (a) Crystal lattice of a Si/SiGe heterostructure. (b) TEM cross-section of a p-channel MOSFET with a Si/SiGe/S quantum well.

extracted from MOSFET measurements. Whereas, the SiGe channel on Si is beneficial for the hole mobility, strained silicon offers both an improved electron and hole mobility, together with a surface channel [5]. The strain is created by a relaxed graded SiGe buffer layer, typically with a thickness of about 3 μm and a Ge concentration of 20–30%. A thin Si layer is grown on top of the relaxed SiGe layer in the range of 10 to 20 nm, which is now under biaxial tensile strain due to the larger lattice constant of the SiGe buffer layer.

Both techniques provide global bi-axial strain on the wafer and are based on Si/SiGe epitaxy. A critical issue here is the increased process complexity, the density of defects and wafer cost. Moreover, the implementation of tensile strain for the n-channel and compressive strain for the p-channel would be desirable, and is difficult to achieve with global strain. Therefore, local uni-axial strain techniques have now become mainstream for mobility enhancement, and these can provide tensile and compressive strain by depositing dedicated layers around the transistor. This method was introduced [6] for the 90-nm CMOS generation. In the n-channel transistor a nitride capping layer with tensile strain is used to improve the drive current by 10–15%. For the p-channel transistor, an embedded SiGe source drain region provides compressive strain and increases the drive current by 25%. TEM cross-sections of the n- and p-channel devices are shown in Figure 1.5 [6].

Another mobility-enhancement technique is based on the crystal orientation dependence of the mobility. Until now, the (1 0 0) surface of silicon wafers has been used with a channel orientation of the transistors in the <0 1 1> direction (see Figure 1.6). This is optimal for the electron mobility but will decrease the hole mobility, which is twice that at the (1 1 0) plane in the <1 0 0> direction. If (1 1 0) wafers are used or rotated (1 0 0) wafers by 45° with the channel in the <1 0 0> direction, the hole mobility is improved remarkably while electron mobility is reduced only moderately (see Figure 1.7) [7].

Therefore, another channel orientation is an effective means to increase p-channel performance, and an improvement of up to 15% has been reported [8]. Unfortunately, the embedded SiGe source drain regions with compressive strain have no remarkable influence in this crystal direction.

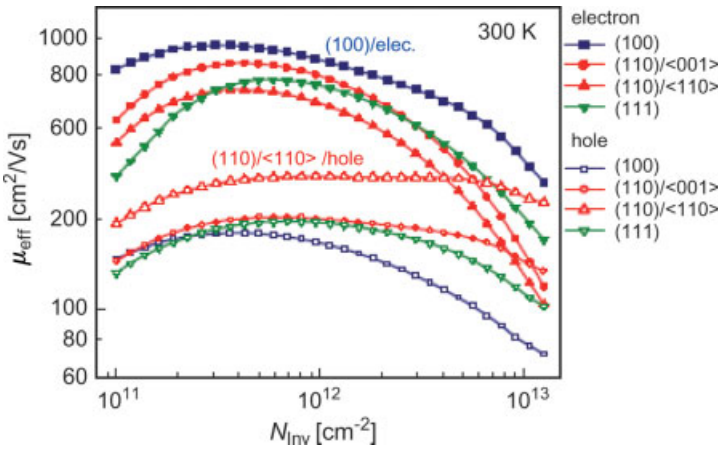

Figure 1.7 Mobility dependence for electrons and holes on crystal orientation and channel direction [7].

1.3
High-*k* Gate Dielectrics and Metal Gate

As indicated in the ITRS roadmap, scaling of the classical SiO_2 gate dielectric and increasing the gate capacitance in order to achieve higher drive currents reached completion at about 2 nm for low standby power, due to Fowler–Nordheim tunneling currents through the gate dielectric. By using nitrided oxides, the minimum thickness could be extended to about 1 nm for high-performance applications with a gate leakage current of about 10^3 A cm^{-2} [9]. The introduction of high-*k* dielectrics allows the use of thicker dielectric layers in order to reduce the tunneling currents at the same equivalent oxide thickness, or to provide thinner dielectrics for continuous scaling. Unfortunately,

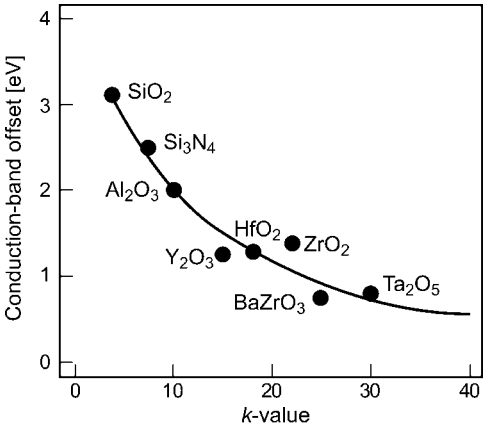

Figure 1.8 Conduction band offset versus k-value for different high-*k* materials [10].

all known high-*k* materials have a smaller bandgap than SiO_2. In Figure 1.8 the conduction band offset as a function of the dielectric constant is shown for different materials [10]. For the highest *k* materials such as Ta_2O_5 ($k = 30$) or TiO_2 ($k = 90$), the bandgap becomes too small and leads to increased gate leakage. Other critical issues are the growth of an interfacial layer during processing. Today, the most mature high-*k* dielectrics are based on Hf. Among these, HfO_2 ($k = 17$–25), HfSiO ($k = 11$) and HfSiON ($k = 9$–11), the latter are the more temperature-stable. An equivalent oxide thickness of below 1 nm has been demonstrated for these high-*k* materials [10]. Other candidates are ZrO_2 and La_2O_3 with dielectric constants between 20 and 30; however, the former is incompatible with a poly silicon gate and requires a metal gate.

For most high-*k* dielectrics a degradation of mobility is observed due to an increased scattering by phonons or a high fixed charge density at the interface. Especially for Al_2O_3, the hole mobility reduction is not acceptable. For the best Hf-based high-*k* dielectrics a 20% lower mobility has been achieved until now, compared to SiO_2.

Closely related to the high-*k* dielectric is a new gate material which avoids the depletion layer of poly silicon gates and the reaction of the high-*k* material with silicon at higher process temperatures. Moreover, metal gates offer the possibility of adjusting the threshold voltage with the workfunction of the gate material instead of doping in the channel, and this decreases the mobility at higher doping concentrations. The desired workfunctions for bulk with n+ poly and p+ poly silicon gates for low-power/high-performance applications with low doped transistor channels are shown in Figure 1.9.

Midgap-like materials such as TiN, TiSiN and W are suitable for n- and p-channel transistors with threshold voltages in the range of 300 to 400 mV, especially for fully depleted SOI or multi-gate transistors with lower channel doping concentrations. For optimized logic processes with low V_t transistors for high performance, in the range of 100 to 200 mV, dual metals with n+ and p+ poly-silicon-like workfunctions must be integrated. For n-channel transistors Ru is a candidate, and for p-channel Ta or RuTa alloys.

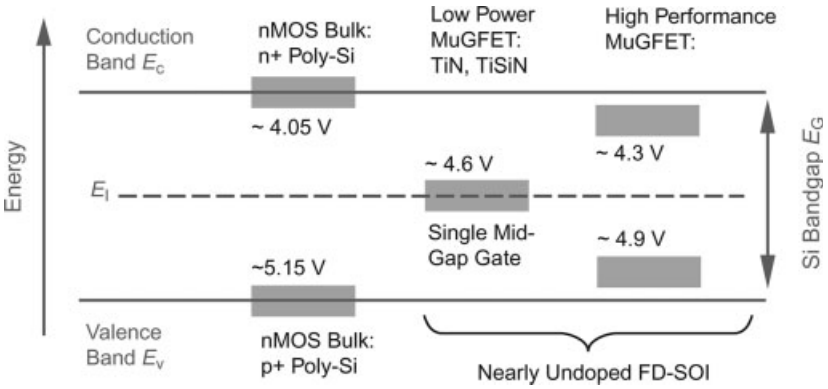

Figure 1.9 Desired workfunction for bulk and FD MOSFETS [24], Pacha ISSCC 2006.

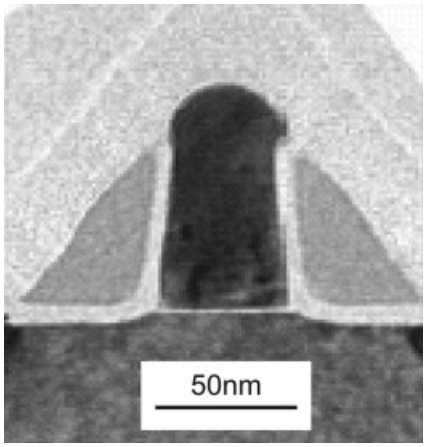

Figure 1.10 A fully silicided NiSi gate transistor [10].

Another gate material option is a tunable workfunction, such as fully silicided NiSi implanted with As and B, or Mo implanted with N. Until now, a shift of the workfunction in a conduction band direction of 200 to 300 mV has been reported [11]. A cross-section of a 50-nm transistor with a fully silicided NiSi gate is shown in Figure 1.10. Here, two approaches have been pursued: the first approach, with Thin Poly, allows the simultaneous silicidation of the source/drain (S/D) and gate, while the second approach uses CMP, offers the independent silicidation of the S/D and gate, and also avoids the formation of thick silicides in the S/D [10].

1.4 Ultra-Thin SOI

Many of the device problems due to short channel effects are related to the silicon bulk. The SOI [12] uses only a thin silicon layer for the channel, which is isolated from

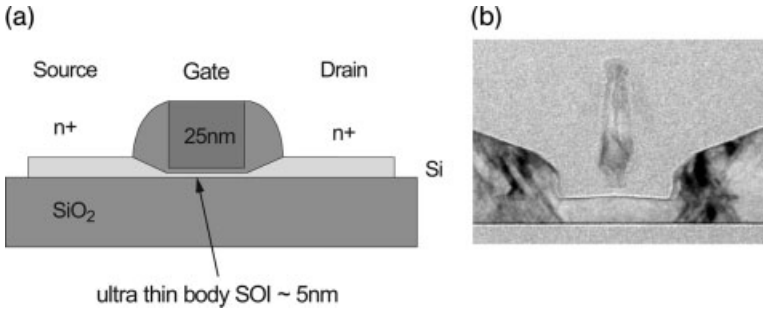

Figure 1.11 (a) A schematic cross-section of a fully depleted SOI transistor with a raised source drain. (b) TEM cross-section of a 12-nm gate fully depleted SOI transistor on 16-nm silicon.

the bulk by a buried oxide. Several companies producing semiconductors have already switched to SOI for high-performance microprocessors or low-power applications. Typically, the thickness of the Si layer is in the range of 50 to 100 nm, and the doping concentrations are comparable to those of bulk devices. This situation, which is referred to as *partially depleted SOI*, has several advantages, most notably a 10–20% higher switching speed. However, further down-scaling faces similar issues as the bulk, and here thinner Si layers [13], which lead to fully depleted channels, are of interest.

A schematic representation and a TEM cross-section of a thin-body SOI transistor with 12-nm gate length and 16-nm Si thickness on 100 nm buried oxide is shown in Figure 1.11. The gate has been defined with e-beam lithography while, for the contacts, raised source drain regions were grown with selective Si epitaxy and a high dose of dopands was implanted into the epi layer.

The experimental current–voltage (I–V) characteristics of n-channel SOI transistors with gate lengths down to 12 nm are shown in Figure 1.12. For gate lengths

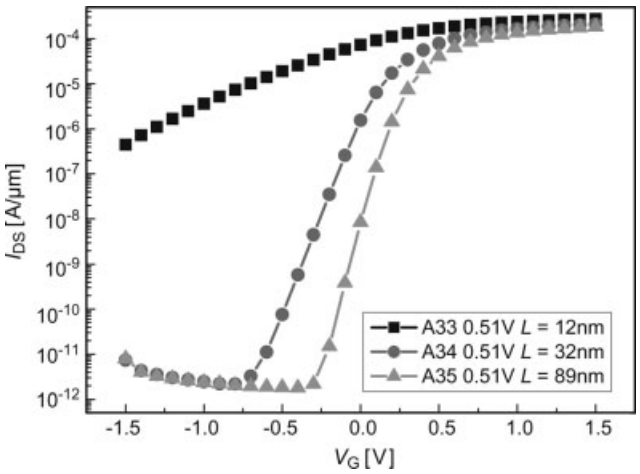

Figure 1.12 Experimental I–V characteristics of 89 to 12-nm SOI transistors on 16-nm silicon with undoped channel, n+ poly gate, $t_{ox} = 1.5$ nm.

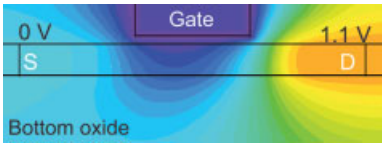

Figure 1.13 Potential distribution in a 30-nm single gate SOI transistor ($t_{Si} = 10$ nm, $t_{ox} = 2$ nm, $V_g = 0$ V, $V_d = 1.1$ V, midgap gate material).

>32 nm, subthreshold slopes of 65 mV dec^{-1} have been reached but, due to the still relatively thick Si body of 16 nm, short channel effects begin to increase below 30 nm gate length, and the transistors with 12 nm gate length cannot easily be turned off.

A two-dimensional (2-D) device simulation of the electrostatic potential of an SOI transistor with undoped channel and a thinner silicon body of 10 nm is shown in Figure 1.13 at a drain voltage of 1.1 V and a gate voltage of 0 V. For a gate length of 30 nm the gate potential controls the channel quite well. However, even with 10 nm Si thickness the potential barrier is slightly lowered at the bottom of the channel.

>This gives rise to an increase in the subthreshold slope as function of gate length, even for 5 nm Si thickness and 1 nm gate oxide (see the device simulation in Figure 1.16). A single-gate SOI exhibits the ideal subthreshold slope of 60 mV dec^{-1} down to about 50-nm gate lengths. In the gate length range of 50 to 20 nm, the turn-off characteristics are still good, and therefore ultra-thin SOI can provide a device architecture which is superior to that of bulk and suitable for the 32-nm node. A simple scaling rule for fully depleted SOI devices proposes a Si thickness of about one-fourth of the gate length in order to achieve good turn-off characteristics.

Whilst in these devices the channel was either low or undoped, this is not feasible in bulk devices because of the punch through from source to drain. The mobility of the charge carriers and the on-current is higher due to lower electric fields; this is shown graphically in Figure 1.14 for different channel doping concentrations. At a

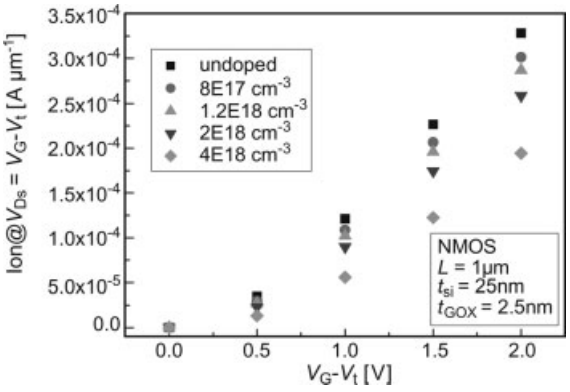

Figure 1.14 Measured on-currents at doped and undoped fully depleted SOI transistors at $V_g - V_t = 1$V.

gate voltage overdrive of 1 V the saturation current of the undoped transistor is twice that of the doped channel, at 4E18 cm^{-3} [14].

Moreover, without channel doping the Zener tunneling currents are reduced as well as electrical parameter variations, due to statistical fluctuations of the doping atoms.

1.5 Multi-Gate Devices

Further reduction of the gate length will require two or more gates for control of the channel, together with thin Si layers. The advantage of a multi-gate is to suppress the drain field much more effectively.

This is illustrated in Figure 1.15, by using the same simulation conditions as in Figure 1.13 and adding a bottom gate to the 30-nm SOI transistor. As shown in Figure 1.15, the electrostatic potential barrier is much higher than in the single-gate device. The better electrostatic control results in a steeper subthreshold slope; this can be seen in Figure 1.16, with a drift diffusion simulation of single- and double-gate transistors. A very thin Si thickness of 5 nm and a equivalent gate oxide thickness of 1 nm has been assumed, with a drain voltage of 1 V. Compared to the single gate, a

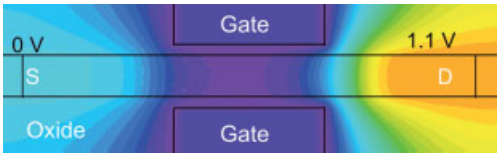

Figure 1.15 Electrostatic potential in a double-gate transistor with 30-nm gate length and 10-nm Si thickness; $V_g = 0\,V$; $V_d = 1.1\,V$; midgap gate material.

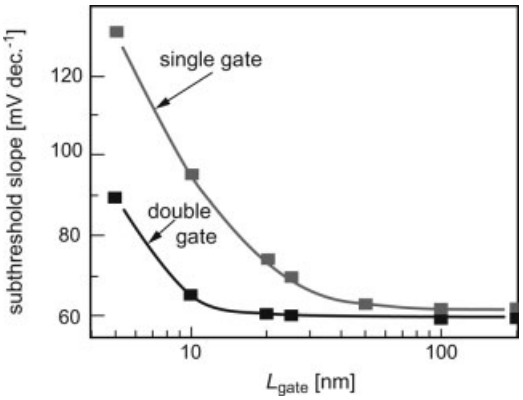

Figure 1.16 Simulated subthreshold slopes of single- and double-gate SOI transistors.

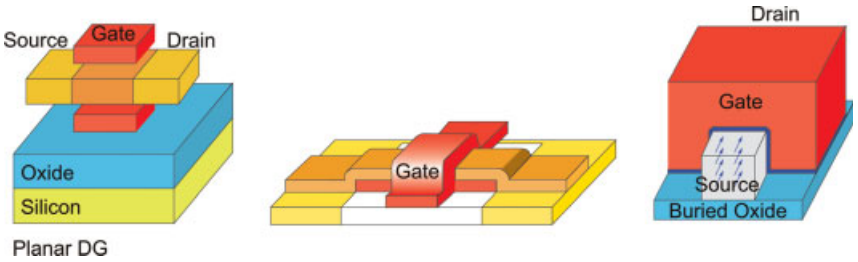

Figure 1.17 Three architectures for multi-gate devices. Left: Planar double-gate wafer-bonded [16]; Center: Gate all-around device [17]; Right: FinFET [18].

10-nm gate length and a subthreshold slope of 65 mV dec^{-1} are predicted for a double gate, and even 5 nm seems feasible with a reasonable subthreshold slope.

The challenge for multi-gate transistors will be to develop a manufacturable process with self-aligned gates to S/D regions. Three promising concepts have been investigated within the EC project NESTOR [15]: the first was a planar double-gate SOI transistor, which uses wafer bonding [16]; the second was a gate all-around device, based on silicon-on-nothing (SON) [17]; and the third was a FinFET type [18] (see Figure 1.17).

1.5.1 Wafer-Bonded Planar Double Gate

The planar double-gate transistor is an evolution of the ultra-thin SOI transistor, with a top and a bottom gate being used for better control of the channel. Processing starts with the bottom gate, spacers and elevated S/D regions using a SOI wafer with a thin silicon layer (see Figure 1.18). The gate is then encapsulated with dielectric layers and planarized with chemical mechanical polishing (CMP). Next, a handle wafer with an oxide layer is bonded onto the wafer with the bottom gate. The bulk Si of the top wafer is then completely removed down to the buried oxide, which acts as an etch stop. After removal of the buried oxide, a gate dielectric is deposited on the thin Si layer. Finally, the top gate and metallization are processed as in a conventional transistor.

An atomic force microscopy (AFM) image of a double-gate transistor test-structure with two separated contacts for the bottom and top gate is depicted in Figure 1.19a, using e-beam litho and an alignment mark for the top gate. A TEM cross-section of the first devices with a p+ poly-Si top and a n+ poly-Si bottom gate for V_t adjustment is shown in Figure 1.19b [19].

Recently, functional double-gate transistors with a TiN metal gate and lengths down to 12 nm and 8 nm for the top and bottom gates have been demonstrated [16] (see Figure 1.20). The 20-nm devices show good short-channel characteristics with $S = 102$ mV dec^{-1}, an off-current in the range of 1 μA μm^{-1}, and an on-current of 1250 μA μm^{-1}.

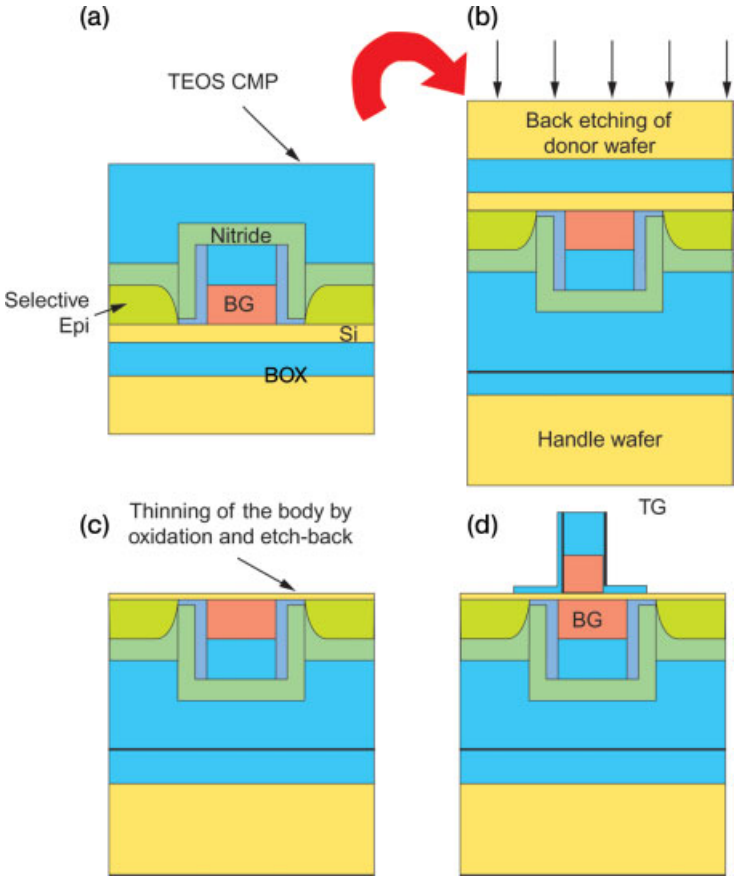

Figure 1.18 Process flow for a wafer-bonded double-gate transistor: Bottom gate, raised source drain and planarization, wafer bonding and back etch of Si bulk wafer, back etch Si channel, gate dielectric and top gate. BOX = Buried Oxide; BG = Buried Gate; TEOS = tetraethyl orthosilicate; CMP = chemical mechanical polishing.

1.5.2
Silicon-On-Nothing Gate All Around

The second approach for multi-gate architectures is based on silicon-on-nothing, as proposed by [20], which uses bulk Si wafers instead of SOI. A SiGe layer is grown with selective chemical vapor deposition (CVD) epitaxy and on top, non-selectively, a thin Si layer for the channel (see Figure 1.21). Next, the SiGe layer is removed by an isotropic etching process. The gate dielectric is then deposited around the silicon bridge, followed by the gate material, which is either poly-Si or a TiN metal gate. A 40-nm gate length and very thin Si channels down to 15 nm have been successfully

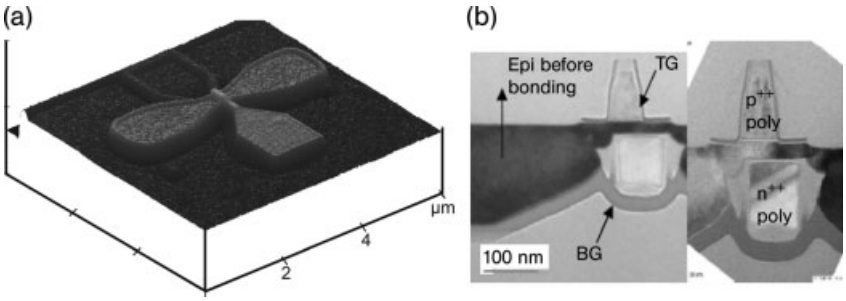

Figure 1.19 (a) AFM image of planar double-gate transistor with top and bottom gate. (b) TEM cross-section of planar double-gate transistor with n+/p+ poly gates.

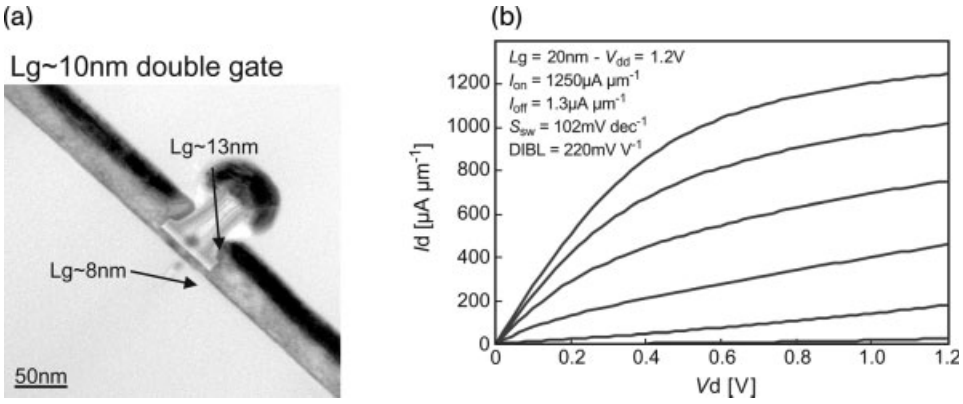

Figure 1.20 (a) TEM cross-section of a 10-nm double-gate transistor realized with wafer bonding [16]. (b) *I–V* characteristics of a 29-nm wafer-bonded double-gate device with a TiN metal gate [16].

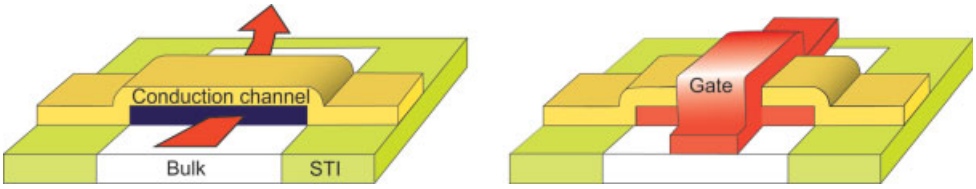

Figure 1.21 Gate all-around transistor processing based on silicon-on-nothing (SON) with a SiGe layer, which is removed for the gate [17].

fabricated [17]. Within the EC project NESTOR, devices with gate lengths of 25 nm have been achieved (see Figure 1.22a). These exhibit excellent short-channel characteristics, with $S = 70\,\mathrm{mV\,dec^{-1}}$, $\mathrm{DIBL} = 11.8\,\mathrm{mV}$, and high on currents of $1540\,\mu\mathrm{A\,\mu m^{-1}}$ ($I_{\mathrm{off}} = 2\,\mu\mathrm{A\,\mu m^{-1}}$, $t_{\mathrm{ox}} = 2\,\mathrm{nm}$) at 1.2 V (see Figure 1.22b). As shown in

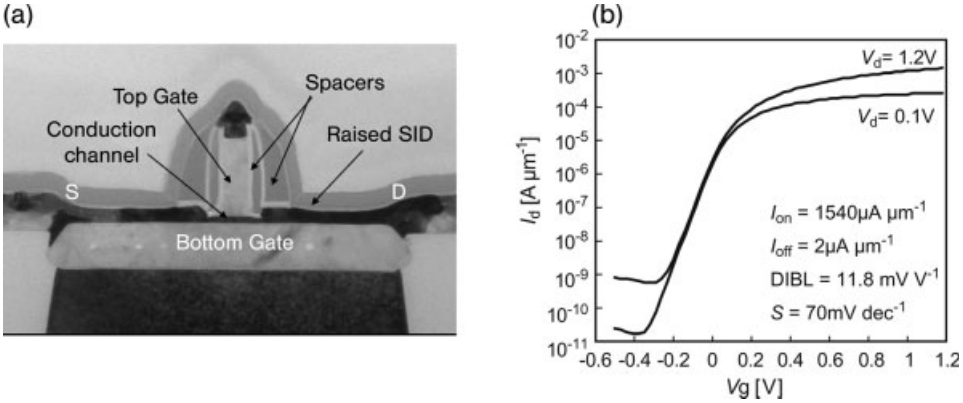

Figure 1.22 (a) TEM cross-section of 25-nm gate all-around SON transistor ($t_{ox} = 2$ nm; $t_{Si} = 10$ nm [15]. (b) Electrical characteristics of 25-nm gate all-around transistor [15].

Figure 1.22a, the bottom gate is still larger than the top gate. Ongoing studies have focused on a reduced bottom gate capacitance and a self-aligned approach.

Recently, multi-bridge transistors [21] have been reported using a similar type of SiGe layer etch technique for the fabrication of two or more channels stacked above each other and with an on-current of up to 4.2 mA μm^{-1} at 1.2 V.

1.5.3 FinFET

The FinFET [18, 22] can provide a double- or triple-gate structure with relatively simple processing (see Figure 1.23). First, the fin on SOI is structured with a tetraethylorthosilicate (TEOS) hardmask (Figure 1.23, left). A Si_3N_4 capping layer shields the top of the fin for a double-gate FinFET, and the same process flow can be used for triple-gate devices, without the capping layer. Next, a gate dielectric and the poly-Si gate are deposited and structured with litho and etching (Figure 1.23, center). The buried oxide provides an etch stop for the definition of the fin height. After this, a gate spacer is formed, raised source/drain regions are grown with epitaxy, and highly doped n+ or p+ regions implanted (Figure 1.23, right). The source/drain regions are enhanced using selective Si epitaxy to lower the sheet resistance. The facet of the Silicon epitaxy has been optimized to reduce the capacitance of drain to gate.

A TEM cross-section of a 20-nm tri-gate FinFET [23] is shown in Figure 1.24. Here, the top of the Si fin is also used for the channel, and no corner effects are observed at low fin doping concentrations. The fin and the gate layer have been processed with e-beam lithography. The smallest fin widths are in the range of 10 nm (see also Figure 1.30).

TEM cross-sections of a tri-gate device with larger fins of about 36 nm are also shown in Figure 1.24. The fin height is in the range of 35 nm, the corners are rounded by sacrificial oxidation, the gate dielectric is 2–3 nm SiO_2, and the poly gate surrounds the fin with a slight under-etch of the buried oxide.

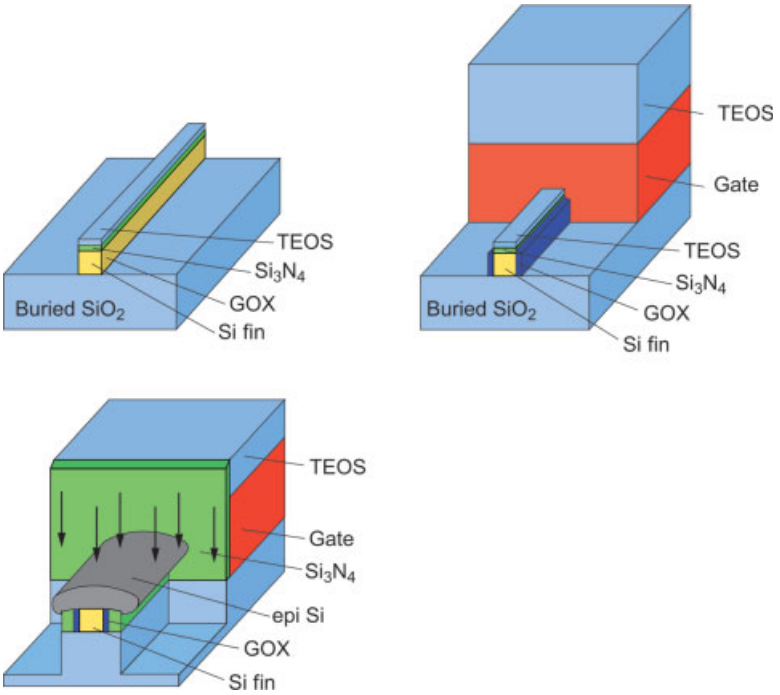

Figure 1.23 Process flow for a FinFET on buried oxide with a capping layer on top of the fin, a poly-Si gate, and raised source/drain regions with implantation. For details, see the text.

The measured I–V_g characteristics of n- and p-channel FinFETs with 20-nm and 30-nm gate length, respectively, are depicted in Figure 1.25. For the n-channel transistor a saturation current of 1.3 mA μm^{-1} (normalized by fin height) at an off-current of 100 nA μm^{-1} has been achieved at a gate voltage of 1.2 V, despite a relaxed

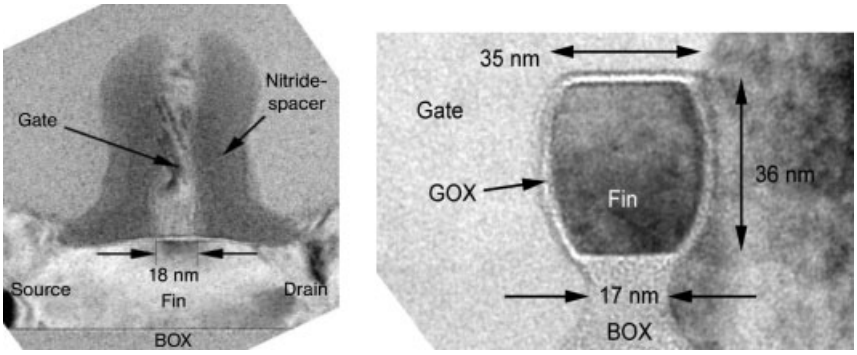

Figure 1.24 TEM cross-sections of a tri-gate FinFET on 100-nm buried oxide along and across the fin. Left: cross section along the fin; only the gate length is visible (18 nm). Right: cross section of the fin; on top it is 35 nm, height 36 nm, bottom ~17 nm.

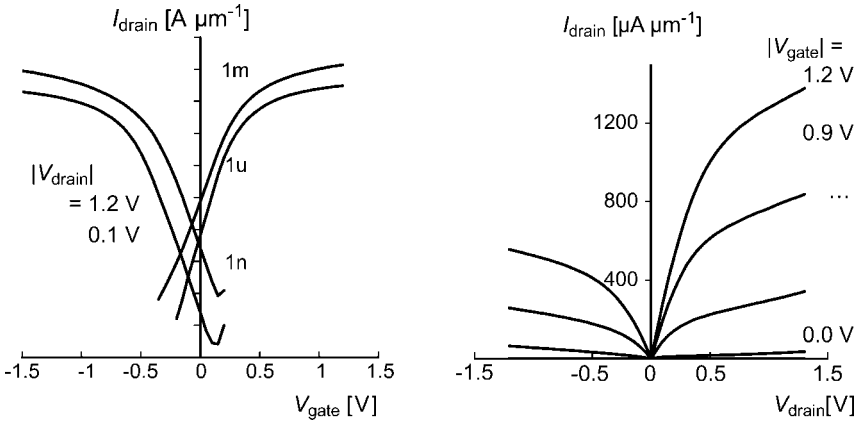

Figure 1.25 Measured *I–V* characteristics of 20-nm n-FinFETs (left) and 30-nm p-FinFETs (right) with $t_{ox} = 3$ nm (n) and 2 nm (p).

gate oxide thickness of 3 nm. For the p-channel, a high on current of 500 µA/µm and an off current in the range of 5 nA µm^{-1} is measured at 30-nm gate length. The FinFET has the advantage of self-aligned source and drain regions.

In Figure 1.25 the current was normalized on the height of a single fin. The electrical width of the device would be 2.2 times larger. For circuit applications, multi-fins are often needed in order to achieve higher drive currents (in Figure 1.26 the device has four fins) [24]. For a comparison with planar transistors it is important how many fins with height, width and pitch can be integrated on the same area as for the conventional device.

With respect to the switching time of multi-gate devices, the drive current together with the gate capacitance must be considered. Here, it was shown by simulation, that multi-gate devices can achieve 10–20% faster delay times compared to single-gate devices, mainly due to the better I_{off}/I_{on} ratio [25]. This was confirmed experimentally in Ref. [24] for inverter FO2 ring oscillators, where tri-gate FinFETs with TiSiN gate,

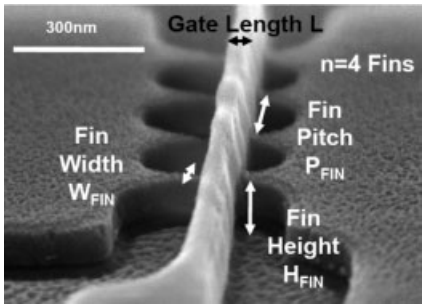

Figure 1.26 Scanning electron microscopy image of a multi-channel FinFET [24] with four fins on SOI. The gate length is 60 nm, fin width 30 nm, and pitch 200 nm.

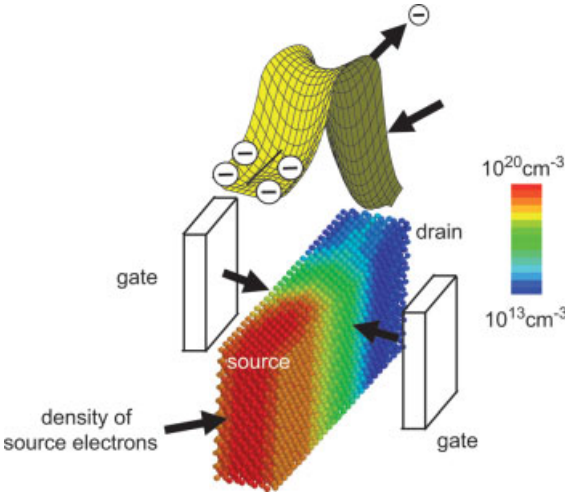

Figure 1.27 Atomistic simulation of a double-gate FinFET using the tight binding method.

55 nm length, and a low-doped channel achieved, with 21 ps, a much better speed performance than comparable planar MOSFETs in a 65 nm low-power CMOS technology, especially for sub-1 V power supply voltages.

1.5.4
Limits of Multi-Gate MOSFETs

The physical limit for the minimum channel length of multi-gate transistors has been investigated with 3-D quantum mechanical simulations using the tight binding method [26]. The device is composed of atoms in the silicon crystal lattice; the current can flow either by thermionic emission across the potential barrier of the channel, or directly via tunneling through the barrier from source to drain (see Figure 1.27).

In Figure 1.28, the simulated source drain current as a function of gate voltage is given with and without band to band tunneling for different gate lengths. An aggressive Si thickness of 2 nm and equivalent oxide thickness of 1 nm has been assumed. For gate lengths of 8 nm the tunneling contribution is on the order of the current over the potential barrier. At 4 nm the current is increased by two orders of magnitude by tunneling, but even 2-nm gates seem possible with off currents in the range of $\mu A\,\mu m^{-1}$, corresponding to ITRS hp specifications. Gate control is still effective and would achieve a subthreshold slope of about $140\,mV\,dec^{-1}$.

1.6
Multi-Gate Flash Cell

Multi-gate transistors are also very suitable for highly integrated memories with small gate lengths. Flash memory cells require thicker gate dielectrics than in logic

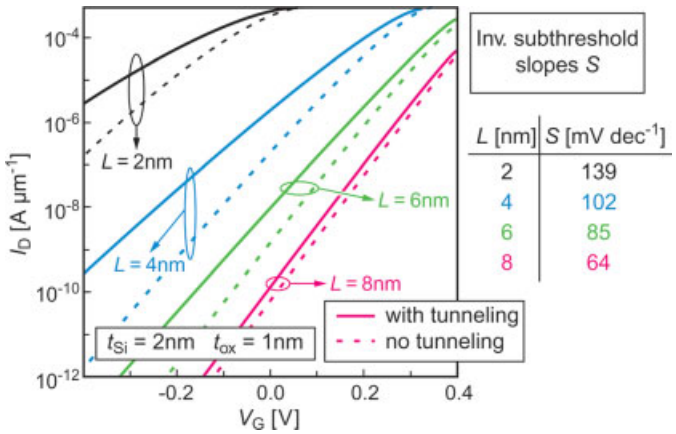

Figure 1.28 Thermionic and total current (+tunneling) of double-gate FinFETs simulated with the tight binding method [26].

applications, and therefore exhibit enhanced short channel effects. Currently, the most widely used Flash cell consists of a transistor with a floating gate [27] or a charge-trapping dielectric [28] sandwiched between the gate electrode and the channel region. A small amount of charge is transferred into the storage region either by tunneling or hot electron injection. This can be stored persistently and read out by a shift in the I–V_g characteristics. A schematic cross-section of a tri-gate FinFET memory transistor with improved electrostatic channel control compared to a planar device is shown in Figure 1.29, where a multilayer ONO gate dielectric around the fin serves as the storage element.

An experimentally realized memory structure [29] with a very small Si fin of 12 nm width and height of 38 nm is shown in Figure 1.30. The multilayer dielectric consisted of 3 nm SiO_2, 4 nm Si_3N_4 and 6.5 nm SiO_2.

The charge is uniformly injected into the nitride trapping layer by Fowler–Nordheim tunneling. The electrical function has been verified experimentally down to

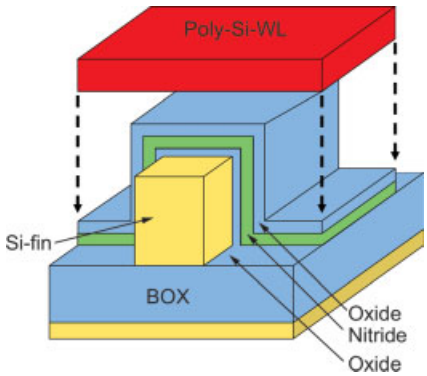

Figure 1.29 Schematic cross-section of a tri-gate charge-trapping memory field-effect transistor (FET).

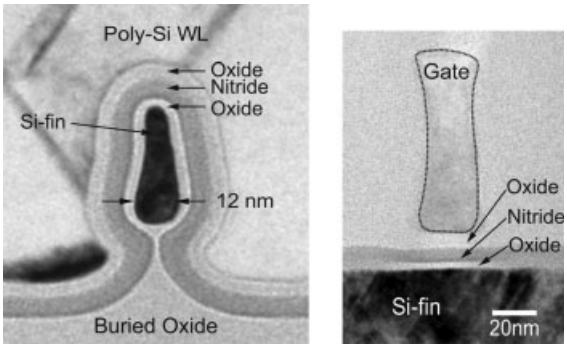

Figure 1.30 TEM cross-section of a tri-gate memory cell with 12 nm fin width and ONO dielectric.

20 nm gate length [29]. During an applied gate voltage of +12.5 V, 2 ms, electrons are injected and shift the I–V_g curves to positive voltages (write) (see Figure 1.31).

A V_t shift of about 4 V (write) was obtained using a fin width of 12 nm at gate lengths of 80 to 20 nm. The application of a negative gate voltage (erase) of 11 V, 2 ms, injects holes into the nitride layer or detraps electrons and shifts the I-Vg curves back to low V_t.

Due to the large V_t shift, multi-level storage becomes also feasible. Four levels with about 1 V separation have been programmed in the 40-nm memory transistor. The charge of one level corresponds to about 100 electrons.

The retention time for the charge-trapping dielectric has been tested, and a programming window of 3.6 V for single level was extrapolated after 10 years. Excellent retention properties between all levels are observed (see Figure 1.32).

If operated in a 4–5 F^2 high-density array such as NAND, the tri-gate cell would enable memory densities up to 32 Gbit at a die size of 130 mm^2 for the 25-nm node. A schematic NAND layout is shown in Figure 1.33. Finally, scaling is limited by the thickness of the two oxide–nitride–oxide layers, plus the minimal gate electrode thickness between the fins.

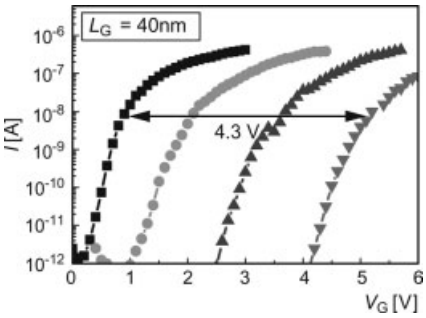

Figure 1.31 Write characteristics of a tri-gate memory cell with 40 nm gate length and multi-level operation. The different symbols represent write voltages between 0 V and 4.3 V.

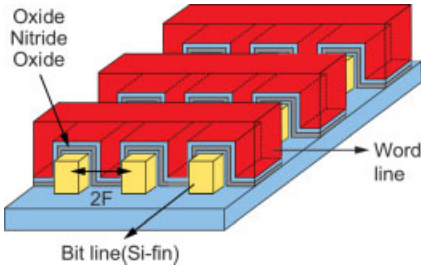

Figure 1.33 4 F^2 NAND array with tri-gate memory cells.

1.7 3d-DRAM Array Devices: RCAT, FinFET

For DRAMs, extremely low leakage current array devices below 1 fA per cell are required in order to avoid too-high charge losses during the refresh time interval. A contribution to the leakage current originates from the sub-V_t current of the cell transistor, while others are junction leakage and tunneling currents through the dielectric of the storage capacitor. With respect to the cell transistor, the channel doping cannot be increased in order to improve the turn-off characteristics, because of the electric field, which will initiate trap-assisted tunneling leakage currents [30] at $E > 0.5\,MV\,cm^{-1}$. Therefore, the planar DRAM cell transistors can be scaled down only to about 70 nm [30]. A schematic and a SEM cross-section of the 70-nm trench DRAM cell are shown in Figure 1.34.

For future applications, new cell transistor structures must be implemented. For stack DRAM cells, the transition to a recessed channel array transistor (RCAT) has already been reported for the 90- to 80-nm generation [31]. Such a device, with a U-shaped groove etched into silicon with a depth of about 200 nm, is shown in

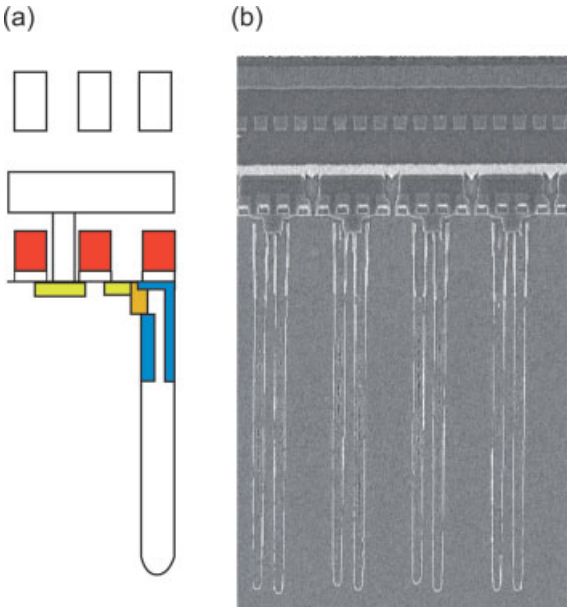

Figure 1.34 (a) Schematic cross-section of a trench DRAM cell with planar cell transistor and buried strap capacitor node contact [30]. The yellow rectangle indicates a n+ doped region in p-well; the red area is the gate (wordline); the blue is an isolation oxide. The other line is the bitline and the second wordline on top. (b) SEM cross-section of the 70-nm trench DRAM cell [30].

Figure 1.35 [32]. After gate dielectric growth, the groove is filled with the poly-silicon gate material. Bitline and storage node contacts are on the planar silicon. Such a structure is suitable for sub-70-nm generations because it provides a longer channel for lower I_{off} currents. In this Extended U-shape Device, a gate wrap-around the Si sidewalls with a depth of 6–10 nm increases the on-current and improves the subthreshold slope. The 3d device has been integrated into a 90-nm DRAM test array [32]. Simulation and measurement are shown in Figure 1.35b, with and without a corner device of about 6 nm. The subthreshold slope is in the range of 95 to 130 mV dec^{-1} at 85 °C, and the side gates enhance the on-current by 30%.

Reducing the width of the cell transistor to sublithographic dimensions and utilizing deeper vertical sidewalls leads to a fully depleted FinFET device with improved electrostatic control and increased on-currents [32]. A schematic cross-section in bitline direction of a trench cell with a FinFET array transistor, together with a SEM cross-section of a realized structure in 90 nm technology, are shown in Figure 1.36. The fin has a width of about 20 nm and a height of 50 nm. The transistor has been implemented using a local Damascene technique for fin and gate. The local gates are connected with a WSi wordline, which is also used for the gate layer of the planar transistors in the periphery circuits. The body is connected to the substrate and isolated to the neighboring fin with Sallow Trench Isolation.

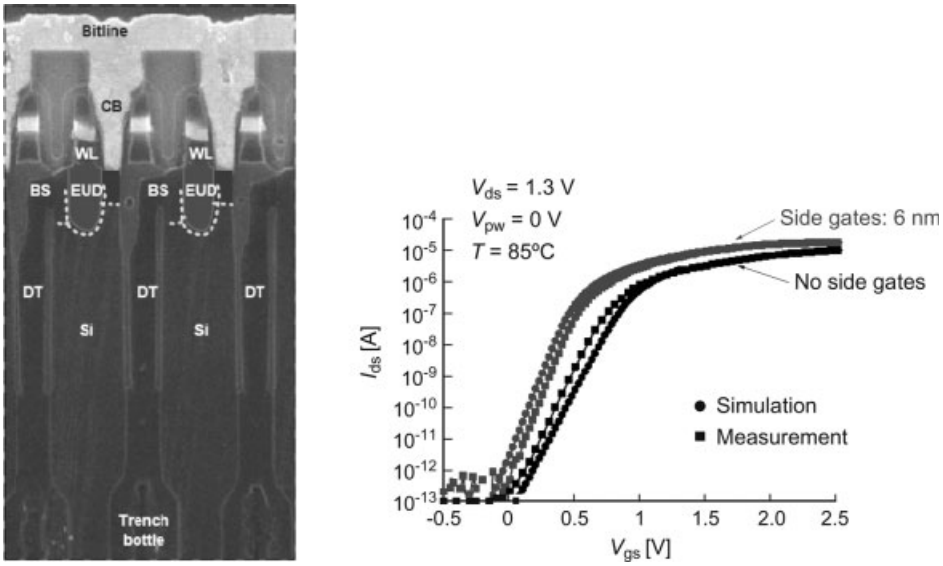

Figure 1.35 (a) SEM cross-section along bitline of a 90-nm trench DRAM cell with Extended U-Shape Device [32]. (b) Measurement and simulation of the *I–V* characteristics of the Extended U-Shape Device with and without 6-nm side gates at the corner [32].

A steep sub-threshold slope of 77 mV dec^{-1} without any drain-induced barrier lowering and back bias effect has been measured [32] in a 90-nm demonstrator (see Figure 1.37). According to simulations, the high I_{off}/I_{on} ratio will be maintained at least down to 40 nm, with a subthreshold slope of 89 mV dec^{-1} and without any remarkable influence of the adjacent trench cells, which can disturb the potential in the array device.

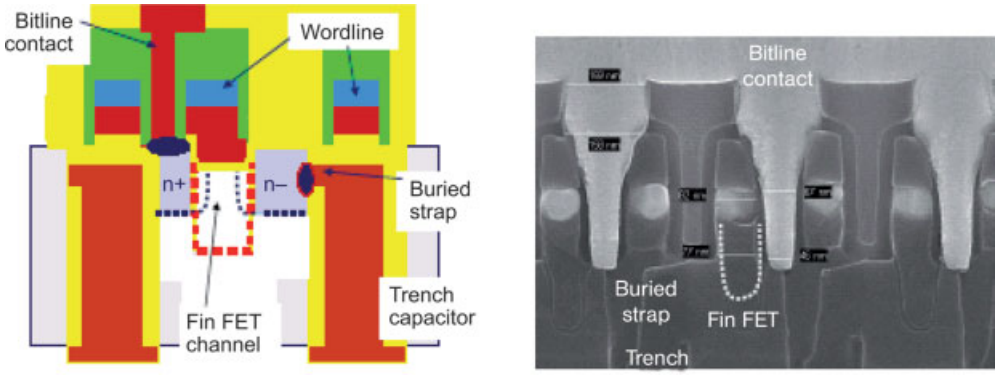

Figure 1.36 Trench DRAM with a FinFET-type cell transistor [32].

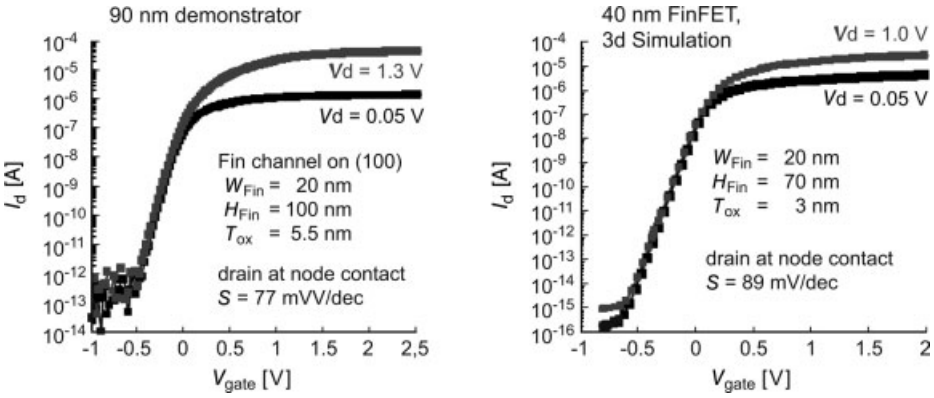

Figure 1.37 Measured FinFET array device *I–V* characteristics in a 90-nm trench cell demonstrator and simulation for 40 nm.

1.8 Prospects

Assuming that lithography tools such as Extreme Ultra-Violet will be available for the sub-45-nm technology nodes, it seems very likely that the scaling of Si CMOS will continue down to the 22-nm node, with the start of production in the year 2016, according to the ITRS roadmap. In this scenario – which is known as *More Moore* – technology costs must be reduced per chip from generation to generation, and performance must be increased. This will be expected especially for memories and microprocessors, and in order to fulfill these requirements more challenging new process modules, such as metal gate, high-*k* dielectrics, and strain will need to be integrated with high yield and in good time. On the other hand, conventional bulk CMOS may run into performance constraints below the 45-nm generation. Multi-gate devices with thin silicon channels and better electrostatic control may take over and will allow further downscaling, but with more complex processing. For DRAMs and Flash, the integration of such 3d transistors with very low leakage currents has already been started. Ultimately, beyond 10 nm the process tolerances and variability of the electrical parameters will become the most limiting factors. In addition, with the consistently good scaling potential of Si MOSFETs, many applications such as low-frequency RF, analogue, and powerFETs, displays and sensors do not require extremely small feature sizes. Therefore, additional functionality on the chip – referred to as *More than Moore* – will be another key trend.

Another important issue is the increasing research into new logic and memory devices. Among these are the 1d wire structures of Si, Ge or carbon with source, drain and gate, such as Si MOSFETs. These devices show similar *I–V* characteristics to Si (or even better), depending on the normalization of the current on the small width of the devices. However, the manufacturability and integration on a large scale has still

to be proven, and the key for success would be the integration capability with Si CMOS.

With regards to memories, many promising new concepts have appeared, based on new materials such as the storage element. Among these are included non-volatile memories, with a large change in resistance, such as Phase-Change or Conductive Bridging. These memories can be combined very well with a Si access transistor and CMOS circuitry. With these evolutionary elements, non-conventional CMOS represents the most realistic approach for high-density logic and memories, and will undoubtedly represent the dominant technology of the nanoelectronics era.

Indium Arsenide (InAs) Nanowire Wrapped-Insulator-Gate Field-Effect Transistor

Lars-Erik Wernersson, Tomas Bryllert, Linus Fröberg, Erik Lind, Claes Thelander, and Lars Samuelson

2.1
Introduction

Semiconductor nanowires [1–9] offer the possibility to form a new class of semiconductor device. Nanowire technology enables new material combinations and also the possibility to enhance the potential control in down-scaled channels using wrap-around gates. As the lateral dimensions of semiconductor materials are scaled down towards 100 nm and below (which can be easily achieved with the nanowire technology), fewer constraints become apparent in terms of lattice matching between materials. This opens the path to a heterogeneous materials integration that cannot be accomplished with conventional bulk semiconductor technology. For example, it has been shown that segments of InP can be incorporated in indium arsenide (InAs) nanowires [10], and that InAs nanowires can be grown on Si substrates [11], in spite of about 3.5% and 7% lattice mismatch, respectively. These material combinations cannot be synthesized in the bulk, nor with planar epitaxial techniques. The second advantage is related to the challenges that the technology is facing as the planar transistors are scaled down towards the 22 nm node and beyond. At this length scale, the transistors are more sensitive to short-channel effects related to the reduced potential control in the channel and the body of the devices. This is reflected in an increased output conductance and sub-threshold swing of the transistors that degrade the transistor performance. Dual gates, trigates and FinFETs have been demonstrated to reduce these issues. Taking the technology one step further is to completely surround the channel with a wrapped gate, and for this technology vertical nanowires are ideal.

Several groups have reported on the successful fabrication of vertical nanowire transistors [12–22]. Various implementations of Si transistors have been reported and, in particular, it has been shown that the wire geometry may be used to fabricate different advanced transistors with benefits in sub-threshold characteristics and switching behavior. The present authors' effort has been focused on the vertical

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

implementation of III–V transistors, and in the following sections are described the processing and characteristics of both long- and short-channel transistors. The importance is also demonstrated of introducing a high-*k* dielectric, its influence on the device characteristics, and the benefits of heterostructure design.

2.2 Nanowire Materials

In these studies, InAs has been the primary choice of material in the transistors. For various reasons, wrap-gate transistors based on silicon will naturally have a very strong standing, due primarily to the compatibility with silicon technology in general and also to the fact that Si nanowires can be made with diameters even <5 nm and yet still be conducting. InAs, on the other hand, shows very strong lateral confinement effects already for diameters around 30 nm, making very narrow uncapped InAs transistors depleted of charge-carriers and, in that sense, less promising. In contrast, n-type InAs has highly attractive material properties, with a reproducible Fermi-level pinning in the conduction-band, with a very high room-temperature mobility and ideal ohmic-contact properties. The remainder of this chapter focuses on the use of InAs as the active transistor channel material and the use of P-containing $InAs_{1-x}P_x$-alloys for enhancement of the transistor functionality and performance.

2.3 Processing

The nanowires used here are grown with chemical beam epitaxy (CBE), using patterned Au discs to locate the nanowire growth and to set the diameter of the nanowires (Figure 2.1). The ability to form well-defined matrices of nanowires is a key feature both for the post-growth device processing and for the transistor design, in that the number of wires determines the drive current and the transconductance of the nanowire transistor. The uniformity in length provides good starting conditions for uniform top contact formation. Typically, nanowire matrices ranging from 1×1 to 10×10 are used to form the vertical transistors in order to reach drive currents approaching 10 mA, but a nanowire transistor may be defined by anything from a single wire to, say, 10^4 wires. Outside the active transistor region, smaller arrays of nanowires are formed to create alignment markers for optical lithography in the post-growth processing described below. The seed for these wires are formed in the same seed and growth steps as the actual transistor wires.

After the growth, either long-channel or short-channel transistors may be formed by processing the transistors in two different ways, as shown in Figures 2.2 and 2.4, respectively [15–22]. For the long-channel transistors, the vertical nanowire matrix is first covered by a SiN_x gate-dielectric layer, followed by a sputtered Ti/Au gate metal that is covering the nanowires uniformly. The sample is spin-coated by a photoresist, which is back-etched to the desired gate length, after which the gate metal is

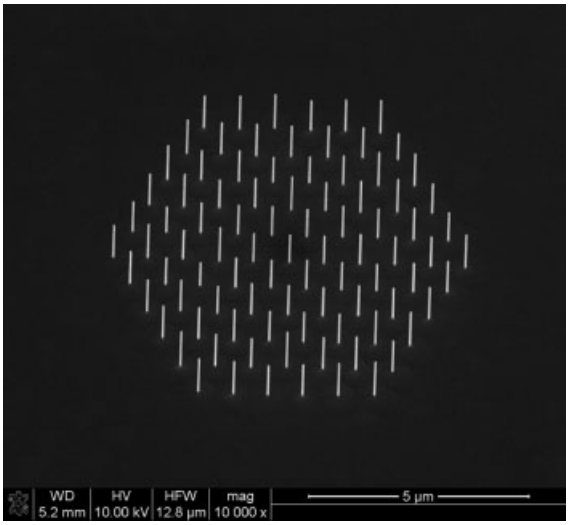

Figure 2.1 Scanning electron microscopy image of a nanowire matrix grown by chemical beam epitaxy.

selectively removed by wet-etching. After removal of the resist, the sample is covered by a second resist layer and the SiN_x is etched to open for formation of the drain Ti/Au top contact by evaporation. Finally, an airbridge is created by electroplating from the drain contact, and the resist is dissolved. With this technology, the transistor structure shown in Figure 2.3 is formed. While this technology provides good long-channel devices, in which fluctuations in the gate-length are less important due to the smaller relative change, is seems difficult to reproducibly scale the definition of the

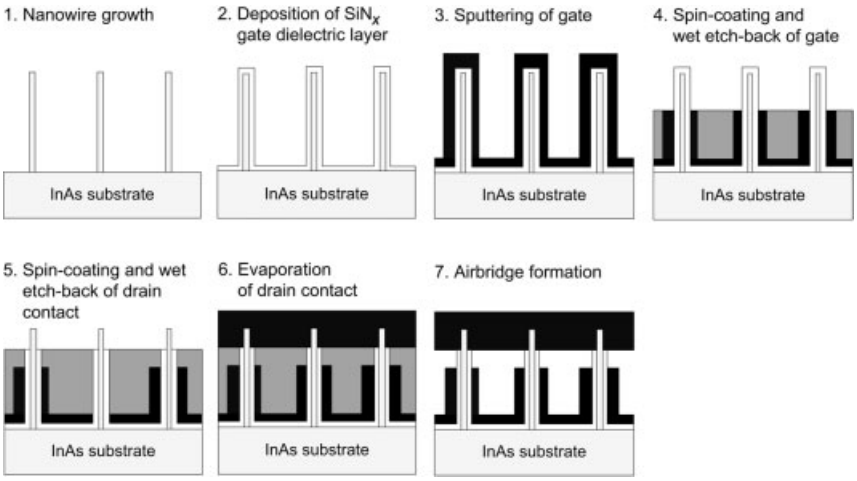

Figure 2.2 Processing scheme for long-channel transistors with sputtering and back-etching.

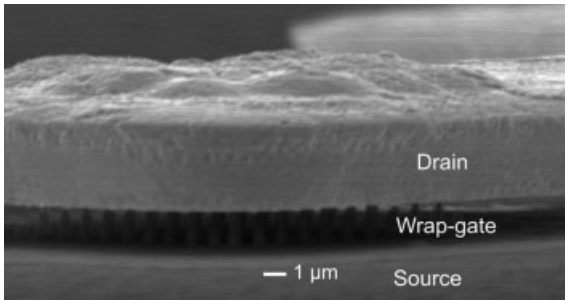

Figure 2.3 Scanning electron microscopy image of wrap-gate transistor with air-bridge drain contact [15].

gate-length below 100 nm when using this back-etch process. Instead, a direct evaporation method is used to form gates with a length below 100 nm, as described next.

For the processing of short-channel transistors, a direct evaporation of the gate metal has been developed. In this process, the metal gate is evaporated onto the SiN_x-covered nanowires, the main benefit of this approach being that the gate-length is determined by the thickness of the evaporated layer. This is in contrast to the previously described long-channel process, where it is set by the thickness of the back-etched polymer film. A scanning electron microscopy (SEM) image of a formed 80 nm-thick gate is shown in Figure 2.5. As can be seen in the image, an intimate contact is formed between the gate layer and the nanowire. Following gate formation, the drain contact is formed by spin-coating the sample with a resist and wet etching of

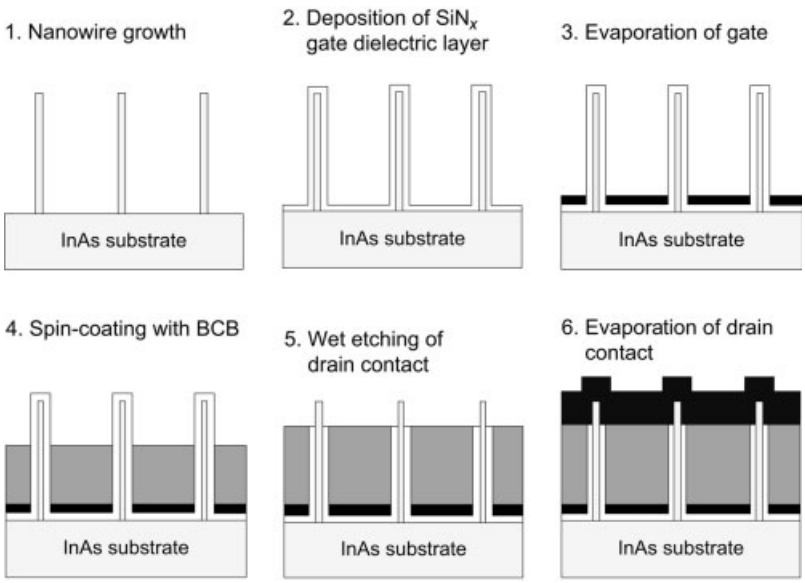

Figure 2.4 Processing scheme for short-channel transistors with evaporation of the gate [21]. BCB = benzocyclobutane.

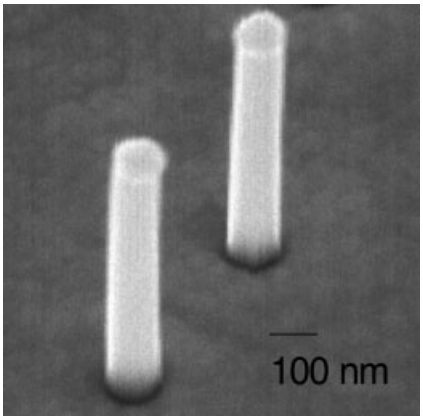

Figure 2.5 InAs nanowires coated with SiNx penetrating an evaporated Ti/Au gate electrode [15].

the tips of the nanowires that penetrate the organic film. Finally, an evaporated drain top contact is formed over the wires.

2.4 Long-Channel Transistors

The long-channel transistors have been characterized using the substrate as a grounded source contact. The data for a 10×10 nanowire matrix with a gate length of 800 nm, a wire diameter of 80 nm, and a thickness of 40 nm in the SiN_x-layer is shown in Figure 2.6. The transistor shows a good current saturation already at low drain biases $V_{sd} = 0.2\,V$ and a transconductance of about 1 mS. At larger drain biases ($V_{sd} > 1\,V$) the transistor shows an increase in the drain current, most likely related to impact ionization processes in the InAs channel. In order to explain the transistor operation, the transistor structure is modeled as a cylindrical version of the planar metal-insulator-semiconductor field-effect transistor (MISFET), as shown in Figure 2.7. In the MISFET, the gate potential is used to deplete carriers in the channel and thus to modulate the conducting area in the cross-sectional core of the nanowire. As the gate length is a factor ten-fold larger than the diameter of the wire and the thickness of the dielectric, a good potential control is obtained in the channel, and this is reflected in the measured low-output conductance of the transistor.

The long-channel transistors show the expected $I_{sd} \sim {V_g}^2$ dependence, as demonstrated for a 40-nanowire transistor in Figure 2.8. From these data the threshold voltage is deduced to be $V_t = -0.16\,V$. From the analytic fitting in Figure 2.8, values are deduced for the carrier concentration and the mobility ($N_d = 3 \times 10^{17}\,cm^{-3}$, $\mu = 9600\,cm^2\,V^{-1}\,s^{-1}$). The sub-threshold characteristics of the transistor are shown in Figure 2.9. At $V_{sd} = 0.2\,V$ an inverse sub-threshold slope of 100 mV decade^{-1} was measured, and a maximum current on-off ratio above 1000. To further verify the mode of operation in the transistor, the transistor characteristics were also simulated

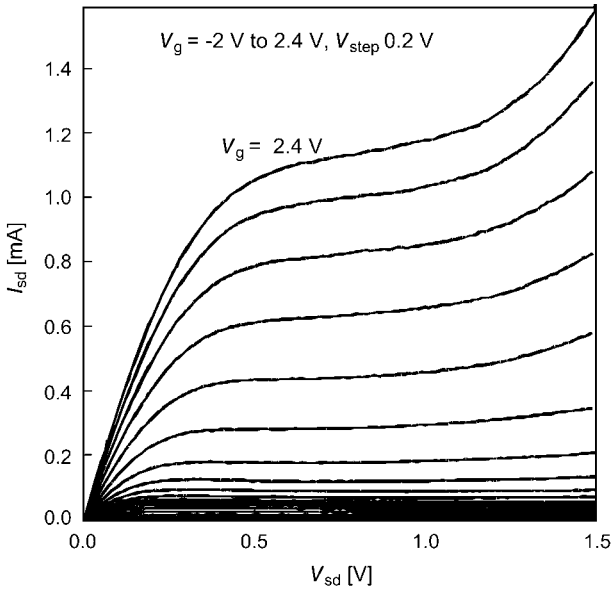

Figure 2.6 Measured *I–V* characteristics for an InAs long-channel NW-transistor [16].

using the Atlas device simulator created by Silvaco [16]. As these devices have a long channel length and a wide diameter, effects related to lateral quantization, doping fluctuations and ballistic transport may be omitted, and the transistors may be modeled within the drift-and-diffusion formalism. The simulated data in Figure 2.9 are obtained for $N_d = 2 \times 10^{17}\,\mathrm{cm}^{-3}$ and $\mu_e = 10\,000\,\mathrm{cm}^2\,\mathrm{V}^{1-1}\,\mathrm{s}^{-1}$, and reproduce the measured data both in the on-state and in the off-state. Thus, the measured data may be reproduced both by analytical modeling and by simulation in a MISFET model.

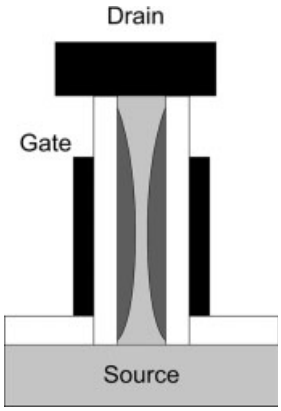

Figure 2.7 Schematic illustration of nanowire MISFET operation.

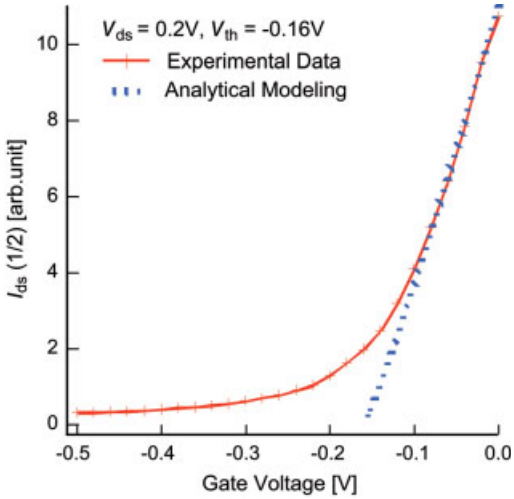

Figure 2.8 Measured transfer characteristics with analytical fitting to deduce the threshold voltage [16].

2.5 Short-Channel Transistors

Scaling is of importance to any FET-technology, and for the nanowire FET the scaling of both the gate length and nanowire diameter must be considered. The processing outlined above has been used the to fabricate transistors with 80 nm nominal gate length [19, 20]. During the growth of these nanowires, matrices with different nanowire diameters (70 and 55 nm) have been included on the same sample. Both types of nanowire transistor were processed in the same batch, and the transistor characteristics compared (see Figure 2.10). In both cases, good transistor characteristics were observed, with both transistors showing a limited current saturation, even

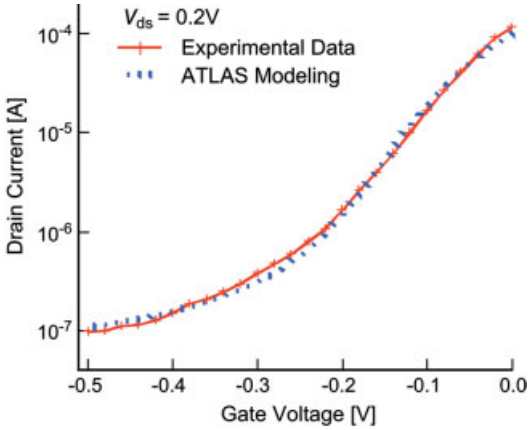

Figure 2.9 Measured and simulated sub-threshold characteristics for a long-channel transistor [15].

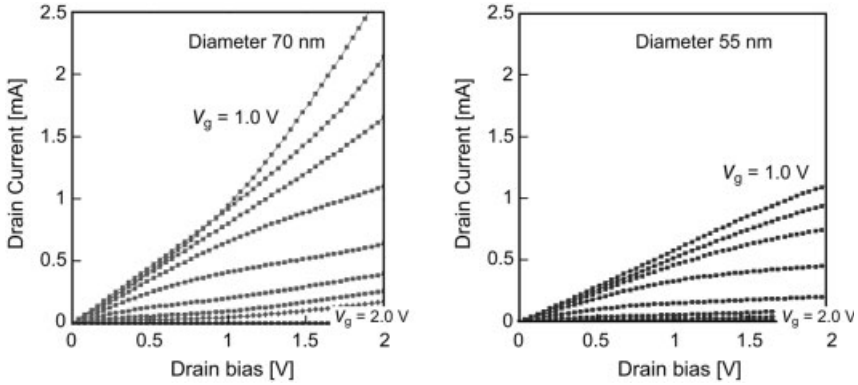

Figure 2.10 Measured transistor characteristics for 80 nm gate-length NW-transistor with 70 nm (left) and 55 nm (right) diameters [20].

at comparably large drain voltages. The increased saturation voltage arises from a series resistance in the 1 μm separation between the gate and the drain. For biases above 1 V, the larger-diameter transistors show a punch-through in the characteristics, a feature that was not observed in the narrower transistors that have a better potential control. When the drain current was normalized with the circumference of the nanowire, only a minor drive current reduction per gate width was observed as the diameter was reduced; this demonstrates good scalability in the technology.

In order to scale the gate length further, the relatively thick SiN_x dielectric was replaced with 10 nm HfO_2, a material with a higher dielectric constant (15) (Figure 2.11) [21, 22]. The HfO_2 was deposited using atomic layer deposition (ALD), which gives a uniform dielectric coverage and a very accurate thickness. A 100-nm layer of silicon oxide was also deposited, to act as a lower-k spacer layer between the InAs substrate and the wrap-gate. Next, a 50-nm Cr gate layer was formed by metal evaporation. Finally, a 100- to 200-nm-thick polymer layer was deposited on top of the gate to provide insulation between the gate and the drain contact. Despite a very short gate length (50 nm), considerably improved dc characteristics were observed compared to previous device designs. Transconductance values up to 0.8 S mm^{-1} were obtained ($V_{sd} = 1$ V), with an inversed sub-threshold slope around 100 mV dec^{-1}. The transconductance values were in this case normalized to the total nanowire circumference for the array. In addition to a gate swing of 0.5 V, an I_{on}/I_{off} ratio >1000 at $V_{sd} = 0.5$ V following the conventional definition [23] was observed, whereas a maximum I_{on}/I_{off} ratio above 10^4 was measured.

2.6 Heterostructure WIGFETs

The wrap-gate transistors show a good on-state characteristics, but even the long gate transistor characteristics suffer from a comparably large inverse sub-threshold slope (100 mV dec^{-1}) and a non-negligible off-state current. This is worse for the devices

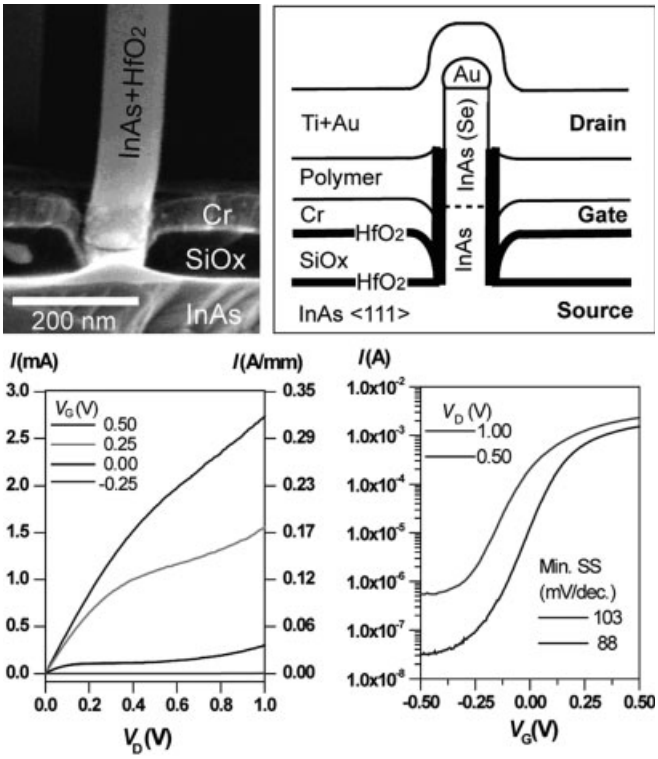

Figure 2.11 (Top left) A cross-section of a test sample showing the SiOx spacer layer, and the Cr wrap gate. (Top right) Illustration of the device design for an individual nanowire element in an array. (Bottom left) Output characteristics for a 61 nanowire wrap-gate array. with a short gate and a comparably thick (40 nm) gate-dielectrics. The transistors with high-*k* gate oxides also show effects related to the narrow InAs band gap that allows for impact ionization processes and thus creates a limited potential barrier in the off-state. The nanowire technology offers alternative transistor designs in that heterostructure segments may be incorporated into the transistor channel to alter the band gap in critical regions. A segment of InAsP was introduced into the InAs channel of a nanowire transistor and the role of the barrier in transistor performance subsequently investigated [24]. A 150 nm-long segment of InAsP was introduced into a 4 μm-long, 50 nm-diameter InAs nanowire grown by CBE. The nominal P content in the InAsP segment was 30%, and the conduction band barrier 180 meV. The nanowire was placed in a lateral geometry with a Si/SiO_2 back gate, where two drain contacts and one source contact was used in order to fabricate and evaluate transistors with the same geometry differing in only the InAsP barrier (Figure 2.12). Room-temperature data for the two types of transistor are shown graphically in Figure 2.13.

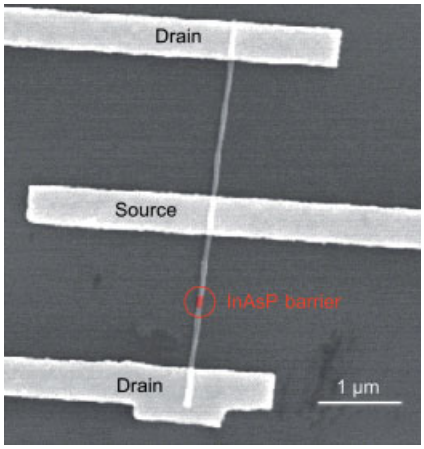

Figure 2.12 Scanning electron microscopy top image of lateral heterostructure nanowire transistor [23].

Both transistors showed good characteristics with current saturation and a decent drive current level. For a given bias condition ($V_{sd} = 0.3$ V and $V_g = 2.0$ V) the InAs transistor had a factor 2:1 higher drive current than the InAsP transistor. This was expected due to the introduction of the barrier. From the transfer characteristics, however, it should be noted that the current reduction was not related to a degradation in the transconductance, but rather to a shift in the threshold voltage. In fact, the measured transconductance remained constant, and for a fixed gate-overdrive the drive current was the same. When turning to the sub-threshold characteristics, major improvements were noted in both the inverse sub-threshold slope and the maximum I_{on}/I_{off} ratio as the barrier was introduced. Finally, temperature-dependent measurement of the current level was used to verify the presence of the barrier and to evaluate its height (Figure 2.14). The role of the barrier in this geometry is not only to block the off-current in the body of the wire, but also (and even more in this lateral geometry) to block the leakage current along the edges of the wires.

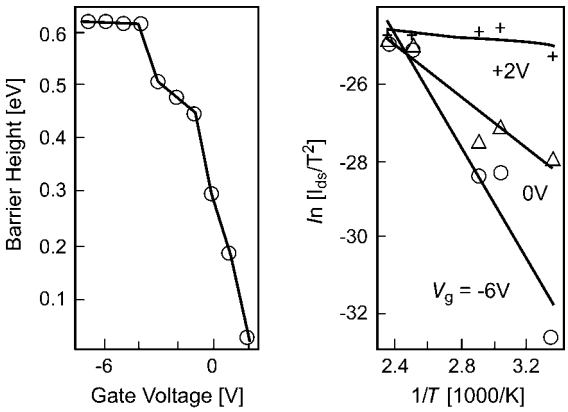

Figure 2.14 Deduced activation energies for varying gate bias (left) and the corresponding Arrhenius plot (right).

2.7 Benchmarking

It is of great value to perform an early evaluation of the potential in this new wrap-gate transistor technology. Hence, the performance of 100 nm gate-length transistors (structure shown in Figure 2.15) has been simulated and the characteristics evaluated according to the metrics of high-performance logic devices, including the gate delay

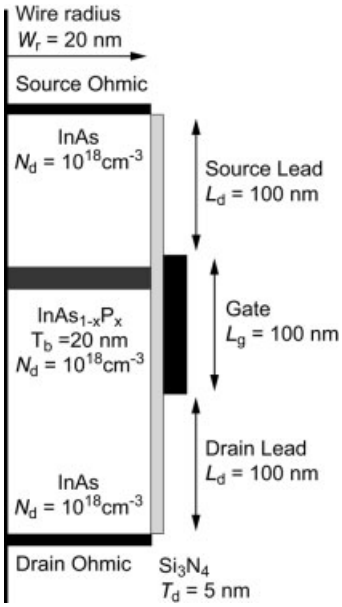

Figure 2.15 Schematic of nanowire geometry used for the bench-marking [25].

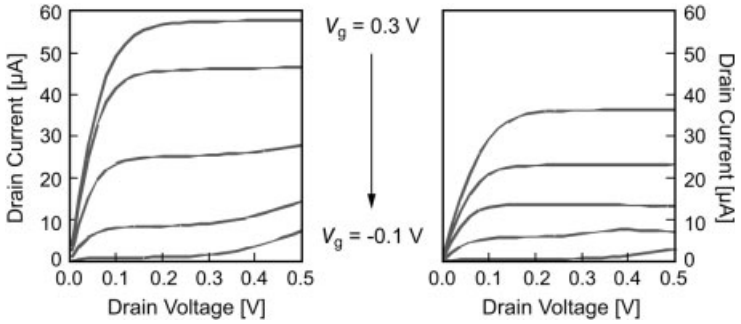

Figure 2.16 Simulated *I–V* characteristics for InAs nanowire wrap-gate transistor (left) and InAs/InAsP nanowire wrap-gate transistor (right) [25].

($\tau = C_{gg} V_{ds}/I_{on}$), the energy-delay-product ($EDP = \tau C_{gg} V_{ds}^2$), the current I_{on}/I_{off} ratio, and the inverse sub-threshold slope [25]. InAsP barriers with different P contents were further introduced into the InAs channel as a way of reducing the off-current, in analogy with the lateral devices previously described. In these simulations, the wire diameter was set to 40 nm and the doping level fixed to $1.0 \times 10^{18}\,cm^{-3}$ in order to obtain usable threshold voltages around $V_t = 0\,V$ and to avoid parasitic access resistance in the source and drain leads. The mobility was set to $10\,000\,cm^2\,V^{-1}\,s^{-1}$ and v_{sat} to $3 \times 10^5\,m\,s^{-1}$, in accordance with the fitting in Figure 2.9. The simulated output characteristics are shown in Figure 2.16 for a pure InAs channel and for a channel with a barrier of 20% P, respectively. Both types of transistor showed a good saturation already at about $V_{sd} = 0.1\,V$, which was a reflection of the low access resistance and the possibility of achieving excellent ohmic contacts to InAs. Obviously, the drive current for fixed gate bias was reduced by a factor 1.5 as the 20% barrier was introduced.

By evaluation of the transfer characteristics (Figure 2.17), this reduction in the drive current was found to be mainly related to a positive shift of the threshold

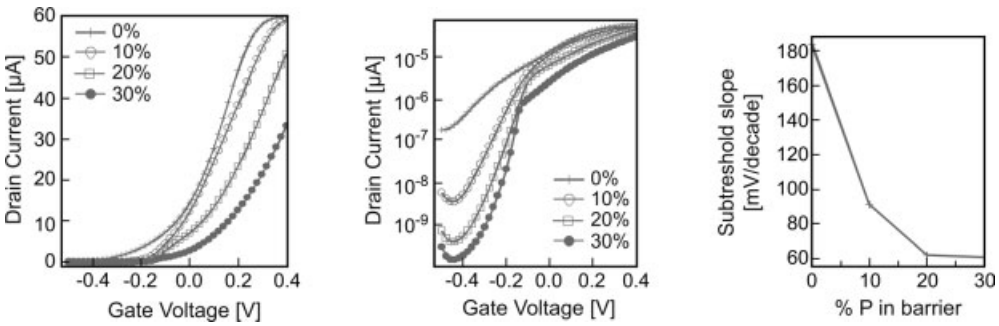

Figure 2.17 Simulated transfer characteristics (left), sub-threshold characteristics, and deduced inverse sub-threshold slope (right) for InAsP nanowire transistors with varying P content [24].

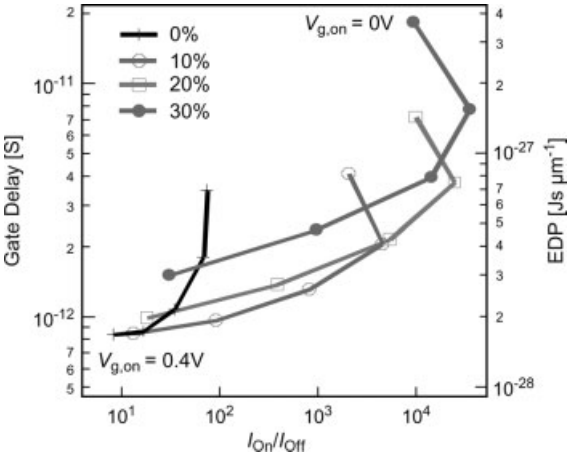

Figure 2.18 Deduced gate delay and energy–delay product as function of current on/off ratio for InAsP nanowire transistors with different P content and at varying bias conditions [25].

voltage, whilst there was only a minor degrading in the transconductance. On a logarithmic scale, it should be noted not only that the barrier provides a way to shift the threshold voltage, but also that the transition from the exponential to the linear characteristics becomes sharper, the current on/off ratio increases, and the inverse sub-threshold slope is reduced. All of these factors reduce the power consumption in circuits. The deduced critical metrics – that is, the gate delay, the energy delay product, the current on/off ratio, and the inverse sub-threshold swing – are shown in Figure 2.17 for various P contents in the barrier. As the threshold voltage shift with the barrier height, the evaluation is performed for various $V_{g,on}$, while the gate swing is kept constant at 0.5 V for all cases. The main point in Figure 2.18 is that the pure InAs channel provides the shortest gate delay due to the largest drive current, but also the lowest current I_{on}/I_{off} ratio related to the narrow band gap. While the introduction of the P barrier into the channel increases the minimum gate delay, it provides a way of increasing the I_{on}/I_{off} ratio to above 10^3 even for a gate swing of 0.5 V, a value required for many circuit applications. As an added benefit, the sharper transition between the on- and off-states further reduces the sensitivity to the choice of gate bias. These simulations show the potential in the technology and also demonstrate the benefit of introducing heterostructures into the nanowires.

2.8 Outlook

Based on the experimental results obtained to date, the question might be asked as to how far the nanowire FET technology may be developed? Critical issues for scaled devices are related to the growth of narrow nanowires with diameters of 10 to 30 nm and the processing of vertical gates on the 20 nm length scale. Based on experimental

results, devices processed on these dimensions seem feasible in the near future. However, in order for these devices to be competitive it will be necessary for the drive current to be increased and the parasitics reduced. Likewise, good control of the carrier concentration in the channel and in the source and drain regions will be needed, as will an understanding and control of the interface properties in capped wires. The main benefit of the wire geometry – the possibility for heterostructure design in the axial and radial directions – may well prove to be the key when addressing these issues.

Single-Electron Transistor and its Logic Application

Yukinori Ono, Hiroshi Inokawa, Yasuo Takahashi, Katsuhiko Nishiguchi, and Akira Fujiwara

3.1
Introduction

Complementary metal-oxide-semiconductor (CMOS) technology will face significant technological limitations shortly after 2010 [1], and intensive studies are currently being conducted in computational architecture, circuit design, and device fabrication to find ways to overcome this impending crisis. The major problem, especially for logic large-scale integrated circuits (LSIs), is that rapidly increasing power dissipation due to ever larger numbers of transistors and higher levels of interconnections is pushing CMOS circuits beyond their cooling limit. This points to the need for some drastic change in how LSIs are built, either at the system architecture or base device level, or both. Roughly speaking, achieving low-power operation of LSIs requires that both the total capacitance of circuits and the operation voltage are reduced, which means in turn that the number of electrons participating in the operation of some unit instruction must also be reduced. Single-electron transistors (SETs) [2–5], the characteristics of which are literally governed by the movement of single electrons, are considered to be the devices that will allow such a change. Their operation is basically guaranteed even when device size is reduced to the molecular level. Their performance, such as the peak-to-valley current ratio, improves as they become smaller. These properties are quite beneficial for large-scale integration. In addition, SETs are able not only to operate as simple switches but also to have high functionality. Many theoretical studies have been conducted to evaluate the possibility of building SET-based LSIs, and fundamental computational capability has already been proved.

In this chapter, after a brief explanation of SET operation principles and fabrication processes, some experimentally tested SET logic circuits will be introduced. In addition, the merits and demerits of the SET as a logic device will also be discussed, and some brief ideas proposed concerning SET logic circuits.

3.2 SET Operation Principle

Before considering the SEToperation principle, imagine a small conductive sphere or "island" floating over the ground. If one electron is taken from the ground and placed in the sphere, then there will be an increase in the electrostatic potential of the sphere. This is given by e/C, where C is the capacitance of the sphere to the ground and e is the elementary charge, 1.6×10^{-19} C. When the sphere – and hence C – is extremely small, the potential increase becomes significant. For example, for a nanometer-scale sphere having a capacitance C of say 1 aF (1×10^{-18} F), the increase in the potential e/C reaches 160 mV. This is much larger than the thermal noise voltage at room temperature, 25.9 mV. The potential increase prevents another electron from entering the sphere unless that electron has an energy larger than e^2/C. This phenomenon is called the *Coulomb blockade*. If the potential can be decreased by e/C, by applying an external bias, then a second electron can (but the third one cannot) enter the sphere. If this occurs by quantum-mechanical tunneling, then it is called *single-electron tunneling*. Any single-electron device, including the SET, has at least one small conductive island and its operation relies on the Coulomb blockade and single-electron tunneling.

The cross-sectional view and equivalent circuit of the SET is shown in Figure 3.1. The SET is, like a conventional transistor, a three-terminal device consisting of a source, drain, and gate. There is however an additional component, called the "Coulomb island", between the source and drain. The Coulomb island is also called

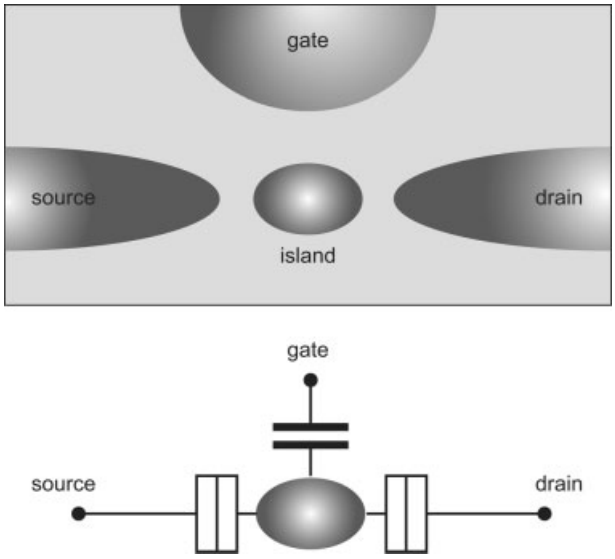

Figure 3.1 Cross-sectional view and equivalent circuit of the SET. In the equivalent circuit, double boxes indicate the tunnel junctions.

simply the island or a quantum dot. The Coulomb island must be conductive so that electrons can travel from the source to the drain via it. The role of this island is to capture/donate one electron from/to the source/drain, and otherwise to hold captured electrons. The region between the island and source (and also drain) must not be a good conductor; it must basically be insulating, so that electrons move to/from the island only by the tunneling. This region is called the *tunnel capacitor* or the *tunnel junction*. One the other hand, the region between the island and the gate should be insulating so as not to allow electrons to flow between them, as in a conventional transistor. In the equivalent circuit, the double box symbolizes a tunnel capacitor, which is a special capacitor that allows quantum mechanical tunneling of electrons, as mentioned above. The region sandwiched by the tunnel capacitors corresponds to the island, which is designated by an oval for visualization. The region between the island and the gate can be expressed as a normal capacitor.

Figure 3.2 explains what happens when the gate voltage is varied with a fixed small source/drain voltage. When a positive voltage V_g is applied to the gate, positive charges are induced there, whose number is given by C_gV_g/e, where C_g is the gate capacitance. Then, in order to minimize the free energy of the system, the SET tries to induce the same number of negative charges (i.e. electrons) in the island, and these electrons are conveyed from the source or drain through the tunnel junctions. If C_gV_g/e is some integer N, the island obtains N electrons. After reaching this number, no more electron movement occurs. This is the *Coulomb blockade state* (the left equivalent circuit in Figure 3.2). When C_gV_g/e is not an integer, for example, a half integer $N + 1/2$, the number of electrons in the island changes with time so that it becomes $N + 1/2$ *on average*. What actually occurs in the SET is as follows. First, one electron enters the island from the source and the number of electrons in the island

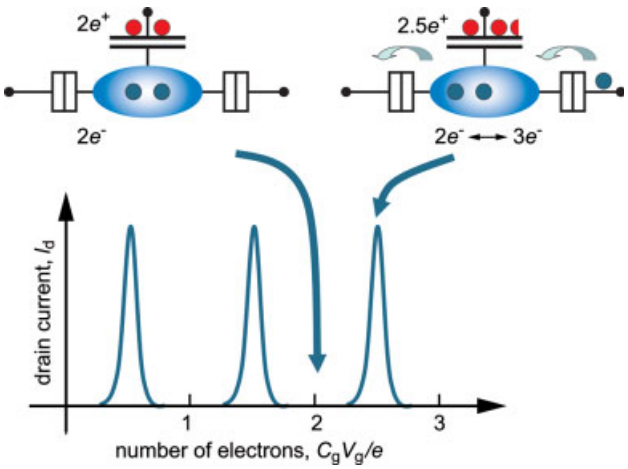

Figure 3.2 Drain current I_d as a function of number of charges C_gV_g/e induced in the gate. C_g and V_g are the capacitance and gate voltage, respectively. The equivalent circuits explain the Coulomb-blockade state (left) and single-electron-tunneling state (right).

becomes $N + 1$. Next, one electron emits to the drain from the island, resulting in N. This one-by-one electron transfer is repeated so that there is a net current between the source and drain. This is the *single-electron-tunneling state* (the right equivalent circuit in Figure 3.2). As a result, when the gate voltage is swept, the Coulomb-blockade state and the single-electron-tunneling state appears by turn, and the drain current versus gate voltage characteristics exhibit a repetition of sharp peaks, as shown in Figure 3.2. This is known as *Coulomb-blockade oscillation*. This ON-OFF characteristic indicates that the SET can function as a switching device.

For the complete description of the SET operation, consider the stability chart in the gate-voltage/drain-voltage plane in Figure 3.3. The rhombic-shaped regions colored in red are the region for the Coulomb-blockade state, and are known as *Coulomb diamonds*. Outside the Coulomb diamonds, the number of electrons in the island fluctuates between certain numbers. The degree of the fluctuation is determined by how far the voltage conditions are from the Coulomb diamonds. In the blue regions, the fluctuation is minimum – that is, the electron number changes only between two adjacent integers. These regions are for the single-electron-tunneling states. The shape and size of the Coulomb diamonds are determined only by the gate and junction capacitances. For example, the maximum drain voltage for the Coulomb blockade is given by e/C_Σ, where $C_\Sigma = C_g + C_d + C_s$ is the total capacitance of the island and C_d and C_s are junction capacitances at the drain and source. Each slope of the diamond is given by $-C_g/C_d$ and $C_g/(C_g + C_s)$.

A more detailed explanation of the SET operation can be found in textbooks [6, 7] and review articles [8, 9]. At this point, mention should be made of only one more item – which is what the SET *cannot* do. As explained above, the SET can convey electrons one by one, but the time interval of each transfer event is uncontrollable.

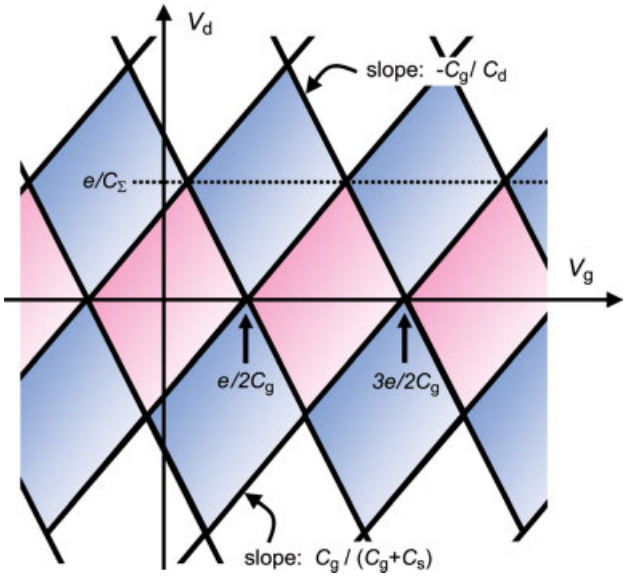

Figure 3.3 Stability chart of the SET in the gate/drain voltage plane.

This is because the transfer relies on tunneling, which is inherently stochastic. Therefore, it is difficult for the SET to transfer just one electron while preventing a second electron from being transferred. In other words, the transfer accuracy is quite low in the SET. In order to overcome this drawback, new single-electron devices have been invented and experimentally demonstrated. Sometimes called *single-charge-transfer devices*, these include the single-electron turnstile [10] and single-electron pump [11]. Although their structure is somewhat complicated (some of them possess two or more islands), they can transfer just one electron in one cycle of the gate clock, thereby providing high transfer accuracy. This function – the clocked single-electron transfer – is quite beneficial for implementing a certain level of logic architecture where one electron represents one bit. In this chapter, however, attention will be focused on the SET, and the single-charge-transfer devices and related logic styles will not be described in any detail. Very few experimental studies have been conducted on the single-charge-transfer logic circuits because of the difficulty of their fabrication. Hence, for single-charge-transfer logic, the reader is referred to review articles [8, 12].

3.3 SET Fabrication

When SETs are fabricated, two criteria should be borne in mind. First, the resistance of the tunnel junction must be sufficiently larger than the quantum resistance $R_q = h/e^2$ ($\sim$25.8 kΩ), where h is the Planck constant. Otherwise, the number of electrons in the island fluctuates because of the Heisenberg uncertainty principle. Because of this requirement, the current drivability is low, which is one major demerit of the SET as a logic element. Second, the energy for adding one electron to the island must be larger than the thermal energy. Otherwise, heated electrons tunnel through the barriers and the Coulomb blockade does not function. For example, as the temperature rises, each peak in Figure 3.2 broadens, and finally smears out. This relationship is expressed as $E \gg kT$, where E is the addition energy. The addition energy can be expressed in the form e^2/C_Σ, and thus a SET with a smaller island can operate at a higher temperature.

When the de Broglie wavelength of electrons is much smaller than the island size – which is the case of metal islands that are not too small ($\gg$1 nm) – charges are induced right at the island surface and E is determined only by the island size and the spatial configuration of the electrodes. However, when the de Broglie wavelength is comparable to the island size – typically as in the case of semiconductor islands with a nanometer size – the quantum size effect causes the kinetic energy of an electron to increase and hence E to increase. Thus, semiconductor islands can have larger addition energy than a metal island of the same size.

In order to explain how small the island must be made, Figure 3.4 shows the relationship between the island size (dot size) and the addition energy for a Si island embedded in SiO_2 dielectrics [13]. Both, the quantized level spacing and the charging energy (which can be defined as the addition energy for ideal metals) increase as the

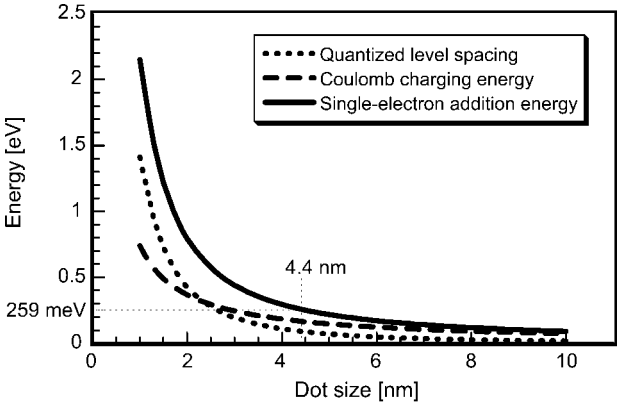

Figure 3.4 Relationship between dot size and addition energy [13].

island size decreases, and this leads to an increase in the resultant addition energy. If an addition energy 10 times larger than the room-temperature energy (25.9 meV) is required for the proper operation of a SET circuit, then an island as small as 4 nm is needed. The creation of such a small island and attaching tunnel junctions to it represents a technological challenge in SET fabrication. However, any conducting material can be used as long as the above criteria are satisfied, and an addition energy much larger than the room-temperature energy has already been demonstrated.

Historically, research into single-electron devices began with metals [4] and then expanded to semiconductors [14–18] and other materials, such as carbon nanotubes [19–22] and some molecules [23–28].

Among metals, a major material is aluminum, because its oxide functions as a good dielectric for tunnel junctions. Tunnel junctions are commonly made using Dolan's shadow evaporation technique [29]. The junction capacitance can be controlled in such structures to within 10% if the Al–AlO_x junctions have a relatively large capacitance of several hundred attofarads. Making smaller junctions is less easy, and thus electrical measurements with this material are commonly carried out below 1 K. However, it has been shown that making an extremely small SET, the island of which has an addition energy much larger than kT of room temperature, is possible [30].

Among semiconductors, Si is the most widely used material in research aimed at practical applications. Si SETs are commonly made on a certain type of Si substrate called silicon-on-insulator (SOI) [31]. In SOI substrate, a thin Si layer (typically 100–400 nm) is formed on a buried SiO_2 layer. Thinning the Si layer and reducing its size in the lateral direction by lithography enables small Si structures to be produced. It is possible to further miniaturize these structures by using thermal oxidation: Si is consumed during the oxidation, and thus the volume of the Si structures is reduced. With Si, it is relatively easy to make smaller islands compared with Al. Common measurement temperatures in Si SET research are 1 K to 100 K, and several groups have observed the Coulomb-blockade oscillation at higher temperatures (100–300 K) [13, 32–48].

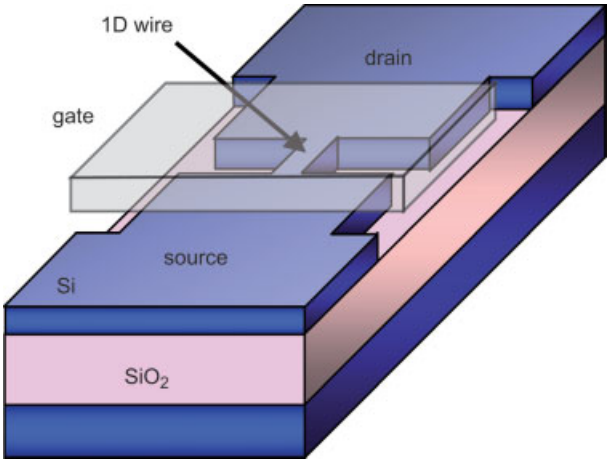

Figure 3.5 Basic device structure of PADOX SETs. The 1-D wire is converted to a Coulomb island and attaching tunnel junctions after thermal oxidation of the Si.

One reliable way of fabricating Si SETs is pattern-dependent oxidation, or PADOX [34, 49], and this has enabled the fabrication of a room-temperature-operating SET for the first time. It has been shown that the gate and junction capacitances are controllable even when their values are very small (a few attofarads) [34, 49, 50]. The PADOX method requires no special material for tunnel junctions as they are made of Si itself. PADOX exploits an oxidation-induced band modification [51], which makes it possible to produce a Coulomb island and tunnel junctions simultaneously during the gate oxidation step [52]. Figure 3.5 shows the basic structure for the PADOX SET. A one-dimensional (1-D) Si wire is converted to an island and tunnel junctions after thermal oxidation. As the name indicates, the final Si structure is dependent on the initial structures before oxidation. By elaborately designing the initial structures, a variety of SET configurations become possible [49, 53]. Figure 3.6 shows the drain current versus gate voltage characteristics of a PADOX SET measured at 27 K. Clear oscillation is observed. The PADOX method has contributed to the fabrication of many experimental SET circuits owing to its high controllability and the stability of the current characteristics.

Recent progress in the SET fabrication process has resulted in a very clear Coulomb blockade oscillation at room temperature; an example of this is shown in Figure 3.7, where a peak-to-valley ratio as large as 400 is achieved [48]. Although the working mechanisms underlining this excellent performance at room temperature are not satisfactorily understood at present, it is evident that room-temperature-operating SETs can be made. The focus of Si SET research is therefore moving from how to make room-temperature-operating SETs to how to control their size, which is still very difficult.

Carbon nanotubes are attractive for attaining small capacitance and thus high operation temperature because they have extremely small diameters of the order of a

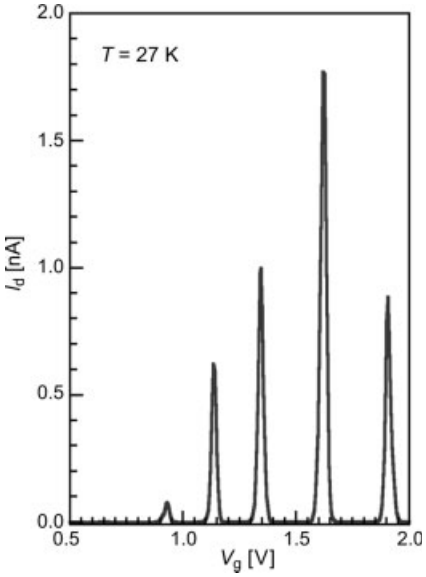

Figure 3.6 Current characteristics of a PADOX SET, measured at 27 K.

few nanometers. In the case of a 1-µm-long single-wall nanotube with a diameter of 1.4 nm suspended 100 nm above a ground plane, the addition energy E would be 8 meV, and this could be further increased by reducing the length. In fact, carbon nanotube SETs with E corresponding to this estimate have been reported [19, 20]. For practical applications, the nanotube diameter, chirality (i.e. electronic structure) and the locations of the tunnel junctions and nanotube itself must be controlled more precisely. Although these issues have already been partly addressed [21, 22], much further improvement is needed.

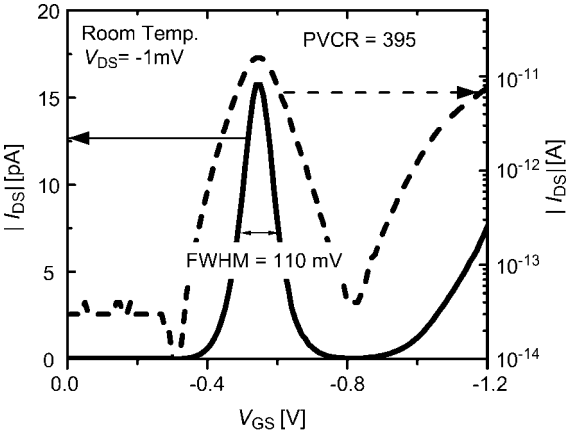

Figure 3.7 Current characteristics of a room-temperature-operating Si SET [48].

Fabrication methods that use molecules as building blocks are anticipated. In such methods, functions and characteristics are determined by chemical synthesis, without relying on lithographic techniques. Research into the charging effect or Coulomb blockade in a molecule began during the mid-1990s [23, 24], and more recently persuasive data showing conductance modulation by gate potential have been obtained [25–28]. Although the present understanding of transport in a molecule is improving, many issues of circuit integration, including architectural design, synthesis, and interfacing with external circuits, remain.

At this point, mention should be made of an infamous problem in SETs, known as the *background charge problem* [54]. Due to randomly distributed mobile and immobile charges in the dielectrics, the device characteristics may change over time and differ from one device to another. This is because SETs have a high sensitivity to charges due to their small size, and it makes the integration of SETs difficult. A typical case is seen in SETs made from metals and GaAs/AlGaAs heterostructures. For example, the characteristics of SEDs with Al–AlOx junctions change at least once a day. In order to stabilize such behavior, it may be necessary to wait for a long time after cooling down before measurements can be made [55]. The situation is similar for carbon nanotubes and some molecules, as these suffer from a large noise superimposed on the current characteristics, the origin of which is unknown.

The background charge problem is not specific to SETs, however, and may occur in any nanoscale *field-effect* device due to their high sensitivity to charges. In addition, the amount, location, and stability of the background charges are highly material- and process-dependent. In fact, it has already been shown that PADOX SETs have excellent long-term stability. The drift of the characteristics is less than $0.01e$ over a period of a week at cryogenic temperatures [56]. More practically, no noticeable change in the characteristics have been observed for more than eight years, during which time thermal cycling between room temperature and $\sim$20 K has occurred several times [57]. It has also been shown that the voltage at which the first Coulomb-blockade-oscillation peak appears is controllable [58]. These results demonstrate that PADOX SETs are not significantly influenced by slowly moving or immovable background charges, which indicates that the background charges problem is not intrinsic but rather can be solved. At present, no clear answers have been identified as to how seriously fewer fixed charges and/or faster motion of charges, which causes 1/f noise, will obstruct integration. However, it is believed that a circuit design with some degree of defect tolerance would relax the effects.

In summary, for room temperature operation, an island smaller than 10 nm is necessary. At present, Si is preferable for the SET fabrication from the viewpoints of operation stability and temperature. Some experimental data are available showing the control of the peak positions and the peak intervals in current characteristics. However, these parameters are still difficult to control in room-temperature-operating SETs. Also, there are no data showing the control of the resistance of room-temperature-operating SETs, and these points remain the subjects of future studies. A more complete description of the fabrication process for Si SETs can be found in Ref. [59].

3.4 Single-Electron Logic

Many logic styles have been proposed and analyzed for single-electron devices. Most of them can be categorized into two groups: charge-state logic; and voltage-state logic.

Charge-state logic [8, 12], which uses one electron to represent one bit, is highly specific to single-electron devices and might be in some sense the ultimate logic. Devices other than SETs, such as single-electron pumps, are building blocks. However, very few experimental studies have been reported regarding circuit operation based on this scheme because of the difficulty of the fabrication.

Voltage-state logic [60–88], which will be described here in detail, uses the SET as a substitute for the conventional MOS field-effect transistor (FET); hence it is referred to as SET logic. Although the circuit characteristics are predominated by the Coulomb blockade and single-electron tunneling, these phenomena are not directly employed for computation. Instead, the current produced by the sequence of single-electron tunnelings is used, and the bit is represented by the voltage generated by the accumulation of plural electrons. Actually, this is not a genuine single-electron logic because 10^1 to 10^3 electrons will be used in the operation. In many aspects, this logic is analogous to CMOS logic. The major advantage is that the accumulated technologies can be employed for CMOS circuit designs. However, the logic is not merely a copy of CMOS logic because the SET has completely different current characteristics from the MOSFET; that is, the current oscillates as a function of gate voltage. Some important elemental circuits such as an inverter, an exclusive-or (XOR) gate, a partial-sum/carry-out circuit, and an analog-to-digital converter, have been experimentally demonstrated [43, 46, 89–102]. Some of these will be introduced in the following three subsections.

3.4.1 Basic SET Logic

The voltage gain of the SET can be defined as for conventional transistors [5]. It is known from Figure 3.3 that when the drain voltage increases with a fixed gate voltage, a current begins to flow at the edge of the Coulomb diamond. As a result, the output drain voltage V_d for a fixed input drain current I_d exhibits a Coulomb diamond as a function of the gate voltage V_g. The measured characteristics for a Si SET are shown in Figure 3.8 (upper panel). The two slopes in the figure correspond to the inverting and non-inverting voltage gains G_I and G_{NI}. As shown in Figure 3.3, their values are determined by the capacitances as

$$G_I = C_g/C_d \tag{3.1}$$

$$G_{NI} = C_g/(C_g + C_s) \tag{3.2}$$

Although G_{NI} is always smaller than unity, G_I exceeds unity if $C_g > C_d$. Therefore, CMOS-like logic circuits can be prepared using SETs as substitutes for MOSFETs. From Eq. (3.1) it is clear that the SET must have a large C_g in order to obtain a high

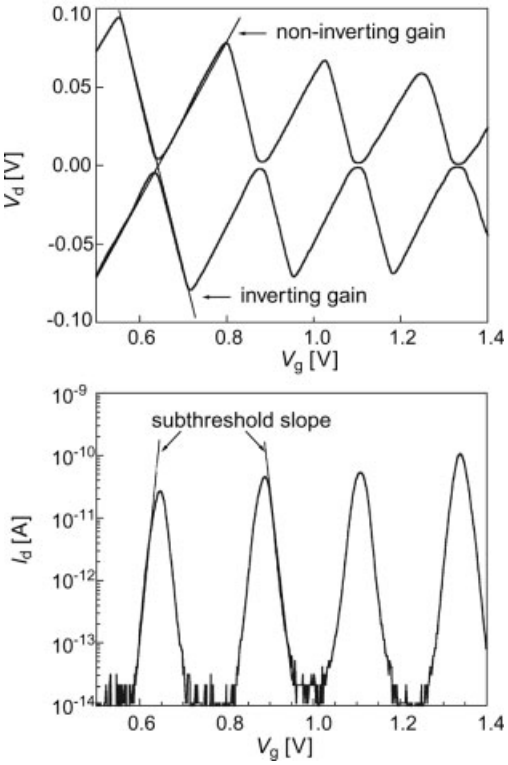

Figure 3.8 Electrical characteristics of a PADOX SET. Upper panel: Drain voltage V_d as a function of gate voltage V_g for a fixed drain current of ± 10 pA. Lower panel: Drain current I_d as a function of V_g for a fixed drain voltage of 10 mV. The measurement temperature was 27 K [50].

inverting gain, which in turn means that the total capacitance of the SET island will tend to increase. Therefore, the voltage gain and operating temperature are in a trade-off relationship and it is not easy to produce SETs with a larger-than-unity gain that operate at high temperatures. A G_I value larger than unity has been achieved in metal-based [103, 104], GaAs-based [105], and Si-based [48, 50, 106] SETs.

The current cut-off characteristics are determined by the subthreshold slope S in the I_d–V_g characteristics that rise and fall almost exponentially at the tails of the peaks. Figure 3.8 (lower panel) shows the output drain current I_d for a fixed input drain voltage V_d plotted as a function of V_g on a logarithmic scale. At a sufficiently low temperature and high tunnel resistance, S is given by

$$S = [d(\log_{10} I_d)/dV_g]^{-1} = \ln 10(C_\Sigma/C_g)kT/e \tag{3.3}$$

This equation is similar to that for a MOSFET. It also indicates that a high inverting voltage gain G_I is needed to obtain a steep subthreshold slope. Upon $C_s = C_d$, a G_I of 4 corresponds to a C_Σ/C_g of 1.5, or $S = 90\,\mathrm{mV\,dec^{-1}}$ at room temperature.

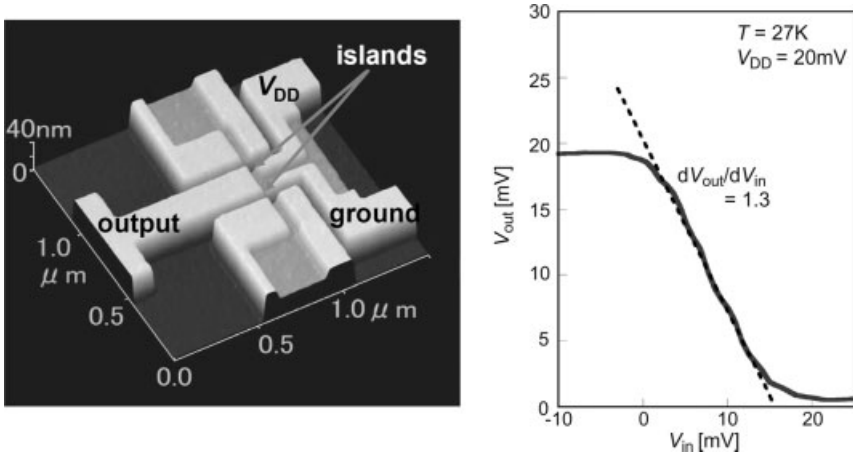

Figure 3.9 Si complementary single-electron inverter. Left: AFM image. Right: Input–output transfer curve measured with a power supply voltage V_{DD} of 20 mV. The measurement temperature was 27 K [89].

A logic circuit can be made by employing the above-mentioned voltage gain. The complementary inverter, which is the most fundamental logic element, was fabricated using Si SETs [89]. Figure 3.9 (left) shows an atomic force microscopy (AFM) image of an SET inverter made by Si. Two SETs with a voltage gain of about 2 were packed in a small (100×200 nm) area. As shown in Figure 3.9 (right), the input and output transfer curve attains both a larger than unity gain and a full logic swing at 27 K. Other complementary SET inverters, made from Al [90] and carbon-nanotube [91] have been reported, and resistive-loaded inverters have also been fabricated [92, 93].

3.4.2 Multiple-Gate SET and Pass-Transistor Logic

An important feature of SETs is that they can have *plural gates*. Such a multi-gate configuration enables the sum-of-products function to be implemented at the gate input level. That is, the total charges induced in the gates are expressed as $\Sigma C_{gi} V_{gi}$, where C_{gi} and V_{gi} are the gate capacitance and input voltage of the i-th gate. Provided that the gate input voltage V_{gi} is set to $e/2C_{gi}$, the SET is ON when the number of the ON gates is odd, and OFF when the number of the ON gates is even (Figure 3.10). This function is XOR. The SET XOR gate [65, 68] is a powerful tool for constructing arithmetic units such as adders and multipliers because XOR is nothing other than what is termed "half-sum", which is the lower order bit calculated by adding two one-bit binary numbers. The XOR gate has also been demonstrated experimentally using a Si dual-gate SET [94]. A scanning electron microscopy (SEM) image of the dual-gate SET is shown in Figure 3.11. The XOR function was confirmed in output drain current at 40 K, as shown in the figure.

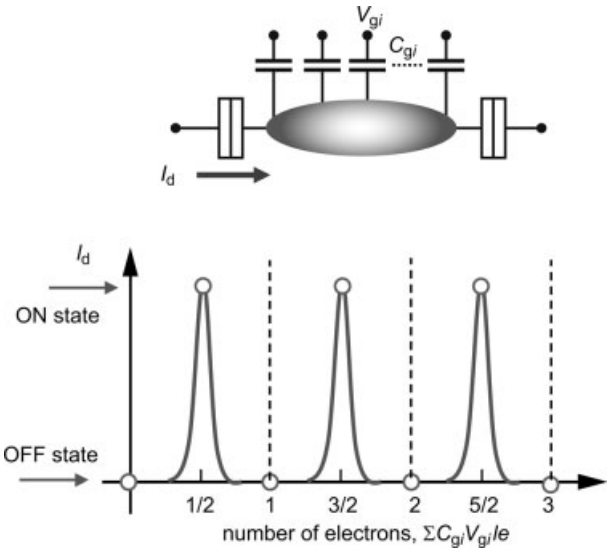

Figure 3.10 A multigate SET. Top: An equivalent circuit. Bottom: Current characteristics as a function of number of charges accumulated at the gates.

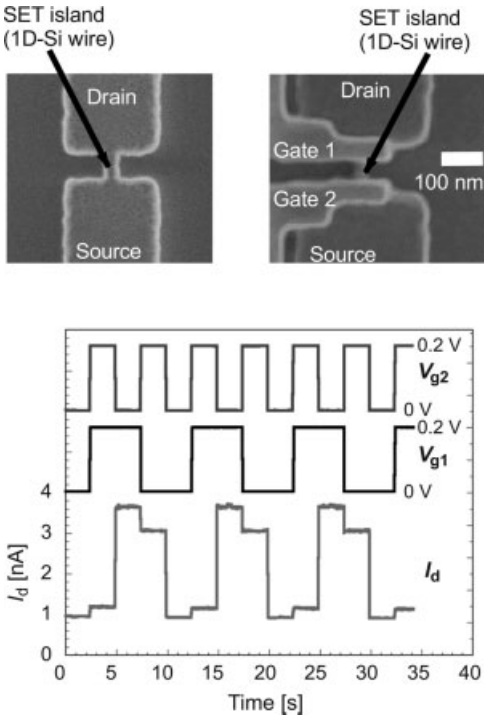

Figure 3.11 An experimental SET X-OR gate. Top: SEM images of the device before (left) and after (right) gate formation. Bottom: Output drain current for square-wave gate inputs [94].

In the multi-gate configuration, the gate capacitance for each gate is inherently smaller than that of the single-gate version. Therefore, it is more difficult to attain the larger-than-unity gain as the number of the gate increases. The CMOS-domino-type logic was proposed as a way of using SETs without a voltage gain [73]. A combinational logic circuit is built in a SET logic tree, where SETs are used as pull-down transistors. The point is that the tree is operated with a sufficiently small drain voltage in order to make the Coulomb blockade effective. The output signal is then amplified by using MOSFETs before being transferred to the next logic segment.

A single-electron pass-transistor logic, where SETs are used both as pull-up and pull-down transistors, has also been studied. The fundamental circuit of the single-electron pass-transistor logic was fabricated using PADOX SETs, and half-sum and carry-out for the half adder has been experimentally demonstrated [95, 96]. Figure 3.12 shows the equivalent circuits and the measurement data. Both half-sum and carry-out are correctly output at 25 K. What is significant here is that the gate and total capacitances, and even the peak positions of the used SETs, were well controlled for these operations. This is the first arithmetic operation ever performed by SET-based circuits. There have been attempts to construct logic elements [97–102] that operate based on the above-mentioned domino-type logic, pass-transistor logic, or the so-called binary-decision-diagram logic.

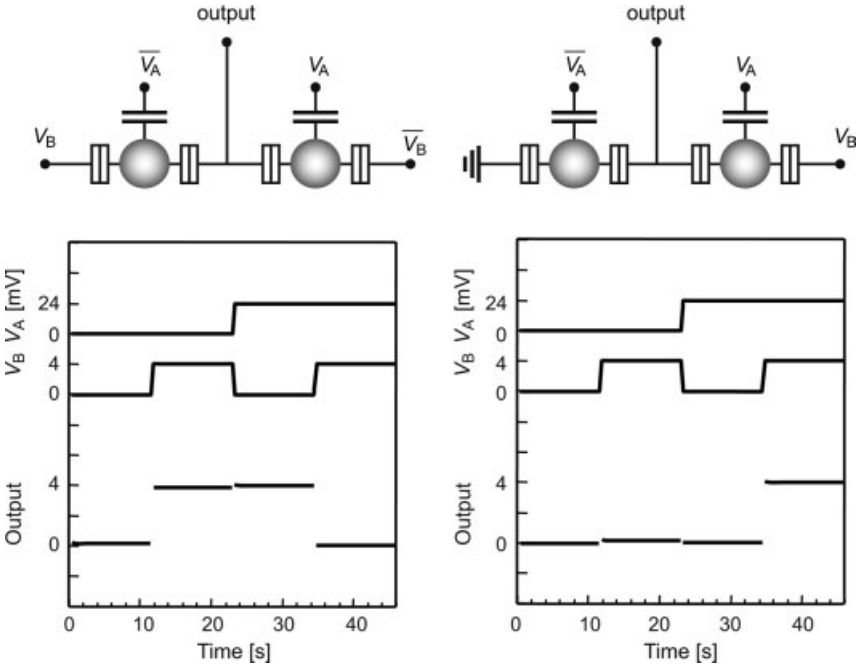

Figure 3.12 "Half-sum" and "carry-out" operations using SETs. In the equivalent circuits, V_A, V_B are inputs for addends and $\bar{V}_A$, $\bar{V}_B$ are their inverses [96].

3.4.3
Combined SET-MOSFET Configuration and Multiple-Valued Logic

In SETs, the applicable drain voltage is limited to a value smaller than e/C_Σ in order to maintain the Coulomb blockade. This may be an obstacle to driving a series of SETs and external circuits that require a high input voltage. A combined SET-MOSFET configuration has been proposed as a way to overcome this drawback [83, 85]. Figure 3.13(left) shows the equivalent circuit of the inverter based on this configuration. A MOSFET with a fixed gate bias V_{gg} is connected to the drain of a SET, and the inverter is driven by a constant current load, I_0. The MOSFET keeps the SET drain voltage sufficiently low, which helps to maintain the Coulomb blockade. As the drain voltage is almost independent of the output voltage, V_{out}, a large output voltage and voltage gain can be obtained.

The output voltage V_{out} and output resistance of the combined SET-MOSFET inverter are given by [86]:

$$V_{out} = -G_{m(SET)} R_{d(SET)} (1 + G_{m(MOS)} R_{d(MOS)}) V_{in}, \tag{3.4}$$

$$R_{out} = R_{d(MOS)} + (1 + G_{m(MOS)} R_{d(MOS)}) R_{d(SET)} \tag{3.5}$$

where $G_{m(SET)}$ is the transconductance of the SET, and $R_{d(SET)}$ and $R_{d(MOS)}$ are the drain resistances of the SET and MOSFET, respectively. The voltage gain of the SET is multiplied by that of the MOSFET, which means that the voltage gain of the SET-MOSFET inverter becomes very large because of the large voltage gain of the

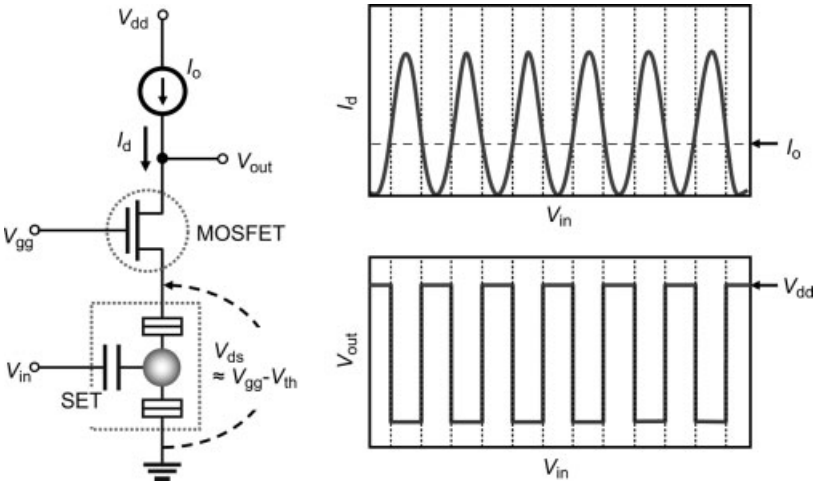

Figure 3.13 Left: Schematic of the universal literal gate comprising a SET, a MOSFET, and a constant-current load I_0. Right: $I_d - V_{in}$, and expected transfer ($V_{in} - V_{out}$) characteristics. $I_d - V_{in}$ characteristics are almost completely independent of V_{out} as the V_{ds} of the SET is kept nearly constant at ($V_{gg} - V_{th}$, the threshold voltage of the MOSFET [86].

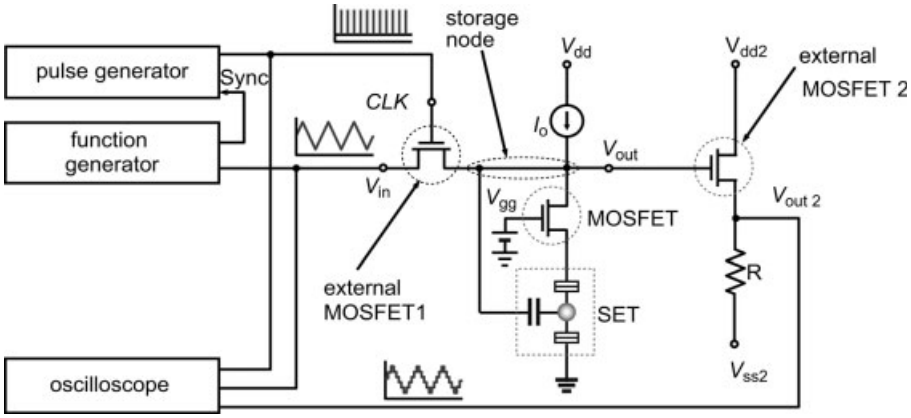

Figure 3.14 Measurement set-up for the single-electron quantizer [85]. CLK = clock.

MOSFET (see Figure 3.13, right). In fact, the measured voltage gain of the SET-MOSFET inverter was about 40 [86].

In this configuration, another important point is that the $I_d - V_g$ characteristics reflect the oscillatory I_d–V_g characteristics (Figure 3.13, right). This characteristic is referred to as the "universal literal", which is a basic unit for multiple-valued logic. Multiple-valued logics have potential advantages over binary logics with respect to the number of elements per function and operating speed. They are also expected to relax the interconnection complexity inside and outside of LSIs. These are advantageous, as they allow a further reduction in the power dissipation in LSIs and the chip sizes. However, success has been limited, partially because the devices that have been used (MOSFETs and negative-differential-resistance devices, such as resonant tunneling diodes) are inherently single-threshold or single-peak, and are not fully suited for multiple-valued logic. The oscillatory behavior seen in Figure 3.13 shows that the SET is suitable for implementing multiple-valued logic. By exploiting this behavior, a quantizer was fabricated. Figures 3.14 and 3.15 show the measurement set-up for the quantizer and the measured data, respectively. The triangular input V_{in} was successfully quantized into six levels.

3.4.4 Considerations on SET Logic

Many research groups have claimed that SETs could provide low-power circuits. In order to make clear the meaning of this claim, two parameters must first be discussed, namely information throughput I and the power density P. These parameters can be written in the following forms:

$$I = \alpha n f \tag{3.6}$$

$$P = E_{bit} n f \tag{3.7}$$

where n is the density of the binary switches, f the operating frequency, and E_{bit} the bit energy. A dimensionless parameter, α, was introduced which was referred to

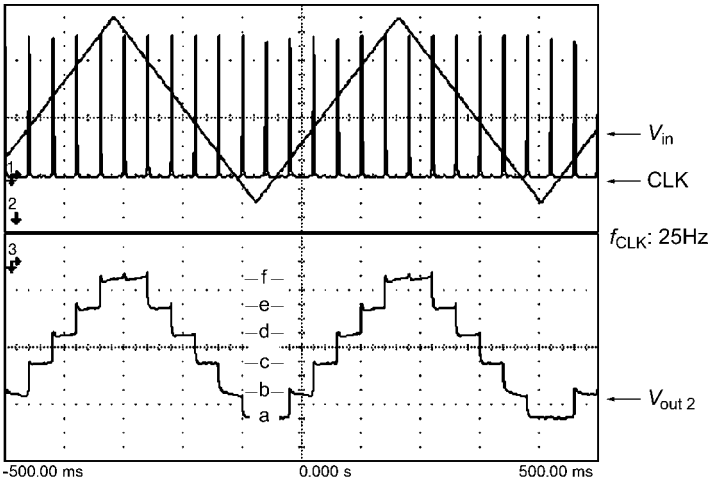

Figure 3.15 Experimental data for the single-electron quantizer [85]. CLK = clock.

as "functionality". The meaning of this parameter is simple; for example, if a transistor is available that can work more efficiently than a simple binary switch, then the information throughput can be increased. In such a case, the transistor has α larger than unity. Then, for low-power operations the aim would be to increase I while keeping P small. Therefore, an important parameter is the information throughput per power density, I/P, which is given by α/E_{bit}. A lower E_{bit} is better for larger I/P, but E_{bit} has a lower bound in order to avoid noise-induced bit errors. This minimum value is dependent on how many errors the system allows, and thus on the system architecture. However, the minimum E_{bit} will not change significantly unless the architecture is changed to an exotic version, like a neural network or fuzzy logic. Thus, the only option is to increase α. If the suggestion was to increase α on the device level, then there would be a need to depart from logic based on simple binary switches. This leads to a very important conclusion – that changing materials for the transistor channel, say, to carbon nanotubes or other molecules, is not the way to reduce dynamic power loss as long when transistors are used as binary switches. Hence, it is expected that the SET be an alternative device and would be highly functional, as shown previously in the chapter.

It should be mentioned, however, that the above discussion is rather too crude to draw any decisive conclusions. Actually, I/P does not include n and f, but indeed a large-scale integration and a fast device is needed in order to accomplish computation within acceptably short periods of time. Therefore, a more reasonable parameter may be $I^2/P\ (=\alpha^2 nf/E_{bit})$, and the size and the speed of the device need still to be discussed. At this time the static power loss should also be considered – that is, the loss due to leakage currents, which is independent of f. These points are discussed in the following sections.

It is important now to highlight once more the difference between voltage-state logic (or SET logic) and charge-state logic. The requirement for the addition energy – and hence for the island size – is different between the two. For charge-state logic, the

addition energy should be sufficiently large so as to avoid bit errors caused by thermal noise. As charge-state logic uses single electrons to represent bit information, the bit energy is given by $(1/2)C_\Sigma V^2$, where $V = e/C_\Sigma$. This is in effect the addition energy. If the bit error requirements for CMOS LSIs are assumed, then the bit energy will have to be 10^2 larger than the thermal noise energy. This means that an additional energy 10^2 larger than the room-temperature energy is needed. From Figure 3.4 it is clear that an island as small as 1 nm is needed. SET logic, on the other hand, uses the voltage generated at output terminals to represent bits, as do CMOS circuits. The bit energy is therefore given by $(1/2)C_L V^2$, where C_L is the load capacitance. If the term $V = e/C_\Sigma$ is adopted for the power supply voltage of SET logic circuits, then the bit energy is C_L/C_Σ larger than the case for charge-state logic. Therefore, for SET logic, the addition energy requirement does not come from the bit error requirement but rather from the static power loss because a small addition energy causes the valley current (i.e. the OFF-current) to increase. There is no clear guideline as to how small the OFF-current should be, because the acceptable static power loss depends on the degree of the power-saving ability of the system. If the requirement for low-operating-power (LOP) applications are adopted – as stated in the International Technology Roadmap for Semiconductors (ITRS) – the source/drain OFF-state leakage current should be on the order of 10^{-9} A μm^{-1}, which corresponds to 10 pA for 10-nm SETs. This will be achievable. It is also necessary to have a large ON/OFF current ratio and, again, considering the requirement for LOP applications, a ratio of 10^5 is needed. From this ratio, the addition energy should be about 16 kT or larger, which was derived based on the standard theory of single-electron tunneling. This estimation does not consider the quantum leakage current, which becomes significant as the junction resistance approaches the quantum resistance. However, as long as the junction resistance is not very close to the quantum resistance, the above criteria for the addition energy will be a reasonable basis for later discussions. With this requirement, an addition energy E as large as 0.4 eV is required for room-temperature operation. This addition energy corresponds to the total island capacitance ($C_\Sigma = e^2/E$) of 0.4 aF, an excitation voltage (e/C_Σ) of 0.4 V and, from Figure 3.4, an island size of about 3 nm.

There are two time scales for evaluating SET speed: one is the intrinsic switching time, and the other for the circuit speed. The intrinsic switching time defines how fast the SET changes its states, and is determined by the RC time constant of the tunneling, $C_\Sigma R_j$, where R_j is the junction resistance. If it is assumed that $C_\Sigma = 0.4$ aF and $R_j = 1$ MΩ ($\sim 4R_q$), the switching speed will be 0.4 ps and thus the SET is a fairly fast switching device. The problem is that only one electron is moved by the switching event, and it thus takes a much longer time to change the state of the output terminal with a larger capacitance. The time for changing the state of the output terminal is determined by $C_L R_{SET}$, where R_{SET} is the resistance of the SET ($\sim 4R_j$). If it is assumed that $C_L = 100$ aF and $R_{SET} = 4$ MΩ, the time is 0.4 ns or 2.5 GHz. It will also be helpful to compare the SET current density with that of the present nMOS transistor (for LOP applications), which is about 600 μA μm^{-1}. Assuming that the size, resistance, and drain voltage of the SET are 3 nm, 4 MΩ, and 0.4 V, respectively, the SET current density will be 33 μA μm^{-1}. Although this is not fatally bad, it implies that the use of SETs is restricted to a local communication with relatively small load capacitances. Crudely

speaking, the SET is inherently slower by the factor of at least 10^{-1} than FETs because the SET cannot operate with the resistance smaller than R_q, whereas FETs can.

The SET can be made very small, but this does not necessarily mean it will be the smallest. Ideally, a molecular-sized FET can be imagined, and could be made as small as the SET. Therefore, small size is not a major merit of the SET; rather, the main merit is that its operation is guaranteed even at the molecular level, and some parameters – such as the switching speed and current peak-to-valley ratio – can be improved owing to the reduced capacitance. At this point, it might be safe to say that SETs have no definite advantage over ultimately scaled-down MOSFETs from the viewpoint of the physical size itself.

Now, a return should be made to Eqs. (3.6) and (3.7). Considering the above arguments that SET size is comparable to that of ultimate future FETs, and that the circuit speed is 10^{-1} to 10^{-2} worse than its CMOS counterparts, the functionality α will need to be increased by 10^1 or more in order to make a drastic improvement in I/P while keeping I^2/P comparable to that for CMOS circuits.

Several ideas for improving the functionality have been reported. One is to use the SET XOR gates introduced in Section 3.4.2. Figure 3.16 shows the equivalent circuit of a full adder based on the SET XOR gate. A full adder can be constructed using six SETs, whereas this requires 28 MOSFETs in CMOS logic [106]. This can be interpreted as $\alpha = 4.7$. It has also been reported that, by integrating SET full adders, multi-bit adders can be constructed in a very area-efficient manner: there are no long wires in the carry-propagation path, which leads to fast operation in spite of a low drivability of the SET [80]. Another idea is based on the SET-MOSFET configuration introduced in Section 3.4.3. Based on this configuration, a SET logic gate family has been proposed [87, 88].

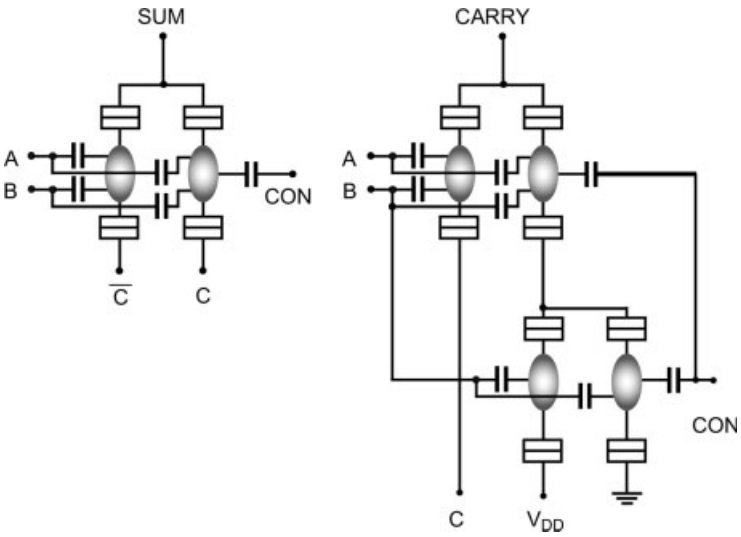

Figure 3.16 The SET full adder. A and B are addends and C is carry. CON is the control signal, which controls the phase of the Coulomb blockade oscillation [80].

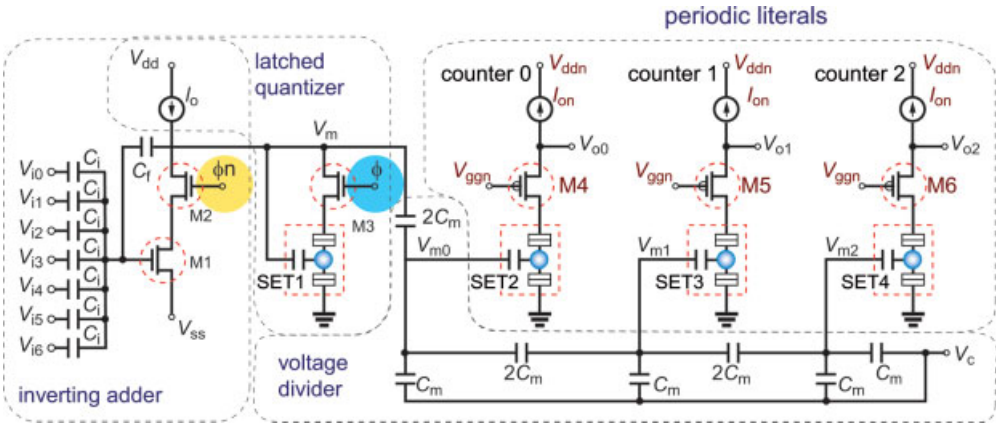

Figure 3.17 Circuit diagram of SET-based 7-3 counter. The circuit consists of five types of device: SETs (SET1–SET4), n-channel MOSFETs (M1–M3), p-channel MOSFETs (M4–M6), and constant current loads for the first stage and literals. No adjustment is required in the device parameters for devices of the same type. Clock ϕ and ϕn are complementary, and the multiple-valued data are latched when ϕ is high. V_{ddn} is set at a negative value to provide consistent voltage levels among the circuit blocks in and out of the counter [87].

These SET logic gates are useful for implementing binary logic circuits, multiple-valued logic circuits, and binary/multiple-valued mixed logic circuits in a highly flexible manner. As an example, a 7-3 counter is shown in Figure 3.17. This is a member of the M-N counters, which are generalized counters defined in the framework of Counter Tree Diagrams. Most adders, including those for redundant number systems, could be represented in this framework. The 7-3 counter can be constructed using four SETs and 10 FETs with some passive components, whereas 198 FETs are required in CMOS logic. The functionality α is of the order of 10^1 in this case.

The increase in α in the two examples is due to the application of the SET periodic function for implementing the operation "add". This is because the parity and the periodic function are the fundamentals of the arithmetic. These examples strongly suggest that the best use of the SETs will be in arithmetic units such as adders, while other arithmetic units such as multipliers are made from adders. Adders can be built by a repetition of relatively simple layouts, and require lesser amounts of long wiring, which will compensate for the low drivability of SETs. It is believed that, by pursuing this direction, a more efficient way to increase the functionality will be found. For this purpose, much larger-scale circuits should be investigated than have been studied to data.

In summary, the SET can function as a fairly fast switching device and, although the SET has low drivability, this will not prove fatal. The periodic function of the SET current characteristics suggests that it should be applied to arithmetic units such as adders and multipliers, which might reduce their dynamic power consumption. The most suitable applications for SET-based voltage-state circuits will be for LOP arithmetic units. However, there may be no merit in using SETs in terms of static

power consumption, and some elaborate system architectures would be required to reduce this. For low standby power applications, charge-state logic circuits should pursued where, in principle, there is no leakage current.

3.5 Conclusions

Despite concern persisting with regards to reducing dynamic power consumption, this problem will not be solved simply by changing the raw materials of transistor production. One way of reducing power requirements is to use functional devices rather than simple switches, and among the large numbers of emerging devices the SET is one of the best functional units, on the basis of its unique current characteristics.

However, two critical problems remain when applying SETs to logic circuits. The first – basically technological – problem is to control the size of the nanometer-scale islands and attached tunnel junctions. During the early 1990s, very few investigators considered that SETs operating at room temperature could be fabricated, yet today they can be prepared with good ON-OFF current ratios. Moreover, their performance continues to improve. With this in mind it is likely that, in the future, a new technology will emerge for integrating millions of room-temperature-operating SETs. The second problem is to identify the "killer" applications for SETs, and this is a more fundamental and critical question. During recent years, much effort has been expended in designing SET circuits, and those which utilize the periodic nature of the SET current characteristics appear to show the greatest promise for the construction of LOP circuits. Nonetheless, further studies will be necessary to develop SET circuits that are sufficiently powerful to surpass CMOS circuits, or at least to replace a proportion of them. For this purpose, a collaboration among system architects, circuit designers, and process engineers is clearly called for.

4
Magnetic Domain Wall Logic

Dan A. Allwood and Russell P. Cowburn

4.1
Introduction

The integrated circuit which, during recent years, has become the basis of modern digital electronics, functions by making use of electron charge. However, electrons also possess the quantum mechanical property of spin, which is responsible for magnetism. New "spintronic" technologies seek to make use of this electron spin, sometimes in conjunction with electron charge, in order to achieve new types of device. Several spintronic devices are currently being developed that outperform traditional electronics. Often, this results from an increased functionality, which means that a single spintronic element performs an operation that requires several electronic elements.

Different approaches to spintronics have been developed by the semiconductor and magnetism communities. Although there have been some very impressive demonstrations of spin-polarized charge transport and ferromagnetism in cooled semiconductors [1–3], the lack of a reliable room-temperature semiconductor ferromagnet has hampered their application. Within the magnetism community, however, considerable success has been achieved at room temperature by using common ferromagnetic materials such as $Ni_{81}Fe_{19}$ (Permalloy). This approach offers the benefits of low power operation, non-volatile data storage (no power required), and a high tolerance of both impurities and radiation.

A great success of electronics has been the ability to use groups of transistors for performing Boolean logic operations. Each type of operation has a particular relationship between its input and output states, each of which can take the value "1" or "0". These relationships are shown in the "truth tables" in Table 4.1 for the Boolean NOT, AND, and OR logic operations. Logical NOT has a single input and a single output, with the output having the opposite state of the input. Logical AND has two independent inputs and has a single output that is "1" for an input combination of "11" and "0" otherwise. Conversely, a logical OR output is "0" for an input combination of "00" and "1" otherwise. Importantly, a suitable combination of NOT

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

Table 4.1 Truth tables of some common Boolean logic functions.

NOT		AND			OR		
Input A	**Output B**	**Input A**	**Input B**	**Output C**	**Input A**	**Input B**	**Output C**
0	1	0	0	0	0	0	0
		0	1	0	0	1	1
1	0	1	0	0	1	0	1
		1	1	1	1	1	1

and AND operations, or NOT and OR operations, allows any computation to be performed. The CMOS architecture of NOT and AND logic gates and other circuit elements are listed in Table 4.2. Logical "1" and "0" are represented by the presence or absence of electrical charge, usually measured as either a high and low (zero) voltage. Signal splitting (fan-out) and signal cross-over is achieved by appropriate routing of wire tracks, although for signal cross-over this requires complex fabrication in three dimensions.

Magnetic logic seeks to perform the functions necessary for a logic system with ferromagnetic metals to make use of the advantages that these materials offer. One approach has been to use magnetic/non-magnetic/magnetic tri-layer structures known as *magnetic tunnel junctions* (MTJs) [4, 5]. These have an electrical resistance that depends on the relative orientation of magnetization of the two magnetic layers, and are commonly used in magnetic random access memory (MRAM) [6, 7]. Logic gates made from MTJs [8–12] can perform the logic operations described in Table 4.1, as well as others such as NAND, NOR and XOR. Alternatively, MTJs may be used to provide a switchable bias to CMOS transistors so that a single logic gate may be capable of performing one of two logic operations, say logical AND and OR, as desired [13]. Rather than the MTJ switching on every logic operation, it would simply toggle when the CMOS logic gate operation needs to be switched. This could dramatically increase the logic density of *field-programmable gate arrays* (FPGAs), which are used as flexible alternatives to printed circuit boards.

The other major approach to performing logic operations with magnetic materials has been to propagate magnetic solitons. This can be achieved using chains of isolated nanoscale dots, each element separated by a few tens of nanometers from its neighbors [14–17]. Each dot has uniform magnetization, but the proximity of adjacent dots means that they undergo magnetostatic interactions so that an ordered magnetization configuration is achieved. The same effect is achieved with a row of freely-rotating macroscopic bar magnets. However, defects in the magnetic ordering can be created in the chain of dots. These defects are magnetic solitons, and can be propagated through dot chains by the application of a suitable magnetic field. Furthermore, junctions of dots can be used to perform various Boolean logic functions [17]. The major challenge with this technology is to control the magnetostatic interactions between different pairs of dots in order to improve reliability and device yield.

Table 4.2 Common electronic circuit symbols and the equivalent CMOS and domain wall logic devices.

Symbol	CMOS Circuit	Domain Wall Logic Circuit
Vdd (+5 V)	Charge	Magnetization
0 V	No charge	Magnetization
Fan-out	Input, Output A, Output B	Input, Output A, Output B, 20°, 1 μm, 200 nm, 125 nm, 200 nm
Cross-over	Input A, Input B, Vias, Output A, Output B	Input A, Input B, Output A, Output B, 200 nm, 183 nm, 500 nm, 1 μm
NOT	Input, Output, Vdd	Input / Output, 500 nm, 225 nm, 20°, 100 nm
AND	Input A, Input B, Output, Vdd, NAND, Inverter	Input A, Input B, Output, 20°, 1 μm, 200 nm, 125 nm, 200 nm
NOT-fan hybrid	Sequential placement of fan and NOT elements above	A, B, C, 1 μm, 500 nm, 225 nm, 200 nm, 20°, 200 nm, 100 nm, 750 nm, 1 μm
Data input	Various	325 nm, 1 μm, 1 μm, 200 nm

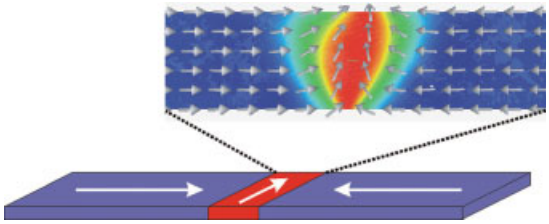

Figure 4.1 Schematic diagram of a transverse 'head-to-head' domain wall in a planar Permalloy nanowire 200 nm wide and 5 nm thick. The expanded region shows a numerically calculated and more detailed view of a domain wall's magnetic structure.

Alternatively, circuits made from planar magnetic nanowires can be used, with wires typically 100 to 250 nm wide and 5 to 10 nm thick. The *shape anisotropy* (geometry) of these wires creates a magnetic easy axis in the wire long axis direction that defines the stable orientations of magnetization (Figure 4.1). This system with two opposite stable magnetization orientations is ideal for representing logical "1" and "0" (see Table 4.2). Where opposite magnetizations meet they are separated by a transition region through which magnetization rotates by 180° (Figure 4.1). This is another form of a magnetic soliton, and is called a *domain wall*. For the wire dimensions relevant here, domain walls are typically approximately 100 nm wide. Domain walls can be moved by applying magnetic fields, and it is this ability which is exploited in magnetic domain wall logic. Domain walls travel down sections of nanowire between nanowire junctions where logic operations are performed. Crucially, the influence of nanowire imperfections on domain wall propagation is very significantly reduced compared with the propagation of solitons in interacting dots. Furthermore, very little power is required either to propagate a domain wall or to perform a logic operation, compared to the lowest power CMOS equivalents or magnetic alternatives. This combination makes magnetic domain wall logic a robust, low-power logic technology. The remainder of this chapter is devoted to explaining how magnetic domain wall logic functions, and what the future prospects of the technology might be.

4.2 Experimental

All of the magnetic structures shown here are fabricated by focused ion beam (FIB) milling [18] of 5 nm-thick Permalloy films. The films were thermally evaporated onto Si(0 0 1) substrates with a native oxide present in a chamber with a base pressure $<10^{-7}$ torr. FIB milling used 30 keV Ga^{+} ions which were focused to a diameter of $\sim$7 nm at the substrate. The Ga^{+} ions sputter the magnetic material and scatter within the film and substrate to implant at lateral distances up to 40 nm from the spot center [19]. Both of these processes lead to a loss of ferromagnetic order in the Permalloy film and allow nanostructures to be defined. A $150 \times 150\,\mu m$ square of magnetic material is cleared around each nanowire circuit to allow optical analysis

of the nanostructure without interference from the surrounding film. Sample images are obtained from secondary electron emission during a single FIB scan.

Magnetization measurements are performed using a magneto-optical Kerr effect (MOKE) magnetometer in the longitudinal MOKE configuration [20]. The instrument has a ~5 μm spatial resolution, given by the focused laser spot diameter, and is sensitive to single magnetization reversal events in individual nanowires [21]. The magnetometer also includes a facility for mapping the sample susceptibility using MOKE signals in order to select particular regions of a structure for measurement. In-plane magnetic fields are applied to samples at a frequency of 27 Hz using a quadrupolar electromagnet. This two-dimensional (2-D) field is characterized by orthogonal fields H_x and H_y, with amplitudes H_x^0 and H_y^0, respectively. The directions of H_x and H_y are defined in the images of each structure.

4.3 Propagating Data

Probably the most common measurement in magnetism is to determine the major hysteresis loop of a magnetic material. Figure 4.2a shows one such measurement from a 100 nm-wide Permalloy wire with field H_x applied along the wire length (along the magnetic easy axis) [22]. The sharpness of the transitions indicates that magnetization reversal most likely occurs by domain wall nucleation from one wire end, rapid propagation through the wire, and annihilation at the other wire end.

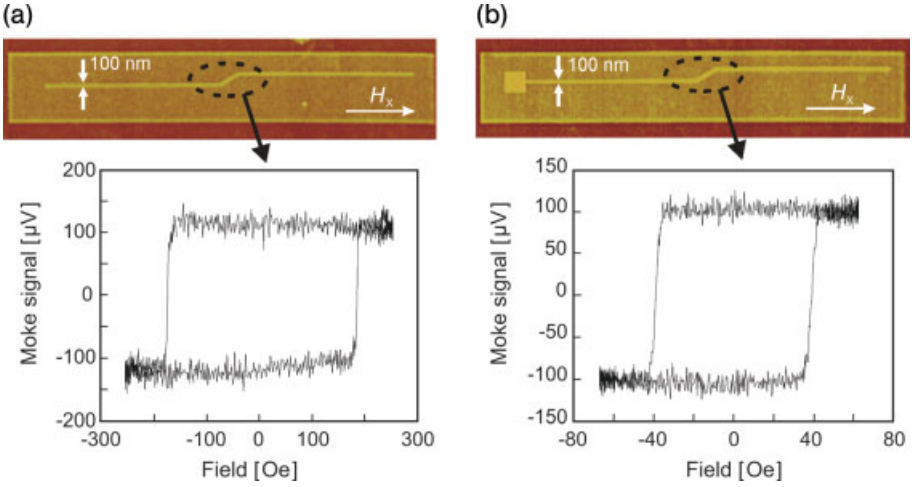

Figure 4.2 Atomic force microscopy images and magneto-optically measured magnetization hysteresis curves from: (a) 100 nm-wide wire and (b) 100 nm-wide wire with a 1 μm × 1 μm square domain wall "injection pad" [22]. Measuring either side of the kink does not change the observed switching field. The direction of the magnetic field H_x is indicated in both images.

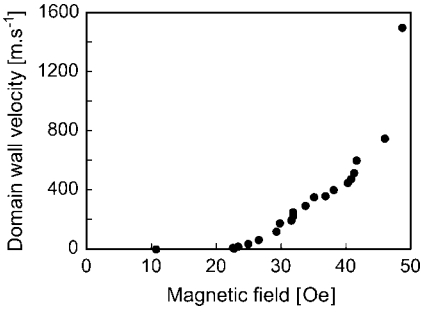

Figure 4.3 Measured domain wall velocity in a 200 nm-wide, 5 nm-thick $Ni_{81}Fe_{19}$ wire as a function of magnetic field along the wire long axis [23].

For this wire, magnetization reversal occurs at a coercive field $H_c = 180$ Oe. Unwanted domain wall nucleation from wire ends, junctions and corners must generally be avoided in logic circuits, as this will corrupt any existing data. It is imperative, therefore, domain walls can be introduced and propagated at magnetic fields lower than, in this case, 180 Oe. Figure 4.2b shows a structure with a similar wire to that in Figure 4.2a, but now with a 1 μm × 1 μm square pad attached to one end. MOKE measurement of the wire shows that $H_c = 39$ Oe. This reduction in H_c is a result of the square pad undergoing magnetization reversal at $H_c = 26$ Oe (not shown) before a domain wall is injected into the wire at $H_x = 39$ Oe. Different regions of the wire all have the same coercive field, even beyond the 30° kink, showing that domain walls can propagate in wires and through changes of wire direction at fields significantly lower than nucleation fields. To quantify this low-field propagation more precisely, the domain wall velocity was measured in a 200 nm-wide Permalloy wire (Figure 4.3), in an experiment described elsewhere [23]. Measured domain wall velocities exceeded 1500 m s^{-1} for certain fields applied along the wire long axis. Other studies [24–27] have shown that domain wall velocity does not increase continually with field, but rather reaches a maximum value before reducing at higher fields. Interestingly, domain wall propagation is still observed at fields as low as 11 Oe [23], albeit with very low velocities of 0.01 m s^{-1}. The data in Figures 4.2 and 4.3 indicate that nanowire devices operating by domain wall propagation will require $11\,\text{Oe} < H_x < 180\,\text{Oe}$, although these field values will change once wire junctions are introduced.

Simply using a unidirectional field will not allow domain walls to be separated reliably and, hence, normal data streams containing both "1"s and "0"s cannot be propagated. Instead, use is made of the orthogonal fields H_x and H_y to create a magnetic field vector that rotates in the plane of the sample to control domain wall propagation around smooth 90° wire corners. An important rule for understanding the nanowire circuits is that domain walls will propagate around corners of the same sense of rotation as the applied field – that is, a clockwise rotating field will lead to domain walls traveling around corners clockwise. In a correctly designed nanowire circuit, the sense of field rotation will define a unique direction of domain wall propagation and, hence, data flow. This is an essential feature of a Boolean logic

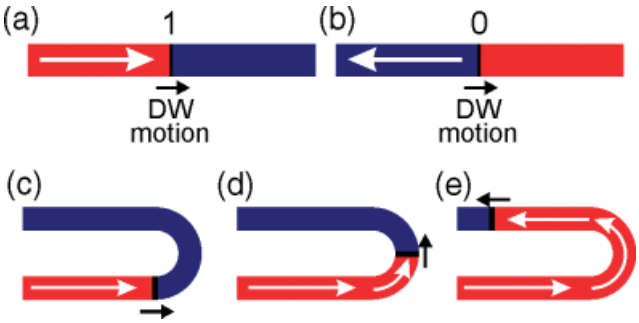

Figure 4.4 Schematic diagrams showing the definition of: (a) logical "1" and (b) logical "0" in magnetic domain wall (DW) logic. Panels (c–e) show sequentially how the wire magnetization changes when a domain wall propagates around a 180° wire corner.

system. Interestingly, the direction of data flow in magnetic domain wall logic can, in principle, be reversed simply by reversing the sense of field rotation.

At this point it must be considered how binary data are represented in magnetic domain wall logic. It was mentioned in Section 4.1 how the two opposite magnetization directions supported in magnetic nanowires can be used to represent the logic states "1" and "0". However, care must be taken here with the definition chosen to use with magnetic nanowire circuits, as the wires can change directions. Figure 4.4a and b show, schematically, two similar magnetic wires with opposite magnetizations containing a single domain wall. A simple approach would be to say that magnetization pointing to the right represents logical "1", and that pointing to the left represents logical "0". However, Figure 4.4c–e shows the magnetization following a domain wall that propagates around a 180° wire corner. In the final situation (Figure 4.4e), the magnetization is continuous up to the domain wall, meaning that there are no changes in logic state up to this point. However, the absolute directions of magnetization are opposite on either side of the turn, and so the simple definition cannot then be valid. Instead, the choice is made to define data representation in terms of the direction of magnetization relative to the direction of domain wall motion. In Figure 4.4c–e, the magnetization following the domain wall is always oriented in the direction of domain wall motion, so the logic state represented remains unchanged. This robust definition allows measurements from different parts of logic circuits to be interpreted correctly.

4.4 Data Processing

The NOT-gate was the first domain wall logic device to be introduced [28–30], and is foundational to the development of all other logic elements. Figure 4.5 shows the geometry of a NOT-gate, and illustrates its principle of operation. The NOT-gate is a junction formed by two wires. For a given field rotation, one wire will act as the input

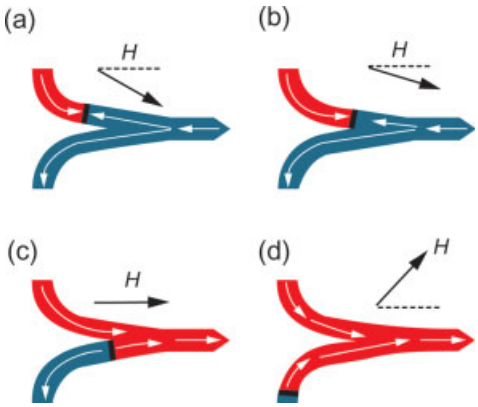

Figure 4.5 Schematic diagrams showing the operating principle of a magnetic nanowire NOT-gate [28]. The black arrows represent the instantaneous magnetic field vector, while the white arrows show the wire's internal magnetization configuration. A domain wall is shown as the black line that separates the oppositely magnetized (red and blue) magnetic domains.

and the other wire as the output. A small central "stub" which emerges from the wire junction is an important part of the device as it ensures there is sufficient shape anisotropy to maintain a magnetization component in the direction in which the stub points. The dimensions for an optimized NOT-gate design are given in Table 4.2. Under a rotating magnetic field, H, a domain wall enters the NOT-gate input wire (Figure 4.5a) before reaching the wire junctions (Figure 4.5b). The magnetization following the domain wall points in the direction of domain wall propagation. Provided that there is sufficient field, the domain wall expands over the junction and splits in two, with one domain wall traveling along the central stub, leaving the stub magnetization reversed, and the other free to propagate on the NOT-gate output wire (Figure 4.5c). As the field continues to rotate, the domain wall in the output wire leaves the NOT-gate. The magnetization following the domain wall is now pointing away from the direction of domain wall motion. The magnetization on either side of the wire junction is reversed, and the device has inverted the input logical state. The reversal in magnetization means that the inversion process would be expected to require a one-half cycle of field.

Figure 4.6a shows a structure containing a NOT-gate fabricated in a square loop of magnetic wire that has not been used to test the operation of the logic device [28–30]. The loop provides feedback to the NOT-gate by joining the output wire to the input wire. Having a single inverter in the loop guarantees that at least one domain wall will be present [28–30] and removes the need, at this stage, for explicit data input. If the principle of operation for a NOT-gate described above is correct, it should be possible to predict the switching period of the NOT-gate/loop structure in terms of field cycles. As mentioned above, a domain wall will take a one-half field cycle to propagate through the NOT-gate junction. Traveling around the 360° wire loop will then add another field cycle. So, magnetization reversal would be expected

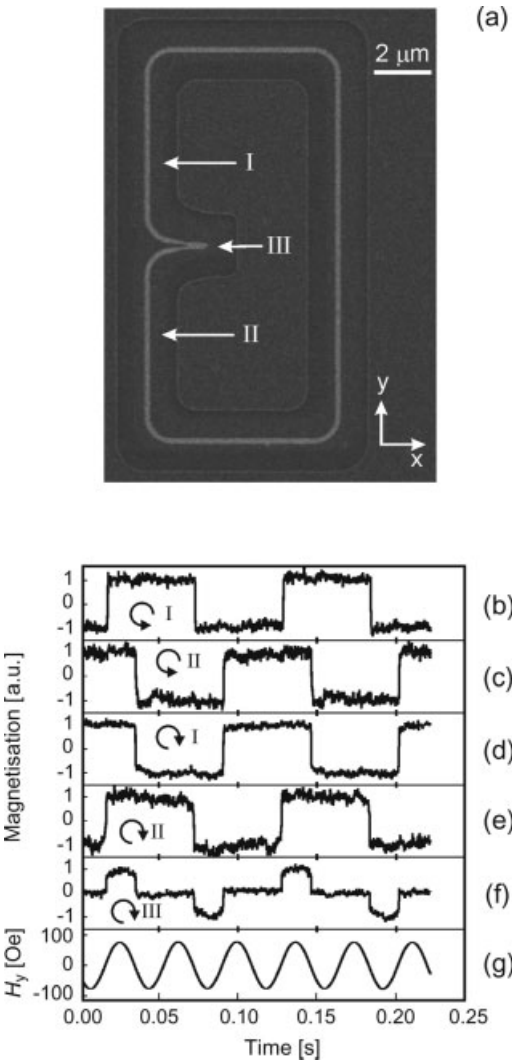

Figure 4.6 (a) Focused ion beam image of a ferromagnetic NOT-gate and feedback loop [29]. Also shown are the *x*- and *y*-directions, and the measurement regions I, II and III where the ∼5 μm diameter magnetometer laser spot was positioned. (b–e) Measured MOKE signals during application of an in-plane rotating magnetic field ($H_x^0 = 77$ Oe, $H_y^0 = 74$ Oe) for anti-clockwise field rotation at measurement position (b) I and (c) II, and clockwise field rotation at measurement position (d) I and (e) II. (f) A measured trace from position III with a clockwise field rotation; (g) the *y*-component of the rotating field.

to be seen at any position in the loop every 3/2 field cycles, giving a switching period of three field cycles.

Figure 4.6b shows a time-averaged MOKE trace obtained from position I on the structure (Figure 4.6a) under anti-clockwise field conditions [29]. As expected, a

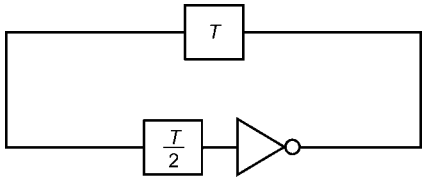

Figure 4.7 An equivalent electronic circuit used to model the ferromagnetic NOT-gate and feedback loop. The square boxes correspond to time delay elements, where T is the periodic time of the applied rotating magnetic field.

three-field cycle switching period was observed, indicating that the wire junction is performing as a NOT-gate. To validate this further, Figure 4.6c shows a MOKE trace obtained from position II, the other side of the NOT-gate (Figure 4.6a), with the same field conditions. This trace is inverted compared to that in Figure 4.6b, except for a one-half field cycle delay, consistent with the operation of a NOT-gate outlined above. As the NOT-gate has an equal number of input and output wires that have identical geometry, it may be operated reversibly. Figure 4.6d and e show measurements from positions I and II, respectively but now under a clockwise-rotating field. The observed phase relationship indicates that position II has now become the input and position I the output. Figure 4.6f shows a MOKE trace that is obtained with the laser spot positioned over the NOT-gate (position III, Figure 4.6a). A domain wall is observed to enter and leave the NOT-gate to correlate with the traces shown in Figure 4.6d and e. An important aspect of this initial demonstration is that the applied field acts as both power supply and clock to the magnetic circuit. The structure in Figure 4.6a can be thought of as having the equivalent electronic circuit shown in Figure 4.7. Electronic invertors do not have a delay in terms of a clock cycle, so a buffer must be introduced with a delay of $T/2$, where T represents a clock period. Another buffer with a delay of T is then introduced within a feedback loop to represent the time spent by a domain wall propagating around the wire loop. The signal from this circuit will replicate those observed in Figure 4.6.

One of the advantages of having input and output wires of identical forms is that logic gates can be directly connected together. Figure 4.8a shows a magnetic shift register circuit made of 11 NOT-gates within a wire loop [28]. The expected switching period can again be calculated by $11 \times 1/2$ field cycles for domain wall propagation through NOT-gates plus one field cycle for the loop to give a magnetization reversal every 6.5 field cycles, or a switching period of 13 field cycles. Figure 4.8b shows the MOKE trace obtained from the structure, in which the 13-field cycle period is clearly observed. The measurement was obtained over 30 min of averaging, indicating that almost 10^5 logical NOT operations were successfully performed. If there was a problem with a domain wall propagating through a NOT-gate on just one occasion, the resultant phase difference introduced would be clearly visible in the time-averaged trace (Figure 4.8b). Although in this case the topology of the shift register structure has been used to ensure the presence of a single domain wall, it will be seen later (in Section 4.5) how similar shift registers can support complex data sequences. The one-half cycle delay for domain wall propagation creates a natural buffer between

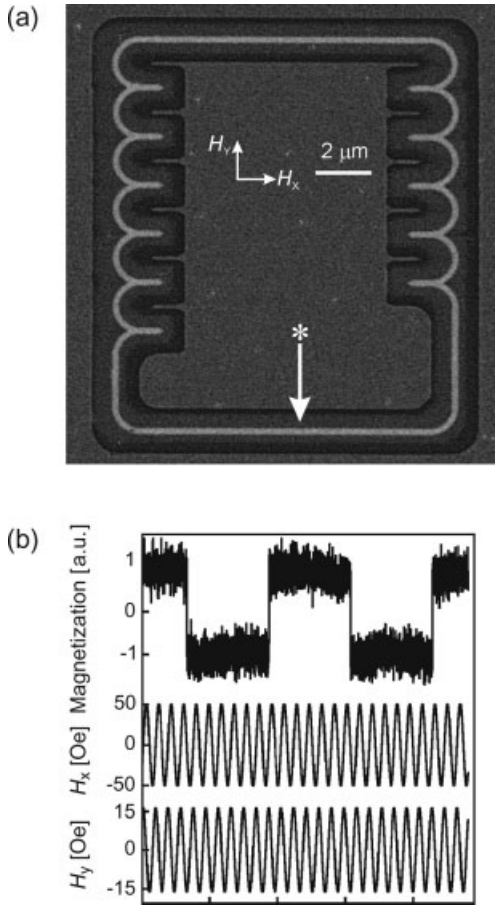

Figure 4.8 (a) Focused ion beam image of a magnetic ring including 11 NOT junctions, where the asterisk indicates the position of MOKE analysis [28]. The directions of the magnetic field components, H_x and H_y, are also indicated. (b) MOKE analysis of an identical structure within a clockwise rotating magnetic field ($H_x^0 = 50$ Oe and $H_y^0 = 15$ Oe).

data bits, removing the need for any complex circuitry, such as the flip-flop circuits that are commonly used in electronic memories.

Characterizing the performance of magnetic domain wall NOT-gates is essential for design optimization [29] and for integrating them with other types of nanowire junction. Here, structures similar to that in Figure 4.6a were used to assess a NOT-gate's operation as a function of in-plane rotating field amplitudes H_x^0 and H_y^0. Three types of operation are observed:

- When the field amplitudes are too low, domain walls experience pinning at the NOT-gate junction, and this leads either to no switching for very low fields or else

de-phasing of the time-averaged MOKE trace when domain walls are pinned even once.

- At high fields, additional domain wall pairs are nucleated in the structure and the magnetization reversal has a single field cycle period.
- At intermediate fields the three-field cycle operation described above is observed.

It should be noted that, after domain wall nucleation is observed at high fields, it is necessary to reduce the number of domain walls back to one by applying field conditions for occasional de-pinning [29]. This allows domain wall pairs to meet and annihilate. Figure 4.9 shows the resulting phase diagram describing NOT-gate operation as a function of field. There are two phase boundaries present, one

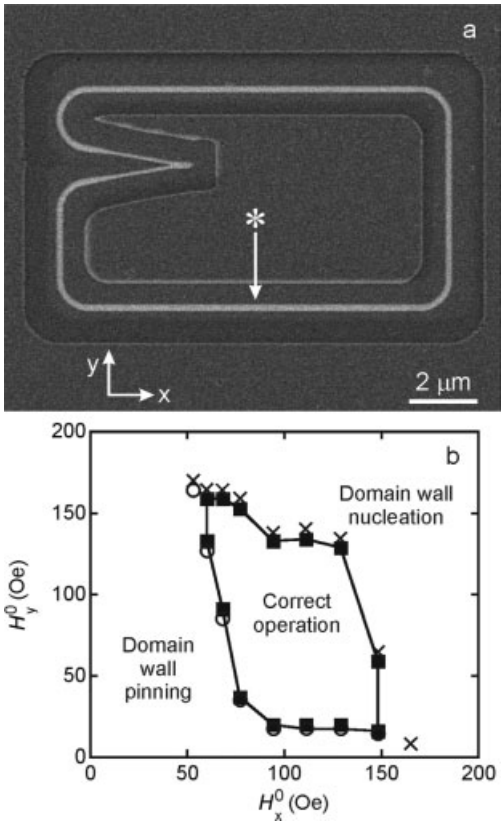

Figure 4.9 (a) Focused ion beam (FIB) image of NOT-gate and feedback loop [29]. The magnetic wire is the light-gray line, and all other features are a result of the FIB milling. Also shown are the measurement position (denoted by "*") and the *x*- and *y*-directions. (b) Experimentally determined phase diagram showing operation of the NOT-gate/feedback loop structure shown in (a) as a function of the rotating magnetic field component amplitudes H_x^0 and H_y^0. × = nucleating; ■ = correct operation; ○ = domain wall pinning. The region bounded by the solid line is the operating region for this device.

separating domain wall pinning from correct operation, and the other separating correct operation from domain wall nucleation. The two boundaries meet to define an area of field phase space in which the NOT-gate operates correctly. Figure 4.9 is taken for a NOT-gate with the optimized dimensions given in Table 4.2.

The other circuit elements that are required for a realistic logic system are a majority gate, signal fan-out, and signal cross-over. The NOT-gate operating phase diagram (Figure 4.9) provides a useful and necessary reference for comparing the performance of these additional elements to ensure compatibility. Figure 4.10a–c shows three structures used for testing the operating fields of majority gate junctions [31]. Each junction has two input wires and one output wire, with the structures having (a) no, (b) one, and (c) two input wires terminated by a domain wall "injection pad". The low field at which domain walls are introduced from an injection pad means that they provide a means of testing majority gate junction operation

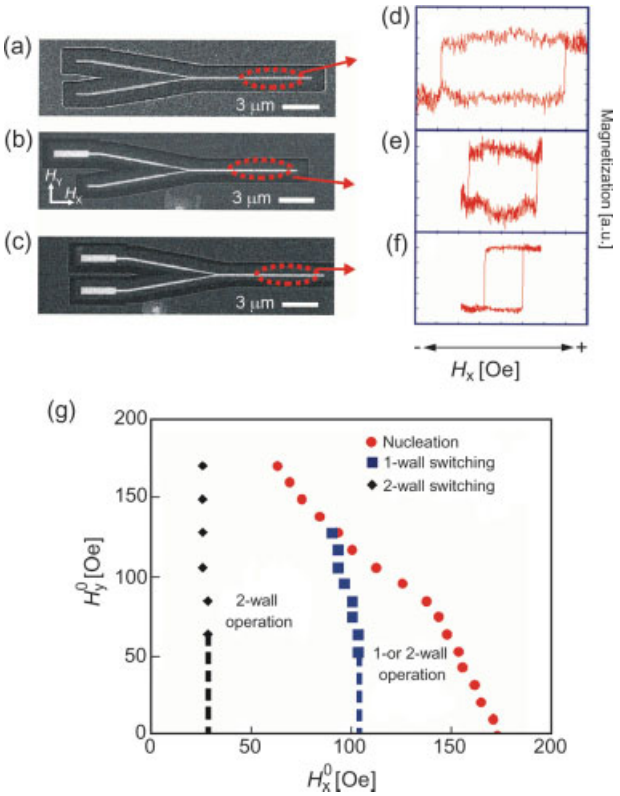

Figure 4.10 (a–c) Focused ion beam images of majority gate test structures with (a) zero, (b) one, and (c) two input wires connected to a 3 μm × 600 nm domain wall "injection pad" [31]. The directions of H_x and H_y are indicated in panel (b). (d–f) MOKE hysteresis loops from the output wires of panels (a)–(c), respectively. (g) Experimentally determined operating phase diagram of the majority gates in an in-plane rotating magnetic field as a function of the field amplitudes H_x^0 and H_y^0.

when 0, 1, or 2 domain walls are present in the input wires. Clearly, the output arm switching fields (Figure 4.10d–f) reduce as the number of domain walls present at the junction increases. In terms of magnetization dynamics, it is interesting that a single domain wall appears capable of expanding across a junction before propagating through the output wire, and that two domain walls are able to interact to enable very low output wire switching fields. Figure 4.10g shows a more detailed analysis of the operation of optimized majority gate junctions (dimensions given in Table 4.2) as a function of the in-plane rotating field amplitudes. The different input conditions now lead to two field-space regions of operation, depending on the number of domain walls present before switching. Crucially, comparison with Figure 4.9 shows that there is overlap between the NOT-gate operating region and both operating regions of the majority gate. The question remains, however, whether to use field amplitudes from the lower-field operating region of the majority gate, or the higher. The answer is to use both. For a majority gate aligned parallel to H_x, field conditions $H_x^0 = 120$ Oe and $H_y^0 = 50$ Oe will mean that the output wire will switch whenever there is just one domain wall present. This corresponds to an input condition of "01" or "10". Clearly, this should not happen for either an AND-gate or an OR-gate. However, by examining the truth tables for each (see Table 4.1), it becomes obvious that a "10" input should always lead to a "0" output for an AND-gate and a "1" output for an OR-gate. However, H_x need not be symmetric; instead, a dc field H_x^{DC} can additionally be applied to bias H_x so that for one sense of H_x the majority gate reverses with a domain wall in either input, while in the other sense of H_x the majority gate requires domain walls in both input wires. The AND/OR function of the gate is then selected by the polarity of H_{dc}.

Signal fan-out and signal cross-over junctions were developed in a similar manner [32], with optimized geometries shown in Table 4.2. Figure 4.11a shows a circuit that integrates all of the structures necessary for performing logic operations: a NOT-gate, a majority gate, two signal fan-out junctions and a signal cross-over element [33]. An anti-clockwise rotating field with amplitudes of $H_x^0 = 75$ Oe and $H_y^0 = 88$ Oe was used with $H_x^{DC} = -5$ Oe (Figure 4.11b) in order to circulate domain walls in an anti-clockwise direction and select logical AND operation for the majority gate. The NOT-gate/loop is similar to those discussed above, and will contain a single domain wall and a magnetization switching period of three field cycles, as before. The difference from Figure 4.11a, however, is that a fan-out structure is incorporated within the loop to split a domain wall each time it is incident on the junction. Part of the domain wall will continue propagating around the loop, while the other part exits the loop to the rest of the circuit. When used in this manner, the NOT-gate/loop acts as a three-field cycle period signal generator for testing the circuit. A domain wall that exits the NOT-gate/loop is then split again at a second fan-out junction. MOKE measurement at position I in Figure 4.11a shows that the three-field cycle period from the NOT-gate loop is preserved through both fan-out junctions (Figure 4.11b, trace I). The domain walls from the second fan-out junction now have separate paths before reaching the AND-gate inputs. The domain wall that passes position I simply has to propagate through two 90° corners and some straight wire sections. The resulting half-field cycle delay between domain walls passing position 1 and arriving at the AND-gate is indicated by trace II in Figure 4.11b. The other domain wall from

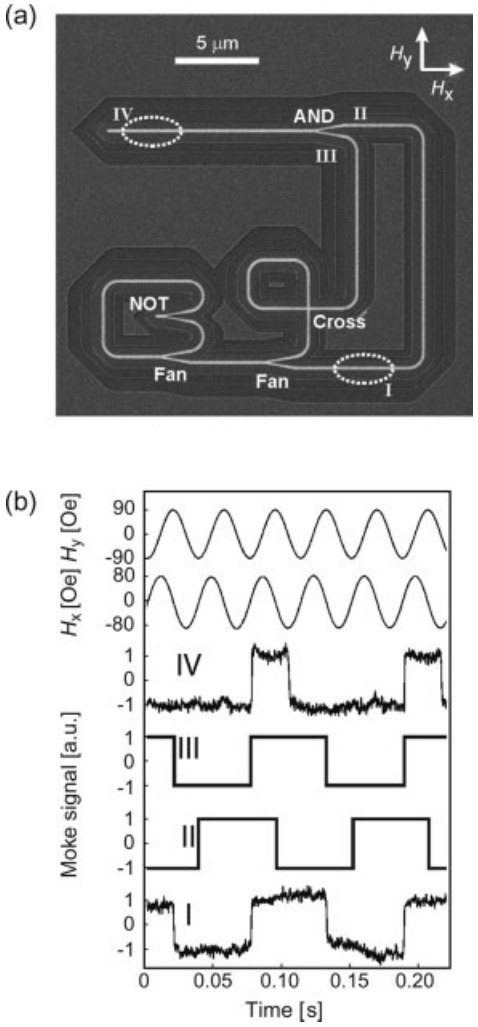

Figure 4.11 (a) Focused ion beam image of a magnetic nanowire circuit containing one NOT-gate, one AND-gate, two fan-out junctions and a cross-over junction [33]. MOKE measurements were made at positions I and IV, while positions II and III denote the inputs to the AND-gate. Also indicated are the directions of field components, H_x and H_y. (b) MOKE traces describing the operation of the magnetic circuit within an anti-clockwise rotating field with $H_x^0 = 75$ Oe, $H_y^0 = 88$ Oe and $H_x^{DC} = -5$ Oe. Experimental MOKE measurements from positions I and IV of the circuit are shown. Traces II and III are inferred from trace I, and show the magnetization state of the AND-gate's input wires.

the fan-out junction has to negotiate a cross-over junction and an additional 360° loop before arriving at an AND-gate input at position III (Figure 4.11a). The inclusion of the loop tests the operation of the cross-over element and will create a one-field cycle delay between domain walls arriving at positions II and III, as indicated in the

inferred trace III in Figure 4.11b. Measurement at position IV in Figure 4.11a shows that the output is high only when both inputs are high, showing that the majority gate is operating correctly as an AND-gate. Furthermore, this demonstrates that all four of the element types can operate under identical field conditions in a single circuit.

4.5 Data Writing and Erasing

In the previous section, domain walls were introduced to nanowire junctions either by using topological constraints of a nanowire circuit or domain wall injection from a large area pad. These are both valid methods for developing logic elements, although a method of entering user-defined data is still required to create a viable logic system. Here, an element for data input is presented that is integrated with a domain wall shift register [33]. Furthermore, it is shown how data can be deleted from the shift register.

The design of the optimized data input element is shown in Table 4.2. Figure 4.12 shows the operating phase diagram of this element, obtained from simple test structures, overlaid with that of a NOT-gate. A single phase boundary for the data input element bisects the NOT-gate field operating area. Above the phase boundary, a domain wall is nucleated from the data input element, whereas below the phase boundary no magnetic reversal occurs. Two sets of field amplitudes can then be identified for operating both NOT-gates and the data input element. Below the data input element phase boundary are the *read* or *no-write* field conditions of

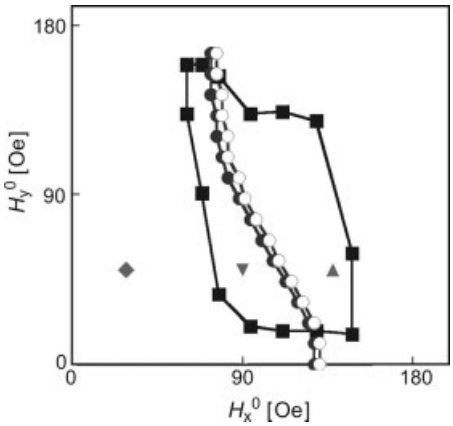

Figure 4.12 Operating field phase diagram of optimized NOT-gate and data input elements. Symbols represent the limits of the NOT-gate operating region (■), maximum field for no domain wall injection (●) and minimum field for reliable domain wall injection (○) from the data input element, and selected *write* field (▲), *read*/*no-write* field (▼) and *erase* field (◆) conditions. The lines are provided only as guides to the eye.

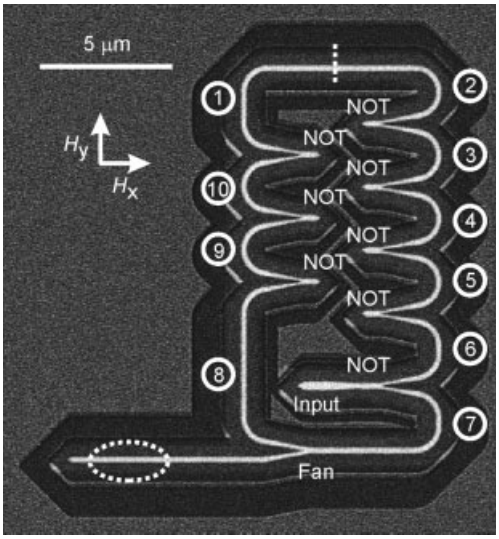

Figure 4.13 Focused ion beam image of a continuous shift register made of eight NOT-gates, a fan-out junction and a data input element connected to the central wire of one of the NOT-gates [33]. The shift register is divided into ten labeled cells, each separated from its neighbors either by a wire junction (NOT or fan-out) or a straight horizontal wire (indicated by dotted line). The field directions H_x and H_y are shown; the position of magneto-optical measurement is indicated by the dotted ellipse.

$H_x^{\text{no-write}} = 90$ Oe and $H_y^0 = 50$ Oe, and above the phase boundary are the *write* field conditions of $H_x^{\text{write}} = 138$ Oe and $H_y^0 = 50$ Oe (Figure 4.12).

Figure 4.13 shows an image of a shift register containing eight NOT-gates and one fan-out junction [33]. In addition, one NOT-gate has a data input element attached to its central stub. The fan-out element provides a monitor arm for MOKE measurement, as used in Section 4.4 above. The shift register can be divided into ten cells, each capable of holding a single domain wall and separated from its neighbors by a total of 180° of wire turn. Due to topological restrictions, domain walls can only be introduced or removed in pairs. Therefore, a data bit is represented by the presence or absence of a domain wall pair, so the shift register in Figure 4.13 contains five data bits.

Figure 4.14a–d shows, schematically, the operating principle of the data input element connected to the NOT-gate [33]. Initially, no domain walls are present and the two connecting wires to the NOT-gate have opposite magnetizations (Figure 4.14a). As the field rotates, the *write* field amplitude is used (Figure 4.14b) so that a domain wall is nucleated at the end of the data input element. This domain wall will propagate to the NOT-gate junction, where it will split into domain walls DW 1 and DW 2, one in each of the input/output wires (Figure 4.14b). As the field rotates further (Figure 4.14c), both domain walls follow the field rotation and propagate clockwise around corners. DW 1 propagates away from the NOT-gate, while DW 2 returns to the junction (Figure 4.14c). Finally, the field rotates to be oriented 180° from when nucleation occurred, but now with *no-write* conditions (Figure 4.14d). DW 1 has

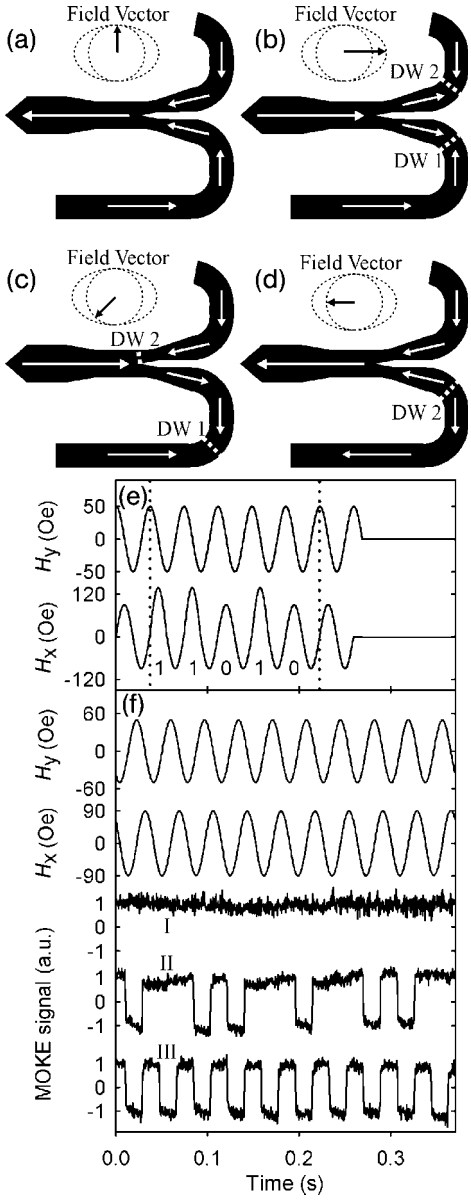

Figure 4.14 (a–d) Schematic diagrams describing the operation of a data input element [33], including instantaneous field vectors (black arrows), magnetization directions (white arrows) and position of domain walls (white dotted line). (e) *Write* field pattern with field amplitudes $H_x^{\text{no-write}} = 90$ Oe, $H_x^{\text{write}} = 138$ Oe and $H_y^0 = 50$ Oe. The five-bit sequence "11010" is generated during the interval between the dotted lines. (f) MOKE measurements ($H_x^0 = 90$ Oe and $H_y^0 = 50$ Oe) from the shift register in Figure 4.13 in reset configuration (trace I), after applying the *write* field pattern shown in (e) (trace II), and after a 1.85-ms duration half-sinusoid field pulse of amplitude $H_x^0 = 234$ Oe (trace III).

propagated out of the section shown in Figure 4.14, while DW 2 has propagated through the NOT-gate, to leave the NOT-gate and data input element's magnetization back in their initial configuration (Figure 4.14d). One single half-cycle of *write* field conditions has created a pair of domain walls – that is, a single data bit has been written.

Figure 4.14e shows a field sequence that is used to write data to the shift register in Figure 4.13. A combination of *write* and *no-write* field conditions is used to write the five-bit data sequence "11010". Time-averaged MOKE measurements were performed during continual application of the *read* field conditions. Trace I in Figure 4.14f shows the MOKE signal obtained prior to the application of the *write* field sequence in Figure 4.14e. No transitions are observed, meaning that no domain walls are present. After a single application of the *write* field sequence, the MOKE signal changes to show that pairs of domain walls are propagating continuously around the shift register (Figure 4.14f, trace II). Crucially, the pattern of domain wall pairs matches the original input data sequence of "11010", although the phase of the measurement is such that the MOKE trace starts part-way through this sequence. Note that in this case logical "1" is represented by a low MOKE signal, due to the 180° wire turn between the data input element and the measurement position. This observation confirms the principle of operation for a data input element outlined above. Delays of an hour between writing and successfully reading data have been seen, demonstrating the intrinsic non-volatility of the data storage. The whole shift register can be filled with domain walls, destroying any data present, by applying an *over-write* half-sinusoid field pulse of amplitude $H_x^0 = 243$ Oe and 1.85 ms pulse length (Figure 4.14f, trace III).

Individual domain wall pairs can also be removed from the shift register in Figure 4.13. This represents a selective bitwise delete operation. Almost all of the ten cells shown in Figure 4.13 are separated from their neighbors by a nanowire junction. The exceptions are cells 1 and 2, which are separated by a straight section of wire. Domain walls require *read* field conditions to propagate successfully through the shift register. However, when *erase* field conditions of $H_x^{\text{erase}} = 24$ Oe and $H_y^0 = 50$ Oe (see Figure 4.12) are used, domain walls cannot overcome the pinning potentials associated with the nanowire junctions. The only possible domain wall motion will be between cells 1 and 2, where there are no wire junctions. Figure 4.15a shows the field sequence for erasing a single pair of domain walls. The first half-cycle has *erase* field conditions, so the only domain wall propagation will be from cell 1 to cell 2. All other domain walls will remain pinned at the junctions between cells. The next half-cycle has *read* field amplitudes, so all domain walls will propagate forward by one cell, with the exception of the pair of domain walls in cell 2 which will meet and annihilate. The second full field cycle continues with *read* field conditions to move all domain walls on by two cells and allowing the field sequence to be repeated on the next domain wall pair. Figure 4.15b shows MOKE traces obtained from the shift register following an *over-write* half-sinusoid pulse and between 0 and 5 erase field sequences (Figure 4.15a). The MOKE traces have a five-cycle period and each erase sequence removes a pair of domain walls, validating the operating principle described above.

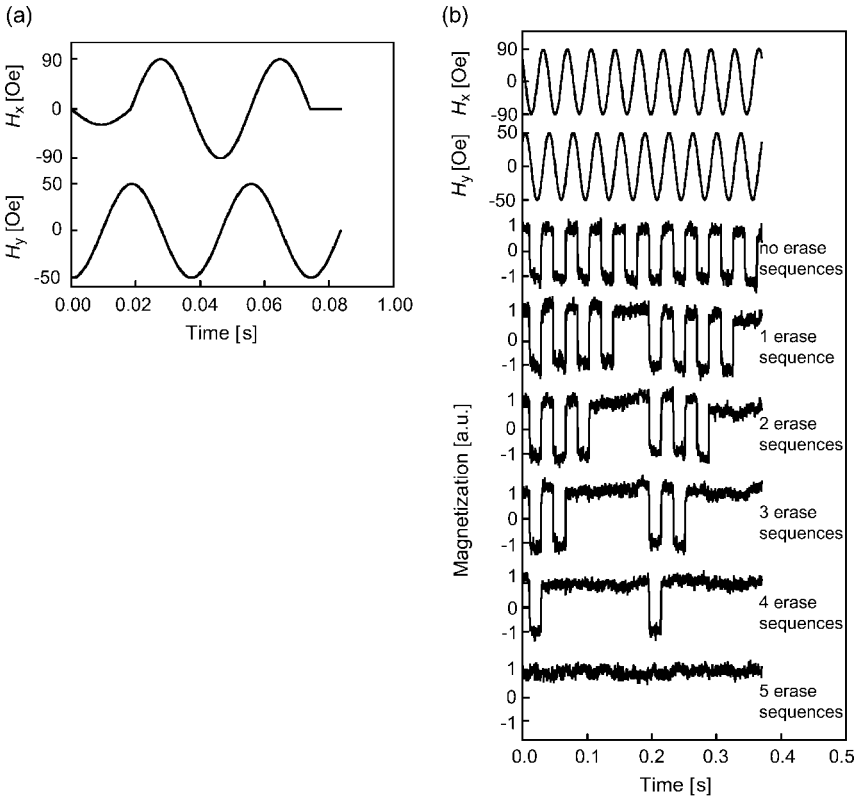

Figure 4.15 (a) *Erase* field sequence ($H_x^0 = 90$ Oe, $H_x^{erase} = 24$ Oe, $H_y^0 = 50$ Oe) applied to the structure in Figure 4.13. (b) *Read* field sequence $H_x^0 = 90$ Oe, $H_y^0 = 50$ Oe) and MOKE signals measured from the structure in Figure 4.13 following a saturating pulse and between zero to five 5 *erase* field sequences, as indicated.

4.6 Outlook and Conclusions

Domain wall logic is not a contender for a wholesale replacement of CMOS microelectronics. CMOS is a highly mature technology with many advantages, and still has many years of scaling available to it. The limited operational speed of domain wall logic does not render it suitable for many applications. However, a strong trend in microelectronics which is expected to apply to the relationship between CMOS and to many other areas of nanotechnology in the future, is to combine multiple technologies on a single platform: the System on Chip (SoC).

So – what does domain wall logic do well? First, it provides a high level of functionality to relatively simple structures. To implement an AND gate in CMOS would take six transistors, but domain wall logic achieves this simply by bringing

two nanowires together. Similarly, the other high-level properties that have been highlighted in this chapter – such as input–output isolation and signal/power gain – are all intrinsic to the nanowire and do not have to be explicitly created.

The power dissipation per logic gate is extremely low. Microelectronic engineers usually measure dissipation from a gate by the power–delay product; that is to say, the product of how much power is dissipated multiplied by how long the gate takes to process a single function. The units of this quantity are energy, corresponding to the energy dissipated during the evaluation of the function performed by the gate. The power–delay product of CMOS depends on the size of the devices. Hence, in order to compare like with like, a 200 nm minimum feature size CMOS value of 10^{-2} pJ is considered [34]. On very general magnetic grounds, it can be said that an upper bound for the power–delay product for domain wall logic is $2M_sVH$, where M_s is the saturation magnetization of the magnetic material, V is the volume of magnetic material in a gate, and H is the amplitude of the applied field. Applying the parameters for a typical 200 nm domain wall logic gate gives 10^{-5} pJ – that is, 1000 times lower than the equivalent CMOS device. Because of the inefficiencies inherent in the generation of high-speed magnetic fields (see above), this does not necessarily mean that domain wall logic chips will not consume much power. What it does mean, however, is that the waste heat will be generated from the global field generator and not from the logic devices themselves. This is of particular relevance if the devices are to be stacked into three-dimensional (3-D), neural-like circuits. The two key technical difficulties in doing this in CMOS are: (i) distributing the power and clock to everywhere inside the volume of network; and (ii) extracting the waste heat from the center of the network so that the device does not melt. It is believed that domain wall logic is an excellent choice of primitive for 3-D architectures.

Non-volatility comes as standard. In a world of mobile computing and portable (or even wearable) devices, the concept of "instant-on" is becoming increasingly important. Users accept that devices cannot be expected to operate when there is no power, but as soon as the power becomes available they want the device to be ready, and not have to undergo a long boot process, or to have forgotten what it was doing when the power last failed. As there are currently very few non-volatile memory technologies available which can be embedded directly into CMOS, a data transfer process is usually required between a high-speed, volatile memory register in the heart of the CMOS logic and an off-chip, low-speed, non-volatile store where the state variables of the system are stored. With domain wall logic, all of this becomes redundant. Provided that the rotating field is properly controlled so that it stops gracefully as power fails, and does not apply intermediate levels of field leading to data corruption, the domain wall logic circuit should simply stop and retain all of its state variables. Then, as soon as the power returns, the logic continues from where it left off.

Domain wall logic can make use of redundant space on top of CMOS. Because no complex heterostructures are required, the logic elements can sit in a single layer fabricated as a Back End Of Line process after the CMOS has been laid down. This can improve the efficiency of the underlying CMOS by farming out some space-consuming task to the domain wall logic on top. As this space was never accessible to CMOS itself anyway, it all counts as a gain.

Being metals, the basic computational elements of domain wall logic are automatically radiation-hard, and so are suitable for use in either space or military applications.

Domain wall logic is very good at forming high-density shift registers that could be used as non-volatile serial memory for storing entire files, and so would not require high-speed random access. The hard disk drive and NAND Flash devices – for example, as used to store photographs in a digital camera – are examples of non-volatile serial memory. At present, both of these devices are 2-D in form, but registers made from domain wall logic elements have the potential to be stacked into three dimensions, without incurring extra wiring complexity, as the data and power can be transmitted remotely through magnetic fields (see above). In a hard disk drive the data are stored as rows of magnetic domains, and this would remain the same in a domain wall logic serial memory. What would differ is that, in a hard disk, the domains are mechanically rotated on their disk underneath a static sensor, whereas in domain wall logic the domains themselves would move under the action of an externally applied magnetic field along static domain wall conduits, potentially stacked into an ultrahigh-density, 3-D array.

Monolithic and Hybrid Spintronics

Supriyo Bandyopadhyay

5.1
Introduction

An electron has three attributes: mass; charge; and spin. An electron's mass is too small to be useful for practical applications, but the charge is an enormously useful quantity that is utilized universally in every electronic device extant. The third attribute – spin – has played mostly a passive role in such gadgets as magnetic disks and magneto-electronic devices, where its role has been to affect the magnetic or the electrical properties in useful ways – for example, in the giant magnetoresistance devices used to read data stored in the magnetic disks of laptops and Apple iPods. Only recently has a conscious effort been made to utilize spin – either singly or in conjunction with the charge degree of freedom – to store, process, and transmit information. This field is referred to as modern "spintronics".

There are two distinct branches of spintronics:

- *Hybrid spintronics:* these devices are very much conventional electronic devices, as information is still encoded in the charge (ultimately detected as voltage or current), but spin augments the functionality of the device and *may* improve device performance. Examples of hybrid spintronic devices are *spin field effect transistors* (SPINFETs) [1] and *spin bipolar junction transistors* (SBJTs) [2], where information is still processed by modulating the charge current flowing between two terminals via the application of either a voltage or a current to the third terminal. The process by which the third terminal controls the voltage or current is spin-mediated – hence the term "spin transistors".
- *Monolithic spintronics:* here, charge has no direct role whatsoever. Rather, the information is encoded entirely in the spin polarization of an electron, which may be made to have only two *stable* values: "upspin" and "downspin", by placing the electron in a static magnetic field. "Upspin" will correspond to polarizations anti-parallel to the magnetic field, while "downspin" will be parallel. These two

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

polarizations can encode binary bits 0 and 1 for digital applications. Toggling a bit merely requires flipping the spin, *without any physical movement of charge*. It has recently been argued that as no charge motion (or current flow) is required, there can be tremendous energy savings during switching [3]. As a result, monolithic spintronic devices are far more likely to yield low-power signal processing units than are hybrid spintronic devices. An example of monolithic spintronic devices is the Single Spin Logic (SSL) paradigm that is described in Section 5.3.

In this chapter, the two most popular hybrid spintronic devices – the SPINFET and the SBJT – will be described, and evidence provided that neither device is likely to produce significant advantages in terms of speed or power dissipation over conventional charge-based transistors. The concept of single spin logic (SSL) will then be discussed, and its significant advantages in power dissipation over SPINFET or SBJT outlined. SSL also has significant advantages over any charge-based paradigm where charge, rather than spin, is used as the state variable to encode information. Finally, it will be shown that the *maximum* energy dissipation in switching a bit in SSL is the Landauer–Shannon limit of $kT\ln(p)$ per bit operation, where $1/p$ is the bit error probability. Some gate operations dissipate less energy than this because of *interactions* between spins, which may reduce dissipation [4], because many spins function collectively, as a single unit, to effect gate operation. This collective, cooperative dynamics is conducive to energy efficiency. Any discussion of adiabatic switching [5], which can reduce energy dissipation even further, is avoided as it is very slow, error-prone, and therefore impractical. The discussion of devices in non-equilibrium statistical distribution, where energy dissipation can be reduced below the Landauer–Shannon limit [6] is also avoided, simply because energy is required to maintain the non-equilibrium distributions over time, and that energy must be dissipated in the long term. The final section includes a very brief engineer's perspective on spin-based quantum computing (included at the request of the editor).

5.2 Hybrid Spintronics

Hybrid spintronic devices are those where spin is used to "enhance" the performance of charge but does not itself play a direct role in storing, processing or communicating information. The two most popular hybrid spintronic devices are the SPINFET and the SBJT.

5.2.1 The Spin Field Effect Transistor (SPINFET)

A schematic representation of the SPINFET, as proposed in the seminal studies of Ref. [1], is shown in Figure 5.1a. This device exactly resembles a conventional metal-

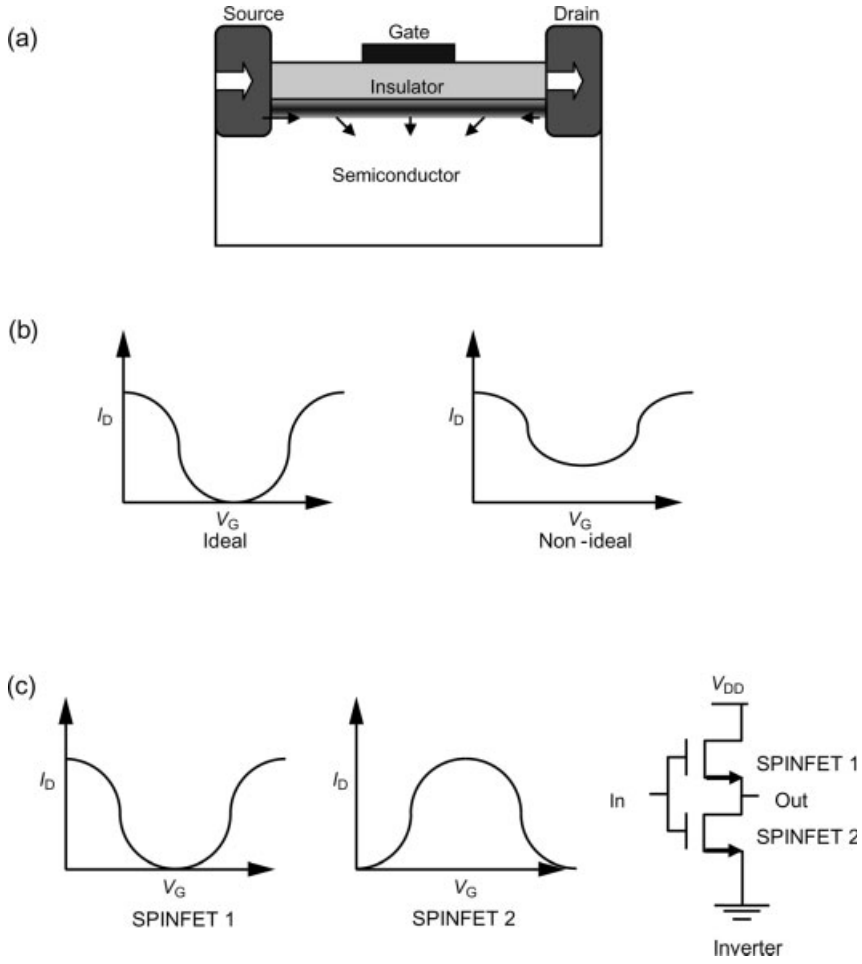

Figure 5.1 (a) Schematic of a spin field effect transistor (SPINFET). (b) Ideal and non-ideal transfer characteristic of a SPINFET. (c) Transfer characteristics of two SPINFETs with different threshold shifts and realization of a CMOS-analog inverter by connecting these two SPINFETs in series.

oxide-semiconductor-field-effect-transistor (MOSFET), except that the source and drain contacts are ferromagnetic. It will be assumed that the channel is strictly one-dimensional (1-D) (quantum wire), and only the lowest transverse subband is occupied by electrons. Both, source and drain contacts are magnetized so that their magnetic moments are parallel and point along the direction of current flow ($+x$-direction). As a result, when the source-to-drain voltage is turned on, the ferromagnetic source injects carriers into the channel with $+x$ polarized spins (the majority spins in the ferromagnet). It will also be assumed that the spin injection efficiency is 100% so that *only* majority spins ($+x$-polarized spins) are injected

from the source contact, and absolutely no minority spin (i.e. $-x$-polarized spin) is injected. Immediately after injection into the channel, all spins are polarized along the $+x$ direction. When the gate voltage is switched on, it induces an electric field in the y-direction that causes a Rashba spin–orbit interaction [7] in the channel. This spin–orbit interaction acts like an effective magnetic field in the z-direction (which is the direction mutually perpendicular to the electron's velocity in the channel and the gate electric field). This pseudo-magnetic field B_{Rashba} causes the spins to precess in the x-y plane, as they travel towards the drain. The angular frequency of spin precession (which is essentially the Larmor frequency) is given by $\Omega = eB_{\text{Rashba}}/m^*$, where e is the electronic charge and m^* is the effective mass of the carrier. The pseudo-magnetic field B_{Rashba} depends on the magnitude of the gate voltage and the carrier velocity along the channel according to

$$B_{\text{Rashba}} = \frac{2(m^*)^2 a_{46}}{e\hbar^2} E_y v_x \tag{5.1}$$

where a_{46} is a material constant, E_y is the gate electric field, and v_x is the electron velocity.[1)]

The spatial rate of spin precession is

$$\frac{d\phi}{dx} = \frac{d\phi}{dt}\frac{1}{\frac{dx}{dt}} = \Omega/v_x = 2\frac{m^* a_{46}}{\hbar^2} E_y \tag{5.2}$$

which is *independent* of the carrier velocity and depends only on the gate voltage (or gate electric field). The total angle by which the spins precess in the x-y plane as they travel through the channel from source to drain is

$$\Phi = \frac{2m^* a_{46}}{\hbar^2} E_y L \tag{5.3}$$

where L is the channel length. This angle is independent of the carrier velocity and therefore is the *same* for every electron, regardless of its initial velocity or scattering history in the channel. If the gate voltage (and E_y) is of such magnitude that Φ is an odd multiple of π, then *every* electron has its spin polarization anti-parallel to the drain's magnetization when it arrives at the drain. These electrons are blocked by the drain, and therefore the source to drain current falls to zero. Here, it has been assumed that the drain is a perfect spin filter that allows only majority spins to transmit, while completely blocking the minority spins. Without a gate voltage, the

1) Some authors assume incorrectly that the Rashba field B_{Rashba} is proportional to wavevector k_x and not the velocity v_x. This makes a difference since, in the presence of the Rashba interaction, $v_x = \hbar k_x/m* \pm \eta/\hbar$, where η is the strength of the Rashba interaction. Following the derivation in this chapter, the reader can easily convince herself/himself that the SPINFET would not work as claimed if B_{Rashba} were proportional to wavevector k_x and not the velocity v_x. As the magnetic field associated with spin–orbit interaction is proportional to $\frac{\vec{v} \times \vec{E}}{2c^2}$ (where c is the speed of light in vacuum and $\vec{E}$ is the electric field seen by the electron), it is obvious that B_{Rashba} should be proportional to v_x and not to k_x.

spins do not precess[2)] and the source to drain current is non-zero. Thus, the gate voltage causes current modulation via spin precession and this realizes transistor action.[3)] This device is also briefly discussed in Chapter 3 in Volume III of this series.

It should be clear that (in this device) although "spin" plays the central role in current modulation, it plays no direct role in information handling. Information is still encoded in "charge" which carries the current from the source to the drain. The transistor is switched between the "on" and "off" states by changing the current with the gate potential, or by controlling the motion of charges in space. The role of spin is only to provide an alternate means of changing the current with the gate voltage. Thus, this device is a quintessential hybrid spintronic device.

5.2.1.1 The Effect of Non-Idealities

The operation of the SPINFET described above is an idealized description. In a real device, there will be many non-idealities. First, there will be a magnetic field along the channel because of the magnetized ferromagnetic contacts. This will cause problems, as it will add to B_{Rashba} and the total effective magnetic field will be $|\vec{B}_{\text{Rashba}} + \vec{B}_{\text{channel}}|$, which is no longer linearly proportional to carrier velocity v_x. As a result, the precession rate in space will no longer be given by Eq. (5.2)[4)] and will *not* be independent of the carrier velocity (or energy). Therefore, at a finite temperature, different electrons having different velocities due to the thermal spread in carrier energy, or because of different scattering history, will suffer different amounts of precession Φ. As a result, when the current drops to a minimum, not all spins at the drain end will have their polarizations exactly anti-parallel to the drain's magnetization. Those that do not, will be transmitted by the drain and contribute to a *leakage current* in the off state [8]. This is extremely undesirable as it decreases the ratio of on- to off-current and will lead to standby power dissipation when the device is off.

A more serious problem is that the magnetic field changes the energy dispersion relations in the channel. In Figure 5.2, the energy dispersion relation (energy versus wavevector) is shown schematically with and without the channel magnetic field [9]. Without the magnetic field, the Rashba interaction lifts the spin degeneracy at any non-zero wavevector, but each spin-split band still has a fixed spin quantization axis (meaning that the spin polarization in each band is always the same and independent of wavevector) (Figure 5.2a). The spin polarizations in the two bands are anti-parallel and the eigenspinors in the two bands are orthogonal. Because of this orthogonality, there can be no scattering between the two bands. Electrons can scatter elastically

2) Even without the gate voltage, there is obviously some Rashba interaction in the channel due to the electric field associated with the hetero-interface. This field exists because the structure lacks inversion symmetry along the direction perpendicular to the hetero-interface. This vestigial interaction will cause some spin precession even at zero gate voltage, but this effect is simply equivalent to causing a fixed threshold shift.

3) The device described here is a "normally on" device. If the magnetizations of the source and drain are anti-parallel instead of parallel, or if the spin polarizations in the source and drain contacts have *opposite* signs (e.g. iron and cobalt), then the device will be a "normally off" device.

4) In Eq. (5.2), B_{Rashba} must be replaced by $|\vec{B}_{\text{Rashba}} + \vec{B}_{\text{channel}}|$ in Ω.

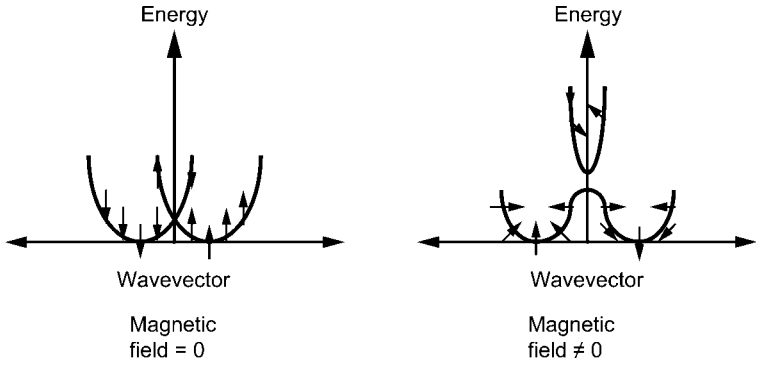

Figure 5.2 Schematic energy dispersion relationships for electrons in the channel of a one-dimensional SPINFET channel, with and without an axial magnetic field. The arrowheads indicate the spin polarization of a carrier in the corresponding wavevector state.

or inelastically only within the same band, but this does not alter the spin polarization since every state in the same band has exactly the same spin polarization. However, if a magnetic field is present in the channel, then the spin polarizations in both bands become *wavevector-dependent* and neither subband has a fixed spin polarization. Two states in two subbands with different wavevectors[5)] will have different spin polarizations that are not completely anti-parallel (orthogonal). Therefore, the matrix element for scattering between them is non-zero, which means that there is finite probability that an electron can scatter between them. Therefore, any momentum randomizing scattering event (due to interactions with impurities or phonons) will rotate the spin as the initial and final states have different spin polarizations. This rotation is random in time or space as the scattering event is random; therefore, it will cause spin relaxation. This is a new type of spin relaxation, and it is introduced solely by the channel magnetic field [10]. It is similar to the Elliott–Yafet spin relaxation mechanism [11] in the sense that it is associated with momentum relaxation. Any such spin relaxation in the channel will randomize the spin polarizations of electrons arriving at the drain and thus give rise to a significant leakage current. Therefore, the channel magnetic field causes leakage current in two different ways, both of which are harmful.

In Ref. [1], where the ideal SPINFET was analyzed, it was assumed that there is no spin relaxation in the channel. The transfer characteristic shown Figure 5.1b, which shows zero leakage drain current in the OFF-state, is predicated on this assumption. A question might arise as to whether the usual spin relaxation mechanisms are operative in the channel even without a channel magnetic field. For the ideal SPINFET, the answer is in the negative. The two spin relaxation mechanisms of concern are the Elliott–Yafet mode [11] and the D'yakonov–Perel' mode [12]. The

5) Eigenspinors in the two bands having the same wavevector are still orthogonal.

former is absent if the eigenspinors are wavevector-independent (as is the case with the ideal SPINFET), and the D'yakonov–Perel' mode is absent if carriers occupy only a single subband [13]. Thus, in the ideal 1-D SPINFET, there can be no significant spin relaxation (even if there is scattering due to interactions with non-magnetic impurities and phonons). If any spin relaxation occurs, it will be due to hyperfine interactions with nuclear spins. Since such interactions are very weak, they can be ignored for the most part. However, if there is an axial magnetic field in the channel, then all this changes and scattering with non-magnetic impurities or phonons will cause spin relaxation (and therefore a large leakage current). Consequently, it is extremely important to eliminate the channel magnetic field.

There are two ways to eliminate (or reduce) the channel magnetic field. One way is to magnetize the contacts in the y-direction instead of the x-direction. Since B_{Rashba} is in the z-direction, it makes no difference as to whether the spins are initially polarized in the x- or y-direction, as they precess in the x-y plane. The SPINFET works just as well if the source and drain contacts are magnetized in the $+y$ direction instead of the $+x$-direction. The advantage is that the magnetic field lines emanating from one contact, and sinking in the other, are no longer directed along the channel. Consequently, the channel magnetic field will be a fringing field, which is much weaker.

A more sophisticated approach is to play off the Dresselhaus spin–orbit interaction [14] against the channel magnetic field. This spin–orbit interaction is present in any zinc-blende semiconductor that lacks crystallographic inversion symmetry. In a 1-D channel oriented along the [100] crystallographic direction, the Dresselhaus spin–orbit interaction gives rise to a pseudo-magnetic field along the channel (x-axis), just as the Rashba spin–orbit interaction gives rise to a pseudo-magnetic field perpendicular to the channel (in the z-direction). The Dresselhaus field $B_{\text{Dresselhaus}}$ can be used to offset the channel magnetic field due to the contacts. Since $B_{\text{Dresselhaus}}$ depends on the carrier velocity v_x, the ensemble average velocity $<v_x>$ (which is the Fermi velocity for a degenerate carrier concentration) can be tuned with a backgate to make $B_{\text{Dresselhaus}}$ equal and opposite to the channel magnetic field, thereby offsetting the effect of the channel field. This was the approach proposed in Ref. [8].

In Figure 5.1b, the transfer characteristic (drain current versus gate voltage) is shown for an ideal SPINFET and a non-ideal SPINFET (with a channel magnetic field), ignoring any fixed threshold shift caused by a non-zero Rashba interaction in the channel at zero gate voltage. It should be noted that the transfer characteristic is "oscillatory" and therefore non-monotonic. As a result, the transconductance ($\partial I_D/\partial V_G$), where I_D is the drain current and V_G is the gate voltage, can be either positive or negative depending on the value of V_G (gate bias). A fixed threshold shift can be caused in any SPINFET by implanting charges in the gate insulator. Imagine now that there are two ideal SPINFETs with transfer characteristics, as shown in Figure 5.1c. These two can be connected in series to behave as a complementary metal oxide semiconductor (CMOS) like inverter where an appreciable current flows only during switching. This would be a tremendous advantage as CMOS like operation can be achieved with just n-type SPINFETs where the majority carriers are electrons. In conventional CMOS technology, both an n-type and a p-type device would have

normally have been needed. Here, we need only n-type devices. However, all this advantage is defeated if there is significant leakage current flowing through the SPINFET when it is "off". Thus, the leakage current is a rather serious issue and care must be taken to eliminate it as much as possible.

5.2.1.2 The SPINFET Based on the Dresselhaus Spin–Orbit Interaction

The Dresselhaus spin–orbit interaction can also be gainfully employed to realize a different kind of SPINFET [15]. In a 1-D channel, the strength of the Dresselhaus interaction depends on the physical width of the channel. If the 1-D channel is defined by a split-gate, then the voltages on the split gate can be varied to change the channel width and therefore the strength of the Dresselhaus interaction. As with the Rashba interaction, the Dresselhaus interaction also causes spins to precess in space at a rate independent of the carrier velocity because it gives rise to a pseudo-magnetic field $B_{\text{Dresselhaus}}$ along the x-axis. The spins precess in the y-z plane. By varying the split gate voltage it is possible to change $B_{\text{Dresselhaus}}$ and the precession rate, and therefore the angle Φ, by which the spins precess as they traverse the channel from source to drain. As the split gate voltage can be used to modulate the source to drain current, transistor action can be realized. A schematic representation of a Dresselhaus-type SPINFET is shown in Figure 5.3.

The advantage of the Dresselhaus-type SPINFET over the Rashba-type is that, in the former, there is never a strong magnetic field in the channel due to contacts [15], as $B_{\text{Dresselhaus}}$ is in the x-direction and therefore the ferromagnetic contacts must be magnetized in the y-z plane (see Figure 5.3). By contrast, B_{Rashba} is in the z-direction, and therefore in the Rashba-type device the ferromagnetic contacts must be magnetized in the x-y plane. As mentioned above, the Rashba-type device could avoid a strong channel magnetic field if the contacts were to be magnetized in the y-direction, but this is difficult to do as the ferromagnetic layer thickness in the y-direction is much smaller than that in the x- or z-directions. Thus, the Rashba-type device will typically have some magnetic field in the channel, while the Dresselhaus-type device will not, except for the fringing fields. This feature eliminates many of the problems

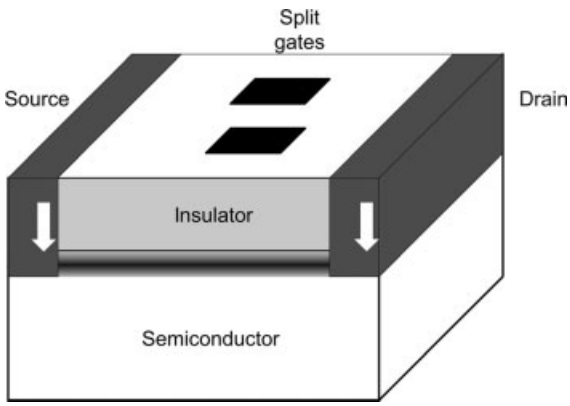

Figure 5.3 Schematic of a SPINFET based on the Dresselhaus spin–orbit interaction.

associated with the channel magnetic field in the Dresselhaus-type SPINFET, and could lead to a reduced leakage current. A comparison between the Rashba-type and Dresselhaus-type SPINFETs is provided in Ref. [15].

5.2.2 Device Performance of SPINFETs

In the world of electronics, the universally accepted benchmark for the transistor device is the celebrated metal-oxide-semiconductor-field-effect-transistor (MOSFET) which has been – and still is – the "workhorse" of all circuits. Therefore, the SPINFET must be compared with an equivalent MOSFET to determine if there are any advantages to utilizing spin. Surprisingly, in spite of many papers extolling the perceived merits of SPINFETs, this elementary exercise was not carried out until recently. When an ideal SPINFET was compared with an equivalent ideal MOSFET at low temperatures [16], the results were quite illuminating.

According to Ref. [1], the switching voltage necessary to turn a 1-D Rashba-type SPINFET from on to off, or vice versa, is given by

$$V_{switching}^{SPINFET} = \frac{\pi\hbar^2}{2m^* L\xi} \tag{5.4}$$

where m^* is the effective mass, L is the channel length (or source-to-drain separation), and ξ is the rate of change of the Rashba interaction strength in the channel per unit change of the gate voltage. This is given by [16]:

$$\xi = \frac{\hbar^2}{2m^*}\frac{\Delta(2E_g+\Delta)}{E_g(E_g+\Delta)(3E_g+2\Delta)}\frac{2\pi e}{d} \tag{5.5}$$

where E_g is the bandgap of the channel semiconductor, Δ is the spin orbit splitting in the valence band of the semiconductor, e is the electronic charge, and d is the gate insulator thickness. If $d = 10$ nm,[6] then it can be calculated that in an InAs channel, $\xi = 10^{-28}$ C-m. This is the theoretical value, but an actual measured value is much less than this [17]. The compound InAs has strong spin–orbit interaction and therefore is an ideal material for SPINFETs.

Now, imagine that the same structure is used as a MOSFET. Then, the switching voltage that turns the MOSFET device off (depletes the channel of mobile carriers) is E_F/e, where E_F is the Fermi energy in the channel.[7] Thus, the ratio of the switching

6) The ideal semiconductor is a narrow gap semiconductor such as InAs, which has strong Rashba spin–orbit interaction. In that case, the gate insulator will probably be AlAs, which is reasonably lattice-matched to InAs. Because the conduction band offset between these two materials is not too large, a minimum of 10 nm gate insulator thickness may be necessary to prevent too much gate leakage.

7) An accumulation mode MOSFET has been assumed that is "normally-on". It has also been assumed that the normal channel carrier concentration is large enough that $E_F \gg kT$, where E_F is the Fermi energy and kT is the thermal energy. Therefore, the comparison is strictly valid at very low temperatures. It is believed that, at higher temperatures, the fundamental conclusions from this comparison will not be significantly altered.

voltages is

$$\frac{V_{switching}^{SPINFET}}{V_{switching}^{MOSFET}} = \frac{\pi\hbar^2 e}{2m^* L\xi E_F} \tag{5.6}$$

In order to maintain single subband occupancy in an InAs 1-D channel of reasonable width, E_F must be less than ~3 meV. Therefore, from Eq. (3.6) it is found that the SPINFET will have a lower threshold voltage than a comparable MOSFET (at low temperature) only if its channel length exceeds 2.4 μm! Thus, no submicron SPINFET has any advantage over a comparable MOSFET in terms of switching voltage or dynamic power dissipation during switching. Currently, MOSFETs with 90 nm channel length are in production [18]. For a SPINFET with this channel length to have a lower threshold voltage than a comparable MOSFET, the channel must be made from a material in which the product $m^*\xi$ is 26-fold larger than it is in InAs, assuming that E_F is still 3 meV. Such materials are not currently available, but of course could become available in the future. The unfortunate spoiler is that materials which have large effective mass also tend to have weak spin–orbit interaction, which makes it difficult to increase the product $m^*\xi$.

One issue that requires some thought here is that the switching voltage of a MOSFET depends on E_F – and therefore the carrier concentration in the channel – while the switching voltage of a SPINFET depends on the channel length. It is not clear which quantity is easier to control in batch processing, but that would determine which device has an advantage in terms of threshold variability and, ultimately, of yield.

5.2.3 Other Types of SPINFET

Slightly different types of SPINFET ideas have also been reported in the literature, with names such as "Non-ballistic SPINFET" [19] or the "Spin Relaxation Transistor" [20–22].

5.2.3.1 The Non-Ballistic SPINFET

The channel of the so-called "non-ballistic SPINFET" has a two-dimensional (2-D) electron gas, like an ordinary MOSFET. Unlike in a 1-D structure (quantum wire), the spin split bands in a 2-D structure (quantum well or 2-D electron gas) do not have a fixed spin quantization axis (meaning that the spin eigenstates are wavevector-dependent; recall Figure 5.2b), even if there is no magnetic field. The only exception to this situation is when the Rashba and Dresselhaus interactions in the channel have exactly the same strength. In that case, each band has a fixed spin quantization axis, and the spin eigenstate in either band is wavevector-independent.

In the non-ballistic SPINFET, the Rashba interaction is first tuned with the gate voltage to make it exactly equal to the Dresselhaus interaction, which is gate voltage-independent in a 2-D electron gas. This makes the spin eigenstates wave-

vector-independent. Electrons are then injected into the channel of the transistor from a ferromagnetic source with a polarization that corresponds to the spin eigenstate in one of the bands. All carriers enter this band. As the spin eigenstate is wavevector-independent, any momentum relaxing scattering in the channel, which will change the electron's wavevector, will not alter the spin polarization (recall the discussion in Section 5.2.1.1). Scattering can couple two states within the same band, but not in two different subbands, as the eigenspinors in two different subbands are orthogonal. Therefore, regardless of how much momentum-relaxing scattering takes place in the channel, there will be no spin relaxation via the Elliott–Yafet mode. There will also be no D'yakonov–Perel' relaxation as it can be shown that the pseudo-magnetic field due to the Rashba and Dresselhaus interactions will be aligned exactly along the direction of the eigenspin. As all spins are initially injected in an eigenstate, they will always be aligned along the pseudo-magnetic field. Consequently, there will be no spin precession which would have caused D'yakonov–Perel' relaxation. As no major spin relaxation mechanism is operative, the carriers at the source will arrive at the drain with their spin polarization intact. If the drain ferromagnetic contact is magnetized parallel to the source magnetization, then all these carriers will exit the device and contribute to current. In order to change the current, the gate voltage is detuned; this makes the Rashba and Dresslhaus interaction strengths unequal, thereby making the spin eigenstates in the channel wavevector-dependent. In that case, if the electrons suffer momentum-relaxing collisions due to impurities, defects, phonons, and surface roughness, their spin polarizations will also rotate and this will result in spin relaxation. Thus, the carriers that arrive at the drain no longer have all their spins aligned along the drain's magnetization. Consequently, the overall transmission probability of the electrons decreases, and the current drops. This is how the gate voltage changes the source-to-drain current and produces transistor action.

One simple way of viewing the transistor action is that when the Rashba and Dresselhaus interactions are balanced, the channel current is 100% spin polarized (all carriers arriving at the drain have exactly the same spin polarization). However, when the two interactions are unbalanced, then the spin polarization of the current decreases owing to spin relaxation. The spin polarization can decrease to zero – *but no less than zero* – which means that, on average, 50% of the spins will be aligned and 50% anti-aligned with the drain's magnetization when the minimum spin polarization is reached. The "aligned" component in the current will transmit and the "anti-aligned" component will be blocked. Thus, the minimum current (off-current) of this transistor *is only one-half* of the maximum current (on-current). As the maximum ratio of the on-to-off conductance is only 2, this device is clearly unsuitable for most – if not all – mainstream applications. A recent simulation has shown that the on-to-off conductance ratio is only about 1.2 [23], which precludes use in any fault-tolerant circuit.

The situation can be improved dramatically if the source and drain contacts have *anti-parallel* magnetizations, instead of parallel. In that case, when the Rashba and Dresselhaus interactions are balanced, the transmitted current will be exactly zero, but when they are unbalanced, it is non-zero. Therefore, the on-to-off conductance

becomes infinity. However, there is a caveat. This argument pre-supposes that the ferromagnetic contacts can inject and detect spins with 100% efficiency, meaning that only the majority spins are injected and transmitted by the ferromagnetic source and drain contacts, respectively. That has never been achieved, and even after more than a decade of research the maximum spin injection efficiency demonstrated to date at room temperature is only about 70% [24]. That means

$$\frac{I_{\mathrm{maj}} - I_{\mathrm{min}}}{I_{\mathrm{maj}} + I_{\mathrm{min}}} = 0.7 \tag{5.7}$$

where $I_{\mathrm{maj(min)}}$ is the majority (minority) spin component of the current. If the spin injection efficiency is only 70%, then 15% of the injected current is due to minority spins. These minority spins will transmit through the drain, even when the Rashba and Dresselhaus interactions are balanced. Thus, the off-current is 15% of the total injected current ($I_{\mathrm{maj}} + I_{\mathrm{min}}$), whereas the on-current is still at best 50% of the total injected current. Therefore, the on-to-off ratio of the conductance is $0.5/0.15 = 3.3$, which is not much better than 2.[8] Consequently, achieving a large conductance ratio is very difficult, particularly at room temperature when the spin injection efficiency tends to be small. In order to make the conductance ratio 10^5 – which is what today's transistors have – the spin injection efficiency must be 99.999% at room temperature. This is indeed a tall order, and may not be possible in the near term. If the off (leakage) current is nearly one-third of the on-current (which is what it will be with present-day technology), then the standby power dissipation will be intolerable and the noise margin unacceptable.

The device described in Ref. [20] is identical to that in Ref. [19], and therefore the same considerations apply.

5.2.3.2 **The Spin Relaxation Transistor**

The proposed "spin relaxation transistor" [21, 22] is very similar to the non-ballistic SPINFET. With zero gate voltage, the spin–orbit interaction in the channel is either weak or non-existent, which makes the spin relaxation time very long. When the gate voltage is turned on, the spin–orbit interaction strength increases, which makes the spin relaxation time short. Thus, with zero gate voltage, the spin polarization in the drain current is large (maximum 100%), while with a non-zero gate voltage it is small (minimum 0%). This device cannot be any better than the non-ballistic SPINFET. If the drain and source magnetizations are parallel, then it is easy to see that in the "on" state, the transmitted current is at best 100% of the injected current, while in the "off" state, it is no less than 50% of the injected current (the same arguments as in Section 5.2.3.1 apply). Therefore, the on-to-off conductance ratio is less than 2. With anti-parallel magnetizations in the source and drain contacts, the off-current approaches 0, and the conductance ratio approaches infinity, but only if the contacts inject and detect spin with 100% efficiency. If the injection efficiency is only 70%

8) Here it has been assumed that the drain is a perfect spin filter, or equivalently, the spin detection efficiency at the drain is 100%.

then, following the previous argument, the conductance ratio is no more than 3.3 [25]. Therefore, this device, too, is unsuitable for mainstream applications.

5.2.4 The Importance of the Spin Injection Efficiency

In every proposal for SPINFETs discussed here [1, 15, 19–22] there has always been the tacit assumption that spin injection and detection efficiencies at the source/channel and drain/channel interfaces are 100%. This is of course unrealistic. It can be shown easily that the ratio of on- to off-conductance of SPINFETs of the type proposed in Refs. [1, 15] is

$$r = \frac{1 + \xi_S \xi_D}{1 - \xi_S \xi_D} \tag{5.8}$$

where ξ_S is the spin injection efficiency at the source/channel interface and ξ_D is the spin detection efficiency at the drain/channel interface. For SPINFETs of the types proposed in Refs. [19–22],

$$r = \frac{1}{1 - \xi_S \xi_D} \tag{5.9}$$

Therefore, the spin injection/detection efficiency ξ is critical in order to obtain a large enough value of r. If the spin injection and detection efficiencies fall from 100% to 90%, the conductance on-off ratio drops from infinity to 5.2! Therefore, without a very high spin injection efficiency, approaching 100%, none of the SPINFETs will have a sufficiently high on-to-off conductance ratio to be of much use for anything. Thus, a closer look at spin injection efficiency is clearly required.

5.2.4.1 Spin Injection Efficiency

The science of "spin injection efficiency" (what controls it, what improves it, what does it depend on, etc.) is controversial (see Chapter 3 in Volume III), and there is scant agreement among research groups in this field. However, to the authors' knowledge nobody has claimed in the open literature that the spin injection efficiency can be 100% (even theoretically), particularly at elevated temperatures, except for Ref. [26]. These authors hold that, as there has been rapid experimental progress in improving spin injection efficiency over the past seven years (as of this writing), 100% efficient spin injection at room temperature should be around the corner. This optimism is not shared by the present author, since the two mechanisms suggested [26] as possible routes to achieving 100% spin injection efficiency are to use 100% spin-polarized half-metallic ferromagnets as spin injectors, and spin-selective barriers. Unfortunately, there are no 100% spin-polarized half-metals at any temperature above 0 K because of phonons and magnons [27], and even at 0 K the 100% spin polarization is destroyed by surfaces and inhomogeneities [27]. Thus, 100% spin-polarized half-metals simply do not exist. The best spin-selective barriers are resonant tunneling devices [28] that have spin-resolved energy levels. When the carrier energy is resonant with one of these levels, only the corresponding spin transits through the barrier. However, at any

temperature exceeding 0 K, the thermal spread in the electron energy will cause injected electrons to tunnel through *both* levels if the level separation is less than kT (which it usually is). Therefore, both spins will be transmitted. This happens even if the spin levels themselves are not broadened by $\sim kT$ because of weak spin–phonon coupling. As long as both spins are transmitted, the spin "selection" suffers and that makes the spin injection efficiency considerably less than 100%.

To summarize, as yet there is no known method to suggest – even theoretically – the possibility of 100% spin injection efficiency. As a result, all SPINFETs discussed in this chapter suffer from the malady of a low on-to-off conductance ratio, and this alone may make them non-competitive with MOSFETs.

5.2.5
Spin Bipolar Junction Transistors (SBJTs)

The SBJT is identical with the normal bipolar junction transistor, except that the base is ferromagnetic and it has a non-zero spin polarization. The conduction energy band diagram of a heterojunction n-p-n SBJT is shown in Figure 5.4. Assuming that the carrier concentration in the base is non-degenerate, so that Boltzmann statistics apply, the spin polarization in the base is

$$\alpha_b = \tanh(\Xi/2kT) \tag{5.10}$$

where 2Ξ is the energy splitting between majority and minority spin bands in the base. Based on a small signal analysis, it was shown that the voltage and current gains afforded by the SBJT is about the same as a conventional BJT [29], but the short-circuit current gain β has a dependence on the degree of spin polarization in the base which can be altered with an external magnetic field using the Zeeman effect. Thus, the external magnetic field can act as a "fourth terminal", and this can lead to non-linear circuits such as mixers/modulators. For example, if the ac base current is a sinusoid with a frequency ω_1 and the magnetic field is an ac field which is another sinusoid with frequency ω_2, then the collector current will contain frequency components

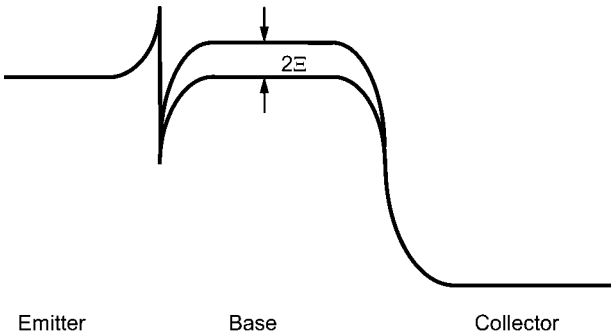

Figure 5.4 Conduction band energy profile for an n-p-n spin bipolar junction transistor (SBJT). The base is spin-polarized (ferromagnetic) and the spin splitting energy in the base is 2Ξ.

$\omega_1 \pm \omega_2$. This is one example where "spin" augments the role of "charge", making the SBJT another "hybrid spintronic" device.

5.2.6 The Switching Speed

The switching delay of any of the SPINFETs discussed above is limited by the transit time of carriers through the channel (or base). This is entirely due to the fact that information is encoded by charge (or current), and therefore the charge transit time is the bottleneck that ultimately limits the switching speed. Thus, hybrid spintronic devices do not promise any better speed than their charge-based counterparts.

5.3 Monolithic Spintronics: Single Spin Logic

At this point the discussion centers on "monolithic spintronics" where charge plays no role whatsoever and spin polarization is used to store, process and transmit information. In 1994, the idea was proposed of "single spin logic" (SSL) where a single electron acts as a binary switch and its two orthogonal (anti-parallel) spin polarizations encode binary bits 0 and 1 [30]. Switching between bits is accomplished by simply flipping the spin *without physically moving charges*. To the author's knowledge, this is the first known logic family (classical or quantum) based on single electron spins.

5.3.1 Spin Polarization as a Bistable Entity

The first step in SSL is to make the spin polarization of an electron a *bistable* quantity that has only two stable "values" that will encode the bits 0 and 1. In charge-based electronics, the state variables representing digital bits (voltage, current or charge), are not bistable but are continuous variables. So, why is the spin polarization required to be bistable? The reason is that in the world of electronics, there are analog-to-digital converters that can convert a continuous variable (analog signal) to a discrete variable (digital signal). More importantly, logic gates act as amplifiers with power gain and can automatically restore digital signal at logic nodes [31] if the signal is corrupted by noise. There are no equivalent analog-to-digital converters for spin polarization and no spin amplifiers, and therefore *Nature* must be relied upon to digitize spin polarization and make signal degeneration impossible. This can happen if *Nature* permits only two values of spin polarization – that is, it inherently makes it "bistable". That can be accomplished by placing an electron in a static magnetic field. The Hamiltonian describing a single electron in a magnetic field is

$$H = (\vec{p} - q\vec{A})^2/2m^* - (g/2)\mu_B \vec{B} \cdot \vec{\sigma} \tag{5.11}$$

where $\vec{A}$ is the vector potential due to the magnetic flux density $\vec{B}$, μ_B is the Bohr magneton, g is the Lande g-factor, and $\vec{\sigma}$ is the Pauli spin matrix. If the magnetic

field is directed in the x-direction ($\vec{B} = B\hat{x}$), then diagonalization of the above Hamiltonian immediately produces two mutually orthogonal eigenspinors [1,1] and [1, − 1] which are the $+x$ and $-x$-polarized spins – that is, states whose spin quantization axes are parallel and anti-parallel to the x-directed magnetic field. Thus, the spin quantization axis (or spin polarization) has only two stable values and therefore becomes a *binary* variable. The "down" (parallel) or "up" (anti-parallel) states can encode logic bits 0 and 1, respectively.

5.3.2
Stability of Spin Polarization

Although the binary bits 0 and 1 can be encoded in the two anti-parallel spin polarizations, there remains a problem in that random bit flips caused by coupling of spins to the environment will cause bit errors and corrupt the data. The probability of a "bit flip" within a clock cycle is $1 - e^{-\frac{T}{\langle\tau\rangle}}$, where T is the clock period and $\langle\tau\rangle$ is the mean time between random spin flips. In order to make this probability small, it must be ensured that $\langle\tau\rangle \gg T$.

If the host for the spin is a "quantum dot", then indeed $\langle\tau\rangle$ can be quite long. In InP quantum dots, the single electron spin flip time has been reported to exceed 100 μs at 2 K [32]. More recently, several experiments have been reported claiming spin flip times (or so-called longitudinal relaxation time, T_1) of several milliseconds, culminating in a recent report of 170 ms in a GaAs quantum dot at low temperature (see the last reference in Ref. [33]). An extremely surprising result is that spin relaxation time $\langle\tau\rangle$ in organic semiconductors can be incredibly long. It was found that the spin relaxation time in tris(8-hydroxyquinolinolate aluminum) – popularly known as Alq_3 – can be as long as 1 s at 100 K [34]. If the clock frequency is 5 GHz, then the clock period T is 200 ps, which is 5×10^9 times smaller than the spin flip time. Therefore, the probability that an unintentional spin flip will occur between two successive clock pulses is $1 - e^{-1/(5\times 10E9)} = 2 \times 10^{-10}$, which can be handled by modern error correction algorithms [35].

Typical error probabilities encountered in today's integrated circuits range from 10^{-10} to 10^{-9}. If a 5-GHz clock is used and an error probability $1/p$ of 10^{-9} is required, the spin flip time needs to be only 200 ms, which is fairly easy to achieve today at low temperatures (77 K).

5.3.3
Reading and Writing Spin

"Spin" has one major disadvantage compared to "charge". Whereas, charge is extremely easy to read (or measure) with voltmeters, ammeters, electrometers, and so on, and extremely easy to write (or inject) with voltage and current sources, spin is much more difficult to read or write. Although reading is more difficult than writing, even single spins have been "read" recently. The following section discusses reading and writing.

5.3.3.1 Writing Spin

Spin bits in SSL are represented by the spin polarizations of single electrons, with each electron being hosted in a quantum dot. There are exotic methods of "writing" spin bits in quantum dots [3], but the easiest and conceptually most simple is to use local magnetic fields generated with inductive loops. These fields will orient the spins in the target dots along the direction of the field and write the chosen bit (see Chapter 4 in Volume III of this series). Local magnetic fields are generated on chip in magnetic random access memory (MRAM), but not with the spatial resolution required in the case of SSL. However, carbon nanotube-based inductive loops may be up to the task in the near future.

The next task is to estimate what amount of energy will be dissipated during the "writing" operation. Previously [3], the idea of writing spin using Rabi oscillation, as is done in electron spin resonance spectroscopy, was proposed. That mode of writing will not dissipate any energy whatsoever, but has no error tolerance as an ac magnetic pulse must be applied for precisely the correct duration. However, if overshoot or undershoot occurs, an error will be incurred that can build up and ultimately cause a bit-writing error. Error-free writing will require some dissipation, though this can be arbitrarily small.

5.3.3.2 Reading Spin

Reading spin bits is more difficult than writing spin bits. Here, the aim is to ascertain the spin polarization of a single electron in a solid (quantum dot), a feat which has been accomplished recently using three different methods [36–38]. The technique reported in Ref. [37] is eminently suitable for application in electronics.

5.3.4 The Universal Single Spin Logic Gate: The NAND Gate

The basic idea behind implementing logic gates in SSL is to engineer the interactions between input and output spin bits in such a way that the input–output relationship represents the "truth table" of the desired logic gate. This approach can be illustrated by showing how a NAND gate can be realized. The NAND gate is a universal gate with which any arbitrary combinational or sequential logic circuit may be implemented, and it is realized with a linear chain of three electrons in three quantum dots (see Figure 5.6). It will be assumed that only nearest-neighbor electrons interact via exchange as their wavefunctions overlap. Second nearest-neighbor interactions are negligible as exchange interaction decays exponentially with distance.

For NAND gate implementation, the leftmost and rightmost spins in Figure 5.5 must be regarded as the two "inputs bits", and the center spin as the corresponding "output bit". Assume that the downspin state ($\downarrow$) represents bit 1, and the upspin state ($\uparrow$) is bit 0. The global magnetic field, defining the spin quantization axes, is in the direction of "downspin". It has been shown recently, using a Heisenberg Hamiltonian to describe the 3-spin array, that as long as the Zeeman splitting energies caused by the local magnetic fields writing bits in the input dots is much larger than the

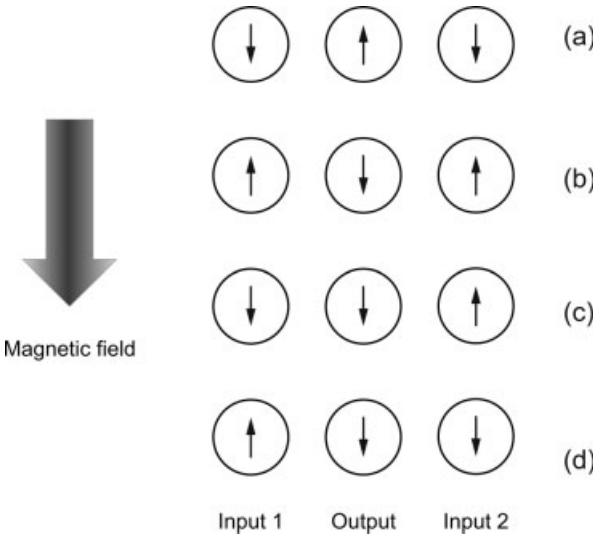

Figure 5.5 Single spin realization of the NAND gate. (a) When two inputs are [1 1]; (b) when two inputs are [0 0]; (c) when two inputs are [1 0]; and (d) when two inputs are [0 1]. Reproduced from Ref. 3 with permission from American Scientific Publishers: http://www.aspbs.com.

exchange coupling strength between neighboring dots, the ground-state spin configurations (determined by the directions of the local magnetic fields) are precisely those shown in Figure 5.5 [39]. In other words, if the input bits are written with local magnetic fields and the array is allowed to relax to the ground state in the presence of the local magnetic fields, then the output bit conforms to the diagrams in Figure 5.5a–d. It is evident that these configurations represent the truth table of the NAND gate:

Input 1	Input 2	Output
1	1	0
0	1	1
1	0	1
1	1	1

Therefore, if there is a 3-spin array, with nearest-neighbor exchange coupling, placed in a global magnetic field, and local magnetic fields align the spins in the peripheral dots to desired input bits, the output bit in the central dot will always be the NAND function of the input bits according to the truth table above, as long as two conditions are fulfilled:

- The array is in the thermodynamic ground state.

- The Zeeman splitting in the input dots caused by the local magnetic fields writing input data is much larger than the exchange coupling strength, which is roughly the energy difference between the triplet and singlet states in two neighboring dots.

Independent quantum mechanical calculations to confirm the working of the NAND gate were carried out by Molotkov and Nazin [40], while further investigations in this area have been conducted by Bychkov and coworkers [41].

Once the NAND gate is realized, only one other component is needed to implement any arbitrary combinational or sequential Boolean logic circuit. That element is a "spin wire" (with fan out) which will ferry spin logic signal from one stage to another *unidirectionally*. A spin wire (see Figure 5.6) consists of a linear array of quantum dots with clock pads between them. When the clock signal at a given pad is high, the potential barrier between the two surrounding dots is lowered and these dots are exchange-coupled because their wavefunctions overlap. This makes the spin states in these dots anti-parallel [42]. Therefore, by sequentially clocking the barriers, the spin bit can be replicated in every other dot, thus moving the spin signal along unidirectionally. Both, Sarkar et al. [43] and Bose et al. [44] have implemented a large array of combinational and sequential logic circuits using this approach. Two examples of their investigations are shown in Figure 5.7. The issue of unidirectionality and clocking will be revisited in Section 5.3.7.

5.3.5
Bit Error Probability

The NAND gate operates by relaxation to the thermodynamic ground state. It is the natural tendency of any physical system to gravitate towards the minimum energy

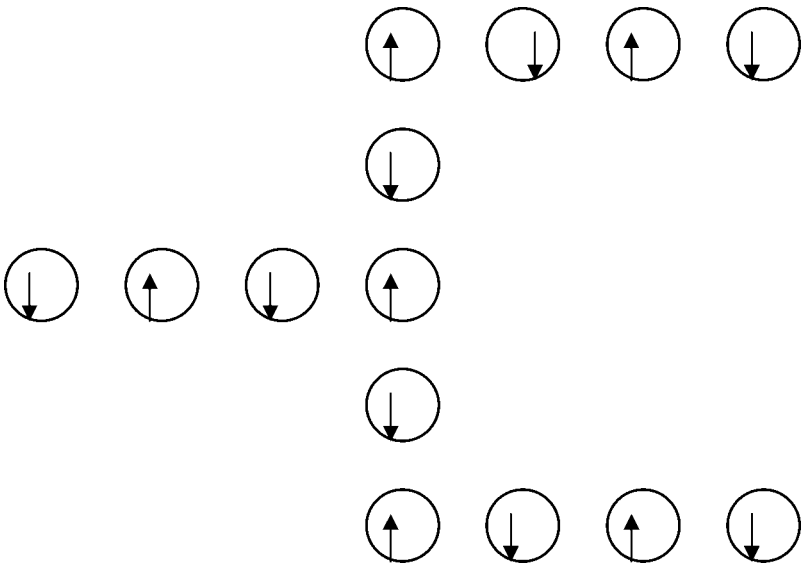

Figure 5.6 Realization of a "spin wire" with fan out.

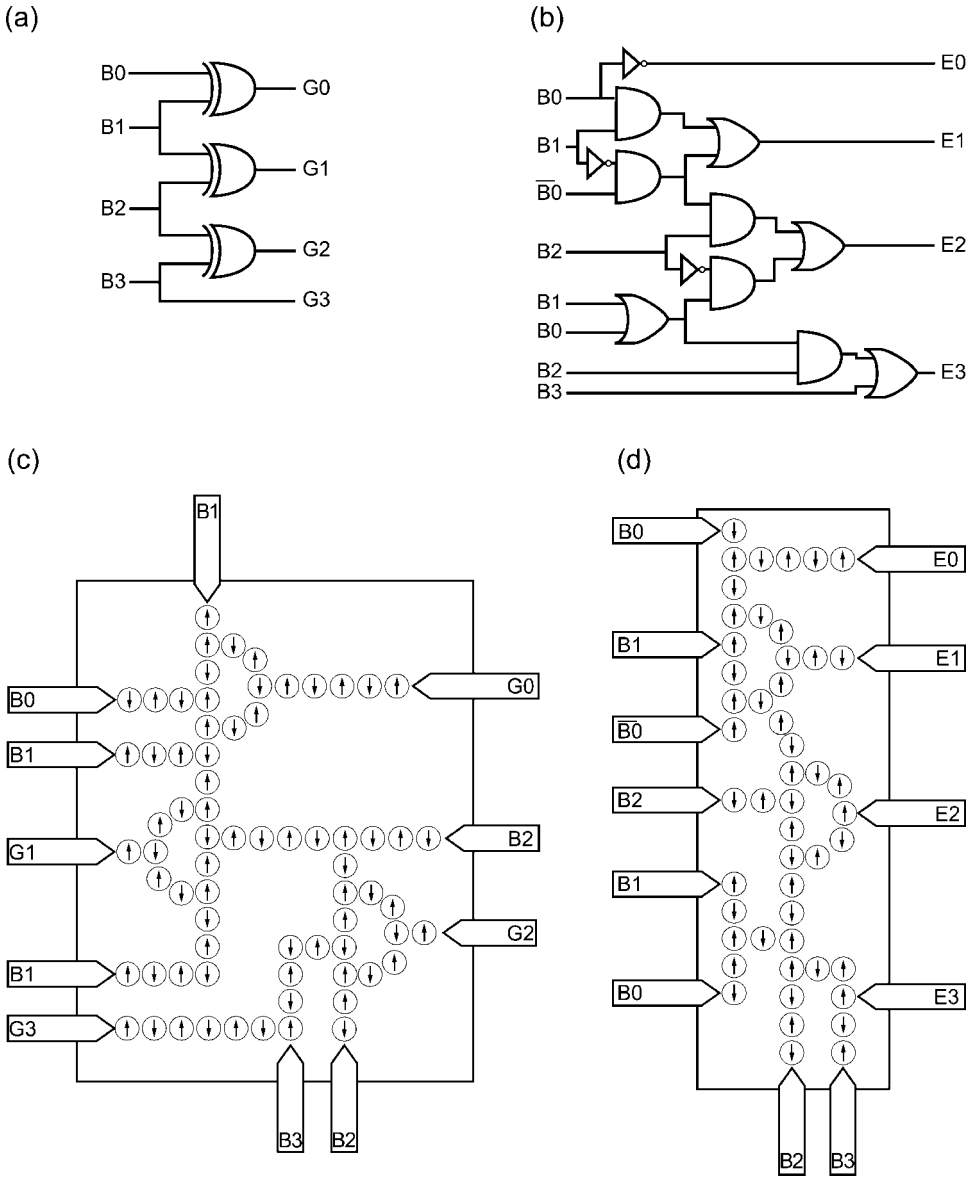

Figure 5.7 Single spin realizations of code converters. (a) Logic diagram for binary to Gray code converter; (b) logic diagram for binary to Excess-3 converter; (c) SSL realization of binary-to-Gray-code converter; and (d) SSL realization of binary-to-Excess-3 converter. The clock pads between successive cells are not shown for the sake of clarity. The input binary code is '1010'. Reproduced from Ref. 43, with permission from Institute of Solid State Physics, Chernogolovka, Russia.

state (ground state), this being the law of thermodynamics. However, when a system achieves the ground state it need not stay there forever, as noise and fluctuations can take it to an excited state. If that happens and the NAND gate strays from the ground state, the results will be in error. This error probability is calculated next.

The NAND gate reaches ground state by exchanging phonons with the thermal environment (phonon bath). This brings it into thermodynamic equilibrium with the surrounding thermal bath. In that case, the occupation probability of any eigenstate of the gate will be given by Fermi–Dirac statistics. The ground-state occupation probability is $1/[\exp(E_{\text{ground}} - E_F)/kT + 1]$ (where E_F is the Fermi energy) and the excited state occupation probability is $1/[\exp(E_{\text{excited}} - E_F)/kT + 1]$. As the occupation probability of the ground state is *not* unity, the gate does not always work correctly with 100% certainty – in other words, the error probability $1/p$ is never zero. However, it does decrease with increasing energy separation between the excited and ground states.

The error probability $1/p$ is the sum of the ratios of the probabilities of being in the excited and ground state, summed over all excited states. This quantity is approximately $\sum_{\text{excited states}} e^{-(E_{\text{excited}} - E_{\text{ground}})/kT}$, if the Fermi–Dirac statistics are approximated with Boltzmann statistics. It transpires that, in the case of the NAND gate, the second and higher excited states are far above in energy than the first excited state [39]. Therefore, only the first excited state E_1 can be retained in the sum above, and hence $E_1 - E_{\text{ground}} = kT\ln(p)$. It was also shown rigorously in Ref. [39] that $E_1 - E_{\text{ground}}$ is: (i) $4J - 2Z$ when the input bits are [1 1]; (ii) $4J + 2Z$ when the input bits are [0 0]; and (iii) $2Z$ when the input bits are [0 1] or [1 0]. Here, J is the exchange coupling strength between two neighboring dots, and $2Z$ is the Zeeman splitting energy in any dot due to the global magnetic field. Therefore, in order to attain an error probability of $1/p$ at a temperature T, it must be ensured that: (a) $2Z = kT\ln(p)$; and (b) $4J - 2Z = kT\ln(p)$, or $2J = kT\ln(p)$. The maximum values of J or Z are usually limited by technological constraints; for example, J is usually limited to 1 meV in gate-defined quantum dots [45]. These limits will then determine the maximum temperature of operation if a certain error probability $1/p$ is insisted on (this issue will be revisited in Section 5.3.10).

5.3.6
Related Charge-Based Paradigms

A similar idea for implementing logic gates using single electron charges confined in "quantum dashes" was proposed by Pradeep Bakshi and coworkers in 1991 [46]. There, logic bits were encoded in bistable charge polarizations of elongated quantum dots known as "quantum dashes". Coulomb interaction between nearest-neighbor quantum dashes pushes the electrons in neighboring dashes into antipodal positions, making the ground-state charge configuration "anti-ferroelectric", just as the exchange interaction in the present case tends to make the ground-state spin configuration almost "anti-ferromagnetic". Three Coulomb-coupled quantum dashes would realize a NAND gate in a way very similar to what was described here.

Bakshi's idea inspired a closely related idea known as "quantum cellular automata" [47], which uses a slightly different host, namely a four- or five-quantum dot "cell" instead of a quantum dash to store a bit. Here too the charge polarization of the cell is bistable and encodes the two logic bits. The only difference from Ref. [46] is that coulomb interaction makes the ground-state charge configuration ferroelectric, instead of anti-ferroelectric.

In the schemes of Refs. [46, 47] it is difficult to implement only nearest-neighbor interactions, at the exclusion of second-nearest-neighbor interactions, mainly because the Coulomb interaction is long range. The interaction in Refs. [46, 47] drops off as a polynomial of distance, but never exponentially with distance, unless strong screening can be implemented. If second-nearest-neighbor interactions are not much weaker than their nearest-neighbor counterparts, the ground-state charge configuration is weakly stable and not sufficiently robust against noise. In this respect, the spin-based approach has an advantage. As exchange interaction is short range (it always drops off exponentially with distance), it is much easier to make the second-nearest-neighbor interactions considerably weaker than the nearest-neighbor interactions.

A second issue is that in Refs. [46, 47], there is internal charge movement within each cell during switching, causing "eddy currents". This is a source of dissipation that is absent in the spin-based paradigm, as there is never any charge movement.

5.3.7
The Issue of Unidirectionality

The "unidirectional" propagation of logic signal was briefly mentioned in Section 5.3.5. This is a vital issue as the input signal should always influence (and determine) the output signal, but not the other way around. Unidirectionality is an important requirement for logic circuits [31]. A transistor is inherently unidirectional as there is *isolation* between its input and output terminals that guarantees unidirectionality. Therefore, it is easy to make logic circuits with transistors. In SSL, there is unfortunately *no isolation* between the input and output of the logic gate as exchange interaction is "bidirectional". Consider just two exchange coupled spins in two neighboring quantum dots; they will form a singlet state and therefore act as a natural NOT gate if one spin is the input and the other is the output (the output is always the logic complement of the input) [42]. However, exchange interaction, being bidirectional, cannot distinguish between which spin is the input bit and which is the output. The input will influence the output just as much as the output influences the input, and the master–slave relationship between input and output is lost. As the input and output are indistinguishable, it becomes ultimately impossible for logic signal to flow *unidirectionally* from an input stage to an output stage, and not the other way around. This issue has been discussed at length elsewhere [30, 48].

It is of course possible to forcibly impose unidirectionality in some (but not all) cases by holding the input cell in a fixed state until the desired output state is produced in the output cell. In that case, the input signal itself enforces unidirectionality because it is a symmetry-breaking influence. This approach was

actually used to demonstrate a "magnetic cellular automaton", where the input enforced unidirectionality and produced the correct output [49]. However, there are problems with this approach. First, it can only work for a small number of cells before the influence of the input dies out. Second – and more important – the input cannot be changed until the final output has been produced, since otherwise the correct output *may not be produced at all*. That makes such architectures *non-pipelined* and therefore unacceptably slow. There may also be additional problems associated with random errors when this approach is employed; these are discussed in Ref. [50].

5.3.8
Unidirectionality in Time: Clocking

If unidirectionality cannot be imposed in *space*, then it must be imposed in *time*. This is accomplished by using clocking to activate successive stages sequentially in time [51, 52]. This strategy is well known and routinely adopted in bucket-brigade devices, such as charge-coupled-device (CCD) shift registers,[9] where a push clock and a drop clock are used to lower and raise barriers between neighboring devices and thus steer a charge packet unidirectionally from one device to the next. The same can be done in single-spin circuits. A gate pad will be delineated between every two neighboring quantum dots, and a clock signal applied to this pad. During the positive clock cycle, a positive potential will appear over the potential barrier, thus isolating two neighboring quantum dots; this will lower the barrier temporarily to exchange-couple the two spins and result in the two spins assuming antiparallel polarizations [42]. Then, during the negative clock cycle, the barrier is raised again to decouple the two spins. In this way, pairs of spin bits can be coupled sequentially in time, and the logic information transferred unidirectionally from one dot to the next in a bucket-brigade fashion. It has been shown previously [52] that a single-phase clock does not work, and that a three-phase clock is required to carry out this task.

The clocking circuit, however, introduces additional dissipation. The energy dissipated in the clock pad is $(1/2)CV^2$ if the clock pulse is applied non-adiabatically, and much less if applied adiabatically [6]. So, what should be the value of V? This is determined by noise considerations. The noise voltage on a capacitor is [53]:

$$U_n = \sqrt{\frac{kT}{C}} \tag{5.12}$$

and Ref. [53] prescribes that $V = 12\ U_n$ for reasonable error rates at clock frequencies over 10 GHz. In that case, the energy dissipated in the clock pads is $72\,kT$ if

9) CCDs also have no inherent unidirectionality. There, a push clock and a drop clock are used to steer charge packets from one device to the next. See, for example, D. K. Schroeder, in: G. W. Neudeck, R. F. Pierret (Eds.), *Advanced MOS Devices, Modular Series in Solid State Devices*, Chapter 3, Addison-Wesley, Reading, MA, **1987**.

applied non-adiabatically. If the clock signal is applied from a sinusoidal voltage source of amplitude V, then the energy dissipated per clock cycle is

$$E_{diss} = \frac{1}{2} CV^2 \frac{\omega}{\omega_{RC}} \tag{5.13}$$

where $\omega_{RC} = 1/RC$. The above formula holds if the clock circuit is modeled as a capacitor C in series with a resistor R representing the resistance in the charging path. Assuming that $R = 1\,\text{k}\Omega$ and $C = 1\,\text{aF}$, $\omega_{RC} = 10^{15}\,\text{rad}\,\text{s}^{-1}$. If the clock frequency is 5 GHz, then $\omega = 3.45 \times 10^{10}\,\text{rad}\,\text{s}^{-1}$. Therefore, $E_{diss} = 2.5 \times 10^{-3} kT$, which is negligible.

When clock pads are used, the most attractive feature of SSL is removed, namely the *absence* of interconnects (or "wires") between successive devices. "Wireless" exchange interaction plays the role of physical wires to transmit signals between neighboring devices, but in order to transmit "unidirectionally", each stage will need to be clocked and this requires a physical interconnect. A clock pad must be placed between pairs of quantum dots and wires must be attached to them to ferry the clock signal. Of course, a clock signal is also needed in traditional digital circuits involving CMOS, so that it is not an additional burden. Nevertheless, it still detracts from the appeal of a "wireless architecture", or the so-called "quantum-coupled architecture".

5.3.9
Energy and Power Dissipation

Most likely, by merely examining Figure 5.5, the reader can understand that the maximum energy dissipated when the gate switches between any two states is $2Z$, which is the Zeeman splitting in the output dot caused by the global magnetic field (this result was proved rigorously in Ref. [39]). Since it was shown in Section 5.3.5 that $2Z = kT\ln(p)$, the *maximum* energy dissipated during switching is $kT\ln(p)$, which was expected from the Landauer–Shannon result. The interesting point however is that the energy dissipated can be *less* than $kT\ln(p)$, depending on the initial and final states – that is, depending on the old and new input bit strings. If the gate switches from the state in Figure 5.5c to that in Figure 5.5a, the energy dissipated is actually $(2/3)\,kT\ln(p)$, while if it switches from the state in Figure 5.5b to that in Figure 5.5c, the energy dissipated is $(1/3)kT\ln(p)$ [39]. The reductions by factors of $1/3$ and $2/3$ are due to *interactions* between spins. Some implications of "interactions" were discussed in Ref. [4] in the context of reducing energy dissipation. What really happens here is that the three spins act collectively in unison as a single unit, because of the exchange-coupling between them, which reduces the total energy dissipation.

The maximum energy dissipation occurs when the gate switches from the state in Figure 5.5b to that in Figure 5.5a. That energy is $kT\ln(p)$. With $p = 10^{-9}$, this energy is $\sim 21\,kT$. By contrast, modern-day logic gates dissipate more than $50\,000\,kT$ when they switch [54].

5.3.10
Operating Temperature

In Section 5.3.5, the following result was established:

$$2J = kT\ln(p)$$
$$2Z = kT\ln(p)$$

The maximum value of J in semiconductor quantum dots is ~1 meV [45], while in molecules it is about 6 meV [55]. Therefore, if an error probability p of 10^{-9} is required, $T = 1.1$ K if semiconductor quantum dots are employed. Room-temperature operation with this error probability will require J to be 270 meV, which is clearly unattainable at present.

Since $Z = J$ from the above relationships, the strength of the global magnetic field required can be estimated. That strength is found by setting $2Z = g\mu_B B_{\text{global}} = 2J = 2$ meV. If a material is used with a g-factor of 15 (e.g. InAs), then $B_{\text{global}} = 2.3$ Tesla, which is very reasonable.

As the energy separation between the spin levels ($g\mu_B B_{\text{global}}$) is 2 meV and kT at 1.1 K = 0.1 meV, it might be considered that a low temperature of 1.1 K was required in order to make the thermal broadening of the spin split levels much less (in this case, 20-fold less) than the level separation. However, this line of thinking would be entirely wrong, as the low temperature was needed for a small error probability ($1/p = 10^{-9}$), and *not* because there was a need to reduce the thermal broadening of levels. Spin, unlike charge, does not couple strongly to phonons, and therefore the thermal broadening of spin levels is much less than kT. If this were not the case, then electron spin resonance experiments at microwave frequencies could not be carried out at room temperature.

Unfortunately, this fact is not often understood or appreciated. For example, in Ref. [56] the authors state (contradicting Ref. [6]) that: "Energy barriers for a spin system play the same role as for a charge transfer system. The barrier must be large enough to make the different bit states distinguishable in a thermal environment". This argument is at best half-correct. For charge-based representation, the energy barrier separating logic states indeed need to be large enough that the different bit states are distinguishable in a thermal environment, since charge couples very strongly to the thermal environment, so that the thermal broadening of the energy states is $\sim kT$. This is *not* true for spin which, unlike charge, does *not* couple strongly with the thermal environment, so that the spin energy states are not broadened by $\sim kT$. As a result, the energy barrier separating logic states (i.e. $|g\mu_B B|$) can be much less than kT if bit error probability were not a concern. The energy barrier merely needs to be equal to $kT\ln(p)$, which would be *less than* kT if an error probability $1/p > 1/e = 0.367$ can be handled.

5.3.11
Energy Dissipation Estimates

It is now possible to estimate how much energy is dissipated in various actions, assuming $T = 1.1$ K:

Clocking	Bit flip
$2.48 \times 10^{-3}\,kT$ (sinusoidal) $= 4 \times 10^{-26}$ Joules ~ 0 (adiabatic)	$kT\ln(p)$ $[1/p = 10^{-9}]$ $= 3 \times 10^{-22}$ Joules

With a bit density of $10^{11}\,\mathrm{cm}^{-2}$, the dissipation per unit area is 3×10^{-22} Joules $\times\, 5\,\mathrm{GHz} \times 10^{11}\,\mathrm{cm}^{-2} = 0.15\,\mathrm{W\,cm}^{-2}$. In comparison, the Pentium IV chip, with a bit density three orders of magnitude smaller, dissipates about $50\,\mathrm{W\,cm}^{-2}$ [57]. SSL dissipates 300 times less power with a bit density three orders of magnitude larger.

5.3.12 Other Issues

In charge-based devices such as MOSFETs, logic bits 0 and 1 are encoded by the *presence* and *absence* of charge in a given region of space. This region of space could be the channel of a MOSFET. When the channel is filled with electrons, the device is "on" and stores the binary bit 0. When the channel is depleted of electrons, the device is "off" and stores the binary bit 1. Switching between bits is accomplished by the physical motion of charges in and out of the channel, and this physical motion consumes energy.[10] There is no easy way out of this problem since charge is a "scalar" quantity and therefore has only a *magnitude*. Bits can be demarcated only by a difference in the magnitude of charge or, in other words, by the relative presence and absence of charge. Therefore, to switch bits the magnitude of charge must be changed, and this invariably causes motion of the charges with an associated current flow. Spin, on the other hand, has a polarization which can be thought of as a "pseudo-vector" with two directions: "up" and "down". Switching between bits is accomplished by simply flipping the direction of the pseudo-vector with no change in magnitude of anything. As switching can be accomplished without physically moving charges (and causing a current to flow), spin-based devices could be inherently much more energy-efficient than charge-based devices, a point which was highlighted in Ref. [3].

It is because of this reason that SSL is much more energy efficient than the Pentium IV chip.

5.4 Spin-Based Quantum Computing: An Engineer's Perspective

Quantum computing is based on the idea of encoding information in a so-called "qubit", which is very different from a classical bit. It is a coherent superposition of

10) In fact, the physical motion of charges causes a current I to flow with an associated I^2R dissipation (where R is the resistance in the path of the current).

classical bits 0 and 1:

$$\begin{aligned} &qubit = a|0\rangle + b|1\rangle \\ &|a|^2 + |b|^2 = 1 \end{aligned} \tag{5.14}$$

The coefficients a and b are complex numbers, and the phase relationship between them is important. The "qubit" is the essential ingredient in the quantum Turing machine first postulated by Deutsch to elucidate the nuances of quantum computing [58].

The power of quantum computing accrues from two attributes: *quantum parallelism* and *entanglement*. Consider two electrons whose spin polarizations are made bistable by placing them in a magnetic field. If the system is classical, these two electrons can encode only two bits of information: the first one can encode either 0 or 1 (downspin or upspin), and the second one can do the same. By analogy, N number of electrons can encode N bits of information, as long as the system is classical.

But now consider the situation when the spin states of the two electrons are quantum mechanically entangled so that the two electrons can no longer be considered separately, but rather as one coherent unit. In that case, there are four possible states that this two-electron system can be in: both spins "up"; first spin "up" and the second spin "down"; the first spin "down" and the second spin "up"; and both spins "down". The corresponding "qubit" can be written as:

$$\begin{aligned} &qubit = a|\uparrow\uparrow\rangle + b|\uparrow\downarrow\rangle + c|\downarrow\uparrow\rangle + d|\downarrow\downarrow\rangle \\ &|a|^2 + |b|^2 + |c|^2 + |d|^2 = 1 \end{aligned} \tag{5.15}$$

Obviously, this system can encode four information states, as opposed to two. By analogy, if N qubits can be quantum mechanically entangled, then the system can encode 2^N bits of information, as opposed to simply N. This becomes a major advantage if N is large. Consider the situation when $N = 300$. There is no way in which a classical computer can be built that can handle 2^{300} bits of information as that number is larger than the number of electrons in the known universe. However, if just 300 electrons could be taken and their spins entangled (a very tall order), then 2^{300} bits of information could be encoded. Thus, entanglement bestows on a quantum computer tremendous information-handling capability.

The above must not be misconstrued to imply that a quantum computer is a "super-memory" that can store 2^N bits of information in N physical objects such as electrons. When a bit is "read", it always collapses to either 0 or 1. In Eq. (5.17), the probability that the qubit will be read as 0 is $|a|^2$, and the probability that it will be read as 1 is $|b|^2$. As either a 0 or a 1 is always read, a quantum computer allows *access* to no more than N bits of information. Thus, it is no better than a classical memory – in fact, it is worse! Because of the probabilistic nature of quantum mechanics, a stored bit will sometimes be read as 0 (with probability $|a|^2$) and sometimes as 1 (with probability $|b|^2 = 1 - |a|^2$). If repeated measurements are made of the stored bits, the exact same result will never be achieved every time, and thus the quantum system is not even a reliable memory.

The power of *entanglement* does not result in a super memory, but it is utilized in a different way, and is exploited in solving certain types of problem super efficiently.

Two well-known examples are Shor's quantum algorithm for factorization [59] and Grover's quantum algorithm for sorting [60]. Factorization is an *NP*-hard problem, but using Shor's algorithm, the complexity can be reduced to *P*. Grover's algorithm for sorting has a similar advantage. Suppose that there is a need to sort an *N*-body ensemble to find one odd object. By using the best classical algorithm, this will take $N/2$ tries, but using Grover's algorithm it will take only $\sqrt{N}$ tries. Thus, entanglement yields super-efficient algorithms that can be executed in a quantum processor where qubits are entangled. That is the advantage of quantum computing.

5.4.1 Quantum Parallelism

In classical computing, "parallelism" refers to the parallel (simultaneous) processing of different information in different processors. Quantum parallelism refers to the simultaneous processing of different information or inputs in the *same* processor. This idea, due to Deutsch, refers to the notion of evaluating a function once on a superposition of all possible inputs to the function to produce a superposition of outputs. Thus, all outputs are produced in the time taken to calculate one output classically. Of course, not all of these outputs are accessible since a measurement on the superposition state of the output will produce only one output. However, it is possible to obtain certain joint properties of the outputs [61], and that is a remarkable possibility.

Quantum parallelism may be illustrated with an example. Consider the situation when *M* inputs $x_1, x_2, x_3, \ldots x_M$ are provided to a computer, and their functions $f(x_1)$, $f(x_2)$, $\ldots f(x_M)$ are to be computed. The results are then fed to another computer to calculate the functional $F(f(x_1), f(x_2), \ldots f(x_M))$.

With a classical computer, $f(x_1), f(x_2), \ldots f(x_M)$ will be calculated serially, one after the other. However, with a quantum computer, the initial state will be prepared as a superposition of the inputs:

$$|I\rangle = \frac{1}{\sqrt{M}}(|x_1\rangle + |x_2\rangle + \ldots |x_M\rangle) \tag{5.16}$$

This input will then be fed to a quantum computer and allowed to evolve in time to produce the output

$$|O\rangle = \frac{1}{\sqrt{M}}(|f(x_1)\rangle + |f(x_2)\rangle + \ldots |f(x_M)\rangle) \tag{5.17}$$

The output $|O\rangle$ has been obtained in the time required to perform a single computation. Now, if the functional $F(f(x_1), f(x_2), \ldots f(x_M))$ can be computed from $|O\rangle$, then a quantum computer will be extremely efficient. This is an example where "quantum parallelism" can speed up the computation tremendously.

There are two questions, however. First, can the functional be computed from a knowledge of the superposition of various $f(x_i)$ and not the individual $f(x_i)$s? The answer is "yes", but for a small class of problems – the so-called *Deutsch–Josza* class of problems which can benefit from quantum parallelism. Second, can the functional be computed correctly with unit probability? The answer is "no". However, if the answer obtained in the first trial is wrong (hopefully, the computing entity can

distinguish right from wrong answers), then the experiment or computation is repeated until the right answer is obtained. The probability of getting the right answer within k iterations is $(1 - p^k)$ where p is the probability of getting the wrong answer in any iteration. The mean number of times the experiment should be repeated to get the correct answer is $M^2 - 2M - 2$.

The following is an example of the Deutsch–Josza class of problems. For integer $0 \leq x \leq 2L$, given that the function $f_{k(x)} \in [0,1]$ has one of two properties – (i) either $f_{k(x)}$ is independent of x; or (ii) one-half of the numbers $f_{k(0)}, f_{k(1)}, \ldots f_{k(2L-1)}$ are zero – determine which type the function belongs to, using the fewest computational steps.

The most efficient classical computer will require $L + 1$ evaluations whereas, according to Deutsch and Josza, a quantum computer can solve this problem with just two iterations.

5.4.2
Physical Realization of a Qubit: Spin of an Electron in a Quantum Dot

The all-important question that stirs physical scientists and engineers is: Which system is most appropriate to implement a qubit? It must be one where the phase relationship between the coefficients a and b in Eq. (5.17) are preserved for the longest time. Charge has a small phase-coherence time which saturates to about 1 ns as the temperature is lowered towards 0 K because of coupling to zero point motion of phonons [62]. Spin has a much longer phase-coherence time as it does not couple to phonons efficiently. As a result, the phase-coherence time may not rapidly decrease with increasing temperature. Measurements of the phase-coherence time (also called the transverse relaxation time, or T_2 time) in an ensemble of CdS quantum dots has recently been shown actually to increase with increasing temperature [63]. It is believed that this is because the primary phase relaxation mechanism for electron spins in these quantum dots is hyperfine interactions with nuclear spins. The nuclear spins are increasingly depolarized with increasing temperature, and that leads to an actual increase in the electron's spin coherence time with increasing temperature. Therefore, it is natural to encode a qubit by the coherent superposition of two spin polarizations of an electron.

In 1996, the idea was proposed of encoding a "qubit" by the spin of an electron in a quantum dot [42]. A simple spin-based "quantum inverter" was designed which utilized two exchange-coupled quantum dots. This was not a universal quantum gate, but relied on quantum mechanics to elicit the Boolean logic NOT function. The spin of the electron was used as a qubit. To the present author's knowledge, this was the first instance where the spin of an electron in a quantum dot was used to implement a qubit in a gate. This idea was inspired by single spin logic and so in many ways SSL could be regarded as the progeny of spin-based quantum computing.

Unlike SSL – which is purely classical and does not require "phase coherence" – quantum computing relies intrinsically on phase coherence and is therefore much more delicate. While the phase coherence of single spins can be quite long, it is doubtful that several entangled spins will have sufficiently long-lived phase coherence to allow a

significant number of computational steps to be carried out, particularly when gate operations are performed on them. At the time of writing, the realization of practical scalable quantum processors based on electron spins appears to be decades away.

5.5 Conclusions

In this chapter, an attempt has been made to distinguish between the two approaches to spintronics, namely "hybrid spintronics" and "monolithic spintronics". It is unlikely that the hybrid approach will bring about significant advances in terms of energy dissipation, speed, or any other metric. The monolithic approach, on the other hand, is more difficult, but also more likely to produce major advances. The SSL idea revisited here is a paradigm that may begin to bear fruit with the most recent advances in manipulating the spins of single electrons in quantum dots [64–71]. This is a classical model and does not require the phase coherence that is difficult to maintain in solid-state circuits. There is also no requirement to "entangle" several bits, but rather a need to exchange-couple two bits pairwise. Thus, SSL is much easier to implement than quantum processors based on single electron spins.

6
Organic Transistors

Hagen Klauk

6.1
Introduction

Organic transistors are metal-insulator-semiconductor (MIS) field-effect transistors (FETs) in which the semiconductor is not an inorganic crystal, but a conjugated organic material. The fact that organic materials can be semiconductors may initially surprise, as most organic materials encountered today are excellent insulators. The fundamental property that leads to electrical conduction in carbon-based solids is conjugation – that is, the presence of alternating single and double bonds between neighboring carbon atoms (see Figure 6.1). Conjugation results in the delocalization of the π-electrons over the entire molecule – or at least over the conjugated portion of the molecule – and this allows electronic charge to be transported along the molecule.

Electrical conductivity in conjugated organic materials has been studied for a century, yet a complete picture of the charge transport physics in organics is still evolving. A central observation is that the intermolecular bonds in organic solids are not covalent bonds, but much weaker van der Waals interactions. As a consequence, electronic states are not delocalized over the entire solid, but are localized to a single molecule (or the conjugated portion of the molecule). Charge transport through organic solids is therefore limited by trapping in localized states, and likely involves some form of hopping between molecules. This means that the carrier mobilities in organic semiconductors are expected to be much smaller than the mobilities in inorganic semiconductor crystals.

In fact, carrier mobilities observed in organic solids vary greatly depending on the choice of material, its chemical purity, and the degree of molecular order in the solid (which determines the orbital overlap between neighboring molecules). Semiconducting polymers that arrange in amorphous films when prepared from solution usually have room-temperature mobilities in the range of 10^{-6} to 10^{-3} $cm^2 V^{-1} s^{-1}$. (For comparison, the carrier mobilities in single-crystalline silicon are near 10^3 $cm^2 V^{-1} s^{-1}$.) Through molecular engineering, improved purification, and better control of the film deposition (so that charges can be transferred more easily

Bruice, *Organic Chemistry*, Pearson Education, Upper Saddle River, NJ, USA.)

between molecules), the mobilities of conjugated polymers can be increased to about $0.5\,cm^2\,V^{-1}\,s^{-1}$. Small-molecule materials, on the other hand, often spontaneously arrange themselves into semicrystalline films when deposited by vacuum sublimation, and this results in room-temperature mobilities as large as $7\,cm^2\,V^{-1}s^{-1}$. Reports on carefully prepared single crystals of ultrapurified naphthalene suggest that mobilities at cryogenic temperatures can be as large as $400\,cm^2\,V^{-1}\,s^{-1}$ [1].

It is generally agreed that no single transport model can account for this wide a range of observed mobilities. Also, the temperature dependence of the mobility can be quite different for different organic materials, and in some cases different temperature-dependent mobility behavior has been observed even for the same organic material. Consequently, several different models for charge transport in organics have been proposed.

The model of *variable-range hopping* (VRH) assumes that carriers hop between localized electronic states by tunneling through energy barriers, and that the probability of a hopping event is determined by the hopping distance and by the energy distribution of the states. Specifically, carriers either hop over short distances with large activation energies, or over long distances with small activation energies. Since the tunneling is thermally activated, the mobility increases with increasing temperature. With increasing gate voltage, carriers accumulated in the channel fill the lower-energy states, thus reducing the activation energy and increasing the mobility. As Vissenberg and Matters have shown [2], the tunneling probability depends heavily on the overlap of the electronic wave functions of the hopping sites, which is consistent with the observation that the carrier mobility is significantly greater in materials with a larger degree of molecular ordering. Thus, the mobility is dependent on temperature, gate voltage, and molecular ordering (see Figure 6.2). The variable-range hopping model is usually discussed in the context of low-mobility amorphous semiconductor films (with room-temperature mobility less than about $10^{-2}\,cm^2\,V^{-1}\,s^{-1}$).

The *multiple trapping and release* (MTR) model adapted for organic transistors by Gilles Horowitz and coworkers [3] is based on the assumption that most of the charge carriers in the channel are trapped in localized states, and that carriers cannot move directly from one state to another. Instead, carriers are temporarily promoted to an

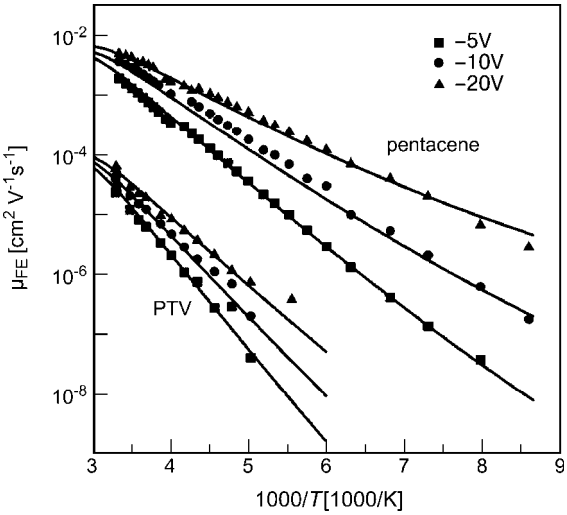

Figure 6.2 Temperature-dependent and gate voltage-dependent carrier mobility in a disordered polythienylenevinylene (PTV) film and in a solution-processed pentacene film. (Reproduced with permission from Ref. [2].)

extended-state band in which charge transport occurs. The number of carriers available for transport then depends on the difference in energy between the trap level and the extended-state band, as well as on the temperature and on the gate voltage (see Figure 6.3). The MTR model is generally considered to apply to materials with a significant degree of molecular ordering, such as polycrystalline films of small-molecule and certain polymeric semiconductors – that is, to materials which show room-temperature mobilities approaching or exceeding $0.1\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$. Carrier mobilities this large are not easily explained in the framework of the VRH model. On the other hand, the existence of an extended-state transport band in organic semiconductors as postulated by the MTR model is still the subject of debate.

6.2 Materials

Organic semiconductors essentially are available as two types: *conjugated polymers* and *conjugated small-molecule materials*. The prototypical semiconducting polymer is polythiophene (Figure 6.4a). While genuine polythiophene is insoluble and thus difficult to deposit in the form of thin films, alkyl-substituted polythiophenes, such as poly(3-hexylthiophene) (P3HT) (Figure 6.4b) have excellent solubility in a variety of organic solvents, and thin films are readily prepared by spin-coating, dip-coating, drop-coating, screen printing, or inkjet printing. Polythiophene was one of the first polymers to be used for organic transistors [4, 5], and remains one of the most popular semiconductors in organic electronics.

Generic polythiophenes usually form amorphous films with virtually no long-range structural order, very short π-conjugation length, and consequently poor mobilities, typically below $10^{-3}\,cm^2\,V^{-1}\,s^{-1}$. Obtaining usefully large mobilities in the polythiophene system requires highly purified derivatives which have been specifically synthesized to allow the molecules to self-organize into crystalline structures with a high degree of molecular order. An early example of such an engineered polythiophene is regioregular (RR) head-to-tail (HT) P3HT, initially synthesized by McCullough and coworkers in 1993 [6] and first employed for transistor fabrication by Bao and colleagues in 1996 [7]. In RR-HT-P3HT, the strong interactions between the regularly oriented alkyl side chains lead to a three-dimensional (3-D) lamellar structure in which the thienylene moieties along the polymer backbone are held in coplanarity (see Figure 6.5). The coplanarity of the thienylene moieties greatly increases the extent of π-conjugation, one consequence of which is a substantially increased carrier mobility (0.05 to $0.1\,cm^2\,V^{-1}\,s^{-1}$) compared with regiorandom P3HT (less than $10^{-3}\,cm^2\,V^{-1}\,s^{-1}$).

The microstructure of regioregular P3HT, its dependence on the degree of regioregularity, molecular weight, and deposition conditions, and the relationship between microstructure and carrier mobility, has been studied in detail by Sirringhaus and coworkers [8]. These authors found that the orientation of the microcrystalline lamellar domains with respect to the substrate surface is influenced by the molecular weight (i.e. the average polymer chain length), by the degree of

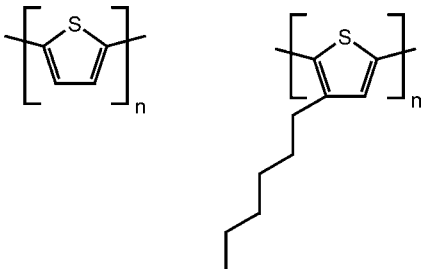

Figure 6.4 The chemical structures of polythiophene (left) and poly(3-hexylthiophene) (P3HT) (right).

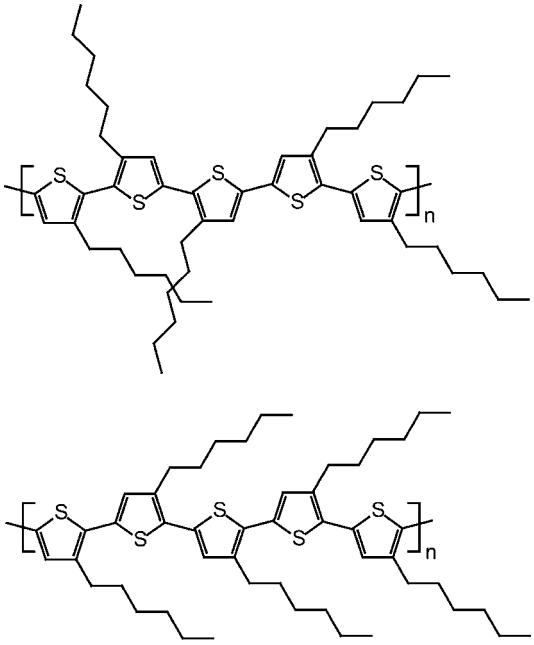

Figure 6.5 Schematic representation of regiorandom P3HT (left) and regioregular P3HT (right).

regioregularity, and by the deposition conditions (i.e. whether the film formation occurred quickly or slowly). The formation of ordered lamellae leads to a substantial overlap of the π-orbitals of neighboring molecules, but only in the direction perpendicular to the lamella plane. As a result, charge carrier transport and mobility in ordered P3HT films is highly anisotropic. In field-effect transistors (FETs), current flows parallel to the substrate, so the orientation of the lamellae with respect to the substrate surface is critical for the electrical performance of the transistors. Sirringhaus et al. were able to show that the transistor-friendly orientation of the lamellae (shown in Figure 6.6a) can be induced by selecting a polymer with a high degree of regioregularity (see Figure 6.6b) and, to a lesser extent, by choosing deposition conditions that favor a slow crystallization of the film.

Unfortunately, the large extent of π-conjugation in regioregular P3HT also leads to a significantly reduced ionization potential that makes the material very susceptible to photoinduced oxidation. This explains the commonly observed instability of P3HT transistors when operated in ambient air without encapsulation. A successful route to environmentally more stable self-organizing, high-mobility polythiophene derivatives was devised by Ong and coworkers [9]. This group recognized that the strategic placement of unsubstituted moieties along the polymer backbone and the resulting torsional deviations from coplanarity would reduce the effective π-conjugation length sufficiently to increase the ionization potential (and thus greatly improve oxidation resistance and environmental stability) while compromising the mobility only slightly, if at all. One particularly successful material which has emerged from this line of study is poly(3,3′′′′-didodecylquaterthiophene), better

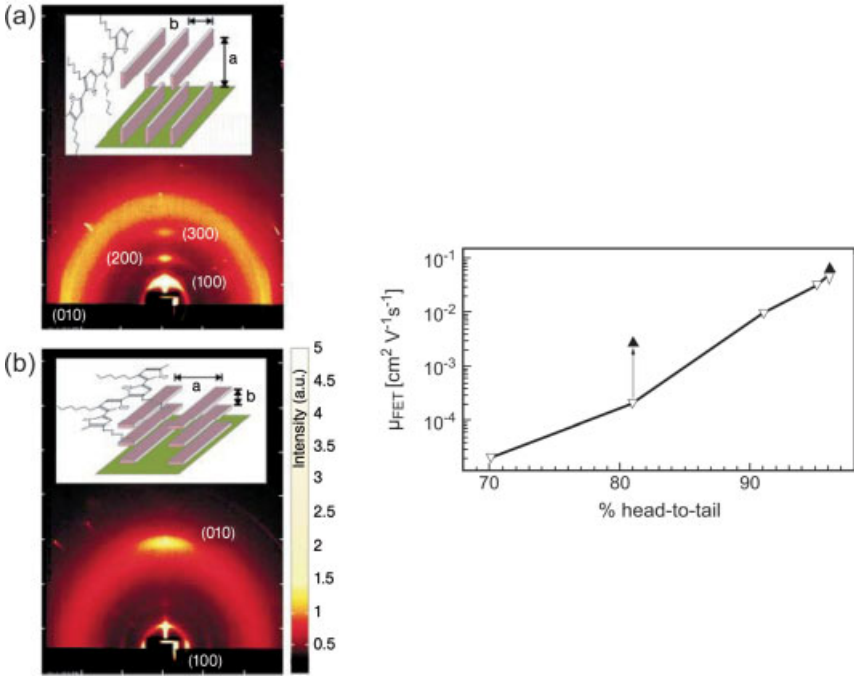

Figure 6.6 Left: Upon deposition on a flat substrate, regioregular poly(3-hexylthiophene) (P3HT) forms ordered lamellar domains, the orientation of which depends on the degree of regioregularity, molecular weight, and deposition conditions. Right: Relationship between the degree of regioregularity (quantified as the head-to-tail ratio) and the carrier mobility of P3HT transistors. (Reproduced with permission from Ref. [8].)

known as PQT-12 (see Figure 6.7). PQT-12 has shown air-stable carrier mobilities as large as $0.2\,cm^2\,V^{-1}\,s^{-1}$, and has been employed successfully in the fabrication of functional organic circuits and displays.

To further improve the performance and stability of alkyl-substituted polythiophenes, researchers at Merck Chemicals incorporated thieno[3,2-*b*]thiophene moieties into the polymer backbone [10] (see Figure 6.8). The effect of this is two-fold:

- The delocalization of carriers from the fused aromatic unit is less favorable than from a single thiophene unit, so the effective π-conjugation length is further reduced and the ionization potential becomes even larger than for polyquaterthiophene.
- The rotational invariance of the thieno[3,2-*b*]thiophene in the backbone promotes the formation of highly ordered crystalline domains with an extent not previously seen in semiconducting polymers. The molecular ordering is induced by annealing the spun-cast films in their liquid-crystalline phase and subsequent crystallization upon cooling. Carrier mobilities of $0.5\,cm^2\,V^{-1}\,s^{-1}$ have been reported.

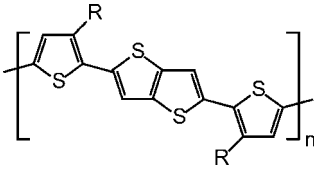

Figure 6.8 The chemical structure of poly(2,5-bis(3-alkylthiophen-2-yl)thieno[3,2-*b*]thiophene (PBTTT).

Among the small-molecule organic semiconductors, the most widely studied systems include pentacene, sexithiophene, copper phthalocyanine, and the fullerene C_{60} (see Figure 6.9). Many small-molecule materials are insoluble in common organic solvents, but they often can be conveniently deposited using vacuum-deposition methods, such as thermal evaporation or organic vapor-phase deposition. In most cases, small-molecule organic semiconductors readily self-organize into semicrystalline films with a significant degree of molecular order (see Figure 6.10).

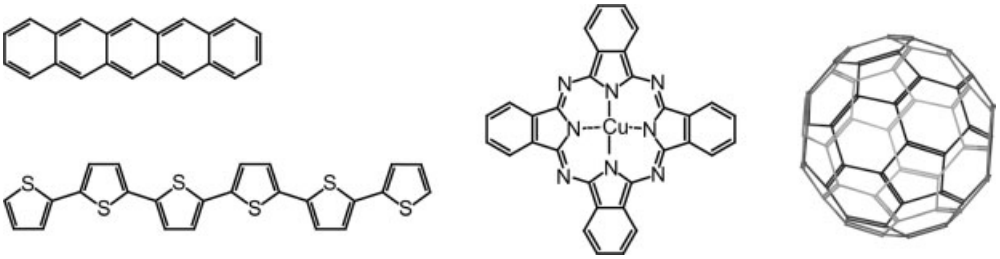

Figure 6.9 Chemical structures of pentacene (top left), sexithiophene (bottom left), copper phthalocyanine (center), and the fullerene C_{60} (right).

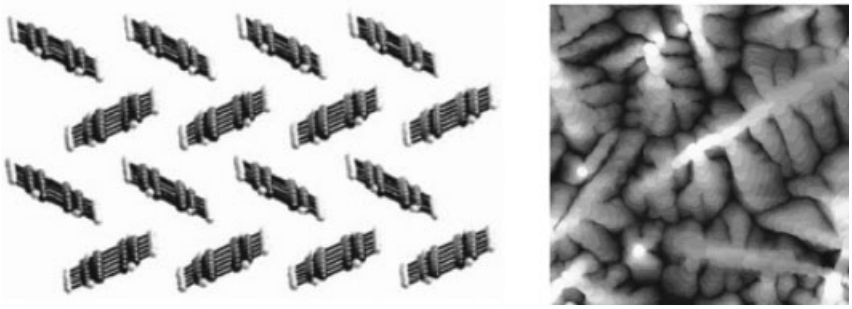

Figure 6.10 Pentacene self-organizes into an edge-to-face, or herringbone structure, forming semicrystalline films when deposited by evaporation onto amorphous substrates (left part of figure from: J. E. Anthony et al., Engineered pentacenes, in: *Organic Electronics*, Wiley-VCH, 2006.)

The use of vacuum-grown films of conjugated small-molecule materials for organic transistors was pioneered during the late 1980s by Madru and Clarisse (using metal phthalocyanines [11, 12]) and by Horowitz and Garnier (using oligothiophenes [13, 14]). Initial carrier mobilities were around $10^{-3}\,cm^2\,V^{-1}\,s^{-1}$, but these quickly improved to about $0.1\,cm^2\,V^{-1}\,s^{-1}$. In 1996, Jackson predicted and demonstrated that the carrier mobility of many organic semiconductors could be substantially improved by growing the films on low-energy surfaces [15, 16]. Inorganic dielectrics, such as silicon dioxide, are usually characterized by large surface energies favoring two-dimensional (2-D) growth of the first organic layer. Two-dimensional film growth typically results in large crystalline grains, and it was long believed that this was desirable to achieve good transistor performance. The surface energy of inorganic dielectrics is readily reduced by covering the surface with a self-assembled monolayer (SAM) of a methyl-terminated alkylsilane, such as octadecyltrichlorosilane (OTS). Organic film growth on low-energy SAM surfaces is distinctly three-dimensional, with much smaller grains and significantly more grain boundaries, yet the transistor mobilities were found to be significantly larger (by as much as an order of magnitude) compared with the large-grain films on high-energy surfaces. One explanation for this apparent discrepancy is that 2-D growth results in voids between disconnected grains, reducing the effective channel width of the transistor, and that such voids are efficiently filled when 3-D growth is favored [17, 18]. Carrier mobilities on high-energy surfaces (such as bare oxides) peak around $0.5\,cm^2\,V^{-1}\,s^{-1}$, while mobilities on low-energy surfaces (SAM-treated oxides or polymer dielectrics) have reached $1\,cm^2\,V^{-1}\,s^{-1}$ for alkyl-substituted oligothiophenes [19] and $5\,cm^2\,V^{-1}\,s^{-1}$ for pentacene [20–22].

An interesting alternative to solution-processed polymers and vacuum-grown small-molecules was developed by Herwig and Müllen during the early 1990s in the form of solution-deposited pentacene [23]. The initial rationale was to combine the best of two worlds – that is, the simplicity of solution-processing with the large carrier mobility of pentacene. Herwig and Müllen (and later Afzali and coworkers [24]; see Figure 6.11) synthesized a soluble pentacene precursor that was

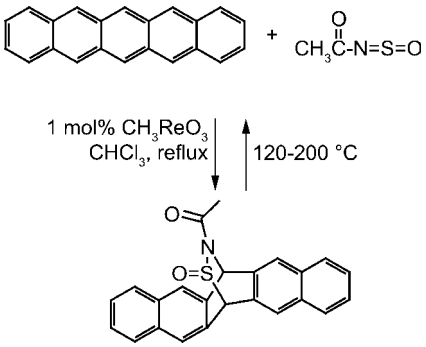

Figure 6.11 Synthesis of a soluble pentacene precursor and thermally induced conversion of the precursor to pentacene. (Reproduced with permission from Ref. [24].)

spin-coated and subsequently converted to pentacene at elevated temperature. Carrier mobilities for thermally converted pentacene are between 0.1 and 1 $cm^2 V^{-1} s^{-1}$, depending on the conversion temperature (130 to 200 °C).

The concept of solution-processable, high-mobility, small-molecule organic semiconductors was further developed by Anthony and colleagues, who designed and synthesized a number of soluble pentacene and anthradithiophene derivatives that do not require chemical conversion after deposition. Two examples – triisopropylsilyl (TIPS) pentacene and triethylsilyl (TES) anthradithiophene – are shown in Figure 6.12 [25]. In addition to providing solubility in common organic solvents, the functionalization of pentacene and anthradithiophene at the center rings can be utilized to strategically tune the molecular packing in the solid state in order to induce π-stacking with reduced intermolecular distances. With optimized solution-deposition, carrier mobilities as large as 3 $cm^2 V^{-1} s^{-1}$ have been achieved with these materials [26–28].

Organic transistors prepared with any of the semiconductors discussed so far operate efficiently only as p-channel transistors; that is, the drain currents in these

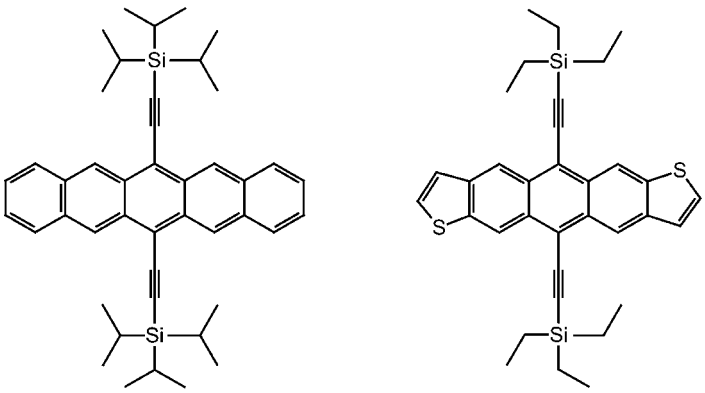

Figure 6.12 Left: Triisopropylsilyl (TIPS) pentacene. Right: Triethylsilyl (TES) anthradithiophene.

transistors are almost exclusively due to positively charged carriers. Currents due to negatively charged carriers are almost always extremely small in these materials, and often too small to be measurable, even when a large positive gate potential is applied to induce a channel of negatively charged carriers. Several explanations for the highly unbalanced currents have been suggested. One explanation is that the difference in mobility between the two carrier types is very large, due either to different scattering probabilities or perhaps to different probabilities for charge trapping, either at grain boundaries within the film or at defects at the dielectric interface [29, 30]. Another explanation is that charge injection from the contacts is highly unbalanced due to different energy barriers for positively and negatively charged carriers.

Interestingly, there are a number of organic semiconductors that show usefully large mobilities for negatively charged carriers. These materials include perfluorinated copper phthalocyanine (F_{16}CuPc), a variety of naphthalene and perylene tetracarboxylic diimide derivates, fluoroalkylated oligothiophenes, and the fullerene C_{60}. The carrier mobilities measured in n-channel FETs based on these materials are in the range of 0.01 to 1 $cm^2 V^{-1} s^{-1}$. Some of these materials are very susceptible to redox reactions and thus have poor environmental stability. For example, C_{60} shows mobilities as large as 5 $cm^2 V^{-1} s^{-1}$ when measured in ultra-high vacuum [31, 32], but when exposed to air the mobility drops rapidly by as many as four or five orders of magnitude. Similar degradation has been reported for some naphthalene and perylene tetracarboxylic diimide derivatives [33, 34]. Other materials, in particular F_{16}CuPc [35], have been found to be very stable in air, although the exact mechanisms that determine the degree of air stability are still unclear. Air-stable n-channel organic FETs with carrier mobilities as large as 0.6 $cm^2 V^{-1} s^{-1}$ [36] have been reported.

6.3 Device Structures and Manufacturing

From a technological perspective, the most useful organic transistor implementation is the thin-film transistor (TFT). The TFT concept was initially proposed and developed by Weimer during the 1960s for transistors based on polycrystalline inorganic semiconductors, such as evaporated cadmium sulfide [37]. The idea was later extended to TFTs based on plasma-enhanced chemical-vapor deposited (PECVD) hydrogenated amorphous silicon (a-Si:H) TFTs [38]. Today, a-Si:H TFTs are widely employed as the pixel drive devices in active-matrix liquid-crystal displays (AMLCDs) which accounted for $50 billion in global sales in 2005. Organic TFTs were first reported during the 1980s [4, 39]. To produce an organic TFT, the organic semiconductor and other materials required (gate electrode, gate dielectric, source and drain contacts) are deposited as thin layers on the surface of an electrically insulating substrate, such as glass or plastic foil. Depending on the sequence in which the materials are deposited, three organic TFT architectures can be distinguished, namely inverted staggered, inverted coplanar, and top-gate (see Figure 6.13).

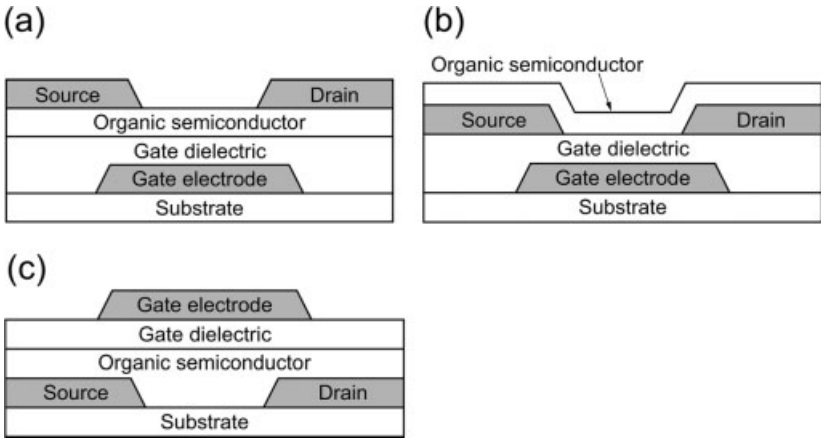

Figure 6.13 Schematic cross-sections of the (a) inverted staggered, (b) inverted coplanar, and (c) top-gate organic TFT structures.

Each of these structures has certain advantages and disadvantages:

- The inverted coplanar architecture allows for the use of photolithography or solution-based printing to pattern source and drain contacts with high resolution and short contact spacing, without exposing the organic semiconductor to potentially harmful process chemicals such as organic solvents, photoresists, and etchants [40]. However, as the contacts in organic transistors are not easily doped, the coplanar structure is often associated with larger contact resistance compared with the staggered architecture [41].
- The inverted staggered TFT structure is usually implemented by evaporating the source/drain metal through a shadow mask (also called an aperture or stencil mask). In this way, the organic semiconductor is not exposed to process chemicals, and the contact resistance can be quite low, as the entire area underneath the contacts is available for charge injection, though with shadow masks it is more difficult to reduce the channel length reliably below about 10 μm.
- For the top-gate structure the source and drain contacts can be patterned with high resolution prior to the deposition of the semiconductor, and the contact resistance can be as low as for the inverted staggered architecture. However, the deposition of a gate dielectric and a gate electrode on top of the semiconductor layer means that great care must be exercised to avoid process-induced degradation of the organic semiconductor, and the possibility of material mixing at the semiconductor/dielectric interface must be taken into account.

A variety of methods exists for the deposition and patterning of the individual layers of the TFT. For example, gate electrodes and source and drain contacts are often made using vacuum-deposited inorganic metals. Non-noble metals, such as aluminum or chromium, are suitable for the gate electrodes in the inverted device

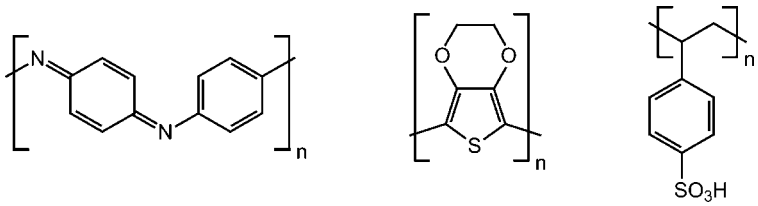

Figure 6.14 Left: Polyaniline. Right: Poly(3,4-ethylenedioxythiophene) (PEDOT) and poly (styrene sulfonic acid) PSS.

structures, as these metals have excellent adhesion on glass substrates. Noble metals (most notably gold) are a popular choice for the source and drain contacts, as they tend to give lower contact resistance than other metals. The metals are conveniently deposited by evaporation in vacuum and can be patterned either by photolithography and etching or lift-off, by lithography using an inkjet-printed wax-based etch resist [42], or simply by deposition through a shadow mask [43].

An alternative to inorganic metals are conducting polymers, such as polyaniline and poly(3,4-ethylenedioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS; see Figure 6.14). These are chemically doped conjugated polymers that have electrical conductance in the range between 0.1 and 1000 S cm^{-1}. The way in which continuous advances in synthesis and material processing have improved the conductivity of Baytron® PEDOT:PSS over the past decade is shown in Figure 6.15. Unlike inorganic metals, conducting polymers can be processed either from organic solutions or from aqueous dispersions, so gate electrodes and source and drain contacts for organic TFTs can be prepared by spin-coating and photolithography [44], or by inkjet-printing [45].

One important aspect in organic TFT manufacturing is the choice of the gate dielectric. Depending on the device architecture (inverted or top-gate), the dielectric material and the processing conditions (temperature, plasma, organic solvents, etc.)

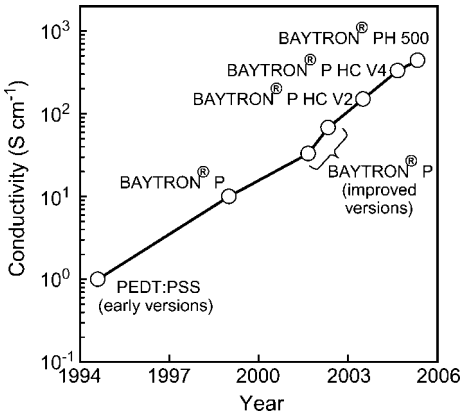

Figure 6.15 Improvements in the electrical conductivity of the conducting polymer PEDOT:PSS. (Adapted from a graph kindly provided by Stephan Kirchmeyer, H. C. Starck, Leverkusen, Germany.)

must be compatible with the previously deposited device layers and with the substrate. For example, chemical-vapor-deposited (CVD) silicon oxide and silicon nitride – which are popular gate dielectric materials for inorganic (amorphous or polycrystalline silicon) TFTs – may not be suitable for use on flexible polymeric substrates, as the high-quality growth of these films often requires temperatures that exceed the glass transition temperature of many polymeric substrate materials.

The thickness of the gate dielectric layer is usually a compromise between the requirements for large gate coupling, low operating voltages, and small leakage currents. Large gate coupling (i.e. a large dielectric capacitance) means that the transistors can be operated with low voltages, which is important when the TFTs are used in portable or handheld devices that are powered by small batteries or by near-field radio-frequency coupling, for example. Also, a large dielectric capacitance ensures that the carrier density in the channel is controlled by the gate and not by the drain potential, which is especially critical for short-channel TFTs. One way to increase the gate dielectric capacitance is to employ a dielectric with larger permittivity ε ($C = \varepsilon/t$). However, as Veres [46], Stassen [47], and Hulea [48] have pointed out, the carrier mobility in organic field effect transistors is systematically reduced as the permittivity of the gate dielectric is increased, presumably due to enhanced localization of carriers by local polarization effects (see Figure 6.16).

Alternatively, low-permittivity dielectrics with reduced thickness or thin multilayer dielectrics with specifically tailored properties may be employed. The greatest concern with thin dielectrics is the inevitable increase in gate leakage due to defects and quantum-mechanical tunneling as the dielectric thickness is reduced. A number of promising paths towards high-quality thin dielectrics with low gate leakage for low-voltage organic TFTs have recently emerged. One such approach is the anodization of aluminum, which has resulted in high-quality aluminum oxide films thinner than 10 nm providing a capacitance around $0.4\,\mu F\,cm^{-2}$. Combined with an ultra-thin molecular SAM, such dielectrics can provide sufficiently low leakage currents to allow the fabrication of functional low-voltage organic TFTs with large carrier

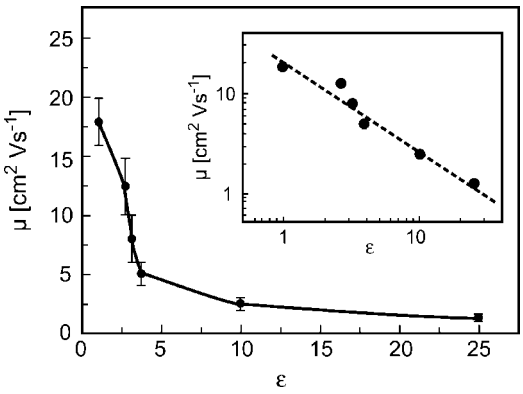

Figure 6.16 Relationship between the permittivity of the gate dielectric and the carrier mobility in the channel. (Reproduced with permission from Ref. [47].)

mobility [49]. Another path is the use of very thin crosslinked polymer films prepared by spin-coating [50, 51]. With a thickness of about 10 nm, these dielectrics provide capacitances as large as $0.3\,\mu F\,cm^{-2}$ and excellent low-voltage TFT characteristics. Finally, the use of high-quality insulating organic SAMs or multilayers provides a promising alternative [52–54]. Such molecular dielectrics typically have a thickness of 2 to 5 nm and a capacitance between 0.3 and $0.7\,\mu F\,cm^{-2}$, depending on the number and structure of the molecular layers employed, and they allow organic TFTs to operate with voltages between 1 and 3 V.

6.4 Electrical Characteristics

Like silicon metal-oxide-semiconductor-field-effect-transistors (MOSFETs), organic TFTs are metal-insulator-semiconductor FETs in which a sheet of mobile charge carriers is induced in the semiconductor by applying an electric field across the gate dielectric. Silicon MOSFETs normally operate in inversion – that is, the drain current is due to minority carriers generated by inverting the conductivity at the semiconductor/dielectric interface from p-type to n-type (for n-channel MOSFETs) or from n-type to p-type (for p-channel MOSFETs). The contact regions of silicon MOSFETs are heavily doped so that minority carriers are easily injected at the source and extracted at the drain, while the undesirable flow of majority carriers from drain to source is efficiently blocked by a space charge region.

Organic TFTs typically utilize intrinsic semiconductors. Positively charged carriers are accumulated near the dielectric interface when a negative gate-source voltage is applied, or negative charges are accumulated with a positive gate bias. Source and drain are usually implemented by directly contacting the intrinsic semiconductor with a metal. Depending on the choice of materials for the semiconductor and the metal, organic TFTs may operate as p-channel, n-channel, or ambipolar transistors. In p-channel and n-channel TFTs, the transport of one type of carrier is far more efficient than that of the other carrier type, either because the semiconductor/metal contacts greatly favor the injection or extraction of one carrier type over the other, or because the mobilities in the semiconductor are very different (perhaps due to different trapping rates), or because the electronic properties of the semiconductor/dielectric interface allow the accumulation of only one type of carrier, but not the other. In ambipolar organic TFTs the injection and transport of both positive and negative carriers is possible and both carrier types contribute to the drain current.

Despite the fact that the transport physics in organic transistors is different from that in silicon MOSFETs, the current–voltage characteristics can often be described with the same formalism:

$$I_D = \frac{\mu C_{diel} W}{L}\left((V_{GS} - V_{th})V_{DS} - \frac{V_{DS}^2}{2}\right) \quad \text{for } |V_{GS} - V_{th}| > |V_{DS}| \tag{6.1}$$

$$I_D = \frac{\mu C_{diel} W}{2L}(V_{GS} - V_{th})^2 \quad \text{for } |V_{DS}| > |V_{GS} - V_{th}| > 0 \tag{6.2}$$

Equation (6.1) describes the relationship between the drain current I_D, the gate-source voltage V_{GS} and the drain-source voltage V_{DS} in the linear regime, while Eq. (6.2) relates I_D, V_{GS} and V_{DS} in the saturation regime. C_{diel} is the gate dielectric capacitance per unit area, μ is the carrier mobility, W is the channel width, and L is the channel length of the transistor. For silicon MOSFETs, the threshold voltage V_{th} is defined as the minimum gate-source voltage required to induce strong inversion. Although this definition cannot strictly be applied to organic TFTs, the concept is nonetheless useful, as the threshold voltage conveniently marks the transition between the different regions of operation.

Figure 6.17 shows the current–voltage characteristics of an organic TFT that was manufactured on a glass substrate using the inverted staggered device structure (see Figure 6.13a) with a thin layer of vacuum-evaporated pentacene as the semiconductor, a self-assembled monolayer gate dielectric, and source/drain contacts prepared by evaporating gold through a shadow mask [54]. The device operates as a p-channel transistor with a threshold voltage of -1.2 V. By fitting the current–voltage characteristics to Eqs. (6.1) or (6.2), the carrier mobility μ can be estimated; for this particular device it is about $0.6\,cm^2\,V^{-1}\,s^{-1}$ ($C_{diel} = 0.7\,\mu F\,cm^{-2}$, $W = 100\,\mu m$, $L = 30\,\mu m$).

Equations (6.1) and (6.2) describe the drain current for gate-source voltages above the threshold voltage. Below the threshold voltage there is a region in which the drain current depends exponentially on the gate-source voltage. This is the *subthreshold region*; for the TFT in Figure 6.17 it extends between about -0.5 V and about -1 V. Within this voltage range the drain current is due to carriers that have sufficient thermal energy to overcome the gate-controlled barrier near the source and mainly diffuse, rather than drift, to the drain:

$$I_D = I_0 \exp\left(\frac{q|V_{GS} - V_{th}|}{nkT}\right) \qquad \text{for } V_{GS} \text{ between } V_{th} \text{ and } V_{SO} \tag{6.3}$$

The slope of the $\log(I_D)$ versus V_{GS} curve in the subthreshold region is determined by the ideality factor n and the temperature T (q is the electronic charge, k is

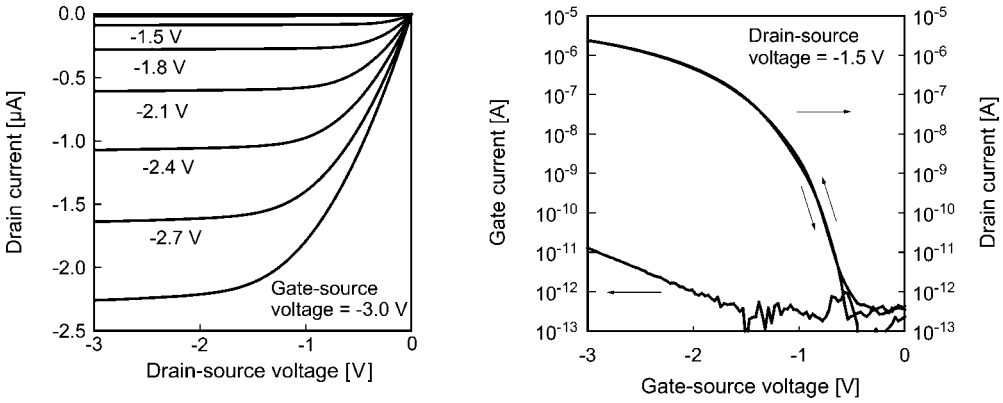

Figure 6.17 The electrical characteristics of a p-channel pentacene TFT.

Boltzmann's constant, and V_{SO} is the switch-on voltage which marks the gate-source voltage at which the drain current reaches a minimum [55]). It is usually quantified as the inverse subthreshold slope S (also called subthreshold swing):

$$S = \frac{\partial V_{GS}}{\partial(\log_{10} I_D)} = \frac{nkT}{q}\ln 10 \tag{6.4}$$

The ideality factor n is determined by the density of trap states at the semiconductor/dielectric interface, N_{it}, and the gate dielectric capacitance, C_{diel}:

$$n = 1 + \frac{qN_{it}}{C_{diel}} \tag{6.5}$$

$$S = \frac{kT}{q}\ln 10\left(1 + \frac{qN_{it}}{C_{diel}}\right) \tag{6.6}$$

When N_{it}/C_{diel} is small, the ideality factor n approaches unity. Silicon MOSFETs often come close to the ideal room-temperature subthreshold swing of 60 mV per decade, as the quality of the Si/SiO_2 interface is very high. In organic TFTs the semiconductor/dielectric interface is typically of lower quality, and thus the subthreshold swing is usually larger. The TFT in Figure 6.17 has a subthreshold swing of 100 mV dec^{-1}, from which an interface trap density of 3×10^{12} cm^{-2} V^{-1} is calculated.

The subthreshold region extends between the threshold voltage V_{th} and the switch-on voltage V_{SO}. Below the switch-on voltage (-0.5 V for the TFT in Figure 6.17) the drain current is limited by leakage through the semiconductor, through the gate dielectric, or across the substrate surface. This off-state current should be as small as possible. The TFT in Figure 6.17 has an off-state current of 0.5 pA, which corresponds to a on off-state resistance of 3 TΩ.

To predict an upper limit for the dynamic performance of the transistor, it is useful to calculate the cut-off frequency [56]. This is the frequency at which the current gain is unity, and is determined by the transconductance and the gate capacitance:

$$f_T = \frac{g_m}{2\pi C_{gate}} \tag{6.7}$$

The transconductance g_m is defined as the change in drain current with respect to the corresponding change in gate-source voltage:

$$g_m = \frac{\partial I_D}{\partial V_{GS}} \tag{6.8}$$

Thus, the transconductance can be extracted from the current–voltage characteristics; for the pentacene TFT in Figure 6.17 the transconductance is about 2 µS at $V_{GS} = -2.5$ V. The transconductance is related to the other transistor parameters as follows:

$$g_m = \frac{\mu C_{diel} W}{L} V_{DS} \quad \text{in the linear regime} \tag{6.9}$$

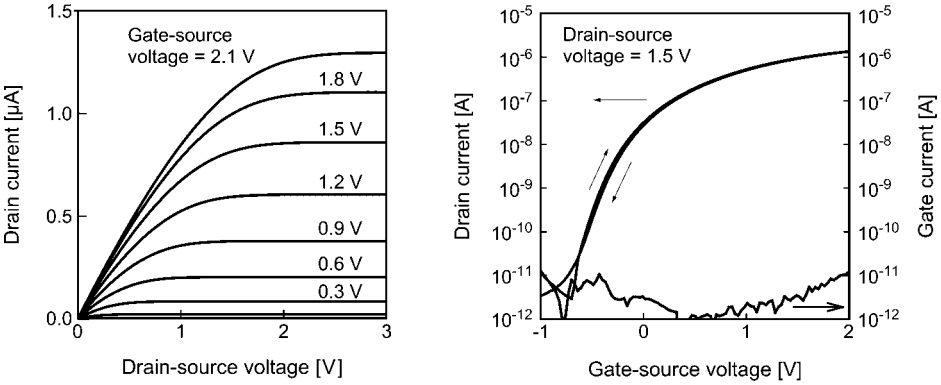

Figure 6.18 The electrical characteristics of an n-channel F_{16}CuPc TFT.

$$g_m = \frac{\mu C_{diel} W}{L}(V_{GS} - V_{th}) \quad \text{in the saturation regime} \tag{6.10}$$

The gate capacitance C_{gate} is the sum of the intrinsic gate capacitance (representing the interaction between the gate and the channel charge) and the parasitic gate capacitances (including the gate/source overlap capacitances and any fringing capacitances). For the transistor in Figure 6.17 the total gate capacitance is estimated to be about 30 pF, so the cut-off frequency will be on the order of 10 kHz.

The current–voltage characteristics of an n-channel TFT based on perfluorinated copper phthalocyanine (F_{16}CuPc) are shown in Figure 6.18 [54]. It has a threshold voltage of -0.2 V, a switch-on voltage of -0.8 V, an off-state current of about 5 pA, and a carrier mobility of about $0.02\,cm^2\,V^{-1}\,s^{-1}$ ($C_{diel} = 0.7\,\mu F\,cm^{-2}$, $W = 1000$ μm, $L = 30\,\mu m$). The transconductance is about 0.8 μS at $V_{GS} = 1.5$ V and the gate capacitance is about 300 pF, so the TFT will have a cut-off frequency of about 500 Hz.

The availability of both p-channel and n-channel organic TFTs makes the implementation of organic complementary circuits possible. From a circuit design perspective, complementary circuits are more desirable than circuits based only on one type of transistor, as complementary circuits have smaller static power dissipation and greater noise margin [54]. The schematic and electrical characteristics of an organic complementary inverter with a p-channel pentacene TFT and an n-channel F_{16}CuPc TFT are shown in Figure 6.19.

In a complementary inverter the p-channel FET is conducting only when the input is low ($V_{in} = 0$ V), while the n-channel FET is conducting only when the input is high ($V_{in} = V_{DD}$). Consequently, the static current in a complementary circuit is essentially determined by the leakage currents of the transistors and can be very small (less than 100 pA for the inverter in Figure 6.19). As a result, the output signals in the steady states are essentially equal to the rail voltages V_{DD} and ground. During switching there is a brief period when both transistors are simultaneously in the low-resistance on-state and a significant current flows between the V_{DD} and ground rails. Thus, most of the power consumption of a complementary circuit is due to switching, while the static power dissipation is very small.

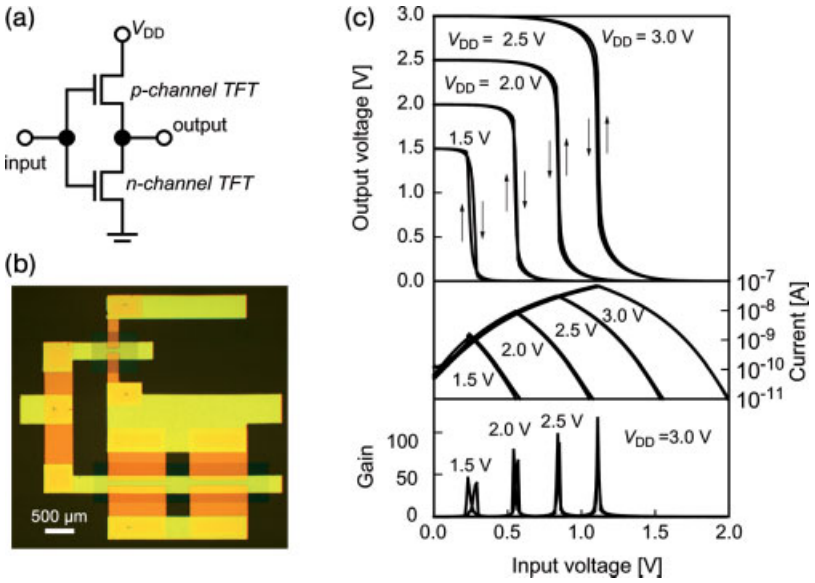

Figure 6.19 (a) Schematic, (b) actual photographic image and (c) transfer characteristics of an organic complementary inverter based on a p-channel pentacene TFT and an n-channel F_{16}CuPc TFT.

The dynamic performance of the inverter is limited by the slower of the two transistors, in this case the n-channel F_{16}CuPc TFT. Figure 6.20 shows, in graphical from, the inverter's response to a square-wave input signal with an amplitude of 2 V and a frequency of 500 Hz – that is, the cut-off frequency of the F_{16}CuPc TFT.

To allow organic circuits to operate at higher frequencies, it is necessary to increase the transconductance and reduce the parasitic capacitances. From a materials point of view, this can be done by developing new organic semiconductors that provide larger carrier mobilities [36]. Ideally, the carrier mobilities of the p- and n-channel TFTs should be similar. From a manufacturing point of view, the critical dimensions of the devices must be reduced – that is, the channel length and overlap capacitances must be made smaller. However, as the channel length of organic TFTs is reduced, the

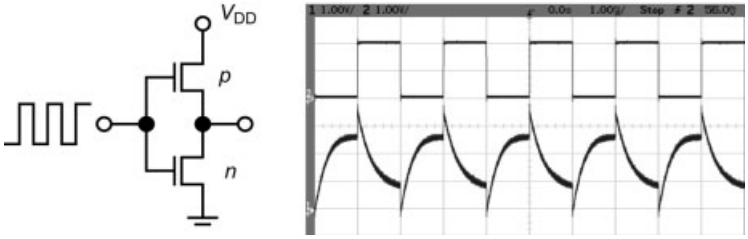

Figure 6.20 Response of an organic complementary inverter to a square-wave input signal with an amplitude of 2 V and a frequency of 500 Hz. Both TFTs have a channel length of 30 µm.

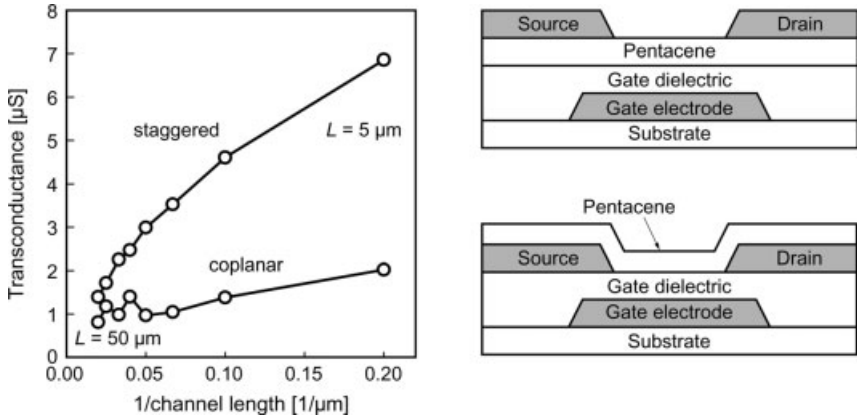

Figure 6.21 Transconductance as a function of channel length for two series of pentacene TFTs (top: inverted staggered configuration; bottom: inverted coplanar configuration). The channel width is 100 μm.

transconductance does not necessarily scale as predicted by Eqs. (6.9) and (6.10). The main reason for this is that the contact resistance in organic TFTs can be very large, as the contacts are typically not doped. Consequently, as the channel length is reduced, the drain current becomes increasingly limited by the contact resistance (which is independent of channel length), rather than by the channel resistance. This is shown in Figure 6.21 for pentacene TFTs in the inverted staggered configuration and in the inverted coplanar configuration, both with channel length ranging from 50 μm to 5 μm and all with a channel width of 100 μm.

For long channels ($L = 50\,\mu m$), where the effect of the contact resistance on the TFT characteristics is small, the transconductance is similar for both technologies ($g_m \sim 1\,\mu S$; $\mu \sim 0.5\,cm^2\,V^{-1}\,s^{-1}$). The difference between the two devices configurations becomes evident when the channel length is reduced. For the coplanar TFTs the potential benefit of channel length scaling is largely lost due to the significant contact resistance ($\sim 5 \times 10^4\,\Omega \cdot cm$). The staggered configuration offers significantly smaller contact resistance ($\sim 10^3\,\Omega \cdot cm$), as the area available for charge injection from the metal into the carrier channel is larger (given by the gate/contact overlap area), and as a result the transconductance for short channels (5 μm) is significantly larger in the case of the staggered TFTs (7 μS versus 2 μS). The staggered TFT with a channel length of 5 μm and a transconductance of 7 μS has a total gate capacitance of about 5 pF, so the cut-off frequency is estimated to be on the order of 200 kHz (at an operating voltage in the range of 2–3 V).

6.5 Applications

Unlike single-crystal silicon transistors, organic TFTs can be readily fabricated on glass or flexible plastic substrates, and this makes them useful for a variety of

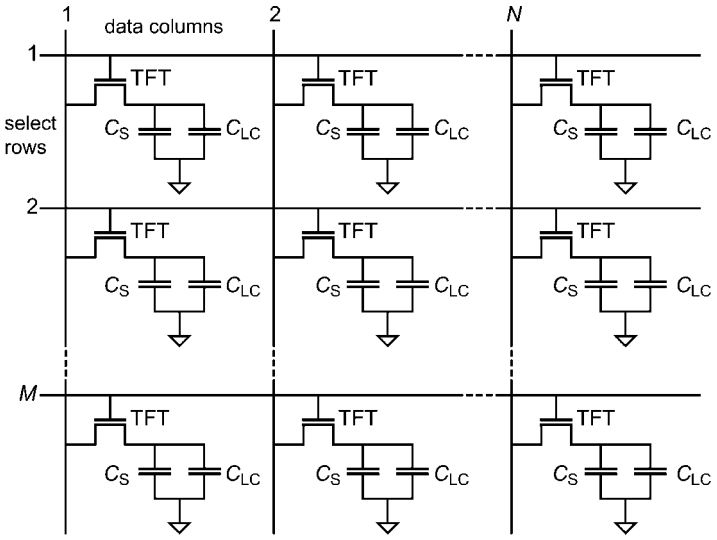

Figure 6.22 Schematic of an active-matrix liquid-crystal display.

large-area electronic applications, such as active-matrix flat-panel displays. In an active-matrix display, each of the pixels is individually controlled (and electrically isolated from the rest of the display) by a TFT circuit in order to reduce undesirable cross-talk and to increase fidelity and color depth. In active-matrix displays that utilize voltage-controlled display elements, such as a liquid crystal or an electrophoretic cell, each pixel circuit consists simply of a single TFT; in this case the display matrix has as many TFTs as it has pixels. If the display employs a current-controlled electro-optical device, such as a light-emitting diode, a more complex TFT circuit with two or more TFTs must be implemented in each pixel.

Figure 6.22 shows the circuit schematic of an active-matrix liquid-crystal display (AMLCD). The display is operated by applying a select voltage to one of the rows in order to switch all TFTs in that row to the low-resistance on-state. (All other rows are held at a lower potential that keeps the TFTs in these rows in the high-resistance off-state.) Data voltages that correspond to the desired brightness levels for each of the pixels in the selected row are then applied to each of the N columns. This charges the capacitors in the selected row to the applied data voltage. The time required to charge the capacitors (t_{select}) is determined by the on-state resistance of the TFTs, by the capacitances of the storage capacitor (C_S), the liquid crystal cell (C_{LC}) and the data lines, and by the maximum allowed deviation from the target voltage. Once the select voltage is removed, the capacitors are isolated and the charge is retained in the pixels. In this manner all rows are addressed one by one, and all pixel capacitors are charged to the desired voltage. The time required to sequentially address all M rows, and thus update the entire display, is the frame time, $t_{\text{frame}} = M \cdot t_{\text{select}}$.

In order to avoid visible flicker, the display information must be updated at least 50 times per second – that is, t_{frame} must be about 20 ms, or less. If a pixel capacitance ($C_S + C_{LC}$) of 1 pF is assumed, and if no more than 1% of the stored charge is allowed

to leak from the pixel during the t_{frame}, then the minimum required TFT off-state resistance can be estimated:

$$R_{\text{off}} \geq \frac{t_{\text{frame}}}{0.01 C_{\text{pixel}}} \tag{6.11}$$

Thus, for a t_{frame} of 20 ms and a pixel capacitance of 1 pF, the TFTs must have an off-state resistance of 2 TΩ, or greater.

For an extended graphics array (XGA) display with 768 rows and a t_{frame} of 20 ms the time available to charge the capacitors in one row is $t_{\text{select}} = t_{\text{frame}}/M = 26\,\mu\text{s}$. If a combined (pixel plus data line) capacitance of 2 pF is assumed, and it is specified that the capacitors be charged to within 1% of the target data voltage, then the maximum allowed TFT on-state resistance can be estimated:

$$R_{\text{on}} \leq \frac{t_{\text{select}}}{4.6 C_{\text{pixel}}} \tag{6.12}$$

For a t_{select} of 26 μs and a capacitance of 2 pF this sets an upper limit of about 2 MΩ for the on-state resistance of the TFTs. In order to create a small on-state resistance the TFTs are operated in the linear regime by applying a select voltage that is larger than the largest data voltage (plus the threshold voltage). In the linear regime (when the gate-source voltage is much larger than the drain-source voltage) the channel resistance is approximately given by:

$$R_{\text{on}} \sim \frac{L}{\mu C_{\text{diel}} W (V_{\text{GS}} - V_{\text{th}})} \tag{6.13}$$

Assuming a carrier mobility of $0.5\,\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$, a gate dielectric capacitance of $0.1\,\mu\text{F}\,\text{cm}^{-2}$, and an overdrive voltage $|V_{\text{GS}} - V_{\text{th}}|$ of 10 V, the on-state resistance requirement (2 MΩ) can be met with a TFT geometry of $W/L = 1$ (where W and L are the channel width and channel length of the transistor, respectively). A W/L ratio near or equal to unity is desirable, as this means that the transistor occupies a relatively small fraction of the total pixel area. Taking into account both the off-state and on-state resistance requirements ($R_{\text{off}} > 2$ TΩ, $R_{\text{on}} < 2$ MΩ), the TFTs must have an on/off ratio of at least 10^6.

These requirements can be met by state-of-the-art organic TFTs. An early demonstration of an active-matrix polymer-dispersed liquid-crystal (PDLC) display with solution-processed polythienylenevinylene (PTV) TFTs was developed by Philips Research in 2001 [57]. In 2005, Sony reported an active-matrix twisted-nematic liquid-crystal (TN-LC) display with vacuum-deposited pentacene TFTs [58]. Also in 2005, Polymer Vision demonstrated a flexible roll-up display based on electrophoretic microcapsules (electronic ink) and solution-processed pentacene TFTs (see Figure 6.23).

Unlike liquid-crystal valves and electrophoretic microcapsules, light-emitting diodes (OLEDs) are current-controlled display elements and thus require a more complex pixel circuit. The simplest implementation of an active-matrix organic light-emitting diode (AMOLED) pixel is shown in Figure 6.24. When a select voltage is

Figure 6.23 Left: A 64 × 64 pixel active-matrix polymer-dispersed liquid-crystal display with solution-processed polymer TFTs developed by Philips. (Reproduced with permission from Ref. [57].) Center: A 160 × 120 pixel active-matrix twisted-nematic liquid-crystal display with vacuum-deposited pentacene TFTs developed by Sony. (Reproduced with permission from Ref. [58].) Right: A 320 × 240 pixel active-matrix electronic-ink display with solution-processed pentacene TFTs developed by Polymer Vision. (Reproduced from: H. E. A. Huitema et al., Roll-up Active-matrix Displays, in: *Organic Electronics*, Wiley-VCH, 2006.)

applied, transistor T_1 switches to the low-resistance on-state so that capacitor C_S can be charged through the data line to a voltage corresponding to the desired luminous intensity. The voltage across C_S is the gate-source voltage of transistor T_2, and thus determines the drain current of T_2 and thereby the luminance of the OLED. When the select voltage is removed, T_1 switches off and the charge is retained on C_S, so T_2 remains active and drives a constant OLED current for the remainder of the frame time.

The on-state and off-state resistance requirements for the select transistor T_1 in an OLED pixel are similar to those for the TFT in a liquid-crystal or electrophoretic pixel – that is, they can be met by a TFT with $W/L \sim 1$. The drive transistor T_2 in an OLED pixel is usually operated in saturation, and must have a sufficiently large drain current to drive the OLED to the desired brightness. State-of-the-art small-molecule OLEDs have luminous efficiencies on the order of 2 to 50 cd A^{-1}, depending on emission color, material selection, and process technology [59]. For a typical display brightness of 100 cd m^{-2} and a pixel size of 6×10^{-4} cm^2 (which corresponds to a resolution of 100 dpi), this requires a maximum drive current up to about 3 μA. In the saturation regime the drain current of the transistor is given by Eq. (6.2). Assuming a carrier mobility of 0.5 $cm^2 V^{-1} s^{-1}$, a gate dielectric capacitance of 0.1 μF cm^{-2}, and an overdrive voltage $|V_{GS} - V_{th}|$ of 5 V, the drive current requirement (3 μA) can be met

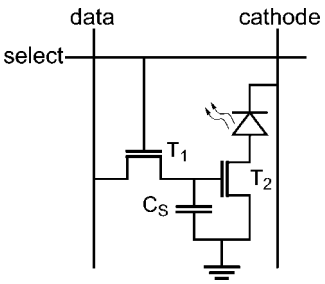

Figure 6.24 Schematic of a two-transistor active-matrix OLED pixel.

Figure 6.25 A flexible 48 × 48 pixel active-matrix organic light-emitting diode (OLED) display with pentacene organic TFTs developed at Penn State University. (Reproduced with permission from Ref. [60].)

with a TFT geometry of $W/L = 5$. Thus, the static transistor performance requirements for active-matrix OLED displays can be met by organic TFTs T_1 and T_2 occupying only a small fraction of the pixel area. A photograph of an active-matrix OLED display with two pentacene TFTs and a bottom-emitting OLED in each pixel [60] is shown in Figure 6.25.

Compared with liquid-crystal and electrophoretic displays, active-matrix OLED displays are far more demanding as far as the uniformity and stability of the TFT parameters are concerned. For example, if the TFT threshold voltage in a liquid-crystal display changes over time, or is not uniform across the display, the image quality is not immediately affected as the select voltage is usually large. In an OLED display, however, the threshold voltage of transistor T_2 directly determines the drive current and thus the OLED brightness. Consequently, even small differences in threshold voltage have a dramatic impact on image quality and color fidelity. In order to reduce or eliminate the effects of non-uniformities or time-dependent changes of the TFT parameters, more complex pixel circuit designs have been proposed [61]. In these designs, additional TFTs are implemented to make the OLED current independent of the threshold voltages of the TFTs. A pixel circuit with a larger number of TFTs is likely to occupy a greater portion of the total pixel area, but may significantly improve the performance of the display.

A second potential application for organic TFTs is in large-area sensors for the spatially resolved detection of physical or chemical quantities, such as temperature, pressure, radiation, or pH. As an example, Figure 6.26 shows the schematic of an active-matrix pressure sensor array. Mechanical pressure exerted on a sensor element leads to a reversible and reproducible change in the resistance of the sensor element. To allow external circuitry to access the resistance of each individual sensor it is necessary to integrate a transistor with each sensor element. During operation, the rows of the array are selected one by one to switch the TFTs in the selected row to the low-resistance state (similar to the row-select procedure in an active-matrix display) and the resistance of the each sensor element in the selected row is measured

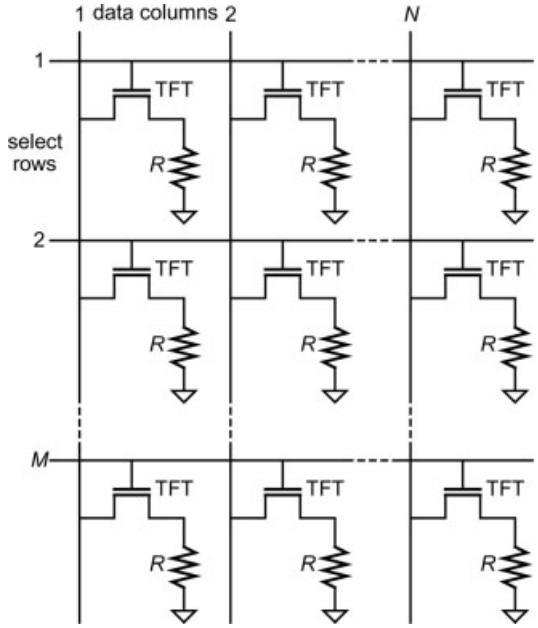

Figure 6.26 Left: Schematic of an active-matrix array with resistive sensor elements. Right: Demonstration of an artificial skin device with organic TFTs. (Reproduced from T. Someya et al., Large-area detectors and sensors, in: *Organic Electronics*, Wiley-VCH, 2006.)

through the data lines by external circuitry. This is repeated for each row until the entire array has been read out. The result is a map of the 2-D distribution of the desired physical quantity (in this case, the pressure) over the array. By reading the array continuously a dynamic image can be created (again, similar to an active-matrix display). One application of a 2-D pressure sensor array is a fingerprint sensor for personal identification purposes. Another interesting application is the combination of spatially resolved pressure and temperature sensing over large conformable surfaces to create the equivalent of sensitive skin for human-like robots capable of navigating in unstructured environments [62].

6.6 Outlook

Organic transistors are potentially useful for applications that require electronic functionality with low or medium complexity distributed over large areas on unconventional substrates, such as glass or flexible plastic film. Generally, these are applications in which the use of single-crystal silicon devices and circuits is either technically or economically not feasible. Examples include flexible displays and sensors. However, organic transistors are unlikely to replace silicon in applications

characterized by large transistor counts, small chip size, large integration densities, or high-frequency operation. The reason is that, in these applications, the use of silicon MOSFETs is very economical. For example, the manufacturing cost of a silicon MOSFET in a 1-Gbit memory chip is on the order of $\$10^{-9}$, which is less than the cost of printing a single letter in a newspaper.

The static and dynamic performance of state-of-the-art organic TFTs is already sufficient for certain applications, most notably small or medium-sized flexible displays in which the TFTs operate with critical frequencies in the range of a few tens of kilohertz. Strategies for increasing the performance of organic TFTs include further improvements in the carrier mobility of the organic semiconductor (either through the synthesis of new materials, through improved purification, or by enhancing the molecular order in the semiconductor layer) and more aggressive scaling of the lateral transistor dimensions (channel length and contact overlap). For example, an increase in cut-off frequency from 200 kHz to about 2 MHz can be achieved either by improving the mobility from $0.5\,cm^2\,V^{-1}\,s^{-1}$ to about $5\,cm^2\,V^{-1}\,s^{-1}$ (assuming critical dimensions of 5 μm and an operating voltage of 3 V), or by reducing the critical dimensions from 5 μm to about 1.6 μm (assuming a mobility of $0.5\,cm^2\,V^{-1}\,s^{-1}$ and an operating voltage of 3 V). A cut-off frequency of about 20 MHz is projected for TFTs with a mobility of $5\,cm^2\,V^{-1}\,s^{-1}$ and critical dimensions of 1.6 μm (again assuming an operating voltage of 3 V).

However, these improvements in performance must be implemented without sacrificing the general manufacturability of the devices, circuits, and systems. This important requirement has fueled the development of a whole range of large-area, high-resolution printing methods for organic electronics. Functional printed organic devices and circuits have indeed been demonstrated using various printing techniques, but further studies are required to address issues such as process yield and parameter uniformity.

One of the most critical problems that must be solved before organic electronics can begin to find use in commercial applications is the stability of the devices and circuits during continuous operation, and while exposed to ambient oxygen and humidity. Early product demonstrators have often suffered from short lifetimes due to a rapid degradation of the organic semiconductor layers. However, recent advances in synthesis, purification, processing, in addition to economically viable encapsulation techniques, have raised the hope that the degradation of organic semiconductors is not an insurmountable problem and that organic thin-film transistors may soon be commercially utilized.

7
Carbon Nanotubes in Electronics

M. Meyyappan

7.1
Introduction

Since the discovery of carbon nanotubes (CNTs) in 1991 [1] by Sumio Iijima of the NEC Corporation, research activities exploring their structure, properties and applications have exploded across the world. This interesting nanostructure exhibits unique electronic properties and extraordinary mechanical properties, and this has prompted the research community to investigate the potential of CNTs in numerous areas including, among others, nanoelectronics, sensors, actuators, field emission devices, and high-strength composites [2]. Although recent progress in all of these areas has been significant, the routine commercial production of CNT-based products is still years away. This chapter focuses on one specific application field of CNTs, namely electronics, and describes the current status of developments in this area. This description is complemented with a brief discussion of the properties and growth methods of CNTs, further details of which are available in Ref. [2].

7.2
Structure and Properties

A carbon nanotube is, configurationally, a graphene sheet rolled up into a tube (see Figure 7.1). If it is a single layer of a graphene sheet, the resultant structure is a single-walled carbon nanotube (SWNT), but with a stack of multiple layers a multi-walled carbon nanotube (MWNT) emerges. The SWNT is a tubular shell made from hexagonal rings of carbon atoms, with the ends of the shells capped by a dome-like, half-fullerene molecules [3]. They are classified using a nomenclature (n, m) where n and m are integer indices of two graphene unit lattice vectors ($\mathbf{a_1}, \mathbf{a_2}$) corresponding to the chiral vector of a nanotube, $c_a = n\mathbf{a_1} + m\mathbf{a_2}$. Based on the geometry, when $n = m$, the resulting structure is commonly known as an "arm chair" nanotube, as shown in Figure 7.1. The (n, 0) structure is called the "zig zag nanotube", while all other

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

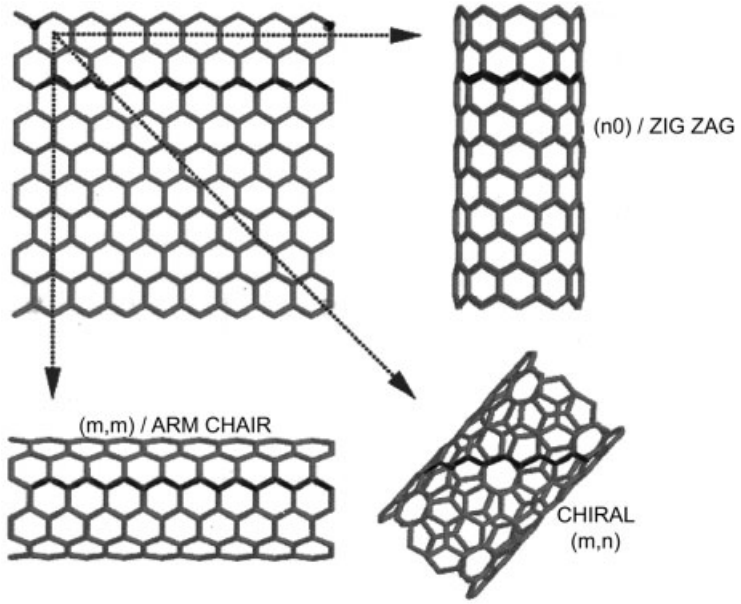

Figure 7.1 A strip of graphene sheet rolled into a carbon nanotube; m and n are chiral vectors.

structures are simply known as "chiral nanotubes". It is important to note that, at the time of this writing, exquisite control over the values of m and n is not possible. Transmission electron microscopy (TEM) images of a SWNT and a MWNT are shown in Figure 7.2, where the individual SWNTs are seen to have a diameter of about 1 nm. The MWNT has a central core with several walls, and a spacing close to 0.34 nm between the two neighboring walls (Figure 7.2b).

A SWNT can be either metallic or semiconducting, depending on its chirality – that is, the values of n and m. When $(n - m)/3$ is an integer, the nanotube is metallic, otherwise it is semiconducting. The diameter of the nanotube is given by $d = (a_g/\pi)(n^2 + mn + m^2)^{0.5}$, where a_g is the lattice constant of graphite. The strain energy

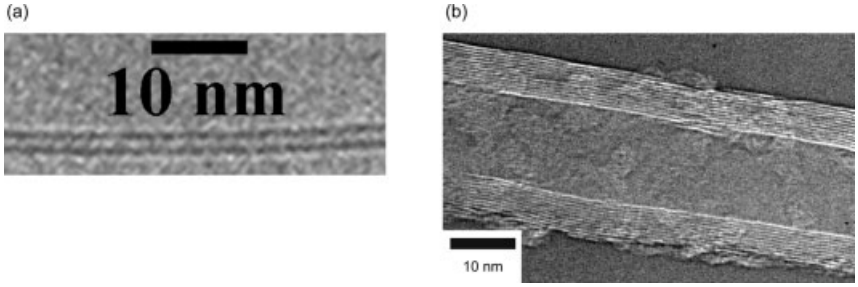

Figure 7.2 Transmission electron microscopy (TEM) images of (a) single-walled carbon nanotube and (b) a multi-walled carbon nanotube. (Image courtesy of Lance Delzeit.)

caused in the SWNT formation from the graphene sheet is inversely proportional to its diameter. There is a minimum diameter that can afford this strain energy, which is about 0.4 nm. On the other hand, the maximum diameter is about 3 nm, beyond which the SWNT may not retain its tubular structure and ultimately will collapse [3].

In the case of MWNTs, the smallest inner diameter found experimentally is about 0.4 nm, but typically is around 2 nm. The outer diameter of MWNT can be as large as 100 nm. Both, SWNTs and MWNTs, while preferentially being defect-free, have been observed experimentally in various defective forms such as bent, branched, helical, and even toroidal nanotubes.

The bandgap of a semiconducting nanotube is given by $E_g = 2d_{cc}\gamma/d$, where d_{cc} is the carbon–carbon bond length (0.142 nm), and γ is the nearest neighbor-hopping parameter (2.5 eV). Thus, the bandgap of semiconducting nanotubes of diameters between 0.5 and 1.5 nm may be in the range of 1.5 to 0.5 eV. The resistance of a metallic SWNT is $h/(4e^2) \approx 6.5\ \mathrm{K\Omega}$, where h is Planck's constant. However, experimental measurements typically show higher resistance due to the presence of defects, impurities, structural distortions and the effects of coupling to the substrate and/or contacts.

In addition to their interesting electronic properties, SWNTs exhibit extraordinary mechanical properties. For example, the Young's modulus of a (10,10) SWNT is over 1 TPa, with a tensile strength of 75 GPa. The corresponding values for graphite (in-plane) are 350 and 2.5 GPa, whereas the values for steel are 208 and 0.4 GPa [3]. Nanotubes can also sustain a tensile strain of 10% before fracturing, which is remarkably higher than other materials. The thermal conductivity of the nanotubes is substantially high [3, 4], with measured values being in the range of 1800 to 6000 $\mathrm{W\,mK^{-1}}$ [5].

7.3 Growth

The oldest process for preparing SWNTs and MWNTs is that of arc synthesis [6], with laser ablation subsequently being introduced during the 1990s to produce CNTs [7]. These bulk production techniques and large quantities are necessary when using CNTs in composites, gas storage. and similar applications. For electronics applications, it may be difficult to adopt "pick and place" strategies using bulk-produced material. Assuming that the need for *in-situ* growth approaches that currently used to produce devices for silicon-based electronics, it is important at this point to describe the techniques of chemical vapor deposition (CVD) and plasma-enhanced chemical vapor deposition (PECVD), both of which allow CNT growth on patterned substrates [8].

Chemical vapor deposition is a frequently used technique in silicon integrated circuit manufacture when depositing thin films of metals, semiconductors and dielectric materials. The CVD of CNTs typically involves a carbon-bearing feedstock such as CO or hydrocarbons including methane, ethylene, and acetylene. It is important to

maintain the growth temperature below that of the pyrolysis temperature of a particular hydrocarbon in order to avoid the production of amorphous carbon. The CNT growth is facilitated by the use of a transition metal catalyst, the choice comprising iron, nickel, palladium, or cobalt. These metals can be thermally evaporated as a thin film on the substrate, or sputtered using ion beam sputtering or magnetron sputtering. Alternatively, the catalyst metal can be applied to the substrate, starting from the metal-containing salt solution and passing through a number of steps such as precipitation, mixing, evaporation, drying, and annealing. It should be noted that solution-based techniques are more cumbersome and much slower than physical techniques such as sputtering. In addition, they may not be amenable for working with patterned substrates. Regardless of the approach used, the key here is to deposit the catalyst in the form of particles in order to facilitate nanotube growth. The characterization of as-deposited catalysts using TEM and atomic force microscopy [9] reveals that the particles are in the range of 1 to 10 nm in size. The catalyst deposition may be restricted to selected locations of the wafer through lithographic patterning. The type of lithography (optical, electron-beam, etc.) needed would be dictated primarily by the feature size of the patterns.

Typically, CNT-CVD is performed at atmospheric pressure and temperatures of 550 to 1000 °C. Low-pressure processes at several torr have also been reported. SWNTs require higher growth temperatures (above 800 °C) than MWNTs, whereas the latter can be grown at temperatures as low as 550 °C. Lower temperatures (<500 °C) may not be possible if the catalytic activation and realistic reaction/growth rates occur only at such elevated temperatures. At present, this restriction poses a serious problem for the adoption of CVD as an *in-situ* process in the device fabrication sequence, as common masking materials cannot withstand such high temperatures. Figure 7.3 shows bundles of SWNTs grown using methane with an iron catalyst prepared by ion beam sputtering. Typically, the SWNTs tend to bunch together to form bundles or ropes. Figure 7.4 shows a patterned MWNT growth on a silicon substrate using an iron catalyst, which appears to yield a vertical array of nanotubes. Although the ensemble appears vertical, a closer inspection would reveal – in all cases of thermal CVD – that the individual MWNT itself is actually not well aligned but is wavy.

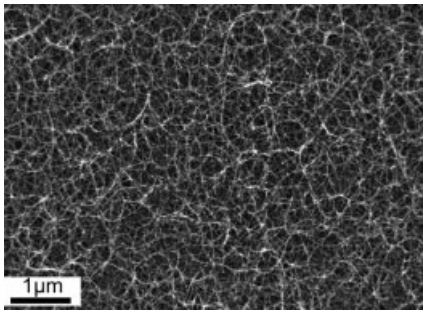

Figure 7.3 Bundles of SWNTs grown by chemical vapor deposition. (Image courtesy of Lance Delzeit.)

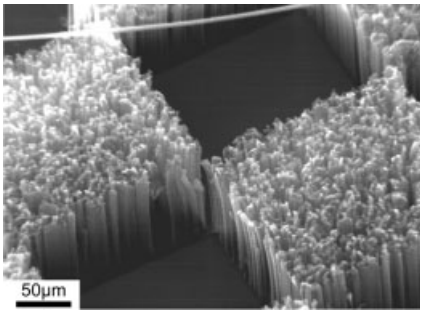

Figure 7.4 Patterned growth of multiwalled carbon nanotubes by CVD. (Image courtesy of H. T. Ng.)

In silicon integrated circuit manufacture, PECVD has emerged as a lower-temperature alternative to thermal CVD for the deposition of thin films of silicon, or its nitride or oxide. This strategy is not entirely successful in CNT growth, primarily because the growth temperature is tied to catalyst effectiveness as opposed to precursor dissociation [10]. Nevertheless, some reports have been made concerning nanotube growth at low temperature, or even at room temperature. However, these results are not reliable as they do not explicitly measure the growth temperature (i.e. the wafer temperature), but instead report only the temperatures on the bottom side of the substrate holder. Neither did any of these studies appreciate the fact that the plasma – and particularly the dc plasma used in most studies – heats the wafer substantially, particularly at the very high bias voltages commonly used. In such a case, even external heating via a heater may not be needed, and in most cases the temperature difference between the wafer and the bottom of the substrate holder may be several hundred degrees or more, depending on the input power [11]. Even if any degree of growth temperature reduction is achieved using PECVD, the material quality is relatively poor. Most of these structures are often conical in terms of configuration, with a continuously tapering diameter from the bottom to the top. Regardless of such issues, PECVD has one clear advantage over CVD, in that it enables the production of individual, freestanding, vertically aligned MWNT structures as opposed to individual, wavy nanotubes. These freestanding structures are invariably disordered with a bamboo-like inner core and, for that reason, are referred to as multi-walled carbon nanofibers (MWNFs) or simply carbon nanofibers (CNFs) [10]. PECVD is also capable of producing wavy MWNTs which are very similar to the thermally grown MWNTs.

To date, a variety of plasma sources have been used in CNT growth, including dc [12, 13], microwave [14], and inductive power sources [15]. The plasma efficiently breaks down the hydrocarbon feedstock, thus creating a variety of reactive radicals which are also the source for amorphous carbon. For this reason the feedstock is typically diluted with hydrogen, ammonia, argon or nitrogen to maintain the hydrocarbon fraction at less than about 20%. PECVD is performed at low pressures, typically in the range of 1 to 20 Torr. A scanning electron microscopy (SEM) image of PECVD-grown MWNFs is shown in Figure 7.5, wherein the individual structures are

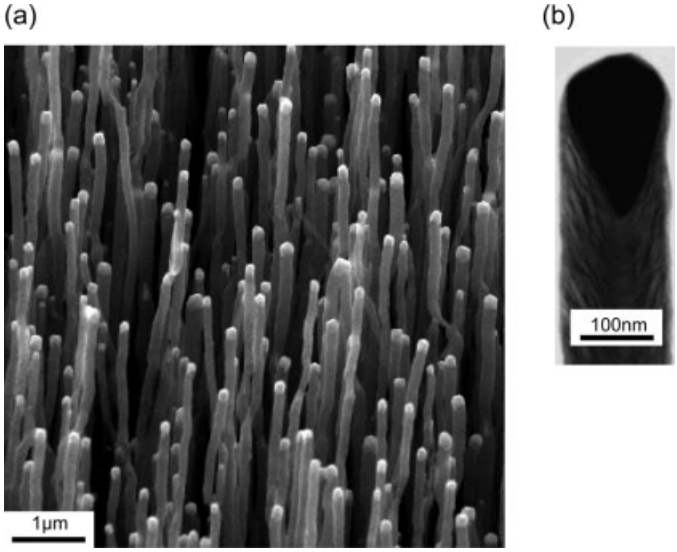

Figure 7.5 (a) SEM image showing vertical, freestanding carbon nanofibers grown by plasma-enhanced CVD. (Image courtesy of Alan Cassell.) (b) TEM image showing bamboo-like morphology and the catalyst particle at the head. (Image courtesy of Quoc Ngo and Alan Cassell.)

well separated and vertical. However, the TEM image reveals a disordered inner core and also the catalyst particle at the top. In contrast, in most cases of MWNT growth by thermal and plasma CVD, the catalyst particle is typically at the base of the nanotubes.

7.4 Nanoelectronics

Silicon complementary metal oxide semiconductor (CMOS) -based electronics has been moving forward impressively according to Moore's law, with 90-nm feature scale devices currently in production and 65-nm devices in the development stage. Research investigations are also well under way on the lower nodes and, as further miniaturization continues, a range of technological difficulties is anticipated, according to the Semiconductor Industry Association Roadmap [16]. These issues include lithography, novel dielectric materials, heat dissipation and efficient chip cooling to name a few. It was thought a few years ago that Si CMOS scaling may end at around 50 nm, beyond which alternatives such as CNT electronics or molecular electronics may be needed. However, this is no longer true as the current evidence suggests that scaling beyond 50 nm is possible, though with increased challenges. Regardless of

when the need for transition to alternatives emerges, there are a few expectations from a viable alternative:

- The new technology must be easier and cheaper to manufacture than Si CMOS.
- A high current drive is needed with the ability to drive capacitances of interconnects of any length.
- A reliability factor enjoyed to date must be available (i.e. operating time > 10 years).
- A high level of integration must be possible (>10^{10} transistors per circuit).
- A very high reproducibility is expected.
- The technology should not be handicapped with high heat dissipation problems currently forecast for the future-generation silicon devices, or attractive solutions must be available to tackle the anticipated heat loads.

Of course, the present status of CNT electronics has not yet reached the point where its performance in terms of the above goals can be evaluated. This is due to the fact that most efforts to date relate to the fabrication of single devices such as diodes and transistors, and little has been targeted at circuits and integration (as will be seen in the next section). In summary, the present status of CNT electronics evolution is similar to that of silicon technology between the invention of the transistor (during the late 1940s) and the development of integrated circuit in the 1960s. It would take at least a decade or more to demonstrate the technological progress required to meet the above-listed expectations.

7.4.1 Field Effect Transistors

The early attempts to investigate CNTs in electronics consisted of fabricating field effect transistors (FETs) with a SWNT as the conducting channel [17]. Tans *et al.* [18] reported first a CNT-FET where a semiconducting SWNT from a bulk-grown sample was transplanted to bridge the source and drain contacts separated by about a micron or more (see Figure 7.6). The contact electrodes were defined on a thick 300-nm SiO_2 layer grown on a silicon wafer acting as the back gate. The 1.4-nm tube with a corresponding bandgap of about 0.6 eV showed *I–V* characteristics indicating gate control of current flow through the nanotube. In the FET, the holes were the majority carriers and the conductance was shown to vary by at least six orders of magnitude. The device gain of this early device was below 1, due primarily to the thick gate oxide and high contact resistance.

At almost the same time, Martel *et al.* [19] presented their CNT-FET results using a similar back-gated structure. The oxide thickness was 140 nm, and 30 nm-thick

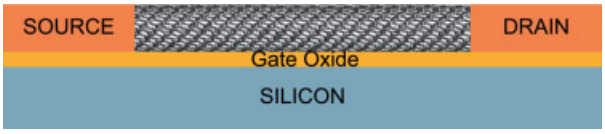

Figure 7.6 Schematic of an early CNT-FET with a back gate. A semiconducting nanotube bridges the source and drain, thus creating the conducting channel.

gold electrodes were defined using electron-beam lithography. The room-temperature I–V_{SD} characteristics showed that the drain current decreased strongly with increasing gate voltage, thus demonstrating CNT-FET operation through hole transport. The conductance modulation in this case spanned five orders of magnitude. The transconductance of this device was 1.7 nS at $V_{SD} = 10$ mV, with a corresponding hole mobility of 20 $cm^2 V^{-1} s^{-1}$. The authors concluded that the transport was diffusive rather than ballistic and, in addition, the high hole concentration was inherent to the nanotubes as a result of processing. This unipolar p-type device behavior suggested a Schottky barrier at the tube–contact metal interface. Later, the same IBM group [20] showed that n-type transistors could be produced simply by annealing the above p-type device in a vacuum, or by intentionally doping the nanotube with an alkali metal such as potassium.

All of the early CNT-FETs used the silicon substrate as the back gate. This unorthodox approach has several disadvantages. First, the resulting thick gate oxide required high gate voltages to turn the device on. Second, the use of the substrate for gating led to influencing all devices simultaneously. For integrated circuit applications, each CNT-FET needs its own gate control. Wind *et al.* [21] reported the first top gate CNT-FET which also featured embedding the SWNT within the insulator rather than exposing it to ambient, as had been done in the early devices. It was considered that such ambient exposure would lead to p-type characteristics and, as expected, the top gate device showed significantly better performance. A p-type CNT-FET with a gate length of 300 nm and gate oxide thickness of 15 nm showed a threshold voltage of –0.5 V and a transconductance of 2321 $\mu S\,\mu m^{-1}$. These results were better than those of a silicon p-MOSFET [22] with a much smaller gate length of 15 nm and an oxide thickness of 1.4 nm performing at a transconductance of 975 $\mu S\,\mu m^{-1}$. The CNT-FET also showed a three- to four-fold higher current drive per unit width compared to the above silicon device. Nihey *et al.* [23] also reported a top-gated device albeit with a thinner (6 nm) gate oxide TiO_2 with a higher dielectric constant. This device showed a 320 nS transconductance at a 100 mV drain voltage.

Most recently, Seidel *et al.* [24] reported CNT-FETs with short channels (18 nm), in contrast to all previous studies with micron-long channels. This group used nanotubes with diameters of 0.7 to 1.1 nm, and bandgaps in the range of 0.8 to 1.3 eV. The impressive performance of these devices included an on/off current ratio of 10^6 and a transconductance of 12 000 $\mu S\,\mu m^{-1}$. The current-carrying capacity was also very high, with a maximum current of 15 μA, corresponding to 10^9 $A\,cm^{-2}$. Another recent innovation involved a nanotube-on-insulator (NOI) approach [25], similar to the adoption of silicon-on-insulator (SOI) by the semiconductor industry, which minimizes parasitic capacitance.

As noted above, many of the CNT-FET studies conducted to date have used SWNTs, this being due to their superior properties compared to other types of nanotubes such as MWNTs and CNFs. As the bandgap is inversely proportional to the diameter, large-diameter MWNTs are invariably metallic. Martel *et al.* [19] fabricated the first MWNT FETs showing a significant gate effect. The real advantage of MWNTs is that they can be grown vertically up to reasonable lengths for a given diameter. Choi *et al.* [26, 27] took advantage of this point to fabricate vertical transistors using MWNTs grown using an anodic alumina template which essentially contained nanopores of various diameter

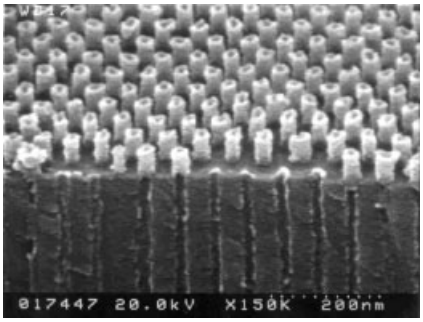

Figure 7.7 Vertically aligned MWNT grown using a nanoporous template. (Image courtesy of W. B. Choi.)

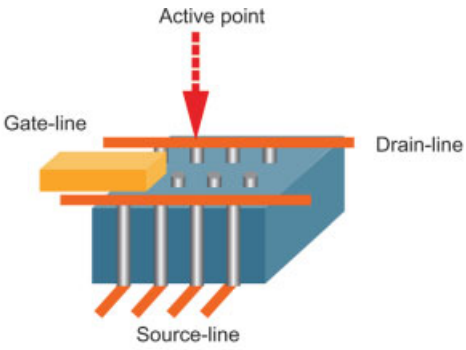
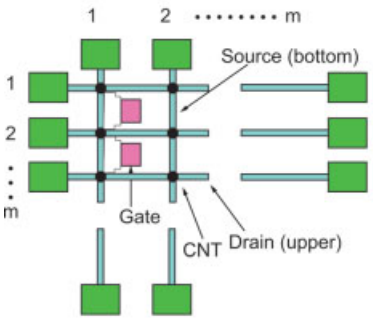
such that they were able to control both the diameter and pore density. The vertically aligned MWNTs grown using nanopores are shown in Figure 7.7. Following this, the device fabrication consisted of depositing SiO_2 on top of the aligned nanotubes. The electrode was then attached to the nanotubes through electron-beam-patterned holes, and finally the top metal electrode was attached. A schematic of the CNT-FET array and a SEM image of a 10×10 array is shown in Figure 7.8. For these devices, the authors claimed a tera-level transistor density of $2 \times 10^{11}\,\mathrm{cm}^{-2}$.





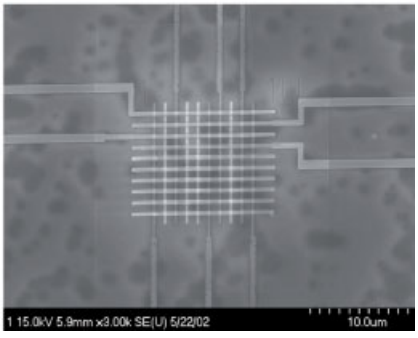


Figure 7.8 An array of CNT-FETs fabricated using the MWNTs in Figure 7.7. A schematic and an SEM image of an $n \times m$ array are shown. (Image courtesy of W. B. Choi.)

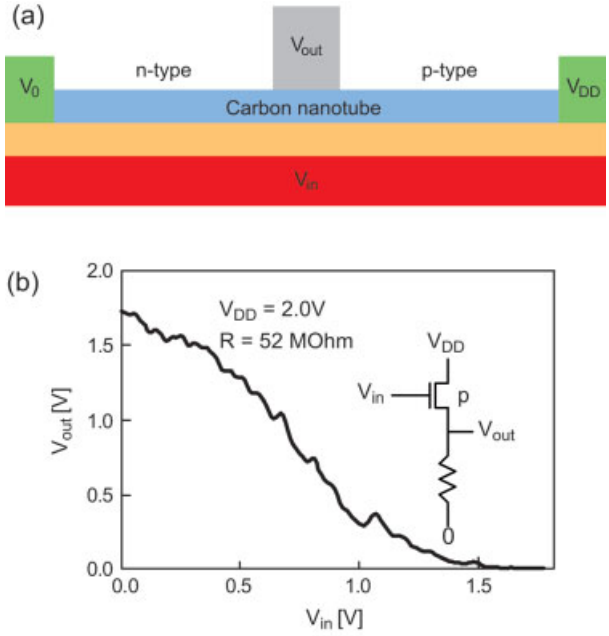

Figure 7.9 (a) n-type and p-type CNT-FETs. (b) Characteristics of an inverter circuit using the devices in (a). The inset shows the inverter circuit. (Reproduced from Ref. [28].)

Beyond single CNT-FETs, early attempts to fabricate circuit components have also been reported [28–30]. Liu *et al.* [28] fabricated both PMOS and CMOS inverters based on CNT-FETs. Their CMOS inverter connected two CNT-FETs in series using an electric lead of 2 mm length. One of the FETs was a p-type device, while the other – an n-type device – was obtained using potassium doping (see Figure 7.9). The devices used the silicon substrate as a back gate. The inverter was constructed and biased in the configuration shown in Figure 7.9b, after which a drain bias of 2.9 V was applied and the gate electrode was swept from 0 to 2.5 V, defining logics 0 and 1, respectively. As seen in the transfer curve in Figure 7.9b, when the input voltage is low (logic 0) the p-type and n-type devices were on and off, respectively (corresponding to their respective high- and low-conductance states). Then, the output is close to V_{DD}, producing a logic output of 1. When the input voltage is high (logic 1), the reverse is the case: the p-type transistor is off and the n-type device is on, with a combined output close to 0, producing a logic 0. The transfer curve in Figure 7.9b should not have a slope if this inverter were functioning ideally (which would correspond to a stepwise V_{out} versus V_{in} behavior). However, this first demonstration had a leaky p-device and so control of the threshold voltage of both devices was not perfect, thus leading to the slope seen in Figure 7.9b. Derycke *et al.* [29] also demonstrated an inverter using p- and n-type CNT-FETs. Beyond inverters, Bachtold *et al.* [30] fabricated circuits to perform logic operations such as NOR, and also constructed an ac ring oscillator.

As efforts continue in this direction, it is also important to consider issues such as $1/f$ noise, shot noise, and other similar concerns arising during operation. An analysis by Lin *et al.* [31] showed that the $1/f$ noise level in semiconducting SWNTs is correlated to the total number of charge carriers in the system. However, the noise level per carrier itself is not larger than that seen in silicon devices. Beyond the conventional binary logic approach, Raychowdry and Kaushik [32] discussed extensively implementation schemes for voltage-mode multiple-value logic (MVL) design. The MVL circuits reduce the number of operations per function and reduce the parasitics associated with routing and the overall power dissipation.

To date, the CNT-FET fabrication has essentially followed the silicon CMOS scheme by simply replacing the silicon conducting channel with a SWNT. This requires the presence of straight, aligned nanotubes controllably bridging a pair of electrodes laid out horizontally. As-grown SWNTs using any of the growth techniques, in contrast, exhibit a spaghetti-like morphology and occasionally consist of Y- and other types of junction. Menon and Srivastava [33, 34] postulated that such Y- and T-junctions are structurally stable and form the basis for three-terminal devices. However, such junctions in as-grown samples are, of course, neither controllable nor really amenable for further device processing. Satishkumer *et al.* [35] then set out to create these Y-junctions in a controllable manner using the anodic alumina template approach. Keeping two of the terminals at the same voltage, the two-terminal operation showed rectifying behavior when the voltage on the third terminal was varied. While their devices were constructed from MWNTs, SWNT Y-junctions have also been reported [36, 37], though FET operation using Y-junctions has not yet been demonstrated. Srivastava *et al.* [38] also proposed a radical neural tree architecture consisting of numerous Y-junctions (see Figure 7.10), wherein the concept is that the switching and processing of signals by these junctions in the tree would be similar to that of dentritic neurons in biological systems. In addition, acoustic, chemical or other signals may also be used instead of electrical signals.

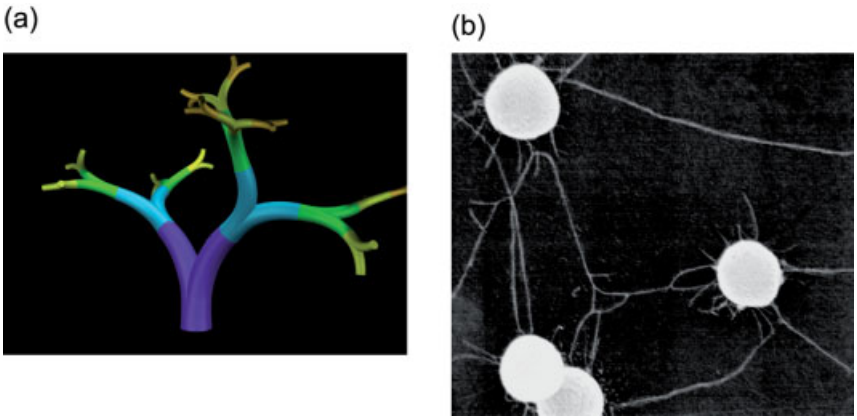

Figure 7.10 (a) A neural tree constructed using numerous Y-junctions of carbon nanotubes. (b) A network of interconnected SWNTs showing a few Y-junctions [36].

Figure 7.10b shows a very rudimentary attempt [36] to create such a CNT tree by utilizing self-assembled porous, collapsible polystrene/divinyl benzene microspheres to hold the catalyst. A controlled collapse of the spheres leads to the creation and release of the catalyst on the substrate for the CVD of SWNTs. Few Y-junctions showing an interconnected three-dimensional network of nanotubes are visible in Figure 7.10b.

7.4.2 Device Physics

The physics describing the operation of the CNT-FETs has been described in several theory papers [39–42] and summarized and reviewed elsewhere [17]. Here, the available information would be used to predict upper limits on CNT-FET performance. Yamada argues [17] that in nanoFETs the properties of the bulk material do not influence the device performance. In micro and macro FETs, the drain current is proportional to carrier mobility, which varies from material to material through its dependence on material-related properties such as effective mass and phonon scattering. In nanoFETs with ideal contacts, the drain current is determined by the transmission coefficient of an electron flux from the source to drain. When the carrier transport is ballistic, this coefficient is 1 and the material properties do not enter the picture directly. However, the material properties in practice enter indirectly as practical contacts (and hence the transmission coefficient at the contact) depend on the channel material and the interaction between the metal–channel semiconductor interface. The same applies to the preparation of the insulation material that determines the gate voltage characteristics. One-dimensional nanomaterials such as SWNTs inherently can suppress the short-channel effects arising from a deeper, broader distribution of carriers away from the gate, which occurs in reduced-size, two-dimensional silicon devices.

By using such an ideal device under ballistic transport and ideal contacts, Guo *et al.* [43] evaluated the performance of CNT-FETs. These authors considered a 1-nm SWNT with an insulator thickness of 1 nm and dielectric constant of 4. The geometry also was idealized to be a coaxial structure with contacts at either end of the nanotubes, and the gate wrapped around the nanotube. The computed on-off current ratio of 1120 was far higher than planar silicon CMOS devices with the same insulator parameters and power supply. The transconductance of this structure was also very high at 63 μS at 0.4 V, which was two orders of magnitude higher than any CNT-FET device discussed in Section 7.4.1. When a planar CNT-FET is compared with a planar Si-MOSFET with similar insulator parameters, the CNT-FET shows an on-current of $790\,\mu A\,\mu m^{-1}$ at $V_{DD} = 0.4$ V, in contrast to the $1100\,\mu A\,\mu m^{-1}$ value for silicon. In a following study, the same authors [44] computed the high-frequency performance of this ideal device and projected a unity gain cut-off frequency (f_T) of 1.8 THz. Their analysis also showed that the parasitic capacitance dominates the intrinsic gate capacitance by three orders of magnitude. In a similar investigation, Hasan *et al.* [45] computed f_T to be a maximum of $130\,L^{-1}$ GHz, where L is the channel length in microns. As there is a desire to increase the current drive and reduce parasitic capacitance per tube, parallel array of nanotubes as the channel warrants

consideration [44]. However, crosstalk becomes a serious issue in multiple tube systems. Leonard [46] analyzed this point, and established a length scale for tube separation below which inter-tube interaction becomes significant. For small channel lengths, this critical separation distance depends on the channel length; for long channel devices, the critical inter-tube separation distance is independent of channel length but depends on gate oxide thickness and dielectric constant.

7.4.3 Memory Devices

In relative terms, very few studies have been conducted on the use of nanotubes as memory devices. Rueckes *et al.* [47] proposed a crossbar architecture for constructing non-volatile random access memory with a density of 10^{12} element per cm^2 and an operation frequency of over 100 GHz. In this architecture, nanotubes suspended in a $n \times m$ array act like electromechanical switches with distinct on and off states. A carbon nanotube-based flash memory was fabricated by Choi *et al.* [48], in which the source-drain gap was bridged with a SWNT as a conducting channel and the structure had a floating gate and a control gate. By grounding the source and applying 5 V and 12 V at the drain and control gate, respectively, a writing of 1 was achieved. This corresponds to the charging of the floating gate. To write 0, the source was biased at 12 V, the control gate fixed at 0 V, and the drain allowed to float. Now, the electrons on the floating gate were tunneled to the source and the floating gate was discharged. In order to read, a voltage V_R was applied to the control gate and, depending on the state of the floating gate (1 or 0), the drain current was either negligible or finite, respectively. Choi *et al.* [48] reported an appreciable threshold modulation for their SWNT flash memory operation.

7.5 Carbon Nanotubes in Silicon CMOS Fabrication

Whilst the active role of CNTs in nanoelectronics (i.e. as a conducting channel in a transistor device) may be far away, it may play an important role in extending silicon nanoelectronics. Several areas exist in the Semiconductor Industry Association Roadmap [16] where CNTs may be useful, such as interconnects, heat dissipation and metrology.

7.5.1 Interconnects

One of the anticipated problems in the next few generations of silicon devices is that the copper interconnect would suffer from electromigration at current densities of 10^6 A cm^{-2} and above. The resistivity of copper increases significantly for wiring line widths lower than 0.5 μm. In addition, the etching of deep vias and trenches and void-free filling of copper in high-aspect ratio structures may pose technological

challenges as progress continues along the Moore's law curve. All of these issues together demand investigation of alternatives to the current copper damascene process. In this regard, it is important to note that CNTs do not break down – even at current densities of 10^8 to 10^9 A cm^{-2} [49] – and hence can be a viable alternative to copper. Kreupl *et al.* [50] were the first to explore CVD-produced MWNTs in vias and contact holes. They measured a resistance of about 1 Ω for a 150 μm^2 via which contained about 10 000 MWNTs, thus yielding a resistance of 10 KΩ per nanotube. Further studies by this group demonstrated current densities of 5×10^8 A cm^{-2}, which exceeds the best results for metals, although the individual resistance of the MWNTs was still high at 7.8 KΩ. Srivastava *et al.* [51] provided a systematic evaluation of CNT and Cu interconnects and showed that, for local interconnects, nanotubes may not offer any advantages, partly due to the fact that practical implementations of nanotube interconnects have an unacceptably high contact resistance. On the other hand, their studies showed an 80% performance improvement with CNTs for long global interconnects. It is important to note that, even in the case of local interconnects, very few studies have been conducted on contact and interface engineering; however, with further investigation the situation may well improve beyond these early expectations.

Given the potential of CNTs as interconnects, it is necessary to devise a processing scheme that is compatible with the silicon integrated circuit fabrication scheme. In the via and contact hole schemes, Kreupl *et al.* [50] followed a traditional approach by simply replacing the copper filling step with a MWNT CVD step. If this proves to be reliable – and specifically if the MWNTs do not become unraveled during the chemical mechanical polishing (CMP) step – then it would be a viable approach, provided that a dense filling of vertical nanotubes can be achieved. Even then, the conventional challenges in deep aspect ratio etching and void-free filling of features, which arise due to shrinking feature sizes, remain. The dry etching of high-aspect ratio vias with vertical sidewalls will increasingly become a problem, and further processing studies must be performed to establish the viability of this approach. In the meantime, Li *et al.* [52] described an alternative bottom-up scheme (see Figure 7.11) wherein the CNT interconnect is first deposited using PECVD at prespecified locations. This is followed by tetraethylorthosilicate (TEOS) CVD of SiO_2 in the space between CNTs, and then by CMP to yield a smooth top surface of SiO_2 with embedded CNT interconnects. Top metallization completes the fabrication. The interconnects grown using PECVD in Ref. [52] are CNFs with a bamboo-like morphology. Whilst they are really vertical and freestanding compared to MWNTs, thus allowing ease of fabrication, their resistance is higher. This, combined with high contact resistance, resulted in a value of about 6 KΩ for a single 50-nm CNF. Further annealing to obtain higher quality CNFs and, more importantly, interface engineering to reduce contact resistance, can prove this approach valuable. It would also be useful for future three-dimensional architectures. A detailed theoretical study conducted by Svizhenko *et al.* [53] showed that almost 90% of the voltage drop occurs at the metal–nanotube interface, while only 10% is due to transport in the nanotube, thus emphasizing the need for contact interface engineering.

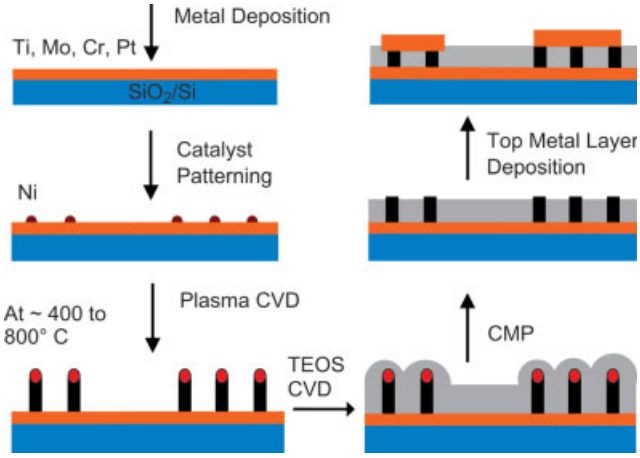

Figure 7.11 Carbon nanotube interconnect processing scheme for DRAM applications. TEOS = tetraethylorthosilicate.

7.5.2
Thermal Interface Material for Chip Cooling

The current trend in microprocessors is increasing operating frequency, decreasing dimensions, high packing density, and increasing power density. Together, these make thermal management in chip design a critical function to maintain the operating temperature at a prescribed, acceptable level. Otherwise, device reliability is severely compromised, and the speed of the microprocessor would also decrease with increasing operating temperatures [54]. The key figure-of-merit in thermal design and packaging is the thermal resistance, which is ΔT/input power. Here, ΔT is the temperature difference between the transistor junction and the ambient, which is fixed by the desirable operating junction temperature. As the power densities are on the rise, Shelling *et al.* [54] point out that the challenge is to develop high-conductivity structures which will accommodate the fixed ΔT, even with increased power densities.

Typically, the thermal packaging of a microprocessor consists of a heat spreader (primarily copper) and a heat sink. A variety of engineering designs is considered in all of the above to increase the heat-transfer efficiency [55] (which is beyond the scope of this chapter and not relevant at this point). However, one aspect which is relevant is a thermal interface material (TIM) commonly used to improve heat transfer between the chip and heat spreader, as well as between the heat spreader and the heat sink. Typically, a thermal grease has been used as TIM in the past, but more recent research on phase-change materials and polymers filled with high-conductivity particles has advanced knowledge of this subject. Carbon nanotubes exhibit very high axial thermal conductivity (see Section 7.2) which can be exploited in creating a TIM to address future thermal management needs.

Ngo *et al.* [56] reported a CNT-Cu composite for this purpose, wherein a PECVD-produced vertical CNF array is intercalated with copper using electrodeposition. As CNF surface coverage on the wafer from PECVD is only about 30–40% and air is a

poor conductor, it becomes necessary to undertake a "gap-filling" effort with copper to cover the space between the nanotubes. This structure maintained its structural integrity at the 60 psi pressure normally used in packaging. Ngo *et al.* [56] reported a thermal resistance of about 0.1 $cm^2\,K\,W^{-1}$ for this structure, which makes it desirable for laptop, desktop, and workstation processor chips, although further improvements and reliability testing are required in this area.

7.5.3 CNT Probes in Metrology

Atomic force microscopy (AFM) is a versatile technique for imaging a wide variety of materials with high resolution. In addition to imaging metallic, semiconducting and dielectric thin films in integrated circuit manufacture, AFM has been advocated for critical dimension metrology. Currently, the conventional probes of either silicon or silicon nitride which are sited at the end of an AFM cantilever have a tip radius of curvature about 20–30 nm, which is obtained by micromachining or reactive ion etching. These probes exhibit significant wear during continuous use, and the worn probes can also break during tapping mode or contact mode operation. Carbon nanotube probes can overcome the above limitations due to their small size, high aspect ratio and the ability to buckle reversibly. Their use in AFM was first demonstrated by Dai *et al.* [57], while a detailed discussion of CNT probes and their construction and applications is also available [58].

A SWNT tip, attached to the end of an AFM cantilever, is capable of functioning as an AFM probe and provides better resolution than conventional probes. This SWNT probe can be grown directly using thermal CVD at the end of a cantilever [59]. An image of an iridium thin film collected using a SWNT probe is shown in Figure 7.12.

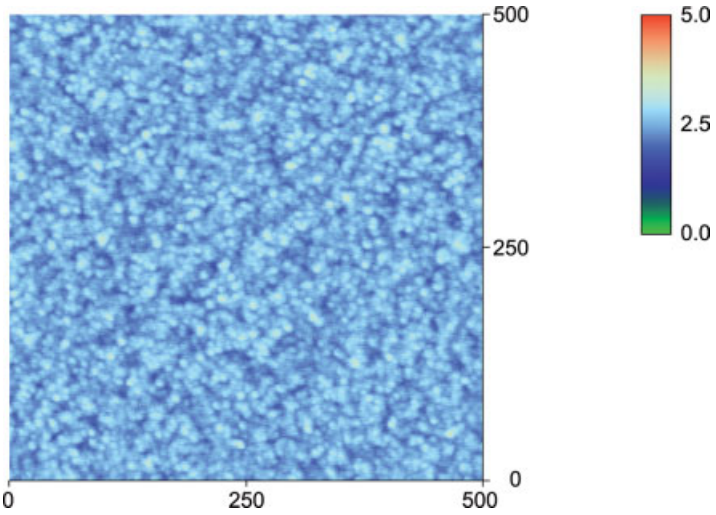

Figure 7.12 Atomic force microscopy image of an iridium thin film collected using a SWNT probe.

The nanoscale resolution is remarkable, but more importantly the tip has been shown to be very robust and significantly slow-wearing compared to conventional probes [59]. Due to thermal vibration problems, the SWNTs with a typical diameter of 1 to 1.5 nm cannot be longer than about 75 nm for probe construction. In contrast, however, the MWNTs – with their larger diameter – can form 2- to 3-μm-long probes. It is also possible to sharpen the tip of MWNTs to reach the same size as SWNTs, thus allowing the construction of long probes without thermal stability issues, but with the resolution of SWNTs [60]. Both, SWNT and sharpened MWNT probes have been used to image the semiconductor, metallic, and dielectric thin films commonly encountered in integrated circuit manufacture [58–60].

In addition to imaging, MWNT probes find another important application in the profilometry associated with integrated circuit manufacture. As via and other feature sizes continue to decrease, it will become increasingly difficult to use conventional profilometers to obtain sidewall profiles and monitor the depth of features. Although AFM is advocated as a replacement in this respect, the pyramidal nature of standard AFM probes would lead to artifacts when constructing the sidewall profiles of trenches. Hence, a 7- to 10-nm MWNT probe might be a natural choice for this task. An image of a MWNT probe for this purpose, and the results of profiling a photoresist pattern generated by interferometric lithography, are shown in Figure 7.13. While early attempts consisted of manually attaching a SWNT to a cantilever [57], followed by direct CVD of a nanoprobe on a cantilever [58, 59], Ye *et al*. [61] reported the first batch fabrication of CNT probes on a 100-mm wafer

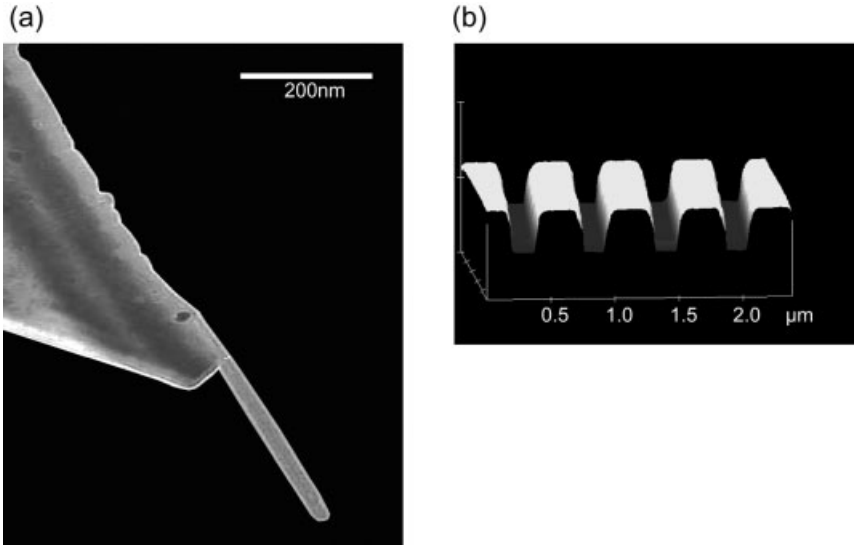

Figure 7.13 (a) Transmission electron microscopy image of a MWNT at the tip of an atomic force microscope cantilever. (b) Profile of a deep-UV photoresist pattern generated by interferometric lithography. The array has a pitch of 500 nm.

using PECVD. Unfortunately, the yield obtained was only modest, due mainly to difficulties encountered in controlling the angle of the nanotube to the plane.

7.6 Summary

In this chapter, the current status of CNT-based electronics for logic and memory devices has been discussed. Single-walled CNTs exhibit intriguing electronic properties that make them very attractive for future nanoelectronics devices, and early studies have confirmed this potential. Even with substantially longer channel lengths and thicker gate oxides, the performance of CNT-FETs is better than that of current silicon devices, although of course the design and performance of the former are far from being optimized. While all of this is impressive, the real challenge is in the integration of a large number of devices at reasonable cost to compete with and exceed the performance status quo of silicon technology at the end of the Moore's law paradigm. In addition, all of the studies conducted to date have been along the lines of following silicon processing schemes, with one-to-one replacement of a silicon channel with a CNT channel while maintaining the circuit and architectural schemes. Thus, aside from changing the channel material, there is no novelty in this approach. The structure and unique properties of SWNTs may be ideal for bold, novel architectures and processing schemes, for example in neural or biomimetic architecture, although very few investigations have been carried out in such non-traditional directions. Clearly, CNTs in active devices are a long-term prospect, at least a decade or more away. In the meantime, opportunities exist to include this extraordinary material into silicon CMOS fabrication not only as a high-current-carrying, robust interconnect but also as an effective heat-dissipating, thermal interface material.

Acknowledgments

The author is grateful to his colleagues at NASA Ames Center for Nanotechnology for providing much of the material described in this chapter.

Concepts in Single-Molecule Electronics

Björn Lüssem and Thomas Bjørnholm

8.1
Introduction

Molecular electronics is a wide field of research, which consists of such diverging topics as organic light-emitting diodes (OLEDs), organic field effect transistors (OFETs; see Chapter 9) or, the topic of this chapter, single-molecule devices. Whereas, OLEDs and OFETs exploit the properties of a large number of molecules, in the field of single-molecule electronics an attempt is made to condense the entire functionality of an electronic device into a single molecule.

The field of (single) molecular electronics owes its significance to the tremendous downscaling that microelectronics has experienced during the past decades. In the ITRS roadmap [1], it is expected that, by the year 2013, the physical gate length of a transistor will scale down to 13 nm – that is, the transistor channel will consist of only a couple of atoms in a row. In order to obtain reliable devices, the composition of the devices must be controlled to only a few atoms – a demand that seems not to be feasible for conventional lithographic methods.

Chemistry – and especially organic chemistry – learned long ago how to control precisely the composition of a molecule to the last atom. Thus, the utilization of single organic molecules can be regarded as the ultimate miniaturization of electronic devices.

The concept of single-molecule electronics was first suggested in 1974 by Aviram and Ratner [2], who proposed that a single molecule consisting of a donor and an acceptor group could function as a diode. Unfortunately, however, at that time it was experimentally not feasible to test these predictions.

Molecular electronics gained impetus during the 1990s and early 2000s, when several molecular devices were proposed, including a single molecular switch [3] or a diode showing a negative differential resistance [4]. These early results raised great expectations, as evidenced by the election of molecular electronics as the "breakthrough of the year 2001" [5]. However, only two years later, the fledgling field

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

of molecular electronics experienced its first drawback when it was reported that some of the early results might be due to artifacts [6].

These reports on possible artifacts helped to settle the expectations laid on molecular electronics to a reasonable level, and in the current phase of development more emphasis has been placed on proving that the observed effects are in fact "molecular", and on identifying experimental set-ups that avoid the possible introduction of artifacts.

In this chapter, a brief overview is provided of the field of single-molecule electronics, beginning with a short theoretical introduction that aims to define the concepts and terminology used. (A more extensive explanation of the theory can be found in Part A of Volume III of this series.) In the following sections the text is more factual, and relates to how single molecules can actually be contacted and which functionalities they can provide. The means by which these molecules may be assembled to implement complex logical functions are then described, followed by a brief summary highlighting the main challenges of molecular electronics.

8.2 The General Set-Up of a Molecular Device

In this section, the basic concepts used in subsequent sections will be explained, and the presence of two domains of current transport – *strong coupling* and *weak coupling* – will be outlined.

Electrical transport across single molecules is remarkably different from conduction in macroscopic wires. In a large conductor, charge carriers move with a mean drift velocity v_d, which is proportional to the electric field, E. Together with the density of free charge carriers, this proportionality gives rise to Ohm's law.

For a single molecule this model is not applicable. Instead of considering drift velocities and resistances, which are only defined as average over a large number of charge carriers, concern is centered on the transmission of electrons across the molecule.

The general set-up of a molecular device is shown in Figure 8.1. The molecule is connected by two electrodes, labeled "source" and "drain", while the electrostatic potential of the molecule can also be varied by using a gate electrode.

If a voltage is applied between the source and drain (i.e. a negative voltage with respect to the drain), the electrochemical potential of the source, μ_S, shifts up and the potential of the drain, μ_D, moves down. An energy window is opened between these two potentials; in this energy window filled states in the source oppose empty states at the same energy in the drain.

However, as the two electrodes are isolated from each other, electrons cannot easily flow from the source to the drain. Only if a molecular level enters the energy window between μ_S and μ_D, can electron transport be mediated by these molecular levels (see Figure 8.1b). Therefore, each time the electrochemical potential of the source aligns with a molecular level the current rises sharply. In Figure 8.1b, for example, the source potential exceeds the lowest unoccupied molecular orbital (LUMO), and

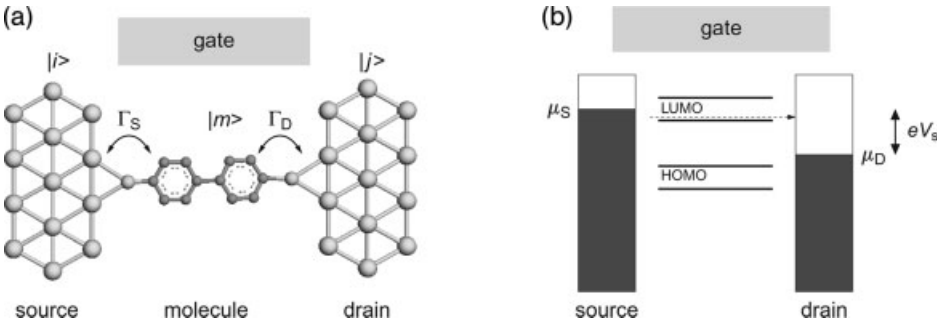

Figure 8.1 General set-up of a molecular device. In (a) a molecule is coupled to the source and drain (coupling strengths Γ_S and Γ_D). In (b) the molecule is replaced by its molecular levels. The electrodes are filled with electrons up to their electrochemical potential (indicated by the hatched area).

electrons can be transmitted across this level. Similarly, the drain potential can drop below the highest occupied molecular orbital (HOMO), which would also initiate electron flow.

8.2.1 The Strong Coupling Regime

Depending on the strength of the coupling of the electrodes with the molecule, there are two domains of the electron transport: the *weak coupling limit* and the *strong coupling limit*. To distinguish between these two limits, coupling strengths Γ_S and Γ_D can be defined that describe how strongly the electronic states of the source or drain $|i\rangle$, $|j\rangle$ interact with the molecular eigenstates $|m\rangle$. Γ_S and Γ_D have the dimension of energy; a high energy means that the electrode states can strongly couple with the molecular states.

High coupling energies therefore result in electronic wavefunctions of the electrodes that can extend into the molecule, so that charge can be easily transmitted from the source, across the molecule towards the drain. Thus, the current across the molecule can be expressed in terms of a transmission coefficient $T(E)$

$$I = \frac{2e}{h} \int_{\mu_D}^{\mu_S} T(E) dE \tag{8.1}$$

where e is the elementary charge and h is Planck's constant.

The transmission coefficient represents the transmission probability of electrons with a certain energy E to be transmitted across the molecule. This probability peaks at the molecular levels. It can be shown that the maximum conductance per molecular level $G_0 = \frac{\Delta I}{\Delta E \cdot e}$ becomes [7, 8]

$$G_0 = \frac{2e^2}{h} \tag{8.2}$$

This maximum conductance of a single electronic level is known as *quantum of conductance*, and corresponds to a resistance of 12.5 kΩ. Most interestingly, this conductance is not dependent on the length of the molecule as long as the ideal molecular level extends between the source and the drain electrodes.

8.2.2 The Weak Coupling Regime

In comparison to the strong coupling limit, current transport is remarkably different, if the coupling strengths Γ_S and Γ_D are weak. Here, the wavefunction of the electrodes cannot extend into the molecule and charge cannot be easily transmitted across the molecule. Rather, electrons must hop or tunnel *sequentially* from the source onto the molecule, and finally from the molecule to the drain. The lowest amount of charge that can be transferred onto the molecule is the elementary charge, e. This has an interesting consequence.

The molecule is electrostatically connected to the source, drain and gate electrode by the capacitances C_S, C_D, and C_G, respectively (see Figure 8.2a). Therefore, it is no longer sufficient that the electrochemical potential of the source aligns with the molecular level. Additionally, it must supply enough energy ($E_C(N)$, where N is the number of electrons) to charge the capacitances with an additional electron.

$$E_C(N+1) = \frac{1}{2}\frac{(N+1)^2e^2 - N^2e^2}{\underbrace{C_S + C_D + C_G}_{C_\Sigma}} = \frac{\left(N+\frac{1}{2}\right)e^2}{C_\Sigma} \tag{8.3}$$

To include this energy, the energy diagram shown in Figure 8.1b may be refined (see Figure 8.2b). Two levels are included in this diagram, which correspond to the HOMO (lower) and LUMO states shown in Figure 8.1b. The LUMO is floated upwards by $E_C(1) = \frac{e^2}{2C_\Sigma}$, while the HOMO is moved down by the same amount.

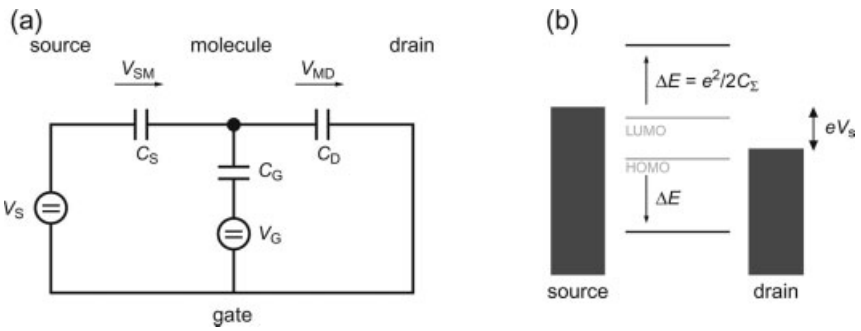

Figure 8.2 (a) The molecule is coupled to source, gate and drain by capacitances. (b) The energy level in the weak coupling limit. Additional charging energy must be provided by the source voltage.

Thereby, a large energy gap is opened within which no electrons can flow and hence the current is blocked; this effect is known as *coulomb blockade*.[1)]

8.3 Realizations of Molecular Devices

In the preceding section, the coupling of the molecule to the electrodes was described by the coupling strengths Γ_S and Γ_D. However, this theoretical description of contact between molecule and electrodes hides the complexity and difficulties that must be overcome in order to contact a single molecule. The main strategy that is followed to contact single molecules is to use specifically designed molecular anchoring groups that bind and self-organize on the contacts. In the following section, some key examples are provided of anchoring groups and self-organization strategies.

8.3.1 Molecular Contacts

Molecular end groups must provide a chemical bond to the contacting metal – that is, they must offer a self-organizing functionality. Furthermore, the nature of the contact determines the coupling strength Γ and, therefore, how strongly the molecular states couple with the electronic states of the electrodes. In the case of strong coupling, electrons can be easily transmitted across the molecule and the resistance of the molecule should be low; conversely, new effects such as coulomb blockade can occur for weak coupling, and this may be exploited for new devices. Thus, the suitable choice of molecular contact is one of the main issues in the design of a molecular device.

Various molecular contacts have been proposed. Besides the most common gold–sulfur bond, sulfur also binds to other metal such as silver [9] or palladium [10]. Sulfur may be replaced by selenium [11], which yields higher electronic coupling. A further increase in coupling strength is provided by dithiocarbamates [12, 13], which is explained by resonant coupling of the binding group to gold. Other binding groups include –CN [14], silanes [15], and molecules directly bound to either carbon [16] or silicon [17].

Using these binding groups, it is possible to contact single or at least a low number of molecules. In the past, several experimental set-ups have been developed which differ in the numbers of molecules contacted. Whereas some set-ups allow contacting single molecules (i.e. the method of *mechanically controlled break junctions, nanogaps* or *scanning probe methods*), in other arrangements the demand of a single molecule is relaxed and a small number of molecules is contacted (e.g. in the *crossed wire set-up* or in a *crossbar structure*). One further distinction between these set-ups is the number of electrodes that can contact each molecule – that is, if besides the source and drain a gate electrode is also present.

1) More details on single-electron effects can be found in Chapter 2 of Volume III in this series.

8.3.2
Mechanically Controlled Break Junctions

The concept of mechanically controlled break junctions dates back to 1985, when the method was used to obtain superconducting tunnel junctions [18]. In 1997, it was applied to contact a single molecule between two gold electrodes [19]. By comparing the current versus voltage characteristic of symmetric and asymmetric molecules, it was shown that only single molecules are contacted [20]. Since then, a variety of different molecules have been studied using this technique, and in particular the use of a low-temperature set-up was seen to provide a significant improvement in data quality [21–29].

The general set-up of a mechanically controlled break junction is shown in Figure 8.3. A metallic wire, which is thinned in the middle, is glued onto a flexible

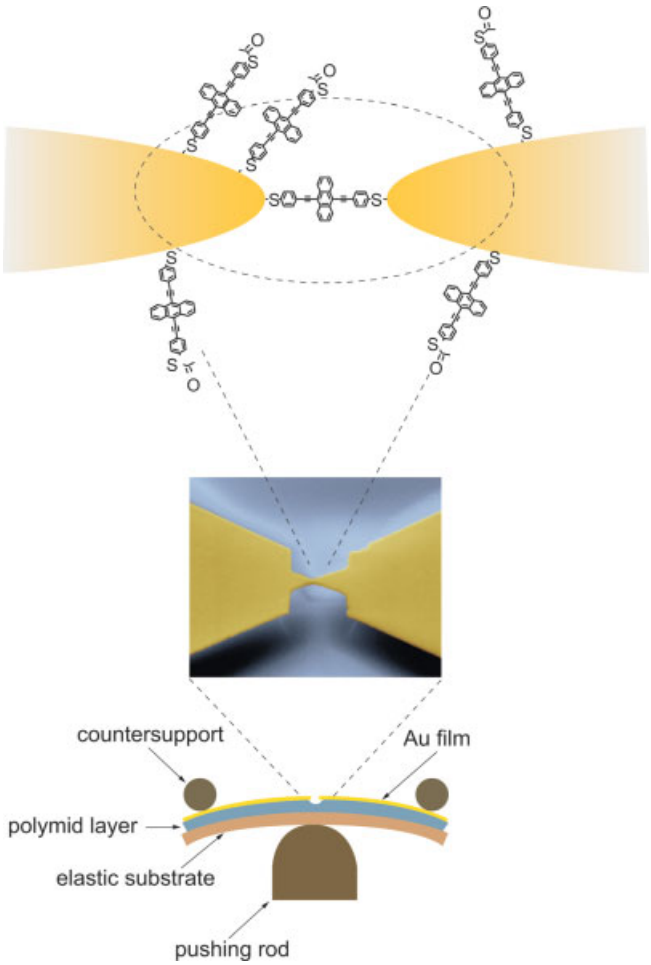

Figure 8.3 The mechanically controlled break junction. (From Ref. [30].)

substrate. Often, the wire is under etched so that a freestanding bridge is formed. Underneath the substrate, a piezo element can press the sample against two countersupports, which causes the substrate to bend upwards such that a strain is induced in the wire. If the strain becomes too large, the wire breaks and a small tunneling gap opens between the two parts of the wire. The length of the tunneling gap can be precisely controlled by the position of the piezo element.

To contact a single molecule, either a solution of the molecule is applied to the broken wire, or the molecules have already been preassembled onto the wire before it is broken. As described above, these molecules have chemical binding groups at both ends that easily bind to the material of the wire. As the molecule has binding groups at both ends it can bridge the tunneling gap if the length of the latter is properly adjusted. In this way a single-molecule device is formed.

Mechanically controlled break junctions represent a stable and reliable method for contacting single molecules. Most importantly, the correlation between molecular structure and current versus voltage characteristic can be studied, which will stimulate the understanding of the conduction through single molecules. At present, however, there is no way of integrating these devices – that is, it is not possible to contact a larger number of molecules in parallel and to combine these molecules into a logic device.

8.3.3
Scanning Probe Set-Ups

Due to its high spatial resolution, scanning probe methods (SPM) are well suited to contact single molecules, and several strategies have evolved during recent years.

One strategy is to contact a so-called self-assembled monolayer (SAM) of the molecule of interest with an atomic force microscope, using a conductive tip [31–34] (see Figure 8.4b). SAMs are formed by immersing a metallic bottom electrode into a solution of molecules (see Figure 8.4a) which must possess an end group that covalently binds to the metal layer. In the first layer, the molecules attach covalently to the metal; all following layers are then physisorbed onto this first chemisorbed layer. The physisorbed layers can easily be washed off using an additional rinsing step, such that only the first, chemisorbed, layer remains on the metal. A famous example of such a molecular end group/metal surface combination is sulfur on gold. Thiolates, and especially alkanethiols, are known to perfectly organize on a gold surface and to build a SAM that covers the gold electrode [35].[2)]

These SAMs can be contacted by a conductive atomic force microscopy (AFM) tip (see Figure 8.4b). Depending on the tip geometry, a low number of molecules (ca. 75) can be contacted [31]. Using this method, it has been shown that the current through alkanethiolates and oligophenylene thiolates decreases exponentially with the length of the molecule, and that the resistance of a molecule is dependent on the metal used to contact the molecule [36].

2) See also Chapter 9, which provides a broader introduction into self-organization and SAMs.

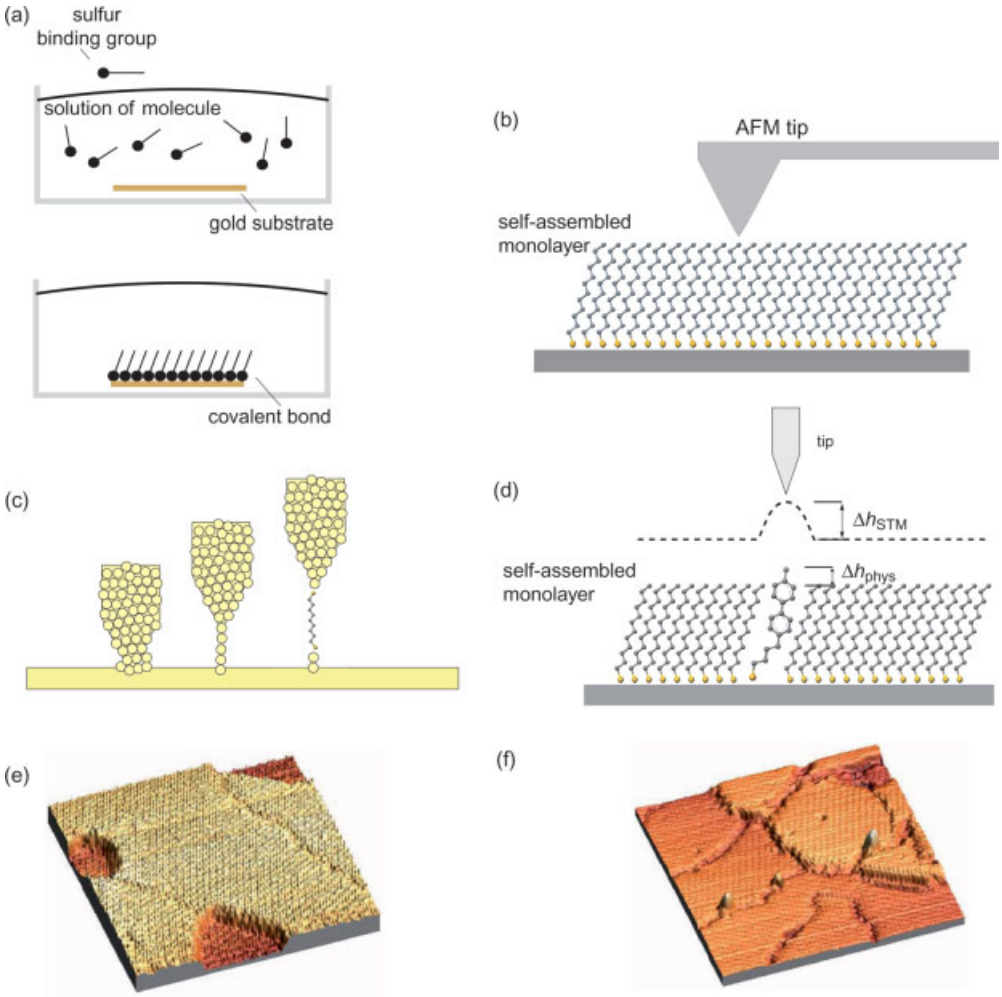

Figure 8.4 The different methods used to contact single molecules with SPM techniques. (a) The basic principle of self-assembled monolayer (SAM) formation. (b) A SAM of molecules is contacted by a conductive AFM tip. (c) The "tip crash" method, which forms a small tunneling gap. (d) Embedding conductive molecules in a SAM of insulating alkanethiols (molecules not drawn to scale). The height of the molecules can be used to deduce their conductivity. (e, f) Scanning tunneling microscopy (STM) image of a SAM of alkanethiols (e) and of oligo-phenylenevinylene molecules embedded into a SAM of alkanethiols. The molecules can be seen protruding from the SAM (f) [37].

An alternative method of contacting molecules using AFM or scanning tunneling microscopy (STM) is very similar to the break junction technique [38, 39]. A gold AFM or STM tip is moved into a gold substrate and subsequently slowly retracted (the "tip-crash" method shown in Figure 8.4c). Thereby, a thin gold filament is formed between the tip and the substrate. If the tip is moved too far away from the substrate,

the filament will break and a small tunneling gap is opened between the substrate and the tip. The whole set-up is immersed in a solution of molecules that have functional binding groups at both ends. If the tunneling gap is approximately the size of the molecule, there is a probability that one molecule will bind to the tip and the substrate and will therefore bridge the gap.

As a third strategy of contacting single molecules, the molecules of interest can be embedded into a SAM of insulating alkanethiols (see Figure 8.4d–f). In this way it is possible to obtain single, isolated molecules which "protrude" from the surrounding alkanethiol SAM (see Figure 8.4f). The conductance of the molecule can be measured either by placing the STM tip above the molecule [40, 41] or by measuring the height difference between the embedded molecule and the surrounding alkanethiol SAM [37, 42, 43]. This height difference is not only dependent on the differences in length of the alkanethiol and the molecule but also reflects differences in the conductivities of the molecules. Therefore, the conductivity of the embedded molecule can be calculated from the height difference.

8.3.4
Crossed Wire Set-Up

This set-up consists of two crossed wires, which almost touch at their crossing point. One of these wires is modified with a SAM of the molecule of interest. A magnetic field is applied perpendicular to one wire, and a dc current is passed through this wire. This causes the wire to be deflected due to the Lorentz force, and consequently the separation of the two wires can be adjusted by setting the dc current [44–47].

It has been shown that the number of contacted molecules is dependent on the wire separation, and that the current versus voltage characteristics measured at different separations are all integer multiplies of a fundamental characteristic. Thus, it is proposed that this fundamental curve represents the characteristic of only a single molecule [45].

These measurements can also be carried out at cryogenic temperatures [46]. In this case, the vibronic states of the molecule can be identified which provide a "molecular fingerprint" and prove that the molecule is actively involved in the conduction process (see also Section 8.4.6) [46].

8.3.5
Nanogaps

Similar to the break junction method, in the nanogap set-up a small gap is formed in a thin metal wire. However, this gap is not formed by bending a flexible substrate and mechanically breaking the wire, but it is prepared on a rigid substrate by using various methods.

One such method is *electromigration*. The preparation of the nanogap starts with the definition of a thin metallic wire on an insulating substrate. A SAM is then deposited on top of this wire by immersing the sample into a molecular solution.

Subsequently, a voltage ramp is applied to the wire. If the current that flows through the wire becomes too large, the wire breaks due to electromigration, which is reflected by a drop in current. Such gaps are approximately 1 nm in width [48] and, with a certain degree of probability, are bridged by a molecule that was deposited onto the wire in advance; thus, a single molecular device has been built.

Alternatively, nanogaps can be formed by preparing an electrode pair with a gap of ~30 nm [49, 50] using electron-beam lithography. This gap can be shrunk to molecular dimensions by electrochemically depositing metal atoms [51, 52]. Combined with electrochemical etching, this method allows a precise control over the wire separation. A combination of lithography and low-temperature evaporation has also been used to fabricate 1- to 2-nm gaps directly on a gate oxide [53].

Although all of these techniques define the gaps laterally, the precise control over the vertical thickness of thin films can be exploited to define a vertical nanogap [54]. The preparation of these gaps starts with the deposition of a thin SiO_2 layer on top of a highly p-doped silicon bottom electrode (see Figure 8.5). A gold electrode is then deposited on top of the SiO_2 layer, and subsequently the oxide can be etched in hydrofluoric acid, thus yielding a thin gap between the Si bottom and Au top electrode.

A rich variety of molecules has been measured using nanogaps, including a coordination complex containing a Co atom [55], a divanadium molecule [56], C60 [57, 58], C140 [59], and phenylenevinylene oligomers [53, 60].

8.3.6
Crossbar Structure

In terms of integration, the crossbar structure is a very interesting device set-up where the demand of single molecules is relaxed, and a rather low number of molecules are contacted.

In order to obtain a crossbar structure, parallel metallic wires are deposited onto an insulating substrate. A SAM of the molecule of interest is then deposited on top of these wires. Orthogonally to the bottom electrodes, metallic wires are deposited onto the SAM. Thus, a single crossbar structure consists of many possible devices (e.g. see Figure 8.21 in Section 8.5.1).

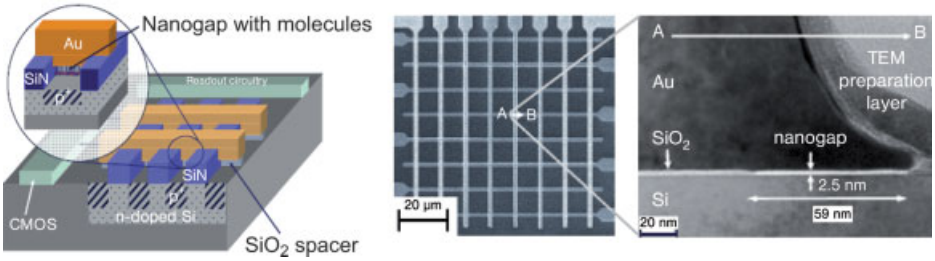

Figure 8.5 Vertical nanogaps integrated in a crossbar structure. (a) A schematic of the set-up. (b) Left: Scanning electron microscopy image of the crossbar, and (right) a transmission electron image of the nanogap. (From Ref. [54].)

The major technological problem in the crossbar set-up lies in the deposition of the top electrode. The metal/molecule interface may be unstable and metal ions can migrate through the molecular layer [61–63], thus shorting the device. The probability of metal ions penetrating the molecular layer is dependent on the molecular top group. A group which binds the metal at the top is more resistant, and many metal/molecular end groups have been examined, including Al on CO_2H [64], OH and OCH_3 [65], Cu, Au, Ag, Ca and Ti on OCH_3 [66, 67] or Au, Al and Ti on disulfides [68]. Ti is shown to be critical for metallization, because it reacts strongly with the molecule and partially destroys the SAM [69].

An alternative to these molecular end groups is to use aromatic end groups and to crosslink them with electron irradiation [70, 71]. This method yields stable Ni films on top of a molecular layer. Similarly, the molecular layer can be protected by a spun-on film of a highly conducting polymer film (e.g. PEDOT) [72].

In most devices the top electrode is deposited by evaporation techniques, so that the metal atoms arrive at the molecular layer with a high energy, and the probability of the atoms punching through the layer is high. Attempts have been made to reduce the energy of the atoms by indirect evaporation and cooling the substrate [73], or by so-called "printing methods" in which the metal film is gently deposited on the molecular layer from a polymeric stamp [74, 75].

8.3.7
Three-Terminal Devices

The incorporation of a third electrode (the gate) opens up new possibilities. First, the molecular levels can be shifted upwards and downwards by the gate relative to the levels of the electrodes, which can be used to analyze the electronic structure of the molecule. The gate is also necessary for building a molecular transistor. As will be shown later, these transistors can be used to build logic circuits.

The basic working principle of a molecular single-electron transistor is illustrated in Figure 8.6. Without a gate voltage applied, no molecular states lie in the energy window between the source and drain potential and thus, the current is blocked. However, the molecular level can be moved down into the energy window, if the gate voltage is increased. Therefore, by applying a gate voltage it is possible to switch the transistor on.

In order to understand, how the gate can shift the molecular levels, the capacitive network shown in Figure 8.2a should be considered. The voltage between the source and the molecule, V_{SM}, and between the molecule and the drain, V_{MD}, is related to the source V_S and source and gate voltage V_G as follows:

$$V_{SM} = \frac{C_D + C_G}{C_\Sigma} V_S - \frac{C_G}{C_\Sigma} V_G \tag{8.4}$$

$$V_{MD} = \frac{C_S}{C_\Sigma} V_S + \frac{C_G}{C_\Sigma} V_G \tag{8.5}$$

with $C_\Sigma = C_S + C_D + C_G$

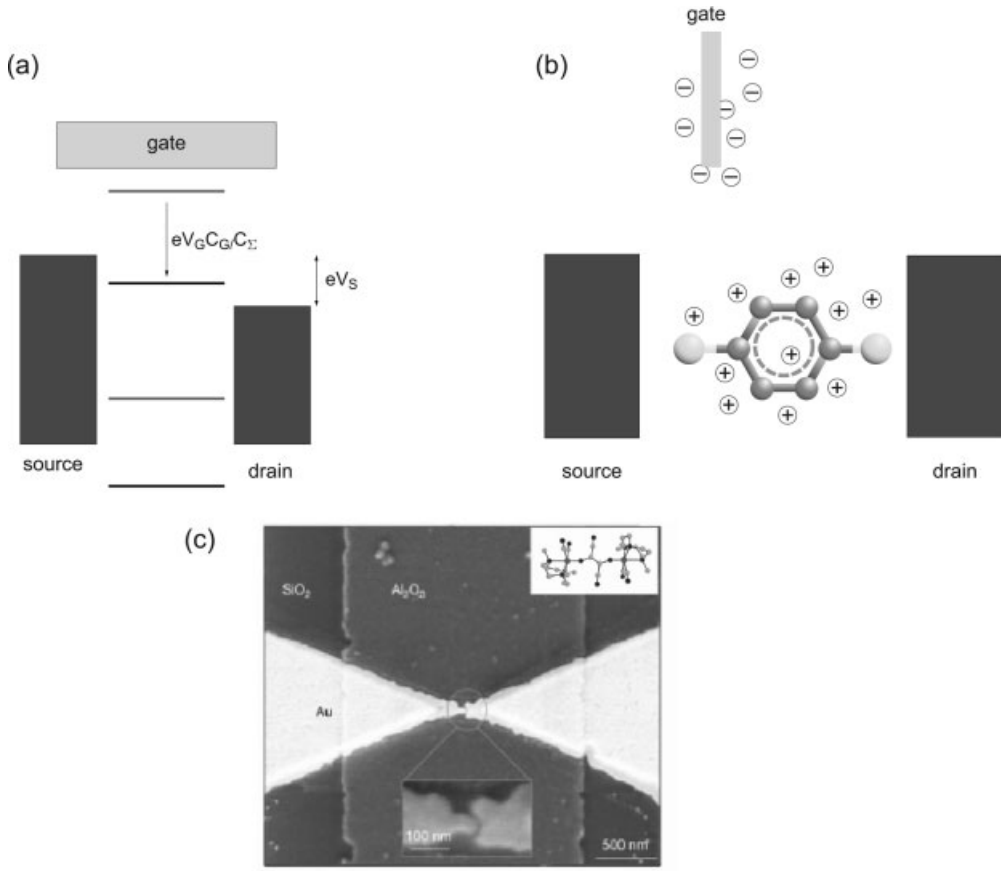

Figure 8.6 The working principle of a molecular single-electron transistor (a) and an electrochemical gate (b). In (c) a scanning electron image of a nanogap fabricated by the electromigration method is shown. The nanogap is prepared on an aluminum strip, which is covered by a thin Al_2O_3 layer and forms the gate. (From Ref. [56].)

Therefore, the molecular level shifts up or down relative to the source and drain energies. The amount of the shift is proportional to the term $\frac{C_G}{C_\Sigma} V_G$. In order to obtain good gate control, $\frac{C_G}{C_\Sigma}$ (the "gate-coupling parameter") must be large and, ideally, close to unity; hence, the gate must be placed very close to the molecule.

One elegant method of obtaining a high gate control is to use an electrochemical gate (c.f. Figure 8.6b). The molecular device (e.g. the nanogap or the STM set-up) is immersed in an electrolyte, and the source and drain voltages are varied relative to a reference electrode which is also immersed in the solution [38, 76, 78] and takes on the function of the gate. The effective gate distance is given by the thickness of the double layer of ions at the electrodes [38], which allows the application of

high electric fields. Several molecules, including peralene tetracarboxylic diimide [76], a molecule containing a viologen group [79], oligo(phenylene ethynylene)s [80] or different transition metal complexes [77], have been studied using this type of gate.

Champagne *et al.* succeeded in including a gate in a break junction set-up [81] which consists of a freestanding, under-etched gold bridge deposited onto a silicon wafer. Underneath the bridge, the silicon is degenerately doped and serves as the gate electrode. The bridge is broken by the electromigration technique, and the size of the so-formed gap is adjusted by bending the silicon substrate. A C_{60} molecule is immobilized in this gap, so that a molecular transistor with a gate-molecule spacing of about 40 nm is realized.

The most straightforward method of including a gate is provided by the nanogap set-up. Here, the source and drain are formed on an insulating substrate; however, the insulating layer (e.g. SiO_2 or Al_2O_3) can be very thin, and the underlying (conductive) substrate may be used as gate [55–58, 82] (cf. Figure 8.6c). Compared to an electrochemical gate, this set-up has the advantage that the measurements can be conducted at cryogenic temperatures, which makes the observance of coulomb blockade effects easier and also allows the use of inelastic electron tunneling spectroscopy (see Section 8.4.6) to study the molecules.

8.3.8
Nanogaps Prepared by Chemical "Bottom-Up" Methods

Several strategies for nanogap preparation have been based on the pioneering studies of Brust *et al.* [83, 84], where the chemical preparation of metal nanoparticles was protected by a ligand shell. Two-dimensional arrays of such particles constitute a test bed that may be used to interconnect metal particles separated by a few nanometers by various organic molecules (see Figure 8.7) [85, 86].

By mixing hydrophobic nanoparticles with surfactants, more one-dimensional structures may be formed where molecules interconnect segments of gold nanowires separated by a few nanometers (see Figure 8.8a) [87, 88].

By using a single metal particle inserted in a metal gap prepared "top-down", two well-defined nanogaps may also be realized at the gap–particle interface (cf. Figure 8.8b) [90, 91].

Although all of these systems are easily prepared and are stable at room temperature, as yet it has not been possible to control the gap formation accurately enough to prepare a single gap bridged by a single molecule. Neither have individual gates been reported.

8.3.9
Conclusion

At present, the list of measurement set-ups used in molecular electronics is by far incomplete, and an ever-growing number of techniques is available, including the mercury drop method [92], nanogap preparation by the deposition of gold electrodes

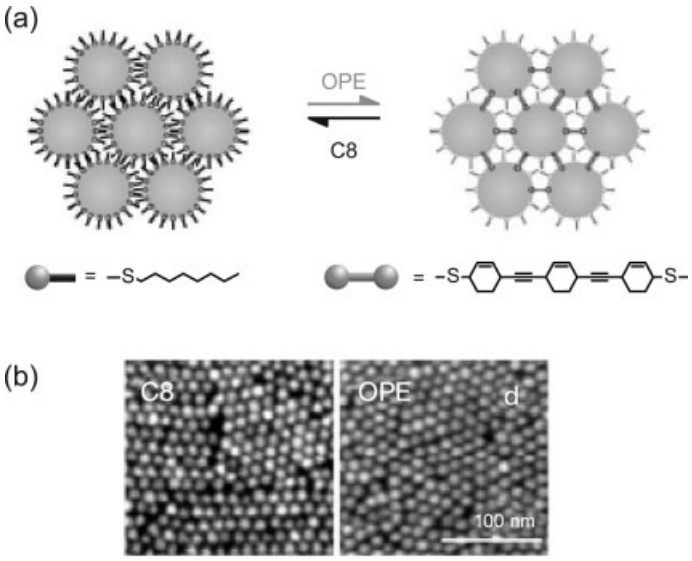

Figure 8.7 Two-dimensional gold nanoparticle arrays interlinked with octanethiol (left) and thiolated oligo(phenylene ethynylene) (right). (a) Schematic representation. (b) SEM image of the nanoparticle arrays. (From Ref. [85].)

through a shadow mask at shallow angles [53], the magnetic bead junction [90, 93], or the nanopore concept [94–97]. Each set-up has its own strengths and weaknesses: some allow the characterization of single molecules (e.g. break junction experiments and SPM set-ups), whereas others are interesting in terms of later applications (e.g. crossbar set-ups) or allow the inclusion of a gate electrode (nanogaps). It appears, however, that there is no ideal set-up, and often the intrinsic molecular behavior may be determined only by a combination of different experimental methods.

8.4 Molecular Functions

In this section, it is shown which molecules have been measured and which functionalities these molecules can provide. As the ultimate goal of molecular electronics is to provide a universal logic, each technology which aims to achieve this must fulfill several basic requirements [30].

The most basic requirement is that *a complete set of Boolean operators* can be built out of the molecular devices, such that every Boolean function can be obtained. One complete set of operators is for example a disjunction (OR) and an inversion (NOT), or alternatively, a conjunction (AND) and inversion. However, all complete sets have to include inverting gates – that is, an inversion.

Disjunction and conjunction can be relatively easily built out of a resistor and a diode (for a description, see Section 8.4.2.4), and so it is vital to identify molecules that conduct current only in one direction.

Similarly, complete fields of disjunctions and conjunctions can be implemented in crossbar structures in the form of so-called *programmable logic arrays* (PLA) (see Section 8.5.1). At the crossing points of these PLAs, molecules that can be switched on or off are needed; that is, the molecules must possess two conduction states, one isolating and one conducting. Molecules which demonstrate this behaviour include *hysteretic switches*, examples of which are described in Section 8.4.4.

These set-ups do not provide inverting logic, as negation is still missing. One set-up which provides inversion is the *molecular single electron transistor* (see Section 8.4.5). Even with only two terminal devices it is pfossible to construct an inversion using a so-called *crossbar latch* (see Section 8.4.4.1). Again, hysteretic switches are required for this. Inverting logic (e.g. an exclusive disjunction, XOR)[3] can also be built from a variant of a simple diode which displays a *negative differential resistance* (NDR) region – that is, a region in which the current drops with increasing voltage. These gates are described in Section 8.4.3.1.

A second requirement for the implementation of logic is that the gates must provide a means of *signal restoration*. At each stage of the circuit the signal voltage, which represents a logical 0 or 1, will be degraded. To be able to concatenate several logic gates, a means of restoring the original levels must be found, and this requirement can only be relaxed for small circuits, as long as the degradation of the signal voltage is tolerable.

In conventional CMOS logic, such restoration is provided by a non-linear transfer characteristic of the gates [30]. This strategy can also be followed with molecular single-electron transistors. Similarly, signal restoration can also be obtained by two terminal devices using hysteretic switches in the form of the crossbar latch or using NDR diodes in the form of the *molecular latch*, as proposed by Goldstein *et al.* [98].

Another requirement for the technology is that there must be elements that transmit signals across longer distances – that is, a type of *molecular wire* (see Section 8.4.1) must

3) The XOR gate can be converted into a negation if one input is fixed to "1".

be found. A molecular wire alone is insufficient, however, and a defined flow of information must be established, with feedback signals being prevented. This, again, can be achieved by using molecular diodes.

8.4.1 Molecular Wires

The most basic electronic device is a simple wire. However, in molecular electronics it is less easy than might be thought to construct a suitable molecule which transmits current with a low conductance across longer distances. So, what makes a molecule a good conductor? Starting from the short theoretical instruction provided in Section 8.2, certain conclusions can be drawn regarding the properties of an ideal molecular wire.

First, in order to obtain a low resistance a strong electronic coupling of the molecule and the electrodes is preferable. As discussed in Section 8.3.1, such a coupling can be obtained by choosing a suitable molecular binding group, for example a group that provides resonant coupling to the electrodes, such as dithiocarbamates.

Due to this choice of molecular binding group, the limit of strong coupling is valid and electrons are transmitted across the molecular levels. However, a prerequisite for such transmission is that this molecular level, extending from source to drain, actually exists. Extended molecular levels can be formed by delocalized π-systems, where in the tight binding approximation p_z orbitals of isolated carbon atoms add and form an extended, delocalized orbital. Therefore, aromatic groups (e.g. polyphenylene) are often used as the building blocks for molecular wires.

Another important property of a molecular wire is its ability to conduct current at a low bias, and therefore the molecular level used for transport should be close to the Fermi level of the contacts. Often, this requirement is expressed in terms of a low HOMO–LUMO gap.

Many molecules have been proposed as molecular wires, including polyene, polythiophene, polyphenylenevinylene, polyphenylene-ethynylene [99] (see Figure 8.9), oligomeric linear porphyrin arrays [100] or carbon nanotubes (CNTs) [[101] and references therein]. CNTs constitute a special category among molecular wire candidates as they may be either metallic or semiconducting, depending on their chirality. However, it is difficult to selectively prepare or isolate only one type of CNT, namely the metallic form. Furthermore, it is still challenging to organize and orient CNTs, although some techniques are available to arrange CNTs in a crossbar structure [e.g. see [102]]. A more detailed discussion on CNTs is provided in Chapter 10.

8.4.2 Molecular Diodes

Molecular diodes are the next step towards a higher complexity. Indeed, when combined with resistors, diodes are already sufficient to build AND and OR gates.

The first molecular electronic device to be proposed by Aviram and Ratner was just such a molecular diode [103], and consisted of a donor and an acceptor group

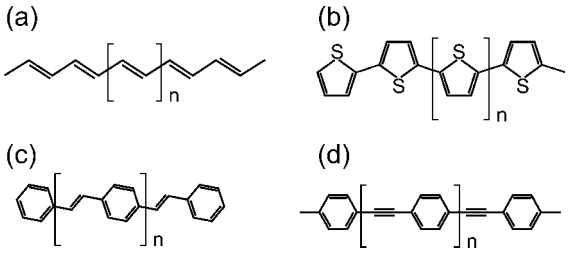

Figure 8.9 Building blocks for molecular wires: (a) polyene; (b) polythiophene; (c) polyphenylenevinylene; and (d) polyphenylene-ethynylene.

separated by a tunneling barrier. This set-up is often compared to the p- and n-layers in a conventional diode. As alternative to the Aviram–Ratner approach, a molecular diode can also be formed by asymmetric tunnel barriers at the source and drain electrodes [104]. This concept is based on the different electrostatic coupling of the electrodes. However, as will be seen later, it is very difficult to couple the molecule *symmetrically* to both electrodes, which in turn makes it difficult to distinguish between rectification due to the Aviram–Ratner mechanism and rectification due to asymmetric coupling.

8.4.2.1 **The Aviram–Ratner Concept**

The Aviram–Ratner concept is illustrated schematically in Figure 8.10. A molecule, which consists of an acceptor and a donor group, is connected to the source and drain. The acceptor and donor are isolated by a tunneling barrier, which ensures that the

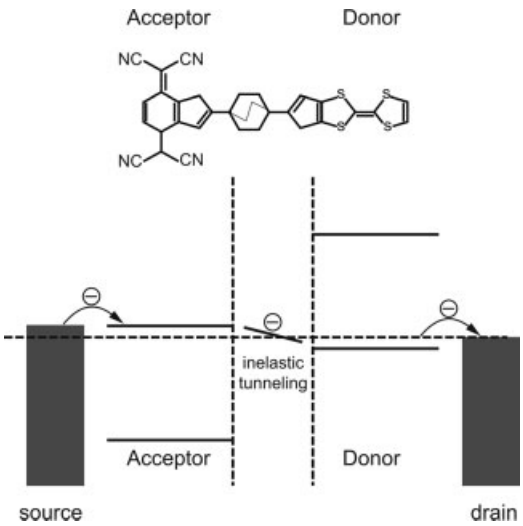

Figure 8.10 The diode proposed by Aviram and Ratner, and the suggested rectifying mechanism. For further details, refer to Section 8.4.2.1.

molecular levels of the two parts do not couple. The HOMO of the donor lies close to the Fermi level, in contrast to the acceptor, where the LUMO is adjacent to the Fermi level.

If a negative voltage V_S is applied to the diode (see Figure 8.2a for polarity), the potential of the source is raised with respect to the drain. Electrons can flow relatively easily from the source, across the acceptor and donor, towards the drain. However, at the opposite polarity a much higher voltage is needed to allow electrons to flow from drain to source. Thus, the molecule is considered to rectify the current.

8.4.2.2 Rectification Due to Asymmetric Tunneling Barriers

In contrast to the Aviram–Ratner mechanism, rectification due to asymmetric tunneling barriers is based on a difference in the source and drain capacitances. This difference can be obtained by attaching two insulating alkane chains to a conjugated part (see Figure 8.11). The alkane chains are functionalized with an end group, which provides binding functionality (e.g. sulfur for gold electrodes). The capacitance between the conjugated part of the molecule and the electrode is inversely proportional to the length of the alkane chains; varying these lengths is therefore a suitable way of adjusting the source and drain capacitances.

The rectifying mechanism can be explained by the energy diagram shown in Figure 8.11. The HOMO and the LUMO levels of the conjugated part of the molecule are included in the figure. These energy levels correspond to the molecular level of the (unbound) molecule plus the charging energy, as explained in Section 8.2. As can be seen in Figure 8.11, the levels lie asymmetrical with respect to the Fermi level of the electrodes.

Current can only flow when the electrochemical potential of the source or the drain aligns with, or even exceeds, the LUMO – that is, when $-eV_{SM} = \Delta$ for electrons flowing from source to drain, or $eV_{MD} = \Delta$ for the reverse bias. Here, Δ is the difference between the Fermi level of source and drain at zero bias and the LUMO.

V_{SM} and V_{MD} are given by Eqs. (8.4) and (8.5) (the gate capacitance must be set to zero). It follows for the voltage $V_{D \to S}$, at which electrons start to flow from drain to

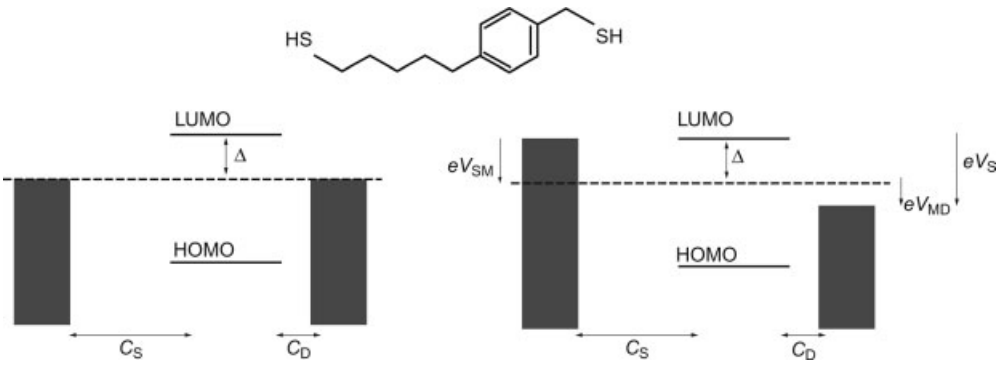

Figure 8.11 The concept of rectification due to asymmetric tunneling barriers.

source (which corresponds to a positive current flow from source to drain), and $V_{S\to D}$, at which electrons flow from source to drain [104]

$$V_{D\to S} = \frac{1 + C_S/C_D}{\underbrace{C_S/C_D}_{\equiv\eta}} \frac{\Delta}{e} = \frac{1+\eta}{\eta} \frac{\Delta}{e} \tag{8.6}$$

$$V_{S\to D} = -(1+\eta)\frac{\Delta}{e} \tag{8.7}$$

If the source capacitance is smaller than the drain capacitance ($\eta < 1$), $|V_{S\to D}|$ is smaller than $|V_{D\to S}|$ and electrons can flow from source to drain at a lower absolute bias than in the opposite direction; that is, the molecule shows a rectification behavior.

8.4.2.3 Examples

Starting from the molecule proposed by Aviram and Ratner (see Figure 8.10) [105], many other molecules containing acceptor and donor groups have been proposed [106]. One of the most extensively studied is γ-hexadecylquinolinium tricyannoquinodimethanide ($C_{16}H_{33}$ Q-3CNQ; c.f. Figure 8.12) [107–110]. Although this molecule consists of a donor and an acceptor group, it deviates from the normal Avriam–Ratner diode in that the two parts are not coupled by an insulating σ-group but rather by a delocalized π-group, which makes an analysis of the rectification behavior more difficult [109]. Furthermore, due to the alkane chain at one side of the molecule, it is often coupled asymmetrically to the electrodes. Thus, it is difficult to distinguish between the Aviram–Ratner mechanism and rectification due to asymmetric tunneling barriers. To circumvent this problem, decanethiol-coated gold STM tips are used as a second contact to a SAM of $C_{10}H_{21}$ Q-3CNQ, which places the same length of alkane groups at both ends of the donor and acceptor groups [111].

8.4.2.4 Diode–Diode Logic

Already with these rather simple diodes it is possible to build AND and OR gates in the form of so-called diode–diode logic [112]. In the AND gate (see Figure 8.13a) both

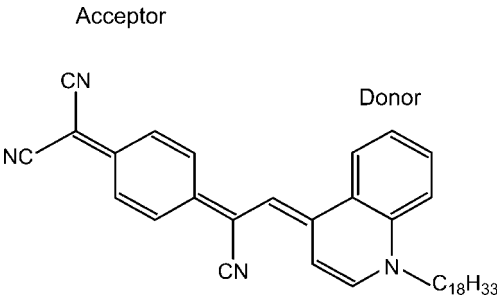

Figure 8.12 The molecular diode $C_{16}H_{33}$ Q-3CNQ in its neutral state.

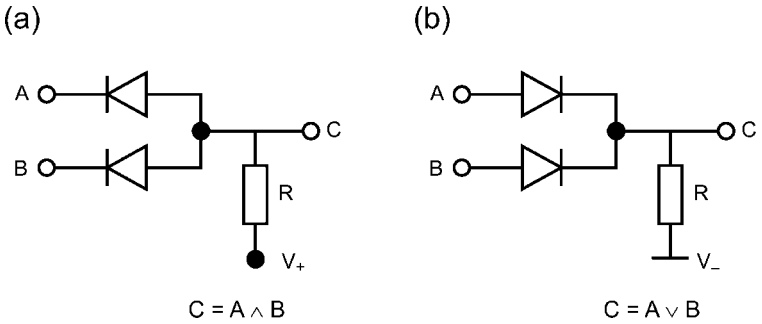

Figure 8.13 AND and OR gate using diode–diode logic.

inputs, A and B, are connected via reversely biased diodes and a resistor to the operating voltage. Only if both inputs are high (i.e. 1) is the output C high, and this results in an AND function.

The OR gate is shown in Figure 8.13b. In contrast to the AND gate, one input is already sufficient to push the output to a high voltage, and thus this gate implements a disjunction.

8.4.3
Negative Differential Resistance Diodes

Diode–diode logic yields AND and OR gates and, in order to obtain a complete set of Boolean variables, these gates can be combined with diodes that show a negative differential resistance (NDR). By using these modified gates it is possible to obtain inversion.

The NDR effect is illustrated schematically in Figure 8.14a. The current of the diode rises with increasing voltage up to a certain threshold voltage, above which the current drops. This rather odd behavior is already known from conventional semiconductors in the form of resonant tunneling diodes.

The concept of resonant tunneling can also be used for molecular NDR devices, as shown in Figure 8.14b and c [113]. The molecule consists of two conjugated molecular leads and an isolated benzene ring in the middle. In the absence of any inelastic processes, current can only flow if the molecular levels of the left lead of the isolated benzene ring and of the right lead, align. Such alignment occurs only at certain voltages, at which the levels are said to be in "resonance". Such resonance is illustrated graphically in Figure 8.14c. If the voltage is detuned from this resonant value – for example, if it is further increased – then the current will drop and the device will show an NDR effect.

Another molecule, which shows a prominent NDR effect, is shown in Figure 8.15b [4, 94]. It exhibits peak-to-valley ratios as high as 1030:1, although the exact nature of the NDR effect observed in this molecule is currently a matter of intense research [114].

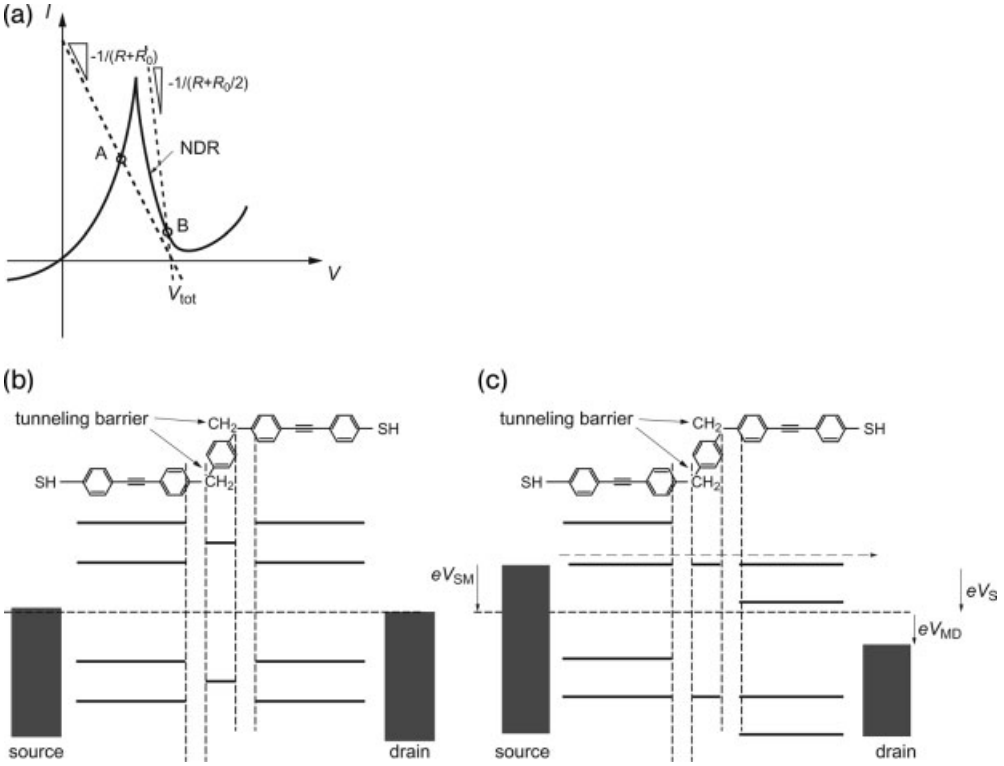

Figure 8.14 (a) The NDR effect. (b, c) The concept of a resonant tunneling diode consisting of a single molecule.

8.4.3.1 Inverting Logic Using NDR Devices

NDR devices can be used to obtain inverting logic. One example is shown in Figure 8.15a [112]; this gate implements an exclusive OR functionality – that is, the output C is high if either A or B is high, and low if both inputs are high or both inputs are low.

The XOR gate shown in Figure 8.15a resembles the normal OR gate shown in Figure 8.13b, the only difference being a NDR diode which is connected to the two diodes of inputs A and B. The voltage drop across the entire XOR circuit (V_{tot}, measured from input A and B to V–) is divided between a voltage drop across the NDR diode (V_{NDR}) and a voltage drop across the resistances R_0 and R (V_R). Assuming ohmic behavior for the resistances, it follows for the current flowing through the resistances:

$$I = \frac{V_R}{R + R_0} = \frac{V_{tot} - V_{NDR}}{R + R_0} \quad \text{if either A or B is high} \tag{8.8}$$

$$I = \frac{V_R}{R + R_0/2} = \frac{V_{tot} - V_{NDR}}{R + R_0/2} \quad \text{if both, A and B, are high} \tag{8.9}$$

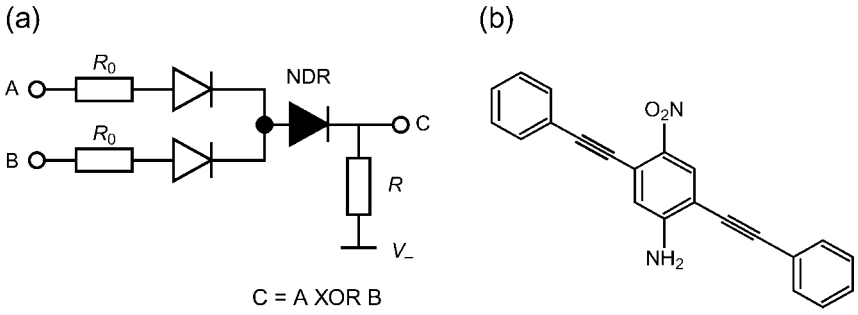

Figure 8.15 (a) XOR gate using NDR-diodes. (b) A well-known molecule that shows NDR.

These two characteristics, called "load lines", are included in Figure 8.14a. The crossing points of the NDR characteristic with these load lines are the operating points for only one input high (point A), or for both inputs high (point B). It transpires that, if both inputs are high, the NDR diode is forced into its valley region, and therefore only a low current flows and only a low voltage drops across *R*. Thereby, the output signal C goes low. From this XOR gate it is easy to obtain inversion; the only change to be made is to set one input (e.g. A) fixed to "1". The output C is then simply the negation of B.

8.4.4
Hysteretic switches

As noted above, hysteretic switches can be used to build PLAs and to yield signal restoration and inversion. The general current versus voltage characteristic of a hysteretic switch is shown in Figure 8.16a.

A hysteretic switch displays two conduction states: one insulating, and one conducting. It is possible to toggle between the two by applying a voltage which

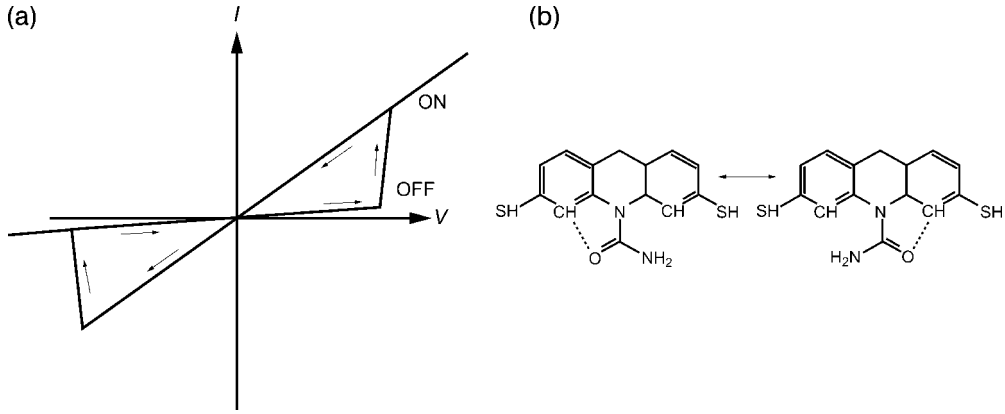

Figure 8.16 (a) General current versus voltage characteristic of a hysteretic switch. (b) A proposed molecule that would be expected to show switching effects.

exceeds a certain threshold value. For example, in Figure 8.16 a positive voltage is needed to switch the device on (i.e. from the insulating to the conducting state), and a negative voltage to switch it off.

Such bistability can be obtained when the molecule possesses two different states that are almost equal in energy, that are separated by an energy barrier, and that show different conduction behaviors. Different origins of these two states are conceivable [99]; for example, they may result from redox processes, from a change in configuration of the molecule, a change in conformation, or a change in electronic excitation.

The molecule shown in Figure 8.16b is an example of a molecule which has been proposed, in theory, to show hysteretic switching [115]. It consists of a fixed molecular backbone (the *stator*) and a side group with a high dipole moment (the *rotor*). By the application of an electric field, the rotor orients its dipole moment in the direction of the field. Bistability is obtained by the formation of hydrogen bonds between the stator and rotor that fix the latter in one of two stable positions relatively to the stator. The two conduction states are due to different conformations of the molecule (stabilized by hydrogen bonds). Switching is initiated by interaction of the dipole moment of the rotor with the electric field.

Bipyridyl-dinitro oligophenylene-ethynylene dithiols (BPDN-DT) are other examples of switching molecules. These are a variation of the molecule shown in Figure 8.15b, and their bistability has recently been confirmed by using various measurement techniques [28, 93].

Rotaxanes and catenanes are, even if controversially discussed, additional candidates for molecular switches. These molecules consist of two interlocked rings such that, by reducing or oxidizing the molecule, one ring rotates within the other. Two stable, neutral states which differ in the position of the inner ring are thus realized. The switching is therefore initiated by a redox process. The two different states are provided by the different conformations of the molecule, similar to the molecule shown in Figure 8.16b.

Although the preliminary results showing a switching effect of this molecule were questioned (see Section 8.4.6), recent results have confirmed the original proposed switching mechanism and indicates that, in the case of earlier results, this mechanism was occasionally hidden by artifacts [75, 116, 117].

8.4.4.1 **The Crossbar Latch: Signal Restoration and Inversion**

As noted in Section 8.4.2.4, AND and OR gates can be built using simple diodes. However, for a complete set of Boolean variables, negation is also required. Signal inversion can be obtained by NDR diodes (c.f. Section 8.4.3.1) or alternatively by the so-called crossbar latch, which also provides a means of signal restoration [118].

The crossbar latch (see Figure 8.17a) consists of two hysteretic switches which are connected to the signal line (at voltage V_L) and one control line (at voltage V_{CA} or V_{CB}). The two switches are oppositely oriented.

The idealized current versus voltage characteristic of a hysteretic switch shown in Figure 8.16 is assumed. By application of a positive voltage, the switch opens; an opposite voltage is then needed to close the switch. These voltages are always those

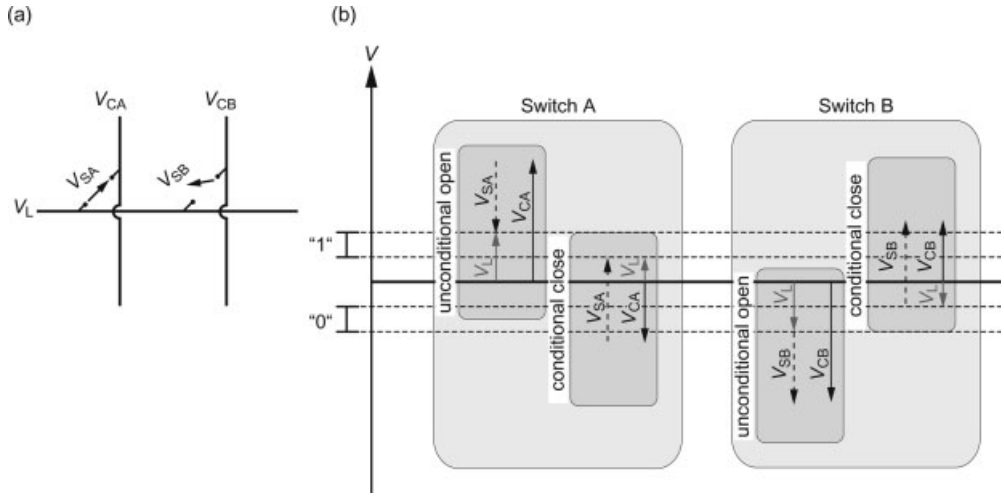

Figure 8.17 The crossbar latch as proposed by Kuekes *et al.* [118].

that are applied *across* the molecules, depicted in Figure 8.17a as V_{SA} and V_{SB}. However, in the circuit shown in Figure 8.17a, only the voltages of the control lines V_{CA} and V_{CB} are set. Therefore, the voltage that is applied *across* the molecule depends on the voltage on the signal line, V_L.

$$V_{SA} = V_L - V_{CA} \tag{8.10}$$

$$V_{SB} = -V_L + V_{CB} \quad \text{(note the opposite orientation of switch B)} \tag{8.11}$$

The voltage on the signal line in Figure 8.17 represents the logical state. Voltage intervals are defined that represent a logical "1" or "0". In general, the signal is degraded, so that the signal level will be at the lower end of the intervals.

To yield signal restoration – that is, to pull the signal level up to the upper end of the defined interval – the following procedure can be followed:

- First, a large positive voltage is applied to the control line A, and a large negative voltage to control line B. This voltage is large enough to always open switches A and B, regardless of the voltage level of the signal line. This is shown in Figure 8.17b (unconditional open).
- Second, a small negative voltage is applied to control line A, and a small positive voltage to control line B. These voltages are so small that they close switch A only if the signal line carries a "1", and they close switch B if there is a "0" on the signal line (see conditional close in Figure 8.17b).
- Therefore, depending on the voltage on the signal line, switch A or B is closed and the opposite switch is open. To yield signal restoration, V_{CA} is connected to a full "1" signal and V_{CB} to "0". Inversion can also be obtained; the only modification is that a logical "1" must be connected to V_{CB} and "0" to V_{CA}.

This scheme shows that it is possible to build a complete set of Boolean variables with only two terminal devices. Therefore, hysteretic switches represent a very valuable element, which explains the high activity in this field of research.

8.4.5
Single-Molecule Single-Electron Transistors

In Section 8.3.7 it was shown how a third electrode – the gate – could be included into the device set-up. The most convenient method to prepare such three-terminal devices is a nanogap that is deposited onto a gate, which is isolated from the device by a thin insulator. A three-terminal device essentially forms a transistor. If the molecule is only weakly coupled to the source and drain, the transistor is termed a *single-molecule single-electron transistor* [119–121]. Whilst the basic working principles of such a transistor were described in Section 8.3.7, and a more extensive explanation is provided in Figure 8.18.

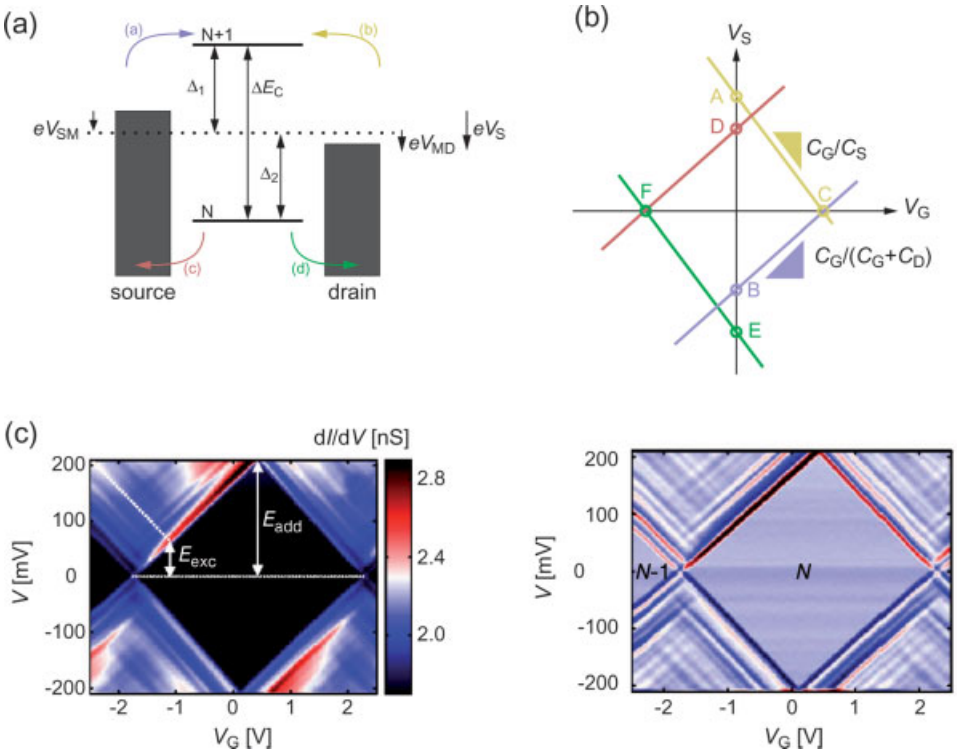

Figure 8.18 (a, b) The working principles of a single-molecule single-electron transistor. For details, see the text. (c) First (upper panel) and second (lower panel) derivatives of the current versus voltage characteristic of a single-molecule single-electron transistor containing an oligophenylenevinylene (OPV5) molecule. The black coulomb blockade diamond is clearly visible. (From Ref. [122].) The fine structure in the open state is due to vibrations of the molecule, and serves as a "fingerprint" of the molecular structure of the OPV5 molecule.

In Figure 8.18a, the N^{th} and $(N + 1)^{th}$ state of the molecule are shown. These two levels correspond, for example, to the HOMO and LUMO in Figure 8.2b. In Figure 8.18a, electrons can hop or tunnel onto or off the molecule by the processes (a) to (d) – that is, from the source or drain onto the molecule (processes a and b), or from the molecule to the source or drain (processes c and d).

Electrons can only flow from the source or the drain onto the molecule if the potential of the electrode aligns with (or exceeds) the molecular level. Below these potentials, no electrons can flow; rather, the current is blocked, which is known as coulomb blockade. This behavior is often visualized in a plot as in Figure 8.18b, in which the source voltage V_S is plotted against the gate voltage V_G.

In Figure 8.18b, four lines build a diamond, the color of these lines corresponding to processes (a) to (d) in Figure 8.18a. In the interior of the diamond, the source and gate voltages are too low to overcome the injection barriers, and the current is blocked. By increasing the source and gate voltage, the working point of the transistor can be moved to outside the diamond. As the working point crosses one line in the V_S/V_G plane, the current sets in (e.g. if it crosses the dark yellow line, electrons can hop from the drain onto the molecule).

Depending on the process, there are different barriers that must be surmounted by the electron. For electrons hopping from source onto the $(N + 1)^{th}$ level (process a), the voltage between source and molecule V_{SM} must exceed the barrier Δ_1 (see Figure 8.18 for a definition of Δ_1) – that is, $eV_{SM} \geq \Delta_1$.

V_{SM} and V_{MD} are governed by Eqs. (8.4) and (8.5), respectively. By combining Eqs. (8.4) and (8.5) with the conditions for current flow (e.g. $eV_{SM} \geq \Delta_1$ for process a), linear relationships are yielded between V_S and V_G that represent the equations of the four lines in Figure 8.18b.

Single-molecule single-electron transistors resemble in one important aspect conventional MOSFETs. The resistance between source and drain can be controlled by the gate voltage – that is, these transistors represent electronic switches and can be used to build logical circuits. As an example, an inverter based on a single-electron transistor is shown in Figure 8.19. In fact, logic circuits consisting of conventional single-electron transistors have already been presented [121, 123]. Single-electron transistors consisting of single molecules have also been realized

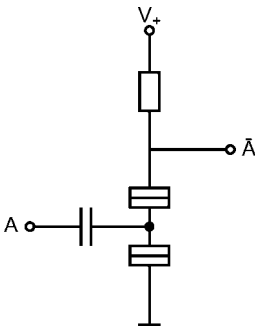

Figure 8.19 Inverting gate using a single-electron transistor.

[53, 55, 57, 59, 60, 82, 122], and an inverter consisting of a multiwall carbon nanotube has also been built [124]. For further information on single-electron devices, the reader is referred to Chapter 2 in Volume I of this Handbook, and to Chapter 6 in the present volume.

8.4.6 Artifacts in Molecular Electronic Devices

As noted above, molecules can provide a rich variety of functions. However, contacting single molecules reaches the limits (or even extends the limits) of current technology, and only recently has it been reported that some results in the field of molecular electronics were due to artifacts [6]. The most prominent example of this was the rotaxanes (see Section 8.4.4). In fact, it has been reported that the observed switching effect is independent of the molecule, and is thus an effect of the entire set-up, including the contacts and interfaces, and is not purely "molecular" [125]. However, this does not necessarily mean that the proposed switching mechanism is incorrect. It is rather covered by artifacts and may in effect exist in other experimental set-ups [75, 116, 126].

8.4.6.1 Sources of Artifacts

Several sources of artifacts are conceivable. One is concerned with the high electric fields that are applied across the molecular junction. Although only low voltages are applied (~1–2 V), the junctions are very thin, which generates high field strengths. These field strengths can cause metal atoms from the electrodes to migrate into the molecular layer and finally to shorten it by a metal filament [6, 128]. These filaments are thin, so that they can be easily broken by high currents flowing through them, for example due to resistive heating or to electromigration. Thus, the filaments can form and break and therefore, they can switch a device into a low- and high-impedance state, which can mitigate molecular switching.

One recent experiment concerning the formation of filaments was conducted by Lau *et al.* [127]. A Langmuir–Blodgett film of steric acid ($C_{18}H_{36}OH$) was sandwiched between a titanium and platinum electrode (see Figure 8.20). It was possible to switch this device between a high and a low conduction state, and a current versus voltage characteristic similar to that shown in Figure 8.16a was obtained. To examine the switching effect, Lau and colleagues scanned the device area using AFM, while simultaneously applying a bias voltage through external leads. In that way, the conductance of the whole device could be measured and correlated to the actual position of the AFM tip. Two-dimensional maps of conductance versus tip position were obtained for the on and off states (see Figure 8.20b).

The AFM tip exerts a certain pressure on the top electrode, which locally compresses the monolayer by ~0.2 Å. This compression did not alter the conductance in the off state. Independently of the position of the AFM tip, the conductance stayed almost constant (see bottom image in Figure 8.20b). However, in the on state, sharp peaks in conductance were observed, which appeared when the tip was scanning across a localized spot on the top electrode (see red spike in the middle

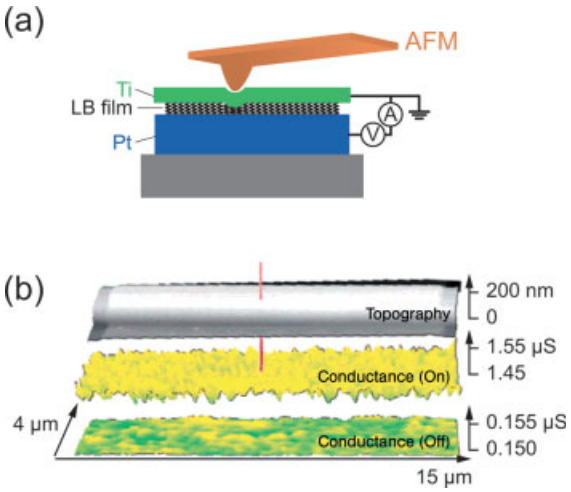

Figure 8.20 An experiment conducted by Lau *et al.* to examine the switching effect observed in their devices. Combining current versus voltage and atomic force measurements, these authors observed nanoscale switching centers, which are interpreted in terms of conductive filaments that almost bridge the two electrodes. (From Ref. [127].)

image in Figure 8.20b). These peaks were interpreted as "nanoasperities", in which the effective distance between the top and bottom electrode is reduced. These nanoasperities might be due to conducting filaments that almost bridge the electrodes.

Besides filaments, there are other sources of artifacts, such as oxidation of the metal electrode (i.e. titanium), which can also induce hysteretic current–voltage responses [129] or the formation of charge traps at the electrode/molecule interface [130]. Similarly, nanogaps produced by the electromigration technique (see Section 8.3.5) can, even in the absence of molecules, show "molecular" features, for example coulomb blockade effects with addition energies that are in the range as would expected for single molecules [82]. These effects are ascribed to small metallic grains within the junction.

To rule out these artifacts and to verify that the observed effect is truly molecular, several strategies have been followed [126]. One straightforward approach is systematically to vary the composition of the molecule (e.g. its length) and to study the influence of this variation on the current versus voltage characteristic [96]. Other strategies are to use a variety of test set-ups to rule out any systematic errors due to the measurement set-up [93], to completely avoid metallic electrodes and thereby eliminate the possibility of metallic filaments [131].

An alternative approach is to study the vibrational states of the molecule by using *inelastic electron tunneling spectroscopy* (IETS). This technique is highly sensitive to the molecular vibrations which open additional inelastic channels through which electrons can tunnel. However, these vibration states smear out in energy at room

temperature, and can only be observed at cryogenic temperatures. In the current versus voltage characteristic, they are visible as peaks in the second derivative [46, 132]. For three-terminal devices, the second derivative can be plotted in the source voltage (V_S) versus gate voltage (V_G) plane, and the vibrational modes are then visible as lines running parallel to the diamond edges (cf. Figure 8.18c) [122].

The vibrational states are an intrinsic property of the molecule, and thus IETS provides a "molecular fingerprint" to prove that the molecule is actively involved in current transport.

8.4.7 Conclusions

Molecular electronic devices provide a wealth of functions. The appeal of molecular electronics is, amongst other things, based on the variety of these functions. The target is to make use of new effects that appear at these small dimensions (e.g. coulomb blockade or resonant tunneling effects, conformational changes of the molecule) for novel electronic devices.

Whilst it has been shown how these molecular devices can be combined to form small logical gates (e.g. in the form of diode–diode logic or the crossbar latch), this raises one important question: How can molecules be assembled so that these gates are formed?

8.5 Building Logical Circuits: Assembly of a Large Number of Molecular Devices

In the previous sections it has been shown how single (or at least a low number of) molecules can be contacted, and which functionalities these molecules can provide. Furthermore, it has been described, how these single molecules can be combined to small logic gates, for example as AND, OR, XOR gates, or as the crossbar latch. In this section, the discussion proceeds one step further to determine how a large number of devices can be assembled. And what implications does the use of single molecules have for the architecture of future logic circuits? As already discussed (in Section 8.3), for single-molecule devices there is at present no method available to deterministically place a single molecule on a chip. Thus, reliance must be placed on statistical processes and the ability of the molecules to self-organize, for example in the form of SAMs.

This dependence on self-organization bears the first implication for the architecture of molecular devices. Self-organization will always result in very regular structures, which have only a low information content [133]. In comparison to current CMOS circuits, in which a huge number of transistors is connected statically to other transistors, and which include therefore a high information content, this lack of information must be fed into the molecular circuit by an additional, post-fabrication training step. In other words, the technology and architecture has to be re-configurable.

A second implication of the self-organization process is given by the fact that these circuits will always contain defective parts, and the high yields necessary for CMOS architectures are not feasible. Again, the defective sites on the molecular chip must be identified and isolated in a post-fabrication step.

Several architectures have been proposed for future molecular circuits, and these differ in how strongly they rely on self-organization. PLAs based on crossbars, for example, use self-organization only for the preparation of the SAMs. The electrodes that contact the SAM are commonly defined by lithography (although techniques are available to prepare crossbars completely by self-organization, e.g. [102]). In contrast to PLAs, the *Nano-Cell* architecture (see Section 8.5.2) relies completely on self-organization.

8.5.1
Programmable Logic Arrays Based on Crossbars

In Section 8.4.2.4 it was described, how simple AND and OR gates can be implemented using diodes and resistances only. In the following it will be shown, how large arrays of these gates can be implemented using crossbars, as described in Section 8.3.6.

The equivalent circuit of a crossbar is shown in Figure 8.21a and b. A SAM of rectifying diodes is contacted by orthogonal top and bottom electrodes. These arrays can easily be converted into AND and OR gates. For an AND circuit, the vertical electrodes must be connected to the high voltage, and the horizontal lines to the input variables (see Figure 8.21a). Similarly, for OR, the horizontal lines are connected to the low voltage and the vertical lines are the signal lines.

However, these circuits have one drawback, in that only a single disjunction or conjunction can be implemented. If, for example, a simple AND connection of two input variables is built, all other horizontal input lines must be set to the high voltage. Therefore, at the end of each vertical line, only the conjunction of A and B is computed.

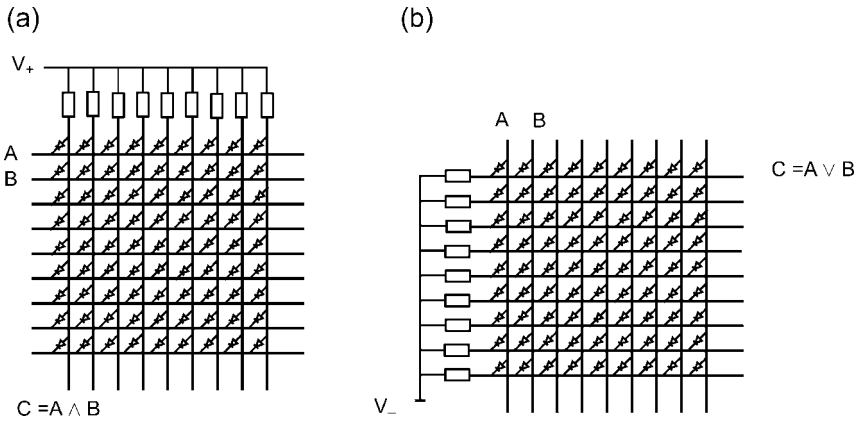

Figure 8.21 Crossbar structure implementing AND (a) and OR (b).

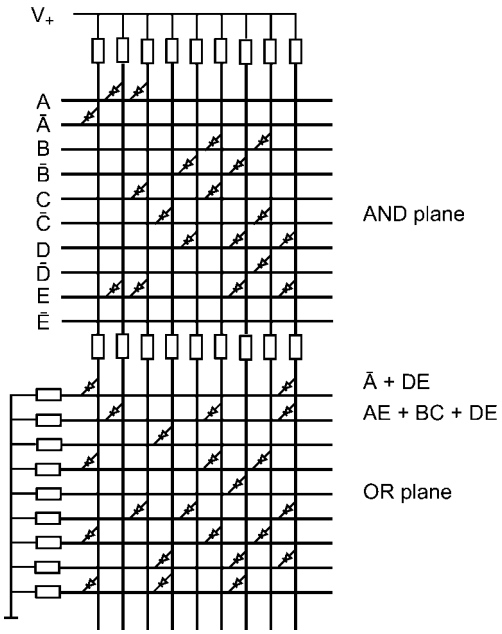

Figure 8.22 A programmable logic array consisting of an AND and an OR plane.

This problem can be circumvented if some diodes can be switched off – that is, if some input lines can be isolated from the output lines. Thus, a combination of a hysteretic switch (as described in Section 8.4.4) and a diode, for example by asymmetrically coupling a bistable molecule to the electrodes, would be highly beneficial. By using these switches, individual crossing points could be switched "off" and "on" by the application of a high-voltage pulse. The state of the molecules at the crossing points will therefore determine the logical function that is computed.

The AND and the OR gate can be combined to a PLA, as shown in Figure 8.22. The output of the AND plane is fed into the OR plane. Most diodes at the crossing points are switched off, so that certain Boolean functions are realized. The Boolean functions of the first two horizontal lines in the OR plane are given in Figure 8.22.

Such a PLA can compute every Boolean function if not only the input variables but also the negation of them is supplied to the PLA. Therefore, the negation of each variable must be computed, which can be done by using NDR-diodes as described in Section 8.4.3.1. Again, these NDR diodes can be implemented in a crossbar, so that all negations of all input signals can be realized simultaneously. As an alternative, the negation can be supplied by the surrounding CMOS circuitry, which would result in hybrid molecular/CMOS circuits.

Based on hysteretic switching diodes, the PLA is re-configurable. Therefore, the logic functions are programmed in a post-fabrication step; defective junctions can be

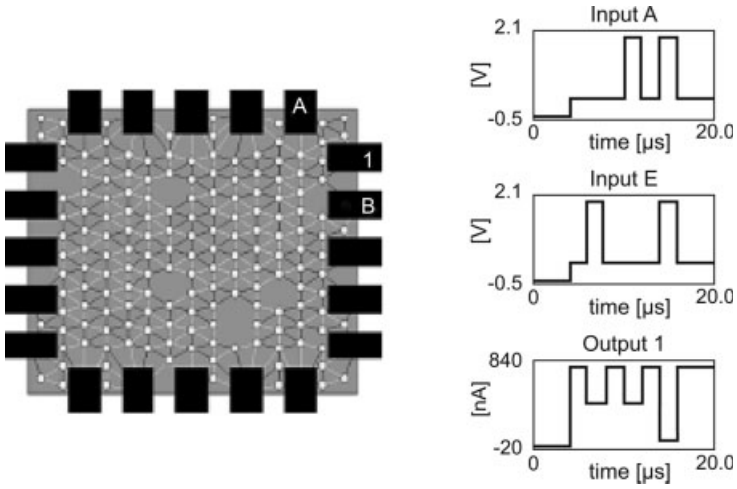

Figure 8.23 NanoCell trained as NAND gate, as proposed by Tour *et al.* (From Ref. [134].)

identified and disregarded in the circuit. This makes the PLA architecture a promising architecture for molecular electronics. A more detailed explanation of architectures based on crossbars is provided in Chapter 11 of this volume.

8.5.2 NanoCell

Although the crossbar set-up relies on self-organization, a "quasi-regular" structure is imposed by the orthogonal top and bottom electrode [133]. An architecture, which consists completely of random patterns, is the so-called NanoCell.

The structure of a NanoCell is shown in Figure 8.23 [134, 135]. It consists of a self-assembled, two-dimensional network of metallic particles which are randomly interlinked with molecules (cf. Section 8.3.8). In order to provide inverting logic, molecules exhibiting an NDR effect are used (see Section 8.4.3.1). The network is contacted by large metallic leads at its sides.

Due to the random arrangement of metal particles and molecules, the NanoCell must be trained or programmed to fulfill a certain task. To train this circuit, the molecules must be bistable and, similar to the PLAs, the molecules can be switched off and on by large voltage pulses. Therefore, the molecules must exhibit a combination of NDR effect and hysteretic switching. In Figure 8.23, the molecules are represented by lines connecting two metal particles; a white line represents an open switch, and a black line a closed switch.

In real applications, the molecular network is completely random – that is, neither are the positions of the individual molecules known, nor can a certain single molecule be addressed. The only knowledge about the circuit can be obtained through the contact pins, and most probably only bundles of molecules and not individual molecules can be switched by the application of voltage pulses to the contacts.

However, for a proof of concept, Tour *et al*. assumed the case of omnipotent programming [134], which means that the position of each molecule is known and that it can be individually programmed to its low or high state.

Based on this assumption, the network can be trained for a certain task; for example, to perform a NAND operation, as shown in Figure 8.23. The state of the network can be described by a list of the switching states of all molecules, typically, which molecule is open or which is closed. A function can be defined, which evaluates by how much the output ("1" in Figure 8.23) resembles a NAND combination of the inputs A and B. The task of training is now reduced to find a network state, which sufficiently minimizes (or, depending on the definition, maximizes) the evaluation function.

Tour and coworkers have used a genetic algorithm to identify such a network state – that is, to determine which molecules must be switched on, and which off. The output signal is determined by a SPICE simulation and compared to the desired functionality. Using this genetic algorithm, Tour and colleagues were able to train NanoCells as inverters, NAND gates, or complete 1-bit adders [134].

8.6 Challenges and Perspectives

Molecular electronics represents an exciting and promising field of research, but it imposes huge demands on the technology and is at the border of what is currently feasible. Many challenges remain for further research, as well in the design of molecules and in the assembly and architecture of future devices. For example, molecular interconnects must be found that can conduct current across larger distances, the rectification ratio of molecular diodes must be increased and, as a key element, bistable switching molecules must be identified and optimized. Future architectures of molecular devices will have to incorporate the statistical nature of the assembly of molecules. The optimum architecture will start from a random arrangement of molecules and will be trained the molecular network, as has been attempted with the NanoCell set-up. However, this training step is mathematically highly complex and has only been solved for the simplifying case of omnipotent programming. It seems that there is a price to pay for the low information content of these random structures with a complex training algorithm.

In CMOS, molecular electronics has a very strong competitor. CMOS has been so successful in the past, because it combines high integration densities, a high switching speed, and a low power consumption [133]. If molecular electronics is to at least complement CMOS in the future, it must outperform CMOS in one or more of these key characteristics. It is proposed that molecular electronics will be small in size and will exhibit low switching energies [1, 133], but the switching speed will be low. However, these predictions are very uncertain and will need to be substantiated by further research.

9
Intermolecular- and Intramolecular-Level Logic Devices

Françoise Remacle and Raphael D. Levine

9.1
Introduction and Background

Today, there is an intense research activity in the field of nanoscale logic devices towards miniaturization and qualitative improvement in the performance of logic circuits [1–16]. A radical and potentially very promising approach is the search for quantum computing [17–24], and this is reviewed as an emerging technology in Ref. [25]. Other alternatives are based on neural networks [26], on DNA-based computing [27–31], or on molecular quantum cellular automata [32–37]. Single-electron devices should also be mentioned because if they use chemically synthesized quantum dots (QDs) they are "molecular" in nature [38–40]. Devices that have been implemented rely on the ability to use molecules as switches and/or as wires, an approach known as "molecular electronics" [5, 12, 41–44]. This approach is currently being extended in several interesting directions, including the modification of the electronic response of the molecule through changing its Hamiltonian [45–47]. In this chapter, these topics are first reviewed, after which ongoing studies on an alternative computational model, where the molecule acts not as a switch but as an entire logic circuit, are discussed. Both, electrical and optical inputs and outputs are considered. Advantage is then taken of the discrete quantum states of molecules to endow the circuits with memory, such that a molecule acts as a finite state logic machine. Speculation is also made as to how such machines can be programmed. Finally, the potential concatenation of molecular logic circuits either by self-assembly or by directed synthesis so as to produce an entire logic array, is discussed. In this regard, directed deposition is also a possible option [48–52].

9.1.1
Quantum Computing

Quantum computing can be traced to Feynman, who advocated [53] the use of a quantum computer instead of a classical computer to simulate quantum systems. The rational is that quantum systems, when simulated classically, are very demanding in computing resources. A quantum state is described by two "numbers" – its amplitude

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

and its phase – and the number of quantum states, N, grows exponentially with the number of degrees of freedom of the system. The sizes of the matrices necessary to describe a system quantum mechanically scales as N^2, and for large systems this number becomes rapidly prohibitively large. A computer that operates quantum mechanically will require far less resources because the computations can be massively parallel due to the superposition principle of quantum mechanics. Conceptually, to compute quantum mechanically required the extension of classical Boolean logic to quantum logic [19, 54] and to set up quantum logic gates [55–61] that operate reversibly [62, 63].

In quantum computing, the logic is processed via the coupling structure between the levels of the Hamiltonian. Typically, this coupling is induced by external electrical and magnetic fields. Nuclear magnetic resonance (NMR) is a particularly promising direction for both pump and probe [20, 64]. Quantum implementations are very encouraging for search algorithms [65–68], where a power law reduction in the number of queries can be obtained. For operations where the answer is more complex than a YES or NO – such as Fourier transform operations – the read-out remains a key problem because of the collapse of the wave function when one of its component is read. One very successful outcome of quantum computing and quantum information is *cryptography* [69], where the very effective factorization algorithms (public key cryptography, Shor algorithm [70, 71]) show the potential that is available. Quantum computing has very much caught the popular imagination, and several excellent introductory books (e.g. Ref. [72]) are now available.

9.1.2
Quasiclassical Computing

The essential difference between quantum computing and the approach discussed here is that a quantum gate operates on both the amplitude and the phase of the quantum state. The phase is very sensitive to noise, and quantum computing theorists have devised various ways to protect the phase from external unwanted perturbations [73–79] or to seek to correct a corrupted phase. Because the authors' background is in molecular dynamics and coherent control, they are aware that the phase of quantum states is extremely difficult to protect, and in this chapter adopt a quasi-classical approach [80] where, while the time evolution of the molecular system is quantal, what matters in terms of inputs and outputs are the populations of the states – that is, the square modulus of the amplitudes. This approach relies on classical logic and does not require reversible gates. There are two special characteristics of quantum computing: parallelism and entanglement. Currently, the authors' investigations center on understanding the potential of the quasi-classical approach in terms of parallelism.

9.1.3
A Molecule as a Bistable Element

Another very successful approach is molecular electronics, which aims to provide molecular-based computing by using the molecule as a switch [5, 11, 12, 42, 43, 81, 82].

In the following sections, it is explained that the essential difference with what is advocated in this chapter is that the molecule can do – and has been shown to do – much more than act as a switch.

Quantum cellular automata (QCA) represents another promising approach to molecular computing where the molecules are not used as switches but as structured charge containers and information transmitted via coupled electric fields [32–34]. The charge configuration of a cell composed of a few QDs – and, more recently, of molecular complexes – is the support for encoding the binary information. Most studies on QCA consists of theoretical design, with very few experimental implementations. While the QD-based implementations [33, 34] operate at very low temperatures, theoretical modeling predicts that molecular quantum cellular automata could be operated at room temperature [36, 37, 83].

9.1.4 Chemical Logic Gates

Early proposed chemical implementations of logic gates were based on the response of molecules in solution to light or changes in chemical species concentrations [84–86]. Using photo-induced electron transfer where the emitted fluorescence is modulated by the concentrations of ions species in solution, different kinds of realizations of uni and binary gates (i.e. OR, NOT, AND, XOR, etc.) have been proposed [11, 14, 87, 88], and it has been shown that AND and XOR gates can be combined to lead to half adder and/or subtractor [4, 8, 30, 89–93] and full adder/subtractor [94–98] implementations. Other well-studied systems that lead to similar levels of logic complexity are those built on molecular motors (catenane, rotaxane), where the inputs can be communicated photochemically and electrochemically [11], or on DNA oligonucleotides [29–31]. These ways of providing the inputs and reading the outputs are rather slow, however, and do not exploit the complexity of the quantum level structure and intra- and inter-molecular couplings. Nor is it clear how to reduce the size of such devices. All of these approaches were largely limited to two bit operations (half adder or subtractors). In 2001 [94, 95], the level of the three bits operation with an optical full adder had already been reached, while more recently a cyclable full adder on a QD by electrical addressing was proposed [99]. This last example shows that QDs, and not only molecules proper, can be used to act as more than a switch.

The emphasis in this chapter is on demonstrating single-molecule rather than chemical computing. The proposal is that it is possible to use the complexity of molecules to integrate logic circuits of increasing sophistication on a single molecule or on supramolecular assemblies. Clearly, at the present time signal-to-noise considerations mean that the independent response of more than a single molecule is needed. Beyond the independent molecule, however, the proposal is to concatenate single molecules in the sense that the logic output from one molecule is the logic input to another. This is achieved by (rapid) intermolecular coupling.

9.1.5
Molecular Combinational Circuits

Combinational circuits are the simplest logic units, being built of logic gates (the most common are NOT, AND, OR, XOR, NOR, NAND) and providing a specific set of outputs, given a specific set of inputs. These circuits have no memory. In transistor-based computer circuits even the simpler such gates require to be built as a network of switches. Studies on molecular combinational circuits forms part of an intense research effort aimed at recasting into logic functions the fact that molecules can respond selectively to stimuli (inputs) of different forms (chemical, optical, electrical) and produce outputs (chemical, optical, electrical). The advantage is that a molecule which implements a combinational circuit acts not as a single switch but as an entire gate. However, most of molecular gates proposed until now have been based on chemistry in solution, and use at one stage or another a chemical stimulus (e.g. concentration of ions such as H^+, Na^+) coupled to optical or electrical stimuli. This leads rather slow rates of processing of the information and concatenation. In contrast, the authors' studies do not involve chemical inputs, and this allows faster rates to be reached. It has already been shown that, within less than 1 ps ($=10^{-12}$ s), it is possible to implement combinational circuits on a single molecule using selective photo-excitation for providing the inputs and the intra- and inter-molecular dynamics for processing the information. (See Refs. [100–102] for an example of sub-ps logic gates using femtosecond ($=10^{-15}$ s) pulses as input, and Refs. [94, 103] for an example of concatenation by intermolecular coupling.)

One advantage of using molecules in the gas phase is that far fewer molecules are required than in solution. In the preliminary gas-phase schemes, the reading of the outputs is achieved by detecting fragments of the molecule used to implement logic, which means that this particular molecule is not available for a new computation. This is not intrinsically a problem because about 10 molecules are needed to obtain a good signal-to-noise ratio; hence, the computation can be continued with other molecules present on the sample. This represents a problem for cycling, however, and is why the target is to explore the possibilities offered by non-destructive optical and electrical reading. Another route to explore is to increase the number of operations (more than 32 bits) performed on a single molecule by using the fast intramolecular dynamics for concatenation, which decreases the need for cycling and the need for I/O. As discussed above and further elaborated below, this will have major implications for the miniaturization of logic devices by implementing compound logic at the hardware level.

In this way it was possible to implement logic functions on a single molecule up to and including the ability to program – that is, to use the same physics to realize different computations.

In terms of technology transfer it is clear, however, that what the industry would very much prefer is some form of extension to the CMOS technology. So, the need is to combine the many advantages of working with molecules in the gas phase with the need to anchor molecules on the surface. In this connection, studies with self-assembled small arrays of QDs is of central interest.

9.1.6
Concatenation, Fan-Out and Other Aspects of Integration

It is an essential characteristic of modern logic circuits that the gates are integrated. Specifically, the output of one gate can be accepted as the input of the next gate; the two gates are thereby *concatenated*. Very simple examples of concatenation are the NotAND (=NAND) or NotOR, etc. gates. It should also be possible to deliver the output of one gate as input to several gates. In 2001, it was shown [94] how to concatenate the logic performed by two molecules using electronic energy transfer as the vehicle for the information forwarding. It is clear that electron transfer – including electron transfer between QDs, proton transfer, and vibration energy transfer – can all be used for this purpose. However, this remains an as-yet poorly traveled course and further studies are clearly called for as it is a possible key to high-density circuits.

9.1.7
Finite-State Machines

So far, only combinational logic has been discussed, where combinational gates combine the inputs to produce an output. A *finite-state machine* does more – and the "more" is very essential and is also something well suited to what a molecule can do. A finite-state machine accepts inputs to produce an output that is dependent both on the inputs *and* on the current state of the machine. In addition to producing an output, such a machine will update the state of the machine so that it is ready for the next operation. Technically, what the finite-state machine has is a memory, and the circuit has as many different states of memory as states of the machine (see Figure 9.1). It has been shown possible to build very simple finite-state and Turing machines at the molecular level [101, 104]. Molecules have a high capacity for memory because of their many quantum states; for example, in conformers, after radiationless transition, the molecule can undergo relaxation and be in a stable state for a long time. Retrieval of the information may then be effected by either optical or electrical pulses (see below).

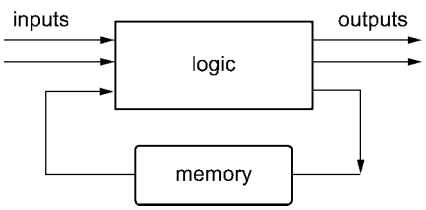

Figure 9.1 A schematic diagram of a finite-state machine. This consists of a combinational circuit ("logic") to which a memory element is connected to form a feedback path. The molecular implementation of this simple machine has been described in the authors' exploratory studies.

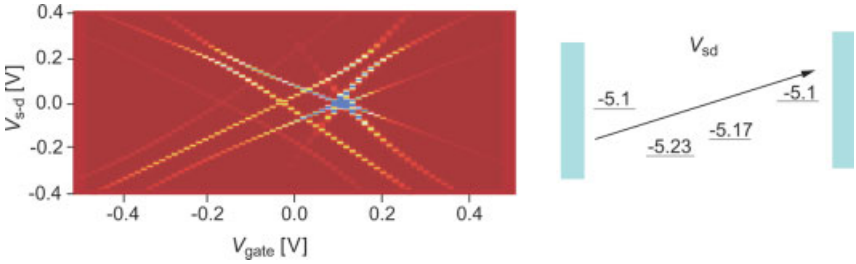

Figure 9.2 Differential conductance, d*I*/d*V* plotted as a function of the gate (V_{gate}) and the source-drain ($V_{s\text{-}d}$) voltages. The computation is for the four-level system shown where the coupling between the sites is 0.05 eV. The Stark shift of the site energies due to the source-drain bias is included in the Hamiltonian. The effect of the gate voltage is to shift the energies of system with respect to the Fermi energy of the electrodes.

A finite-state molecular machine has been proposed that can be cycled based on laser pulses [101, 104]. In recent investigations, the same optical finite-state machine has been used to implement a cyclable full adder and subtractor [96]. In a different direction, recently a molecular finite-state machine in the gas phase has been proposed by showing that a linear sequential machine can be designed using the vibrational relaxation process of diatomic molecules in a buffer gas. An alternative to optical pulses for providing inputs is to apply *voltage pulses*. In a recent study on QD assemblies (e.g. Refs. [105, 106]), it was shown that the application of a gate voltage allows the molecular orbitals to be tuned in resonance with the nanoelectrodes so that a current flows, whereas there is no current in the absence of the gate voltage (see Figures 9.2 and 9.3). A similar control is also possible on a single molecule [107–109] and for single QDs or several coupled dots.

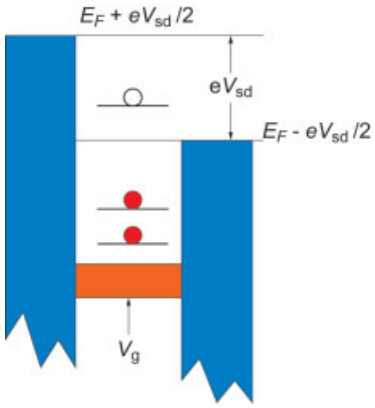

Figure 9.3 Schematic representation of a three-terminal device. The gating voltage is applied to a dieletric layer perpendicularly to the direction of the source-drain voltage. This scheme, which is equally useful for molecules and quantum dots, shows that either can be made to act as a finite-state device.

9.1.8
Multi-Valued Logic

So far, it has been taken as given that an input or an output can have one of two possible values. A laser beam can be on or off, a molecule can fluoresce or not, and a charge can transfer or not, and so on. Therefore, two-valued or Boolean logic is being implemented. Ever since Shannon showed, in 1938, the equivalence between a Boolean logic gate and a network of switches, computer circuits have been assembled from switches. First, the switches were electromechanical in nature, followed by vacuum tubes and then the transistor. Now that the discrete nature of the carriers of electrical charge has made it unclear as to how the size of the transistor might be further reduced, a major – and very serious – effort has been made to use a molecule as a switch.

Previously, several ways have been discussed of using a molecule as an entire logic gate (= a connected net of switches), or even as a finite-state machine rather than simply as a switch. There is, however, another possible generalization, which also is well-suited to what molecules are and what they can do – namely, to go to *multi-valued logic* [110–112]. What this means is that there are more than two allowed mutually exclusive answers to every question. This makes the numbers to be dealt with shorter (e.g. 1001 is the binary number that is written as 9 in base 10). In their studies, the present authors took three as a compromise between shorter numbers (e.g. 10 is ternary for 9) and the errors that can result in making a choice between too many alternatives. The molecular physics is straightforward, to take zero, one or two electrons in the valence orbital [113]. But clearly, there are other choices such as a Raman transition to several different final vibrational states. Molecules are willing and able to be pumped and to be probed to multiple states. It is not clear, however, if the industry is willing to learn to go beyond two.

9.2
Combinational Circuits by Molecular Photophysics

Combinational circuits are made of concatenated combinational gates. A logic gate accepts inputs and implements a particular function of the inputs to provide an output. In most implementations to date, the inputs and outputs are Boolean (binary) variables that can take one of two values, that is 0 or 1. Boolean logic gates can be one input–one output gates, like the NOT gate or two input–one output gates. There are in total 16 functions of two binary variables, and among these the AND, OR, XOR and INH gates are among the most commonly used in combinational circuits. The way in which half adders and full adders can be implemented are discussed in the following section, but initially attention is centered on elementary gates such as AND or OR to set the scene. The truth tables of these gates are provided in Table 9.1, and correspond respectively to taking the MIN and the MAX of the two Boolean inputs x and y. The AND gate can also be viewed as the product of the two inputs, $x \times y$. This gives an output 1 only if the two inputs are both 1. It can be implemented by two switches in series, while two switches in

Table 9.1 Truth tables of the binary AND, OR, XOR and INH gates.

INPUT		OUTPUT			
x	*y*	*x* AND *y*	*x* OR *y*	*x* XOR *y*	*x* INH *y*
0	0	0	0	0	0
1	0	0	1	1	1
0	1	0	1	1	0
1	1	1	1	0	0

parallel correspond to the OR gate. Another binary gate which is often used in combinational circuits is the XOR gate (see Table 9.1) which corresponds to the addition of the binary inputs modulo 2, $x \times y$.

The addition modulo 2 of two binary numbers works exactly as would be expected, in base 10. When the two binary inputs are both 1, the result of their sum modulo 2 is 0, but a 1 (the carry digit) must be reported in the next column of binary digits [114] (see Table 9.2).

When using the XOR and the AND gates, it is possible to build a half adder. This has two inputs, the two numbers to be added modulo 2, and two outputs, the sum modulo 2 of the two inputs, realized by a XOR gate and the carry, realized by an AND gate, the truth tables for which are shown in Table 9.1. A half adder is an important building block for molecular combinational circuits because, by concatenating two half adders, a full adder can be built. Usually, as shown by an example in Table 9.2, binary numbers of length more than one digit must be added. A full adder is more complex than a half adder, in that it takes the carry digit from the addition of the previous two digits into account (called the "carry in"). A full adder has therefore three inputs – the two digits to be added and the carry digit from the previous addition – and two outputs – the sum modulo 2 of the three inputs and the carry digit for the next addition (see Table 9.2) – called the "carry out".

In photophysics logic implementations, the inputs are provided by laser pulses, their physical action being to excite the molecule, typically to electronic excited states. The logical value 1 is encoded as the laser being "on", and the logical value 0 as the laser being "off". The molecules in the sample act independently of one another, and there is uncertainty as to whether every molecule absorbs light. It is therefore not the case that a single molecule suffices to provide an output. When working with an ensemble of molecules, there is no need to read a strict "yes" or a strict "no" from each molecule.

Table 9.2 Addition of the two binary numbers $x = 010$ and $y = 111$.

Carry	**1**	**1**		
x		0	1	0
y		1	1	1
Sum	1	0	0	1

What is needed is to excite enough molecules to be above the threshold for the detection of light absorption. The detection of the outputs is by fluorescence and/or by detecting ions. The detection of ions is relatively easy, so by monitoring the absorption by photoionization of the molecule, it is sufficient if only a small number of molecules respond to the input. An excited molecular ion typically fragments, and the detection of ionic fragments can also be used to encode outputs. Although ionic fragments can be detected very efficiently, the price is that the molecule self-destructs at the end of the computation and so the gate cannot be cycled. The details of an optically addressed half and full adder that can be cycled are provided in Section 9.1.3 [96].

First, however, the implementation of a half adder will be discussed and two approaches for doing this will be compared. It will then be shown how to implement a fault-tolerant full adder on a single molecule [115] using photophysics in the gas phase of the 2-phenylethyl-*N*,*N*-dimethylamine (PENNA) molecule [116–118]. This implementation follows the lines of the 2001 implementation of a full adder on the NO molecule [95]. Finally, the realization of a full adder by concatenation of two half adders is discussed, where the logic variables are transmitted between the two half adders by energy transfer between two aromatic molecules that are photoexcited [94] in solution.

9.2.1
Molecular Logic Implementations of a Half Adder by Photophysics

A discussed above, a half adder has two outputs: Addition modulo 2 is implemented by the XOR gate, and the carry digit is the result of an AND operation. A molecular realization of the logical XOR operation is challenging because the output must be 0 when both inputs are applied. For a photophysics implementation of the inputs this means that when both lasers are on, there is not the output that is observed when only one laser is on. The realization of the AND gate is comparatively easier because an output is produced only if both inputs are on, and so any reproducible experiment, which requires two inputs for generating an output can implement an AND gate [103]. The truth table for the implementation of a half-adder by optical excitation is given in Table 9.3.

Two-photon resonance-enhanced absorption by aromatic chromophores has been used as an effective way to implement an XOR operation on optical inputs at the molecular level [94, 95, 104]. The two photons (each of a somewhat different color and

Table 9.3 Truth table for an implementation of a half-adder by photoexcitation.

x(laser 1)	*y* (laser 2)	Carry (AND)	Sum (XOR)	(carry, sum)
0	0	0	0	(0,0)
1	0	0	1	(0,1)
0	1	0	1	(1,0)
1	1	1	0	(1,1)

therefore distinguishable) represent the possible inputs. For an XOR gate to be physically realizable, the following conditions must be satisfied. First, for aromatic molecules or for molecules with aromatic chromophores the resonant level, typically the first optically bright electronically excited state, S_1, has a fairly broad absorption band consisting of many vibronic transitions. So, two photons of different frequencies (and therefore distinguishable) can be absorbed with a similar cross-section. This provide the OR part of the XOR gate (second and third lines of Table 9.3): if laser light of either frequency is on, the output can be identified as the fluorescence. The exclusive part results from the following effect: it is often the case that, having absorbed one photon, the cross-section of an aromatic chromophore to absorb a second photon is higher. That the bottleneck for two-UV photon absorption is often the absorption of the first photon has been realized since the earliest days of visible/UV multiphoton ionization/dissociation [119, 120], and has been used extensively since then. Therefore, when two light pulses are applied the system need not remain in S_1 for a significant length of time because it can absorb a second photon. Whether it preferentially does so depends on the particular molecule. Either input laser can excite from the ground state to S_1. Therefore, the fluorescence signal will increase when both lasers are on. The input in this case is 1,1 and from Table 9.3 the need is to detect the output 1,0. In the presence of two photons the fluorescence from S_1 (a rather slow, >5 ns scale, process in PENNA) may fall, but the more secure detection of the presence of both input beams is the increase of the number of ions. There is an increase rather than pure onset because a single laser can also cause ionization, but this occurs with low intensity. A high ionization intensity corresponds to a simultaneous input of both lasers. In practice, the two events "high ionization efficiency" and "low ionization efficiency" can easily be distinguished by the use of discriminators and analog electronics. A simulation of the temporal response of the molecule to the laser pulses, so as to show that this is possible, is available in Ref. [115]. To conclude, the 1,1 input is identified as a high ionization signal.

The use of two lasers of different colors is dictated by the need to represent two distinct inputs, but there is a clear physical advantage if the two frequencies differ by more than a vibrational frequency in S_1: because the S_1 and S_0 vibrational frequencies are not exactly the same, the down-pumping by the other laser is not resonance enhanced and thus improbable, as shown schematically in Figure 9.4.

There are therefore two ways to implement a half adder (see Table 9.4). The direct way is to detect separately the sum and the carry and to assign them to a different experimental probe. In the case of the PENNA molecule (see Figure 9.5) the inputs are encoded as UV lasers being off or on. For the sum digit, the experimental probe is the detection of the fluorescence from the S_1 electronic state. The carry digit is the result of the absorption of two photons. In the case of PENNA, the absorption of two UV photons at the chromophore end causes local ionization, followed by charge migration to the N-end of the chain. The carry digit is therefore encoded as the detection of N-fragments. As discussed above, the absorption of a second photon decreases the intensity of the fluorescence from S_1, but typically does not quench it enough so that detection of the carry digit through N-end ions is preferable.

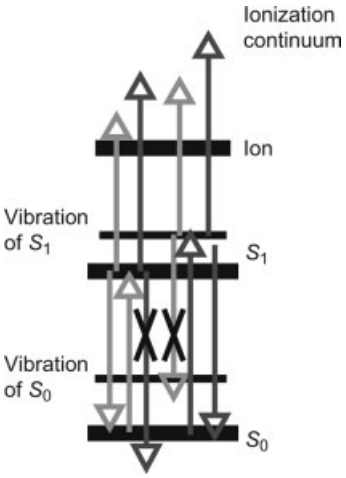

Figure 9.4 Two-photon ionization with the two inputs being lasers of unequal frequency can be made fault-tolerant to stimulated emission. This is particularly so if one laser operates on the 0,0 transition while the other pumps a vibrationally excited level of S_1. For details, see the text.

One way of implementing a fault-tolerant half adder is to combine the result of the carry and the sum digit into one word (carry, sum). This is shown in the fifth column of Table 9.3. As can be seen, the four distinct pairs of inputs of the half adder – that is, (0,0), (1,0), (0,1) and (1,1) – corresponds only to three distinct outputs of (0,0), (0,1) and (1,0). This is because in addition modulo 2, if the carry is 1, the value of the sum is necessarily 0. Therefore, instead of assigning a separate physical probe for the sum and the carry, it is possible to assign a physical probe for the three different logical values of the word (carry, sum). It should be noted that the binary meaning of the word (carry, sum) corresponds to the number of inputs with value 1. In the case of PENNA, the choice was made to assign the word (0,1) to the presence above threshold

Table 9.4 Truth table and experimental probes used for the two ways of implementing a half-adder on PENNA.

x (UV(1))	*y* (UV(2))	Carry (AND)	Sum (XOR)	Probe for carry (AND)	Probe for XOR	Probe for words (carry,sum)
0	0	0	0	no N-end fragment	no fluo from S_1	no output signal (0,0)
1	0	0	1	no N-end fragment	fluo from S_1	fluorescence from S_1 (0,1)
0	1	0	1	no N-end fragment	fluo from S_1	fluorescence from S_1 (0,1)
1	1	1	0	N-end fragment	no fluo from S_1	N-end fragment (1,0)

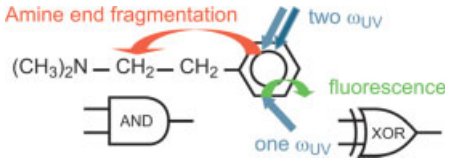

Figure 9.5 Schematic representation of the two-photon excitation scheme used to implement a half adder on PENNA.

of a fluorescence signal from S_1, and the word (1,0) to the detection above a threshold value of a N-end fragments. The fault tolerance of this scheme arises from the fact that in case of inputs (1,1), a N-end fragment ion detection will be reported, irrespective of the intensity of the fluorescence signal from S_1. The scheme is fault tolerant with respect to the extent of fluorescence from S_1 in case of two-photon excitation. Detecting the (0,0) output is straightforward as no excitation is provided. The two ways of implementing a half adder on PENNA are summarized in Table 9.4.

This half-adder self-destructs at the end of the computation because the local ionization at the chromophore end causes the PENNA ion to fragment. However, this scheme allows for a remarkable sensitivity in the detection of the outputs because very few ions can already be detected with a good signal-to-noise ratio. Although this involves an ensemble of molecules, not all of which provide an answer,. However, response is needed from only 100 molecules to obtain acceptable statistics, and this response occurs quite rapidly.

In a full adder, the word (1,1) as an output is allowed, so that a full adder has four distinct binary words as outputs, namely (0,0), (0,1), (1,0) and (1,1). As discussed above, it has also one more input than the half adder, the carry digit. It is shown in the next section how a full adder can be implemented on the PENNA molecule using the same fault-tolerant scheme for probing the outputs. This manner of implementation of a full adder is contrasted with the implementation based on the concatenation of two half adders, in which the sum and the carry are detected separately.

9.2.2
Two Manners of Optically Implementing a Full Adder

A full adder has three inputs and produces two outputs, the sum which is the addition modulo 2 of the two inputs and the carry in digit and the carry out, which for the next cycle of computation becomes the carry in:

$$\text{sum out} = x \oplus y \oplus \text{carry in} \tag{9.1}$$

$$\begin{aligned}\text{carry out} &= (x \otimes y) + ((x \oplus y) \otimes \text{carry in}) \\ &= (x \otimes y) + (x \otimes \text{carry in}) + (y \otimes \text{carry in})\end{aligned} \tag{9.2}$$

where $\oplus$ means addition modulo 2 (XOR), $\otimes$ means binary product (AND) and $+$ means OR. The carry out logic equation can be simplified to

$$\text{carry out} = x \otimes y + x \otimes \text{carry in} + y \otimes \text{carry in} \tag{9.3}$$

In the implementation on PENNA that was proposed above, the two inputs x and y are encoded as for the half adder, by two UV photons with slightly different wavelengths. The carry in digit is encoded as a laser pulse of green light which is intense enough that two photons can be absorbed to allow the transition to the S_1 state by a non-resonance-enhanced two-green photon transition. The four outputs words (carry out, sum): (0,0), (0,1), (1,0) and (1,1) are detected each by a distinct experimental probe. As in the half adder implementation of PENNA, the output word (0,1) is detected as fluorescence from the S_1 state while the output (1,0) as the presence of N-end fragment ions. The detection of the output (0,0) is straightforward as it corresponds to no inputs. The output (1,1) corresponds to the three inputs having the value 1; that is, the PENNA molecule is excited by two UV (x and y) and two green photons (carry in). Experimentally, this amount of energy is causing fragmentation at the C-end (instead of fragmentation at the N-end which occurs when only two inputs are 1, in which case it is only the equivalent in energy of two UV photons). The presence of C-end fragment ions above a given threshold is therefore used to detect the (1,1) output. The excitation scheme and experimental probes of the outputs are shown in Figure 9.6 and the corresponding truth table in Table 9.5. Note that, as in the case of the half adder, the output word (carry, sum) counts in binary how many inputs are 1.

Another way to implement a full adder is by concatenation of two half adders. The corresponding combination logic circuit is shown in Figure 9.7.

The physical implementation, by photoexcitation of a donor–acceptor complex in solution[94], is an example of intermolecular concatenation of two half adders by energy transfer. It demonstrates that one molecule is able to communicate its logical output to another molecule. The implementation is on a specific pair (rhodamine 6G–azulene), for which considerable data are available, but the scheme is general enough to allow a wide choice of donor and acceptor pairs. The first half-adder is realized on rhodamine 6G, and the second half adder on azulene. The midway sum is transmitted from the first to the second half adder by electronic energy transfer between rhodamine 6G and azulene.

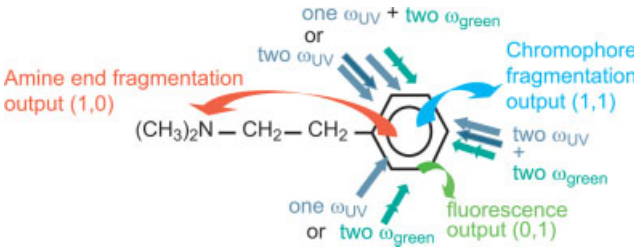

Figure 9.6 Excitation scheme of PENNA for implementing a full adder. Fluorescence from the S_1 state of the phenyl ring codes for carry-out = 0, sum-out = 1, fragmentation at the amine end codes for carry out = 1, sum out = 0 and fragmentation at the chromophore end for carry out = 1, sum out = 1 (see also Table 9.5). The two binary digits to be added are encoded as the two UV photons being on or off. The carry-in is encoded as excitation by two green photons.

Table 9.5 Truth table and detection scheme for the outputs for the optical implementation of a full adder on PENNA.

x (UV(1))	*y* (UV(2))	Carry in (vis, two-photon)	Carry out	Sum out	Output word (carry,sum)	Probe for output word
0	0	0	0	0	(0,0)	No signal
1	0	0	0	1	(0,1)	fluorescence from S_1
0	1	0	0	1	(0,1)	Fluorescence from S_1
1	1	0	1	0	(1,0)	N-end fragment
0	0	1	0	1	(0,1)	Fluorescence from S_1
1	0	1	1	0	(1,0)	N-end fragment
0	1	1	1	0	(1,0)	N-end fragment
1	1	1	1	1	(1,1)	C-end fragment

The physical realization of the two half adders relies (as in the case of the half adder implementation on PENNA discussed above) on the fact that the absorption of one or two UV photons (inputs x and y) by the donor (acceptor) molecule leads to distinct outputs. However here, unlike the case of PENNA, the absorption of the second photon does not lead to ionization, but rather to absorption by a second excited electronic state, S_2. In general, a molecular half adder will be available for molecules which have a detectable one-photon and a detectable two-photon absorption. This seems to go against Kasha's rule [121], but in fact there are enough exceptions. Azulene and many of its derivatives provide one class. The emission from the second electronically excited state, S_2, is often as strong or stronger as the fluorescence from S_1 [122, 123]. More in general, emission from S_2 is not forbidden; rather, due to competing non-radiative processes it often has a low quantum yield but it is definitely detectable, particularly so as it is much to the blue as compared to the emission from S_1. If necessary, the emission from S_2 can be detected by photon counting. There is, therefore, a case where the outputs of the XOR gate and the AND gate that constitute the half adder can be probed separately, with sufficient fidelity. The output of the XOR gate of the first half adder is encoded as populating the S_1 state of rhodamine 6G, while the output of the XOR gate of the second half adder (the sum out) is encoded as detecting fluorescence of the S_1 state of azulene. The output of the first AND gate

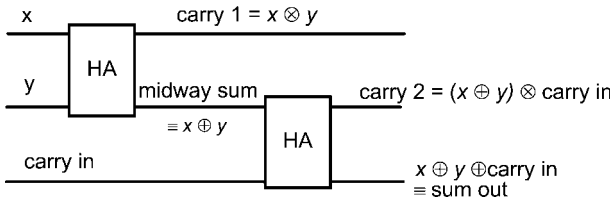

Figure 9.7 Combinational circuit of a full adder implemented by concatenation of two half adders.

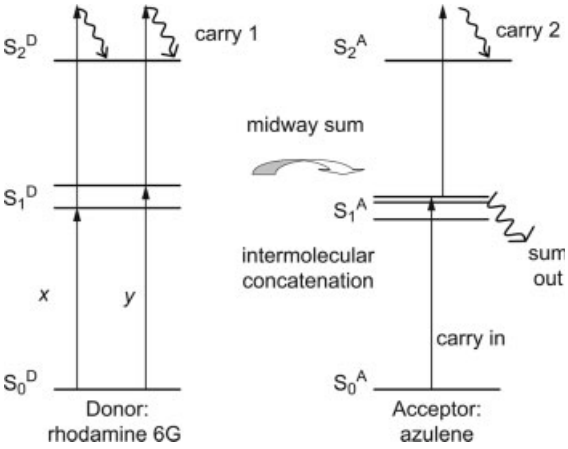

Figure 9.8 Photophysics of the implementation of a full adder by concatenation of two half adders on the donor–acceptor complex rhodamine 6G–azulene in solution.

(carry 1 in Figure 9.7) is probed by fluorescence from the S_2 of rhodamine 6G and correspondingly, the output of the AND of second half-adder (carry 2 in Figure 9.7) by fluorescence of the S_2 state of azulene. The concatenation between the two half adders is performed by the fairly rapid [124] intermolecular electronic energy transfer. Specifically, the well-characterized [125–127] transfer from the S_1 level of rhodamine 6G to the S_1 of azulene was proposed.

The photophysical scheme for the implementation of a full adder on the donor–acceptor complex rhodamine 6G–azulene is summarized in Figure 9.8. The S_1 level of rhodamine 6G can be readily pumped with photons absorbed within the $S_0 \rightarrow S_1$ band. The frequencies ω_1 ($\equiv$ input x) $= 18\,797\,\text{cm}^{-1}$ (the second harmonic of the Nd-YAG laser) and ω_2 ($\equiv$ input y) $= 18\,900\,\text{cm}^{-1}$ are taken. This is not needed for the full adder, but the absorption to S_1 can be detected through its emission at about $17\,500\,\text{cm}^{-1}$ [125, 126]. This emission is logically equivalent to $x \oplus y$ because if the intensity is high enough due to two photons being present, the donor will be pumped either directly to S_2 or to higher levels, followed by ultrafast non-radiative relaxation to S_2. The large absorption cross-section of $2.5 \times 10^{-18}\,\text{cm}^2\,\text{molecule}^{-1}$ [128] for the $S_1 \rightarrow S_n$ ($n \geq 2$) of rhodamine 6G ensures efficient pumping of S_2. The emission from S_2 is at about $23\,250\,\text{cm}^{-1}$, with a quantum yield of about 10^{-4} [126]. It is this emission which serves to logically implement the left AND gate, and it is equivalent to $x \otimes y$ (denoted as carry 1). The S_1 level of the donor transfers the energy, via the Forster mechanism [124] to the azulene acceptor, the S_1 level of which is at $14\,400\,\text{cm}^{-1}$, that emits in the 13 400 to $11\,000\,\text{cm}^{-1}$ range [129]. This emission provides the logical sum output [Eq. (9.1)]. The S_2 level of azulene has its absorption origin at $28\,300\,\text{cm}^{-1}$, and so it can be reached from S_1 by a third photon of frequency $14\,400\,\text{cm}^{-1}$. The same photon can also pump ground-state azulene to its S_1 level. Emission (or lack thereof) from S_2 of azulene at $26\,670\,\text{cm}^{-1}$ [127] provides the carry 2 bit. The carry 1 and the carry 2 cannot be equal to 1 together, because if the carry 1 is 0,

the midway sum is 0, meaning that even if the carry in is 1, the carry 2 cannot be 1. In other words:

$$carry\,out = carry\,1 + carry\,2 \tag{9.4}$$

The carry out is therefore physically probed by monitoring the fluorescence from the S_2 states of rhodamine 6G and azulene, which logically corresponds to the first line of Eq. (9.2).

The advantage of an all-optical scheme for the full adder implementation compared to the implementation on PENNA as discussed above is that the adder does not self-destruct at the end of the computation. Another advantage is that it operates relatively rapidly. The energy transfer rate for a solution of 10^{-3} M azulene, estimated using the S_1 fluorescence spectrum of rhodamine 6G and the absorption spectrum of azulene, is about $10^{10}\,s^{-1}$. This rate is sufficient for present needs, but it can be increased [130] if the two chromophores are incorporated within a single molecular unit using a short bridge to connect them [124]. The increase in the rate will be particularly significant (five orders of magnitude) if the bridge is rigid [130, 131]. It should be emphasized that a rigid bridge is required to achieve a very high rate. Many other couples based on commonly used laser dyes as donors and azulene derivatives [128, 132] may also be utilized for implementation of the logic gate [133, 134].

9.3 Finite-State Machines

Finite-state (also called sequential) machines are combinational circuits with memory capability. The memory registers are the internal state(s) of the machine [135, 136]. As in a combinational circuit, the outputs of the machine depend on the inputs, but in addition the output also depends on the current state of the machine. It is this dependence of the output on the state of the machine that endows finite-state machines with a "memory". The memory of the machine corresponds to the state of the experimental system, and this state can be changed by applying suitable perturbations, such as optical or voltage pulses. As in the other logic schemes, the "logic" part is an encoding of the subsequent dynamics of the system.

The finite-state machine computational model takes advantage of two aspects that are natural for quantum systems:

- A physical quantum system has discrete internal states and its response to perturbation will in general depend on what state it is in.
- Perturbations can be applied sequentially, so that the machine can be cycled.

By taking advantage of the two points above, the implementation of several forms of finite-state machine was proposed: a simple set-reset that can be either optically [101] or electrically addressed [106]; an optical flip-flop [104] and full adder and subtractor [96]; an electrically addressed full adder [106] and a electro-optically addressed counter [137]. Beyond that it has been shown, using optical addressing,

that a molecule can be programmed and behaves (almost) like a Turing machine [101]. The caveat "almost" is introduced because a molecule can have only a finite number of quantum states, whereas a Turing machine has an unlimited memory. Possibly this is not a true limitation since if indeed the number of quantum states of the universe is finite – sometimes known as the "holographic bound" – then no physical system can strictly act as a Turing machine.

In this section, a review is conducted of optically addressed finite-state machines, up to a full adder (Section 9.3.1) and an electrically addressed machine (Section 9.3.2). If molecules and/or supramolecular assemblies are to offer an inherent advantage over the paradigm of switching networks, it will likely be through each molecule acting as a finite-state unit.

9.3.1
Optically Addressed Finite-State Machines

Laser pulses are used to optically address atomic or molecular discrete quantum states. All of the schemes discussed here are based on the Stimulated Raman Adiabatic passage (STIRAP) pump-probe control scheme, that allows the population of the quantum states of atoms or molecules to be manipulated. The advantages of the STIRAP control scheme for implementing finite-state machines are that the external perturbation can induce a change of state with a very high efficiency (close to 100%), and that the residual noise which accumulates when the machine is cycled can be erased by resetting it. Moreover, the perturbation has a distinctly different effect on the system depending on the initial state. These advantages are supported by experimental results for atomic (i.e. Ne [138]) and molecular systems (i.e. SO_2 [139], NO [140]), and the dynamics is well-described by solving the quantum mechanical time-dependent Schrödinger equation [141–143].

Here, the operation of finite-state machines using quantum simulations on a three-level system with a Λ-level scheme is described (see Figure 9.9). The pump pulse, with photons of frequency ω_P, is nearly resonant (up to a detuning Δ_P) with the $1 \rightarrow 2$ transition, while the Stokes pulse, with photons of frequency ω_S, is nearly resonant (up to a detuning Δ_S) with the $2 \rightarrow 3$ transition. Levels 1 and 3 are long-lived, but level 2 is metastable because it can fluoresce. The spontaneous emission from level 2 provides a readable output. The important feature of this level structure is that there are two routes for going from level 1 to level 3. The first route is a kinetic or

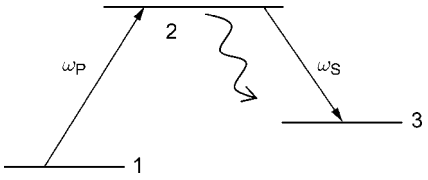

Figure 9.9 The Λ-level scheme is a STIRAP experiment. The pump transition driven by ω_P is between levels 1 and 2, while the Stokes or dump transition is between levels 2 and 3 induced by ω_S. The population from level 2 is detected by its fluorescence.

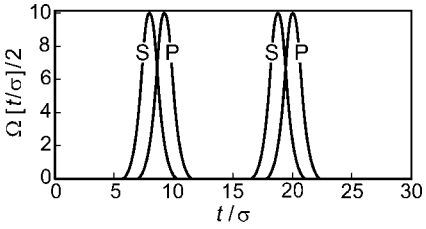

Figure 9.10 Resistance–time profile of an individual SP pulse and of the sequence of the two pulses, as used in the simulation reported in Figure 9.11. The plot is as a function of time in reduced units t/σ, where σ is the width of the S and the P pulses and the two widths are taken as equal.

"intuitive" pump scheme where first a pulse of frequency ω_P is applied so that population is transferred from level 1 to the excited level 2. From this level, the population can fluoresce or be transferred to level 3 by induced emission, using a Stokes pulse of frequency ω_S. The second route is the counter-intuitive or STIRAP route that takes population from level 1 to level 3 with almost no population in level 2, and therefore no spontaneous emission from level 2. In this counter-intuitive route, the Stokes (S) pulse of frequency ω_S is applied first and the Pump (P) pulse of frequency ω_P is somewhat delayed and applied subsequent to the dump pulse, preferably so that its front still overlaps the tail of the pulse of frequency ω_S (see also Figure 9.10).

For the purpose of constructing a finite machine, the following observation is used. Suppose that passage occurs from level 1 to level 3 by the counter-intuitive route; this means that the S pulse is on first and the P pulse is delayed. This promotes (almost) all molecules from level 1 to level 3. The same set of two pulses can now be applied, keeping their respective order in time, and this will drive almost all molecules back to level 1. However, since the system is in level 3 this order of pulses constitutes a kinetic route, and therefore state 2 is populated as an intermediate state. In the simulation of finite-state machines, the pulse conditions are chosen such that the kinetic route leaves a few percent of molecules in level 2. The level 2 will fluoresce, and this will serve as the signature of the kinetic route. In other words, the set of two pulses – Stokes followed immediately by pump – drives the molecule from level 1 to level 3, or vice-versa, depending on what state it is in. The fluorescence from level 2 is the signature of which transition was driven. It should be noted that, by using the S and the P pulses as two distinct inputs, with either one being on or off, it could be shown possible to implement a set–reset finite-state machine and also a programmable Turing machine on the Λ-level structure [94]. In order to keep the discussion as simple as possible, these schemes will not be discussed here. In the present discussion the input is the presence or absence of the superposition of both pulses.

For the purpose of implementing a flip-flop and a full adder and subtractor, the optical input is defined as a Stokes pulse at the frequency ω_S, followed in time by a pump pulse at frequency ω_P. The input is referred to as a SP pulse (see Figure 9.10). The overlap in time between the two pulses and their intensity is adjusted such that if

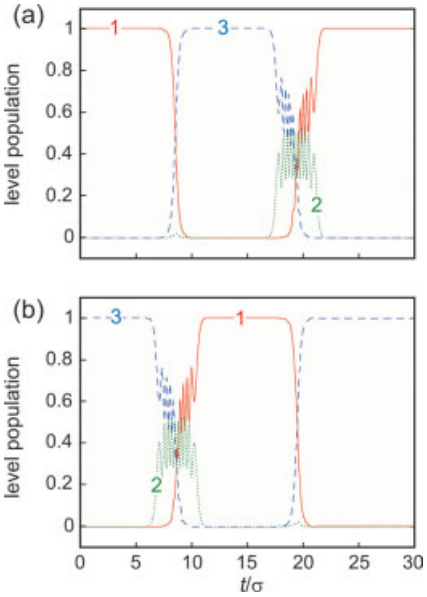

Figure 9.11 Population of the levels 1 (red), 2 (green) and 3 (blue) as a function of time when two SP pulses are applied (see Figure 9.10). The reason why such a sequence of two pulses is useful as a way of reading the state of the machine is explained in the text. The populations are computed as $|c_i(t/\sigma)|^2$ by numerical integration of the time-dependent Schrödinger equation. (a) The system is initially in level 1. The first SP pulse takes it to level 3 via the STIRAP route, with essentially no transient population in level 2. The second SP pulse takes the population in level 3 back to level 1. This second transition occurs via the kinetic route and significant transient population in level 2. (b) The system is initially in level 3. The population transfer from level 3 to level 1 goes via the kinetic route while the second SP pulse takes the system back to level 3 via the STIRAP route.

the system is initially in level 1, the SP pulse transfers to level 3 via the STIRAP route, without any significant population in level 2. On the other hand, if the system is initially in level 3, the SP pulse will pump it down to level 1 via the kinetic route, that can be detected by spontaneous emission from level 2. The time profile of the SP pulse is shown in Figure 9.10.

The quantum simulations illustrating the two routes that are possible using a SP pulse as an input are shown in Figure 9.11. The purpose of the simulation is to show that, by either route, the SP pulse achieves an essentially 100% population transfer between levels 1 and 3. The main source of noise is the spontaneous emission from level 2 that can end up either in level 1 or 3 or to yet another level, in which case the molecule is lost from the ensemble. To achieve a population transfer close to 100% between levels 1 and 3, rather intense pulses are needed, with the result that in the kinetic route the population in level 2 remains low (see Figure 9.10). Only a few photons are necessary to detect the output, so that detecting the output does not introduce too much noise. After a few cycles, the noise accumulation can be corrected for by resetting the machine (see Ref. [104]).

For the three-level structure shown in Figure 1.9, the Hamiltonian in the rotating wave approximation takes the form [141, 144, 145]:

$$\mathbf{H} = \frac{1}{2}\begin{pmatrix} 2\omega_1 & \Omega_P(t)\exp(i\omega_P t) & 0 \\ \Omega_P(t)\exp(-i\omega_P t) & 2\omega_2 & \Omega_S(t)\exp(-i\omega_S t) \\ 0 & \Omega_S(t)\exp(i\omega_S t) & 2\omega_3 \end{pmatrix} \tag{9.5}$$

where the two pairs of levels are coupled by nearly resonant transient laser pulses. The Rabi frequency [141, 146] is denoted as $\Omega(t)$. It is given by the product of the amplitude of the laser pulse, $E(t)$ and the transition dipole, μ: $\Omega(t) = \mu\, E(t)/h$. The central frequency of the Pump and Stokes lasers is almost resonant with the $1 \rightarrow 2$ and the $2 \rightarrow 3$ transitions; that is, $\omega_P = \omega_2 - \omega_1 - \Delta_P$ and $\omega_S = \omega_2 - \omega_3 - \Delta_S$ and the detunings are small and taken to be equal in the simulation, $\Delta_P = \Delta_S = \Delta$. Therefore, the two lasers are off resonance for the transitions for which they are not intended. In the rotating-wave approximation, the Hamiltonian couples between levels using only the component of the oscillating electrical field that is in resonance or nearly so for the two levels. The Hamiltonian [Eq. (9.5)] is that used in earlier studies of STIRAP [141, 147–149].

The Hamiltonian [Eq. (9.5)] can be recast in the interaction picture where it takes the form:

$$\tilde{\mathbf{H}} = \frac{1}{2}\begin{pmatrix} 0 & \Omega_P(t)\exp(-i\Delta_P t) & 0 \\ \Omega_P(t)\exp(i\Delta_P t) & 0 & \Omega_S(t)\exp(i\Delta_S t) \\ 0 & \Omega_S(t)\exp(-i\Delta_S t) & 0 \end{pmatrix} \tag{9.6}$$

The wavefunction of the system, $\psi(t)$, is a linear combination of the three levels, with time-dependent coefficients:

$$\psi(t) = \sum_{i=1}^{3} \tilde{c}_i(t)|i\rangle, \quad \tilde{c}_i(t) = c_i(t)\exp(-i\omega_i t) \tag{9.7}$$

where $\tilde{c}(t)$ are the coefficients in the interaction picture. These satisfy the matrix equation of the time-dependent Schrödinger equation, $i\, d\tilde{\mathbf{c}}/dt = \mathbf{H}\tilde{\mathbf{c}}$, which is solved numerically without invoking the adiabatic approximation [150]. The total probability, $\mathbf{c}^T\mathbf{c} = \tilde{\mathbf{c}}^T\tilde{\mathbf{c}}$, is conserved because the Hamiltonian is Hermitian.

Figure 1.11 shows the effect of acting with two SP pulses successively, for the system being initially in level 1 [panel a and in level 3 (panel b)]. The time profile of the sequence of two SP pulses in shown in Figure 9.10.

The simulations start with the molecule either in level 1 (Figure 9.11, panel a), or level 3 (panel b). The sequence of pulses as shown in Figure 9.10 returns the system to the level it started from. In a single cycle of the machine the SP pulse is applied only once. Parameters of the simulation given in reduced time units (t/σ) are: $\Omega_P(t/\sigma) = \Omega_S(t/\sigma) = 20.05\ \exp\ (-((t/\sigma)-\tau_i)^2/2)$, with $\tau_{s1} = 8$, $\tau_{p1} = 9.25$, $\tau_{s2} = 18.75$, $\tau_{p2} = 20$. The detuning $\Delta = \Delta_S = \Delta_P = 4(\sigma/t)$. The area of the pulse, $A(t) = \int \Omega(t/\sigma)d(t/\sigma)$ is 6.38 π. These details are quoted since the achievement of an essentially complete population transfer by the kinetic route (as shown in Figure 9.11) is sensitive to the intensity of the pulse and also to the detuning.

The physics shown in Figure 9.11 is all that is required to implement finite-state machines. The implementation of a full adder and a full subtractor are discussed

below; these are implemented in a cyclable manner, with each full addition or subtraction requiring two steps. The inputs x and y are both encoded as an SP pulse. The duration of a computer time step is taken to be somewhat longer than the duration of the input SP pulse. Here (unlike Section 9.3.1, where the combinational circuits implement a full adder) there is no need for concatenation because the carry (borrow) is encoded in the state of the machine for the first step and the midway sum (the midway difference) is encoded in the state of the machine for the second step. This is a major advantage of finite-state machines. The state of the machine encodes intermediate values needed for the computation.

A logic value of 0 is encoded for the carry-in or of the borrow digit as the molecule being in level 1, and a logic value of 1 as the molecule being in level 3. During the course of the discussion, it will also be shown (see Table 9.8) how the first cycle of the operation can also be logically interpreted as a T-flip-flop [136] (T for toggle) machine.

In order to cycle an adder after two optical inputs, the machine should be in a state that corresponds to the carry for the next addition, so that it is ready for the next operation. At present, a scheme which does exactly that cannot be devised, as two more operations are required in order for the machine to be ready for the next cycle. The reason for this is that, as shown below, at the end of the two cycles, the sum out is encoded in the state of the machine. So, the first requirement is to read the state of the machine in order to obtain the sum out as an output. This can be readily done by applying a SP pulse (as explained in Ref. [104] and shown in Figure 9.11). If the machine is in logical state 1 (level 3), an output from level 2 will be obtained, whereas if it is in logical state 0 (level 1) there will be no input. The machine is then restored to state 0 (level 1) by applying a second SP pulse if needed. Next, the carry out must be encoded in the internal state of the machine. If fluorescence was observed either in the first step or in the second step of the addition, it means that the carry is 1 and a SP pulse must be input in order to bring the machine to internal state 1 (level 3). Depending on the value of the sum and the carry out, the preparation of the machine for the next cycle may be automatic, in the sense that reading the sum out can coincide with encoding the carry in.

In a full addition, the order into which the three inputs, x, y and carry in, are added does not matter. This is unlike the case of a full subtractor, where the order does matter – that is, $x - y$ and $y - x$ differ by a sign. In order that the first step is the same for the full addition and the full subtraction discussed below, the process is started by adding the carry in and the y input digit. The finite-state machine implementation of a full adder goes along lines similar to the combinational circuit implementation by concatenation of two half adders. It is simply the order of adding the three inputs that differs, in order to take advantage of the memory provided by the internal state of the machine. The first step can be summarized by the Boolean equations:

$$\begin{aligned} state(t+1) &= carry\,in \oplus y \\ carry\,1 &= carry\,in \otimes y \end{aligned} \tag{9.8}$$

The corresponding truth table is given in Table 9.6.

The carry 1 is logically represented as the output of the machine after the first step (at time $t + 1$) and if its value is 1, fluorescence is detected from level 2. This only

Table 9.6 Truth table for the first half addition.

***state*(*t*) ≡ carry in**	***y*(*t*) ≡ SP pulse**	***state*(*t* + 1) (XOR) ≡ midway sum**	***output*(*t* + 1) (AND) ≡ carry 1**
0 (level 1)	0	0 (level 1)	0
0 (level 1)	1	1 (level 3)	0
1 (level 3)	0	1 (level 3)	0
1 (level 3)	1	0 (level 1)	1

occurs if the input is (1,1) – that is, the carry in was 1 (system in level 3) and the input SP pulse is 1, so that is induces a transition from level 3 to level 1 via the kinetic route. At the next interval the second digit, *x*, is input as a SP pulse. The truth table is given in Table 9.7, and corresponds to the following logic equations.

State ($t + 2$) is the XOR sum of the three inputs (*x*, *y*, and the *carry in*):

$$state(t+2) = state(t+1) \oplus x = (state(t) \oplus y) \oplus x = carry\,in \oplus y \oplus x \quad (9.9)$$

and corresponds the sum out given by Eq. (9.1) above. Using a bar to denote negation

$$\begin{aligned} carry2 &= state(t+1) \otimes x = (carry\,in \oplus y) \otimes x \\ &= (\overline{carry\,in} \otimes y + carry\,in \otimes \bar{y}) \otimes x \\ &= x \otimes y \otimes \overline{carry\,in} + x \otimes \bar{y} \otimes carry\,in \end{aligned} \quad (9.10)$$

The carry out is obtained by reading fluorescence from level 2, either at time $t + 1$ or at $t + 2$, *carry out* = *carry* 1 + *carry* 2, which corresponds to Eq. (9.4) above.

It can now be shown how encoding level 1 as the logical value 1 of the internal state of the machine and level 3 as the logical value 0 and still using a SP pulse as the input, known as *y*, leads to different state equations and different machines. With this convention, the following logic equations are obtained:

$$state(t+1) = \bar{y}\,(t) \otimes state(t) + y(t) \otimes \overline{state(t)} \quad (9.11)$$

$$Output(t) = y(t) \otimes \overline{state(t)} \quad (9.12)$$

0 (level 1)	1	1 (level 3)	0
1 (level 3)	0	1 (level 3)	0
1 (level 3)	1	0 (level 1)	1

Table 9.8 Truth table for the operation of the machine with logical encoding level 1 ≡ 1 and level 3 ≡ 0.

State (t)	$\gamma(t)$ (SP pulse)	*State* ($t+1$)	*Output* (t)
0 (level 3)	0	0 (level 3)	0
0 (level 3)	1	1 (level 1)	1 (kinetic)
1 (level 1)	0	1 (level 1)	0
1 (level 1)	1	0 (level 3)	0 (STIRAP)

The equation for the next state corresponds to a XOR operation identical to Eq. (9.8), while the logical equation for the output corresponds to an INH gate (see Table 9.1). The truth table corresponding to the logic Eqs. (9.11) and (9.12) is given in Table 9.8.

This machine can be logically interpreted in two different ways. The first approach is to note that the machine's output monitors the direction of the change of state as induced by the input. The output is 1 if the pulse induces the logical change of state is $0 \rightarrow 1$. For the change $1 \rightarrow 0$ there is no output. Viewed in this manner [104], the machine is a flip-flop because it maintains a binary state until directed by the input to switch state. Specifically, the machine is similar to a T flip-flop [136] because a single input toggles the state. Flip-flops are key components as they provide a memory element for storing one bit. The data in Table 9.8 show that the state indeed flips, but the machine has no provision for knowing what is the present state of the machine. As discussed above, knowledge of the state of the machine can be readily implemented by applying two SP pulses – one to interrogate the state and one to restore the machine to its initial state. This is in the sense that the machine is endowed with memory.

Another way in which to view the machine represented by Eqs. [9.11–9.12] and Table 9.8 is to see it as a half subtractor, where the minuent digit x is encoded in the state of the machine and the subtrahend γ as a SP pulse, so that the machine computes $x - \gamma$. In a half subtractor, the difference is given by the XOR of the two digits (so that it is equivalent to the sum) but instead of a carry a borrow is needed, which is given by the INH function (see Table 9.1).

$$diff = x \oplus \gamma \tag{9.13}$$

$$borrow = x \otimes \bar{\gamma} \tag{9.14}$$

Therefore, the state at $t + 1$ [Eq. (9.11)] gives the difference while the output [Eq. (9.12)] gives the borrow. Another way of implementing a half subtractor is discussed in Ref. [96], where the initial convention of level $1 \equiv 0$ and level $3 \equiv 1$ is maintained but the input is "reverse" and is now a PS pulse. It can be readily checked that by encoding x in the state and γ as a PS pulse, Eqs. [9.11–9.12] are obtained for the next state and for the output.

There are two ways to implement a full subtractor (see Ref. [96] for details). The first method is by combining two half subtractors, along the lines used for the full adder discussed above. The other method is more interesting because it closely mimics the

implementation of the full adder, which means that the same logic device can be used, either to add or to subtract. This is what is meant by the ability to program a molecule: the same set of levels and of inputs can be used to implement different logic operations.

9.3.2 Finite-State Machines by Electrical Addressing

Until now, only the implementation of combinational circuits and finite-state machines in the gas phase or in solution have been discussed. Here, attention is focused on logic machine implementations on QD arrays. Because of the confinement induced by their nanometer size, QDs have also discrete quantum states but otherwise they are closer to solid-state devices. This is particularly the case for lithographic QDs where the confinement is induced by external voltages that confine electrons in a finite region embedded in a solid-state semi-conductor layer with a high dielectric constant. In this case, the electrons in the QD behave in good approximation as a 2-D electron gas[151]. At this point, interested is centered on a more "chemical" form of QDs – that is, metallic or semiconducting nanosize clusters passivated by organic ligands, for example thioalkane chains. The role of the ligands is to prevent aggregation of the colloidal nanoparticles and to ensure confinement of the electrons in the nanocluster. These QDs are prepared using a wet chemical method, and typically present a size dispersion of at best 5 to 10% in diameter of the cluster. When the size dispersion is narrow enough, they can self-assemble into ordered chains or arrays, and in that sense that they become closer to solid-state devices. They behave in many respects like artificial atoms [152–155] and can be used to make artificial solids [156–161]. When an ordered domain [105] or a chain of QDs [40]can be tethered between electrodes, they can be electrically addressed and probed. This is this type of arrangement used for implementing logic.

Although the details of the system matter a great deal, when discussing the principle of operation of the first logic implementation the only observation needed is that there can be one or more discrete level(s) that can be accessed by varying the electric potential across the dot. The second example discussed in this subsection is built on a system of coupled QDs, and such assemblies have been realized experimentally [162].

Initially, a three-terminal device is considered (see Figure 9.3) so that both a source-drain voltage, V_{sd}, can be applied across the system, and a gate voltage, V_g, in the perpendicular direction. Advantage is taken of the discrete level structure of the QD tethered between the three electrodes of the device to perform more complex operations at the hardware level than is usually done on a transistor.

The implementation of a set–reset finite-state machine is discussed in detail at this point. This is a machine with two logical states, that can accept two inputs, a set input and a reset input. The role of the set input is to bring the machine to logical state 1 if it was in logical state 0, and to do nothing if it is already in state 1. The role of the reset input is to bring the machine back to logical state 0 if it was in state 1 and to do nothing

Table 9.9 Operation of a set–reset machine.

Present state	Set input	Reset input	Name of action	Next State
0	0	0	No change	0
0	1	0	set	1
1	1	0	set	1
1	0	0	No change	1
1	0	1	reset	0
0	0	1	reset	0

if it is already in 0. The case where the two inputs are both 1 is not defined. The operation of the set–reset machine is summarized in Table 9.9, and a state diagram is shown in Figure 9.12.

Here, a single QD tethered in a three-terminal device is considered, that is submitted to a source-drain and to a gate bias. Its discrete level structure is described using the "orthodox" theory [163–165], which assumes that discrete level structure of the QD is due solely to quantization of charge on the dot. The one-electron level spacing of the dot is assumed to be continuous because it is much smaller than the change in electrostatic energy of the QD that occurs when an electron is added to or removed from it by varying the source-drain or the gate bias. The electrostatic energy of a QD with N electrons in a three-terminal device is given by

$$U_N = \frac{Q^2}{2C_T} = \frac{N^2e^2}{2C_T} + \frac{Ne}{C_T}\sum_i C_iV_i + \frac{1}{2C_T}\left(\sum_i C_iV_i\right)^2 \tag{9.15}$$

where Q the effective charge on the dot is given by

$$Q = C_T\Phi = Ne + \sum_{i=l,r,g} C_iV_i \tag{9.16}$$

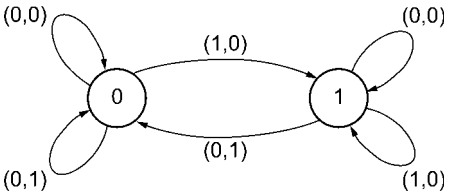

Figure 9.12 State diagram of a set–reset machine. The two possible values of the logical state of the machine are represented by the two circles denoted as 0 or 1. The arrows show the state changing transitions induced by the inputs. The inputs are given next to the arrows as (set,reset).

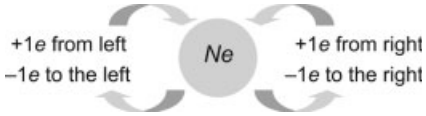

Figure 9.13 Electron transfer to/from the left and right electrode possible for a *N* QD in a three-terminal device.

In Eqs. (9.16) and (9.15), Φ is the electrostatic potential, C_T is the total capacitance of the system ($C_T = C_l + C_r + C_g$ where $C_{l,r}$ are the capacitances of the junctions to the left and right electrodes), and C_g is the capacitance of the gate electrode. $V_{l,r}$ are the source and the drain voltages. For a given gate voltage, an electron will be transferred to the dot or will leave the dot to the left or the right electrode when one of its discrete level falls within the energy window opened by the source-drain bias, V_{sd}, which is the difference between the bias of the right and on the left electrode. As shown in Figure 9.13, if the dot possesses initially N electrons, there are therefore four resonance conditions for electron transfer to/from the left and the right electrodes.

The four resonance conditions are:

$$\begin{aligned}
\Delta E_{l\to QD} &= \frac{e}{C_T}\left(\frac{e}{2} + (Ne + C_g V_g)\right) - e\frac{V}{2} \\
\Delta E_{QD\to l} &= \frac{e}{C_T}\left(\frac{e}{2} - (Ne + C_g V_g)\right) + e\frac{V}{2} \\
\Delta E_{r\to QD} &= \frac{e}{C_T}\left(\frac{e}{2} + (Ne + C_g V_g)\right) + e\frac{V}{2} \\
\Delta E_{QD\to R} &= \frac{e}{C_T}\left(\frac{e}{2} - (Ne + C_g V_g)\right) - e\frac{V}{2}
\end{aligned} \tag{9.17}$$

where $V = V_{sd}$ and a symmetric junction is assumed so that $C_l = C_r$ and $V_l = V_r = V/2$. $\Delta E = U_N - U_{N\pm1}$ must be ≤ 0 for the process to be allowed. It is the free energy difference for adding or removing an electron to the QD. Note that when only the charge on the dot is quantized, $U_N - U_{N\pm1}$ varies linearly with the applied source-drain and gate bias. The threshold for transferring an electron is given by the resonance condition, $\Delta E = 0$, which allows stability maps to be drawn of the charged QD as a function the gate and the source-drain bias. A stability map for $N = 0, 1$ electrons on the dot is shown in Figure 9.14. The areas in gray are the zones where the number of electrons on the QD is stable.

In the "orthodox" theory [164] the rates of transfer from the QD to the source and the drain electrodes are given by

$$\Gamma = \frac{2}{e^2 R}\,\frac{-\Delta E}{1+\exp(\Delta E/kT)} \overset{T\to 0K}{\longrightarrow} \frac{2}{e^2 R}\,|\Delta E|\theta(-\Delta E) \tag{9.18}$$

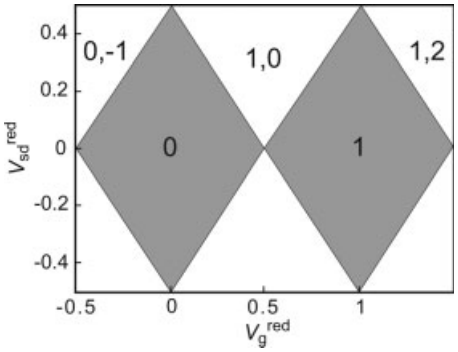

Figure 9.14 Stability map for a quantum dot with $N = 0$ and $N = 1$ electrons, plotted using Eq. (9.17) as a function of the V_g and V_{sd} in reduced units. $V_g^{red} = C_g V_g / e$ corresponds to the number of electrons on the dot, $V_g^{red} = V_{sd} C_T / 2e$.

where R is the resistance of the junction through which the electron passes, and is inversely proportional to the coupling between the QD and the electrode.

For implementation of the set–reset, two charges states of the QD are used, namely $N-1$ and N, where N is the number of extra electrons on the QD. For the simulation shown below, $N=0$ and $N=1$ were utilized. The logical state 0 of the set–reset machine was encoded as the QD with $N=0$ extra electrons, and the logical state 1 of the machine was encoded as the QD with $N=1$ extra electrons. From Figure 9.13, it can be seen that there are two rates for adding an electron to a QD with $N=0$, $\Gamma_{r\rightarrow QD}$ and $\Gamma_{l\rightarrow QD}$, and two rates for removing an electron from a $N=1$ QD, $\Gamma_{QD\rightarrow r}$ and $\Gamma_{QD\rightarrow l}$. Their analytical forms at $T=0$ K are

$$\begin{aligned}\Gamma_{QD\rightarrow l,l\rightarrow QD} &\propto \pm\left(\frac{e}{2C_T}+\frac{C_g V_g}{C_T}\right)\mp\frac{V}{2}\\ \Gamma_{QD\rightarrow r,r\rightarrow QD} &\propto \pm\left(\frac{e}{2C_T}+\frac{C_g V_g}{C_T}\right)\pm\frac{V}{2}\end{aligned} \tag{9.19}$$

These four rates are plotted in Figure 9.15 for a fixed gate voltage as a function of the source-drain bias, V.

In order for the set–reset machine to operate properly, a set voltage must be chosen such that the rate of transfer of an electron from the left electrode to the QD with $N=0$ is much larger than the rate for leaving the dot with $N=1$ to the right electrode, so that an electron is added to the dot and stays on the dot for a finite time. For the reset voltage, it is sufficient that the rate of leaving the dot with $N=1$ to the left electrode is significant. The rate $\Gamma_{r\rightarrow QD}$ corresponds to adding an electron to the QD with $N=0$. The operation of the set–reset device is more robust if the resistance of the right junction is much larger than that of the left one.

To check that the set–reset machine operates properly, the probability of getting an extra electron on the QD is monitored as a function of time while applying a time-dependent source-drain bias. By defining Q as the probability for having $N=1$ extra

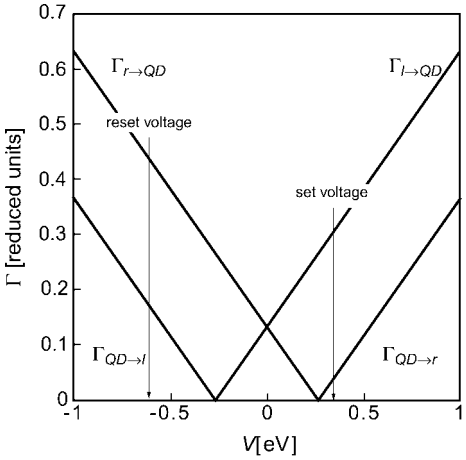

Figure 9.15 The four rates relevant for a QD with $N = 0$ and $N = 1$ electrons computed as a function of the source-drain bias V with a value of the gate voltage $V_g = -0.8$ V. $C_g = C_l = C_r = 0.2$ aF. The reduced units for Γ are $2/e^2R$, where R is the resistance of the junction. A symmetric junction is considered so that $R = R_l = R_r$. R is inversely proportional to the coupling between the QD and the left (right) electrode.

electrons on the dot, and P_l and P_r as the probabilities for this extra electron to be on the left and on right electrode, respectively, the following kinetic scheme is obtained:

$$\begin{aligned}
\frac{dP_l}{dt} &= \Gamma_{QD\to l}Q(t) - \Gamma_{l\to QD}P_l(t) \\
\frac{dQ}{dt} &= \Gamma_{l\to QD}P_l(t) + \Gamma_{r\to QD}P_r(t) - (\Gamma_{QD\to l} + \Gamma_{QD\to r})Q(t) \\
\frac{dP_r}{dt} &= \Gamma_{QD\to r}Q(t) - \Gamma_{r\to QD}P_r(t)
\end{aligned} \tag{9.20}$$

The time profile of the applied source-drain bias (a) and result of the integration of the kinetic scheme (b) are shown in Figure 9.16. The logical state 0 of the device is defined as $P_l \gg Q$, while state 1 is defined as $Q \gg P_l$. It can be seen that the effect of the set voltage is to fill the dot with one extra electron, whilst applying the reset pulse empties the dot of that extra electron. This shows that a single QD with two electrically addressable discrete levels can operate as a set–reset machine. It has also been shown that varying not only the source-drain but also the gate bias allows a full adder to be implemented on this system [106].

This subsection is concluded with a description of the implementation of another form of finite-state machine, a counter, on an array of two QDs anchored on a surface. This implementation is based on a scheme for addressing and/or reading the states of the dots electrically or optically that has been experimentally realized and characterized [162] (see Figure 9.17).

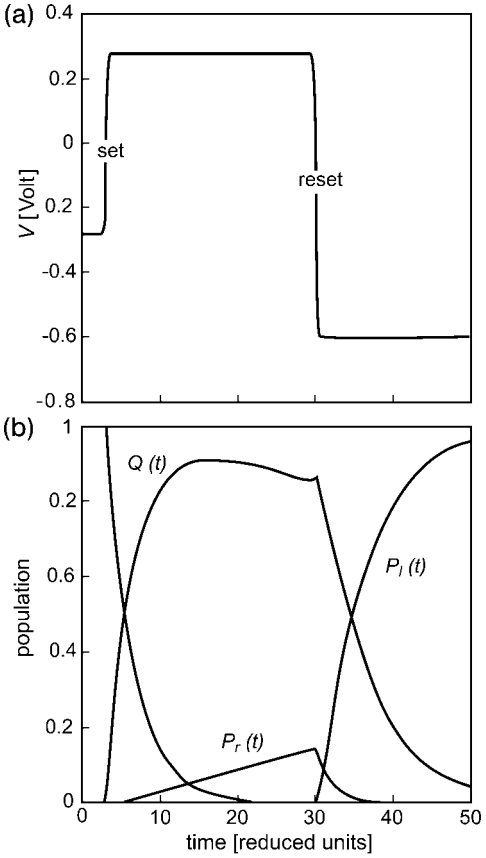

Figure 9.16 (a) Voltage–time profile and (b) time-dependent probability for the extra electron to be localized on the QD, $Q(t)$, on the left electrode, $P_l(t)$, and on the right electrode, $P_r(t)$. In Eq. (9.20), the rates are expressed in reduced units and the time is scaled correspondingly.

A counter [136] is a machine that is able to accept N inputs and to provide an output for every N inputs. The states of the counter are S_i, $i = 0, 1, 2, \ldots, N-1$ and transition can occur between successive states only when an input i, $i = 0, 1, 2, \ldots, N-1$, is received. After the count of N inputs, the state S_{N-1} is reached, an output is produced and the next input resets the counter to its initial state, S_0.

In the implementation based on the device shown in Figure 9.17 the index of the state is determined by the number of extra electrons on the Au QD. This number can be controlled optically or electrically (further details may be found in Refs. [137, 162]).

The counter functions as follows. First, the CdS QD is irradiated in a solution of TEA (10^{-2} M) so as to charge the Au QD. The irradiation is then stopped. The initial state, S_0, corresponds physically to the Au QD charged with four extra electrons. This number can be determined using surface plasmon resonance spectroscopy, by measuring the shift of the plasmon resonance of the gold surface due to the charging

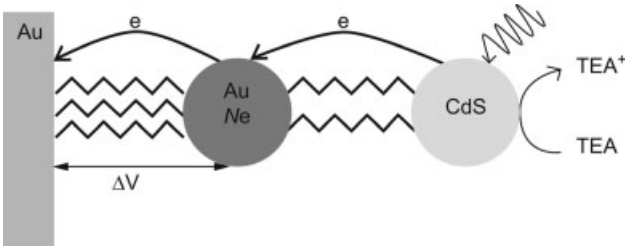

Figure 9.17 An experimentally realized [162] opto-electrically addressed array of two QDs anchored on a surface. The device can be used as a counter. The Au QDs are linked to the gold surface by a long-chain alkyl monolayer, and covalently to a semi-conducting CdS QD. The optical excitation of the CdS QD induces an electron transfer to the Au QD that is compensated by triethanolamine (TEA) present in the electrolyte solution. While the optical excitation is on, extra electrons accumulate on the Au QD and a potential drop is maintained across the junction between the Au QDs and the conductive gold surface. The charging of the Au QD can be optically monitored by changes in the resonance spectrum of the surface plasmon.

of the Au QD. On each occasion that an input is to be provided an input the index of the state must be incremented; this is done by decreasing the potential applied to the Au surface by a step sufficient to discharge an electron onto the surface. The magnitude of the required voltage drop is determined by the capacitance of the Au QD – that is, by the energy needed to charge or discharge the dot by one electron [137]. In the experiment the Au QD is passivated by a ligand, tiopronin, that has a high dielectric constant (16; see Ref. [162]), so that the charging energy is exceptionally low ($\approx$30 meV for Au QD of 2.3 ± 0.5 nm diameter). When the dot is fully discharged, after four voltage drops, S_4 is reached; this is the last state of the counter for which there are no extra electrons on the dot. At this point, the counter must be returned to the state S_0, so that it is available for the next counting cycle, and an output signal must then be provided. Unlike the usual system for counters, in this scheme the last input does not reset the counter to the state S_0. For this reason, even though for a dot with four extra electrons, there are five states – S_0, S_1, S_2, S_3, and S_4 – and modulo 4 is counted rather than modulo 5, the last step, $S_3 \rightarrow S_4$, is used to produce the output and reset the counter. The output is produced by monitoring the disappearance of the plasmon angle shift or by measuring the value of the surface potential. To reset the counter, the CdS dot is irradiated again. It should be noted that, in principle, the maximal number of four extra electrons on the dot is not a limitation, but up to 15 oxidation states of monolayer-protected Au QDs have been reported [166]. It is possible, therefore, to implement counters with a higher value of N.

9.4 Perspectives

The entire discussion in this chapter is based on the premise that there is a desire to design molecule-based logic circuits and not only switches. Results to date that have

been validated by *proof of concept* experiments, include:

- the implementation of *combinational circuits on a single molecule;*
- the *concatenation of logic operations*, whether performed on different molecules (intermolecular) or performed within the same molecule by communicating results carried out on different functional groups (intramolecular);
- the implementation of a *finite-state logic machine on a single molecule* and beyond that, *programming* of a single molecule; and
- using both electrical and optical addressing and readout with the advantage that it is not necessary to be able to address many states, because with two states a full adder can already be performed.

Technical studies in progress exploit these results towards increasing the logical capacity and depth (= number of switches) that can be implemented on a single molecule, or on a supramolecular assembly by the application to multifunctional group molecules where the intramolecular dynamics are used to concatenate the logical operations carried separately by the different groups. Next, in the order of integration is the assembly and concatenation of an array of molecules or an array of quantum dots.

Further studies are also needed to take even greater advantage of the large number of quantum states available, in a hierarchical order (electronic, backbone vibrations, torsions, rotations), which allows the processing in one cycle of far more information than a binary (classical or quantum) gate and, in the same direction, the use of more sophisticated optical and electrical inputs and readouts.

The first results to reach the level of technological implementation will most likely be the use of a single molecule not as a switch but rather as a combinational circuit. This will likely happen in the context of the architecture of a 2-D array cross-bar, which is the favored device geometry as foreseen by Hewlett Packard and others. However, even this progress will take time before it becomes a technology. The essential difference to be advocated is that at each node is placed not a switch but a single molecule acting as the equivalent of an entire network of switches. The very fast logic is conducted within the node, but the slower, wire-mediated communication between the nodes will remain. In the second round, communication between the nodes will be carried out by concatenation through self-assembly of the array using molecular recognition. Part of this endeavor is to achieve realistic programming abilities with special reference to selective intramolecular dynamics.

The key further breakthroughs that are currently required include:

- The design of molecular logic circuits that can be cycled reliably many times, and to explore whether this can be done using all-optical schemes.
- Input/output operations that reduce dissipation and allow fan-out and macroscopic interface, with special reference to the use of pulse shaping, electrical read/write and integrate storage within the logic unit.
- Beyond what is already available, it will be necessary to improve concatenation in order to reduce not only the need for cycling but also for interfacing with the macroscopic world. This will in turn lead to a need for molecular systems with special reference to devices on surfaces and their application as logic units.

A Survey of Bio-Inspired and Other Alternative Architectures

Dan Hammerstrom

10.1
Introduction

Since the earliest days of the electronic computer, there has always been a small group of people who have seen the computer as an extension of biology, and have endeavored to build computing models and even hardware that are inspired by, and in some cases are direct copies of, biological systems. Although biology spans a wide range of systems, the primary model for these early efforts has been neural circuits. Likewise, in this chapter the discussion will be limited to neural computation.

Several examples of these early investigations include McCulloch-Pitts *Logical Calculus of Nervous System Activity* [2], Steinbuch's *Die Lernmatrix* [3], and Rosenblatt's *Perceptron* [4]. At the same time, an alternate approach to intelligent computing, *Artificial Intelligence* (AI), that relied on higher-order symbolic functions, such as structured and rule-based representations of knowledge, began to demonstrate significantly greater success than the neural approach. In 1969, Minsky and Papert [5] of the Massachusetts Institute of Technology published a book that was critical of the then current "bio-inspired" algorithms, and which succeeded in eventually ending most research funding for that approach. Consequently, significant research funding was directed towards AI, and the field subsequently flourished. The AI approach, which relied on symbolic reasoning often represented by a first-order calculus and sets of rules, began to exhibit real intelligence, at least on toy problems. One reasonably successful application was the "expert" system, and there was even the development of a complete language, ProLog, dedicated to logical rule-based inference.

A few expert system successes were also enjoyed in actually fielded systems, such as Soar [6], the development of which was started by Alan Newell's group at Carnegie Mellon University. However, by the 1980s AI in general was beginning to lose its luster after 40 years of funding with ever-diminishing returns.

Since the 1960s, however, there have always been groups that continued to study biologically inspired algorithms, and two such projects – mostly as a result of their

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

being in the right place at the right time – had a huge impact which re-energized the field and led to an explosion of research and funding. The first project incorporated the investigations [7] of John Hopfield, a physicist at Caltech, who proposed a model of auto-associative memory based on physical principles such as the Ising theory of spin-glass. Although Hopfield nets were limited in capability and size, and others had proposed similar algorithms previously, Hopfield's formulation was both clean and elegant. It also succeeded in bringing many physicists, armed with sophisticated mathematical tools, into the field. The second project was the "invention" of the back-propagation algorithm by Rumelhart, Hinton, and Williams [8]. Although there too similar studies had been conducted previously [9], the difference with Rumelhart and colleagues was that they were cognitive scientists creating a set of techniques called parallel distributed processing (PDP) models of cognitive phenomena, where back-propagation was a part of a larger whole.

At this point, it would be useful to present some basic neuroscience, followed by details of some of the simpler algorithms inspired by this biology. This information will provide a strong foundation for discussing various biologically inspired hardware efforts.

10.1.1 Basic Neuroscience

In simplified terms, neural circuits consist of large numbers of parallel processing components, the *neurons*. These tend to be slow in operation, with typical switching times on the order of milliseconds, and consequently the brain uses significant parallelism rather than speed to perform its complex tasks. Adaptation comes in short- and long-term versions, and can result from a variety of complex interactions.

Although most neurons are exceptions to the canonical neuron shown in Figure 10.1, the neuron illustrated is sufficiently complex to demonstrate the basic principles. Via various ion channels, neurons maintain a constant negative voltage of approximately -70 mV relative to the ambient environment. This neuron consists of a *dendritic* tree for taking inputs from other neurons, a body or *soma*, which basically

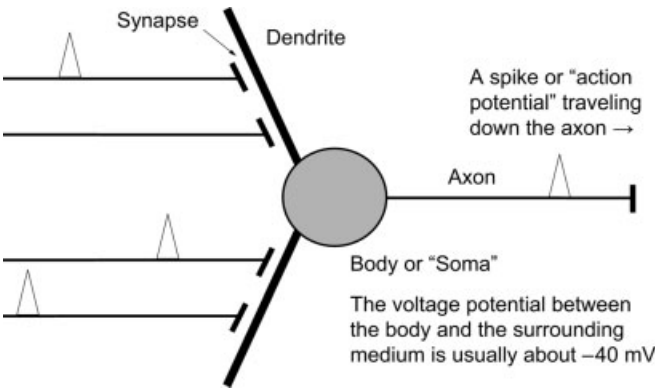

Figure 10.1 An abstract neuron.

performs charge summation, and an output, the *axon*. Inter-neuron communication is generally via pulses or spikes. Axons form synapses on dendrites and signal the dendrite by releasing small amounts of neurotransmitter, which is taken up by the dendrite.

Axons from other neurons connect via synapses onto the dendritic tree of each neuron. When an axon fires it releases a neurotransmitter into the junction between the *presynaptic* axon and the *postsynaptic* dendrite. The neurotransmitter causes the dendrite to depolarize slightly, and this charge differential eventually reaches the body or soma of the neuron, depolarizing the neuron.

When a neuron is sufficiently depolarized it passes a threshold which causes it to generate an *action potential*, or output spike, which moves down the axon to the next synapse. When an output spike is traveling down an axon, it is continuously regenerated allowing for arbitrary fan-out.

While the dendrites are depolarizing the neuron, the resting potential is slowly being restored, creating what is known as a "leaky integrator." Unless enough action potentials arrive within a certain time window of each other, the depolarization of the soma will not be sufficient to generate an output action potential.

In addition to accumulating signals and creating new signals, neurons also learn. When a spike arrives via an axon at a synapse, it "presynaptically" releases a neurotransmitter, which causes some depolarization of the postsynaptic dendrite. Under certain conditions, the effect of a single spike can be modified, typically increased or "facilitated", where it causes a greater depolarization at the synapse. When the effect that an action potential has on the postsynaptic neurons is enhanced, the synapse is said to be *potentiated*, and learning has occurred. One form of this is called long-term potentiation (LTP), as such potentiation has been shown to last for several weeks at a time and may possibly last much longer. LTP is one of the more common learning mechanisms, and has been shown to occur in several areas of the brain whenever the inputs to the neuron and the output of the neuron correlate within some time window. Learning correlated inputs and outputs is also called Hebb's law, named after Donald Hebb who proposed it in 1947. Synapses can also lose their facilitation; one example of this is a similar mechanism called long-term depression (LTD), which generally occurs when an output is generated and there is no input at a particular synapses.

Postsynaptic excitation can either be *excitatory* (an excitatory postsynaptic potential or EPSP), which leads to accumulating even more charge in the soma, or *inhibitory* (an inhibitory postsynaptic potential or IPSP), which tends to drain charge off of the soma, making it harder for a neuron to fire an action potential. Both capabilities are needed to control and balance the activation of groups of neurons. In one model, the first neuron that fires tends to inhibit the others in the group leading to what is called a "winner-take-all" function.

10.1.2 A Very Simple Neural Model: The Perceptron

One of the first biologically inspired models was the perceptron which, although very simple, was still based on biological neurons. The primary goal of a perceptron is to

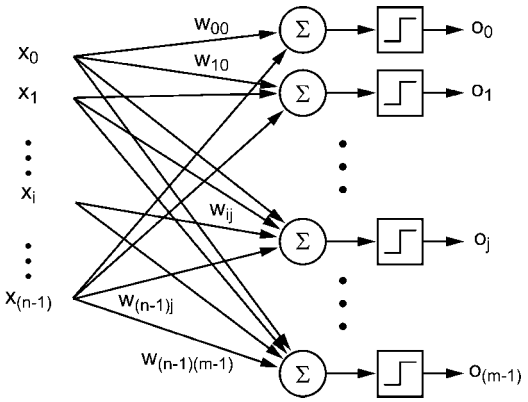

Figure 10.2 A single-layer perceptron.

do classification. Perceptron operation is very simple, as it has a one-dimensional synaptic weight vector and takes another, equal size, one-dimensional vector as input. Normally the input vector is binary and the weight vectors positive or negative integers. During training, a "desired" signal is also presented to the perceptron. If the output matches the training signal, then no action is taken; however, if the output is incorrect and does not match the training signal, then the weights in the weight vector are adjusted accordingly. The perceptron learning rule, which was one of the first instances of the "delta rule" used in most artificial neural models, incremented or decremented the individual weights depending on whether they were predictive of the output or not. A single-layer perceptron is shown in Figure 10.2. Basic perceptron operation is

$$o_j = f\left(\sum_{i=1}^{n} w_{ij}x_i\right) = f(W_j^T X)$$
$$O = f(W^T X)$$

where $f()$ is an activation function, and is a step function here (if $sum > 0$, then $f(sum) = 1$); however, $f()$ can also be a smooth function (see below). A "layer" has some number (two or more) of perceptrons, each with its own weight vector and individual output value, leading to a weight matrix and an output vector. In a single "layer" of perceptrons, each one sees the same input vector.

The Delta Rule, which is used during learning is,

$$\Delta w_{ij} = \alpha(d_j - o_j)x_i$$

where d_j is the desired output, and o_j is the actual output.

The delta rule is fundamental to most adaptive neural network algorithms. Rosenblatt proved that if a data set is linearly separable, the perceptron will eventually find a plane that separates the set. Figure 10.3 shows the two-dimensional (2-D) layout of data for, first, a linearly separable set of data and, second, for a non-linearly separable set. Unfortunately, if the data are not linearly separable the perceptron fails miserably, and this was the point of "...the book that killed neural networks",

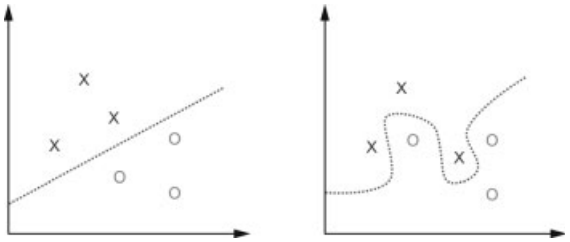

Figure 10.3 Linear (left) and non-linear (right) classification.

Perceptrons by Marvin Minsky and Seymour Papert (1968). Perceptrons cannot solve non-linearly separable problems; neither do they function in the kind of multiple layer structures that may be able to solve non-linear problems, as the algorithm is such that the output layer cannot tell the middle layer what its desired output should be. Attention is now turned to a description of the multi-layer perceptron.

10.1.3 A Slightly More Complex Neural Model: The Multiple Layer Perceptron

The invention of the multi-layer perceptron constituted, to some degree, a "victory" against the "evil empire" of symbolic computing. The Minsky and Papert book focused primarily, through numerous sophisticated examples, on how perceptrons, as envisioned at that time, could not solve non-linear problems, an excellent example being the XOR problem. Although there are a number of variations, back-propagation (BP) allowed the use of multiple, non-linear layers, and is sometimes referred to as a multi-layer perceptron (MLP).

Although the derivation of BP is beyond the scope of this chapter, some of the characteristics that allowed it to extend perceptron-like learning to multiple layers can be briefly summarized. First, instead of a discrete step function for output, a continuous activation function is used. As with the perceptron, there is also a training or "desired" signal, and by actually quantifying the error of the output as a function (generally least means square) an error surface is created. The gradient of the error surface can then be found and used to adjust the weights. By using the chain rule from calculus the error can then be back-propagated through the various levels.

In summary, the steps of the BP algorithm are:

- Present an input vector to the first layer of the network.
- Calculate the output for each layer, moving forward to network output.
- Calculate the error delta at the output (using actual output and the externally supplied target output, d).
- Use the computed error deltas at the output to compute the error deltas at the next layer, etc., moving backward through the net.
- After all error deltas have been computed for every node, use the delta rule to incrementally update all the weights in the network. (Note: the feedforward input activation values for each connection must be remembered.)

Even two-level networks can approximate complex, non-linear functions. Moreover, this technique generally finds good solutions, which are compact, leading to fast, feed-forward (non-learning) execution time. Although it has been shown to approximate Bayesian decisions (i.e. it results in a generally good estimate of where Baye's techniques would put the decision surface), it can have convergence problems due to many non-local minima. It is also computationally intensive, often taking days to train with complex large feature sets.

10.1.4 Auto-Association

Another important family of networks are associative networks, one example of which (as given above) is the Hopfield net. Here, details of a simple associative network developed by G. Palm [10] will be presented (this was in fact developed before the studies of Hopfield). One useful variation implements an *auto-associative network* that is an overly simplistic approximation of the circuits in the mammalian neocortex. Auto-associative networks have been studied extensively. In its simplest form, an associative memory maps an input vector to an output vector. When an input is supplied to the memory, its output is a "trained" vector with the closest match, assuming some metric, to the given input. Auto-association results when the input and output vectors are in the same space, with the input vector being a corrupted version of one of the training vectors. With *best-match association*, when a noisy or incomplete input vector is presented to the network, the "closest" training vector can usually be recalled reliably. In auto-association the output is fed back to the input, which may require several iterations to stabilize to a trained vector.

Here, it is assumed that the vectors are binary and the distance metric between two vectors is simply the number of bits that are different – that is, the Hamming distance.

The Palm associative network maps input vectors to output vectors, where the set of input vector to output vector mappings are noted as $\{(x^\mu, y^\mu), \mu = 1, 2, \ldots, M\}$. There are M mappings, and both x^μ and y^μ are binary vectors with size of m and n respectively. x^μ and y^μ are sparsely encoded, with $\sum_{i=1}^{m} x_i = l\,(l \ll m)$ and $\sum_{j=1}^{n} y_j = k$ $(k \ll n)$. Here, l and k are the numbers of active nodes (non-zero) in the input and output vectors, respectively. In training, the "clipped" Hebbian "outer-product," learning rule is generally used, and a binary weight matrix W is formed by $W = \vee_{\mu=1}^{M}[y^\mu \cdot (x^\mu)^T]$. Such batch computation has the weights computed off-line and then down-loaded into the network. It is also possible to learn the weights adaptively [11].

During recall, a noisy or incomplete input vector $\tilde{x}$ is applied to the network, and the network output is computed by $\tilde{y} = f(W \cdot \tilde{x} - \theta)$, θ is a global threshold, and $f()$ is the Heaviside step function, where an output node will be 1 (active) if its dendritic sum $x_i = \sum_{j=1}^{m} w_{ij}\tilde{x}_j$ is greater than the threshold θ; otherwise, it is 0. To set the threshold, the "k winners take all (k-WTA) rule" is used, where k is the number of active nodes in an output vector. The threshold, θ, is set so that only those nodes that have the k maximum dendritic sums are set to "1", and the remaining nodes are set to "0". The k-WTA threshold is very close to the minimum error threshold. The k-WTA

operation plays the role of competitive lateral inhibition, which is a major component in all cortical circuits. In the BCPNN model of Lansner and his group [11], the nodes are divided into hypercolumns, typically $\sqrt{N}$ nodes in each of the $\sqrt{N}$ columns, with 1-WTA being performed in each column.

An auto-associative network starts with the associative model just presented and feeds the output back to the input, so that the x and y are in the same vector space and $l = k$. This auto-associative model is called an *attractor model* in that its state space creates an energy surface with most minima ("attractor basins") occurring when the state is equal to a training vector. Under certain conditions, given an input vector x', then the output vector y that has the largest conditional probability $P(x'|y)$ is the most likely training vector in a Bayesian sense. It is possible to define a more complex version with variable weights, as would be found during dynamic learning, which also allows the incorporation of prior probabilities [12].

10.1.5
The Development of Biologically Inspired Hardware

With BP and other non-linear techniques in hand, research groups began to solve more complex problems. Concurrent to this there was an explosion in neuroscience that was enabled by high-performance computing and sophisticated experimental technologies, coupled with an increasing willingness in the neuroscience community to begin to speculate about the function of the neural circuits being studied. As a result, research into artificial neural networks (ANNs) of all types gained considerable momentum during the late 1980s, continuing until the mid-1990s when the research results began to slow down. However, like AI before it – and fuzzy logic, which occurred concurrently – ANNs had trouble in scaling to solve the difficult problems in intelligent computing. Nevertheless, ANNs still constitute an important area of research, and ANN technologies play a key role in a number of real-world applications [13, 14]. In addition, they are responsible for a number of important breakthroughs.

During the heady years of the late 1980s and early 1990s, while many research groups were investigating theory, algorithms, and applications, others began to examine hardware implementation. As a consequence, there quickly evolved three schools of thought, though with imprecise dividing lines between them:

- The first concept was to build very specialized analog chips where, for the most part, the algorithms were hard-wired into silicon. Perhaps the best known was the aVLSI (low-power analog VLSI) technology developed by Carver Mead and his students at Caltech.

- The second concept was to build more general, highly parallel digital, but still fairly specialized chips. Many of the ANN algorithms were very computer-intensive, and it seemed that simply speeding up algorithm execution – and especially the learning phase – would be a big help in solving the more difficult problems and the commercialization of ANN technology. During the late 1980s and early 1990s these chips were also significantly faster than mainstream desktop technology; however, this second group of chips incorporated less biological realism than the analog chips.

- The third option was to use off-the-shelf hardware, digital signal processing (DSP) and media chips, and this ultimately was the winning strategy. This approach was successful because the chips were used in a broader set of applications and had manufacturing volume and software inertia in their favor. Their success was also assisted by Amdahl's law (see Section 10.2.1).

The aim of this chapter is to review examples of these biologically inspired chips in each of the main categories, and to provide detailed discussions of the motivation for these chips, the algorithms they were emulating, and architecture issues. Each of the general categories presented is discussed in greater detail as appropriate. Finally, with the realm of nano- and molecular-scale technology rapidly approaching, the chapter concludes with a preview of the future of biologically inspired hardware.

10.2 Early Studies in Biologically Inspired Hardware

The hardware discussed in this chapter is based on neural structures similar to those presented above, and, as such, is designed to solve a particular class of problems that are sometimes referred to as "intelligent computing". These problems generally involve the transformation of data across the boundary between the real world and the digital world, in essence from sensor readings to symbolic representations usable by a computer; indeed, this boundary has been called "the digital seashore".[1)] Such transformations are found wherever a computer is sampling and/or acting on real-world data. Examples include the computer recognition of human speech, computer vision, textual and image content recognition, robot control, optical character recognition (OCR), automatic target recognition, and so on. These are difficult problems to solve on a computer, as they require the computer to find *complex structures and relationships* in massive quantities of low-precision, ambiguous, and noisy data. These problems are also very important, and an inability to solve them adequately constitutes a significant barrier to computer usage. Moreover, the list of ideas has been exhausted, as neither AI, ANNs, fuzzy logic, nor Bayesian networks[2)] have yet enabled robust solutions.

At the risk of oversimplifying a complex family of problems, the solution to these problems will, somewhat arbitrarily, be partitioned into two domains: the "front end" and the "back end" (see Figure 10.4):

- *Front-end* operations involve more direct access to a signal, and include filtering and feature extraction.

1) Hiroshi Ishii, MIT Media Lab.

2) "A Bayesian network (or a belief network) is a probabilistic graphical model that represents a set of variables and their probabilistic independencies". Wikipedia, http://www.wikipedia.org/.

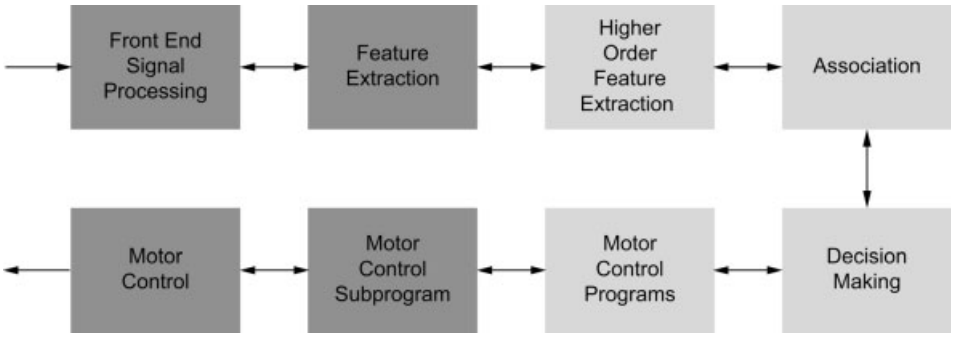

Figure 10.4 A canonical system.

- *Back-end* operations are more "intelligent", and include storing abstract views of objects or inter-word relationships.

In moving from front end to back end, the computation becomes increasingly interconnect driven, leveraging ever-larger amounts of diffuse data at the synapses for the connections. Much has been learned about the front end, where the data are input to the system and where there are developments in traditional as well as neural implementations. Whilst these studies have led to a useful set of tools and techniques, they have not solved the whole problem, and consequently more groups are beginning to examine the back-end – the realm of the cerebral cortex – as a source of inspiration for solving the remainder of the problem. Moreover, as difficult as the front-end problems are, the back-end problems are even more so. One manifestation of this difficulty is the "perception gap" discussed by Lazzaro and Wawrzynek [15], where the feature representations produced by more biologically inspired front-end processing are incompatible with existing back-end algorithms.

A number of research groups are beginning to refer to this "backend" as intelligent signal processing (ISP), which augments and enhances existing DSP by incorporating contextual and higher level knowledge of the application domain into the data transformation process. Simon Haykin (McMaster University) and Bart Kosko (USC) were editors of a special issue of the *Proceedings of the IEEE* [16] on ISP, and in their introduction stated:

> "*ISP uses learning and other 'smart' techniques to extract as much information as possible from signal and noise data.*"

If you are classifying at Baye's optimal rates and you are still not solving the problem, what do you do next? The solution is to add more knowledge of the process being classified to your classification procedures, which is the goal of ISP. One way to do this is to increase the contextual information (e.g. higher-order relationships such as sentence structure and word meaning in a text-based application) available to the algorithm. It is these complex, "higher-order" relationships that are so difficult for us to communicate to existing computers and, subsequently, for them to utilize efficiently when processing signal data.

Humans make extensive use of contextual information. We are not particularly good classifiers of raw data where little or no context is provided, but we are masters of leveraging even the smallest amount of context to significantly improve our pattern-recognition capabilities.

One of the most common contextual analysis techniques in use today is the Hidden Markov Model (HMM) [17]. An HMM is a discrete Markov model with a finite number of states, that can be likened to a probabilistic finite-state machine. Transitions from one state to the next are determined probabilistically. Like a finite-state machine, a symbol is emitted during each state transition. In an HMM the selection of the symbol emission during each state transition is also probabilistic. If the HMM is being used to model a word, the symbols could be phonemes in a speech system. As the symbols are not necessarily unique to a particular state, it is difficult to determine the state that the HMM is in simply by observing the emitted symbols – hence the term "hidden." These probabilities can be determined from data of the real-world process that the HMM is being used to model. One variation is the study of Morgan and Bourlard [18], who used a large BP network to provide HMM emission probabilities.

In many speech-recognition systems, HMMs are used to find simple contextual structure in candidate phoneme streams. Most HMM implementations generate parallel hypotheses and then use a dynamic programming algorithm (such as the Viterbi algorithm) to find a match that is the most likely utterance (or most likely path through the model) based on the phonemes captured by preprocessing and capturing features from the speech stream, and the probabilities used in constructing the HMM. However, HMMs have several limitations:

- They grow very large if the probability space is complex, such as when pairs of symbols are modeled rather than single symbols; yet most human language has very high order structure.
- The "Markov horizon", which is a fundamental definition of Markov models and makes them tractable analytically, also contributes to the inability to capture higher-order knowledge. Many now believe that we have passed the point of diminishing returns for HMMs in speech recognition.

The key point here is that most neuro-inspired silicon – and in particular the analog-based components – is primarily focused on the front-end "DSP" part of the problem, since robust, generic back-end algorithms (and subsequently hardware) have eluded identification. It has been argued by some that if the front end was performed correctly, then the back-end would be easier, but whilst it is always easier to do better in front-end processing the room for improvement is smaller there. Without robust back-end capabilities, general solutions will be more limited.

10.2.1 Flexibility Trade-Offs and Amdhal's Law

During the 1980s and early 1990s, when most of the hardware surveyed in this chapter was created, there was a perception that the algorithms were large and

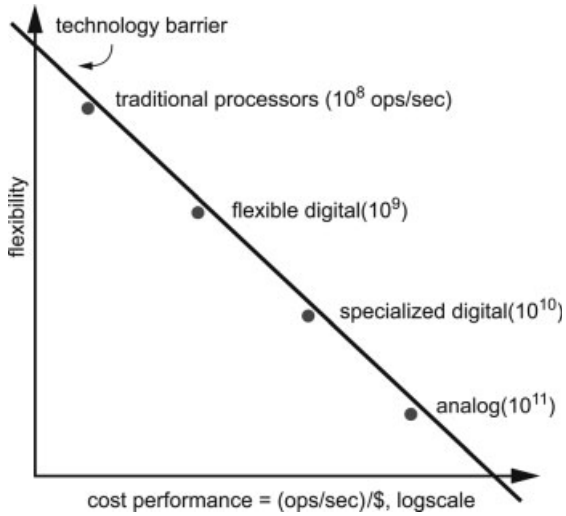

Figure 10.5 The flexibility–cost/performance trade-off.

complex and therefore slow to emulate on the computers of that time. Consequently, specialized hardware to accelerate these algorithms was required for successful applications. What was not fully appreciated by many was that the performance of general-purpose hardware was increasing faster than Moore's law, and that the existing neural algorithms did not scale well to the large sizes that would have fully benefited from special purpose hardware. The other problem was *Amdahl's law*.

As discussed above, these models have extensive concurrency which naturally leads to massively parallel implementations. The basic computation in these models is the multiply-accumulate operation that forms the core of almost all DSP and which can be performed with minimal, fixed point, precision. Also during the early 1990s, when many of the studies on neural inspired silicon were carried out, microprocessor technology was actually not fast enough for many applications.

The problem is that neural network silicon is highly specialized and there are specific risks involved in its development. One way to conceptualize the trade-offs involved in designing custom hardware is shown in Figure 10.5. Although *cost-performance*[3)] can be measured, flexibility cannot be assessed as easily, and so the graph in Figure 10.5 is more conceptual than quantitative. The general idea is that the more a designer hard-wires an algorithm into silicon, the better the cost-performance of the device, but the less flexible.

The line, which is moving slowly to the right according to Moore's law, shows these basic trade-offs and is, incidentally, not likely to be linear in the real world. Another

3) In this chapter, cost-performance is measured by (operations/second)/cost. The cost of producing a silicon chip is directly related (in a complex, non-linear manner) to the *area* of the chip. Larger chips are generally more expensive, as used here. More recently, however, other factors such as *power consumption* have become equally, if not more, important.

assumption is that the algorithms being emulated can be implemented at many different points on that scale, which is not always true either.

An important assumption in this analysis is that most applications require a wide range of computations, although there are exceptions, as in most real-world systems the "recognition" component is only a part of a larger system. So, when considering specialized silicon for such a system, the trade-off shown in Figure 10.5 must be factored into the analysis. More general-purpose chips tend to be useful on a larger part of the problem, but will lead to a sacrifice in cost-performance. On the other hand, the more specialized chips tend to be useful on a smaller part of the problem, but at a much higher cost-performance. Related to this trade-off then is Amdahl's law [19], which has always been a fundamental limitation to fully leveraging parallel computing,

> *Amdahl's law*: the speed-up due to parallelizing a computation is proportional to that portion of the computation that cannot be parallelized.

Imagine, for example, that there is a speech-recognition application, and 20% of the problem can be cast into a simplified parallel form. If a special-purpose chip was available that speeded up that 20% portion by 1000-fold, then the total system performance increase would be about 25%:

$$1/(0.8 + (0.2/1000)) = 1.25$$

Of course, depending on the cost of the 1000-fold chip, the 25% may still be worthwhile. However, if a comparably priced chip was available that was slower but more flexible and could parallelize 80% of the application, albeit with a more moderate speed increase (say 20-fold), then the total system performance would be over 400%:

$$1/(0.2 + (0.8/20)) = 4.17$$

Almost all computationally intensive pattern recognition problems have portions of sequential computation, even if it is just moving data into and out of the system, data reformatting, feature extraction, post-recognition tasks, or computing a final result. Amdahl's law shows that these sequential components have a significant impact on total system performance. As a result, the biggest problem encountered by many early neural network chips was that they tended to speed up a small portion of a large problem by moving to the right in Figure 10.5. For many commercial applications, after all was said and done, the cost of a specialized neural chip did not always justify the resulting modest increase in total system performance.

During the mid-1990s, desktop chips were doubling their performance every 18 to 24 months. Then, during the mid-1990s both Intel and AMD added on-chip SIMD coprocessing in the form of MMX which, for the Intel chips, has eventually evolved to SSE3 [20]. These developments, for the most part, spelled the death of most commercial neural net chips. However, in spite of limited commercial success most neural network chips were very interesting implementations, often with elegant engineering. A representative sample of some of these chips will be examined briefly in the remainder of this chapter.

It should not be concluded from the discussions so far that specialized chips are never economically viable. Rather, the continued success of graphics processors and DSPs are examples of specialized high-volume chips, and some neural networks chips[4] have found very successful niches. Nonetheless, it does illustrate some of the problems involved in architecting a successful niche chip. An example is the commercial DSP chips used for signal processing and related applications, these provide unique cost-performance, efficient power utilization, and just the right amount of specialization in their niche to hold their own in volume applications against general-purpose processors. In addition, they have enough volume and history to justify a significant software infrastructure.

In light of what is now known about Amdahl's law and ISP, the history and state of the art of neuro-inspired silicon can now be surveyed.

10.2.2
Analog Very-Large-Scale Integration (VLSI)

There is no question that the most elegant implementation technique developed for neural emulation is the sub-threshold CMOS technology pioneered by Carver Mead and his students at CalTech [21]. Most MOS field effect transistors (MOSFETs) used in digital logic are operated in two modes, either off (0) and on (1). For the *off* state the gate voltage is more or less zero and the channel is completely closed. For the *on* state, the gate voltage is significantly above the transistor threshold and the channel is saturated. A saturated *on* state works fine for digital, and is generally desired to maximize current drive. However, the limited gain in that regime restricts the effectiveness of the device in analog computation. This is due to the fact that the more gain the device has, the easier it is to leverage this gain to create circuits that perform useful computation and which also are insensitive to temperature and device variability.

However, if the gate voltage is positive (for the nMOS gate) but below the point where the channel saturates, the FET is still on, though with a much lower current. In this mode, which sometimes is referred to as "weak inversion", there is useful gain and the small currents significantly lower the power requirements, though FETs operating in this mode tend to be slower. Carver Mead's great insight was that when modeling biologically inspired circuits, significant computation could be carried out using simple FETs operating in the sub-threshold regime where, like real neurons, performance resulted from parallelism and not the speed of the switching devices. Moreover, as Carver and colleagues have shown, these circuits do a very good job approximating a number of neuroscience functions.

By using analog voltage and currents to represent signals, the considerable expense of converting signal data into digital, computing the various functions in digital, and then converting the signal data back to analog, was eliminated. Neurons operate slowly and are not particularly precise, yet when combined appropriately they perform complex and remarkably precise computations. The goal of the aVLSI

4) One example is General Vision; http://www.general-vision.com/.

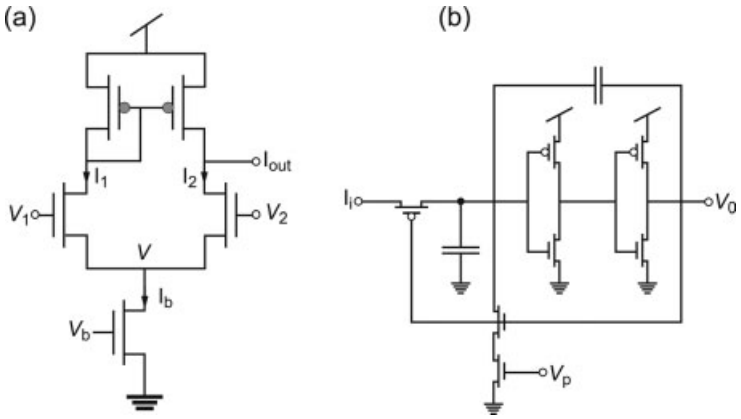

Figure 10.6 Basic aVLSI building blocks. (a) A transconductance amplifier; (b) an integrate and fire neuron.

research community has been to create elegant VLSI sub-threshold circuits that approximate biological computation.

One of the first chips developed by Carver *et al*. was the silicon retina [22]. This was an image sensor that performed localized adaptive gain control and temporal/spatial edge detection using simple "local neighborhood" functional extensions to the basic photosensitive cell. There subsequently followed a silicon cochlea and numerous other simulations of biological circuits.

Two examples of these circuits are shown in Figure 10.6. A transconductance amplifier (voltage input, current output) and an "integrate and fire" neuron are two of the most basic building blocks for this technology. The current state of aVLSI research is very well described by Douglas [23], of the Neuroinformatics Institute, ETH-Zurich:

> *Fifteen years of Neuromorphic Engineering: progress, problems, and prospects*. Neuromorphic engineers currently design and fabricate artificial neural systems: from adaptive single chip sensors, through reflexive sensorimotor systems, to behaving mobile robots. Typically, knowledge of biological architecture and principles of operation are used to construct a physical emulation of the target neuronal system in an electronic medium such as CMOS analog very large scale integrated (aVLSI) technology.
>
> Initial successes of neuromorphic engineering have included smart sensors for vision and audition; circuits for non-linear adaptive control; non-volatile analog memory; circuits that provide rapid solutions of constraint-satisfaction problems such as coherent motion and stereo-correspondence; and methods for asynchronous event-based communication between analog computational nodes distributed across multiple chips.

> *These working chips and systems have provided insights into the general principles by which large arrays of imprecise processing elements could cooperate to provide robust real-time computation of sophisticated problems. However, progress is retarded by the small size of the development community, a lack of appropriate high-level configuration languages, and a lack of practical concepts of neuronal computation.*

Although still a modest-sized community, research continues in this area, the largest group being that at ETH in Zurich. The commercialization of this technology has been limited, however, with the most notable success to date being that of Synaptics, Inc. This company created several products which used the basic aVLSI technology, the most successful being the first laptop touch pads.

10.2.3
Intel's Analog Neural Network Chip and Digital Neural Network Chip

During the "heyday" of neural network silicon, between 1986 and 1996, a major semiconductor vendor, Intel, produced two neural network chips. The first, the ETANN [24] (Intel part number 80170NX), was completely analog, but it was designed as a general-purpose chip for non-linear feed-forward ANN operation. There were two grids of analog "inner product" networks, each with 80 inputs and 64 outputs, and a total of 10 K (5 K for each grid) weights. The chip computed the two inner products simultaneously, taking about 5 μs for the entire operation. This resulted in a total performance (feed-forward only, no learning) of over two billion connections computed per second, where a connection is a single multiply-accumulate of an input-weight pair. All inputs and outputs were in analog. The weights were analog voltages stored on floating gates – with the chip being developed and manufactured by the flash memory group at Intel. Complementary signals for each input provided positive and negative inputs. An analog multiplier was used to multiply each input by a weight, current summation of multiplier outputs provided the accumulation, with the output being sent through a non-linear amplifier (giving roughly a sigmoid function) to the output pins.

Although not designed specifically to do real-time learning, it was possible to carry out "chip in the loop" learning where incremental modification of the weights was performed in an approximately stochastic fashion. Learning could also be done off-line and the weights then downloaded to the chip.

The ETANN chip had very impressive computational density, although the awkward learning and total analog design made it somewhat difficult to use. The multipliers were non-linear, which made the computation sensitive to temperature and voltage fluctuations. Ultimately, Intel retired the chip and moved to a significantly more powerful and robust all digital chip, the Ni1000.

The Ni1000 [25, 26] implemented a family of algorithms based on radial basis function networks (RBF [26]). This family included a variation of a proprietary algorithm created by Nestor, Inc., a neural network algorithm and software company.

Rather than doing incremental gradient descent learning, as can be seen with the BP algorithm, the Ni1000 used more of a template approach where each node represented a "basis" vector in the input space. The width of these regions, which was controlled by varying the node threshold, was reduced incrementally when errors were made, allowing the chip to start with crude over-generalizations of an input to output space mapping, and then fine-tune the mapping to capture more complex variations as more data are input. An input vector would then be compared to all the basis vectors, with the closest basis vector being the winner. The chip performed a number of concurrent basis computations simultaneously, and then, also concurrently, determined the classification of the winning output, both functions were performed by specialized hardware.

The Ni1000 was a two-layer architecture. All arithmetic was digital and the network parameters/weights were stored in Flash EEPROM. The first or hidden layer had 256 inputs of 16 bits each with 16 bit weights. The hidden layer had 1024 nodes and the second or output layer 64 nodes (classes). The hidden layer precision was 5 to 8 bits for input and weight precision. The output layer used a special 16-bit floating point format. One usage model was that of Bayesian classification, where the hidden layer learns an estimate of a probability density function (PDF) and the output layer classifies certain regions of that PDF into up to 64 different classes. At 40 MHz the chip was capable of over 10 billion connection computations per second, evaluating the entire network 40 K times per second with roughly 4 W peak power dissipation.

The Ni1000 used a powerful, compact, specialized architecture (unfortunately, space limitations prevent a more detailed description here, but the interested reader is referred to Refs. [25, 26]). The Ni1000 was much easier to use than the ETANN and provided very fast dedicated functionality. However, referring back to Figure 10.5, this chip was a specific family of algorithms wired into silicon. Having a narrower functionality it was much more at risk from Amdahl's law, as it was speeding up an even smaller part of the total problem. Like CNAPS (the Connected Network of Adapted Processors), it too was ultimately "run over by the silicon steam roller".

10.2.4
Cellular Neural Networks

Cellular neural networks (CNN) constitute another family of analog VLSI neural networks. This was proposed by Leon Chua in 1988 [27], who called it the "Cellular Neural Network", although now it is known as the "Cellular Non-Linear Network". Like aVLSI, CNN has a dedicated following, the most well-known being the Analogic and Neural Computing Laboratory of the Computer and Automation Research Institute of the Hungarian Academy of Sciences under the leadership of Tamas Roska. CNN-based chips have been used to implement vision systems, and complex image processing similar to that of the retina has been investigated by a number of groups [28].

Although there are variations, the basic architecture is a 2-D rectangular grid of processing nodes. Although the model allows arbitrary inter-node connectivity, most CNN implementations have only nearest-neighbor connections. Each cell computes its state based on the values of its four immediate neighbors, where the neighbor's

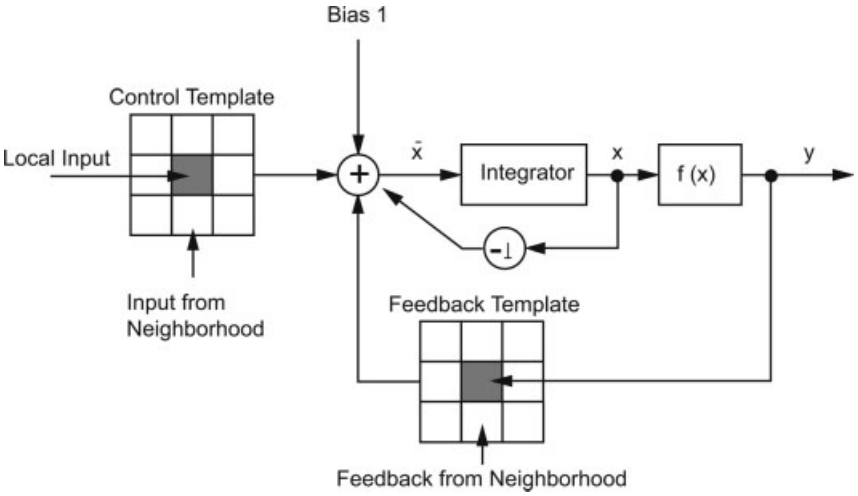

Figure 10.7 Basic cellular neural network (CNN) operation [72].

voltage and the derivative of this voltage are each multiplied by constants and summed. Each node then takes its new value and the process continues for another clock. This computation is generally specified as a type of filter, and is done entirely in the analog domain. However, as the algorithm steps are programmable one of the real strengths of CNN is that the inter-node functions and data transfer is programmable, with the entire array appearing as a digitally programmed array of analog-based processing elements. This is an example of a Single Instruction, Multiple Data (SIMD) architecture, which consists of an array of computation units, where each unit performs the same operation, but each on its own data. CNN programming can be complex and requires an intimate understanding of the basic analog circuits involved. The limited inter-node connectivity also restricts the chip to mostly "front-end" types of processing, primarily of images. A schematic of the basic CNN cell is shown in Figure 10.7.

Whereas, research and development continue, the technology has had only limited commercial success. As with aVLSI, it is a fascinating and technically challenging system, but in real applications it tends to be used for front-end problems and consequently is subject to Amdahl's law.

10.2.5
Other Analog/Mixed Signal Work

It is difficult to do justice to the large and rich area of biologically inspired analog design that has developed over the years. Other investigations include those of Murray [29], the former neural networks group at AT&T Bell Labs [30], Ettienne-Cummings [31], Principe [32], and many more that cannot be mentioned due to limited space. And today, some workers, such as Boahan, are beginning to move the processing further into the back end [33] by looking at cortical structures for early vision.

On returning to Figure 10.4, it can be seen that the first few boxes of processing require the type of massively parallel, locally connected feature extraction that CNN, aVLSI and other analog techniques provide. With regards to sensors, these can perform enhanced signal processing, and demonstrate better signal-to-noise ratios than more traditional implementations, providing such capabilities in compact, low-power implementations.

Although further studies are needed, there is a concern that the limited connectivity and computational flexibility make it difficult to apply these technologies to the back end. Although not a universally held opinion, the author feels that these higher-level association areas require a different approach to implementation. This general idea will be presented in more detail below, but first, it is important to examine another major family of neural network chips, the massively parallel digital processors.

10.2.6 Digital SIMD Parallel Processing

Concurrent with the development of analog neural chips, parallel effort was devoted to architecting and building digital neural chips. Although these could have dealt with a larger subset of pattern-recognition solutions they, like the analog chips, were mostly focused on neural network solutions to simple classification. A common design style that was well matched to the basic ANN algorithms was that of SIMD processor arrays. One chip that embodied that architecture was CNAPS, developed by Adaptive Solutions [34, 35].

The world of digital silicon has always flirted with specialized processors. During the early days of microprocessors, silicon limitations restricted the available functionality and as a result many specialized computations were provided by coprocessor chips. Early examples of this were specialized floating point chips, as well as graphics and signal processing. Following Moore's law, the chip vendors found that they could add increasing amounts of function and so began to pull some of these capabilities into the processor.

Interestingly, graphics and signal processing have managed to maintain some independence, and remain as external coprocessors in many systems. Some of the reasons for this were the significant complexity in the tasks performed, the software inertia that had built up around these functions, and the potential for very low power dissipation which is required for embedded signal processing applications, such as cell phones, PDAs, and MP3 players.

During the early 1990s it was clear that there was an opportunity to provide a significant speed-up of basic neural network algorithms because of their natural parallelism. This was particularly true in situations involving complex, incremental, gradient descent adaptation, as can be seen in many learning models. As a result, a number of digital chips were produced that aimed squarely at supporting both learning and non-learning network emulation.

It was clear from Moore's law that performance improvements and enhanced functionality continued for mainline microprocessors. This relentless march of the

desktop processors was referred to as the "silicon steam roller" where, as the 1990s continued, it became increasingly difficult for the developers of specialized silicon to stay ahead of. At Adaptive Solutions, the goal was to avoid the steam roller by steering between having enough flexibility to solve most of the problem, to avoid Amdahl's law, and yet to have a sufficiently specialized function that allowed enough performance to make the chip cost-effective – essentially sitting somewhere in the middle of the line in Figure 10.5. This balancing act became increasingly difficult until eventually the chip did not offer enough cost-performance improvement in its target applications to justify the expense of a specialized coprocessor chip and board.

The CNAPS architecture consisted of a one-dimensional (1-D) processor node (PN) array in an SIMD parallel architecture [36]. To allow as much performance-price as possible, modest fixed point precision was used to keep the PNs simple. With small PNs the chip could leverage a specialized redundancy technique developed by Adaptive Solution's silicon partner, Inova Corporation. During chip testing, each PN could be added to the 1-D processor chain, or bypassed. In addition, each PN had a large power transistor (with a width of 20 000 λ) connecting the PN to ground. Laser fuses on the 1-D interconnect and the power transistor were used to disconnect and power down defective PNs. The testing of the individual PNs was done at wafer sort, after which an additional lasing stage (before packaging and assembly) would configure the dice, fusing in the good PNs and fusing out and powering down the bad PNs. The first CNAPS chip had an array of 8×10 (80) PNs fabricated, of which only 64 needed to work to form a fully functional die. The system architecture and internal PN architecture is shown in Figure 10.8.

Simulation and analysis was used to determine approximately the optimal PN size (the "unit of redundancy") and the optimal number of PNs. Ultimately, the die was almost exactly 2.5 cm (1 inch) on a side with 14 million transistors fabricated; this led to 12 dice per 15-cm (6-inch) wafer which, until recently, made it physically the largest processor chip ever made (see Figure 10.9).

The large version of the chip, called the CNAPS-1064, had 64 operational PNs and operated at 25 MHz with 6 W worst-case power consumption. Each PN was a complete 16-bit DSP with its own memory. Neural network algorithms tend to be vector/matrix-based and map fairly cleanly to a 1-D grid, so it was easy to have all PNs performing useful work simultaneously. The maximum compute rate then was 1.2 billion multiply-accumulates per second per chip, which was about 1000-fold faster than the fastest workstation at that time. Part of this speed up was due to the fact that each PN did several things in one clock to realize a single clock multiply-accumulate: input data to the PN, perform a multiply, perform an accumulate, perform a memory fetch, and compute the next memory address. During the late 1980s, DSP chips were able to perform such a single multiply-accumulate in one clock, but it was not until the Pentium Pro that desktop microprocessors reached a point where they performed most of these operations simultaneously.

When developing the CNAPS architecture, a number of key decisions were made, including the use of limited precision and local memories, architecture support for the C programming language, and I/O bandwidth.

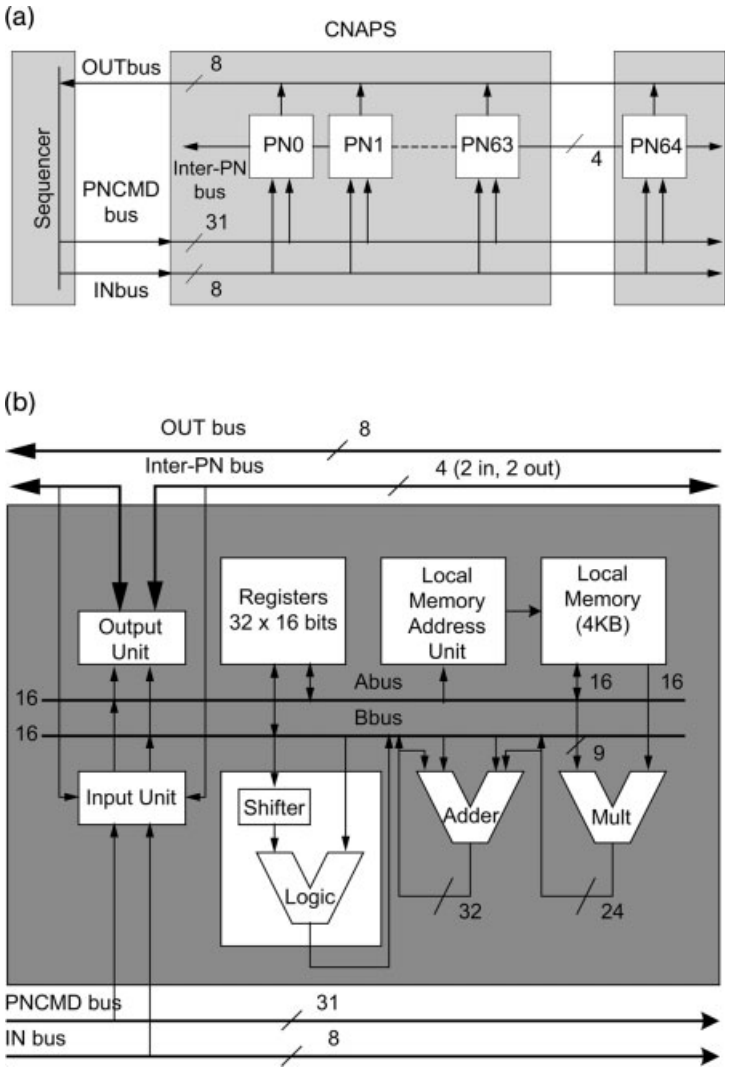

Figure 10.8 Connected Network of Adaptive Processors (CNAPS) architecture. (a) System architecture; (b) PN architecture.

At a time when the computing community was moving to floating-point computation, and the microprocessor vendors were pulling floating processing onto the processor chips and optimizing its performance, the CNAPS used limited precision, fixed point arithmetic. The primary reason for this decision was based on yield calculations, which indicated that a floating-point PN was too large to take advantage of PN redundancy. This redundancy bought an approximately twofold cost-performance improvement. Since a floating-point PN would have been two to three times larger than a fixed-point PN, the use of modest precision fixed-point arithmetic meant an almost sixfold difference in cost-performance. Likewise, simulation showed that

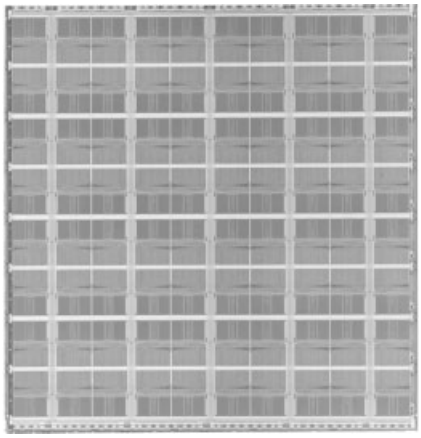

Figure 10.9 A photograph of the CNAPS die.

most of the intended algorithms could get by with limited precision fixed-point arithmetic, and this proved to be, in general, a good decision, as problems were rarely encountered with the limited precision. In fact, the major disadvantage was that it made programming more difficult, although DSP programmers had been effectively using fixed-point precision for many years.

The second decision was to use local, per PN, memory (4 KB of SRAM per PN). Although this significantly constrained the set of applications that could leverage the chip, it was absolutely necessary in achieving the performance goals. The reality was that it was unlikely that the CNAPS chip would have ever been built had performance been reduced enough to allow the use of off-chip memory. As with DSP applications, almost all memory access was in the form of long arrays that can benefit from some pre-fetching, but not much from caching.

The last two decisions – architecture and I/O bandwidth limitations – were driven by performance-price and design time limitations. One objective of the architecture was that it be possible for two integrated circuit (IC) engineers to create the circuits, logic schematics and layout (with some additional layout help) in one year. As a result, the architecture was very simple, which in turn made the design simpler and the PNs smaller, but programming was more difficult. One result of this strategy was that the architecture did not support the C language efficiently. Although there were some fabrication delays, the architecture, board, and software rolled out simultaneously and worked very well, and the first system was shipped in December 1991 and quickly ramped to a modest volume. One of the biggest selling products was an accelerator card for Adobe Photoshop which, in spite of Amdahl problems (poor I/O bandwidth), offered unprecedented performance.

By 1996, desktop processors had increased their performance significantly, and Intel was on the verge of providing the MMX SIMD coprocessor instructions. Although this first version of an SIMD coprocessor was not complete and was not particularly easy to use, the performance of a desktop processor with MMX reduced

the advantages of the CNAPS chipset even further in the eyes of their customers, and people stopped buying.

Everybody knew that the silicon steam roller was coming, but it was moving much faster (and perhaps even accelerating, as some had suggested) than expected. In addition, Intel quickly enhanced the MMx coprocessor to the now current SSE3, which is a complete and highly functional capability. DSPs were also vulnerable to the microprocessor steam roller, but managed, primarily through software inertia and very low power dissipation, to hold their own.

Although there were other digital neural network processors, none of them achieved any significant level of success, and basically for the same reasons. Although at this point the discussion of all but a few of these others is limited by space, two in particular deserve mention.

10.2.7 Other Digital Architectures

One important digital neural network architecture was the Siemens SYNAPSE-1 processor developed by Ramacher and colleagues at Siemens Research in Munich [37]. The chip was similar to CNAPS in terms of precision, fixed-point arithmetic, and basic processor node architecture, but differed by using off-chip memory to store the weight matrices.

A SYNAPSE-1 chip contained a 2×4 array of MA16 "neural signal processors," each with a 16-bit multiplier and 48-bit accumulator. The chip frequency was 40 MHz, and one chip could compute about five billion connections per second with feedforward (non-learning) execution.

Recall that, in architecting the CNAPS, one of the most important decisions was whether to use on-chip per PN memory, or off-chip shared memory for storing the primary weight matrices. For a number of reasons, including the targeted problems space and the availability of a state-of-the-art SRAM process, Adaptive Solutions chose to use on-chip memory for CNAPS. However, for performance reasons this decision limited the algorithm and application space to those whose parameters fit into the on-chip memories. Although optimized for matrix-vector operations, CNAPS was designed to perform efficiently over a fairly wide range of computations.

The SYNAPSE-1 processor was much more of a matrix–matrix multiplication algorithm mapped into silicon. In particular, Ramacher and colleagues were able to take advantage of a very clever insight – the fact that in any matrix multiplication, the individual elements of the matrix are used multiple times. The SYNAPSE-1 broke all matrices into 4×4 chunks. Then, while the elements of one matrix were broadcast to the array, 4×4 chunks of the other matrix would be read from external memory into the array. In a 4×4-matrix by 4×4-matrix multiplication, each element in the matrix was actually used four times, which allowed the processor chip to support four times as many processor units for a given memory bandwidth than a processor not using this optimization.

On returning to Figure 10.5, it can be seen that the SYNAPSE-1 architecture increased performance by specializing the architecture to matrix–matrix multiplications.

Fortunately, most neural network computations can be cast in a matrix form, though it did restrict maximum machine performance to algorithms that performed matrix–matrix multiples. However, like the other digital neural network chips, the SYNAPSE-1 eventually lost out to high-performance microprocessor and DSP hardware.

10.2.8 General Vision

A similar chip to the Ni1000 was the ZISC (Zero Instruction Set Computer) developed by Paillet and colleagues at IBM in Paris. The ZISC chip was digital, employed basically a "vector template" approach, and was simpler and cheaper than the Ni1000 but implemented approximately the same algorithms. Today, the ZISC chip survives as the primary product of General Vision, Petaluma, California.

In addition to the CNAPS, SYNAPSE-1, ZISC, and Ni1000, several other digital chips have been developed either specifically or in part to emulate neural networks. HNC developed the SNAP, a floating-point SIMD standard cell-based architecture [38]. One excellent architecture is the SPERT [39], which was developed by groups at the University of California Berkeley and the International Computer Science Institute (ICSI) in Berkeley. SPERT was designed to perform efficient integer vector arithmetic and to be configured into large parallel arrays. A similar parallel processor array that was created from field-programmable gate arrays (FPGAs) and suited to neural network emulation was REMAP [40].

10.3 Current Directions in Neuro-Inspired Hardware

One limitation of traditional ANN algorithms is that they did not scale particularly well to very large configurations. As a result, commercial silicon was generally fast enough to emulate these models, thus reducing the need for specialized hardware. Consequently, with the exception of on-going studies in aVLSI and CNN, general research in neural inspired hardware has languished.

Today, however, activity in this area is picking up again, for two main reasons. The first reason is that computational neuroscience is beginning to yield algorithms that can scale to large configurations and have the potential for solving large, very complex problems. The second reason is the excitement of using molecular-scale electronics, which makes possible comparably scalable hardware. As will be seen, at least one of the projected nanoelectronic technologies is a complementary match to biologically inspired algorithms.

Today, a number of challenges face the semiconductor industry, including power density, interconnect reverse scaling, device defects and variability, memory bandwidth limitations, performance overkill, density overkill, and increasing design complexity. *Performance overkill* is where the highest-volume segments of the market are no longer performance/clock frequency-driven. *Density overkill* is where it is

difficult for a design team to effectively design and verify all the transistors available to them on a single die. Although neither of these is a potential show-stopper, taken together they do create some significant challenges.

Another challenge is the growing reliance on parallelism for performance improvements. In general purpose applications, the primary source of parallelism has been within a single instruction stream, where many instructions can be executed simultaneously, sometimes even out of order. However, this instruction level parallelism (ILP) has its limits and becomes exponentially expensive to capture. Microprocessor manufacturers are now developing "multiple core" architectures, the goal of which is to execute multiple threads efficiently. As multiple core machines become more commonplace, software and application vendors will struggle to create parallel variations of their software.

Due to very small, high-resistance wires, many nano-scale circuits will be slow, and power density will be a problem because of high electric fields. Consequently, performance improvements at the nano-scale will also need to come almost exclusively from parallelism and to an even greater extent than traditional architectures.

When considering these various challenges, it is unclear which ones are addressed by nanoelectronics. In fact, nanoelectronics only addresses the end of Moore's law, and perhaps also the memory bandwidth problem. However, it also aggravates most other existing problems, notably signal/clock delay, device variability, manufacturing defects, and design complexity.

In proceeding down the path of creating nanoscale electronics, by far the biggest question is, how exactly will this technology be used? Can it be assumed that computation, algorithms, and applications will continue more or less as they have in the past? What should the research agenda be? Will the nanoscale processor of the future consist of thousands of $\times 86$ cores with a handful of application-specific coprocessors? The effective use of nanoelectronics will require solutions to more than just an increased density; rather, total system solutions will need to be considered. Today, computing structures cannot be created in the absence of some sense of how they will be used and what applications they will enable. Any paradigm shift in applications and architecture will have a profound impact on the entire design process and the tools required, as well as the requirements placed on the circuits and devices themselves.

As discussed above, algorithms inspired by neuroscience have a number of interesting and potentially useful properties, including fine-grain and massive parallelism. These are constructed from slow, low-power, unreliable components, are tolerant of manufacturing defects, and are robust in the presence of faulty and failing hardware. They adapt rather than be programmed, they are asynchronous, compute with low precision, and degrade gracefully in the presence of faults. Most importantly, they are adaptive, *self-organizing* structures which promise some degree of design error tolerance, and solve problems dealing with the interaction of an organism/system with the real world. The functional characteristics of neurons, such such as analog operation, fault tolerance, slow, massive parallelism, are radically different from those of typical digital electronics. Yet, some of these characteristics match very well the basic characteristics such as large numbers of faults and defects,

low speed, and massive parallelism that many research groups feel will characterize nanoelectronics systems.

Self-organization involves a system adapting (usually increasing in complexity) in response to an external stimulus. In this context, a system will learn about its environment and adjust itself accordingly, without any additional intervention. In order to achieve some level of self-organization, a few fundamental operating principles are required. Self-organizing systems are those that have been built with these principles in mind.

Recently, Professor Christoph von der Malsburg has defined a new form of computing science – "organic computing" – which deals with a variety of computations that are performed by biology. Organic computations are massively parallel, low precision, distributed, adaptive, and self-organizing. The neural algorithms discussed in this chapter form an important subset of this area (the interested reader is referred to the web site: www.organic-computing.org).

Several very important points should be made about biologically inspired models. The first point concerns the computational models and the applications they support. Biologically inspired computing uses a very different set of computational models than have traditionally been used. And subsequently they are aimed at a fairly specialized set of applications. Consequently, for the most part biological models are not a replacement for existing computation, but rather they are an enhancement to what is available now. Specialized hardware for implementing these models needs to be evaluated accordingly, and in the next few sections some of these models will be explored at different levels.

10.3.1
Moving to a More Sophisticated Neuro-Inspired Hardware

As mentioned above, it is the back end where the struggle with algorithms and implementation continues, and it is also the back end where potential strategic inflection points lie. Hence, the remainder of the chapter will focus on back-end algorithms and hardware.

The ultimate cognitive processor is the *cerebral cortex*. The cortex is remarkably uniform, not only across its different parts, but also across almost all mammalian species. Although current knowledge is far from providing an understanding of how the cerebral cortex does what it does, some of the basic computations are beginning to take shape. Nature has, it appears, produced a general-purpose computational device that is a fundamental component of higher level intelligence in mammals.

Some generally accepted notions about the cerebral cortex are that it represents knowledge in a sparse, distributed, hierarchical manner, and that it performs a type of Bayesian inference over this knowledge base, which it does with remarkable efficiency. This knowledge is added to the cortical data base by a complex process of adaptive learning.

One of the fundamental requirements of intelligent computing, the need to capture higher-order relationships. The problem with Bayesian inference is that it

is an exponentially increasing computation in the number of variables (it has been shown to be NP-Hard, which means that the number of computational steps increases exponentially with the size of the problem); in other words, as order increases the computational overhead increases even more rapidly. Consequently, to use Bayesian inference in real problems, order is reduced to make them computationally tractable.

One common way to do this is to create a Bayesian network, which is a graph structure where the nodes represent variables and the arcs connecting the nodes represent dependencies. If there is reasonable independence between many of the variables then the network itself will be sparsely connected. Bayesian networks "factorize" the inference computation by taking advantage of the independence between different variables. Factorization does reduce the computational load, but at the cost of limiting the knowledge represented in the network. A custom network is also required for each problem.

Cortical networks appear to use sparse distributed data representations, where each neuron participates in a number of specific data representations. Distributed representations also diffuse information, topologically localizing it to the areas where it is needed and reducing global connectivity. Computing with distributed representations can be thought of as the hardware equivalent of spread spectrum communication, where pseudo-random sequences of bits are used to spread a signal across time and frequency. In addition to spreading inter-node communication, distributed representations also spread the computation itself. One hypothesis of cortex operation is that distributed representations of information are a form of extreme factorization, allowing efficient, massively parallel Bayesian inference.

Mountcastle [41, 42] conducted many pioneering studies in understanding the structural architecture of the cortex, including proposing the columnar organization. The fundamental unit of computation appears to be the *cortical minicolumn*, a vertically organized group of about 80 to 100 neurons which traverses the thickness of the gray matter ($\sim$3 mm) and is about 50 μm in diameter. Neurons in a column tend to communicate vertically with other neurons on different layers in the same column. These are subsequently organized into larger columns variously called just "columns", "cortical columns", "hypercolumns", or "modules." Braitenberg [43] postulates two general connectivity systems in cortex: "metric" (high-density connections to physically local cells, based on actual 2-D layout); and "ametric" (low-density point-to-point connections to all large groups of densely connected cells). Connectivity is significantly denser in the metric system, but to a limited extent.

One approach to creating cortical-like algorithms is to model each column as an auto-associative network, such as the Palm model discussed above. The columns are then sparsely connected to each other, but the specifics of the inter-column connections are still not certain and different research groups have expressed different ideas about this [44]. In addition, the neocortex has a definite hierarchical organization where there are as many feedback paths as feed-forward paths.

Among other things, the massive scale is probably one of the more important advantages of biological computation. Consequently, it is likely that useful versions of

these algorithms will require networks with a million or more nodes. Back-end processing, because of a need to store large amounts of unique synaptic information, will most likely have simpler processing than is seen at the front end, albeit on a much larger scale.

Hecht-Nielsen [45] bases the inter-column (which he calls "regions") connections on conditional probabilities, which capture higher-order relationships. He also uses abstraction columns to represent groups of lower-level columns. He has demonstrated networks that perform a remarkable job of capturing aspects of English, as these networks consist of several billion connections and require a large computer cluster to execute.

Granger [46, 47] leverages nested distributed representations in a way that adds the temporal dimension, creating hierarchical networks that learn sequences of sequences. George and Hawkins [48] use model likelihood information ascending a hierarchy with model confidence information being fed back. Other researchers are also contributing to these ideas include Grossberg [49], Lansner [50, 51], Arbib [52], Roudi and Treves [53], Renart *et al.* [54], Levy *et al.* [55], and Anderson [56]. Clearly, this remains a dynamic area of research, and at this point there is no clear "winning" approach.

Another key feature of some of these algorithms is that there is an oscillatory sliding threshold that causes the more "confident" columns to converge to their attractors more quickly, the less-confident more slowly, while those of low confidence do not converge at all, taking a "NULL" state. This process is remarkably similar to the electromagnetic waves that flow through the cortex when it is processing data.

Connectivity remains one of the most important problems when first considering scaling to very large models. Axons are very fine and can be packed very densely in a three-dimensional (3-D) mesh. Interconnect in silicon generally operates in a 2-D plane, although with several levels, nine or more with today's semiconductor technologies. Most importantly, silicon communication is not continuously amplifying, as can be seen in axonal and some dendritic processes. The following result [57–59] demonstrates this particular problem.

> *Theorem*: Assume an unbounded or large rectangular array of silicon neurons where each neuron receives input from its N nearest neighbors; that is, the fan-out (divergence) and fan-in (convergence) is N. Each such connection consists of a single metal line, and the number of 2-D metal layers is much less than N. Then, the area required by the metal interconnect is $O(N^3)$.

So, if the fan-in per node is doubled from 100 to 200, the silicon area required for the metal interconnect increases by a factor of 8. This result means that, even for modest local connectivity, that portion of silicon area devoted to the metal interconnect will dominate. It has been shown that for some models even moderate multiplexing of interconnect would significantly decrease the silicon area requirements, without any real loss in performance [60]. Carver Mead's group at Caltech, and others, developed the address event representation (AER), a technique for multiplexing a number of pulse streams on a single metal wire [61, 62]. When analog computation is

used, signals can be represented by the time between action-potential-like "spikes". These signal "packets" or "pulses" are transmitted asynchronously the moment they occur, with the originating unit's address, on a single shared bus. This "pseudo-digital" representation allows multiplexing of the bus and the retention of analog and temporal information, without expensive conversions.

In studying the potential implementations of cortical structures, an efficient connection multiplexing architecture was developed where data transfer occurs via overlapping, hierarchical buses [63]. This structure, *The Broadcast Hierarchy* (TBH), allows simultaneous high-bandwidth local connectivity and long-range connectivity, thereby providing a reasonable match to many biological connectivity patterns.

The details of a relevant proposed hybrid CMOS/nanoelectronic technology, CMOL, are presented in the next section.

10.3.2 CMOL

Likharev has proposed CMOL (Cmos/MOLecular hybrid) as an implementation strategy for charge-based[5)] nanoelectronic devices. Likharev's group has analyzed a number of examples of CMOL configurations, including memory, reconfigurable logic, and neuromorphic CrossNets [64–66]. In addition, nanogrids are most likely to be the first commercial deployment of nanoelectronic circuits [67].

CMOL consists of a set of nanogrids fabricated on top of traditional CMOS, with the CMOS being used, among other things, for signal restoration and current drive, nanogrid addressing, and to communicate signals into and out of the nanogrids. The nanogrids themselves will generally have more specialized computation such as a memory, which augments the computation being performed by the CMOS.

A *nanogrid* consists of a set of parallel wires, with another set of parallel wires fabricated on top of and orthogonal to the first set. Likharev has shown that such grids need not be laid out in perfect dimensions or alignment, but can be reproduced by using nanoimprint templates. Sandwiched between the two grids is a planar material made from a specific molecular structure such that, where the horizontal and vertical wires cross, a molecular switch is created. Several mechanisms have been identified to effect the desirable electrical properties where two nanowires cross.

The most important property is of a binary "latching switch" with two metastable internal states [68]. This nanoscale device can be programmed to either an "on" or an "off" state by using two sets of voltages. The lower set is used to read out the device to determine its state, while the higher set is used to change the state of the device. The programming voltages are used to switch the device between high- and low-resistance states. The lower read-out voltages are used to determine the resistance or

5) Researchers are investigating a number of molecular technologies based on computational paradigms other than charge, such as spintronics, quantum cellular automata, and DNA computing. However, as neural circuits operate on the principle of charge accumulation, charge-based computation seems a better match, although further study of these other technologies is required.

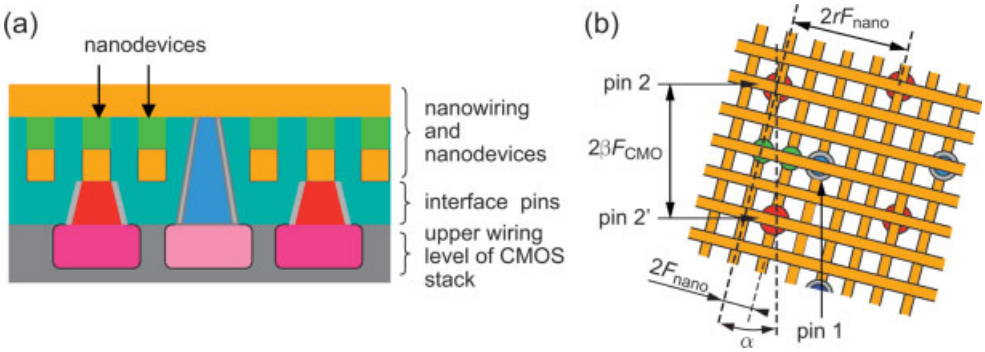

Figure 10.10 CMOL [1]. (a) A schematic side view. (b) Top view showing that any nanodevice may be addressed via the appropriate pin pair (e.g. pins 1 and 2 for the leftmost of the two shown devices, and pins 1 and 2′ for the rightmost device). Panel (b) shows only two devices; in reality, similar nanodevices are formed at all nanowire crosspoints. Also not seen on panel (b) are CMOS cells and wiring.

"state" of the molecule. Another required characteristic of these devices is rectification, where current flow is allowed only in one direction.

One of the most important characteristics of CMOL is the unique way in which the grids are laid at an angle with respect to the CMOS grid. Each nanowire is connected to the upper metal layers of the CMOS circuitry through a pin. In order for the CMOS to address each nanowire in the denser nanowire crossbar arrays, when it is fabricated, the nanowire crossbar is turned by an angle α, where α is the tangent of the ratio of the CMOS inter-pin distance to the nanogrid inter-pin distance. This technique allows the grid to be aligned arbitrarily with the CMOS and still have most nanowires addressable by some selection of CMOS cells. A nanowire is contacted by two CMOS cells, both of which are required to input a signal or read a signal. This basic connectivity structure is shown in Figure 10.10.

Although CMOL is not necessarily biologically inspired, it represents a promising technology for implementing such algorithms, as will be seen in the next section. CMOL uses charge-accumulation as its basic computational paradigm, which is also used by neural structures. Other nanoscale devices such as spin technologies do not implement a charge accumulation model, so such structures would have to emulate a charge-accumulation model, probably in digital.

10.3.3
An Example: CMOL Nano-Cortex

A high-level analysis has been performed of the implementation of a cortical column in CMOL. It is assumed that column operation is based on the Palm model discussed above. For this analysis, multiple column communication will be ignored and, for the sake of simplicity, a non-learning model will be assumed where the weights are computed off-line and downloaded into the nanogrid. Some typical values for the

Table 10.1 Typical values of parameters used for a cortical column analysis.

Parameter	Range	Typical Value I	Typical Value II
Hypercolumn node size	$128 \sim 128$ K	1 K	16 K
Weight matrix size (single-weight-bit)	$2^{14} \sim 2^{34}$ bits	2^{20} bits	2^{28} bits
Weight matrix size (multi-weight-bit)	$2^{18} \sim 2^{51}$ bits	2^{30} bits	2^{42} bits
Multi-weight-bits	$7 \sim 17$ bits	10 bits	14 bits
No. of active nodes in hypercolumn	$7 \sim 17$	16	16
Inner-product result bits (single-weight-bit)	$3 \sim 5$ bits	5 bits	5 bits
Inner-product result bits (multi-weight-bit)	$11 \sim 21$ bits	14 bits	18 bits

parameters used in the cortical column architectural analysis are listed in Table 10.1. These values represent typical numbers used by several different simulation models, in particular, Lansner and his group at KTH [69]. Related investigations have been conducted at IBM [70], where a mouse cortex-sized model has been simulated on a 32 K processor IBM BlueGene/L.

Four basic designs have been analyzed, as shown in Figure 10.11:

- All-digital CMOS
- Mixed-signal CMOS
- All-digital hybrid CMOS/CMOL
- Mixed-signal hybrid CMOS/CMOL.

For the CMOS designs and the CMOS portion of CMOL, a 22-nm process was assumed as a "maximally" scaled CMOS. To approximate the features for this process, a simple linear scaling of a 250-nm process was made. The results of this

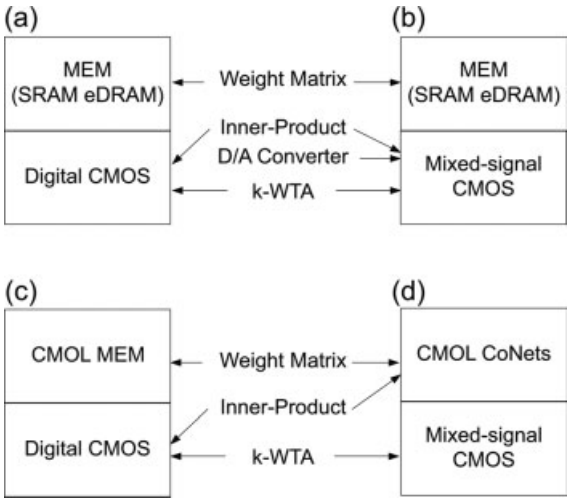

Figure 10.11 Architecture space - biologically inspired models. (a) All-digital CMOS; (b) mixed-signal CMOS; (c) all-digital hybrid CMOS/CMOL; (d) mixed-signal hybrid CMOS/CMOL.

Table 10.2 Analysis results.

Design		No. of column processors	Power (W)	Update rate (G nodes s^{-1})	Memory (%)
CMOS All Digital	1-bit eDRAM	6600	528	3072	2.9
CMOS Mixed-Signal	1-bit eDRAM	19 500	487	22 187	9.0
CMOL All Digital	1-bit CMOL Mm	4 042 752	317	4492	40
CMOL MS	1-bit CoNets	10 093 568	165	11 216	100

analysis, where the cost-performance for the four systems with the assumption of an 858 mm^2 die size (the maximum lithographic field size expected for a 22-nm process), are presented in Table 10.2.

With regards to Table 10.2, with the mixed signal CMOL it was possible to implement approximately 10 M columns, each having 1 K nodes, with 1 K connections each, for a total of 10 Tera-connections. In addition, this entire network can be updated once every millisecond – which is approaching biological densities and speeds, although of course with less functionality. Such technology could be built into a portable platform, with the biggest constraint being the high power requirements. Current studies include investigations into spike-based models [71] that should allow a significant lowering of the duty cycle and the power consumed.

Although real-time learning/adaptation was not included in the circuits analyzed here, deployed systems will need to be capable of real-time adaptation. It is expected that additional learning circuitry will reduce density by about two- to threefold. Neither has the issue of fault tolerance been addressed, although the Palm model has been found to tolerate errors, single 1 bits set to 0, in the weight matrix of up to 10%. For this reason, and given the excellent results of Likharev and Strukov [66] on the fault tolerance of CMOL arrays used as memory, it is expected that some additional hardware will be required to complement algorithmic fault tolerance, although this should not reduce the density in any significant way.

10.4 Summary and Conclusions

In this chapter, a brief and somewhat superficial survey has been provided of the specialized hardware developed over the past 20 years to support neurobiological models of computation. A brief examination was made of the current efforts and speculation made on how such hardware, especially when implemented in nanoscale electronics, could offer unprecedented compute density, possibly leading to new capabilities in computational intelligence. Biologically inspired models seem to be a better match to nanoscale circuits.

The mix of continued Moore's law scaling, models from computational neuroscience and molecular-scale technology portends a potential paradigm shift in how computing is carried out. Among other points, the future of computing is most likely not about discrete logic but rather about encoding, learning, and performing

inference over stochastic variables. There may be a wide range of applications for such devices in robotics, in the reduction and compression of widely distributed sensor data, and power management.

One of the leading lights of the first computer revolution saw this clearly. At the IEEE Centenary in 1984 (*The Next 100 Years*; IEEE Technical Convocation), Dr. Robert Noyce, the co-founder of Intel and co-inventor of the Integrated Circuit, noted that:

> *Until now we have been going the other way; that is, in order to understand the brain we have used the computer as a model for it. Perhaps it is time to reverse this reasoning: to understand where we should go with the computer, we should look to the brain for some clues.*

11
Nanowire-Based Programmable Architectures

André DeHon

11.1
Introduction

Today, chemists are demonstrating bottom-up synthesis techniques which can construct atomic-scale switches, field-effect devices, and wires (see Section 11.2). While these are key components of a computing system, it must also be understood if these can be assembled and organized into useful computing devices. That is, can arbitrary logic be built from nanowire building blocks and atomic-scale switches?

- Do we have an adequate set of capabilities to build logic?
- How do we cope with the regularity demanded by bottom-up assembly?
- How do we accommodate the high defect rates and statistical assembly which accompany bottom-up assembly techniques?
- How do we organize and interconnect these atomic-scale building blocks?
- How do we address nanowires from the lithographic scale for testing, configuration, and IO?
- How do we get logic restoration and inversion?
- What net benefit do these building blocks offer us?

The regular synthesis techniques can be used to assemble tight-pitch, parallel nanowires; this immediately suggests that programmable crossbar arrays (Section 11.4.1) are built as the key building blocks in these architectures. These crossbar arrays can be used as memory cores (Section 11.5), wired-OR logic arrays (Section 11.6.1), and programmable interconnect (Section 11.6.3) – memory, logic, and interconnect – all of which are the key components needed for computation.

The length of the nanowires must be limited for yield, performance, and logical efficiency. Consequently, the nanowires are organized into a collection of

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

modest-sized, interconnected crossbar arrays (Section 11.6.3). A reliable, lithographic-scale support structure provides power, clocking, control, and bootstrap testing for the nanowire crossbar arrays. Each nanowire is coded so that it can be uniquely addressed from the lithographic support wires (Section 11.4.2). With the ability to address individual nanowires, individual crosspoints can be programmed (Section 11.8) to personalize the logic function and routing of each array and to avoid defective nanowires and switches (Section 11.7).

As specific nanowires cannot, deterministically, be placed in precise locations using these bottom-up techniques, stochastic assembly is exploited to achieve unique addressability (Section 11.4.2). Stochastic assembly is further exploited to provide signal restoration and inversion at the nanoscale (Section 11.4.3). Remarkably, starting from regular arrays of programmable diode switches and stochastic assembly of non-programmable field-effect controlled nanowires, it is possible to build fully programmable architectures with all logic and restoration occurring at the nanoscale.

The resulting architectures (Section 11.6) provide a high-level view similar to island-style field-programmable gate arrays (FPGAs), and conventional logic mapping tools can be adapted to compile logic to these arrays. Owing to the high defect rates likely to be associated with *any* atomic-scale manufacturing technology, all viable architectures at this scale are likely to be post-fabrication configurable (Section 11.7). That is, while nanowire architectures can be customized for various application domains by tuning their gross architecture (e.g. ratio of logic and memory), there will be no separate notion of custom atomic-scale logic.

Even after accounting for the required, regular structure, high defect rates, stochastic assembly, and the lithographic support structure, a net benefit is seen from being able to build with nanowires which are just a few atoms in diameter and programmable crosspoints that fit in the space of a nanowire junction. Mapping conventional FPGA benchmarks from the Toronto20 benchmark set [1], the designs presented here should achieve one to two orders of magnitude greater density than FPGAs in 22 nm CMOS lithography, even if the 22 nm lithography delivers defect-free components (Section 11.10).

The design approach taken here represents a significant shift in design styles compared to conventional lithographic fabrication. In the past, reliance has been placed on virtually perfect and deterministic construction and complete control of features down to a minimum technology feature size. Here, it is possible to exploit very small feature sizes, although there is no complete control of device location in all dimensions. Instead, it is necessary to rely on the statistical properties of large ensembles of wires and devices to achieve the desired, aggregate component features. Further, post-fabrication configuration becomes essential to device yield and personalization.

This chapter describes a complete assembly of a set of complementary technologies and architectural building blocks. The particular ensemble presented is one of several architectural proposals which have a similar flavor (Section 11.11) based on these types of technologies and building blocks.

11.2 Technology

11.2.1 Nanowires

Atomic-scale nanowires (NWs) can be engineered to have a variety of conduction properties, from insulating to semiconducting to metallic. The composition of a NW can be varied along its axis and along its radius, offering powerful heterostructures to provide both controllable devices and interconnect integrated into a single structure.

Seed catalysts are used to control the diameter of a NW during the composition process and constrain the growth to a small region [2, 3].

In addition, semiconducting can be doped during the growth process by controlling the mix of elements in the ambient environment [4]. This can produce conducting NWs with heavy doping and field effect controllable NWs with a suitably light doping [5].

The doping profile or material composition can change along the length of a NW by controlling the ambient process environment over the time [6–8]. This leads to properties such as gateable and not-gateable regions within a single NW (Figure 11.1). After the axial growth, the NW's surface can be used as a substrate for atomic layer growth to produce a radial material composition (Figure 11.2), for example with SiO_2 as an insulator and spacer [9–11].

In order to increase the conductivity of NWs beyond heavily doped semiconductors, nickel silicide (NiSi) can be generated by coating selected regions with nickel and subsequently annealing the area [12].

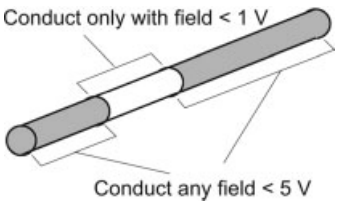

Figure 11.1 Axial doping profile places selective gateable regions in a nanowire.

Figure 11.2 Radial doping profile.

11.2.2
Assembly

Langmuir–Blodgett (LB) flow techniques can be used to align a set of NWs into a single orientation, close pack them, and transfer them onto a surface [11, 13]. The resulting wires are all parallel with nematic alignment. By using wires with an oxide sheath around the conducting core, the wires can be packed tightly. The oxide sheath defines the spacing between conductors and can, optionally, be etched away after assembly. The LB step can be rotated and repeated so that multiple layers of NWs are obtained [11, 13] such as crossed NWs for building a crossbar array or memory core (see Section 11.4.1).

11.2.3
Crosspoints

Many technologies have been demonstrated for non-volatile, switched crosspoints. Common features include:

- resistance which changes significantly between on and off states;
- the ability to be made rectifying;
- the ability to turn the device on or off by applying a large voltage differential across the junction;
- the ability to operate at a low voltage differential without switching the device state; and
- the ability to be placed within the area of a crossed NW junction.

Chen *et al*. [14] demonstrated a nanoscale Ti/Pt-[2]rotaxane-Ti/Pt sandwich which exhibits hysteresis and non-volatile state storage showing an order of magnitude resistance difference between on and off states for several write cycles. With 1600 nm^2 junctions, the on resistance ($R_{ondiode}$) was roughly 500 KΩ, and the off resistance ($R_{offdiode}$) 9 MΩ. After an initial burn-in step, the state of these devices can be switched at ±2 V and read at ±0.2 V. The basic hysteretic molecular memory effect is not unique to the [2]rotaxane, and the junction resistance is continuously tunable [15]. The exact nature of the physical phenomena involved is the subject of active investigation.

In conventional very large-scale integration (VLSI), the area of an SRAM-based programmable crosspoint switch is much larger than the area of a wire crossing. A typical, CMOS switch might be $2500\lambda^2$ [16], compared to a $5\lambda \times 5\lambda$ bottom-level metal wire crossing, making the crosspoint 100-times the area of the wire crossing. Consequently, the nanoscale crosspoints offer an additional device size reduction beyond that implied by the smaller NW feature sizes. This particular device size benefit reduces the overhead for configurability associated with programmable architectures [e.g. FPGAs, programmable logic arrays (PLAs)] in this technology compared to conventional CMOS.

11.2.4
Technology Roundup

It is possible to create wires which are nanometers in diameter and which can be arranged into crossbar arrays with nanometer pitch. Crosspoints which both switch conduction between the crossed wires and store their own state can be placed at every wire crossing without increasing the pitch of the crossbar array. NWs can be controlled in FET-like manner, and can be designed with selectively gateable regions. This can all be done without relying on ultrafine lithography to create the nanoscale feature sizes. Consequently, these techniques promise smaller feature sizes and an alternate – perhaps more economical – path to atomic-scale computing structures than top-down lithography. Each of the capabilities previously described has been demonstrated in a laboratory setting as detailed in the reports cited. It is assumed that, in future, it will be possible to combine these capabilities and to scale them into a repeatable manufacturing process.

11.3
Challenges

In the top-down lithographic model, a minimum, lithographically imageable feature size is defined, and devices are built that are multiples of this imageable feature size (e.g. half-pitch). Within the limits of this feature size, the size of features and their relative location to each other in three dimensions – both in the two-dimensional (2-D) plane of each lithographic layer and with adequate registration between layers – could be perfectly specified. This provided complete flexibility in the design of circuit structures as long as the minimum imageable and repeatable feature size rules were adhered to.

When approaching the atomic-scale, it becomes increasingly difficult to maintain this model. The precise location of atoms becomes relevant, and the discreteness of the underlying atoms begins to show up as a significant fraction of feature size. Variations occur due to statistical doping and dopant placement and interferometric mask patterning. Perfect repeatability may be extremely difficult or infeasible for these feature sizes.

These bottom-up approaches, in contrast, promise finer feature sizes that are controlled by physical phenomena but do not promise perfect, deterministic alignment in three dimensions. It may be possible to achieve good repeatability of certain types of small feature sizes (e.g. NW diameters) and correlation of tiny features within a single NW using axial and radial composition, but there may be little correlation from NW to NW in the plane or between NW planes. This may prompt the question of whether it would be reasonable to forego the perfect correlation and complete design freedom in three dimensions in order to exploit smaller feature sizes. The techniques summarized here suggest that this is a viable alternative.

11.3.1 Regular Assembly

The assembly techniques described above (see Sections 11.2.2 and 11.2.3) suggest that regular arrays can be built at tight pitch with both NW trace width and trace spacing using controlled NW diameters. While this provides nanometer pitches and crosspoints that are tens of nanometers in area, it is impossible to differentiate deterministically between features at this scale; that is, one particular crosspoint cannot be made different in some way from the other crosspoints in the array.

11.3.2 Nanowire Lengths

Nanowire lengths can be grown to hundreds of microns [17] or perhaps millimeters [18] in length. However, at this high length to diameter ratio, they become highly susceptible to bending and ultimately breaking. Assembly puts stresses along the NW axis which can break excessively long NWs. Consequently, a modest limit must be placed on the NW lengths (tens of microns) in order to yield a large fraction of the NWs in a given array. Gudiksen *et al.* [19] reported the reliable growth of Si NWs which are over 9 μm long, while Whang et al. [11, 20] demonstrated collections of arrays of NWs of size 10 μm × 10 μm. Even if it was possible physically to build longer NWs, the high resistivity of small-diameter NWs would force the lengths to be kept down to the tens of microns range.

11.3.3 Defective Wires and Crosspoints

At this scale, wires and crosspoints are expected to be defective in the 1 to 10% range:

- NWs may break along their axis during assembly as suggested earlier, and the integrity of each NW depends on the ~100 atoms in each radial cross-section.
- NW to microwire junctions depend on a small number of atomic scale bounds which are statistical in nature and subject to variation in NW properties.
- Junctions between crossed NWs will be composed of only tens of atoms or molecules, and individual bond formation is statistical in nature.
- Statistical doping of NWs may lead to high variation among NWs.

For example, Huang *et al.* [13] reports that 95% of the wires measured had good contacts, while Chen *et al.* [21] reported that 85% of crosspoint junctions measured were usable. Both of these were early experiments, however, and the yield rates would be expected to improve. Nonetheless, based on the physical phenomena involved it is anticipated that the defect rates will be closer to the few percent range than the minuscule rates frequently seen with conven-

tional, lithographic processing. Consequently, two main defect types may be considered:

- *Wire defects:* a wire is either functional or defective. A functional wire has good contacts on both ends, conducts current with a resistance within a designated range, and is not shorted to any other NWs. Broken wires will not conduct current. Poor contacts will increase the resistance of the wire, leaving it outside of the designated resistance range. Excessive variation in NW doping from the engineered target can also leave the wire out of the specified resistance range. It can be determined if a wire is in the appropriate resistance range during testing (see Section 11.8.1) and arranged not to use those which are defective (see Section 11.7.1).
- *Non-programmable crosspoint defects:* a crosspoint is programmable, non-programmable, or shorted into the on state. A programmable junction can be switched between the resistance range associated with the on-state and the resistance range associates with the off-state. A non-programmable junction can be turned off, but cannot be programmed into the on-state; a non-programmable junction could result from the statistical assembly of too few molecules in the junction, or from poor contacts between some of the molecules in the junction and either of the attached conductors. A shorted junction cannot be programmed into the off-state. Based on the physical phenomena involved, non-programmable junctions are considered to be much more common than shorted junctions. Further, it is expected that fabrication can be tuned to guarantee that this is the case. Consequently, shorted junctions will be treated like a pair of defective wires, and both wires associated with the short will be avoided.

Currently, the bridging of adjacent NWs is considered NOT to be a major defect source. Radial shells around the (semi) conducting NW cores prevent the shorting of adjacent NWs. At present, there is insufficient experience to determine if variations in core shell thickness, imperfect planar NW alignment, or other effects may, nonetheless, lead to bridging defects between adjacent NWs. If such bridging were to occur, it could make a pair of NWs indistinguishable, perhaps effectively giving two addresses to the NW pair. These bridged NW pairs could be detected and avoided but their occurrence would necessitate slightly more complicated testing and verification algorithms than those detailed in Section 11.8.

After describing the building blocks and architecture, the way in which the two main defect types within the architecture are accommodated is described in Section 11.7.

11.4 Building Blocks

By working from the technological capabilities and within the regular assembly requirements, it is possible to construct a few building blocks which enable the creation of a wide range of interesting programmable architectures.

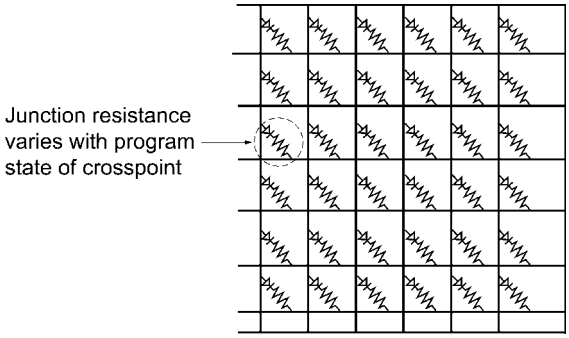

Figure 11.3 Logical diode crossbar formed by crossed nanowires.

11.4.1 Crosspoint Arrays

As suggested in Section 11.2.2 and demonstrated by Chen *et al.* [21] and Wu *et al.* [22], assembly processes allow the creation of tight-pitch arrays of crossed NWs with switchable diodes at the crosspoints (see Figure 11.3). Assuming for the moment that contact can be made to individual NWs in these tight-pitch arrays (see Section 11.4.2), these arrays can serve as:

- memory cores
- programmable, wired-OR planes
- programmable crossbar interconnect arrays.

11.4.1.1 Memory Core

As noted in Section 11.2.3, by applying a large voltage across a crosspoint junction, the crosspoint can be switched into a high or low resistance state. Consequently, if the voltage on a single row and a single column line can be set to desired voltages, each of the crosspoints can be set to a particular conduction state. It is further noted that the system can operate at a lower voltage without resetting the crosspoint. Consequently, a crosspoint's state can be read back by applying a small, test voltage to a column input and observing the current flow, or rate of charging, of a row line to tell if the crosspoint has been set into a high or low resistance state.

11.4.1.2 Programmable, Wired-OR Plane

When a method of programming the crosspoints into high or low resistance states has been effected, the OR logic can be programmed into a crosspoint array. Each row output NW serves as a wired-OR for all of the inputs programmed into the low resistance state. Consider a single row NW, and assume for the moment that the means is available to pull a non-driven NW down to ground. Now, if any of the column NWs which cross this row NW are connected with low resistance crosspoint junctions and are driven to a high voltage level, the current into the column NW will be able to flow into the row NW and charge the row NW up to a higher voltage value (see O1, O3, O4, and O5 in Figure 11.4). However, if none of the connected column NWs is high,

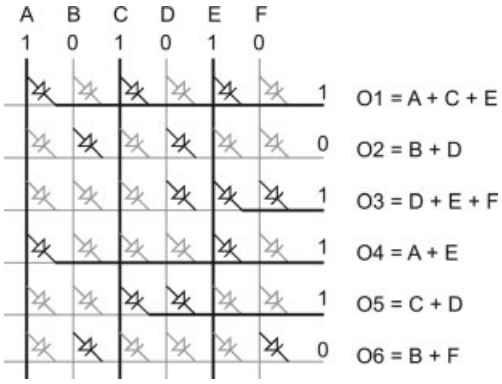

Figure 11.4 Wired-OR plane operation. Programmed on crosspoints are shown in black; off crosspoints are shown in gray. Dark lines represent a nanowire (NW) pulled high, while light lines remain low. Output NWs are marked dark, starting at the diode that pulls them high, in order to illustrate current flow; the entire output NW would be pulled high in actual operation.

the row NW will remain low (see O2 and O6 in Figure 11.4). Consequently, the row NW effectively computes the OR of its programmed inputs.

The output NWs do pull their current directly off the inputs and may not be driven as high as the input voltage. Hence, these outputs will need restoration (see Section 11.4.3).

11.4.1.3 **Programmable Crossbar Interconnect Arrays**

A special use of the Wired-OR programmable array is for interconnect. That is, if a restriction is introduced to connecting a *single* row wire to each column wire, the crosspoint array can serve as a crossbar switch. This allows any input (column) to be routed to any output (row) (e.g. see Figure 11.5). This structure is useful for

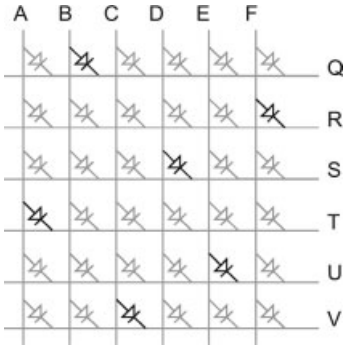

Figure 11.5 Example of crossbar routing configuration. Programmed on crosspoints are shown in black; off crosspoints are shown in gray. Here, the crossbar is shown programmed to connect A → T, B → Q, C → V, D → S, E → U, and F → R.

post-fabrication programmable routing to define a logic function and to avoid defective resources (see Section 11.3.3).

11.4.2 Decoders

A key challenge is bridging the length scale between the lithographic-scale wires that can be created using conventional top-down lithography and the small-diameter NWs that can be grown and assembled into tight-pitch arrays. As noted above, it must be possible to establish a voltage differential across a single row and column NW to write a bit in the tight-pitch NW array. It must also be possible to drive and sense individual NWs to read back the memory bit. By building a decoder between the coarse-pitch lithographic wires and the tight-pitch NWs, it is possible to bridge this length scale and to address a single NW at this tight pitch [23–26].

11.4.2.1 NW Coding

One way to build such a decoder is to place an address on each NW using the axial doping or material composition profile described previously. In order to interface with lithographic-scale wires, address bit regions are marked off at the lithographic pitch. Each such region is then either doped heavily so that it is oblivious to the field applied by a crossed lithographic-scale wire, or is doped lightly so that it can be controlled by a crossed lithographic scale wire. In this way, the NW will only conduct if all of the lithographic-scale wires crossing its lightly doped, controllable regions have a suitable voltage to allow conduction. If any of the lithographic-scale wires crossing controllable regions provide a suitable voltage to turn off conduction, then the NW will not be able to conduct.

It should be noted that each bit position can only be made controllable or non-controllable with respect to the lithographic-scale control wire; different bit positions cannot be made sensitive to different polarities of the input. Consequently, the addresses must be encoded differently from the dense, binary address normally used for memories. One simple way to generate addresses is to use a dual-rail binary code. That is, for each logical input bit, the value and its complement are provided. This results in two bit positions on the NW for each logical input address bit – one for the true sense and one for the false sense. To code a NW with an address, either bit position is simply coded to be sensitive to exactly one sense of each of the bit positions (see Figure 11.6). This results in a decoder which requires $2\log_2(N)$ address bits to address N NWs.

Denser addressing can be achieved by using $N_a/2$-hot codes; that is, rather than forcing one bit of each pair of address lines to be off and one to be on, it is simply required that half of the address bits, N_a, be set to a voltage which allows conduction, and half to be set to a voltage that prevents conduction. This scheme requires only $1.1\log_2(N) + 3$ address bits [24].

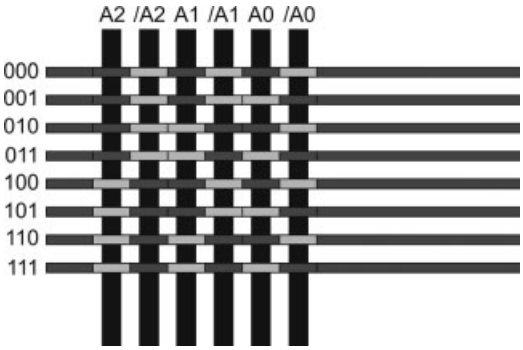

Figure 11.6 Dual-rail address coding.

11.4.2.2 **Decoder Assembly**

If each NW in the array has a unique address in the selected coding scheme, then each individual NW in the array can be uniquely addressed. However, the NW assembly techniques do not allow particular NWs to be placed in particular locations – it can only be arranged to create a tight-pitch parallel ensemble of a collection of NWs.

Instead, it appears that if the code space for the NWs is made large compared to the size of the array to be addressed, it can be guaranteed statistically (with arbitrarily high probability) that every NW in an array has a unique address. Starting with a very large number of NW codes, the NWs can be mixed up before assembly so that a random selection occurs of which NW codes go into each of the crosspoint arrays being assembled. As long as the array formed is sufficiently small compared to the code space for the NWs, strong guarantees can be provide that each array contains NWs with unique codes [24]. It transpires that there is no need for a large number of address bits in order to guarantee this uniqueness. For example, the $N_a/2$-hot codes need a total of only $\lceil 2.2 \log_2(N) \rceil + 11$ bits to achieve over a 99% probability that all NWs in an array will have unique addresses. If a few duplicates are tolerable, the codes can be much tighter [25, 26].

Wires can be coded to tolerate misalignment during assembly. Hybrid addressing schemes which segment the collection of NWs in an array into lithographic-scale contact groups can be used to reduce the size of the NW codespace needed (for further details see Ref. [24]).

11.4.2.3 **Decoder and Multiplexer Operation**

Now it is known that uniquely coded NWs can be assembled into an array, it can be seen how the decoder operates. First, assume that all the NWs are either precharged or weakly pulled to a nominal voltage. The desired NW address is then applied to the lithographic-scale address lines. The desired drive voltage is also applied to a common line attached to all the NWs. If the selected address is present in the array, it will allow conduction from the common line into the array charging up the selected NW. All other NWs will differ in at least one bit position, and will thus be disabled by the address lines. Consequently, only the selected NW is charged strongly to the

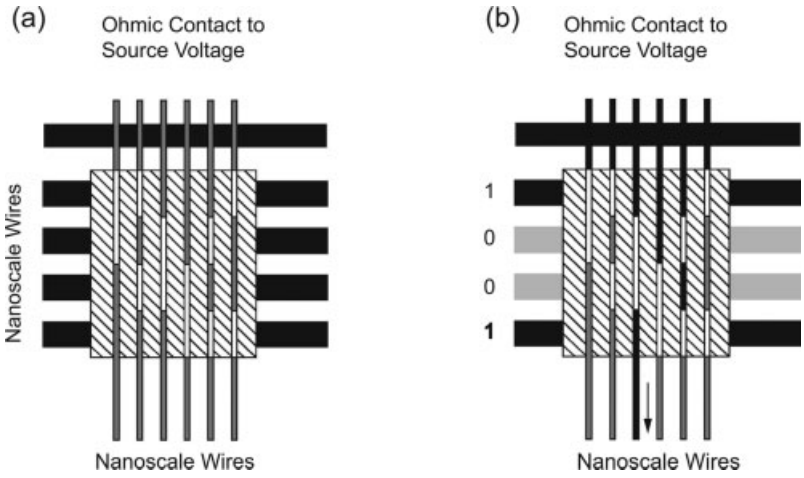

Figure 11.7 Coded NW decoder. (a) Decoder configuration: white NW regions are coded and controllable, while gray regions are not controllable and acts as wires. (b) Dark represents lines driven high; light gray shows lines low or undriven. Only the coding on the third line matches the applied address (1 0 0 1) and allows conduction. All other cases have a high address voltage crossing a lightly doped region, which prevents conduction.

voltage driven on the common line, and all other NWs are held at the nominal voltage (see Figure 11.7).

It should be noted that there is no directionality to the decoder, and consequently this same unit can serve equally well as a multiplexer. That is, when an address is applied to the lithographic-scale wires it allows conduction through the addressing region for only one of the NWs. Consequently, the voltage on the common line can be sensed rather than driven. Now, the one line which is allowed to conduct through the array can potentially pull the common line high or low. All other lines have a high resistance path across the lithographic-scale address wires and will not be able to strongly effect the common line. This allows a single NW to be sensed at a time (see Figure 11.8) as there is a need to read out the crosspoint state, as described in Section 11.4.1.1.

11.4.3 Restoration and Inversion

As noted in Section 11.4.1.2, the programmable, wired-OR logic is passive and non-restoring, drawing current from the input. Further, OR logic is not universal, and to build a good composable logic family an ability will be required to isolate inputs from output loads, restore signal strength and current drive, and invert signals.

Fortunately, NWs can be field-effect controlled, and this provides the potential to build FET-like gates for restoration. However, in order to realize these ways must be found to create the appropriate gate topology within the regular assembly constraints (see Section 11.3.1).

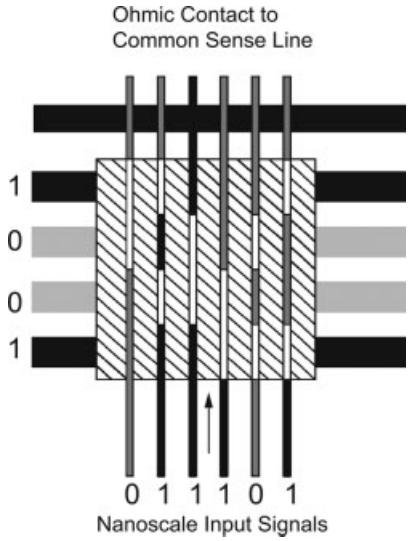

Figure 11.8 Coded NW multiplexer operation.

11.4.3.1 NW Inverter and Buffer

If two NWs are separated by an insulator, perhaps using an oxide core shell (see Section 11.2.1), then the field from one NW can potentially be used to control the other NW. Figure 11.9 shows an inverter which has been built using this basic idea. The horizontal NW serves as the input and the vertical NW as the output. This

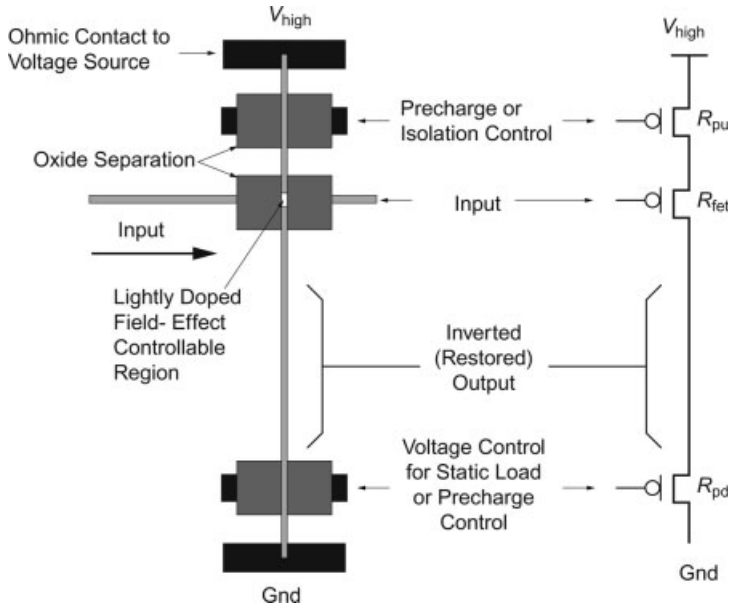

Figure 11.9 NW inverter.

gives a voltage transfer equation:

$$V_{\text{out}} = V_{\text{high}}\left(\frac{R_{\text{pd}}}{R_{\text{pd}} + R_{\text{fet}}(\text{input}) + R_{\text{pu}}}\right) \tag{11.1}$$

For the sake of illustration, the vertical NW has a lightly doped p-type depletion mode region at the input crossing forming a FET controlled by the input voltage (R_{fet}(Input)). Consequently, a low voltage on the input NW will allow conduction through the vertical NW ($R_{\text{fet}} = R_{\text{onfet}}$ is small), and a high input will deplete the carriers from the vertical NW and prevent conduction ($R_{\text{fet}} = R_{\text{offfet}}$ is large). As a result, a low input allows the NW to conduct and pull the output region of the vertical NW up to a high voltage. A high input prevents conduction and the output region remains low. A second crossed region on the NW is used for the pull down (R_{pd}); this region can be used as a gate for predischarge, so the inverter is pulled low before the input is applied, then left high to disconnect the pulldown voltage during evaluation. Alternately, it can be used as a static load for PMOS-like ratioed logic. By swapping the location of the high- and low-power supplies, this same arrangement can be used to buffer rather than invert the input.

Note that the gate only loads the input capacitively, and consequently current isolation is achieved at this inverter or buffer. Further, NW field-effect gating has sufficient non-linearity so that this gate provides gain to restore logic signal levels [27].

11.4.3.2 Ideal Restoration Array

In many scenarios, there is a need to restore a set of tight-pitch NWs such as the outputs of a programmable, wired-OR array. To do this, the approach would be to build a restoration array as shown in Figure 11.10a. This array is a set of crossed NWs

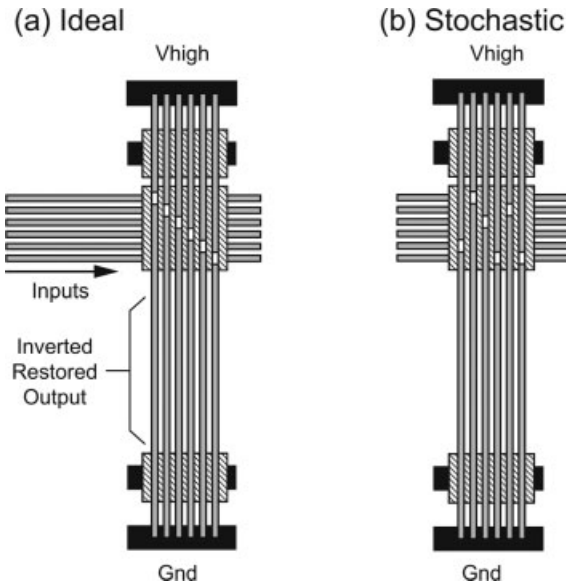

Figure 11.10 Restoration array.

which can be assembled using NW assembly techniques. If each of the NWs was sensitive to all of the crossed inputs, the result would be that all of the outputs would actually compute the NOR of the same set of inputs. To avoid computing a redundant set of NORs and instead simply to invert each of the inputs independently, these NWs are coded using an axial doping or material composition profile. In this way, each NW is field-effect sensitive to only a single NW, and hence provides the NW inversion described for a single one of the crossed NWs and is oblivious to the inputs of the other NWs.

The only problem here is that there is no way to align and place axially doped NWs so that they provide exactly this pattern, as the assembly treats all NWs as identical.

11.4.3.3 **Restoration Array Construction**

Although the region for active FETs is a nanoscale feature, it does not require small pitch or tight alignment. As such, there may be ways to mask and provide material differentiation along a diagonal as required to build this decoder.

Nonetheless, it is also possible to stochastically construct this restoration array in a manner similar to the construction of the address decoder. That is, an assembly is provided with a set of NWs with their restoration regions in various locations. The restoration array will be built by randomly selecting a set of restoration NWs for each array (see Figure 11.10b).

Two points differ compared to the address decoder case.

- The code space will be the same size as the desired restoration population.
- Duplication is allowed.

The question then is how large a fraction of the inputs will be successfully restored for a given number of randomly selected restoration NWs? This is an instance of the Coupon Collector Problem [28]. If the restoration array is populated with the same number of NWs as inputs, the array will typically contain restoration wires for 50–60% of the NW inputs. One way to consider this is that the array must be populated with 1.7- to 2-fold as many wires as would be hoped to yield due to these

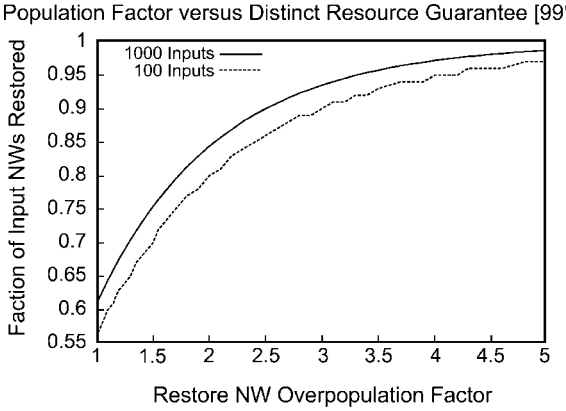

Figure 11.11 Fraction of input NWs restored as a function of restoration overpopulation.

stochastic assembly effects. If the number of restoration wires is increased relative to the number of input NWs, then a higher fraction of the inputs can be restored (as shown in Figure 11.11). For further details on these yield calculations, see Refs. [26, 29].

11.5 Memory Array

By combining the crosspoint memory cores with a pair of decoders, it is possible to build a tight-pitch, NW-based memory array [30]. Figure 11.12 shows how these elements come together in a small memory array, which is formed using crossed, tight-pitch NWs. Programmable diode crosspoints are assembled in the NW–NW crossings, while lithographic-scale address wires form row and column addresses. Write operations into the memory array can be performed by driving the appropriate write voltages onto a single row and column line. Read operations occur by driving a reference voltage onto the common column line, setting the row and column addresses, and sensing the voltage on the common row read line.

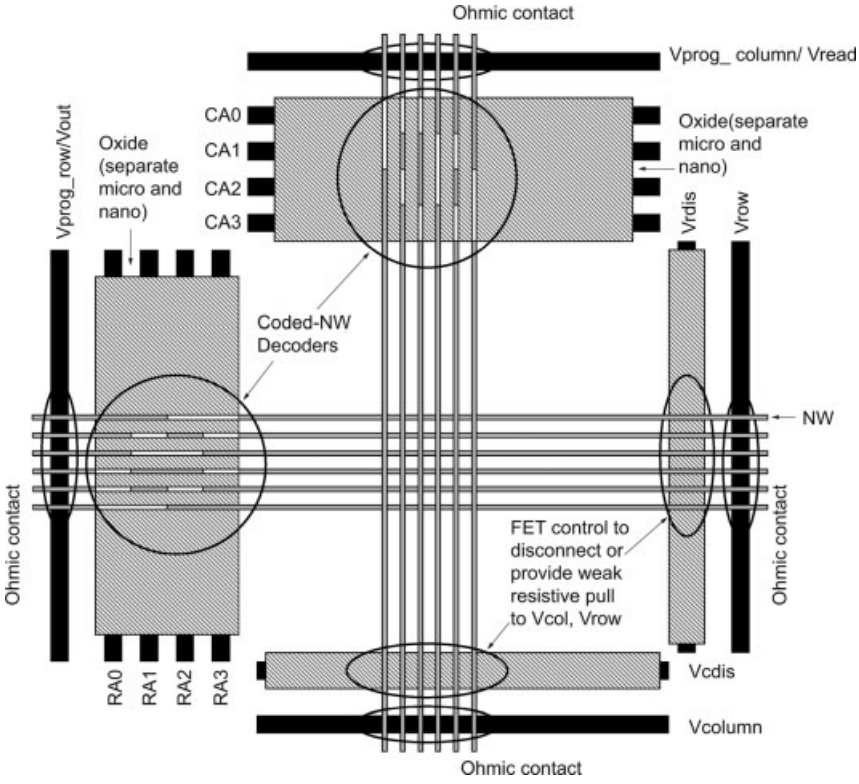

Figure 11.12 Memory array built from coded NW decoder and crosspoint memory core.

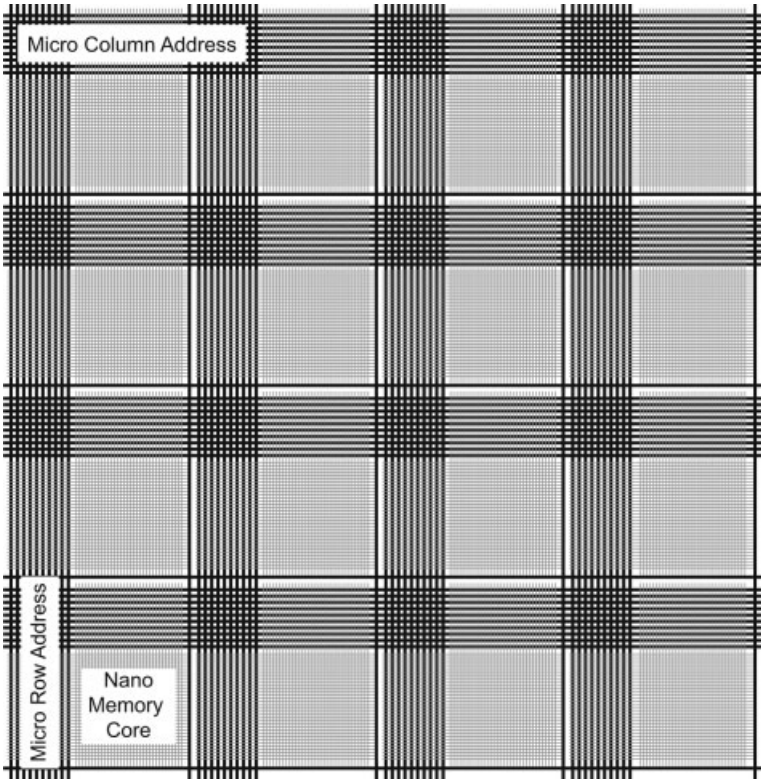

Figure 11.13 Tile of NW-based memory banks to construct large-scale memory.

Limitations on reliable NW length and the capacitance and resistance of long NWs prevent the building of arbitrarily large memory arrays. Instead, the large NW memories are broken up into banks similar to the banking used in conventional DRAMs (see Figure 11.13). Reliable, lithographic-scale wires provide address and control inputs and data inputs and outputs to each of the NW-based memory banks. The expected yield would be only a fraction of the NWs in the array due to wire defects. Error-correcting codes (ECC) can be used to tolerate non-programmable crosspoint defects. After accounting for defects, ECC overhead, and lithographic control overhead, net densities on the order of 10^{11} bits cm^{-2} appear achievable, using NW pitches of about 10 nm [29].

11.6 Logic Architecture

By combining the building blocks introduced in Section 11.4 it is possible to construct complete, programmable logic architectures with all logic, interconnect, and restoration occurring in the atomic-scale NWs. Diode crosspoints organized into Wired-OR logic arrays provide programmable logic, field-effect restoration arrays

provide gain and signal inversion, and the NWs themselves provide interconnect among arrays. Lithographic scale wires provide a reliable support infrastructure which allows device testing and programming (see Section 11.8), addressing individual NWs using the decoders introduced in Section 11.4.2. Lithographic-scale wires also provide power and control logic evaluation.

11.6.1 Logic

Figure 11.14 shows a simple PLA created using the building blocks from Section 11.4 and first introduced by DeHon and Wilson [31]. The design includes two interconnected logic planes, each of which is composed of a programmable Wired-OR array, followed by a restoration array. It should be noted here that two restoration arrays are actually used – one providing the inverted sense of the OR-term logic and one providing the non-inverted buffered sense. This arrangement is similar to conventional PLAs where the true and complement sense of each input is provided in each PLA plane. Since Wired-OR logic NWs can be inverted in this nanoPLA, each plane effectively serves as a programmable NOR plane. The combination of the two coupled NOR–NOR planes can be viewed as an AND–OR PLA with suitable application of DeMorgan's laws and signal complementation.

11.6.1.1 Construction

The entire construction is simply a set of crossed NWs as allowed by the regular assembly constraints (see Section 11.3.1). Lithographic-scale etches are used to differentiate regions (e.g. programmable-diode regions for the Wired-OR). The topology allows the same NWs that perform logic or restoration to carry their outputs across as inputs to the array that follows it.

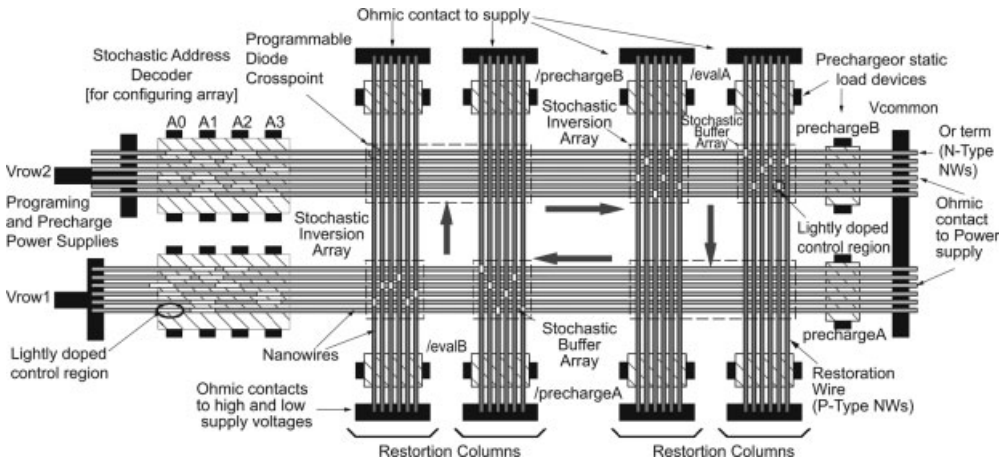

Figure 11.14 Simple nanoPLA block.

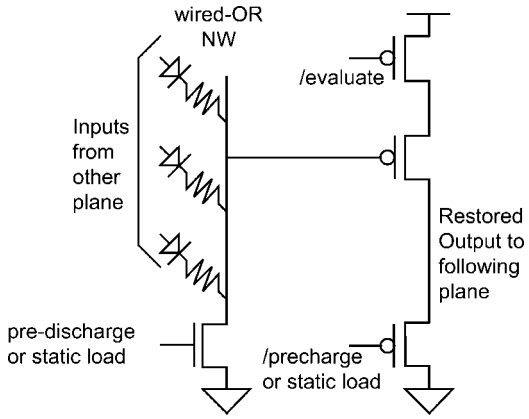

Figure 11.15 Rough circuit equivalent for each nanoPLA plane.

11.6.1.2 **Logic Circuit**

The logic gates in each PLA plane are composed of a diode-programmable Wired-OR NW, followed by a field-effect buffer or inverter NW (see Figure 11.15). The field-effect stage provides isolation as there is no current flow between the diode stage and the field-effect stage output. That is, the entire OR stage is capacitively loaded rather than resistively loaded. The OR stage simply needs to charge up its output which provides the field for the field-effect-based restoration stage. When the field is high enough (low enough for P-type NWs) to enable conduction in the field-effect stage, the NW will allow the source voltage to drive its output.

11.6.1.3 **Programming**

At the left-hand side of Figure 11.14 a decoder is formed (as introduced in Section 11.4.2) using the vertical microscale wires A0 to A3. These lithographic-scale wires allow the selection of individual NWs for programming. Each usable vertical restoration NW is driven by a horizontal NW. Consequently, decoders are only needed to address the horizontal NWs (see Section 11.8).

11.6.2
Registers and Sequential Logic

With slight modification as to how the control signals on the identified logic stages are driven, this can be turned into a clocked logic scheme. An immediate benefit is the ability to create a finite-state machine out of a single pair of PLA planes. A second benefit is the ability to use precharge logic evaluation for inverting restoration stages.

11.6.2.1 **Basic Clocking**

The basic nanoPLA cycle shown in Figure 11.14 is simply two restoring logic stages back-to-back (see Figure 11.16). For the present clocking scheme, the two stages are evaluated at altering times.

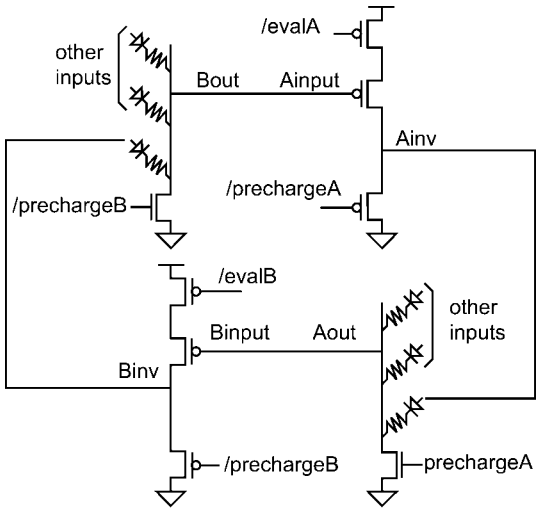

Figure 11.16 Precharge clocked INV-OR-INV-OR (NOR-NOR, AND-OR) cycle.

First, it should be noted that if all three of the control transistors in the restoring stages (restoring precharge and evaluate and diode precharge; e.g. evalA and prechargeA in Figure 11.16) are turned off, there is no current path from the input to the diode output stage. Hence, the input is effectively isolated from the output. As the output stage is capacitively loaded, the output will hold its value. As with any dynamic scheme, eventually leakage on the output will be an issue which will set a lower bound on the clock frequency.

With a stage isolated and holding its output, the following stage can be evaluated. It computes its value from its input, the output of the previous stage, and produces its result by suitably charging its output line. When this is done, this stage can be isolated and the succeeding stage (which in this simple case is also its predecessor) can be evaluated. This is the same strategy as two-phase clocking in conventional VLSI (e.g. Refs. [32, 33]).

In this manner, there is never an open current path all the way around the PLA (see Figures 11.16 and 11.17). In the two phases of operation, there is effectively a single register on any PLA outputs which feed back to PLA inputs.

11.6.2.2 **Precharge Evaluation**

For the inverting stage, the pulldown gate is driven hard during precharge and turned off during evaluation. In this manner, the line (A_{inv}) is precharged low and pulled it up only if the input (A_{input}) is low. This works conveniently in this case because the output will also be precharged low. If the input is high, then there is no need to pullup the output and it is simply left low. If the input is low, the current path is allowed to pullup the output. The net benefit is that inverter pulldown and pullup are both controlled by strongly driven gates and can be fast, whereas in a static logic scheme, the pulldown transistor must be weak, making pulldown slow compared to pullup. Typically, the weak pulldown transistor would be set to have an order of magnitude

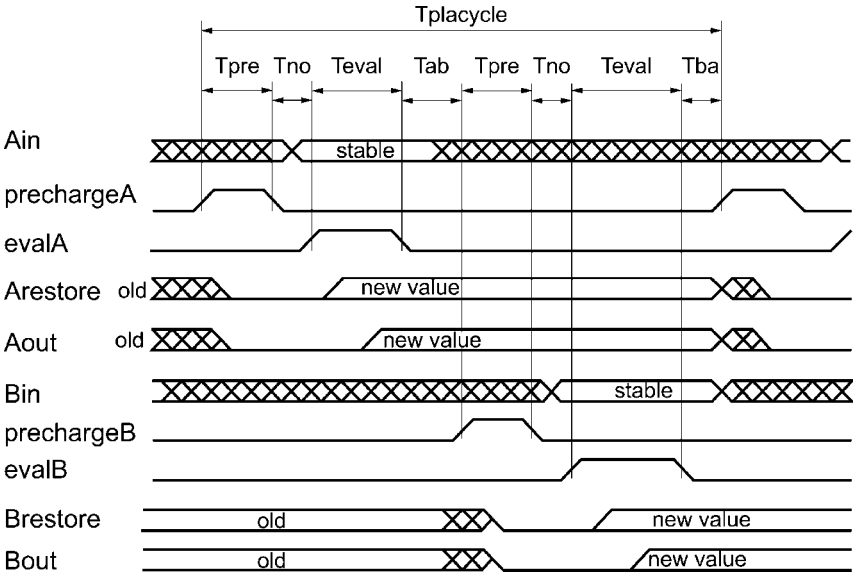

Figure 11.17 Clocking/precharge timing diagram.

higher resistance than the pullup transistor so this can be a significant reduction in worst-case gate evaluation latency.

Unfortunately, in the buffer case the weak pullup resistor can neither be precharged to high nor turned off, and so there are no comparable benefits there. It is possible that new devices or circuit organizations will eventually allow precharge buffer stages to be built.

11.6.3 Interconnect

It is known from VLSI that large PLAs do not always allow the structure which exists in logic to be exploited. For example, an *n*-input XOR requires an exponential number of product terms to construct in the two-level logic of a single PLA. Further, the limitation on NW length (see Section 11.3.2) bounds the size of the PLAs that can reasonably be built. Consequently, in order to scale up to large-capacity logic devices, modest size nanoPLA blocks must be interconnected; these nanoPLA blocks are extended to include input and output to other nanoPLA blocks and then assembled into a large array (see Figure 11.18), as first introduced by DeHon [34].

11.6.3.1 Basic Idea

The key idea for interconnecting nanoPLA blocks is to overlap the restored output NWs from each such block with the wired-OR input region of adjacent nanoPLA blocks (see Figure 11.18). In turn, this means that each nanoPLA block receives inputs from a number of different nanoPLA blocks. With multiple input sources and outputs routed in multiple directions, this allows the nanoPLA block also to serve as a

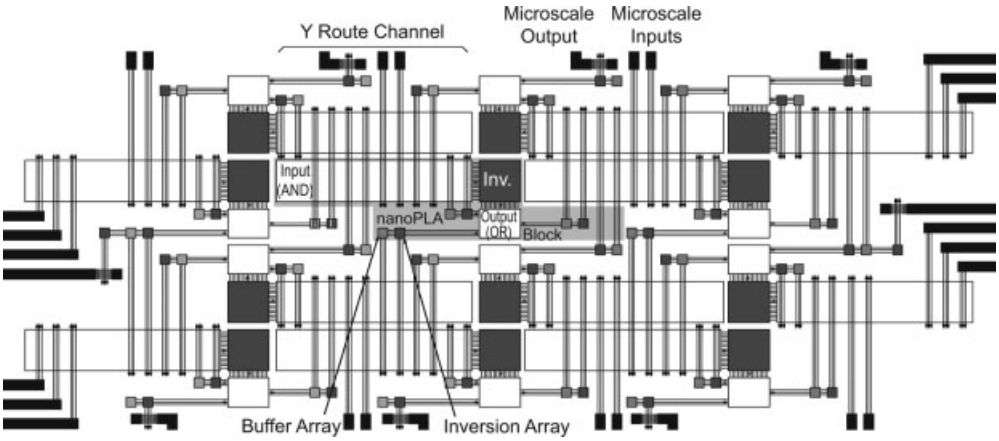

Figure 11.18 nanoPLA block tiling with edge IO to lithographic scale.

switching block. By arranging the overlap appropriately, Manhattan routing can be supported, thereby allowing the array of nanoPLA blocks to be configured to route signals between any of the blocks in the array.

11.6.3.2 **NanoPLA Block**

- *Input wired-OR region*. One or more regions of programmable crosspoints serves as the input to the nanoPLA block. Figures 11.18 and 11.19 show a nanoPLA block design with a single such input region. The inputs to this region are restored output NWs from a number of different nanoPLA blocks. The programmable crosspoints

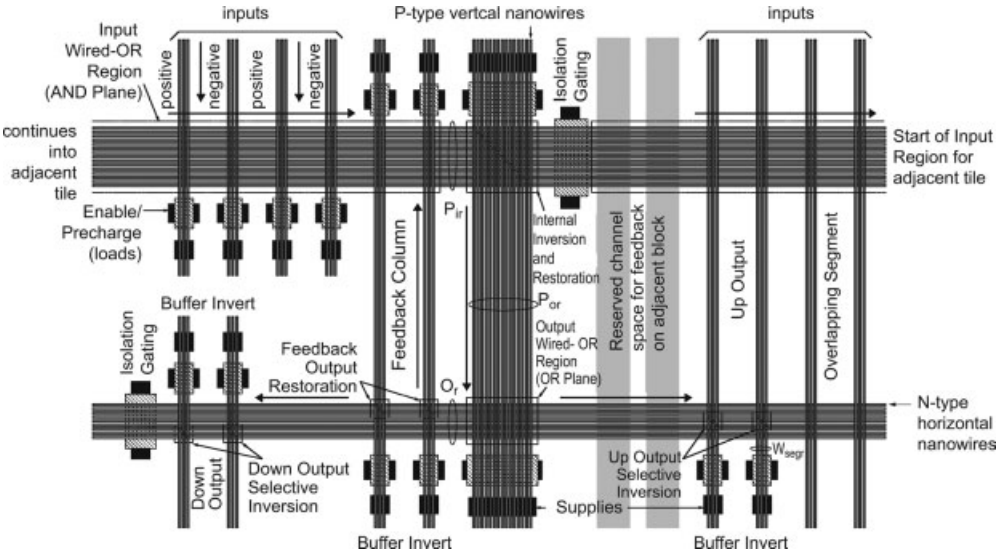

Figure 11.19 nanoPLA block tile.

allow those inputs to be selected which participate in each logical product term (PTERM) building a wired-OR array, as in the base nanoPLA (see Section 11.6.1).

- *Internal inversion and restoration array.* The NW outputs from the input block are restored by a restoration array. The restoration logic is arranged at this stage to be inverting, thus providing the logical NOR of the selected input signals into the second plane of the nanoPLA.
- *Output OR plane.* The restored outputs from the internal inversion plane become inputs to a second programmable crosspoint region. Physically, this region is the same as the input plane. Each NW in this plane computes the wired-OR of one or more of the restored PTERMs computed by the input plane.
- *Selective output inversion.* The outputs of the output OR plane are then restored in the same way as the internal restoration plane. On this output, however, the selective inversion scheme introduced in Section 11.6.1 is used. This provides both polarities of each output, and these can then be provided to the succeeding input planes. This selective inversion plays the same role as a local inverter on the inputs of conventional, VLSI PLA; here it is placed with the output to avoid introducing an additional logic plane into the design. As with the nanoPLA block, these two planes provide NOR–NOR logic. With suitable application of DeMorgan's laws, these can be viewed as a conventional AND–OR PLA.
- *Feedback.* As shown in Figures 11.18 and 11.19, one set of outputs from each nanoPLA block feeds back to its own input region. This completes a PLA cycle similar to the nanoPLA design (see Section 11.6.1). These feedback paths serve the role of intracluster routing similar to internal feedback in conventional Island-style [35] FPGAs. The nanoPLA block implements registers by routing signals around the feedback path (Section 11.6.2.1). The signals can be routed around this feedback path multiple times to form long register delay chains for data retiming.

11.6.3.3 **Interconnect**

- *Block outputs.* In addition to self feedback, output groups are placed on either side of the nanoPLA block and can be arranged so they cross input blocks of nanoPLA blocks above or below the source nanoPLA block (see Figure 11.18). Like segmented FPGAs [36, 37], output groups can run across multiple nanoPLA block inputs (i.e. Connection Boxes) in a given direction. The nanoPLA block shown in Figure 11.19 has a single output group on each side, one routing up and the other routing down. It will be seen that the design shown is sufficient to construct a minimally complete topology.
- Since the output NWs are directly the outputs of gated fields: (i) an output wire can be driven from only one source; and (ii) it can only drive in one direction. Consequently, unlike segmented FPGA wire runs, directional wires must be present that are dedicated to a single producer. If multiple control regions were coded into the NW runs, conduction would be the AND of the producers crossing the coded regions. Single direction drive arises from the fact that one side of the

gate must be the source logic signal being gated so the logical output is only available on the opposite side of the controllable region. Interestingly, the results of recent studies have suggested that conventional, VLSI-based FPGA designs also benefit from directional wires [38].

- *Y route channels.* With each nanoPLA block producing output groups which run one or more nanoPLA block heights above or below the array, the result is vertical (Y) routing channels between the logic cores of the nanoPLA blocks (see Figure 11.18). The segmented, NW output groups allow a signal to pass a number of nanoPLA blocks. For longer routes, the signal may be switched and rebuffered through a nanoPLA block (see Figure 11.20). Because of the output directionality, the result is separate sets of wires for routing up and routing down in each channel.
- *X routing.* While Y route channels are immediately obvious in Figure 11.18, the X route channels are less apparent. All X routing occurs through the nanoPLA block. As shown in Figure 11.19, one output group is placed on the opposite side of the nanoPLA block from the input. In this way, it is possible to route in the X direction by going through a logic block and configuring the signal to drive a NW in the

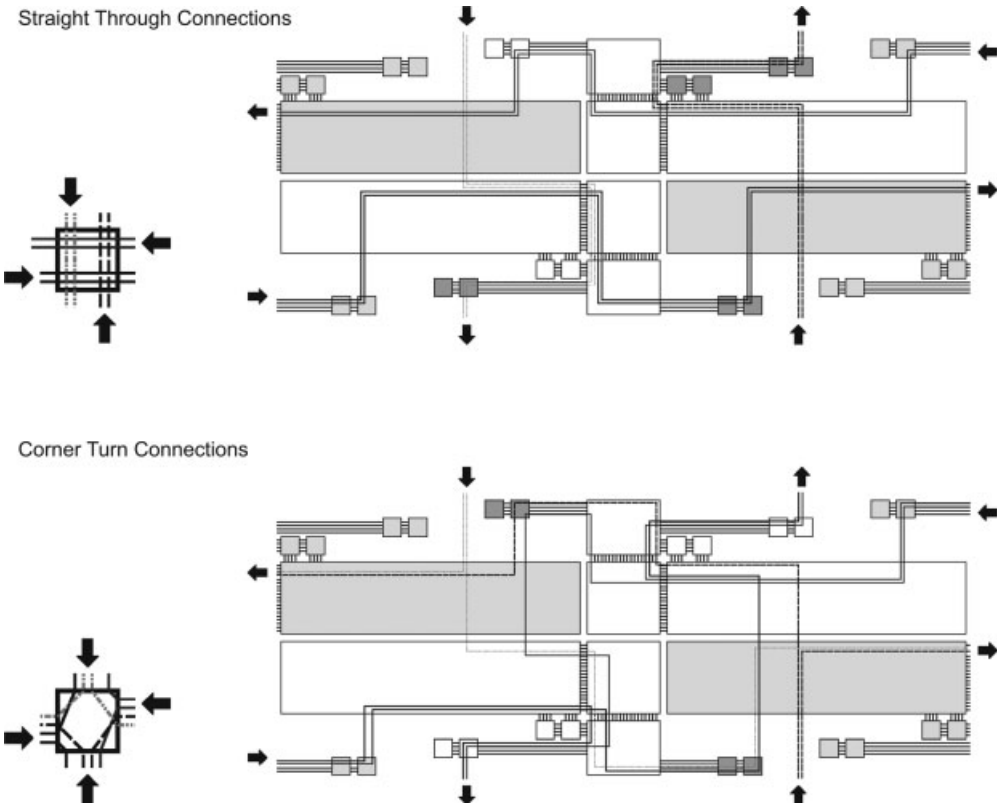

Figure 11.20 Routing view of nanoPLA logic block.

output group on the opposite side of the input. If all X routing blocks had their inputs on the left, then it would be possible only to route from left to right. To allow both left-to-right and right-to-left routing, the orientation of the inputs is alternated in alternate rows of the nanoPLA array (see Figures 11.18 and 11.20). In this manner, even rows provide left-to-right routing, while odd rows allow right-to-left routing.

- *Relation to Island-style Manhattan design.* Logically viewed, this interconnected nanoPLA block is very similar to conventional, Island-style FPGA designs, especially when the Island-style designs use directional routing [38]. As shown in Figure 11.20, there are X and Y routing channels, with switching to provide X–X, Y–Y, and X–Y routing.

11.6.4 CMOS IO

These nanoPLAs will be built on top of a lithographic substrate. The lithographic circuitry and wiring provides a reliable structure from which to probe the NWs to map their defects and to configure the logic (see Section 11.8).

For input and output to the lithographic scale during operation, IO blocks can be provided to connect the nanoscale logic to lithographic-scale wires, in much the same way that lithographic-scale wires are connected to bond pads on FPGAs. The simplest arrangement resembles the traditional, edge IO form of a symmetric FPGA with inputs and outputs attached to NWs at the edges of the routing channels (see Figure 11.18).

NW inputs can easily be driven directly by lithographic-scale wires. As the lithographic-scale wires are wider pitch, a single lithographic wire will connect to a number of NWs. With the lithographic wire connected to the NWs, the NW crosspoints in the nanoPLA block inputs can be programmed in the same way they are for NW inputs.

It is possible to connect outputs in a similar manner. Such a direct arrangement could be particularly slow, as the small NWs must drive the capacitance of a large, lithographic-scale wire. Alternately, the NWs can be used as gates on a lithographic-scale field-effect transistor (FET) (see Figure 11.21). In this manner, the NWs are only

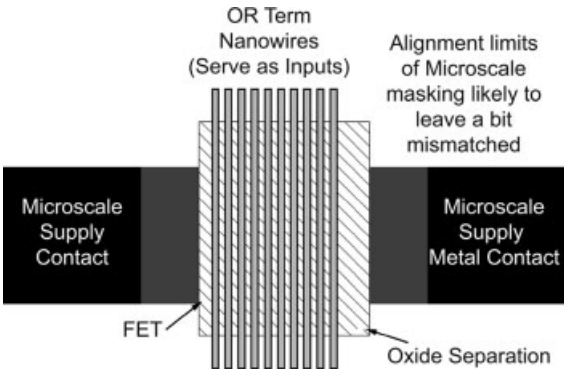

Figure 11.21 Nanoscale to lithographic-scale FET output structure.

loaded capacitively by the lithographic-scale output, and only for a short distance. The NW thresholds and lithographic FET thresholds can be tuned into comparable voltage regions so that the NWs can drive the lithographic FET at adequate voltages for switching. As shown, multiple NWs will cross the lithographic-scale gate. The OR-terms driving these outputs are all programmed identically, allowing the multiple-gate configuration to provide strong switching for the lithographic-scale FET.

11.6.5 Parameters

The key parameters in the design of the nanoPLA block are shown in Figure 11.22, where:

- W_{seg} is the number of NWs in each output group.
- L_{seg} is the number of nanoPLA block heights up or down which each output crosses; equivalently, the number of parallel wire groups across each Y route channel in each direction. In Figure 11.1 $L_{seg} = 2$, and this is maintained throughout the chapter.
- F is the number of NWs in the feedback group; for simplicity, $F = W_{seg}$ is maintained throughout the chapter.
- P is the number of logical PTERMs in the input (AND) plane of the nanoPLA logic block.
- O_p is the number of totals outputs in the OR plane. As each output is driven by a separate wired-OR NW, $O_p = 2 \times W_{seg} + F$ for the nanoPLA block focused on in this chapter, with two routing output groups and a feedback output group.
- P_p is the number of total PTERMs in the input (AND) plane. As these are also used for route-through connections, this is larger than the number of logical PTERMs in each logic block.

$$P_p \leq P + 2 \times W_{seg} + F \tag{11.2}$$

That is, in addition to the P logical PTERMs, one physical wire may be needed for each signal that routes through the array for buffering; there will be at most O_p of these.

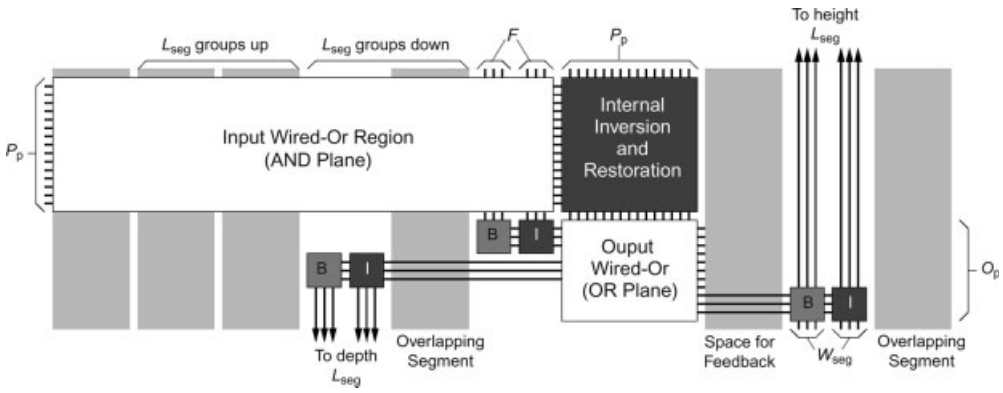

Figure 11.22 nanoPLA block parameters.

Additionally, the number and distribution of inputs [e.g. one side (as shown in Figure 11.22), from both sides, subsets of PTERMs from each side], the output topology (e.g. route both up and down on each side of the array), and segment length distributions could be parameterized. However, in this chapter attention is focused on this simple topology, with $L_{seg} = 2$. Consequently, the main physical parameters determining nanoPLA array size are W_{seg} and P_p.

11.7 Defect Tolerance

As noted in Section 11.3.3, it is likely that a small percentage of wires are defective and crosspoints are non-programmable. Furthermore, stochastic assembly (see Sections 11.4.2.2 and 11.4.3.3) and misalignment will also result in a percentage of NWs which are unusable. Fortunately, NWs are interchangeable and the crosspoints are small. Consequently, spare NWs can be provisioned into an array (e.g. overpopulate compared to the desired P_p and W_{seg}), NWs can be tested for usability (see Section 11.8.1), and the array configured using only the non-defective NWs. Further, a NW need not have a perfect set of junctions to be usable (see Section 11.7.4).

11.7.1 NW Sparing

Tolerating wire defects is a simple matter of provisioning adequate spares, separating the good wires from the bad, and configuring the nanoPLA blocks accordingly. For a given PLA design, each block should have a minimum number of usable wires (P_p and W_{seg}). As there will then be wire losses, the physical array is designed to include a larger number of physical wires to ensure that the yield of usable wires is sufficient to meet the logical requirements.

Using the restoration scheme described in Section 11.4.3, wires work in pairs. A horizontal OR-term wire provides the programmable computation or programmable interconnect, and a vertical restoration wire provides signal restoration and perhaps inversion. A defect in either wire will result in an unusable pair. Consequently, each logical OR-term or output will yield only when both wires yield. Let P_{wire} be the probability that a wire is not defective; then, the probability of yielding each OR-term is:

$$P_{OR} = (P_{input\text{-}wire} \times P_{restore\text{-}wire}). \tag{11.3}$$

An M-choose-N calculation can then be performed to determine the number of wires that must physically populate (N) to achieve a given number of functional wires (M) in the array. The probability of yielding exactly i restored OR-terms is:

$$P_{yield}(N, i) = \left(\binom{N}{i} (P_{OR})^i (1 - P_{OR})^{N-i} \right). \tag{11.4}$$

That is, there are $\binom{N}{i}$ ways to select i functional OR-terms from N total wires, and the yield probability of each case is: $(P_{OR})^i(1 - P_{OR})^{N-i}$. An ensemble is yielded with M items whenever M or more items yield, so the system yield is actually the cumulative distribution function:

$$P_{\text{M of N}} = \sum_{M \le i \le N} \left(\binom{N}{i} (P_{OR})^i (1 - P_{OR})^{N-i} \right) \tag{11.5}$$

Given the desired probability for yielding at least M functional OR-terms, $P_{\text{M of N}}$, Eq. (11.5) provides a way of finding the number of physical wires, N, that must be populated to achieve this. For the interconnected nanoPLA blocks, the product terms (P_p) and interconnect wires (W_{seg}) will be the Ms in Eq. (11.5), and a corresponding pair of raw numbers N will be calculated to determine the number of physical wires that must be placed in the fabricated nanoPLA block. Here, P_r will be used to refer to the number of raw product term NWs needed to assemble, and W_{segr} to the number of raw interconnect NWs. Figure 11.23 illustrates how much larger N needs to be than $M = 100$ for various defect rates and yield targets.

11.7.2 NW Defect Modeling

A NW could fail to be usable for several reasons:

- The NW may make poor electrical contact to microwires on either end (let P_c be the probability the NW makes a good connection on one end).
- The NW may be broken along its length (let P_j be the probability that there is no break in a NW in a segment of length L_{unit}).
- The NW may be poorly aligned with address region (wired-OR NWs) or restoration region (restoration NW) (let P_{ctrl} be the probability that a the NW is aligned adequately for use).

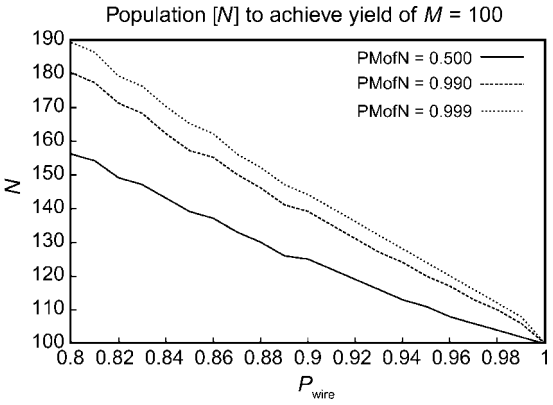

Figure 11.23 Physical population (N) of wires to achieve 100 restored OR-terms (M).

Consequently, the base NW yield looks like:

$$P_{\text{wire}} = (P_{\text{C}})^2 \times (P_{\text{j}})^{L_{\text{wire}}/L_{\text{unit}}} \times P_{\text{ctrl}} \tag{11.6}$$

Typically, $P_{\text{c}} = 0.95$ (after Ref. [5] and $P_{\text{j}} = 0.9999$ with $L_{\text{unit}} = 10\,\text{nm}$ (after Ref. [19]; see also Refs. [27, 34]). P_{ctrl} can be calculated from the geometry of the doped regions [24]. P_{wire} is typically about 0.8.

11.7.3
Net NW Yield Calculation

A detailed calculation for NW population includes both wire defect effects and stochastic population effects. Starting with a raw population number for the NWs in each piece of the array, it is possible to:

- calculate the number of non-defective wired-OR wires within the confidence bound [Eqs. (11.6) and (11.5)];
- calculate the number of those which can be uniquely addressed using the following recurrence:

$$\begin{aligned} P_{\text{different}}(T, N, u) = &\left(\frac{T-(u-1)}{T}\right) \times P_{\text{different}}(T, N-1, u-1) \\ &+ \left(\frac{u}{T}\right) \times P_{\text{different}}(T, N-1, u) \end{aligned} \tag{11.7}$$

where T is the number of different wire types (i.e. the size of the address space), N is the raw number of nanowires populated in the array, and u is the number of unique NWs in the array.

- calculate the number of net non-defective restored wire pairs within the confidence bound [Eqs. (11.3), (11.6), and (11.5)];
- calculate the number of uniquely restored OR terms using Eq. (11.7); in this case, T is the number of possible restoration wires rather than the number of different NW addresses.

These calculations indicate how to obtain P_{r} and W_{segr} to achieve a target P_{p} and W_{seg}.

11.7.4
Tolerating Non-Programmable Crosspoints

As will be seen in Table 11.1, PLA crosspoint arrays are typically built with approximately 100 net junctions. If were demanded that all 100 crosspoint junctions on a NW were programmable in order for the NW to yield, then an unreasonably high yield rate per crosspoint would be required. That is, assuming a crosspoint is programmable with probability P_{pgm} and a NW has N_{junc} input NWs – and hence crosspoint junctions

Table 11.1 Area minimizing nanoPLA design points (Ideal Restoration, with $W_{litho} = 105$ nm, $W_{fnano} = W_{dnano} = 10$ nm); area ratios estimate how much larger 22 nm lithographic FPGAs would be compared to the mapped nanoPLA designs.

Design	P_p	W_{seg}	Area ratio
alu4	60	8	340

tseng	78	25	20

– then the probability that all junctions on a NW are programmable is

$$P_{\text{pgmwire}} = (P_{\text{pgm}})^{N_{\text{junc}}} \tag{11.8}$$

To have $P_{\text{pgmwire}} \geq 0.5$, P_{pgm} would need to be >0.993. However, as was noted in Section 11.3.3, the non-programmable crosspoint defect rates would be expected to be in the range of 1 to 10% ($0.9 \leq P_{\text{pgm}} \leq 0.99$).

As introduced by Naeimi and DeHon [39], it is apparent that a NW with non-programmable crosspoints can still be used to implement a particular OR-term, as long as it has programmable crosspoints where the OR-term needs on-programmed junctions. Furthermore, as the array has a large number of otherwise interchangeable NWs (e.g. 100), it is possible to search through the array for NWs that can implement each particular OR-term.

For example, if a logic array (AND or OR plane) of a nanoPLA has defective junctions (as marked in Figure 11.24), the OR-term $f = A + B + C + E$ can be assigned to NW $W3$, despite the fact that it has a defective (non-programmable) junction at ($W3$, D); that is, the OR-term f is compatible with the defect pattern of NW $W3$.

As the number of programmed junctions needed for a given OR-term is usually small (e.g. 8–20) compared to the number of inputs in an array (e.g. 100), the probability that a NW can support a given OR-term is much larger than the probability that it has no junction defects. Assuming that C is the fan-in to the OR-term, and assuming random

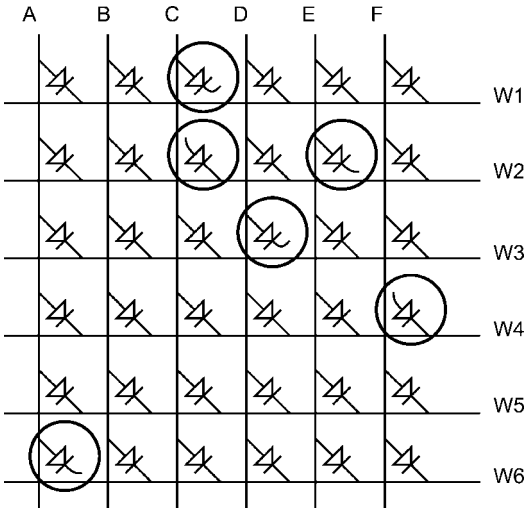

Figure 11.24 OR array with defective junctions.

junction defects, the probability that the NW can support the OR-term is

$$P_{\text{support}}(C) = (P_{\text{pgm}})^{C}. \tag{11.9}$$

For example, in a 100 NW array, if $P_{\text{pgm}} = 0.95$, $P_{\text{support}}(13) \approx 0.51$, and $P_{\text{pgmwire}} \approx 0.006$. Furthermore, as multiple NWs can be used in an array to find a compatible match, failure to map a NW will only occur if there are no compatible NWs in the array.

$$P_{\text{match}} = (C,\ N_{\text{wire}}) = (1 - (1 - P_{\text{support}}(C)^{N_{\text{wire}}}). \tag{11.10}$$

Hence, the probability of failing to find a match for the $C = 13$ OR-term in a 100 NW array is $[1 - P_{\text{match}}(13, 100) \leq 10^{-31}]$. Alternately, this means we have a 99% chance of finding a match after checking only 8 NWs ($P_{\text{match}}(13, 8) > 0.99$).

Naeimi and DeHon [39] developed the analysis and mapping strategy in greater detail for tolerating non-programmable crosspoints. DeHon and Naeimi [30] further expanded the mapping strategy to the interconnected nanoPLAs described in Section 11.6.3, and showed that non-programmable defect rates of up to 5% could be accommodated, with no additional overhead.

11.8 Bootstrap Testing

11.8.1 Discovery

Since addressing and restoration is stochastic, there is a need to discover the live addresses and their restoration polarity. Further, as the NWs will be defective it is vital

to identify those NWs which are usable and those which are not. Here, the restoration columns (see Figures 11.14 and 11.19) are used to help identify useful addresses. The gate side supply (e.g. the top set of lithographic wire contacts in Figure 11.10) can be driven to a high value, after which a voltage is sought on the opposite supply line (e.g. the bottom set of lithographic wire contacts in Figure 11.10; these contacts are marked V_{high} and Gnd in Figure 11.10, but will be controlled independently as described here during discovery). There will be current flow into the bottom supply only if the control associated with the p-type restoration wire can be driven to a sufficiently low voltage. The process is started by driving all the row lines high, using the row precharge path. A test address is then applied and the supply (V_{row} in Figure 11.14) is driven low. If a NW with the test address is present, only that line will now be strongly pulled low. If the associated row line can control one or more wires in the restoration plane, the selected wires will now see a low voltage on their field-effect control regions and enable conduction from the top supply to the bottom supply. By sensing the voltage change on the bottom supply, the presence of a restored address can be deduced. Broken NWs will not be able to effect the bottom supply. NWs with excessively high resistance due to doping variations or poor contacts will not be able to pull the bottom supply contact up quickly enough. As the buffering and inverting column supplies are sensed separately it will be known whether the line is buffering, inverting, or binate.

No more than $O((P_p)^2)$ unique addresses are needed to achieve virtually unique row addressing [24], so the search will require at most $O((P_p)^2)$ such probes. A typical address width for the nanoPLA blocks is $N_a = 14$, which provides 3432 distinct 7-hot codes, and a typical number of OR-terms might be 90 (see Table 11.1). Hence, 3432 addresses may need to be probed to find 90 live row wires.

When all the present addresses in an array and the restoration status associated with each address are known, logic can be assigned to logical addresses within each plane, based on the required restoration for the output. With logic assigned to live addresses in each row, the address of the producing and consuming row wires can now be used to select and program a single junction in a diode-programmable OR plane.

11.8.2 Programming

In order to program any diode crosspoint in the OR planes (e.g. Figure 11.14), one address is driven into the top address decoder, and the second address into the bottom. The stochastic restoration performs the corner turn, so that the desired programming voltage differential is effectively placed across a single crosspoint. The voltages and control gating on the restoration columns are then set to define which programmable diode array is actually programmed during a programming operation. For example, in Figure 11.14 the ohmic supply contacts at the top and bottom are the control voltages; the signals used for control gating are labeled with precharge and eval signal names. To illustrate the discovery and programming process, DeHon [29] presents the steps involved in discovering and programming an exemplary PLA.

11.8.3 Scaling

It should be noted that each nanoPLA array is addressed separately from its set of microscale wires ($A0$, $A1$, ... and V_{row}, V_{bot}, and V_{top}; see Figure 11.14). Consequently, the programming task is localized to each nanoPLA plane, and the work required to program a collection of planes (e.g. Figure 11.18) only scales linearly with the number of planes.

11.9 Area, Delay, and Energy

11.9.1 Area

From Figures 11.19 and 11.22 the basic area composition of each tile can be seen. For this, the following feature size parameters are used:

- W_{litho} is the lithographic interconnect pitch; for example, for the 45-nm node, $W_{litho} = 105$ nm [40].
- W_{dnano} is the NW pitch for NWs which are inputs to diodes (i.e. Y route channel segments and restored PTERM outputs).
- W_{fnano} is the NW pitch for NWs which are inputs to field-effect gated NWs; this may be larger than W_{dnano} in order to prevent inputs from activating adjacent gates and to avoid short-channel FET limitations.

The tile area is computed by first determining the tile width, TW, and tile height, TH:

$$TW = (3 + 4(L_{seg} + 1)) \times W_{litho} + (P_{or} + 4(L_{seg} + 1)W_{segr}) \times W_{dnano} \quad (11.11)$$

$$TH = 12 \times W_{litho} + (O_r + P_{ir}) \times W_{fnano} \quad (11.12)$$

$$AW = (N_a + 2) \times W_{litho} \quad (11.13)$$

$$Area = (AW + TW) \times TH \quad (11.14)$$

where P_{or}, P_{ir}, O_r, and W_{segr} (shown in Figure 11.19) are the raw number of wires needed to populate in the array in order to yield P_p restored inputs, O_p restored outputs, and W_{seg} routing channels (see Section 11.7.3). The two 4s in TW arise from the fact that there are $L_{seg} + 1$ wire groups on each side of the array ($2\times$), and each of those is composed of a buffer/inverter selective inversion pair ($2\times$). A lithographic spacing is charged for each of these groups as they must be etched for isolation and controlled independently by lithographic scale wires. The 12 lithographic pitches in TH account for the three lithographic pitches needed on each side of a group of wires for the restoration supply and enable gating. As segmented wire runs end and begin

between the input and output horizontal wire runs, these three lithographic pitches are paid for four-fold in the height of a single nanoPLA block: once at the bottom top of the block (see Figure 11.19).

N_a is the number of microscale address wires needed to address individual, horizontal nanoscale wires [24]; for the nanoPLA blocks in these studies, N_a is typically 14 to 20. Two extra wire pitches in the AddressWidth (*AW*) are the two power supply contacts at either end of an address run.

11.9.2 Delay

Figures 11.16 and 11.17 show the basic nanoPLA clock cycle, $T_{placycle}$. The component delays shown in Figure 11.17 (e.g. nanowire precharge and evaluation times) are calculated based on the NW resistances and capacitances, the crosspoint resistances, and the nanowire FET resistances [29]. NW resistance and capacitance can be calculated based on geometry and material properties using the NW lengths, which are roughly multiples of the tile width, *TW*, and tile height, *TH*, identified in the previous section. If simply heavily doped silicon nanowires are used, the NW resistances can be close to 10 MΩ, and this results in nanoPLA clock cycle times in the tens of nanoseconds. However, if the regions of the NW which do not need to be semiconducting are converted selectively – that is, everything except the diode crosspoint region and the field-effect restoration region – into a nickel silicide (NiSi) [12], the NW resistances can be reduced to the 1 MΩ range. As a result, the nanoPLA clock cycle is brought down to the nanosecond region. This selective conversion can be performed as a lithographic-scale masking step and, with careful engineering, subnanosecond nanoPLA cycle times may be possible. As long as the NW resistance is in the 1 MΩ range, it will dominate the on-resistance of both the field-effect gating in the restoration NW (R_{onfet}) and diode on-resistances ($R_{ondiode}$) in the 100 KΩ range.

11.9.3 Energy and Power

The nanoPLAs will dissipate active energy, charging and discharging the functional and configured NWs.

$$E_{NW} = \frac{1}{2} C_{Wire} V^2. \tag{11.15}$$

As noted in the previous section, C_{wire} can be computed from the material properties and geometry. To tolerate variations in NW doping, it is likely the operating voltage will need to be 0.5 to 1 V.

The raw E_{NW} can be discounted by the fraction of NWs typically used in a routing channel or a logic array, *F*. This tends to be 70–80% with the current tools and designs. When using the selective inversion scheme, both polarities of most signals will typically be driven to guarantee a close to 50% activity factor, *A*.

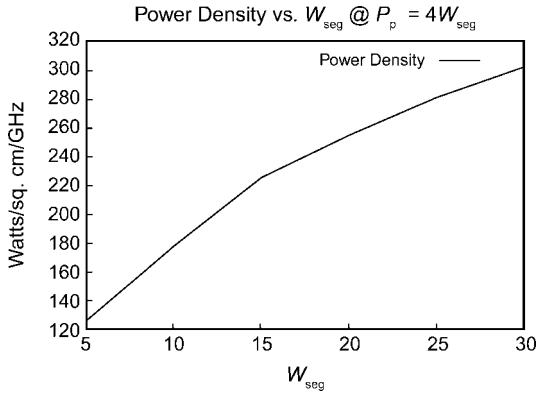

Figure 11.25 Power density as a function of W_{seg} for ideal restore, stochastic address case with $W_{litho} = 105$ nm, $W_{fnano} = 10$ nm, $W_{dnano} = 10$ nm.

Assuming an operating frequency of f, the power for a nanoPLA tile is

$$P_{array} = \sum_{\text{all NWs}} (A \times F \times E_{NW} \times f). \tag{11.16}$$

The power density is then

$$P_{density} = \frac{P_{array}}{Area}. \tag{11.17}$$

Here, *Area is* the area for the tile as calculated in Eq. (11.14).

Figure 11.25 shows the power density associated with interconnected nanoPLAs, and suggests that the designs may dissipate a few hundred Watts per cm^2. In typical designs, compute arrays would be interleaved with memory banks (see Section 11.5), which have much lower power densities. Nonetheless, this suggests that power management is as much an issue in these designs as it is in traditional, lithographic, designs.

11.10 Net Area Density

Recent developments in technology suggest that it is possible to build and assemble 10 nm-pitch NWs with crosspoints at every NW–NW crossing. To use these, it is necessary to pay for lithographic addressing overhead, to use regular architectures, and tolerate defects. In order to understand the net benefits, the characteristics of composite designs are analyzed. As an example, conventional FPGA benchmarks are mapped from the Toronto 20 benchmark suite [1] to NW logic with $W_{litho} = 105$ nm (45 nm roadmap node) and $W_{fnano} = W_{dnano} = 10$ nm. This provides a count of nanoPLA blocks and the logical P_p and W_{seg} parameters identified in Section 11.6.5, and these calculations can then be used for yield and statistical assembly

(see Section 11.7) to compute physical nanowire population, and the area equations in Section 11.9.1 to compute composite area. Subsequently, the resultant minimum area obtainable is compared with the nanoPLA designs to lithographic 4-LUT FPGAs at the 22 nm node [40]. As shown in Table 11.1, and further detailed in Ref. [29], the routed nanoPLA designs are one to two orders of magnitude smaller than 22 nm lithographic FPGAs, even after accounting for lithographic addressing overhead, defects, and statistical addressing.

The datapoints in Table 11.1 are based on a number of assumptions about lithographic and nanowire pitches and statistical assembly. DeHon [29] also examined the sensitivity to these various parameters, and showed that the statistical restoration assembly costs a factor of three in density for large arrays, while the cost of statistical addressing is negligible. If the diode pitch (W_{dnano}) could be reduced to 5 nm, another factor of almost two in area could be saved. Moreover, if the lithographic support were also reduced to the 22 nm node ($W_{\text{litho}} = 45$ nm), a further three-fold factor in density advantage would be gained compared to the data in Table 11.1.

11.11 Alternate Approaches

During recent years, several groups have been studying variants of these nanowire-based architectures (see Table 11.2). Heath *et al.* [41] articulated the first vision for constructing defect-tolerant architectures based on molecular switching and bottom-up construction. Luo *et al.* [42] elaborated the molecular details and diode-logic structure, while Williams and Kuekes [23] introduced a random particle decoder scheme for addressing individual NWs from lithographic-scale wires. These early designs assumed that diode logic was restored and inverted using lithographic scale CMOS buffers and inverters.

Goldstein and Budiu [43] described an interconnected set of these chemically-assembled diode-based devices, while Goldstein and Rosewater [44] used only two-terminal non-restoring devices in the array, but added latches based on resonant-tunneling diodes (RTDs) for clocking and restoration. Snider *et al.* [45] suggested nanoFET-based logic and also tolerated non-programmable crosspoint defects by matching logic to the programmability of the device.

Strukov and Likharev [46] also explored crosspoint-programmable nanowire-based programmable logic and used lithographic-scale buffers with an angled topology and nanovias so that each long NW could be directly attached to a CMOS-scale buffer. Later, Snider and Williams [47] built on the Strukov and Likharev interfacing concept and introduced a more modest design which used NWs and molecular-scale switches only for interconnect, performing all logic in CMOS.

These designs all share many high-level goals and strategies, as have been described in this chapter. They suggest a variety of solutions to the individual technical components including the crosspoint technologies, NW formation, lithographic-scale interfacing, and restoration (see Table 11.2). The wealth of technologies

Table 11.2 Comparison of NW-based logic designs.

Design source	Component

and construction alternatives identified by these and other research groups has increased the general confidence that there are options to bypass any of the challenges that might arise when realizing any single technique or feature in these designs.

11.12 Research Issues

While the key building blocks have been demonstrated as previously cited, considerable research and development remains in device synthesis, assembly, integration, and process development. At present, no complete fundamental understanding of the device physics at these scales is available, and a detailed and broader characterization of the devices, junctions, interconnects, and assemblies is necessary to refine the models, to better predict the system properties, and to drive architectural designs and optimization.

The mapping results outlined in Section 11.10 were both area- and defect-tolerance driven. For high-performance designs, additional techniques, design transformations, and optimizations will be needed, including interconnect pipelining (e.g. Ref. [48]) and fan-out management (e.g. Ref. [49]).

In Section 11.7 it was noted that high defect rates could be tolerated when the defects occurred before operation. However, new defects are likely to arise during operation, and additional techniques and mechanisms will be necessary to detect their occurrence, to guard the computation against corruption when they do occur, and rapidly to reconfigure around the new defects.

Further, it is expected that these small feature devices will encounter transient faults during operation. Although the exact fault rates are at present unknown, they are certainly expected to exceed those rates traditionally seen in lithographic silicon. This suggests the need for new lightweight techniques and architectures for fault identification and correction.

11.13 Conclusions

Bottom-up synthesis techniques can be used to produce single nanometer-scale feature sizes. By using decorated NWs – for example, by varying composition at the nanometer scale, both axially and radially – the key nanoscale features may be built into the NWs. Moreover, the NWs can be assembled at tight, nanoscale pitch into dense arrays, contacted to a reliable, lithographic-scale infrastructure, and individually addressed from the lithographic scale. The aggregate set of synthesis and assembly techniques appears adequate for the building of arbitrary logic at the nanoscale, even if the only programmable elements are non-restoring diodes.

Bottom-up self-assembly demands that highly regular structures are built that can be differentiated stochastically for addressing and restoration. NW field-effect gating provides signal restoration and inversion while keeping signals at the dense,

nanoscale pitch. Post-fabrication configuration allows the definition of deterministic computation on top of the regular array, despite random differentiation and high rates of randomly placed defects. When these NWs are assembled into modest-sized interconnected PLA arrays, it is estimated that the net density would be one-to-two orders of magnitude higher than for defect-free lithographic-scale FPGAs built in 22 nm CMOS. This should provide a pathway by which to exploit nanometer-pitch devices, interconnect, and systems without pushing lithography into providing these smallest feature sizes.

Acknowledgments

The architectural studies into devices and construction techniques which emerge from scientific research do so only after close and meaningful with the physical scientists. These studies have been enabled by collaboration with Charles M. Lieber and his students. The suite of solutions summarized here includes joint investigations with Helia Naeimi, Michael Wilson, John E. Savage, and Patrick Lincoln.

These research investigations were funded in part by National Science Foundation Grant CCF-0403674 and the Defense Advanced Research Projects Agency under ONR contracts N00014-01-0651 and N00014-04-1-0591.

Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors, and do not necessarily reflect the views of the National Science Foundation or the Office of Naval Research.

Christian Nauenheim and Rainer Waser helped to produce this brief chapter as a digested version of Ref. [29].

Quantum Cellular Automata

Massimo Macucci

12.1
Introduction

The concept of quantum cellular automata (QCA) was first proposed by Craig Lent and coworkers [1] at the University of Notre Dame in 1993, as an alternative based on bistable electrostatically coupled cells to traditional architectures for computation. Overall, the QCA architecture probably represents the proposal for an alternative computing paradigm that has been developed furthest, up to the experimental proof of principle [2]. As will be discussed in the following sections, its strengths are represented by the reduced complexity (in particular for the implementation based on ground-state relaxation), extremely low power consumption, and potential for ultimate miniaturization; its drawbacks are the extreme sensitivity to fabrication tolerances and stray charges, the difficulty in achieving operating temperatures reasonably close to room temperature, the undesired interaction among electrodes operating on different cells, and the very challenging control of dot occupancy.

The initial formulation of the QCA architecture relied on the relaxation to the ground state of an array of cells: computation was performed enforcing the polarization state of a number of "input" cells and then reading the state of a number of "output" cells, once the array had relaxed down to the ground state consistent with the input data. Such an approach is characterized (as will be discussed in the following) by a simple – at least in principle – layout, but suffers from the presence of many states very close in energy to the actual ground state. This leads to an extremely slow and stochastic relaxation, which may lead to unacceptable computational times.

The slow and unreliable evolution of the ground-state relaxation approach was addressed with the introduction of a modified QCA architecture based on clocked cells [3], which can exist in three different conditions, depending on the value of a clock signal:

- The "locked" condition corresponds to having tunneling between dots inhibited, and therefore the cell can be used to "drive" nearby cells.

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

- The "null" condition corresponds to having no electrons in the cell and therefore no polarization.
- The "active" condition is the one in which the cell adiabatically reaches the polarization condition resulting from that of the nearby cells.

The clocked QCA architecture solves the problem of unreliable evolution and allows data pipelining, but introduces a remarkable complication: the clock signal must be distributed, with proper phases, to all the cells in the array. Unless a "wireless" technique for clock distribution could be devised (some proposals have been made in this direction, but a definite solution is yet to be found), one of the most attractive features of QCA circuits – the lack of interconnections – would be lost.

Current research is focusing on the possibility of implementing QCA cells with molecules [4] or with nanomagnets [5], in order to explore the opportunities for further miniaturization (molecular cells) and for overcoming the limitations imposed by Coulomb coupling (nanomagnetic cells). However, these technologies do not seem to be suitable for fast operation: highly parallel approaches could make up for the reduced speed, but this would further complicate system design and the definition of the algorithms.

Although the basic principle of operation is sound, the above-mentioned technological difficulties and the reliability problems make practical application of QCA technology unlikely, at least in the near future. Nevertheless, the QCA concept remains of interest and the subject of lively research, because of its innovation potential and because it opens up a perspective beyond the so far unchallenged three-terminal device paradigm for computation.

In this chapter, an overview of the QCA architecture will be provided, with a discussion of its two main formulations: the ground-state relaxation approach and the clocked QCA approach. In Section 12.2 the issue of operation with cells with more than two electrons will also be addressed, as well as the details of intercell interaction. Section 12.3 will focus on the various techniques that have been developed to model QCA devices and circuits, while Section 12.4 will be devoted to the challenges facing the implementation of QCA technology. Actual physical implementations of QCA arrays will be addressed in Section 12.5, and an overlook for the future will be presented in Section 12.6.

12.2
The Quantum Cellular Automaton Concept

12.2.1
A New Architectural Paradigm for Computation

An early proposal for an architecture based on interacting quantum dots was formulated by Bakshi *et al.* in 1991 [6]: these authors considered parallel elongated quantum dots, defined "quantum dashes" (see Figure 12.1), each of which should have an occupancy of one electron. Their basic argument was that, once the electron

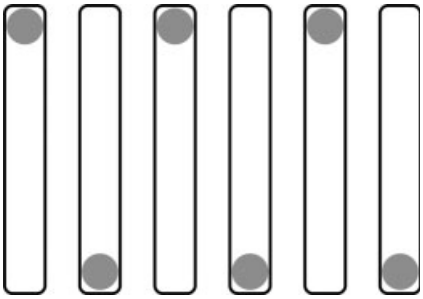

Figure 12.1 Series of elongated quantum dots (quantum dashes) with the hypothesized anti-ferroelectric ordering.

in the first dash was confined into one end of the dash, the electron in the next dash would be confined into the opposite end, as a result of electrostatic repulsion. This configuration would propagate along the line of dashes, leading to a sort of anti-ferroelectric ordering that could then be exploited for the implementation of more complex functions. This initial concept, however, had a serious problem, consisting in the fact that the localization of electrons along the chain of dashes would soon decay (See Figure 12.2), because the electrostatic repulsion due to an electron localized at the end of a dash is not sufficient to significantly localize the electron in the nearby dash, the probability density of which would just be slightly displaced. The Notre Dame group realized that this problem could be solved with the insertion of a barrier in the middle of the dash: in this way, the electron wave function must be localized on either side of the barrier and the electrostatic interaction from the electron in the nearby dash is sufficient to push the electron into the opposite half of the dash (Figure 12.3). This concept can be easily understood considering a two-level system subject to an external perturbing potential V [7]. The Hamiltonian of such a system in second quantization reads:

$$\hat{H} = \sum_{i=1,2} n_i E_i + t(b_1^\dagger b_2 + b_2^\dagger b_1) + \sum_{i=1,2} n_i q V_i, \tag{12.1}$$

where n_1 and n_2 are the occupation numbers of levels 1 and 2, respectively, $b_i^\dagger$ and b_j are the creation and annihilation operators for levels i and j, t is the coupling between

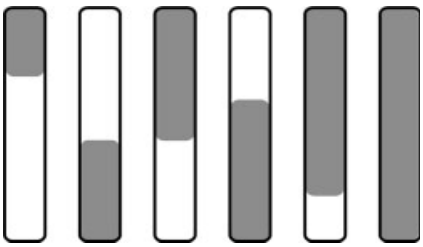

Figure 12.2 Sketch of the actual electron density within a chain of dashes.

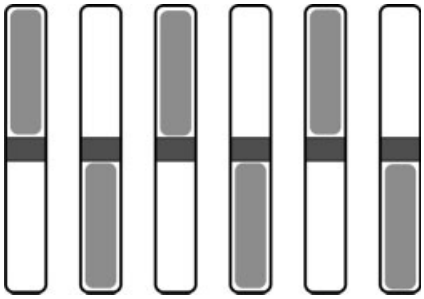

Figure 12.3 Chain of dashes with the inclusion of potential barriers: electrons are now localized on either side of the barriers and an anti-ferroelectric ordering is achieved.

the two levels and V_i is the external perturbing potential at the location of the i-th level. The creation operator $b_i^\dagger$ applied to a state with $(n-1)$ electrons yields a state with n electrons, thereby "creating" an electron in state i, while the annihilation operator b_j applied to a state with n electrons yields a state with $(n-1)$ electrons, thereby "destroying" an electron from state j. For example, the application of $b_i^\dagger b_2$ transfers an electron from level 2 to level 1. Each level can be associated with one of the sides into which the dash is divided by a potential barrier: if the barrier is exactly in the middle of the dash, $E_1 = E_2$ and the value of t depends on the height and thickness of the barrier; the higher and the thicker the barrier, the smaller t will be. A sketch of the potential profile is provided in Figure 12.4, where the dots represent the locations of the two levels 1 and 2. If $E_1 + V_1$ is chosen as the energy reference and ε is defined as $E_2 + V_2 - E_1 - V_1$, the Hamiltonian can be represented in the basis ($|0\rangle$ ($n_1 = 1$, $n_2 = 0$), $|1\rangle$ ($n_1 = 0$, $n_2 = 1$)) simply as (computing the matrix elements between the basis states)

$$\mathbf{H} = \begin{pmatrix} 0 & t \\ t & \varepsilon \end{pmatrix}. \tag{12.2}$$

The state $|0\rangle$ corresponds to having an electron in level 1 and no electron in level 2, while $|1\rangle$ corresponds to the situation with level 1 empty and an electron in level 2. The eigenvalues of this representation can be easily computed:

$$e_1 = \frac{1}{2}\left(\varepsilon - \sqrt{\varepsilon^2 + 4t^2}\right) \quad e_2 = \frac{1}{2}\left(\varepsilon + \sqrt{\varepsilon^2 + 4t^2}\right). \tag{12.3}$$

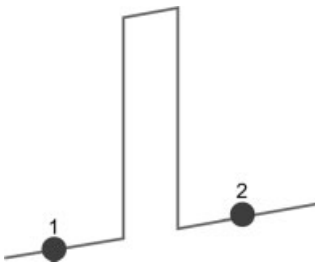

Figure 12.4 Sketch of the potential landscape defining the two levels, 1 and 2, separated by a barrier.

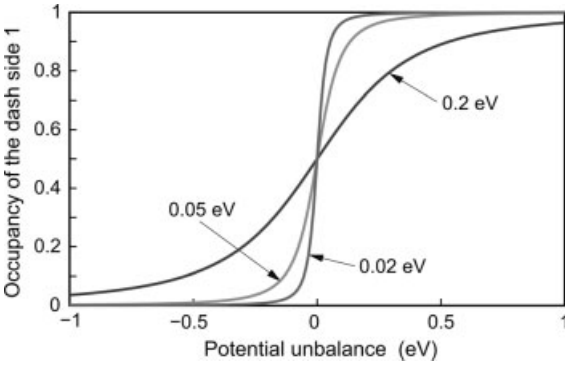

Figure 12.5 Occupancy of one of the levels of a two-level system, as a function of the potential unbalance resulting from an external applied electric field, for different values of the coupling parameter *t*.

The unbalance term ε in this case depends only on the external potential produced by the electron in the nearby dash: it will vary between a negative and a positive value, depending on the position of the electron.

The occupancy of the first level – that is, of the dash side labeled with 1 – will be given by the square modulus of the corresponding coefficient of the ground-state eigenvector, which can be computed along with the eigenvalues. Such a quantity is plotted in Figure 12.5 as a function of the unbalance ε for different values of the coupling energy *t*. It is apparent that, for low values of *t* (and therefore for an opaque barrier), the electron moves abruptly from one level to the other, as the external field is varied. Therefore, it is strongly localized even for very small values of such a field, while for high values of *t* (and therefore for a transparent or inexistent barrier) a very smooth transfer of the probability density from one level to the other are needed and large values of the perturbing field are required to achieve some degree of localization. Thus, the introduction of a barrier in the middle of the dash creates a sort of bistability – that is, a strongly non-linear response to external perturbations, which is at the heart of QCA operation and allows the regeneration of logic values. From the wire of dashes with barriers of Figure 12.3, the next step is represented by joining two adjacent dashes to form a square cell, which is the basis of the Notre Dame QCA architecture. The square cell allows the creation of two-dimensional (2-D) arrays, as shown in Figure 12.6, which can implement any combinatorial logic function. In an isolated cell the two configurations or polarization states, with the electrons along one or the other diagonal, are equally likely. However, if an external perturbation is applied, or in the presence of a nearby cell with a fixed polarization, one of them will be energetically favored. The two logic states, 1 and 0, can be associated with the two possible polarization configurations, as shown in Figure 12.7, where the solid dots represent the electrons. If a linear array of dots is created, enforcing the polarization corresponding to a given logic state on the first cell will lead to the propagation of the same polarization state along the whole chain, in a domino fashion. Such a linear array is usually defined a "binary wire", and can be used to propagate a logic variable

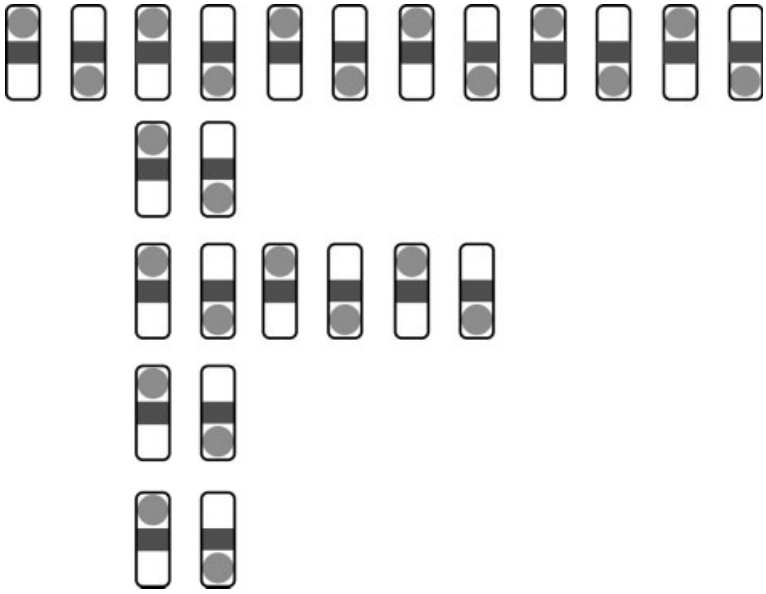

Figure 12.6 Two-dimensional array of cells made up of two adjacent dashes: this is the basis of the QCA architecture.

across a circuit: here, the strength and, at the same time, the weakness of the QCA architecture is noticed. Indeed, signal regeneration occurs during propagation along the chain, as a result of the non-linear response of the cells, but the transfer of a logic variable from one location in the circuit to a different location may require a relatively large number of cells. In other words, there are no interconnects, but the number of elementary devices needed to implement a given logic function may become much larger than in a traditional architecture.

The basic gate in QCA logic is represented by the majority voting gate, which is shown in Figure 12.8. Cells A, B and C are input cells, whose polarization state is enforced from the outside (here and in the following such "driver" cells are represented with a double boundary), while cell Y is the output cell, the polarization of which represents the result of the calculation. On the basis of a full quantum calculation or of simple considerations based on a classical electrostatic model, it is possible to show that the logic value at the output will correspond to the majority of the input values. Thus, for example, if $A = 1$, $B = 0$, $C = 0$, then $Y = 0$, or, if $A = 1$, $B = 0$, $C = 1$, the output will be $Y = 1$. From the majority voting gate it is

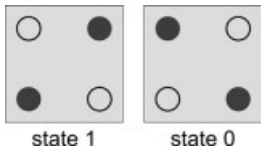

Figure 12.7 Basic configurations of a QCA cell with two electrons.

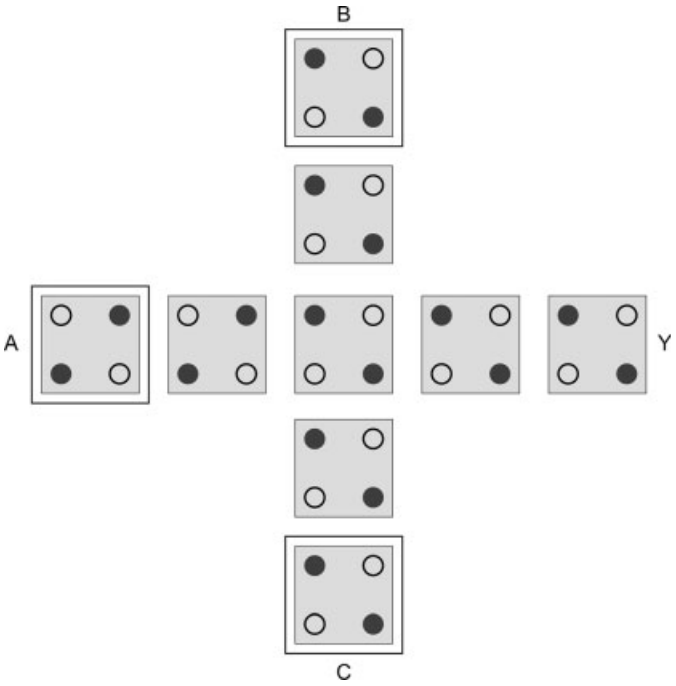

Figure 12.8 Layout of a majority voting gate.

straightforward to derive a two-input AND and OR gate: if A = 1, B and C will be the inputs of an OR gate, while if A = 0, B and C will represent the inputs of an AND gate. In order to be able to create an arbitrary combinatorial network, there is also a need for the NOT gate: this is just slightly more complex, and can be implemented with the layout shown in Figure 12.9 [15].

A generic logic function can thus be obtained with a 2-D array of cells: a number of cells at the perimeter of the array will be used as input cells, by enforcing their polarization condition with properly biased gates, and another group of perimetral

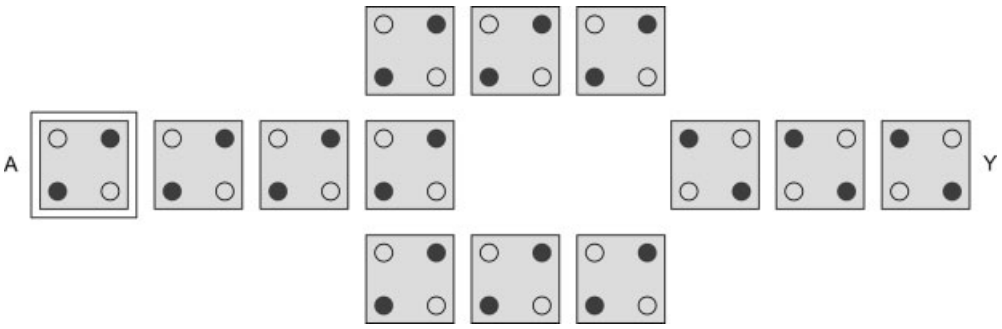

Figure 12.9 Layout for a NOT gate in the QCA architecture.

cells will act as outputs. Once the input values have been enforced, the array is allowed to evolve into the ground state and, when this has been reached, the state of the output cells corresponds to the result of the computation.

As the number of cells in the array increases, its energy spectrum – that is, the set of energies corresponding to all the possible configurations – becomes more complex, with a large number of configurations that have energies very close to the actual ground state. As a result, the evolution of the array may become stuck in one of these configurations for a long time, thus leading to a very slow computation. Furthermore, due to the appearance of states that are very close in energy to the ground state, the maximum operating temperature decreases as the number of cells is increased. In particular, it has been shown with entropy considerations [8] or by means of an analytical model [9] that, for the specific case of a binary wire, the maximum operating temperature falls logarithmically with the number of cells.

12.2.2
From the Ground-State Approach to the Clocked QCA Architecture

The above-mentioned problems severely limit the applicability of ground-state computation to real-life situations, and make the evolution of a large QCA system unreliable. To solve such problems, a modified architecture was proposed by Lent and coworkers [3], inspired, in its implementation with metal tunnel junctions, to the parametron concept introduced by Korotkov [10]. The so-called "clocked QCA architecture" derives from the concept of adiabatic switching [3]: based on the adiabatic theorem [11], it is possible to show that if the Hamiltonian of a system is made to evolve slowly from one initial form H_i to a final form H_f, a particle starting in the n-th eigenstate of H_i will be carried over into the n-th eigenstate of H_f. Thus, starting with particles in the ground state of the system, they will never leave the ground state during the evolution of the Hamiltonian, thereby preventing the previously mentioned problems of trapping into metastable states.

To implement this concept of adiabatic switching, the confinement potential defining the cell must be variable in time. In practice, the barriers separating the dots are modulated by an external potential, representing the clock signal. When the barriers are low, the cell is in the "null" state and has no polarization. In contrast, when the barriers reach their maximum height the cell is in the "locked" state and its polarization cannot be modified as a result of the action of the nearby cells (the electrons are prevented from tunneling between dots). It is only during the "active" phase, when the barriers have an intermediate height, that the polarization state can change according to the that of the nearby cells.

Attention should now be focused on the particular implementation of a clocked cell that has been experimentally realized [12]. This consists of a six-dot cell as proposed by Tóth and Lent [13], developed from the metal-island cells used in the first experimental demonstration of QCA action [2]. The barriers are represented by tunnel junctions obtained by including a very thin dielectric (usually created by oxidation) between two metallic electrodes (usually aluminum), and the quantum dots are replaced with metal islands. The six-island clocked cell is represented in

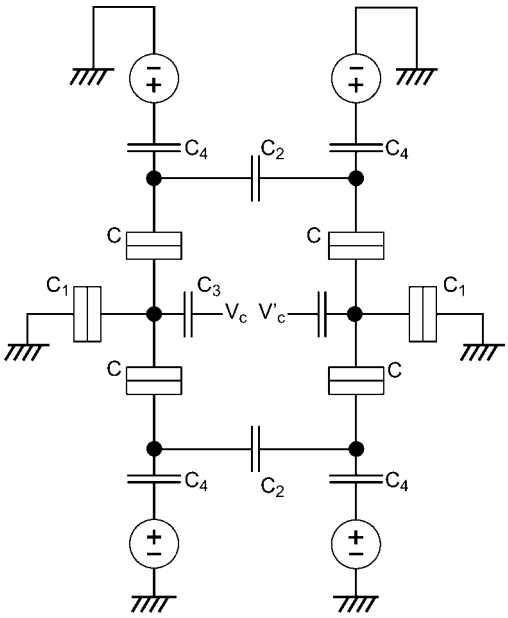

Figure 12.10 Clocked cell for implementation with tunnel junctions: tunneling between the dots of each half cell is controlled by the voltages applied to the middle dots through the C_3 capacitors.

Figure 12.10. Tunneling is possible only between the upper and the lower dot of each half of the cell (it can be shown that this does not limit in any way the logic operation of the cell) and the barrier height between the active islands is controlled by means of the potential applied to the central island. If the potential on the central island is low, then the electron will be trapped there (null state). As the potential on the central island is raised, a condition will be reached in which the electron can tunnel into one of the active dots, the one that is favored at the time by the potential created by the nearby cells (active state). Finally, as the potential on the central dot is further raised, the electron will be trapped in the dot into which it has previously tunneled, even if the polarization of the other cells is reversed (locked state).

Ideally, the computation should evolve with a cell in the locked state driving the next cell that moves from the null state to the locked state, going through the active state. When the state of a cell must be the result of that of more than one neighboring cell (as in the case of the central cell of a majority voting gate), all the cells acting on it should be at the same time in the locked state. The sequence of clock phases would allow the information to travel along the circuit in a controlled way, thus achieving a deterministic evolution and eliminating the uncertainty about the time when the calculation is actually completed that plagues the ground-state relaxation scheme. Furthermore, since the flux of data is steered by the clock, it would also possible to have data pipelining: new input data could be fed into the inputs of the array as soon as the previous data have left the first level of logic gates

and moved to the second. Ideally, within this scheme each cell should be fed a different clock phase with respect to its nearest neighbors, which would imply an extremely complex wiring structure. Such a solution has been adopted in the experiments performed so far to demonstrate the principle of operation of clocked QCA logic [12]. However, in large-scale circuits it would forfeit one of the main advantages of the QCA architecture – that is, the simplicity deriving from the lack of interconnections. In order to address this problem, it has been proposed to divide the overall QCA array into "clocking zones": such regions consist of a number of QCA cells and would be subject to the same clock phase and evolve together while in the active state (similarly to a small array operating according to the ground-state relaxation principle). They would then be locked all at the same time, in order to drive the following clocking zone. This would reduce the complexity of the required wiring, and has been proposed in particular for the implementation of QCA circuits at the molecular scale, where it is impossible to provide different clock phases to each molecule, as the wires needed for clocking would be much larger than the molecules themselves! There are many difficulties involved, however, because each clocking zone is affected by the problems typical of ground-state relaxation (although on a smaller scale), and the clock distribution is still extremely challenging. For example, conducting nanowires have been suggested as a possible solution to bring the clock signal to regions of a molecular QCA circuit, but achieving uniformity in the clocking action of a nanowire on many molecular cells is certainly a very challenging task.

Notwithstanding all of these difficulties, the clocked scheme appears to be the only one capable of yielding a reasonably reliable QCA operation in realistic circuits, as will be discussed in the following sections.

12.2.3 Cell Polarization

At this point it is necessary to provide a rigorous definition of cell polarization, in order to be able to describe quantitatively the interaction between neighboring cells and to determine whether cells with an occupancy of more than two electrons could possibly be used. Indeed, according to the initial definition of cell polarization given by the Notre Dame group, the operation of cells with more than two electrons would not be possible. Their original definition of cell polarization was

$$P = \frac{\rho_1 + \rho_3 - \rho_2 - \rho_4}{\rho_1 + \rho_2 + \rho_3 + \rho_4}, \tag{12.4}$$

where ρ_i is the charge in the i-th dot (dots are numbered counterclockwise starting from the one in the upper right quadrant). With such an expression, as soon as the number of electrons increases above two, full polarization can no longer be achieved, as the maximum possible value for the numerator is 2. There can be at most a difference of two electrons between the occupancy of one diagonal and that of the other, since configurations with a larger difference would require an extremely large external electric field (to overcome the electrostatic repulsion between electrons).

Starting from the observation that a QCA cell is overall electrically neutral, because of the presence of ionized donors, of the positive charge induced on the metal electrodes, and of the screening from surface charges, Girlanda *et al.* [14] proposed a different expression for the polarization of a cell, which is more representative of its action upon the neighboring cells. Indeed, neutralization occurs over an extended region of space; thus, although the global monopole component of the field due to a cell is zero, there can be some effect on the neighboring cells associated with the total number of electrons. However, in practical cases this turns out to be negligible compared to the dipole component associated with the charge unbalance between the two diagonals. The alternative expression for cell polarization introduced in Ref. [14] reads

$$P = \frac{\rho_1 + \rho_3 - \rho_2 - \rho_4}{2q}, \tag{12.5}$$

where q is the electron charge. Use of this expression is supported by semiclassical electrostatic considerations and by detailed quantum simulations [14], and leads to the conclusion that QCA action can be observed whenever the cell occupancy is of $4N + 2$ electrons, where N is the integer. This means that control of the occupancy of the dots is less stringent than previously expected, but is still quite difficult.

12.3 Approaches to QCA Modeling

12.3.1 Hubbard-Like Hamiltonian

The first approach to QCA simulation was developed by the Notre Dame group [15], based on an occupation number, Hubbard-like formalism. Within such an approach the details of the electronic structure of each quantum dot are neglected, and a few parameters are used to provide a description of the dots and their interaction. Although based on a few phenomenological parameters, this technique has been successful in providing a good basic understanding of the operation of QCA cells.

The occupation number Hamiltonian for a single, isolated cell reads

$$\begin{aligned} H_0 = &\sum_{i,\sigma} E_{0,i}, n_{i,\sigma} + \sum_{i>j,\sigma} t(b^{\dagger}_{i,\sigma} b_{i,\sigma} + b^{\dagger}_{j,\sigma} b_{i,\sigma}) \\ &+ \sum_{i} E_{Qi} n_{i,\uparrow} n_{i,\downarrow} + \sum_{i>j,\sigma,\sigma'} V_Q \frac{n_{i,\sigma} n_{j,\sigma'}}{|\vec{R_i} - \vec{R_j}|}, \end{aligned} \tag{12.6}$$

where $E_{0,i}$ is the ground-state energy of the i-th dot (assumed to be isolated), $b^{\dagger}_{j,\sigma}$ and $b_{j,\sigma}$ are the creation and annihilation operators, respectively, for an electron in the j-th dot with spin σ, $n_{j,\sigma}$ is the number operator for electrons in the i-th dot with spin σ, t is the tunneling energy between neighboring dots, V_Q is equal to $e^2/(4\pi\varepsilon)$ (e is the electron charge and ε is the dielectric permittivity), E_{Qi} is the on-site charging energy

for the i-th dot [16], and $\vec{R_i}$ is the position of the i-th dot center. The tunneling energy t cannot be computed directly, and must be evaluated with some approximation. A commonly used approximation consists in assuming t to be equal to half of the level-splitting resulting because of the presence of a barrier of finite height between the dots. In the presence of a driver cell in a given polarization state, the above-written Hamiltonian must be augmented with a term that expresses the electrostatic contribution from such a cell:

$$H_{int} = \sum_{i \in \text{cell1}} \sum_{j \in \text{cell2}} V_Q \frac{\rho_{j,2} - \bar{\rho}}{|\vec{R}_{j,2} - \vec{R}_{i,1}|}, \tag{12.7}$$

where $\rho_{j,2}$ is the number of electrons in the j-th dot of the driver cell, ρ is the average number of positive neutralizing charges per dot, $\vec{R}_{j,2}$ and $\vec{R}_{i,1}$ are the positions of the j-th dot of the driver cell (cell 2) and of the i-th dot of the driven cell (cell 1), respectively.

Diagonalization of the total Hamiltonian can be performed easily using an occupation number representation: $|n_{1,\uparrow}, n_{1,\downarrow}; n_{2,\uparrow}, n_{2,\downarrow}; n_{3,\uparrow}, n_{3,\downarrow}; n_{4,\uparrow}, n_{4,\downarrow}\rangle$.

The dimension of the basis, considering only two-electron states, would be 256 but, on the basis of spin considerations [17], the number of basis vectors required for the determination of the ground state is just 16.

A representation of the complete Hamiltonian on such a basis consists in a sparse matrix with only four non-zero off-diagonal elements in each row. Eigenvalues and eigenvectors can be obtained numerically, and the ground state of the driven cell will be

$$|\psi_0\rangle = \sum_{i=1}^{16} \alpha_i |i\rangle, \tag{12.8}$$

where α_i is the i-th element of the eigenvector, corresponding to the lowest eigenvalue, and $|i\rangle$ is the i-th element of the basis used for the representation of the Hamiltonian. The average charge in each dot is given by

$$\rho_i = \langle \psi_0 | n_{i\uparrow} + n_{i\downarrow} | \psi_0 \rangle, \tag{12.9}$$

from which the cell polarization can then be computed. In Figure 12.11 the polarization of the driven cell computed as a function of the polarization of the driver cell is reported; that is, the cell-to-cell response function. Calculations have been performed for a cell with four dots located at the vertices of a square with a 24 nm side. The dots have a diameter of 16 nm, except for one, the diameter of which varies between 15.94 and 16.06 nm, and the separation between the centers of the driver and driven cells is 32 nm. Material parameters for GaAs have been considered, with an effective mass $m^* = 0.067\ m_0$ and a relative permittivity $\varepsilon_r = 12.9$; furthermore the tunneling energy t has been assumed to be 0.1×10^{-3} eV.

In the case of identical dots (all with the same 16-nm diameter), the response function is symmetric, while just an extremely small variation in the diameter of a dot leads to strong asymmetry and eventually to failure of operation, with the driven cell always stuck in the same state for any value of the polarization of the driver cell. It appears that such a sensitivity to geometric tolerances is a very serious practical

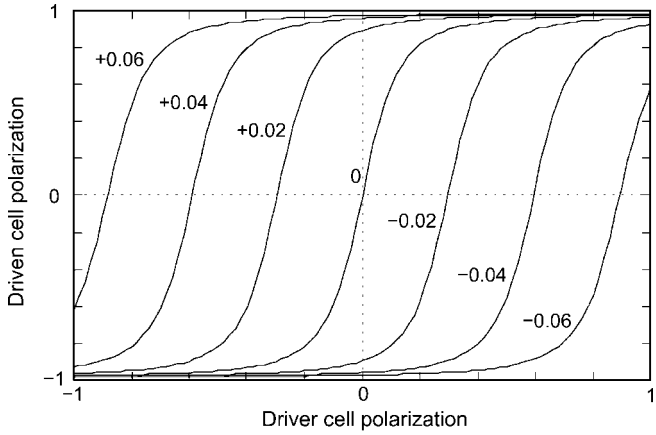

Figure 12.11 Cell-to-cell response function for cells with a separation of 32 nm, an interdot distance of 24 nm, and dots with a diameter of 16 nm. The different curves correspond to an error on the diameter of the lower left dot varying between − 0.06 nm and 0.06 nm.

problem, but cannot be fully gauged with the occupation-number Hamiltonian approach, because it is not possible to directly relate the diameter of idealized quantum dots to actual geometric quantities, such as the size of the gates defining the quantum dots.

In order to be able to provide reliable estimates of the acceptable errors on actual geometric parameters, a more realistic model is needed which takes into account the detailed structure of the cell. To this purpose, the approach described in the following subsection has been developed.

12.3.2 Configuration–Interaction

More traditional, iterative self-consistent approaches, such as the Hartree technique or techniques based on the local density functional approximation (LDA), perform very poorly in the simulation of an active QCA cell, in particular in the region around zero polarization. The main problem with iterative self-consistent methods is that, in the application to QCA problem, they tend to become unstable, as a result of the strong degeneracies and of the marked bistability of the system. One effective technique to treat a realistic model for a QCA cell consists in configuration–interaction. This method is very well known in the field of molecular chemistry [18], and has found significant application also for treating semiconductor quantum dots [19, 20].

While, for example, the Hartree–Fock method consists in finding an optimized Slater determinant representing the single-determinant solution for the many-body Schrödinger equation (i.e. the Slater determinant that minimizes the ground-state energy), in the configuration–interaction picture the many-particle wave function is

expressed as a linear combination of Slater determinants. In principle, if the basis of determinants were infinite, the solution would be exact; however, in practice a finite basis must be considered, which introduces some degree of approximation, depending on the number of elements and on how good their choice is in terms of the actual solution.

The application of configuration–interaction to the analysis of QCA cells is presented in Ref. [21]: the Hamiltonian for a cell is written as

$$\begin{aligned}\hat{H} = & -\frac{\hbar^2}{2m^*}\nabla_1^2 - \frac{\hbar^2}{2m^*}\nabla_2^2 + V_{\text{con}}(\vec{r_1}) + V_{\text{con}}(\vec{r_2}) + V_{\text{driv}}(\vec{r_1}) + V_{\text{driv}}(\vec{r_2}) \\ & + \frac{1}{4\pi\varepsilon}\frac{e^2}{|\vec{r_1}-\vec{r_2}|} - \frac{1}{4\pi\varepsilon}\frac{e^2}{\sqrt{|\vec{r_1}-\vec{r_2}|^2+(2z)^2}} - \frac{1}{4\pi\varepsilon}\frac{e^2}{2z},\end{aligned} \tag{12.10}$$

where $\hbar$ is the reduced Planck constant, m^* is the electron effective mass, V_{con} is the bare confinement potential (due to the electrodes, the ionized donors, the charged impurities, and the bandgap discontinuities), V_{driv} is the Coulomb potential due to the charge distribution in the neighboring driver cell, e is the electron charge, the last two terms include the effects of the image charges (since, for simplicity, a Dirichlet boundary condition is assumed at the surface and at an infinitely far away conducting substrate), and z is the distance of the 2DEG from the surface of the heterostructure where the boundary condition is enforced.

A matrix representation of this Hamiltonian is derived by computing the matrix elements of Eq. (12.10) between the elements of the basis of Slater determinants, and is then diagonalized, obtaining the ground-state energy as the lowest eigenvalue and the ground-state wave function as a linear combination of the basis elements with coefficients corresponding to the elements of the associated eigenvector.

This technique does not have convergence problems, as it is intrinsically a one-shot method and allows the consideration of a realistic confinement potential, obtained from a detailed numerical calculation. However, if the intention was to introduce more realistic boundary conditions for the semiconductor surface, or in general to provide a more refined treatment of the electrostatic problem, going beyond the method of images, the problem would, computationally, be very intensive. This is because, in order to compute the matrix elements of the Hamiltonian, the complete Green's function of the Poisson equation between each pair of points in the domain would be needed.

If an occupancy of only two electrons per cell were to be considered, the actual two-electron wave function is very close to the Slater determinant constructed from the one-electron wave functions of the isolated dots. Therefore, the size of the basis needed to obtain a good configuration–interaction solution is small, of the order of 100 determinants. Instead, if there are more than four electrons per cell (and thus more than one electron per dot), the strong electron–electron interaction determines a significant deformation of the wave functions and therefore a large number of basis elements constructed from the single-electron orbitals is needed. For example, in the case of a six-electron cell, more than 1000 determinants are necessary. As the number

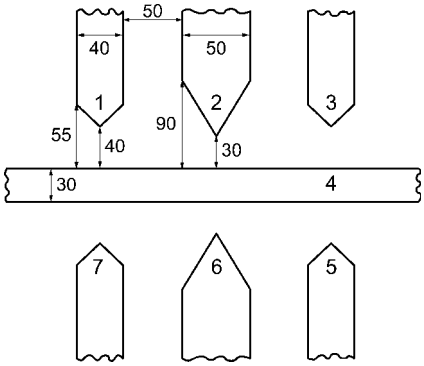

Figure 12.12 Gate layout for the definition of a working QCA cell (all measures are in nanometers).

of electrons is raised, there is a combinatorial increase in the size of the basis, and consequently the problem soon becomes intractable from a computational point of view.

Notwithstanding the above-mentioned limitations on the way that Coulomb that interaction can be included, and on the maximum number of electrons that can be considered, configuration–interaction has been very successfully applied to the simulation of QCA systems. In fact, it has allowed the demonstration that, for a semiconductor implementation, an array of holes (defining the quantum dots) in a depletion gate held at constant potential cannot possibly be fabricated with the required precision. Alternative gate arrangements, such as those shown in Figure 12.12, are possible [21], and have been used in the experimental demonstration of QCA action in GaAs/AlGaAs heterostructure-based devices [22]. However, they imply severe technological difficulties and the need for adjustment of individual gate voltages to correct for geometrical imperfections and for the unintentional asymmetries introduced by the presence of nearby cells [23].

12.3.3
Semi-Classical Models

Quantum models of QCA cells are needed to describe the bistable behavior of the single cell, and also to provide information on the technological requirements needed to obtain successful QCA operation. They are, however, too complex (from a computational point of view) to be applied to the analysis of complete QCA circuits consisting of a large number of cells. The time required to complete a simulation of a circuit made up of just a few tens of cells would be prohibitive. Therefore, a multiscale approach is needed, which is structured in a way similar to that of traditional microelectronics, where circuit portions of increasing complexity are treated with models based on progressively more simplified physical models.

It should be noted that the effect at the core of QCA action is purely classical – that is, it is the Coulomb interaction between electrons. As long as electrons are strongly localized, they behave substantially as classical particles, and a semi-classical model,

based on the minimization of the electrostatic energy, can capture most of the behavior of a QCA circuit.

If the only point of interest is to determine the ground-state configuration of an array of QCA cells and in computing the energy separation ΔE between the first excited state and the ground state, then a simple electrostatic model can be used. The quantity ΔE is essential to determine the maximum operating temperature of the circuit: it must be at least a few tens of kT (where k is the Boltzmann constant and T is the absolute temperature); otherwise, the system will not remain stably in the ground state. The basic electrostatic model developed in Ref. [9] relies on a cell model in which the charge of the two electrons is neutralized either by positive charges of value $e/2$ located in each dot, or by image charges located at a distance from the dots and representing the effect of metal electrodes or of Fermi level pinning at the semiconductor surface. Although a cell can be in the two configurations with the electrons aligned along one of the diagonals, other configurations are also possible. However, in most cases they are not energetically favored. A more complete model must also introduce such configurations, corresponding to the two electrons occupying the dots along one of the four sides of the cell. While the configurations with the electrons on the diagonals are associated with the logical values 1 and 0, the other configurations do not correspond to any logical value and are thus indicated with X in Figure 12.13, where all possible configurations are represented.

The total electrostatic energy is given by [24]:

$$E = \sum_{i \neq j} \frac{q_i q_j}{4\pi\varepsilon_0 \varepsilon_r r_{ij}} \tag{12.11}$$

If, for the sake of simplicity, the neutralizing charge is considered to be located directly in each dot (in an amount $e/2$), the total charge in each dot can assume only two values: either $+e/2$ or $-e/2$, thereby leading to

$$q_i q_j = \frac{1}{4} e^2 \mathrm{sgn}(q_i q_j) \tag{12.12}$$

If the distance between the dots is expressed in terms of the ratio $R = d/a$ and of the electron positions, the following can be written:

$$E = \frac{e^2}{4a} \frac{1}{4\pi\varepsilon_0 \varepsilon_r} \sum_{i \neq j} \frac{s_{ij}}{\sqrt{(n_{ij} R + l_{ij})^2 + m_{ij}^2}}, \tag{12.13}$$

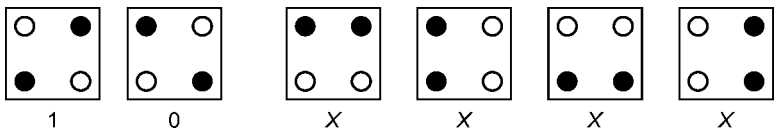

Figure 12.13 Possible configurations of a four-dot cell with two electrons. The configurations marked with *X* do not correspond to a well-defined logic state.

where $n_{ij} \in \{0, \ldots, N_{\text{cell}} - 1\}$ is the separation, in terms of number of cells, between the cell with dot i and the cell with dot j, $s_{ij} \in \{-1, 1\}$ is the sign of $q_i q_j$, $l_{ij} \in \{-1, 0, 1\}$ and $m_{ij} \in \{0, 1\}$, is the position of dots i and j within the relative cells. The quantity l_{ij} is equal to 0 if both the i and the j dots are on the left side or on the right side of the cell, to -1 if dot i is on the right side and dot j is on the left side, and to 1 if dot i is on the left side and dot j is on the right. Analogously, m_{ij} is equal to 0 if both dots i and j are on the top or on the bottom of a cell, to 1 if one dot is on the top and the other is on the bottom.

The most direct approach consists of computing the energy associated with each possible configuration by means of the direct evaluation of Eq. (12.13) and choosing the configuration that corresponds to the minimum energy. With this procedure the complete energy spectrum for the circuit is also obtained; that is, the energy values corresponding to all possible configurations. However, such a method soon becomes prohibitively expensive from a computational point of view, as the number of configurations to be considered is 6^N, where N is the number of active cells (i.e. of cells whose polarization is not enforced from the outside, as in the case of the driver cells). As the number of cells is increased, a simplified model can be used in which only the two basic states of a cell are considered, thus reducing the total number of configurations down to 2^N. This does not introduce significant errors, as long as the X states are unlikely (which is in general true), except for the case of intercell separation equal to or smaller than the cell size, when X states with both electrons vertically aligned may occur.

An example of application of the semi-classical simulation technique with six states per cell is shown in Figure 12.14, where the maximum operating temperature of a binary wire is reported as a function of the number of cells, for a 60%, 90% and 99% probability of obtaining the correct logical output, assuming an interdot distance of 40 nm, an intercell separation of 100 nm and GaAs material parameters. It should

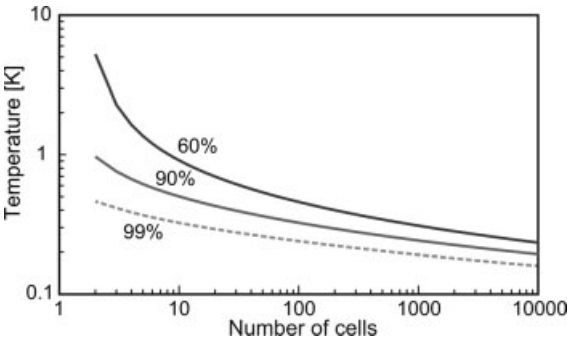

Figure 12.14 Maximum operating temperature, as a function of the number of cells, for a binary wire made up of GaAs cells with an interdot separation of 40 nm and an intercell separation of 100 nm. The maximum operating temperature has been computed for a 99%, 90% and 66% probability of obtaining the correct logical output.

be noted that the probability of obtaining the correct logical output is in general larger than the probability of being in the ground state, as there are also a number of excited states in which the polarization of the output cell has the correct value.

It is apparent that, even with the simplification down to just two states per cell, large circuits cannot be simulated with the semi-classical approach just described, because of the exponential increase in the time required to perform a complete exploration of the configuration space. This has led to the development of techniques based on an incomplete, targeted exploration of the configuration space, such as that described in the following subsection.

12.3.4 Simulated Annealing

The concept of simulated annealing derives from that of thermal annealing, whereby a material is brought into a more crystalline and regular phase by heating it and allowing it to cool slowly. Analogously, in simulated annealing the aim is to reach the ground state of the system, starting from a generic state at a relatively high temperature, and then to perform a Monte Carlo simulation in which at each step an elementary transition within a cell (chosen at random) is accepted with a probability P depending on the energy E_{old} of the system before the transition, and on the energy E_{new} after the transition:

$$P = \begin{cases} 1 & \text{if} \quad E_{\text{new}} \leq E_{\text{old}} \\ \exp[-(E_{\text{new}} - E_{\text{old}})/kT] & \text{if} \quad E_{\text{new}} > E_{\text{old}} \end{cases} \tag{12.14}$$

It is apparent that, in this way, the evolution of the system is steered along a path of decreasing energy, whilst at the same time trapping in a local minimum is prevented in most cases by the non-zero probability of climbing to a higher energy configuration. This procedure is iterated many times, gradually decreasing the temperature, until convergence to a stable configuration is achieved [17].

The application of simulated annealing to QCA circuits was originally proposed for their operation [25], and has since been applied to their modeling [26]. This has allowed the analysis of circuits with a number of cells of the order of 100 with limited computational resources and with just a few hours of CPU time. With large circuits, the simulated evolution of the circuit may occasionally become stuck in a local energy minimum, which would then be erroneously assumed as the ground state. The probability of this happening can be minimized by performing the equivalent of "thermal cycling". Once a stable state has been reached, the temperature is raised again, driving the circuit into an excited state, and a new annealing run is performed, reaching a new stable state. If the whole procedure is repeated several times, there is a better chance of reaching the ground state. It is possible to show that the probability P of the computational procedure stopping in the ground state is given by $P = 1 - (1 - \mathrm{P}_0)^m$, where P_0 is the probability of reaching the ground state without cycling, and m is the number of cycles. With this technique it is possible to reliably simulate QCA circuits with a few hundreds of cells.

12.3.5 Existing Simulators

A number of simulators have been developed to study both the static and dynamic behaviors of QCA circuits. One of the first available was AQUINAS (A Quantum Interconnected Network Array Simulator, from the Notre Dame group), where cells are modeled within a Hartree–Fock approximation and the time-dependent Schrödinger equation is solved with the Crank–Nickolson algorithm. Relatively large systems can be handled, as a result of an approximation consisting in the representation of the state of a single cell with a simplified two-dimensional basis [27]. NASA researchers have added to AQUINAS capabilities for the statistical analysis of data, thus creating TOMAS (Topology Optimization Methodology using Applied Statistics) AQUINAS [28].

A static simulator for the determination of the ground state of a QCA circuit on the basis of a classical electrostatic model has been developed by the group in Pisa, and is currently available on the Phantoms Computational Hub (http://vonbiber.iet.unipi.it). The simulator has been named QCAsim, and operates according to the approach described in Section 12.3.3. In general, it can compute the ground-state configuration of a generic array of cells via a complete exploration of the configuration space, assuming for each cell six possible configurations for the two electrons. It is possible to specify whether neutralization charges should be included and in which positions (on the same plane as the electrons, on a different plane, as image charges, etc.).

The group in Pisa has also developed a dynamic simulator, MCDot (also available on the Phantoms HUB). This was conceived specifically for the QCA implementation based on metal tunnel junctions, and is therefore based on the Orthodox Theory of the Coulomb Blockade [29] with the addition of cotunneling effects treated to first order in perturbation theory [30]. The operation of such a code will be described in more detail in Section 12.4.3 while discussing limitations for the operating speed. Although the code was originally developed for circuits with metallic tunnel junctions, its range of applicability can be easily extended to different technologies, extracting appropriate circuit parameters and defining an equivalent circuit. For example, it has been successfully applied to the simulation of silicon-based QCA cells [17]. To this purpose, linearized circuit parameters can be determined from three-dimensional simulations around a bias point and then used in MCDot. The most challenging part of the parameter extraction procedure is represented by the capacitances and resistances of the tunneling junctions obtained by defining a lithographic constriction in silicon wires [31]: the detailed geometry and the actual distribution of dopants cannot be known exactly, and resort to experimental data is often necessary.

Recently, another simulator has been developed at the University of Calgary, QCADesigner (http://www.qcadesigner.ca). This uses a two-state model for the representation of each cell, derived from the theory developed by the Notre Dame group. QCADesigner is meant to be an actual CAD (computer-aided design) tool, applicable to the design of generic QCA circuits and with the capability for testing their operation with a targeted or exhaustive choice of input vectors.

12.4
Challenges and Characteristics of QCA Technology

12.4.1
Operating Temperature

As mentioned previously, the maximum achievable operating temperature is one of the main challenges in QCA technology. Indeed, the energy separation ΔE between the first excited state and the ground state of the system must be much larger than the thermal energy, if disruption of the operation as a result of thermal fluctuations is to be prevented. Unfortunately, the magnitude of the dipole interaction between cells is very small, of the order of millielectronvolts for cells with a size of a few tens of nanometers, and is further reduced by the screening action of nearby conducting electrodes and surfaces. This is why, with currently available technologies, the operation of a QCA circuit is not conceivable at temperatures beyond 10–20 K, and has so far been demonstrated only in the 100 mK range.

An increase in operating temperature requires an increase in the strength of the dipole interaction between cells, which can be achieved by reducing the size of the cell, by decreasing the dielectric permittivity of the material in which cells are embedded, or by resorting to a new type of interaction. As far as the dielectric permittivity is concerned, for semiconductor implementations silicon is more promising than gallium arsenide, because silicon dots can be defined by etching and be embedded in silicon oxide, which has a permittivity of 3.9 (much smaller than that of gallium arsenide, which is about 12). In Figure 12.15 the maximum operating temperature is plotted as a function of cell size for the silicon–silicon oxide and the gallium arsenide–aluminum gallium arsenide material systems. While for the GaAs/AlGaAs system the variation of the permittivity between the two materials is small, and can be neglected in approximate calculations, for silicon it is assumed that most of the electric field lines go through silicon-oxide (which encompasses the dots on all sides) and therefore its permittivity is used in the calculations. It is apparent that the

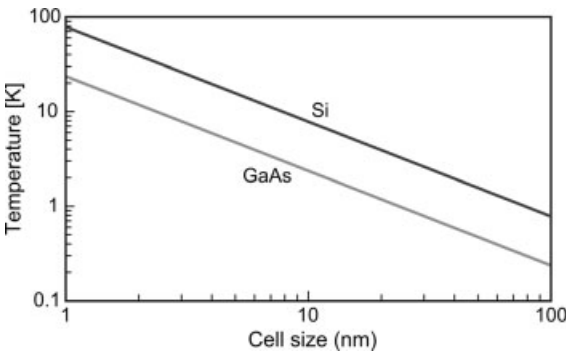

Figure 12.15 Maximum operating temperature as a function of the interdot separation within the cell, for gallium arsenide and silicon material systems.

stronger electrostatic interaction in silicon dots makes them suitable for relatively higher operating temperatures.

From Figure 12.15 it is however clear that an extremely small feature size would be needed to achieve operation at temperatures that are easily attainable.

An interaction that could allow QCA operation at room temperature is the one between nanomagnets characterized by a bistable behavior [17] (this will be discussed further in the next section). The magnetic interaction can be made strong enough to allow proper behavior of the circuit up to room temperature, but the achievable data processing speed is probably very low, of the order of a few kilohertz. On the other hand, a magnetic QCA circuit could exhibit an extremely reduced power dissipation, which could make it of interest for specific applications where speed is not a major issue, while keeping power consumption low is essential.

12.4.2 Fabrication Tolerances

The issue of fabrication tolerances has been introduced previously, and is probably the major limitation of the QCA concept, particularly for its implementation with semiconductor technologies. Detailed simulations [21] have shown that an approach based on the creation of an array of cells with dots defined by means of openings in a depletion gate cannot possibly lead to a working circuit. This is due to the fact that even extremely small errors in the geometry of such holes are sufficient to perturb the value of the confinement energy for the corresponding quantum dot to make it permanently empty or permanently occupied, no matter what the occupancy of the nearby dots is. Although shrinking the size of the cell the electrostatic interaction energy is increased, the above-mentioned problem becomes even more serious, due to the larger increase of the quantum confinement energy. An evaluation was made of the precision that could be achieved with state-of-the-art lithographic techniques and compared with the requirements for proper operation of a QCA circuit [32]. An array of square holes was obtained on a metal gate by means of electron beam lithography (Figure 12.16), after which the contour of the holes was extracted from a scanning

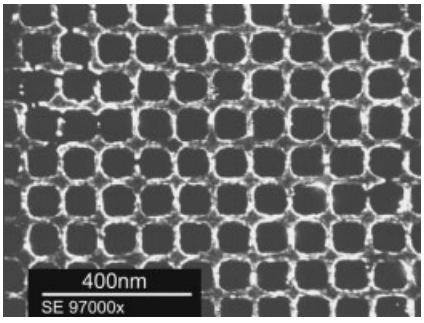

Figure 12.16 Scanning electron microscope image of the "hole array" that has been defined with state-of-the-art electron beam lithography for the purpose of evaluating the achievable precision.

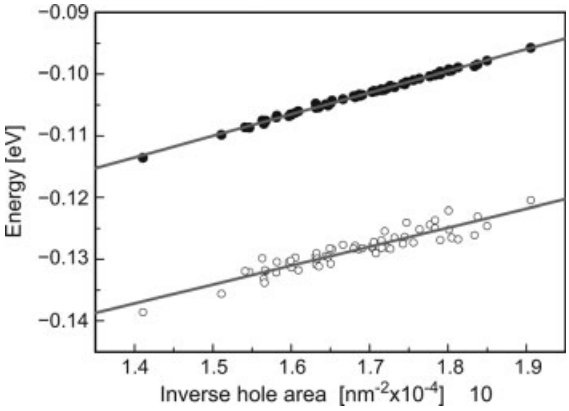

Figure 12.17 Scattering plot of the ground-state energy of single isolated quantum dots (closed circles) or of dots included in a cell (open circles) as a function of the inverse hole area.

electron microscope image and a solution of the Schrödinger equation was performed for the confinement potential obtained from each group of four holes (corresponding to a cell). The results showed a significant variance for the values of the confinement energy, as shown in Figure 12.17, where the ground-state energy for single dots and for four-dot cells is reported as a function of the inverse area of the holes defining them. From the almost linear dependence of the energy on the inverse area, it can be deduced that the local irregularities on the contour do not play an essential role, while the overall area is quite critical. It is clear that there is a dispersion of about 4 meV around the average value, while, from configuration–interaction calculations, it is shown that the allowed dispersion would be only 3 μeV, more than three orders of magnitude smaller.

Sensitivity to fabrication tolerances is ultimately the consequence of the same issue preventing operation at higher temperatures – that is, the smallness of the electrostatic interaction between cells. Imperfections are expected to play a role also with molecular-scale QCA circuits because, although molecules are in principle identical, once they are attached to a substrate any defects and stray charges from the substrate will disrupt the symmetry of the cells.

12.4.3 Limitations for the Operating Speed

The maximum operating speed of QCA circuits is ultimately limited by the dynamics of the evolution toward the ground state (if the ground-state relaxation paradigm is used), or by the tunneling rate between quantum dots. First, consider a non-clocked circuit, such as that represented for the case of a binary wire in Figure 12.18. The polarization state of the first cell is switched by inverting the bias voltages, and the cells of the wire will follow; however, according to a time evolution that may be rather

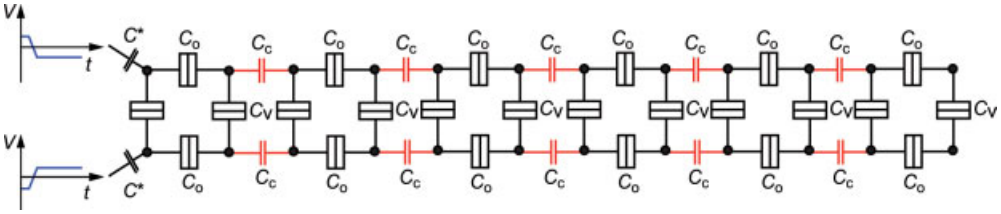

Figure 12.18 Equivalent circuit of a non-clocked binary wire; the voltages applied at the left end enforce the polarization state of the driver cell.

complex and involved. In particular, the presence of states that are very close in energy to the ground state, although corresponding to different configurations, will increase the time required for settling.

It is possible to obtain estimates of the time required for completion of the computation in a QCA array by performing simulations with a Monte Carlo approach. A Monte Carlo simulator specifically devised for QCA circuits was presented in Ref. [33]. This is based on the Orthodox Coulomb Blockade theory: the transition rate between two configurations differing by the position of one electron (which has tunneled through one of the junctions) and by a free energy variation ΔE can be expressed as

$$\Gamma = \frac{1}{e^2 R_T} \frac{\Delta E}{1 - \exp \frac{-\Delta E}{kT}}, \tag{12.15}$$

where R_T is the tunneling resistance of the junction.

Such a quantity is computed for all possible transitions, after which one of the transitions is chosen with a probability proportional to the corresponding rate. This procedure is repeated for each elementary time step into which the simulation period is divided, and the time-dependent currents in the branches of the circuit can be calculated from the contribution of the electron transitions.

This simulator can be used for the analysis of both clocked and unclocked circuits [17], as well as of a wide variety of single-electron circuits. By applying it to a six-cell binary wire with capacitances of the order of a few attofarads (values that are within the reach of lithographic technologies in the near future [33]), relaxation times of the order of 0.1 ms have been obtained; these are quite large, considering the extremely advanced technology needed for the fabrication of such devices. The reason for the slow operation is in the stochastic relaxation process, which brings the system to the ground state through a rather irregular path in the configuration space.

The Monte Carlo simulator MCdot can also be applied to the simulation of clocked QCA circuits. It has, for example, been used for the investigation of a clocked binary wire, as represented in Figure 12.19. The capacitance values are of the order of a few attofarads [33] and, at a temperature of 2.5 K, clock periods down to 0.1 μs can be achieved, as can be deduced from Figure 12.20, where the probability P_{co} of obtaining the correct logical state is plotted as a function of the clock interval for the second

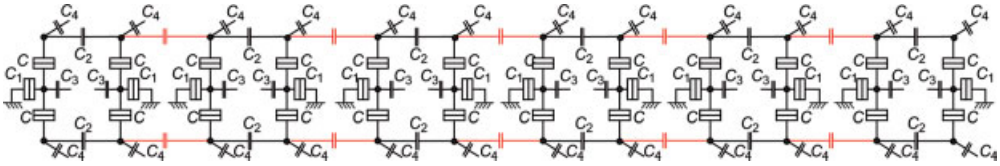

Figure 12.19 Equivalent circuit of a clocked binary wire; the C_4 capacitors are connected to voltage sources providing the bias required for proper operation, while the C_3 capacitors are connected to the clock signals.

(circles) and the last (squares) cells in the chain. As the tunneling resistances are assumed to be 200 kΩ, the resulting *RC* constant is of the order of 10^{-12} s. There is therefore a difference of about five orders of magnitude between the *RC* time constant of the circuit and the minimum clock period. This is due to a series of reasons [17]: the average time an electron takes to tunnel through a 200-kΩ junction with a 1.5-mV voltage is around 20 ps; furthermore the time during which the cell is active is only about one-tenth of the actual ramp duration; the active time, to be reasonably sure of regular operation, must be at least ten times the tunneling time; a clock period is made up of four ramps; and the intercell coupling is about five times smaller than the intracell coupling, which involves a further slow-down. Taken together, all of these effects lead to the above-mentioned reduction of the speed by five orders of magnitude with respect to the *RC* time constant, and make QCA technology not very suitable for high-speed applications.

On the other hand, the relatively slow operation of QCA circuits further limits their power dissipation, and in particular makes the power dissipated in capacitor charging–discharging negligible, as will be discussed in the next subsection.

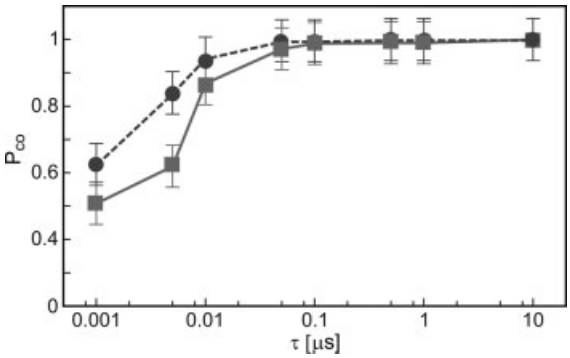

Figure 12.20 Probability (P_{co}) of correct logical output for the second (circles) and the third (squares) cell in a clocked binary wire as a function of the clock period. The *RC* constants of the circuit are of the order of 10 ps.

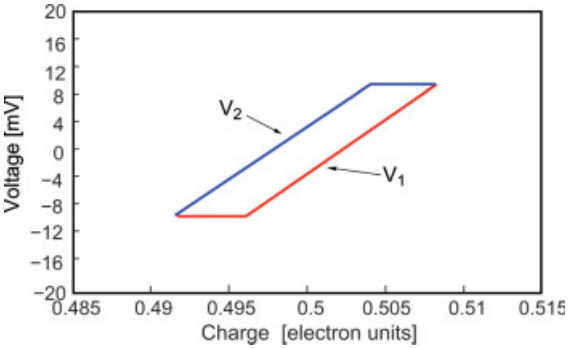

Figure 12.21 Representation of the voltages applied to a driver cell as a function of the charge flowing in the leads: the area inside the parallelogram corresponds to the work performed by the voltage sources on the QCA circuit.

12.4.4
Power Dissipation

One of the most attractive features of QCA circuits is represented by the limited power dissipation, which results mainly from the fact that there is no net transfer of charge across the whole circuit: electrons move only within the corresponding cell. The energy dissipated can be computed by integrating over the $V_i - Q$ plane [34] (Figure 12.21), where Q is the charge transferred from the source, for each external voltage source V_i and taking the algebraic sum of the results. The voltage V_2 is varied linearly until the unbalance is reversed: up to this point the charge variation corresponds to charging of the equivalent capacitance seen by V_2; then, some time after the new bias condition has been established, the electrons in the cell will tunnel, thus leading to a charge variation at constant voltage, which is represented by the horizontal segment. It is this tunneling event that makes the switch operation irreversible: without it, the area comprised between the two curves would be zero, as the voltage would simply be reversed across an equivalent capacitor, without changing its magnitude.

The energy dissipation depends on the voltage unbalance that is applied to the input cells, and that is reversed when the input data change: the larger the unbalance, the faster the switch, but the larger the dissipation, too. In the case of a single driven cell, for a typical unbalance of a few millivolts the power dissipation for a single switching event is about 10^{-22} J [35]. When considering a binary wire, the energy dissipated when the polarization of the driver cell is reversed, followed by all the other cells, and then increases very slowly as the number of cells is increased: the value for a six-cell wire is just 1% larger than that for a three-cell wire. This is due to the fact that the external voltage sources that provide energy are directly connected only to the driver cell, and the electrostatic action of the electrodes of the driver cell decays rapidly when moving along the chain. This leads to a very marginal contribution to the dissipated energy from the cells further away but, at the same

time, is the fundamental reason for the above-mentioned slow and irregular switching of a long chain.

So far, the energy loss associated with the capacitor charging process has not been included. If the unbalance reversal were abrupt, such an energy loss would be (as well known) equal to the electrostatic energy stored in the capacitor, and therefore it would represent the main contribution to dissipation. However, due to the other limitations in switching speed, there is no reason to perform such a switching with very steep ramps. It transpires from calculations, applying the expressions typically used in adiabatic logic [36], that the energy loss in capacitor charging performed with a speed compatible with the response of the circuit is negligible with respect to that due to electron tunneling in all practical cases [35].

For the case of clocked circuits the simulation is more complex and must be performed over a complete clock cycle; the conclusion is however similar, as far as a single cell is concerned: about 6×10^{-22} J dissipated in a clock cycle for the above-mentioned typical circuit parameters. In the clocked case, however, the dissipated energy is supplied by the clock electrodes directly to each cell (or clocking zone, in the case of groups of cells sharing the same clock phase), and therefore there is a linear increase in the energy dissipation as the number of cells is increased, contrary to what happens with the unclocked circuits. Indeed, with the clocked architecture there is an improvement in terms of speed and regularity of operation, but the power consumption in increased. Also in this case, it is possible to show that the contribution from the energy loss associated with capacitor charging is negligible, because the clock ramps can be much slower than the relevant time constants in the circuit.

Overall, the dissipation for a switching event of a single QCA cell is four orders of magnitude smaller than that projected for an end-of-the-roadmap MOS transistor by the ITRS Roadmap. However, the transistor operates at 300 K, while the simulations have been performed, for the clocked case, at 2.5 K. Cooling down to such a temperature requires energy, which can be estimated on the basis of the efficiency of a Carnot cycle refrigerator [37]. Inclusion of the energy lost for cooling reduces the ratio of the energy dissipated in a transistor to that dissipated in a QCA cell by two orders of magnitude. The advantage of the QCA cell still remains two orders of magnitude, but a fair comparison would require a relatively large effort, as a larger number of QCA cells is in general needed than transistors in order to obtain the same logic function. Furthermore, the energy savings that can be obtained in CMOS adiabatic logic should also be taken into consideration.

12.5
Physical Implementations of the QCA Architecture

12.5.1
Implementation with Metallic Junctions

The implementation of QCA circuits with metal islands connected by tunnel junctions was introduced in the previous sections. Tunnel junctions with extremely

small area (and therefore very small capacitance) can be fabricated between slightly overlapping electrodes, on top of a silicon oxide substrate, using the shadow mask evaporation technique. The QCA array in this case corresponds to a single-electron circuit, with tunnel junctions, capacitors, and voltage sources. From a technological point of view, a circuit with metallic junctions is relatively simple to implement, but has the major drawback, with currently available fabrication capabilities, of yielding capacitances no smaller than a few hundred attofarads [17], thus making operation possible only at temperatures of 100 mK or lower.

With such a technique, several QCA circuits have been demonstrated by the Notre Dame group: the basic driver cell-driven cell interaction [2], the operation of a clocked cell [12], a clocked QCA latch [38], and power gain in a QCA chain [34].

The problems connected with the undesired influence of each electrode on the proper balance of the cells via stray capacitances have been solved with a clever experimental scheme, based on an initial evaluation of the capacitance matrix among all electrodes. Once this is known, when the voltage of one electrode is varied, the voltages applied to all the other electrodes can be corrected in such a way as to compensate for the effects deriving from undesired capacitive couplings.

Although this technology has been very successful in the experimental demonstration of QCA operation, it appears very difficult to scale it down in order to increase the operating temperature so that it can be applied to large-scale circuits.

12.5.2 Semiconductor-Based Implementation

There are two main semiconductor implementations of QCA technology that have been attempted: one based on the Si/SiO_2 material system, and the other on the GaAs/AlGaAs material system. As previously stated, silicon has the advantage of the reduced permittivity of SiO_2, which allows the operating temperature to be raised but the fabrication of nanostructures in GaAs (defined by means of depletion gates) is more developed and tested.

For the approach based on GaAs/AsGaAs, a high-mobility, two-dimensional electron gas (2DEG) is formed at the heterointerface, and the quantum dots forming a cell are obtained by means of electrostatic depletion performed with properly shaped metal gates (Figure 12.22). In the experiments conducted to date, there is a hint of QCA effect, but it has not been possible to obtain full cell operation due to the too-small value of the capacitance coupling the upper with the lower dots across the barrier created by the horizontal electrode.

As the 2DEG is a few tens of nanometers below the surface, it is not possible to effectively define (at the 2DEG level) features that are significantly smaller; this also implies that dots cannot be made very close to each other, which represents a limitation on the maximum achievable interdot capacitance.

The advantage of GaAs technology is that tunnel barriers between dots can be finely tuned (contrary to what happens with the silicon–silicon oxide material system; see Section 12.5.3) by adjusting the bias voltage applied to the split gates defining them. In the cell represented in Figure 12.22, tunneling can occur between the top dots and

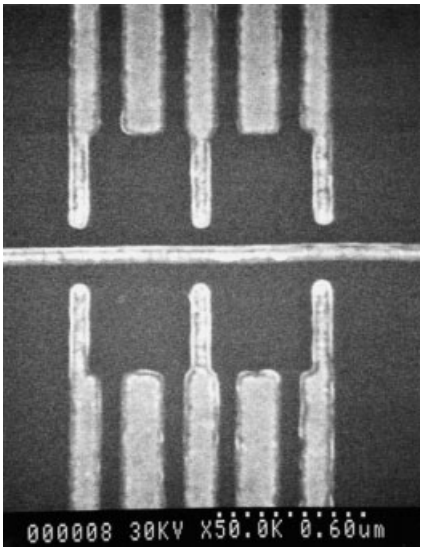

Figure 12.22 Scanning electron microscope image of the gate layout used for the investigation of the feasibility of a QCA cell in the GaAs/AlGaAs material system.

between the bottom dots, but not between one of the top dots and one of the bottom dots. This is not a problem, however, as the two configurations, with the electrons aligned along either diagonal, can still be achieved, and thus cell operation is unaltered.

A series of experiments has been performed on the prototype GaAs cell, operating, for example, the bottom part, while using one of the split gates in the top part as a non-invasive charge detector [39, 40], to monitor the motion of electrons between the two bottom dots. The outer quantum point contacts (QPC) in the bottom part are pinched off, to guarantee that the total number of electrons remains constant. Therefore, as a result of a variation of the voltage applied to the plunger gate of the dot at the bottom left (the shorter gate in the middle of the dot region), it is possible to observe motion of an electron from one dot to the other: as the plunger gate becomes more negative, an electron is moved from left to right. It has been observed [39] that the motion of an electron between the two bottom dots causes a shift of the Coulomb blockade peaks relative to one of the upper dots by about 20% of the separation between two consecutive peaks: this coupling is estimated to be sufficient to determine a reverse motion of an electron between the upper dots (i.e. the basic QCA effect).

The gate layout used for this experiment can also be applied to the implementation of a binary wire, but not for general logic circuits, because lateral branching is not possible due to the presence of the leads reaching each gate. It should also be pointed out that, even for the implementation of a simple binary wire, a careful balancing procedure would be needed, because even the finite length of the wire may be sufficient to create a fatal unbalance for all the cells, except for the one in the middle [23].

The other semiconductor implementation that has been attempted is based on silicon dots embedded in silicon oxide. As mentioned above, this material system has

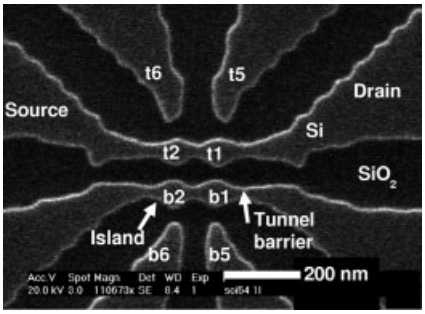

Figure 12.23 Scanning electron microscope image of a prototype QCA cell fabricated with the silicon/silicon oxide material system.

the advantage of the lower permittivity of silicon oxide with respect to gallium arsenide. However, although smaller feature sizes are achievable, control of the tunnel barriers is quite difficult as they are obtained by lithographically defining a narrower silicon region between two adjacent dots [31]. A prototype silicon QCA cell was fabricated at the University of Tübingen starting from a SOI (Silicon-On-Insulator) substrate, defining the structure by means of electron-beam lithography and reactive ion etching. The lithographically defined features are then further shrunk by means of successive oxidations [41]. It can be seen in Figure 12.23 that the tunneling junctions (between the two upper and the two lower dots) have been obtained by creating a narrower region, with a cross-section small enough that it does not allow propagation of electrons at the Fermi energy.

Such tunnel junctions are not easily controllable and, depending on the value of the Fermi energy and on the distribution of charged impurities, they may contain multiple barriers. However, it has been shown [17, 42] that, by properly tuning the back-gate voltage and the bias voltages applied to the gates, it is possible to achieve a condition in which both junctions contain a single barrier. Clear control of dot occupancy by means of the external gates has been demonstrated, by monitoring the conductance of the upper and lower double-dot systems. A clear demonstration of the QCA effect has not yet been possible due to the limited capacitive coupling between the upper and the lower double dots. However, simulations have shown [17] that a modified layout, with reduced spacing between the upper and the lower parts, should allow the observation of cell operation at a temperature of 0.3 K (probably up to 1 K), which is definitely higher than that required for metal dots and for GaAs. Unfortunately, also in this case, the basic layout used for the experiments should be significantly modified to make it suitable for complex circuits.

12.5.3
Molecular QCA

Another possible approach to the implementation of QCA circuits, as pioneered by Lent [4], is based on single molecules: this would satisfy the ultimate miniaturization requirement (a single molecule for a single computational function) and possibly

reduce the precision constraints, exploiting the fact that molecules are identical by construction. Furthermore, approaches to fabrication based on self-assembly could be envisioned, which would significantly decrease fabrication costs.

The molecular QCA concept relies on molecules containing four (or possibly two) sites where excess electrons can be located and which are separated by potential barriers. It has been demonstrated that potential barriers do exist at the molecular level and that they do lead to bistability effects [7]: a simple example is represented by a methylene group ($–CH_2–$) placed between two phenyl rings.

For the implementation of a complete cell, several candidate molecular structures have been proposed, such as metallorganic mixed-valence compounds containing four ruthenium atoms that represent the four dots. However, investigations are continuing to determine whether sufficient coupling is achievable between cells, because the screening action of the electronic clouds of the ligand atoms may determine too large a suppression of the electrostatic interaction. Furthermore, the problem of attaching the molecules to a substrate, in order to create properly structured arrays, is still only partially solved. In particular, the presence of imperfections or unavoidable stray charges at the surface of the substrate may create asymmetries preventing correct QCA operation, notwithstanding the identity of all molecules.

A simple molecule that has been proposed by the Notre Dame group as a model system for half of a cell is the so-called Aviram molecule [43], in which the two dots are represented by allyl groups at the ends of an alkane chain. Quantum chemistry calculations have shown that some bistability effects can be obtained, as well as sufficient electrostatic interaction between neighboring molecules, although, due to the reactivity of the allyl groups and to the difficulty to attach this molecule to a substrate, it does not seem a likely candidate for experiments.

Whilst overall the molecular approach seems the most appropriate solution for the implementation of the QCA concept in the long term, many problems – some of which are fundamental in nature – remain unsolved, such as finding a reliable way to assemble molecular arrays, managing the effect of stray charges, and determining whether the interplay of molecular sizes and screening effects will allow reasonably high operating temperatures.

12.5.4 Nanomagnetic QCA

To date, implementations of the QCA concept have been considered that rely on an electrostatic interaction between dots within a cell and between neighboring cells. It is also possible, as mentioned in the introduction, to exploit other forms of interaction, which may be less susceptible to the effects of temperature and of imperfections. One such alternative solution is represented by nanomagnetic QCA circuits. The concept is rather simple: an array of elongated single-domain dots obtained from properly chosen magnetic material will relax into an antiferromagnetic ordering, and it will be possible to drive the evolution of the system with an external clock consisting in an oscillating magnetic field that also supplies the energy needed for power gain

along the circuit. The first experimental investigation into the possibility of propagating the magnetic polarization along a chain of nanomagnets was performed by Cowburn and Welland [44], who managed to show the operation of a chain of magnetic nanodots.

The specific nanomagnetic approach to QCA circuits has been investigated mainly by Csaba and Porod, who have determined that an energy difference between the ground state and the first excited state of $150\,kT$ at room temperature can be achieved with elongated nanomagnets that are manufacturable with existing technologies. However, there is also a relatively high barrier ($100\,kT$) between the two states, and therefore at room temperature the system would be stable in both configurations. Thus, a pure ground-state relaxation scheme is not applicable, and resort must be made to the above-mentioned oscillating clock field. Such a field is used to turn the magnetic moments of all nanomagnets into a neutral state, from which they can relax into the ground state (as long as they remain in the instantaneous ground state).

A chain with an even number of cells (including the driver cell) will act as an inverter, as antiferromagnetic ordering is present. Thus, implementation of the NOT gate is straightforward; the majority voting gate can be implemented [17] in a way similar to that for electrostatically coupled QCA systems, with three binary wires converging on a single cell, from which another binary wire representing the output departs. Therefore, a generic combinatorial network can be realized in a way quite similar to what has been seen for other QCA technologies.

Simulators for nanomagnetic QCA circuits have been developed by Csaba and Porod [45], in which the complete micromagnetic equations are solved numerically. It has also been noticed that, for dot sizes below 100 nm, a significant simplification can be used – the single-domain approximation – in which the magnetization condition of the dots can be represented by means of single vectors instead of vector fields. Such an approximation is valid because magnetic dots below a size of 100 nm operate as single domains. The equations governing the evolution of single domains can be written as a system of ordinary differential equations and may then be recast into the form of a standard SPICE model. This allows efficient and easy simulation of relatively complex architectures of nanomagnetic QCAs, and has made it possible to show that logic signal restoration and power gain can be achieved, at the expense of the external oscillating magnetic field.

12.5.5 Split-Current QCA

An alternative approach to QCA implementation has been proposed by Walus *et al.* [46], who suggested a QCA cell in which tunneling of electrons between the dots does not take place; rather, the interaction is between tunneling currents that flow vertically through a double resonant tunneling diode structure. The cross-section of the cell proposed by Walus *et al.* is shown in Figure 12.24: the lower quantum well region of the double-resonant tunneling structure is partitioned into four dots in the horizontal plane.

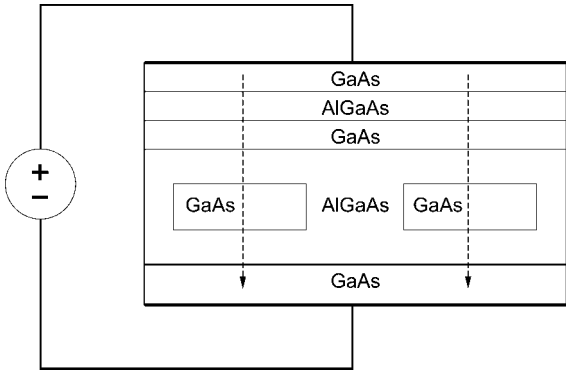

Figure 12.24 Cross-section of the split-current QCA cell, based on four parallel double-resonant tunneling structures.

The current flows mainly through these four dots, and the actual value of the current through each dot is strongly dependent on the position of the alignment of the energy levels in the upper and lower GaAs wells. Starting from a situation where the upper and lower levels are aligned, the flow of current will create a charge density that, in turn, will perturb the position of the resonant levels in the nearby dots: the larger the current, the greater the induced level shift. Therefore, for an isolated cell, the rest condition will be with current flowing mainly through either pair of antipodal dots (i.e. the dots that are furthest from each other), so that the resonant level shift is minimized. If another, driver, cell is placed next to it, with a well-defined polarization, the same polarization state will be obtained, as a result of Coulomb interaction between dots. Thus, operation similar to that of previously discussed electrostatically coupled cells will be achieved. The authors of Ref. [46] suggest that clocking is also possible, by controlling the voltage applied in the vertical direction across the resonant tunneling structures.

Although interesting in principle, this approach forfeits one of the main advantages of the QCA architecture, namely the potentially extremely low power consumption, since non-zero currents flowing in the vertical direction through the resonant tunneling diodes are always present, except for the "null" phase of the clock.

12.6 Outlook

The QCA concept has been the subject of significant research activity throughout the past decade, leading to results of general interest in the field of nanoelectronics. The practical implementation of QCA circuits is, however, still elusive, because of a few major problems connected with the weakness of the proposed cell-to-cell interaction mechanisms and with the extreme sensitivity to fabrication tolerances. Novel concepts are being explored, in particular aimed at the ultimate miniaturization, with cells consisting of single molecules, or aimed at an increase of inter-cell interaction, with cells made up of single-domain nanomagnets.

It is possible that these will lead to applications in niche markets in which extremely low power consumption is essential and high data processing speed is not a requirement. On the basis of the limited achievable switching speed and of the functional density not expected (if realistically evaluated) to be much higher than that achievable with CMOS technology, it is unlikely that QCA circuits will find application in large-scale integration. The QCA concept, however, can be at the basis of applications that go beyond its original purpose, for example in the field of metrology, where some of its weaknesses, such as the extreme sensitivity to external charges, may become important assets.

Overall, in the – so far unsuccessful – quest for a technology capable of succeeding CMOS, QCA have represented a very interesting diversion. Although such an approach may be too bold in relation to existing and near-future technological capabilities, it has contributed a wealth of novel understanding about the ultimate limitations of computation at the nanoscale.

Quantum Computation: Principles and Solid-State Concepts

Martin Weides and Edward Goldobin

> *. . . how can we simulate the quantum mechanics? . . . Can you do it with a new kind of computer - a quantum computer? It is not a Turing machine, but a machine of a different kind.* R. P. Feynman, 1982 [1]

13.1
Introduction to Quantum Computing

For half a century the conventional electronic information processing based on Boolean logic and using a von Neumann-type architecture has been very successful in solving many numerical problems, and its computational power is still increasing. The term *Neumann-type architecture* describes a device, which implements a so-called *Turing machine* by a specifying sequential architectures of information processing. In short, a *Turing machine* contains a program (software), a finite state control, a tape (memory) and a read-write tape-head [2]. It can be proven that conventional computers are equivalent to a Turing machine.

However, there are – and will continue to be – some restrictions for conventional computation, as will be seen below. Most of today's electronics is based on devices with digital logics, apart from the very specialized analog computers, which can solve for example differential equations up to a certain size. Both the feature size and energy consumption per logic step of conventional computers have been much reduced in the recent decades, and will continue to do so for some more years [3]. The *total* energy dissipation per unit area is still increasing due to increasing packaging density. A power density of $\sim 100\,\mathrm{W\,cm^{-2}}$ can be regarded as a reasonable limit, given by the thermal conductivity of materials and the geometry for setting up temperature gradients. Note that a common kitchen heating plate at full power has as a tenth of this power density. This limit will be reached in a few decades.

If one day the energy dissipation per a single logic step is equal to $k_B T \ln 2$, where $k_B = 1.38 \times 10^{-23}\,\mathrm{J\,K^{-1}}$ is the Boltzmann constant and T the theoretical limiting

Nanotechnology. Volume 4: Information Technology II. Edited by Rainer Waser

ISBN: 978-3-527-31737-0

value of temperature, the device has to use a so-called reversible logic (see Section 13.2). The implementation of reversible computing demands a precise control of the physical dynamics of the computation machine to prevent a partial dissipation of the input information (i.e. energy) into the form of heat. One type of reversible computer is the *quantum computer* which, by definition, relies on the time-reversible quantum mechanics.

A quantum computer is a device for information processing that is based on distinctively quantum mechanical phenomena, such as quantization of physical quantities, superposition and entanglement of states, to perform operations on data. The amount of data in a quantum computer is measured in quantum bits or *qubits*, whereas a conventional digital computer uses binary digits, in short: *bits*. The quantum computation relies on the quantum information carriers, which are single quantities, whereas the conventional computer uses a huge number of information carriers. In addition, the quantum devices may be much more powerful than the conventional devices, as a different class of (quantum) algorithm exploiting quantum parallelism can be implemented. Some specific problems cannot be solved efficiently on classical computers because the computation time would be astronomically large. However, they could be solved in reasonable time by quantum computers. This emerging technology attracts much attention and effort, both from the scientific community and industry, although the possibility of building such a device with a large number ($\gg$10) of qubits is still not answered.

For a more detailed introduction to classical and quantum computation, the interested reader is referred to a great selection of excellent textbooks such as, for example, Feynman Lectures on Computation [2] and others [4, 5].

13.1.1 The Power of Quantum Computers

In recent years there has been a growing interest in quantum computation, as some problems, which are practically intractable with classical algorithms based on digital logic, can be solved much faster by massive parallelism provided by the superposition principle of quantum mechanics.

In theoretical computer science, all problems can be divided into several classes of complexity, which represents the number of steps of the most efficient algorithm needed to solve the problem. The class **P** consists of all problems that can be solved on a Turing machine in a time which is a *polynomial* function of the input size. The class **BPP** (Bound-error, Probabilistic, Polynomial time) is solvable by a *probabilistic* Turing machine in polynomial time, with a given small (but non-zero) error probability for all instances. It contains all problems that could be solved by a conventional computer within a certain probability. It comprises all problems of **P**. The class **NP** consists of all problems whose solutions can be *verified* in polynomial time, or equivalently, whose solution can be *found* in polynomial time on a non-deterministic machine. Interestingly, no proof for $\mathbf{P} \neq \mathbf{NP}$ – that is, whether **NP** is the same set as **P** – has yet been found. Thus, the possibility that $\mathbf{P} = \mathbf{NP}$ remains, although this is not believed by many computer scientists.

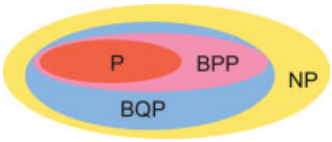

Figure 13.1 Diagram of complexity classes. A quantum computer can solve **BQP** (Bounded error, Quantum, Polynomial time) problems, whereas digital logic can just solve problems from the **P** (polynomial) class efficiently.

The class of problems that can be efficiently solved by *quantum computers*, called **BQP** (bounded error, quantum, polynomial time), is a strict superset of **BPP** (see Figure 13.1). For details on complexity classes, see Nielsen and Chuang [4].

The most important problems from the **BQP** class that cannot be solved efficiently by conventional computation (i.e. they do not belong to **P** or **BPP** class) but by quantum computation, are summarized below.

13.1.1.1 Sorting and Searching of Databases (Grover's Algorithm)

Quantum computers should be able to search unsorted databases of N elements in $\sim\sqrt{N}$ queries, as shown by Grover [6], rather than the linear classical search algorithm which takes $\sim N$ steps of a conventional machine (see Figure 13.2). This speedup is considerable when N is getting large.

13.1.1.2 Factorizing of Large Numbers (Shor's Algorithm)

A quantum algorithm for the factorization of large numbers was proposed by Shor [7], who showed that quantum computers could factor large numbers into their prime factors in a polynomial number of steps, compared to an exponential

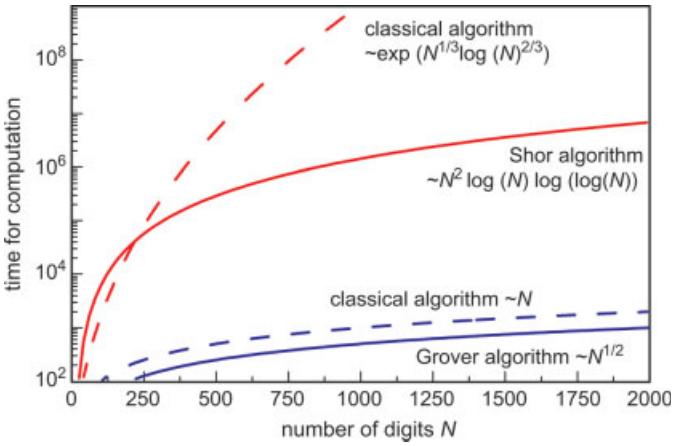

Figure 13.2 (In red): Factorization of a N digit number. (In blue): searching an unsorted database of N elements. Time requested for classical (dashed line) versus quantum (continuous line) algorithm. Note the logarithmic scale of the ordinate.

number of steps on classical computers (see Figure 13.2). The difficulty of prime factorization is a cornerstone of modern public key cryptographic protocols. The successful implementation of Shor's algorithm may lead to a revolution in cryptography.

13.1.1.3 Cryptography and Quantum Communication

Contrary to the classical bit, an arbitrary quantum state cannot be copied (no-cloning theorem; see Section 13.3.4) and may be used for secure communication by means of quantum key distribution or quantum teleportation. By sharing an entangled pair of qubits (so-called EPS-pair after a famous paper from Einstein, Podolski and Rosen [8]), signals can be transmitted that cannot be eavesdropped upon without leaving a trace; that is, performing a measurement and thereby destroying the entangled state.

All of these three important challenges for quantum computations have been implemented on NMR qubits or photons; that is, their feasibility has been proven using a small set of qubits.

13.2 Types of Computation

Here, information theory and logic will be briefly reviewed.

13.2.1 Mathematical Definition of Information

From statistical thermodynamics it is known that the entropy S of a system is defined as

$$S = k_B \ln \Omega$$

where Ω is the number of possible configurations or microscopic states. If an ideal gas is considered in a given volume and compressed under *isothermal* ($T = \text{const.}$) conditions, the mean translational kinetic energy of the gas is not changed. However, its entropy is reduced, because fewer possible positions are available for the gas atoms in the new volume. Conservation of the total energy leads to a dissipation of thermal energy

$$\Delta W = T \Delta S$$

to the outside thermal reservoir.

In information theory the situation is similar, the aim being to measure information [9]. The number Ω of possible configurations of a binary code with m elements is

$$\Omega = 2^m.$$

A stored bit can be in one of two states. If these states have the same probability (i.e. $\Omega = 2$), the minimum entropy associated with this bit is

$$S = k_B \ln\Omega = k_B \ln 2.$$

In case that the number of bits m is reduced during the computation process, for example by logic gates with less output than input bits, the energy dissipation per lost bit is given by

$$\Delta W = T\Delta S = k_B T \ln 2.$$

This is the so-called *Landauer principle* [10], which states that erasure is not thermodynamically reversible. Any loss of information inherently leads to a (minimum) energy dissipation of this amount per reduced bit in the case of an isothermal operation, as the entropy of the systems changes. In contrast, to prevent the thermal energy destroying the stored information, the minimum power for storage of information is $k_B T \ln 2$. The *energy consumption* in computation is closely linked to the *reversibility* of the computation.

13.2.2 Irreversible Computation

In all switching elements with more input than output bits, a loss of information occurs upon the information processing. For example, the Boolean function AND is defined as

$$(0,0) \to 0; \quad (0,1) \to 0; \quad (1,0) \to 0; \quad (1,1) \to 1\,.$$

The 0 output of this conventional two-valued gate can be caused by three possible input signal configurations. This type of computing is called *irreversible*.

13.2.3 Reversible Computation

Reversible computation needs to be based on switching elements which do not lose information. An example is the NOT gate, which is a single bit in- and output

$$(0) \to (1); \quad (1) \to (0)$$

or the controlled NOT (CNOT) gate, which makes the XOR operation reversible $(x, y) \to (x, x\ XOR\ y)$:

$$(0,0) \to (0,0); \quad (0,1) \to (0,1); \quad (1,0) \to (1,1); \quad (1,1) \to (1,0)\,.$$

The input can always be deduced from the output.

Now, this should be considered from the physical point of view. The classical two-state system is prepared and stored in the two stable states 0 or 1, respectively. It can be characterized by a particle placed in a double-well potential (see Figure 13.3a). To start the controlled reversible switching of a bit, some definite energy must be fed into the system to overcome the energy barrier separating the two minima of the double well potential. The energy is then available to perform a switching in an adjacent minimum of the potential, and remains available for subsequent switching processes

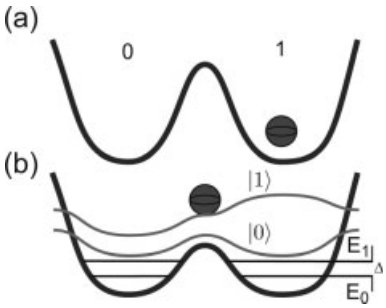

Figure 13.3 Representation of information in (a) a classical computer by a bit with two states (0, 1) and (b) a quantum computer by a quantum-mechanical two-level systems. $|0\rangle$, $|1\rangle$ denote the two quantum states.

or to switch the system back into its original state. Thus, both forward- and backward-switching processes have the same probabilities and the net speed of the computational process is zero. The flow of information must be determined by the gates and an adequate feedback prevention must be built into the logic gates.

13.2.4
Information Carriers

In classical information-processing systems the information transfer is based on the flow of particles, that is, electronic charges. A huge number of information carriers is involved for fault-tolerant operations. The information processing itself can be done by either reversible or irreversible logic gates.

A pure reversible information transfer could be implemented by means of discrete stationary states of a microscopic system which interacts by fields to move the information and to set the logic states. For example, the Quantum Cellular Automata (QCA) (see Chapter 12) are based on elementary cells with two stable states (0 or 1), which can be toggled by fields emerging from neighboring cells. There is no flow of charges or particles, as single atomistic entities (electrons, electron spin, small molecules) solely change their position in a potential well. In principle, an ideal QCA circuit would operate in the thermodynamic limit of information processing and at the same time is still calculating with conventional Boolean logic.

13.3
Quantum Mechanics and Qubits

In quantum computation the information is represented by the quantum properties of particles, so-called *qubits*, and its operations are devised and built by quantum mechanisms. The information content of a single qubit is obtained by a measurement process. An ideal quantum mechanical measurement of a single qubit can only measure one degree of freedom, and returns either 0 or 1. The information encoded

in a quantum mechanical system is described by a vector in the Hilbert space. The components of the Hilbert space vector denote probability amplitudes related to the outcome of certain measurements. Physical pure states are unit-norm vectors in the Hilbert space. Any observable of a system – that is, any quantity which can be measured in a physical experiment – should be associated with a self-adjoint linear operator. The measurable values are the eigenvalues of this operator and their probability is related to the projection of the physical state on the respective subspace. To keep the norm of the physical state fixed the operator should be unitary; that is, all eigenvalues of the operator matrix are complex numbers having absolute value 1.

Shortly, the aim of this subchapter is to summarize the important features of quantum mechanics. A good introduction can be found in various textbooks, for example in Ref. [11].

- *Quantization of states:* The observable quantities do not vary continuously but come in discrete *quanta*. In real systems they can be represented by electric charge, spin, magnetic flux, phase of electromagnetic wave, chemical structure, and so on.
- *Superposition of states:* The linear combination of two or more eigenstates results in a quantum superposition. If the quantity is measured, the state will randomly collapse onto one of the values in the superposition with a probability proportional to the square of the amplitude of that eigenstate in the linear combination. This superposition of states makes quantum computation qualitatively more powerful than classical one, because if we have $\alpha|0\rangle + \beta|1\rangle$ we simultaneously make computations with $|0\rangle$ and $|1\rangle$, roughly speaking.
- *Entanglement of states:* Two spatially separated and non-interacting quantum systems (qubits) that have been interacting may have some locally inaccessible information in common. An entangled state cannot be written as a direct product of two states from two subsystem Hilbert spaces. The entanglement of states makes quantum cryptography possible.

13.3.1 Bit versus Qubit

In a classical computer the information is encoded in a sequence of bits, having two distinguishable and stable states, for example, as a particle placed in a double-well potential, which are conventionally read as either a 0 or a 1 (Figure 13.3a). Apart from some similarities with a classical bit the qubit is overall very different. As in case of the bit, two distinguishable states – that is, different eigenstates of an operator – are needed. For example, a spin $\frac{1}{2}$ particle has two possible states ($\uparrow$ or $\downarrow$), or a photon can be polarized either vertically or horizontally. The state of a qubit may be expressed by basis states (or vectors) of the Hilbert space. The Dirac, or the so-called bra-ket, notation is used to represent them. This means that the two logical basis states, so-called eigenstates, are conventionally written as $|0\rangle$ and $|1\rangle$ (pronounced: "ket 0" and "ket 1").

Unlike the bit (being either 0 or 1) the qubit is not necessarily in the $|0\rangle$ or $|1\rangle$ state, but it can be rather in a superposition of both states. A particle representing a qubit is

described by a quantum-mechanical wave function and can tunnel under the barrier which separates two wells (i.e. the two states). As a consequence, a quantum system in a double-well potential has the two lowest energy states $|0\rangle = \frac{1}{\sqrt{2}}(|\uparrow\rangle + |\downarrow\rangle)$ and $|1\rangle = \frac{1}{\sqrt{2}}(|\uparrow\rangle - |\downarrow\rangle)$. Here $\uparrow$ and $\downarrow$ are two classical states, like the states 0 and 1 in the double-well potential (Figure 13.3a). In the ground state $|0\rangle$ the wave function is symmetric, whereas for the first excited state $|1\rangle$ it is antisymmetric, Figure 13.3b). A system prepared in a superposition state exhibits coherent oscillations between the two wells, and the measuring probability for finding the particle in each well oscillates with frequency $\omega = \Delta\,\hbar^{-1}$, where Δ is the splitting of the lowest energy level (see Figure 13.3b).

13.3.2 Qubit States

A pure qubit state is a linear superposition of both eigenstates. This means that the qubit can be represented as a linear combination of $|0\rangle$ and $|1\rangle$:

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle, \tag{13.1}$$

where α and β are probability amplitudes and can, in general, be complex.

When measuring this qubit in the standard eigen-basis, the probability of outcome $|0\rangle$ is $|\alpha|^2$ and of $|1\rangle$ is $|\beta|^2$. Because the absolute squares of the amplitudes are equal to probabilities, α and β must be constrained by the equation $|\alpha|^2 + |\beta|^2 = 1$. The Eq. (13.1) could be rewritten as

$$|\psi\rangle = |\psi(\varphi,\theta)\rangle = e^{-i\varphi/2}\cos\frac{\theta}{2}|0\rangle + e^{i\varphi/2}\sin\frac{\theta}{2}|1\rangle.$$

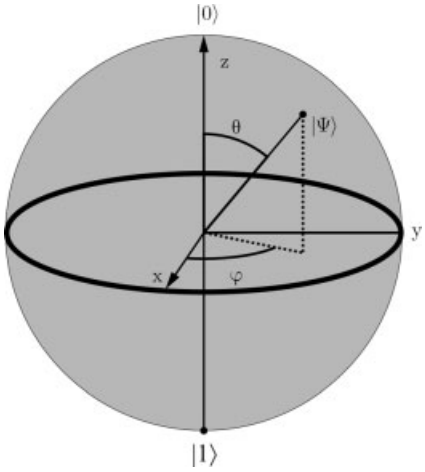

Figure 13.4 The qubit $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$ is represented as point (θ,φ) on a unit sphere, the so-called Bloch sphere. θ and φ are defined by $\alpha = e^{-i\varphi/2}\cos(\theta/2)$ and $\beta = e^{i\varphi}\sin(\theta/2)$. $|\psi\rangle$ is represented by the unit vector $[\cos(\varphi)\sin(\theta), \sin(\varphi)\sin(\theta), \cos(\theta)]$, called the Bloch vector.

The common phase factor resulting from the complex nature of α and β was neglected. The state of a single qubit can be represented geometrically by a point on the surface of the Bloch sphere (see Figure 13.4). A single qubit has two degrees of freedom φ, θ. A classical bit can only be represented by two discrete values 0 or 1. Note that the two complex numbers α, β in Eq. 13.1 in fact correspond to four numbers: Re(α), Im(α), Re(β), Im(β). However, these numbers are not independent; they are linked by the unity norm and the physical irrelevant common phase factor can be neglected. Any two-level quantum physical system can be used as a qubit; for example, the electron charge, polarization of photons, the spin of electrons or atoms and the charge, flux or phase of Josephson junctions could be used for implementation of qubits.

13.3.3 Entanglement

The entanglement of qubits is a subtle non-local correlation that has no classical analog. It allows a set of qubits to express a higher correlation than is possible in classical systems. As an example, consider the two entangled qubits A and B

$$|\Phi\rangle = |\phi\rangle_A|\psi\rangle_B = |\phi_A\psi_B\rangle = |\phi\psi\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle).$$

The first system is in state $|\phi\rangle_A$ and the second in state $|\psi\rangle_B$. Both systems have the two basis vectors $|0\rangle$ and $|1\rangle$. When measuring state $|\Phi\rangle$ the outcomes $|00\rangle$ and $|11\rangle$ have equal probabilities. It is impossible to attribute to either system A or system B a definite pure state as their states are superposed with one another. It is seen that if a 0 state is measured in A, then there will be an obligatory 0 state when measuring B. So A and B are not independent, they are *entangled*.

Entanglement allows multiple states to be acted on simultaneously, unlike classical bits that can only have one value at a time.

A number of entangled qubits taken together is a *qubit register*, with basis states of the form $|x_1x_2\ldots x_n\rangle$. An n-qubit register has a 2^n dimensional space, being much larger than a classical n-bit register.

Entanglement of states in quantum computing has been referred to as *quantum parallelism*, as the state can be in a quantum superposition of many different classical computational paths which can all proceed concurrently.

13.3.4 Physical State

The quantum Hamiltonian operator $\hat{H}$ generates the time evolution of quantum states and applied to the state vector yields the observable corresponding to the total energy of the system. The eigenvectors of $\hat{H}$, denoted by $|x\rangle$, provide an orthonormal basis for the Hilbert space of the system. The equation

$$\hat{H}|x\rangle = E_x|x\rangle.$$

yields the spectrum of allowed energy levels of the system, given by the set of eigenvalues E_x. Since $\hat{H}$ is a Hermitian operator, the energy is always a real number.

The time evolution $|\psi(t)\rangle$ of quantum states is given by the time-dependent Schrödinger equation:

$$\hat{H}\,|\psi(t)\rangle = \mathrm{i}\hbar\frac{\partial}{\partial t}|\psi(t)\rangle.$$

If $\hat{H}$ is independent of time this equation can be integrated to obtain the state at any time:

$$|\psi(t)\rangle = \exp\left(-\frac{\mathrm{i}\hat{H}\,t}{\hbar}\right)|\psi(0)\rangle,$$

where $|\psi(0)\rangle$ is the state at some initial time ($t = 0$).

13.3.4.1 Measurement

A measurement of a quantum state inevitably alters the system, as it projects the state onto the basis states of the measuring operator. Only if the state is already the eigenstate of the measuring operator then the state does not change. Thus, the superposition of states collapse into one or the other eigenstate of the operator, defined by the probabilities amplitudes. The precise amplitudes (α and β of a single qubit) can be found by multiple recreation of the superposition and subsequent measurements.

13.3.4.2 No-Cloning Theorem

Unlike the classical bit, of which multiple copies can be made, it is not possible to make a copy (clone) of an unknown quantum state [12, 13]. This so-called *no-cloning theorem* has profound implications for error correction of quantum computing as well as quantum cryptography. For example, such as it prevents the use of classical error correction techniques on quantum states, no backup copy of a state to correct subsequent errors could be made. However, error correction in quantum computation is still possible (see Section 13.5 for details). The no-cloning theorem protects the uncertainty principle in quantum mechanics, as the availability of several copies of an unknown system, on which each dynamical variable could be measured separately with arbitrary precision would bypass the Heisenberg uncertainty principle $\Delta x \Delta p$, $\Delta E \Delta t \geq \hbar/2$.

13.4 Operation Scheme

Quantum bits must be coupled and controlled by gates in order to process the information. At the same time, they must be completely decoupled from external influences such as thermal noise. It is only during well-defined periods that the control, write and readout operations take place to prevent an untimely readout.

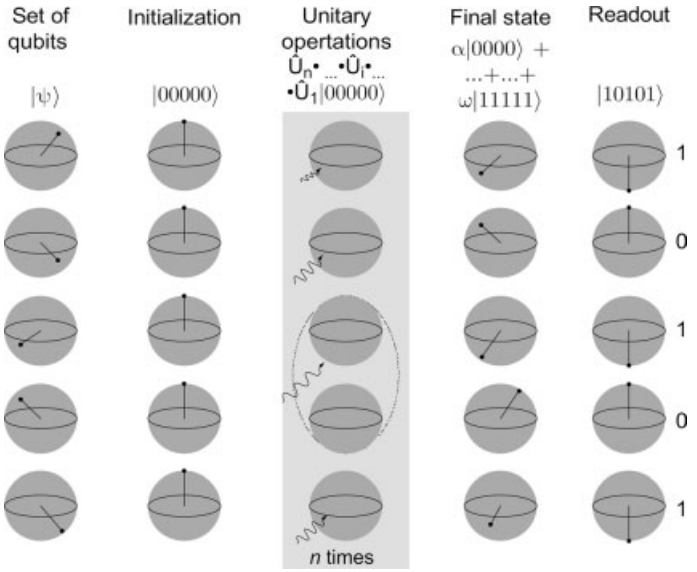

Figure 13.5 Operation scheme of quantum computation. After the system is prepared as a quantum register, controlled unitary operations $\hat{U}$ on single or entangled qubits are performed by gate operations in a controlled manner $\hat{U} = \exp(-i\hat{H}t/\hbar)$ ($\hat{H}$: Hamiltonian, t: time). The readout is done by projection onto basis states, yielding probability distributed Boolean values.

13.4.1
Quantum Algorithms: Initialization, Execution and Termination

The operation scheme of quantum computation is depicted in Figure 13.5. To start an quantum algorithm the qubit register must be initialized in some specified well-defined state, for example by a dissipative process to the ground state $|00\ldots0\rangle$.

Then, the computation is done by an appropriate sequence of applied unitary operations $\hat{U} = \exp(-i\hat{H}t/\hbar)$ with Hamiltonian $\hat{H}$ to the qubits. The actual mechanism – that is, electromagnetic waves, voltages or magnetic fields of well-defined energy/amplitude and time t – depends strongly on the type of qubit. In each step of the algorithm, the qubit vector is modified by multiplying it by a unitary matrix. The components of the matrix are determined by the physics of the device. The unitary character of the matrix ensures that the matrix is invertible, making the computation reversible.

For a given algorithm the operations will always be done in exactly the same order. Since there is no way to read the qubit state before the final destructive readout measurement, there are no conditional statements such as 'IF... THEN...'. However, there are conditional gate operations such as the controlled NOT (CNOT) gate.

After termination of the algorithm the qubit vector must be read out by measurement. Quantum mechanics ensure that the measurement will destroy the qubit

vector by projection onto the eigenstate of the corresponding observable, and only a probability distributed n-bit vector is obtained.

Even when neglecting the decoherence sources during the unitary transformations, the experimental readout schemes can never be perfectly efficient. Thus, it should be possible to repeat the measurement to enhance the probability of the obtained results by a majority polled output.

13.4.2 Quantum Gates

Once a quantum register is initialized the qubits must be manipulated in order to process the information by quantum gates, just as in case of the classical logic gates for conventional digital information processing. Quantum logic gates are represented by unitary matrices, as they are reversible, unlike many classical logic gates. However, some universal classical logic gates, such as the *Toffoli* gate, also provide reversibility, and can be directly mapped onto quantum logic gates. Mostly quantum gates operate on spaces of one or two qubits, thus written as matrices the quantum gates can be described by 2×2 or 4×4 matrices with orthonormal rows.

Examples of a single qubit operation are the *Hadamard* gate, which puts the initialized qubit in superposition state, represented by the Hadamard matrix

$$\hat{H}_{\text{Hadamard}} = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix},$$

and the CNOT gate for two qubit operations, defined as

$$\hat{H}_{\text{CNOT}} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix} = \begin{bmatrix} \mathbf{1} & \mathbf{0} \\ \mathbf{0} & \mathbf{X} \end{bmatrix},$$

with $\mathbf{1}$ the identity matrix and $\mathbf{X}$ the first Pauli matrix.

Both, in classical and quantum computation, all possible operations can be reduced to a finite set of *universal* gates, which can be used to construct the specific algorithm of the information processing. To achieve universality for classical reversible gates, three-bit operations are needed, whereas in the quantum regime only one- and two-qubit gate operations are sufficient. This underlines the versatile character of quantum logic.

13.5 Quantum Decoherence and Error Correction

Decoherence is the mechanism by which the information encoded in the superposed and entangled qubits register degrades over time. For example, dephasing caused by fluctuations of the energy level of two quantum mechanical states gives an additional phase proportional to the energy change of the superposition states. With increasing number of qubits the computation power, as well as the probability for decoherence,

will increase, and the need for decoherence control becomes predominant. This could be done by the implementing of quantum error correcting gates. In general, the sources of error can be: (i) non-ideal gate operations; (ii) interaction with environment causing relaxation or decay of phase coherence; and (iii) deviations of the quantum system from an idealized model system.

In classical computers every bit of information can be re-adjusted after every logical step by using non-linear devices to re-set the information bit to the 0 or 1 state. Contrary in a quantum system, no copy can be made of a qubit state without projecting it onto one of its eigenstates and thus destroying the superposition state.

Quantum information processing attracted much attention after Shor's surprising discovery that quantum information stored in a superposition state can be protected against decoherence. The single qubit is encoded in multiple qubits, followed by a measurement yielding the type of error, if any, which happened on the quantum state. With this information the original state is recovered by applying a proper unitary transformation to the system. This stimulated much research on quantum error correction, and led to the demonstration that arbitrarily complicated computations could be performed, provided that the error per operation is reduced below a certain error threshold.

By repeated runs of the quantum algorithm and measurement of the output, the correct value can be determined to a high probability. In brief, quantum computations are probabilistic.

13.6 Qubit Requirements

Di Vincenzo [14] listed criteria that any implementation for quantum computers should fulfill to be considered as *useful*:

- A scalable physical system with well-characterized qubits. A quantum computer consisting of a few qubits is not sufficient for useful computation.
- The ability to initialize the state of all qubits to a simple basis state.
- Relative long decoherence times τ_{dec}, much longer than the gate-operating time. To observe quantum-coherent oscillations the requirement $\tau_{dec}\Delta \gg \hbar$ must be fulfilled, and the fidelity loss per single quantum gate operation should be below some criteria.
- A universal set of quantum gates is needed to control the quantum system.
- A qubit-specific measurement capability to perform a readout and to transfer the information to conventional computers.

13.7 Candidates for Qubits

Various quantum mechanical two-level systems have been examined as potential candidates for qubits. In this overview, the aim is to concentrate on the first system

where the feasibility of quantum computation was demonstrated, and highlight some potential *solid-state* systems. The solid-state technology is easily scalable and can be integrated into conventional electric circuits. At the time of writing [15] there is no notable clear favorite for quantum computing, because on one hand the known systems must be improved, while on the other hand new promising candidates for quantum computing hardware are continuously appearing.

13.7.1
Nuclear Magnetic Resonance (NMR)-Based Qubits

Atomic nuclei are relatively isolated from the environment and thus well protected against decoherence. Their spins can be manipulated by properly chosen radio frequency irradiation. Elementary quantum logic operations have been carried out on the spin $\frac{1}{2}$ nuclei as qubits by using nuclear magnetic resonance (NMR) spectroscopy [16]. This system is restricted by the low polarization and the limited numbers of resolvable qubits. The nuclei (see Figure 13.6) were in molecules in a solution, and a magnetic field defined the two energy-separated states of the nuclei. These macroscopic samples with many nuclear qubits provide massive redundancy, as each molecule serves as a single quantum computer. The qubits interact through the electronic wave function of the molecule. Quantum calculations with up to seven qubits have been demonstrated. For example, the Shor algorithm was implemented to factorize the number 15 [17].

13.7.2
Advantages of Solid-State-Based Qubits

Large number of qubits could be assembled using existing solid-state technology. The main drawback is that the accuracy of the devices is not as high as established NMR-based qubits described above. Solid-state quantum computers encounter a new set of problems, as the spatial inhomogeneity during processing causes differences between nominally identical devices. Digital logic tolerates imperfection by restoring a signal to its intended value, whereas quantum computing forsakes this

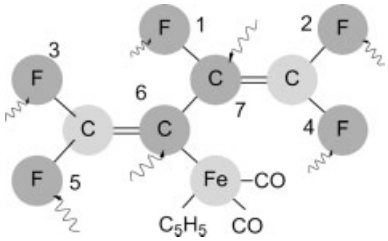

Figure 13.6 One molecule acts as seven-qubit system. The nuclei of five fluorine and two carbon atoms in the molecule form seven nuclear spin qubits (light gray), which are programmed by radiofrequency pulses and can be detected by nuclear magnetic resonance (NMR) spectroscopy [16].

methodology. Until now the imprecision of conventional solid-state devices prevents the storage of more than a few bits in a single device. A solid-state quantum computing device should be cooled down to a few mK to prevent thermal noise, caused for example, by phonons and destroying the coherent superposition of states.

The computations are performed by microwave pulses, that decrease the barrier separating the two states and brings the system into quantum realm. Subsequent pulses manipulate the Hamiltonian, *viz*. the probability weighting of the state vector to perform useful operations.

The spread between qubit parameters could be compensated by individually chosen biases, managed by a conventional computer. However, leaving the reduced coherence time due to additional noise aside, this would complicate the layout of a quantum computer, as at least one additional wire per qubit is needed.

Fortunately, it transpires that quantum error correction can even take care of error caused by defective implementation of a quantum gate, in case that the error is not larger than 10^{-4} per operation [18].

13.7.3
Kane Quantum Computer

In 1998, Kane [19] suggested imbedding a large number of nuclear spin qubits, made up by isotopically pure ^{31}P (nuclear spin 1/2) donor atoms, at a moderate depth in a ^{28}Si (nuclear spin 0) crystal to build a quantum computer (see Figure 13.7). When placed in a magnetic field, two distinguishable states for the spin 1/2 nuclei of the P atoms appear. By a controllable overlap of the wave functions of electrons bound to this atom in the deliberately doped semiconductor, some interaction may take place between adjacent nuclear qubits. Voltages applied to electrodes (gate A) placed above the phosphorus atoms can modify the strength of the electron–nuclear coupling. Individual qubits are addressed by the A-gates to shift their energies in and out of resonance with an external radiofrequency. The strength of the qubit–qubit coupling by overlapping wavefunctions is controlled by electrodes placed midway between the P atoms (gate B). The operation principle is similar to the NMR-based qubits in a macroscopic molecule solution, except that the nuclei are addressed by potentials rather than by the radiofrequency pulses.

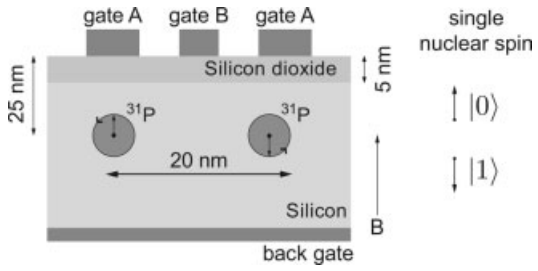

Figure 13.7 The Kane quantum computer: ^{31}P in a ^{28}Si matrix are controlled by gate electrodes (A, B) placed above them [19].

13.7.4
Quantum Dot

Beside the nucleus, the spin and charge of electrons may also be used to construct a double degenerate system. The electron spin-based qubits have the advantage that the Hilbert space consists of only two spin states, which strongly suppresses the leakage of quantum information into other states. In addition, the spin is less coupled to the environment than the charge, which results in longer decoherence times.

Quantum dots of 5 to 50 nm are thin, semiconducting multilayers on the substrate surface, where confined electrons with discrete energy spectra appear. By using Group III–V compound semiconductor materials such as GaAs and InAs of different lattice sizes, two-dimensional electron gas systems with high electron mobility can be constructed. To use these as qubits, their quantized electron number or spin is utilized [20]. The switching of the quantum state can be achieved either by optical or electrical means. In case of the spin-based quantum dot the electrons are localized in electrostatically defined dots (see Figure 13.8). The coupling between the electron spins is made via the exchange interaction, and the electron tunneling between the dots is controlled by a gate-voltage (gate B in Figure 13.8).

13.7.5
Superconducting Qubits

Superconductivity is a macroscopic quantum mechanical state, in which electrons with opposite spin and momenta form the so-called Cooper pairs and an energy gap in the quasi-particle spectrum appears. The interaction between the electrons is mediated by phonons. The superconducting qubits are based on *Josephson junctions* – that is, two superconductors separated by a tunnel barrier. The supercurrent that

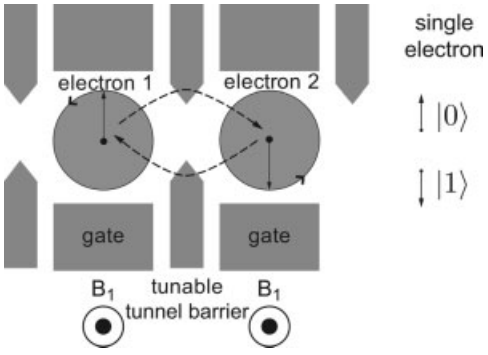

Figure 13.8 Scheme of spin-based quantum dots as a qubit system. The coupling of spins of localized electrons is formed by exchange interaction due to gate-voltage-controlled tunneling. Two electrons are localized in the regions defined by the gates. Single spin operations are performed by local magnetic fields [20].

crosses the weak link is the Josephson supercurrent. For details on superconductivity and the Josephson effect, see Refs. [21, 22].

Until now, several possible systems differing by 2e have been described for constructing a superconducting qubit. In the *charge* qubit a coherent state with a well-defined charge of individual Cooper pairs is used, while the *flux* qubit employs two degenerate magnetic flux states and the *phase* qubit is based on the phase difference of superconducting wavefunctions in two electrodes for quantum computation [23, 24].

13.7.5.1 Charge Qubits

The basis states of a charge qubit are two charge states. The qubit is formed by a tiny ~100-nm superconducting island – a Cooper pair box. Thus the charging electrostatic energy of a Cooper pair dominates in comparison with all other energies. An external gate voltage controls the charge, and the operation can be performed by controlling the applied gate voltages V_g and magnetic fields. A superconducting reservoir, coupled by a Josephson junction to the Cooper pair box, supplies the neutral reference charge level (see Figure 13.9). The state of the qubit is determined by the number of Cooper pairs which have tunneled across the junction. The readout is performed by a single-electron transistor attached to the island (not shown). By applying a voltage to this transistor, the dissipative current through the probe destroys the coherence of charge states and its charge can be measured [25].

13.7.5.2 Flux Qubits

A flux qubit is formed by a superconducting loop (1 μm size) interrupted by several Josephson junctions with well-chosen parameters (c.f. Figure 13.10) [26]. To obtain a double-well potential, as in Figure 13.10, either an external flux $\Phi_0/2$ or a π junction is needed. By including a π junction [27–29] in the loop the persistent current,

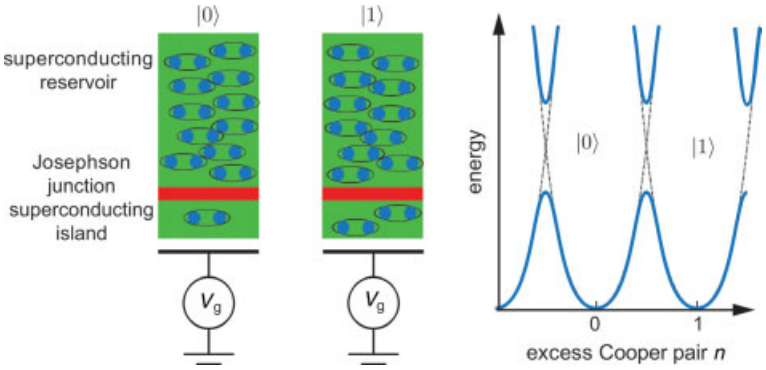

Figure 13.9 The charge qubit is formed by a Cooper pair box (CPB), separated from the superconducting reservoir (top) by a Josephson tunnel junction [25]. The basis states $|0\rangle$ and $|1\rangle$ differ by the number of excess Cooper pairs *n* on the CPB.

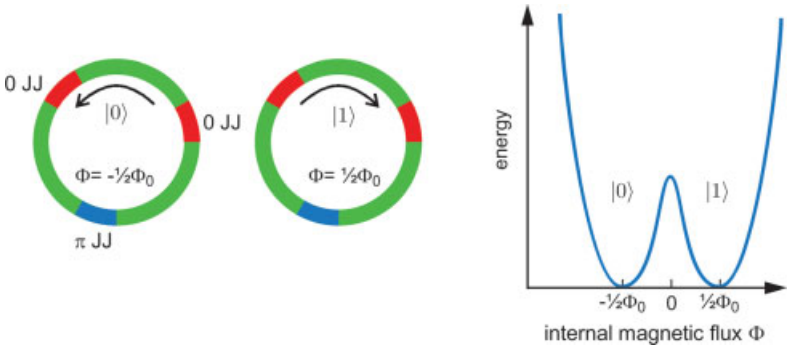

Figure 13.10 The basis states $|0\rangle$ and $|1\rangle$ of the flux qubit are determined by the direction of a persistent current circulating in three-junctions qubit [26]. The basis states $|0\rangle$ and $|1\rangle$ differ by the direction of the current in the superconducting loop. The π-Josephson junction (JJ) self-biases the qubit to the working point and, thus, substitutes an external magnetic flux.

generating the magnetic flux, may spontaneously appear and flow continuously, even in absence of an applied magnetic field [30]. The basis states of the qubit are defined by the direction of the circulating current (clockwise or counter-clockwise). The currents screen the intrinsic phase shift of π of the loop, such that the total flux through the loop is equal to $\pm\Phi_0/2$, i.e. half a magnetic flux quanta. The two energy levels corresponding to the two directions of circulating supercurrent are degenerate. If the system is in the quantum mechanical regime (low temperature to suppress thermal contributions) and the coupling between the two states (clockwise/counter-clockwise current flow) is strong enough (*viz*. the barriers are low), the system can be in the superposition of clockwise and counter clockwise states. This *quiet* qubit [31], is expected to be robust to the decoherence by the environment because it is self-biased by a π Josephson junction. Note that this flux-qubit device with a π junction is an optimization of the earlier scheme, where the phase shift of π was generated by an individual outer magnetic field of $\pm\Phi_0/2$ for each qubit [26].

The readout could by made by an additional superconducting loop with one or two Josephson junctions (i.e. SQUID loop) that is inductively coupled to the qubit.

To process the input and output of flux qubits an interface hardware based on the rapid single flux quantum (RSFQ) circuits could be used. These well-developed superconducting digital logics work by manipulating and transmitting a single flux quanta. In fact, this logic overcomes many problems of conventional CMOS-logics as it has a very low power consumption, an operating frequency of several hundred GHz, and is compatible with the flux qubit technology [32].

13.7.5.3 **Fractional Flux Qubits**

One variation of a flux π qubit is a fractional flux qubit. At the boundary between a 0 and a π coupled Josephson junction (i.e. a 0–π JJ) a *spontaneous* vortex of supercurrent

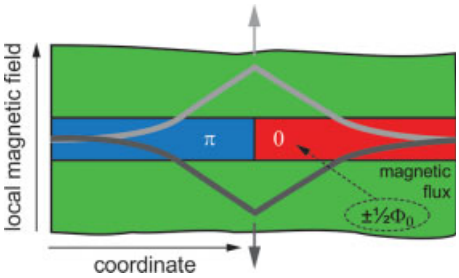

Figure 13.11 Sketch of a 0–π JJ with circulating supercurrent around 0–π phase boundary. The magnetic flux is equal to half of a flux quantum Φ_0 (semifluxon).

may appear under certain circumstances. Depending on the length L of the junction, the supercurrent carries a half-integer flux quantum $\Phi_0/2$ (called *semifluxon*) or fractions of it. Figure 13.11 depicts the cross-section of a symmetric 0–π *long* JJ. Classically, the semifluxon has a degenerate ground state of either positive or negative polarity, that corresponds to clockwise and counter-clockwise circulation of supercurrent around the 0–π boundary. The magnetic flux localized at the 0–π boundary is $\Phi_0/2$ and represents two degenerate classical states [33].

0–π Josephson junctions with a spontaneous flux in the ground state are realized with various technologies. The presence of spontaneous flux has been demonstrated experimentally in *d*-wave superconductor-based ramp zigzag junctions [34], in long Josephson 0–π junctions fabricated using the conventional Nb/Al-Al_2O_3/Nb technology with a pair of current injectors [35], in the so-called tricrystal grain-boundary long junctions [36–38] or in SIFS Josephson junctions [39] with a *step-like* ferromagnetic barrier. In the latter systems the Josephson phase is set to 0 or π by choosing a proper F-layer thicknesses d_F. The advantages of this system are that it can be prepared in a multilayer geometry (allowing topological flexibility) and it can be easily combined with the well-developed Nb/Al-Al_2O_3/Nb technology.

A *single* semifluxon ground state is double degenerate with basis flux states $|\uparrow\rangle, |\downarrow\rangle$. It transpires that the energy barrier scales proportionally to the junction length L, and the probability of tunneling between $|\uparrow\rangle$ and $|\downarrow\rangle$ decreases exponentially for increasing L [40]. Hence, a single semifluxon will always be in the classical regime with thermal activated tunneling for long junctions. As a modification, a junction of finite, rather small length L may be considered. In this case, the barrier height is finite and approaches zero when the junction length $L \to 0$. At this limit, the situation is not really a semifluxon, as the flux Φ present in the junction is much smaller than $\Phi_0/2$.

A 0–π–0 Josephson junction (see Figure 13.12) has *two* antiparallel coupled semifluxons for a distance a larger than the critical distance a_c [40]. The ground state of this system is either $|\uparrow\downarrow\rangle$ or $|\downarrow\uparrow\rangle$. For symmetry reasons both states are degenerate. The tunnel barrier can be made rather small, which results in a rather strong coupling with appreciable energy level splitting due to the wave functions overlap. Estimations show that this system can be mapped to a particle in a double-well potential, and thus can be used as a qubit like other Josephson junctions-based

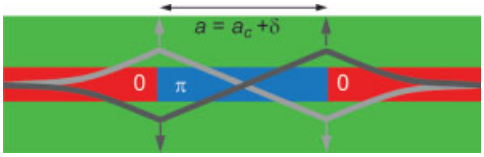

Figure 13.12 The two basis states are $|\uparrow\downarrow\rangle$ and $|\downarrow\uparrow\rangle$ of two coupled fractional vortices in a long linear 0–π–0 Josephson junction.

qubits. Thus, the 0–π–0 junctions are supposed to show the motion of a point-like particle in a double-well potential, and may be used as the basis cell of a fractional flux qubit.

13.8 Perspectives

Today, quantum computer algorithms allow to solve some specific **NP** problems, including factoring, sorting, calculating discrete logarithms, and simulating quantum physics. However, conventional computers will still be needed for addressing the quantum computer, for databases and for applications where either high computation power is not needed or sufficient coherence could not be provided, as in mobile devices. Quantum computers could be used as coprocessors for specific tasks such as en/decryption. The use of quantum computers may have several consequence, as today's data security algorithms could stay secure only if the keylength exceeds the storage capacity of quantum computers. The simulations of quantum mechanics might contribute to a variety of scientific and practical applications based on physics, chemistry, biology, medicine and related fields.

1
Introduction

Viola Vogel

1.1
Great Hopes and Expectations are Colliding with Wild Hype and Some Fantasies

What is nanomedicine? Will nanomedicine indeed help to cure major diseases and live up to the great hopes and expectations? What innovations are on the horizon and how can sound predictions be distinguished from wild hype and plain fantasy? What are realistic timescales in which the public might benefit from their ongoing investments?

When first exploring whether nanotechnology might reshape the future ways of diagnosing and treating diseases, the National Institutes of Health stated in the report of their very first nanoscience and nanotechnology workshop in 2000 (http://www.becon.nih.gov/nanotechsympreport.pdf. Bioengineering Consortium):

> *Every once in a while, a new field of science and technology emerges that enables the development of a new generation of scientific and technological approaches. Nanotechnology holds such promise.*

Our macroscopic bodies and tissues are highly structured at smaller and smaller length scales, with each length scale having its own secrets as to how life-supporting tasks are mastered. While we can still touch and feel our organs, they are all composed of cells which are a little less than one million times smaller and only visible under the light microscope (microscopic). Zooming further into the cell, about one thousand times, we find the nanoscale molecular machineries that drive and control the cellular biochemistry, and thereby distinguish living systems from dead matter. Faced with a rest of new technologies that has enabled researchers to visualize and manipulate atoms and molecules, as well as to engineer new materials and devices at this tiny length scale [1], major think tanks have begun since the late 1990's to evaluate the future potential of nanotechnology [2], and later at the interface to medicine [3–11]. These efforts were paralleled by a rapid worldwide increase in funding and research activities since 2000. The offset of a gold rush into the 'nano', by which the world of the very small is currently discovered, will surely also lead to splendid new entrepreneurial opportunities. Progress impacting on human health came much faster than expected.

1.2
The First Medical Applications are Coming to the Patients' Bedside

The public most commonly associates nanomedicine with engineered nanoparticles in the context of drug delivery devices or advanced medical imagine applications. Novel is that the molecules which are coassembled into nanoparticles can nowadays carry many different chemical functionalities. It has thereby become feasible to integrate multiple tasks into drug delivery device, from targeting specific tissues to releasing drugs, from enhancing contrast to probing their environment. How is this all done? First of all, the nanoparticles are loaded with drugs. The particles might then carry molecules on their surfaces that bind with great specificity to complementary molecules that are unique to cancers or to other diseased tissues, as reviewed later in this volume [12, 13]. For example, by using antibody– antigen recognition such engineered nanoparticles can be accumulated in the targeted tissues rather than being distributed over the entire body. Local accumulation greatly enhances the efficiency of drugs and reduces any unintended adverse side effects that might otherwise harm other organs. The selectivity by which disease can be treated by using engineered nanoparticles is thus in stark contrast to how conventional drugs operate; as conventional drugs lack the capacity to target specific tissues, they are distributed much more uniformly over the entire body, and must therefore be administered at much higher doses. Beyond tissue targeting, the nanoparticles might further be engineered to absorb therapeutic radiation, which might heat them up when they have reached the diseased tissues to damage the local tissue, either by heat or by the release of drugs [11, 12, 14]. Alternatively, the nanoparticles might hold on to drugs by bonds that can be locally cleaved by enzymes or be broken by light or radiation, thereby releasing the drug under the control of a physician (as reviewed elsewhere in this volume [12, 13]). The goal here is to design new strategies to inflict damage only to the aberrant cells, while leaving the surrounding tissues unharmed. This multifunctional integration of many different diagnostic and therapeutic tasks in single particles thereby enables applications that go far beyond those of conventional drugs.

Engineered nanoparticles can also change the future of medical imaging, as they enable us to combine structural imaging with spatially resolved diagnostics and interventions. Only eight years after wondering whether nanotechnology will revolutionize medicine, the US National Cancer Institute (NCI) stated that [15]:

> *Nanodevices are used in detecting cancer at its earliest stages, pinpointing its location within the body, delivering anticancer drugs specifically to malignant cells, and determining if these drugs are killing malignant cells.*

Increasingly sophisticated medical imaging technologies continue to revolutionize medicine. X-ray imaging, which was later complemented by ultrasound, positron emission tomography (PET) and magnetic resonance imaging (MRI), opened the possibility to visualize *nonintrusively* first bones, and then the inner organs, of our bodies. The objectives now are to obtain images of the structure of organs, at much

higher resolution, together with spatially resolved biochemical information which is reflective of how well cells and organs function. This includes probing noninvasively whether certain organs produce the hormones and enzymes at normal rates, and whether other metabolic activities might deviate from the norm. Major advances are about to come from the usage of nanoparticles that are engineered to serve both, as drug delivery systems and to enhance the contrast in ultrasound, PET and MRI images (for a review, see Ref. [16] and elsewhere in this volume [12, 13]). Enhancing the contrast and spatial resolution of images will enable the detection of cancers and other structural abnormalities of organs at much earlier stages, which in turn will enhance the chances of an effective therapy. Such multitasking approaches might also one day substitute for a variety of surgical interventions. Today, many books and articles have been published discussing the various medical applications of such engineered nanoparticles, while the pharmaceutical industry continues to invest heavily in their development (for reviews, see Refs [6, 15–22]).

1.3 Major Advances in Medicine Have Always been Driven by New Technologies

During the past few decades, the deciphering of the molecular origins of many diseases has had a most profound impact on improving human health. One historical step was the deciphering of the first protein structure in 1958 [23]. This opened a new era in medicinal chemistry, as drugs could since then be designed in a rational manner – that is, drugs that fit tightly into essential binding pockets thereby regulating protein and DNA functions. The invention of how to harness DNA polymerase in order to amplify genetic material in the test tube – which we now know as the polymerase chain reaction (PCR) [24] – then opened the field of molecular biology during the 1980s. PCR also enabled targeted genetic alterations of cells to identify the functional roles of many proteins, and this in turn led to the discovery that cell signaling pathways of many interacting proteins existed, and could be altered by diseases. The explosion of knowledge into how cell behavior is controlled by biochemical factors opened the door to target drugs to very specific players in cell signaling pathways. This also led to a host of new biotechnology start-up companies, the first of which became profitable only around 2000.

The next major breakthrough came with the solving of the human genome in 2001 [25–29]. Access to a complete genetic inventory of more than 30 000 proteins in our body, combined with high-resolution structures for many of them, enables a far more systematic search for correlations between genetic abnormalities and diseases. Finally, various diseases could for the first time be traced to inherited point mutations of proteins. In achieving this, much insight was gained into the regulatory roles of these proteins in cell signaling and disease development [30]. This includes recognizing genetic predispositions to various cancers [31], as well as to inherited syndromes where larger sets of seemingly uncorrelated symptoms could finally be explained by the malfunctioning of particular proteins or cell signaling pathways [32–38], including ion channel diseases [39–42].

1.4 Nanotechnologies Foster an Explosion of New Quantitative Information How Biological Nanosystems Work

Far less noticed by the general public are the next approaching waves of medical innovations, made possible by an explosion of new quantitative information how biological systems work.

The ultimate goal is to achieve an understanding of all the structural and dynamic processes by which the molecular players work with each other in living cells and coregulate cellular functions. Driven by the many technologies that have emerged from the physical, chemical, biological and engineering sciences, to visualize (see elsewhere in this volume [43, 44]) and manipulate the nanoworld, numerous discoveries are currently being made (as highlighted in later chapters [43–51]). These findings result from the new capabilities to create, analyze and manipulate nanostructures, as well as to probe their nanochemistry, nanomechanics and other properties within living and manmade systems. New technologies will continuously be developed that can interrogate biological samples with unprecedented temporal and spatial resolution [52]. Novel computational technologies have, furthermore, been developed to simulate cellular machineries in action with atomic precision [53]. New engineering design principles and technologies will be derived from deciphering how natural systems are engineered and how they master all the complex tasks that enable life. Take the natural machineries apart, and then learn how to reassemble their components (as exemplified here in Chapter 8 for molecular motors [48]).

How effectively will these novel insights into the biological nanoworld are recognized in their clinical significance, and translated into addressing grand medical challenges? This defines the time that it takes for the emergence of a next generation of diagnostic and therapeutic tools. As these insights change the way we think about the inner workings of cells and cell-made materials, totally new ways of treating diseases will emerge. As described in detail elsewhere in this volume, new developments are already under way of how to probe and control cellular activities [45, 47, 49–51, 54, 55]. This implicates the emergence of new methodologies of how to correct tissue and organ malfunctions. Clearly, we need to know exactly how each disease is associated with defects in the cellular machinery before medication can be rationally designed to effectively cure them.

Since every one of the new (nano)analytical techniques has the potency of revealing something never seen before, a plethora of opportunities can be envisioned. Their realization, however, hinges on the scientists' ability to recognize the physiological and medical relevance of their discoveries. This can best be accomplished in the framework of interdisciplinary efforts aimed at learning from each other what the new technologies can provide, and how this knowledge can be effectively translated to address major clinical challenges. Exploring exactly how these novel insights into the nanoworld will impact medicine has been the goal of many recent workshops [3–11, 56–58]). This stimulated the creation of the NIH

Roadmap Initiative in Nanomedicine [57, 58], and is the major focus of this volume.

1.5 Insights Gained from Quantifying how the Cellular Machinery Works will lead to Totally New Ways of Diagnosing and Treating Disease

Which are some of the central medical fields that will be impacted? Despite these stunning scientific advances, and the successful suppression or even eradication of a variety of infectious diseases during the past 100 years, the goal has not yet been reached of having medication at hand to truly cure many of the diseases that currently kill the largest fraction of humans per year, including cancers, cardiovascular diseases and AIDS. Much of the current medication against these diseases fights symptoms or inhibits their progression, often inflicting considerable side effects. Unfortunately, however, much of the medication can slow down but it cannot *reverse* disease progression in any major way – all of which contributes to healthcare becoming unaffordable, even in the richest nations of the world. For instance, intense cancer research over the past decades has revealed that the malignancy of cancer cells progresses with the gradual accumulation of genetic alterations [12, 50, 59–65]. Yet, little remains known as to how cancer stem cells form, in the first place, and about the basic mechanisms that trigger the initiation of their differentiation into more malignant cancer cells after having remained dormant, sometimes for decades [66–69]. While much has been learned in the past about the molecular players and their interactions, the above-mentioned shortcomings in translating certain advances in molecular and cell biology into more effective medication reflect substantial gaps in our knowledge of how all these components within the cells work in the framework of an integrated system. How can so many molecular players be tightly coordinated in a crowded cellular environment to generate predictable cell and tissue responses? Whilst lipid membranes create barriers that enclose the inner volumes of cells and control which molecules enter and leave (among other tasks), it is the proteins that are the 'workhorses' that enable most cell functions. In fact, some proteins function as motors that ultimately allow cells to move, as discussed in different contexts in the following chapters [46, 48, 50]. Other proteins transcribe and translate genetic information, and efforts to visualize these in cells have been summarized in Chapter 6 [45]. Yet other sets of proteins are responsible for the cell signaling through which all metabolic functions are enabled, orchestrated and regulated. But what are the underlying rules by which they play and interact together to regulate diverse cell functions? How do cells sense their environments, integrate that information, and translate it to ultimately adjust their metabolic functions if needed? Can this knowledge help to develop interventions which could possibly reverse pathogenic cells such that they performed their normal tasks again? Deciphering how all of these processes are regulated by the physical and biochemical microenvironment of cells is key to addressing various biomedical challenges with new perceptions, and is described as one of the major foci in this volume. But, how can this be accomplished?

1.6
Engineering Cell Functions with Nanoscale Precision

The engineering of nanoenvironments, nanoprobes and nanomanipulators, together with novel modalities to visualize phenomena at this tiny scale, have already led to the discovery of many unexpected mechanisms of how cellular nanoparts function, and how they cooperate synergistically when integrated into larger complex systems [43, 46–51]. Today, nanotechnology tools are particularly well suited to explore and quantify the physical aspects of biology, thereby complementing the tool chests of biochemists, molecular biologists and geneticists. Such nanotechnology approaches could already reveal that not only biochemical factors but also mechanical aspects as well as the micro- and nanoscale features of a cell's microenvironment, play pivotal roles in regulating their fate. The insights and implications thereof are described in chapters 9 to 14 [47, 49–51].

These discoveries are particularly relevant since most of our biomedical knowledge of how cells function has been derived in the past from the study of cells cultured on flat polymer surfaces (Petri dishes or on multi-welled plates). Cells in a more tissue-like environment, however, often show a vastly different behavior [70–75] (and chapters 9 to 14). With a still poorly understood cell signaling response system, cells in tissues thus 'see' and 'feel' an environment that is poorly mimicked by the common cell culturing conditions or scaffolds used in tissue engineering. Nanotechnologies will thus be pivotal to deciphering how cells sense and integrate a broad set of cues that regulate cell fate, from the moment that a sperm fertilizes an egg, to sustained, normal tissue functions. Moreover, these dependencies must be known in order to develop far more efficient drugs and treatment methods. However, ultimately it is the combination of many different technologies – some of which may originate from the physical sciences and others from biology – that must be combined to understand and quantify biology. Unfortunately, today an insufficient number of research workers are trained to perform these tasks [76].

1.7
Advancing Regenerative Medicine Therapies

Virtually any disease that results from malfunctioning, damaged or failing tissues may be potentially cured through regenerative medicine therapies, as was recently stated in the first NIH report on Regenerative Medicine [4]. But, how will nanotechnology make a difference? The repair – or ultimately replacement – of diseased organs, from larger bone segments to the spinal cord, or from the kidneys to the heart, still poses major challenges as discussed in chapters 9 to 14 [47, 49, 50, 54, 55, 77]. The current need for organ transplants surpasses the availability of suitable donor organs by at least an order of magnitude, and the patients who finally receive an organ transplant must receive immune suppressant drugs for the rest of their life. Thus, one goal will be to apply the mounting insights into how cells work, and how their functions are controlled by matrix interactions, to design alternate therapies that stimulate regenerative healing

processes of previously irreparable organs. In a most promising approach, some molecules have been designed that can self-assemble in the body into provisional matrices [55]. If these are injected shortly after injury, they help to repair spinal cord injuries and heart tissues damaged by an infarction. And if such strategies do not work, then another possibility might be to seed the patient's cells or stem cells into engineered biohybrid matrices to grow simple tissues *ex vivo* – that is, in the laboratory – and later implant them to support or regenerate failing organ functions [51, 54]. This could provide new ways of treating diabetes, liver and kidney failures, cardiovascular and many other diseases, or of replacing or repairing organs damaged in accidents or removed during surgery. Learning how to control the differentiation of stem cells in engineered matrices is therefore central to advancing our technical abilities in tissue engineering and regenerative medicine, and the challenges ahead as discussed in chapters 9 to 14 [50, 51, 54]. Nanofibers thereby mimic much better the fibrous nature of extracellular matrices [54], and the nanoscale patterning of ligands can control cell activation [49], including the activation of cells that play central roles in the immune response system (for a review, see [49]). In summary, the insights derived with the help of nanotechnology will enable the engineering of tissue-mimetic scaffolds that better control and regulate tissue function and repair. Improving human health will thus critically hinge upon translating nanotechnology-derived insights about cellular and tissue functions into novel diagnostic and therapeutic technologies.

1.8
Many More Relevant Medical Fields Will be Innovated by Nanotechnologies

Whilst the major focus of this volume is to outline the biomedical implications derived from revealing the underpinning mechanisms of how human cells function, it should also be mentioned that fascinating developments that are prone to alter medicine are being made in equally relevant other biomedical sectors. Future ways to treat infection will change when the underpinning mechanisms of how microbial systems function are deciphered, and how they interact with our cells and tissues. Many beautiful discoveries have already been made that will help us for example to interfere more effectively with the sophisticated machinery that bacteria have evolved to target, adhere and infect cells and tissues. Nanotechnology tools have revealed much about the function of the nano-engines that bacteria and other microbes have evolved for their movement [78–80], how bacteria adhere to surfaces [81–83], and how microbes infect other organisms [81–85]. Equally important when combating infection is an ability to exploit micro- and nanofabricated tools in order to understand the language by which microorganisms communicate with each other [86, 87] and how their inner machineries function [88–90]. A satisfying understanding of how a machine works can only be reached when we are capable of reassembling it from its components. It is thus crucial to learn how these machineries can be reassembled *ex vivo*, potentially even in nonbiological environments, as this should open the door to many technical and medical applications [84, 91–93]. Today, we have only just started along the route to combining the natural and synthetic worlds, with the community

seeking how bacteria might be used as 'delivery men' for nanocargoes [94], or in manmade devices to move fluids and objects [95, 96].

Finally, microfabricated devices with integrated nanosensors, nanomonitors and nanoreporters – all of which are intrinsic to a technology sector enabled by (micro/nano)biotechnology – will surely also lead to changes in medical practice. In the case of chemotherapies and many other drugs, it is well known that they may function well in some patients, but fail in others. It is feasable that this 'one-size-fits-all' approach might soon be replaced by a more patient-specific system. *Personalized medicine* refers to the use of genetic and other screening methods to determine the unique predisposition of a patient to a disease, and the likelihood of them responding to particular drugs and treatments [30, 97–100]. Cheap diagnostic systems that can automatically conduct measurements on small gas or fluid volumes, such as human breath or blood, will furthermore enable patients to be tested rapidly, without the need to send samples to costly medical laboratories. Needless to say, portable integrated technologies that will allow the testing and treatment of patients on the spot (point-of-care) will save many lives, and are urgently needed to improve human health in the Third World [101–104].

Faced with major challenges in human healthcare, an understanding what each of the many nanotechnologies can do – and how they each can best contribute to address the major challenges ahead – is crucial to drive innovation forwards. An improved awareness of how new technologies will help to unravel underpinning mechanisms of disease is crucial to setting realistic expectations and timescales, as well as to prepare for the innovations to come.

Since ultimately, thriving towards providing access to efficient and affordable healthcare, by improving upon technology, is not just an intellectual luxury, but our responsibility.

Acknowledgments

Many of the thoughts about the future of nanomedicine were seeded during exciting discussions with Drs Eleni Kousvelari (NIH) and Jeff Schloss (NIH), as well as with Dr Mike Roco (NSF), when preparing for the interagency workshop on Nanobiotechnology [9]. The many inspirations and contributions from colleagues and friends worldwide are gratefully acknowledged, several of whom have contributed chapters here, as well as from my students and collaborators and the many authors whose articles and conference talks have left long-lasting impressions.

2.1
Introduction

Advances and recent developments in the scientific areas of genomics and molecular biology have created an unprecedented opportunity to identify clinical pathology in pre-disease states. Building on these advances, the field of molecular imaging has emerged, leveraging the sensitivity and specificity of molecular markers together with advanced noninvasive imaging modalities to enable and expand the role of noninvasive diagnostic imaging. However, the detection of small aggregates of precancerous cells and their biochemical signatures remains an elusive target that is often beyond the resolution and sensitivity of conventional magnetic resonance and acoustic imaging techniques. The identification of these molecular markers requires target-specific probes, a robust signal amplification strategy, and sensitive high-resolution imaging modalities.

Currently, several nanoparticle or microparticle systems are under development for targeted diagnostic imaging and drug delivery [1]. Perfluorocarbon (PFC) nanoparticles represent a unique platform technology, which may be applied to multiple clinically relevant imaging modalities. They exploit many of the key principles employed by other imaging agents. Ligand-directed, lipid-encapsulated PFC nanoparticles (with a nominal diameter of 250 nm) have inherent physicochemical properties which provide acoustic contrast when the agent is bound to a surface layer. The high surface area of the nanoparticle accommodates 100 to 500 targeting molecules (or ligands), which impart high avidity and provides the agent with a robust 'stick and stay' quality (Figure 2.1). The incorporation of large payloads of lipid-anchored gadolinium chelate conjugates further extends the utility of the agent to detect sparse concentrations of cell-surface biochemical markers with magnetic resonance imaging (MRI) [2]. Moreover, for MRI the high fluorine signal from the nanoparticle core allows the noninvasive quantification of ligand-bound particles, which enables clinicians to confirm tissue concentrations of drugs when

The platform is extremely versatile, applicable to almost any imaging modality, and capable of carrying other payloads such as drugs or genes.

the functionality of the nanoparticles is extended to include targeted therapy (Figure 2.2). The detection of sparse concentrations of cell-surface biochemical markers is also possible with ultrasound [3]; however, novel signal processing is required for this application [4–6].

2.2 Active versus Passive Approaches to Contrast Agent Targeting

The passive targeting of a contrast agent is achieved by exploiting the body's inherent defense mechanisms for the clearance of foreign particles. Macrophages of the macrophage phagocytic system are responsible for the removal of most of these contrast agents from the circulation; these are produced, in size-dependent fashion,

from the lung, spleen, liver and bone marrow. Phagocytosis and accumulation within specific sites can be enhanced by biologic tagging (i.e. *opsonization*) with blood proteins such as immunoglobulins, complement proteins or nonimmune serum factors. In general, sequestration in the liver appears to be complement-mediated, while the spleen removes foreign particulate matter via antibody F_c receptors [8]. This natural process of nondirected and nonspecific uptake of particles is generally referred to as '*passive targeting*' (e.g. Feridex in the liver, or iron oxide in the sentinel lymph nodes [9]).

Distinguished from passive contrast agents, targeted (i.e. 'ligand-directed') contrast agents are designed to enhance specific pathological tissue that otherwise might be difficult to distinguish from the surrounding normal tissues. Here, an extensive array of ligands can be utilized, including monoclonal antibodies and fragments, peptides, polysaccharides, aptamers and drugs. These ligands may be attached either covalently (i.e. by direct conjugation) or noncovalently (i.e. by indirect conjugation) to the contrast agent. Engineered surface modifications, such as the incorporation of polyethylene glycol (PEG), are used to delay or avoid the rapid systemic removal of the agents, such that ligand-to-target binding is allowed to occur.

The effectiveness of this concept of contrast agent targeting is demonstrated with the application of paramagnetic MRI contrast agents. Paramagnetic agents influence only those protons in their immediate vicinity, and removal of these contrast agents by the macrophage phagocytic system during passive targeting may decrease their effectiveness via two mechanisms: (i) an accumulation of contrast agent in specific organs that are distal to region of interest; and (ii) endocytosis, which further decreases their exposure to free water protons. By targeting the contrast agent, the paramagnetic ions can be brought in close proximity to the region of interest with sufficient accumulation to overcome the partial dilution effect that plagues some MRI contrast agents. Its efficacy is further enhanced with some targeting platforms by delivering multiple contrast ions per particle [2].

2.3
Principles of Magnetic Resonance Contrast Agents

The fundamental physics underpinning MRI is grounded in the quantum mechanical magnetic properties of the atomic nucleus. All atomic nuclei have a fundamental property known as the *nuclear magnetic momentum* or *spin quantum number*. Individual protons and neutrons are fermions that possess an intrinsic angular momentum, or 'spin', quantized with a value of 1/2 [10, 11].

The overall spin of a nucleus (a composite fermion) is determined by the numbers of neutrons and protons. In nuclei with even numbers of protons and an even numbers of neutrons, these nucleons pair up to result in a net spin of zero. Nuclei with an odd number of protons or neutrons will have a nonzero net spin which, when placed in a strong magnetic field (with magnitude B_0), will have an associated net magnetic moment, $\vec{\mu}$, that will orient either with ('parallel') or against ('anti-parallel') the direction of B_0. For a nucleus with a net spin of 1/2 (e.g. ^{1}H), this results in two

possible spin states with an energy of separation $\Delta E = h\gamma B_0/2\pi$ (where $h = 6.626 \times 10^{-34}$ J s is Planck's constant and γ is the *gyromagnetic ratio*, which for hydrogen is equal to 42.58 MHz T^{-1}).

For a given population of nuclei in a static magnetic field, an equilibrium exists, described by Maxwell–Boltzmann statistics, in which only a slight majority of nuclei are oriented in the 'parallel' position (i.e. a lower energy state); however, this small difference in spin distribution results in a net magnetization that is perceptible. Absorption of the appropriately tuned radiofrequency (RF) radiation by the nuclei can alter the equilibrium distribution of 'anti-parallel' states. On a macroscopic level, this is equivalent to tilting the net magnetization away from the direction of the main magnetic field (B_0). Once the RF energy is removed, decay to the previous lower energy state takes place and occurs in two distinct and independent processes known as longitudinal relaxation (T_1) and transverse relaxation (T_2). The relaxation times, T_1 and T_2, as well as the proton density of the nuclei of interest, determine the signal intensity for various types of tissue in MRI.

Magnetic resonance contrast agents function by accelerating the longitudinal and/or transverse relaxation rates. The most commonly used nontargeted MR contrast agents are paramagnetic ions (e.g. gadolinium chelates), and these predominantly shorten T_1 relaxation to result in a bright signal on T_1-weighted images. The mechanism by which paramagnetic ions affect T_1 relaxation depends upon close nuclear interaction with protons (^{1}H) in water molecules (H_2O). Therefore, T_1 agents only influence protons proximate to themselves and are highly dependent on local water flux [12].

Superparamagnetic and ferromagnetic compounds have a high magnetic susceptibility, and when placed in a magnetic field (B_0) they concentrate the field; this results in a large local net positive magnetization [13]. This large magnetic susceptibility heterogeneity induces spin dephasing in tissue and results in a loss of the T_2-weighted signal. In contrast to T_1 contrast agents, superparamagnetic agents disturb the magnetic field and have a net effect far beyond their immediate vicinity.

2.3.1
Mathematics of Signal Contrast

To elucidate the source of image contrast, let us assume that two adjacent tissue types (A and B) manifest identical longitudinal (T_1) and transverse (T_2) relaxation times prior to nanoparticle binding, but only one tissue (say, type B) expresses the molecular epitope of interest that binds the targeted paramagnetic nanoparticles. The bound paramagnetic nanoparticles affect the relaxation times in the targeted tissue according to the following equations [14]:

$$\frac{1}{T_{1B}} = \frac{1}{T_{1A}} + r_{1P}\langle NP\rangle \tag{2.1}$$

$$\frac{1}{T_{2B}} = \frac{1}{T_{2A}} + r_{2P}\langle NP\rangle \tag{2.2}$$

where T_{1B} and T_{2B} are the observed relaxation times after the nanoparticle binding, T_{1A} and T_{2A} are the original relaxation times, r_{1P} and r_{2P} are the particle-based

relaxivities, and $\langle NP \rangle$ represents the average nanoparticle concentration within the imaging voxel. For the purpose of this example, the assumption is made that targeted binding does not affect particle relaxivity (i.e. r_{1p} and r_{2p} are constant).

The contrast-to-noise ratio (CNR) between the two tissues for a given sequence is calculated as the absolute difference between their signal intensities. If I_A and I_B represent the signal intensities of tissue A and B respectively, and N is the expected level of noise in the resulting image, the CNR ratio is given by:

$$\mathrm{CNR} = \frac{I_A - I_B}{N} \tag{2.3}$$

For a spin echo pulse sequence, the signal intensity of each tissue is related to the chosen scan parameters (echo time, TE, and repetition time, TR) as well as its magnetic properties (T_1 and T_2), which change due to binding of the contrast agent, and is described with the following relationships for tissues A and B [15]:

$$I_A = k_A(1 - 2e^{-(TR - TE/2)/T_{1A}} + e^{-TR/T_{1A}})e^{-TE/T_{2A}} \tag{2.4}$$

$$I_B = k_B(1 - 2e^{-(TR - TE/2)/T_{1B}} + e^{-TR/T_{1B}})e^{-TE/T_{2B}} \tag{2.5}$$

The constants k_A and k_B incorporate factors such as proton density, RF excitation and coil sensitivity. As these tissues are assumed identical, except for binding of the contrast agent, k_A and k_B are identical except for relative coil sensitivity to the positional differences between the two tissues for this simulation. Substituting Equations (2.4) and (2.5) into Equation (2.3) and optimizing the resulting equation for TR provides a relationship between the T_1 values for the two tissues and the repetition time that will create the highest CNR [15].

$$TR_{\mathrm{opt}} = \frac{T_{1A}T_{1B}}{T_{1B} - T_{1A}} \log\left(\frac{k_A T_{1B}}{k_B T_{1A}}\right) \tag{2.6}$$

With use of the field-dependent input parameters specified, model predictions for the minimum concentration of contrast agent required to generate visually apparent contrast between the two tissues may easily be determined [16]. As a point of reference, visually apparent contrast is typically defined as a $\mathrm{CNR} \geq 5:1$ [17].

2.3.2
Perfluorocarbon Nanoparticles for Enhancing Magnetic Resonance Contrast

For use as a T_1-weighted paramagnetic contrast agent, perfluorocarbon nanoparticles can be functionalized by surface incorporation of homing ligands and more than 50 000 gadolinium chelates (Gd^{3+}) per particle [7]. In addition, all of the paramagnetic ions are present in the outer aqueous phase to achieve maximum relaxivity of T_1 [18]. The result is a perfluorocarbon nanoparticle that is capable of overcoming the diluting partial volume effects that plague most magnetic resonance contrast agents [19]. The efficiency of an magnetic resonance contrast agent can be described by its relaxivity ($\mathrm{m}M^{-1}\,\mathrm{s}^{-1}$), which is simply calculated as the change in relaxation rate ($1/T_1$ or $1/T_2$) divided by the concentration of the contrast agent. The relaxivity

of Gd^{3+} in saline (4.5 $mM^{-1}s^{-1}$) [20] is lower when compared to Gd^{3+} bound to the surface of a PFC nanoparticle (33.7 $mM^{-1}s^{-1}$) [18] at a field strength of 1.5 Tesla. Considering that each nanoparticle carries approximately 50 000 to 100 000 Gd^{3+}, the 'particle' relaxivity has been measured at over 2 000 000 $mM^{-1}s^{-1}$ [18]. The high level of relaxivity achieved using this paramagnetic liquid PFC nanoparticle allows for the detection and quantification of nanoparticle concentrations as low as 100 picomolar, with a CNR of 5 : 1 [16].

2.3.3
Perfluorocarbon Nanoparticles for Fluorine (^{19}F) Imaging and Spectroscopy

The intensity of a magnetic resonance signal is directly proportional to the gyromagnetic ratio (γ) and the number of nuclei in the volume of interest [21]. Although there are seven medically relevant nuclei, the ^{1}H proton is the most commonly imaged nuclei in clinical practice because of its high γ and natural abundance. The isotopes, their γ-values, natural abundance and relative sensitivity compared to ^{1}H with a constant field are listed in Table 2.1. With a gyromagnetic ratio second only to ^{1}H and a natural abundance of 100%, ^{19}F is an attractive nucleus for MRI [22]. Its sensitivity is 83% (when compared to ^{1}H) at a constant field strength and with an equivalent number of nuclei. In biological tissue, low ^{19}F concentrations (in the range of micromoles) makes MRI impractical at clinically relevant field strengths without ^{19}F-specific contrast agents [23]. Perfluorocarbon nanoparticles are 98% perfluorocarbon by volume, which for perfluoro-octylbromide (1.98 g ml^{-1}, 498.97 g mol^{-1}) equates to an approximately 100 M concentration of fluorine within a nanoparticle. The paucity of endogenous fluorine in biological tissue allows the use of exogenous PFC nanoparticles as an effective ^{19}F MR contrast agent, without any interference from significant background signal. When combined with local drug delivery, detection of the ^{19}F signal serves as a highly specific marker for the presence of nanoparticles that would permit the quantitative assessment of drug dosing.

^{19}F has seven outer-shell electrons rather than a single electron (as is the case for hydrogen); as a result, the range and sensitivity to the details of the local environment of chemical shifts are much higher for fluorine than hydrogen. Consequently,

Table 2.1 Medically relevant MRI nuclei.

Isotope	γ (MHz T^{-1})	Natural abundance (%)	Relative sensitivity
^{1}H	42.58	99.98	1.00
^{19}F	40.05	100	0.83
^{23}Na	11.26	100	0.093
^{31}P	17.24	100	0.066
^{13}C	10.71	1.11	0.015
^{2}H	6.54	0.015	0.0097
^{15}N	3.08	4.31	0.0010

distinct spectra from different PFC species can be obtained and utilized for simultaneous targeting of multiple biochemical markers.

For use as a clinically applicable contrast agent, the biocompatibility of PFC nanoparticles must be considered. Liquid PFCs were first developed for use as a blood substitute [24], and no toxicity, carcinogenicity, mutagenicity or teratogenic effects have been reported for pure fluorocarbons within the 460 to 520 molecular-weight range. Perfluorocarbons, which inert biologically, are removed via the macrophage phagocytic system and excreted primarily through the lungs and in small amounts through the skin, as a consequence of their high vapor pressure relative to their mass [25]. The tissue half-lives of PFCs range from 4 days for perfluoro-octylbromide up to 65 days for perfluorotripropylamine. The prolonged systemic half-life of PFC nanoparticles, in conjunction with the local concentrating effect produced by ligand-directed binding, permits ^{19}F spectroscopy and imaging studies to be conducted at clinically relevant magnetic field strengths.

2.3.4
Fibrin-Imaging for the Detection of Unstable Plaque and Thrombus

Of the over 720 000 cardiac-related deaths that occur each year in the United States, approximately 63% are classified as sudden cardiac death [26]. Unfortunately, for the majority of patients, this is the first and only symptom of their atherosclerotic heart disease [27]. Atherosclerosis manifests initially as a fatty streak but, without proper treatment, it can progress to a vulnerable plaque that is characterized by a large lipid core, a thin fibrous cap and macrophage infiltrates [28]. These vulnerable plaques are prone to rupture, which can lead to thrombosis, vascular occlusion and subsequent myocardial infarction [29] or stroke. Routine angiography is the most common method of diagnosing atherosclerotic heart disease, with the identification of high-grade lesions (>70% stenosis) being referred for immediate therapeutic intervention. Ironically, most ruptured plaques originate from coronary lesions classified as nonstenotic [28]. Even nuclear and ultrasound-based stress tests are only designed to detect flow-limiting lesions. Because the most common source of thromboembolism comes from atherosclerotic plaques with 50–60% stenosis [30], diagnosis by traditional techniques remains elusive. In addition, there appears to be a 'window of opportunity' that exists between the detection of a vulnerable or ruptured plaque and acute myocardial infarction (measured in a few days to months) [31], when intervention could prove to be beneficial.

The acoustic enhancement of thrombi using fibrin-targeted nanoparticles was first demonstrated *in vitro* as well as *in vivo* in a canine model at frequencies typically used in clinical transcutaneous scanning [32]. The detection of thrombi was later expanded to MRI in a study by Flacke *et al.* [7] Fibrin clots were targeted *in vitro* with paramagnetic nanoparticles and imaged using typical low-resolution T_1-weighted proton imaging protocols with a field strength of 1.5 Tesla. Low-resolution images show the effect of increasing the amount of Gd^{3+} incorporated in the nanoparticles: a higher gadolinium loading results in brighter T_1 signals from the fibrin-bound PFC nanoparticles (Figure 2.3). In the same study, *in vivo* MR images were obtained of

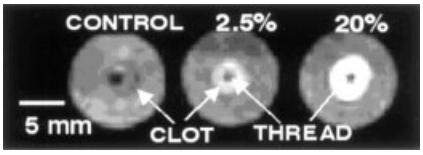

Figure 2.3 Low-resolution images (three-dimensional, T_1-weighted) of control and fibrin-targeted clot with paramagnetic nanoparticles presenting a homogeneous, T_1-weighted enhancement.

fibrin clots in the external jugular vein of dogs. Enhancement with fibrin-targeted PFC nanoparticles produced a high signal intensity in treated clots (1780 ± 327), whereas the control clot exhibited a signal intensity (815 ± 41) similar to that of the adjacent muscle (768 ± 47).

This method was extended to the detection of ruptured plaque in human carotid artery endarterectomy specimens resected from a symptomatic patient (Figure 2.4). Fibrin depositions ('hot spots') were localized to microfissures in the shoulders of the ruptured plaque in the targeted vessel (where fibrin was deposited), but this was not appreciated in the control. Further investigation towards the molecular imaging of small quantities of fibrin in ruptured plaque may someday detect this silent pathology sooner in order to pre-empt stroke or myocardial infarction.

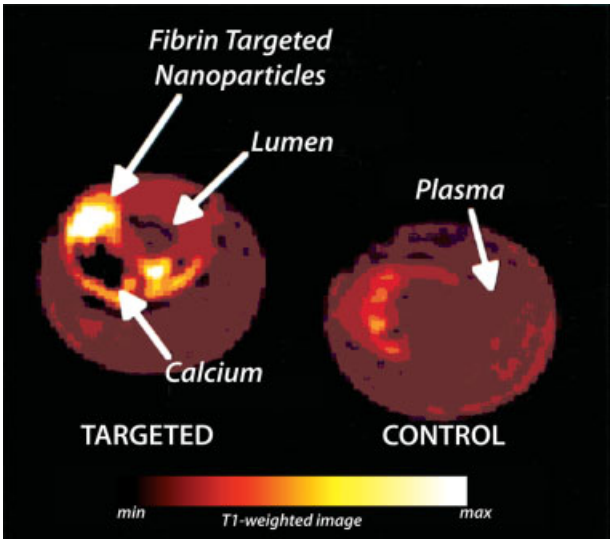

Figure 2.4 Color-enhanced magnetic resonance imaging of fibrin-targeted and control carotid endarterectomy specimens, revealing contrast enhancement (white) of a small fibrin deposit on a symptomatic ruptured plaque. The black area shows a calcium deposit. Three-dimensional, fat-suppressed, T_1-weighted fast gradient echo.

The high fluorine content of fibrin-targeted PFC nanoparticles, as well as the lack of background signal, can also be exploited for ^{19}F MRI and spectroscopy. In a recent study conducted by Morawski *et al.*, several methods were described for quantifying the number of nanoparticles bound to a fibrin clot using the ^{19}F signal [16]. First, fibrin-targeted paramagnetic perfluoro-crown-ether nanoparticles and trichlorofluoromethane ^{19}F spectra were obtained (Figure 2.5a). The relative crown ether signal intensity (with respect to the trichlorofluoromethane peak) from known emulsion volumes provided a calibration curve for nanoparticle quantification (Figure 2.5b). The perfluorocarbon (crown ether) nanoparticles then were mixed in titrated ratios with fibrin-targeted nanoparticles containing safflower oil and bound to plasma clots *in vitro*. As the competing amount of nonsignaling safflower-oil agent was increased, there was a linear decrease in the ^{19}F and Gd^{3+} signal. The number of bound nanoparticles was calculated from the ^{19}F signal and the calibration curve described above, and compared with mass of Gd^{3+} as determined by neutron activation analysis. As expected, there was excellent agreement between measured Gd^{3+} mass and number of bound nanoparticles (calculated from the ^{19}F signal) (Figure 2.5c).

In addition, clots were treated with fibrin-targeted nanoparticles containing either of two distinct PFC cores: crown ether and perfluoro-octyl bromide (PFOB) [33]. These exhibited two distinct ^{19}F spectra at a field strength of 4.7 Tesla, and the signal from the sample was highly related to the ratio of PFOB and crown ether emulsion applied. These findings demonstrated the possibility of simultaneous imaging and quantification of two separate populations of nanoparticles, and hence two distinct biomarkers.

These quantification techniques were applied to the analysis of human carotid endarterectomy samples (see Figure 2.6). An optical image of the carotid reveals extensive plaques, wall thickening and luminal irregularities. Multislice ^{19}F images showed high levels of signal enhancement along the luminal surface due to the binding of targeted paramagnetic nanoparticles to fibrin deposits (not shown in Figure 2.6). The ^{19}F projection images of the artery, taken over approximately 5 min, showed an asymmetric distribution of fibrin-targeted nanoparticles around the vessel wall, corroborating the signal enhancement observed with ^{1}H MRI. Concomitant visualization of ^{1}H and ^{19}F images would permit the visualization of anatomical and pathological information in a single image. In theory, the atherosclerotic plaque burden could be visualized with paramagnetic PFC contrast-enhanced ^{1}H images, while ^{19}F could be used localize identify plaques with high levels of fibrin and thus prone to rupture.

2.3.5
Detection of Angiogenesis and Vascular Injury

As described previously, ligand-directed PFC nanoparticles are well suited to the detection of very sparse biomarkers, such as integrins involved in the process of *angiogenesis* [12, 33, 34]. Although angiogenesis is a critical physiological process in wound healing, inflammation and organ development, it also contributes to the

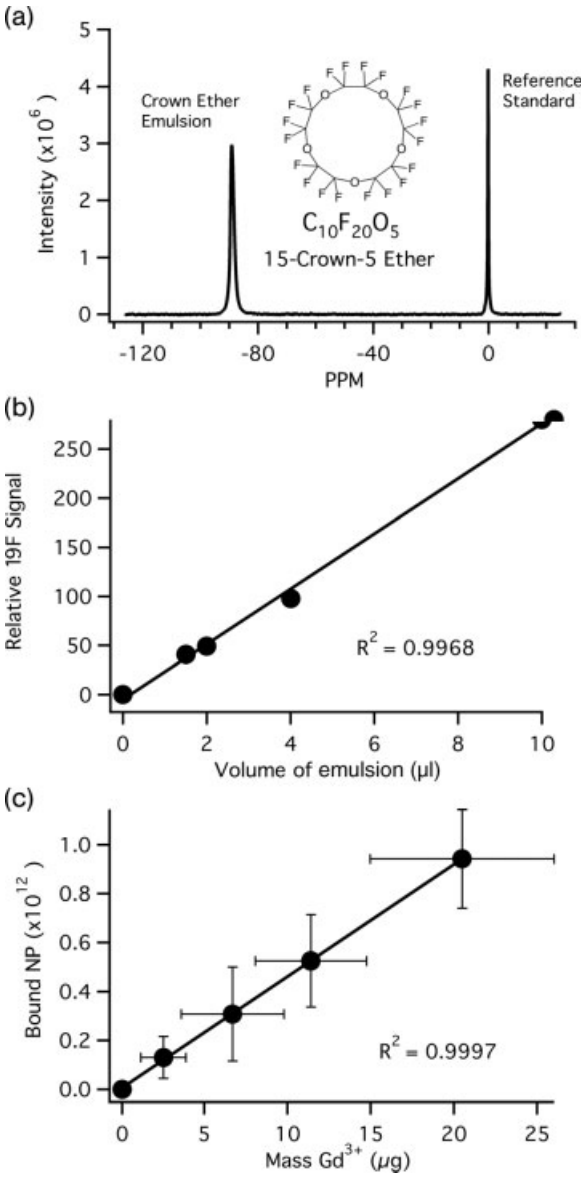

Figure 2.5 (a) Representative spectrum, taken at a field strength of 4.7 T, showing crown ether emulsion (~90 ppm) and trichlorofluoromethane (0 ppm) references; (b) The calibration curve for the crown ether emulsion has a slope of 28.06 with an R^2 of 0.9968; (c) Number of bound nanoparticles (mean ± SE) as calculated from ^{19}F spectroscopy versus the mass of total gadolinium (Gd^{3+}) in the sample as determined by neutron activation analysis, showing excellent agreement as independent measures of fibrin-targeted nanoparticles binding to clots. The linear regression line has an R^2 of 0.9997.

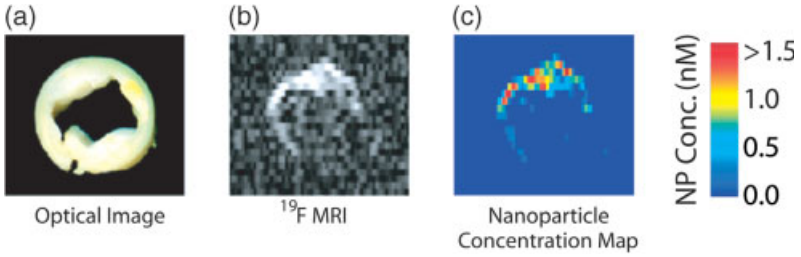

Figure 2.6 (a) Optical image of a 5 mm cross-section of a human carotid endarterectomy sample. The section showed moderate lumenal narrowing, and several atherosclerotic lesions; (b) A ^{19}F projection image acquired at 4.7 T through the entire carotid artery sample, showing a high signal along the lumen due to nanoparticles bound to fibrin; (c) Concentration map of bound nanoparticles in the carotid sample.

pathology of many disease processes such as diabetic retinopathy, rheumatoid arthritis, cancer and atherosclerosis. The process of angiogenesis depends on the adhesive interactions of vascular cells, and the integrin $\alpha_v\beta_3$ has been identified as playing a vital role in angiogenic vascular tissue. The functions of integrin $\alpha_v\beta_3$ includes vascular cell apoptosis (i.e. cell death), smooth muscle cell (SMC) migration and proliferation, and vascular remodeling [35]. The integrin is expressed on the luminal surface of activated endothelial cells, but not on mature quiescent cells. These findings support the fact that the role of $\alpha_v\beta_3$ in pathological conditions characterized by neovascularization may be an important diagnostic and therapeutic target. In fact, the use of a monoclonal antibody against $\alpha_v\beta_3$ has demonstrated an inhibition of angiogenesis, without affecting mature vessels [36]. Although $\alpha_v\beta_3$ integrins are expressed on other mature cells, such as SMCs, tissue macrophages, and on neovascular tissues in gut and developing bone, the PFC-based nanoparticles are too large to escape the normal vasculature and bind in sufficient quantities to create a detectable signal.

Perfluorocarbon nanoparticles have been developed to detect the sparse expression of the $\alpha_v\beta_3$ integrin on the neovasculature, and to deliver anti-angiogenic therapy (Figure 2.7) [37]. This approach has been used to visualize tumor-related angiogenesis in New Zealand White rabbits bearing Vx-2 tumors (<1.0 cm) using a 1.5 Tesla field [38]. MRI signals monitored at 2 h post-injection of $\alpha_v\beta_3$-targeted nanoparticles showed an enhancement of 126%, predominantly in an asymmetrical distribution along the tumor border. These results were consistent with the immunohistochemical staining results. Moreover, *in vivo* competitive blocking with $\alpha_v\beta_3$-targeted nonparamagnetic nanoparticles resulted in a decreased signal enhancement to a level attributable to local extravasation.

In a similar study, athymic nude mice bearing human melanoma tumors (C32, ATCC; 33 mm^3) were injected with $\alpha_v\beta_3$-targeted PFC nanoparticles and imaged at 2 h [39]. MR enhancement was apparent within 30 min and had increased by 173% at 2 h (Figure 2.8). Again, MRI results were correlated with

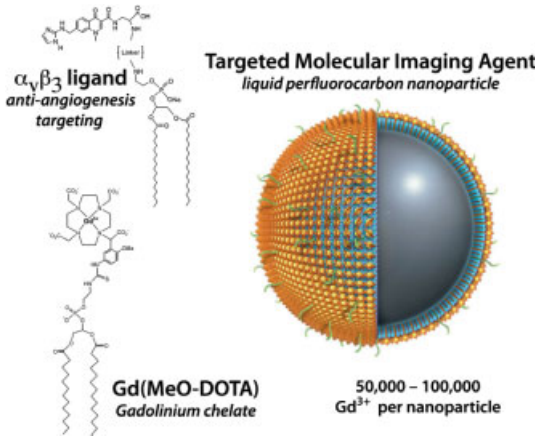

Figure 2.7 Schematic depicting the $\alpha_v\beta_3$ targeting aspect and the Gd^{3+} component that are incorporated into the lipid shell of the liquid perfluorocarbon nanoparticle agent.

histological results. In both studies, *in vivo* competitive blocking with $\alpha_v\beta_3$-targeted nonparamagnetic nanoparticles showed a 50% decrease of signal enhancement. These findings demonstrated the high specificity achievable with $\alpha_v\beta_3$-targeted nanoparticles.

2.4
Perfluorocarbon Nanoparticles as an Ultrasound Contrast Agent

Using the bubbles produced by agitating saline, Gramiak and Shah introduced the concept of an ultrasonic contrast agent in 1968 [40]. Today, commercially available ultrasound contrast agents are based on gas-filled encapsulated microbubbles (average diameter 2–5 μm) that transiently enhance the blood pool signal, which is otherwise weakly echogenic. When insonified by an ultrasound wave, microbubbles improve the gray scale images and Doppler signal via three distinct mechanisms [41–43]. First, at lower acoustic power, microbubbles are highly efficient scatterers due to their large differences in acoustic impedance ($Z = \rho c$, where ρ is the mass density and c is the speed of sound) compared to the surrounding tissue or blood [44]. With increasing acoustic energies, microbubbles begin nonlinear oscillations and emit harmonics of the fundamental (incident) frequency, thus behaving as a source of sound, rather than as a passive reflector [44, 46]. As biological tissue does not display this degree of harmonics, the contrast signal can be exploited to preferentially image microbubbles and improve signal-to-noise ratios (SNRs).

At even higher acoustic power, the destruction of microbubbles occurs allowing the release of free gas bubbles. Although not desirable for most forms of imaging, this results in a strong but transient scattering effect and provides the most sensitive detection of microbubbles. To emphasize these strong echogenic properties, it has been shown that even one microbubble can be detected with medical ultrasound systems [47]. Interestingly, the destruction and cavitation of microbubbles by ultrasound waves have been shown to facilitate drug delivery by 'sonoporating' membranes and allowing drugs and gene therapy to enter the cell [48, 49]. When this process occurs in capillary beds, the permeability increases allowing a subset of particles access to surrounding tissue for further drug deposition [50].

The wide use of microbubbles in everyday clinical applications highlight its effectiveness as a blood pool agent [45]. For example, microbubbles enhance the blood–tissue boundary of the left ventricular cavity, allowing for better diagnostic yield in resting as well as stress echocardiograms [51]. Improved Doppler signals are beneficial in the diagnosis of valvular stenosis and regurgitation [52]. Additionally, microbubbles are removed from the circulation via the macrophage phagocytic system and accumulate in the liver and spleen – that is, passive targeting. This mechanism can be employed for the detection of focal liver lesions and malignancies [48, 53]. When used as targeted contrast agents, microbubbles have been conjugated with ligands for a variety of vascular biomarkers including integrins expressed during angiogenesis, the glycoprotein IIb/IIIa receptor on activated platelets in clots, and L-selectin for the selective enhancement of peripheral lymph nodes, *in vivo* [54–56]. One disadvantage associated with the targeting of microbubbles is the 'tethering' of these particles to a surface. This interaction with a solid structure limits the ability of insonified microbubbles to oscillate, and dampens its echogenicity.

Unlike microbubble formulations that are naturally echogenic, liquid PFC nanoparticles have a weaker inherent acoustic reflectivity, and suspensions of them

have been shown to exhibit backscattering levels 30 dB below that of whole blood [57]. However, when collective deposition occur on the surfaces of tissues or a cell in a layering effect, these particles create a local acoustic impedance mismatch that produces a strong ultrasound signal, without any concomitant increase in the background level [58]. The echogenicity of nanoparticles does not depend upon the generation of harmonics, and therefore is not affected by binding with molecular epitopes. Due to their small size and inherent *in vivo* stability, PFC nanoparticle emulsions have a long circulatory half-life compared to microbubble contrast agents. This is accomplished without modification of their outer lipid surfaces with PEG or the incorporation of polymerized lipids, which may detract from the targeting efficacy. Acquired data have suggested that the PFC nanoparticles remain bound to the tissues for up to 24 h. In additionally, nongaseous PFOB-filled nanoparticles neither easily deform nor cavitate with ultrasound imaging.

The successful detection of cancer *in vivo* depends on a variety of factors when using molecularly targeted contrast agents. The number of epitopes to which the ligand can bind must be sufficient to allow enough of the contrast agent to accumulate for detection, while the ligand specificity must be maintained to ensure that nonspecific binding remains negligible. As stated above, the background signal from unbound, circulating contrast agent is low enough (or even absent) so as to not interfere with the assessment of bound, targeted agent. Previous studies have already demonstrated the use of high-frequency ultrasound in epitope-rich pathologies, such as fibrin in thrombus, where targeted PFC nanoparticles can act as a suitable molecular imaging agent by modifying the acoustic impedance on the surface to which they bind in a configuration that is well-approximated by a reflective layer [59]. However, at lower frequencies and for sparse molecular epitopes, in the typically tortuous vascular bed associated with the advancing front of a growing tumor, the clear delineation between nontargeted normal tissue and angiogenic vessels remains a challenge. The imaging technology itself must be highly sensitive and capable of detecting and/or quantifying the level of contrast agent bound to the pathological tissue. In clinical ultrasonic imaging, the sensitivity of detection depends on a physical difference in the way sound interacts with a surface covered by targeted contrast agent versus one that is not. The data presented below show that, in many cases, the sensitivity of this determination can be improved by applying novel and specific signal-processing techniques based on thermodynamic or information-theoretic analogues.

Site-targeted nanoparticle contrast agents, when bound to the appropriate receptor, must be detected in the presence of bright echoes returned from the surrounding tissue. One approach to the challenge of detecting the acoustic signature of site-specific contrast is through the use of novel signal receivers (i.e. mathematical operations that reduce an entire RF waveform, or a portion of it, to a single number) based on information-theoretic quantities, such as Shannon entropy (H), or its counterpart for continuous signal (H_f). These receivers have been shown to be sensitive to diffuse, low-amplitude features of the signal that often are obscured by noise, or else are lost in large specular echoes and, hence, not usually perceivable by a human observer [60–64].

Although entropy-based techniques have a long history in image processing for image enhancement and the post-processing of reconstructed images, the approach we take is different in that entropy is used directly as the quantity defining the pixel values in the image. Specifically, images are reconstructed by computing the entropy (or a limiting form of it: H_f) of segments of the individual RF A-lines that comprise a typical medical image by applying a 'moving window' or 'box-car' analysis. The computation of an entropy value for each location within an image is therefore possible, and the results can be superimposed over the conventional grayscale image as a parametric map.

2.4.1 Entropy-Based Approach

Radiofrequency data are obtained by sampling a continuous function $y = f(t)$. For an 8-bit digitizer, the sampled waveform is quantized into 256 (2^8) different levels. If we compute the probability, p_k of the k^{th} digitizer value appearing in the digital waveform, then we may compute the Shannon entropy of the resultant probability distribution

$$H - \sum_{k=0}^{255} p_k \log(p_k). \tag{2.7}$$

While this quantity has demonstrated utility for signal characterization [60], it also has the undesirable feature that it depends critically on the attributes of the digitizer used to acquire the data. This dependence may be removed by taking the limit where the sampling rate and dynamic range are taken to infinity [61, 62]. In that case, the probabilities, p_k, are replaced by density function, $wf(y)$, of the signal $f(t)$. While the Shannon entropy H_S becomes infinite in this limit, we may extract a finite portion of it, called H_f, that is also useful for signal characterization.

This well-behaved quantity can be expressed as

$$H_f = \int_{f\min}^{f_{\max}} w_f(y) \log w_f(y) dy. \tag{2.8}$$

This quantity has been shown to be very sensitive to local changes in backscattered ultrasound that arise from the accumulation of targeted nanoparticles in the acoustic field of view [4–6, 57, 65]. In contrast to most methods used to construct medical images, the waveform $f(t)$ does not directly enter the expression used to compute pixel values. Instead, the density function of the waveform is used.

2.4.2 The Density Function $w_f(y)$

The density function $w_f(y)$ corresponds to the density functions that are the primary mathematical objects in statistical signal processing and the description from which other mathematical quantities are subsequently derived (e.g. mean values, variances, covariances) [66–68]. In that setting, the density function constitutes the most

fundamental unit of information that the experimentalist has about a measured variable. It is important to note that the density function $w_f(\gamma)$ may be used to compute not only the entropy H_f but also the signal energy E_f, and hence all conventional energy-based signal analysis may be placed within this same mathematical framework.

Without loss of generality, we may adopt the convention that the domain of $f(t)$ is over the unit interval [0,1], then $w_f(\gamma)$, the density function of $f(t)$, can be defined by the basic integral relationship

$$\int_0^1 \phi(f(t))dt = \int_{f\min}^{f\max} \phi(\gamma)\, w_f(\gamma)d\gamma \tag{2.9}$$

for any continuous function $\phi(\gamma)$. This should be compared with the expression for the expectation value of a function ϕ of a random variable X with density $p_X(x)$, which is given by

$$\int \phi(x)_{p_X}(x)dx,$$

which explains why $w_f(\gamma)$ is referred to as the density function for $f(t)$ [69]. If we chose $\phi(x) = x^2$, then

$$\int_0^1 f(t)^2 dt = \int_{f\min}^{f\max} \gamma^2 w_f(\gamma)d\gamma, \tag{2.10}$$

an expression which represents the signal energy.

Many applications of either probability or information theory to signal processing proceed, usually very early in the discussion, by an *a priori* assumption of a specific underlying density function [70–72]. In contrast, the analysis steps detailed for H_f begin with the measured time-domain waveform data and proceed to calculate the density functions without imposing any additional assumptions.

2.4.3
Ultrasound in a Precancerous Animal Model

The capabilities of entropy-based signal processing for the acoustic detection of nanoparticles targeted to neovasculature has been demonstrated in several animal models [5, 6, 57]. One relevant example was obtained using the transgenic K14-HPV16 mouse [6]. This animal model contains human papilloma virus (HPV)-16 oncoproteins driven by a keratin promoter, so that lesions develop in the skin. Typically, the ears exhibit squamous metaplasia, a precancerous condition, associated with abundant neovasculature that expresses the $\alpha_v\beta_3$ integrin. Eight of these transgenic mice [73, 74] were treated intravenously with 1.0 mg kg^{-1} of either $\alpha_v\beta_3$ integrin-targeted nanoparticles ($n = 4$) or untargeted nanoparticles ($n = 4$), and subsequently imaged subsequently using a research ultrasound system (Vevo 660; Visualsonics, Toronto, Canada). Imaging was accomplished with the mouse ears positioned in the focal zone of a 40 MHz single-element 'wobbler' sector-scan

transducer, with an F-number of 2 (diameter 3 mm, focal length 6 mm). Radio-frequency ultrasonic backscatter waveforms corresponding to a region 80 mm wide × 30 mm deep, were digitized at time points 0, 15, 30 and 60 min after administration of the nanoparticle contrast agent. All of these RF data were processed off-line to reconstruct images using information theoretic (entropy-based) and conventional (energy-based) receivers. Image segmentation was performed automatically using the threshold, which excluded 93% of the area under the composite histogram for all data sets. The mean value of segmented pixels was computed at each time point post injection.

A diagram depicting the placement of transducer, gel standoff and mouse ear is shown in the left side of Figure 2.9, together with a representative B-mode grayscale image (i.e. logarithm of the analytic signal magnitude). The labels indicate the location of the skin (top of image insert), the structural cartilage in the middle of the ear, and a short distance below this, the echo from the skin at the bottom of the ear. To the right of this ultrasound image, is an histological view of a HPV mouse ear that has been magnified 20-fold to permit a better assessment of the thickness and architecture of the sites where the $\alpha_v\beta_3$ integrin-targeted nanoparticle might attach (red by β_3 staining). Both, the skin and tumor are both visible in the image. On either side of the cartilage (center band in image), extending to the dermal–epidermal junction, is the stroma, which is filled with neoangiogenic microvessels. These microvessels are also decorated with targeted $\alpha_v\beta_3$ nanoparticles, as indicated by the fluorescent image (labeled, upper right of Figure 2.9) of a bisected ear from an $\alpha_v\beta_3$-injected K14-HPV16 transgenic mouse. It is in this region that the $\alpha_v\beta_3$-targeted nanoparticles are expected to accumulate, as indicated by the presence of red β_3 stain in the magnified image of an immunohistological specimen also shown in the image.

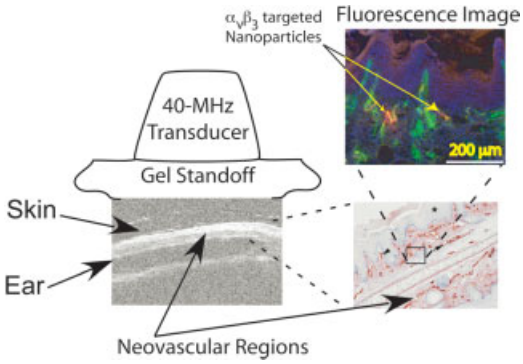

Figure 2.9 Close-up of transducer, standoff and B-mode image of ear, with an enlarged histological view showing the location of the binding sites, and a fluorescent image from the same anatomical region. This shows that the $\alpha_v\beta_3$-targeted nanoparticles accumulate in this portion of the mouse ear.

2.4.3.1 Image Analysis

For this study, in which the same portion of the anatomy was imaged at successive intervals, the objective was to quantify changes in image features as a function of time. The first step in this process was the creation of a composite image from the images obtained at 0 through 60 min. Next, an estimate of the probability density function (PDF) of this composite image was computed by normalizing the pixel value histogram to have unit area. It must be emphasized that this function is not related to the density functions $w_f(\gamma)$ as were defined in Equation (2.8). Rather, it is a calculational device used to objectively segment H_f and $\log[E_f]$ images into 'enhanced' and 'unenhanced' regions. A typical histogram is shown in Figure 2.10. The first, larger maxima, corresponds to the relatively homogeneous gray background visible in most H_f images, while the smaller peak corresponds to tissue interfaces, which appear also as bright features in grayscale B-mode images, such as that shown in the inset of Figure 2.9 [76].

Several different methods of image segmentation based on the PDF were investigated. In all of these a specific value, or threshold, in the histogram was chosen and the images divided into two regions: (i) those having pixel values above the threshold (considered to be unenhanced); and (ii) those having pixel values below (referred to subsequently as enhanced pixels). The PDF of all composite images exhibited a two- peak structure with a large and small peak. Thresholds were set at the second minimum, and at the half-way point between the large and small peaks. The full width at half maximum (FWHM) was also computed, and thresholds set at: 4.5, 3.5, 3.25, 3, 2.75 and 2.5 FWHM below the large peak. Thresholds were also set at points such that 97, 95, 93, 90, 87 and 80% of the pixel values were above the threshold. After selection of a threshold value, regions of interest (ROI) were

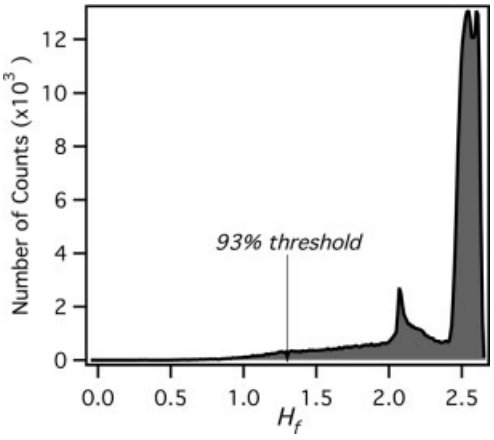

Figure 2.10 A histogram from the composite H_f images acquired at 0, 15, 30, 45 and 60 min post injection. The histogram has two peaks; these have been characteristically observed in several studies using different equipment and animal models. The 93% threshold level used is indicated by the arrow.

selected using NIH ImageJ (http://rsb.info.nih.gov/ij/), and the mean value of the pixels lying below the threshold were computed for each of the images acquired at 0, 15, 30, 45 and 60 min post injection. The mean value at zero minutes was subtracted from the values obtained for all subsequent times, to obtain a sequence of changes in receiver output as a function of time post injection. This was done for all four animals injected with targeted nanoparticles, and also for the four control animals. The sequences of relative changes were then averaged over the targeted and control groups to obtain a sequence of time points for change in receiver output for both groups of animals. The threshold of 93% was finally chosen as it produced the smallest *p*-value (0.00 043) for a *t*-test comparing the mean values of the ROI at 15 min as compared to 60 min. The corresponding *p*-value for the control group was 0.27.

The average change, with time after injection, of the mean value of the enhanced regions of H_f images obtained from all eight of the animals reported in the study are compared in Figure 2.11a [6]. As these data show, the mean value, or enhancements, obtained in the targeted group increased steadily with time. After 30 min the mean

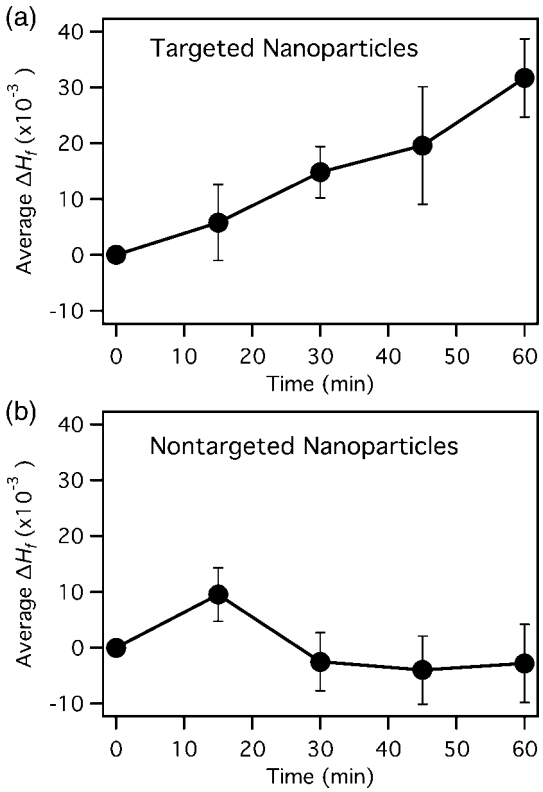

Figure 2.11 Plots of average enhancement obtained by analysis of H_f images from (a) four HPV mice injected with $\alpha_v\beta_3$-targeted nanoparticles, and (b) four HPV mice injected with nontargeted nanoparticles.

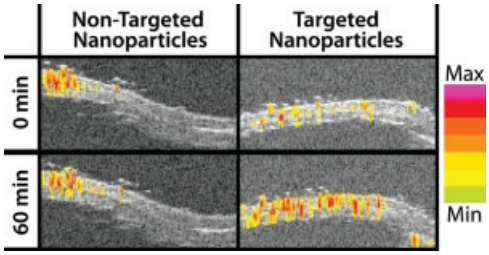

Figure 2.12 Cropped images of transverse cross-sections of HPV mouse ear showing of H_f-enhanced conventional images comparing the effects of targeting (right column) versus nontargeted (left column) both at 0 min (top row) and 60 min (bottom row) after injection.

value of enhancement was measurably different from baseline values ($p < 0.005$). Moreover, the values at 15 and 60 min were also statistically different ($p < 0.005$). The corresponding results obtained from control animals that were injected with nontargeted nanoparticles are shown in Figure 2.11b. There was no discernible trend in the group, and the last three time points were not statistically different from zero. A comparison of the enhancement measured at 15 and 60 min yielded a p-value ≈ 0.27. The enhancement in H_f observed after 60 min for representative instances of targeted and nontargeted nanoparticles is shown in Figure 2.12. These images were generated by overlaying a 93% thresholded version of the H_f using a look-up table (LUT) on top of the conventional grayscale B-mode image.

For comparison, and to illustrate the potential value of the entropy-based analysis, the corresponding results obtained using the $\log[E_f]$ analysis are shown in Figure 2.13a for same data used to generate Figure 2.11. These data were obtained by computing the mean value of pixels lying below the 93% threshold at each time point (0, 15, 30, 45 and 60 min) for each animal (four injected with targeted nanoparticles, and four with nontargeted nanoparticles), as discussed above. Unlike the entropy case, the values at 15 and 60 min were not statistically different ($p = 0.10$). Figure 2.13b shows the corresponding result obtained from the control group of animals that were injected with nontargeted nanoparticles. There was no discernible trend in the group, and the last three time points were not statistically different from zero.

2.4.4
Targeting of MDA-435 Tumors

In a separate investigation, nascent MDA 435 tumors implanted in athymic nude mice reproducibly stimulated neovascular growth and the expresses ion of $\alpha_v\beta_3$ integrin [75]. Human MDA 435 cancer cells were implanted, by injection, in the left hindquarters of athymic nude mice between 10 and 22 days prior to acquisition of the data. Figure 2.14 shows an immunohistologically stained (β_3 staining) section of an excised MDA 435 tumor. β_3 expression, a marker for $\alpha_v\beta_3$-integrin, was found in

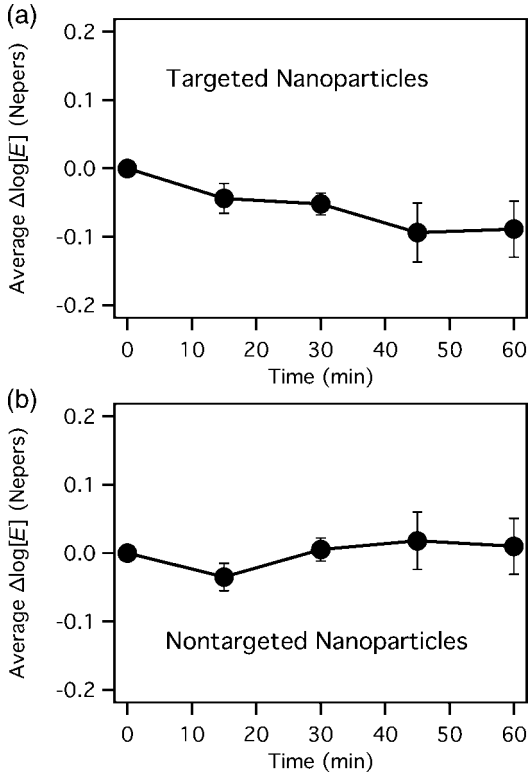

Figure 2.13 Plots of average enhancement obtained by analysis of log [E_f] images from (a) four HPV mice injected with $\alpha_v\beta_3$-targeted nanoparticles and (b) four control HPV mice given nontargeted nanoparticles.

abundance (red regions), although not exclusively, between the skin and the tumor capsule. The close proximity of these binding sites to the skin–transducer interface is one of the primary obstacles that must be overcome by any quantitative detection scheme intended to determine the extent of this region. Accordingly, the acoustic portion of the experiment was designed to maximize system sensitivity near this interface. This was carried out in order to maximize the opportunity to detect nanoparticles targeted towards angiogenic neovasculature. It also provided a stringent test of the H_f entropy-based metric's ability to separate signals near the confounding skin–tissue interface, which was one of the primary goals of this study.

Nine animals were injected with targeted nanoparticles, and seven with nontargeted nanoparticles to serve as controls. Each mouse was preanesthesitized with ketamine, after which an intravenous catheter was inserted into the right jugular vein to permit the injection of nanoparticles (either $\alpha_v\beta_3$-targeted or untargeted). The mouse was then placed on a heated platform maintained at 37 °C, and anesthesia administered continually with isoflurane gas through a nose cone.

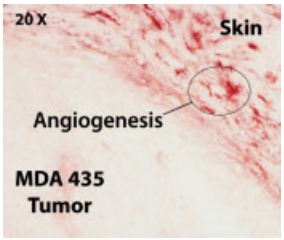

Figure 2.14 A histological specimen extracted from a MDA 435 mouse model, magnified 20-fold, to permit a better assessment of the thickness and architecture of the sites (red by β_3 staining) where $\alpha_v\beta_3$-targeted nanoparticle might attach. The skin and tumor are both visible in the image. The close proximity of neovasculature to the skin–transducer interface is one of the primary obstacles that must be overcome by any quantitative detection scheme intended to determine the extent of this region.

Subsequently, the mouse was injected with 0.030 ml of nanoparticle emulsion (equivalent to a whole-body dose of 1 mg kg^{-1} body mass). Ultrasound data were then acquired at 0, 15, 30, 60 and 120 min intervals.

No evidence of change was observed between the zero-minute and 120-min conventional grayscale B-mode images, while there was a slight (but nonsignificant) change with the color LUT (Figure 2.15). The lower part of Figure 2.15 shows images reconstructed from the same raw RF data, again, with a grayscale LUT in the top row and color LUT in the bottom row. Significant changes in the size of the brightest (red) region, located between the skin–tumor capsule boundary, were observed as expected. Unlike the conventional B-mode processing case, here the H_f processed data showed the region to comprise pixel values far brighter than the mean pixel value that occurred in the rest of the image.

A loss of spatial resolution between skin and tumor capsule was also observable in the image, as expected; this resulted from the smoothing effect of the moving window analysis. In view of this smoothing, which tends to reduce the variations in magnitude of a function, it was somewhat surprising that the image showed a greater separation between the background and enhanced regions. From the images, it could also be seen that the magnitude of values in the region between the skin and the tumor boundary increased with post-injection time. Moreover, the shape and location of the regions were consistent with a brightening effect due to an accumulation of nanoparticles in the angiogenic neovasculature [77, 78].

The data in Figure 2.16 compare the change in mean value of the 3% thresholded region (i.e. enhancement) for the B-mode images (logarithm of signal envelope) as a function of time post injection for controls versus targeted. The plots show that the conventional B-mode images cannot be used to distinguish between 0 and 120 min post injection.

Corresponding results, obtained using entropy imaging, are shown in Figure 2.17, using the same vertical and horizontal scales as in Figure 2.16, for ease of comparison. The plots show that only the entropy-based receiver was able to distinguish between 0 and 120 min post injection (paired t-test produces $p < 0.05$). Moreover,

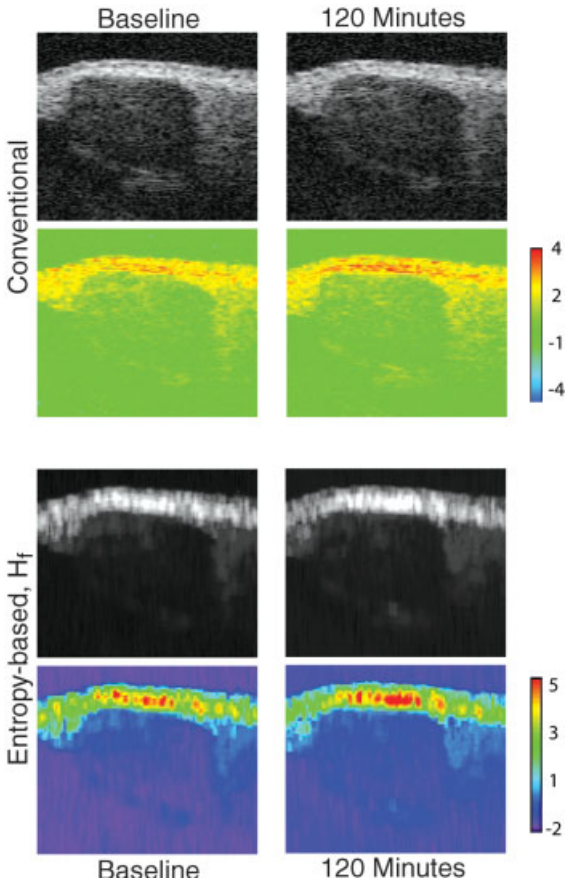

Figure 2.15 A comparison of 0-min and 120-min (post-injection) images obtained from conventional energy-based signal processing (upper part of figure) and the entropy-based H_f metrics (lower part of figure). Grayscale images of before and after data are presented for both types of signal processing. No change is evident in the B-mode images, and at most there is a slight change in the images. However, the application of a color look-up table (LUT) to the images revealed more detail. The same color LUT mapping was applied to both B-mode images to facilitate comparisons. The calibration bar of the mapping is shown to the right of the images in both cases. The images show a greater change with time and a greater separation of the neovascular region from the rest of the image than the B-mode images. Replication of this experiment in nine animals showed the change to be statistically significant only for the H_f-processed images.

the mean values increased in an approximately linear fashion versus time. The plot of control experiments showed there was no significant change in enhancement with time in these animals. However, a careful visual inspection of the image sequence revealed measurable changes in tumor shape and position that most likely were induced by respiration and relaxation of the animal over the 2-h experiment.

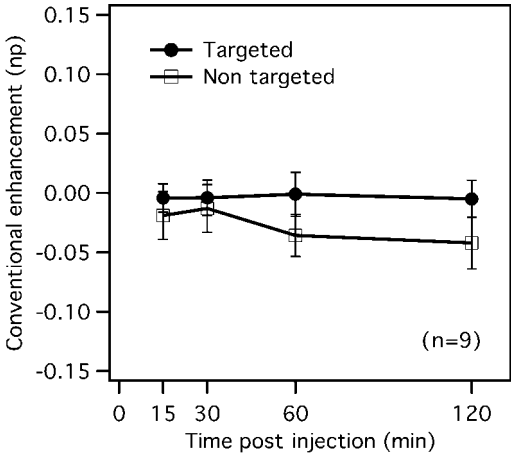

Figure 2.16 Quantitative comparison of enhancement and B-mode images obtained using targeted nanoparticles. No significant changes were observed with either untargeted or targeted nanoparticles. All plots have vertical units of nepers, as the image analysis was performed on noise-scaled or normalized images (which are unitless). As explained in the text, this does not alter the quantitative conclusion presented in these plots.

2.4.5
In Vivo Tumor Imaging at Clinical Frequencies

A separate ultrasound study utilizing targeted nanoparticles was designed to assess the feasibility of image-based angiogenic neovasculature using backscattered

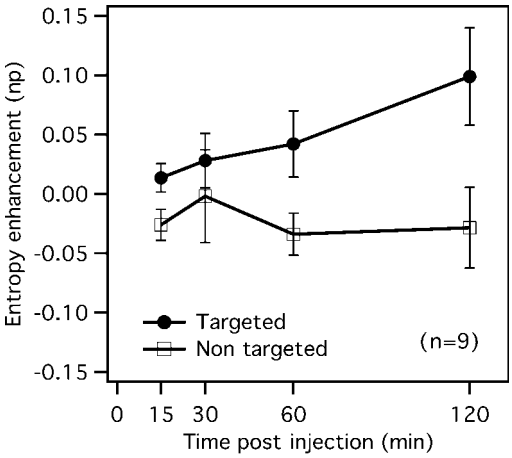

Figure 2.17 Quantitative comparison of enhancement for a thermodynamic receiver (H_f) obtained using targeted and untargeted nanoparticles. Only the targeted nanoparticles produced a significant change in enhancement ($p < 0.05$).

ultrasound in the frequency range between 7 and 15 MHz [79]. These investigators employed a liquid–PFC nanoparticle conjugation of an $\alpha_v\beta_3$ peptidomimetic to target the expression of $\alpha_v\beta_3$ in Vx-2 tumors implanted in the hindquarters of New Zealand White rabbits ($n = 9$). Anesthesia was administered continually with isoflurane gas, the model was injected with a whole-body dose of 0.66 ml kg^{-1} of nanoparticle emulsion, after which the ultrasound data were acquired at 0, 15, 30, 60 and 120 min. Six control rabbits were also imaged using the same methodology, but were not injected with nanoparticles. Beam-formed RF data were acquired using a modified research version of a clinical ultrasound system (Philips HDI-5000). Data were analyzed for all rabbits at all times post injection, using three different techniques: (i) conventional grayscale; (ii) H_f (an entropy-based quantity); and (iii) $\log[E_f]$ (i.e. the logarithm of the signal energy, E_f). Representative image data are shown in Figure 2.18, depicting the tumor in cross-section. A paired t-test comparing H_f image enhancement obtained at 0 and 120 min for the rabbits injected with targeted nanoparticles indicated a significant difference ($p < 0.005$). For control rabbits there was no significant difference between 0 and 120 min ($p = 0.54$). Conventional grayscale imaging at the fundamental frequency and $\log[E_f]$ imaging failed to detect a coherent signal, and did not show any systematic pattern of signal change.

2.5
Contact-Facilitated Drug Delivery and Radiation Forces

2.5.1
Primary and Secondary Radiation Forces

Acoustic radiation force is a phenomenon associated with the propagation of acoustic waves through a dissipative medium. It is caused by a transfer of momentum from the wave to the medium, arising either from absorption or reflection of the wave [80, 81]. For particles suspended in a liquid medium, these forces manifest themselves in two ways. The first way, which is referred to as the *primary radiation force*, tends to accelerate the suspended particles away from the source. The second way, referred to as the *secondary force*, is an interparticle force that can be completely attractive, if the particles lie in contours perpendicular to the incident field and can be completely repulsive if the particles are oriented parallel to the incident field. One very useful form for these primary and interparticle (secondary) forces is given by [82]

$$F_{\text{primary}} = \frac{V_0 P_A^2}{4\rho_0 c_0^2} k \sin(2k) f\left(\frac{\rho}{\rho_0}\right) \tag{2.11}$$

where

$$f\left(\frac{\rho}{\rho_0}\right) = \frac{\rho_0 c_0^2}{\rho c^2} - \frac{5\rho - 2\rho_0}{3\rho + \rho_0}, \tag{2.12}$$

Here, V_0 is the sphere volume, P_A is the acoustic pressure amplitude, ρ and ρ_0 are the sphere and fluid densities, respectively, and c and c_0 are the sound velocity in the

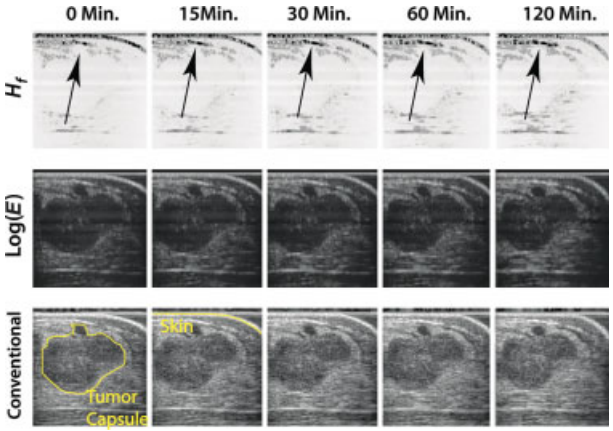

Figure 2.18 Images produced from beam-formed RF acquired from a rabbit injected with $\alpha_v\beta_3$-targeted nanoparticles. The three rows show composite images formed by the application of three different signal processing techniques: H_f, log[E_f] signal receiver (both applied with a moving window), and conventional image processing. Each composite image is comprised of five sub-images reconstructed from beam-formed RF acquired at 0, 15, 30, 60 and 120 min post injection, as indicated by the labels. Only the H_f composite image showed any evidence of change after injection (black arrows).

sphere and fluid, respectively. The interparticle force given by

$$F_{i.p.} = \xi r^{-4} f(\theta) \tag{2.13}$$

where

$$\xi = \frac{2\pi}{3}\frac{(\rho - \rho_0)^2}{\rho_0} a^3 b^3 u_0^2, \tag{2.14}$$

and a, b are the sphere radii, r is their separation distance, and u_0 is the velocity amplitude of the suspending medium.

The action of these forces *in vivo* is to concentrate the suspended nanoparticles and push them away from the acoustic source (i.e. away from the center of arterial flow and onto the capillary wall), as shown in Figure 2.19. This effect increases the potential to increase their therapeutic efficacy.

2.5.2 *In Vitro* Results

Besides detecting sparse epitopes for noninvasive imaging, PFC nanoparticles are capable of specifically and locally delivering drugs and other therapeutic agents through a novel process known as *contact-facilitated drug delivery* [12]. The direct transfer of lipids and drugs from the nanoparticles' surfactant layer to the cell membrane of the targeted cell is usually a slow and inefficient process. However, through ligand-directed targeting this process can be accelerated by minimizing the separation of the lipids and surfaces, and increasing the frequency and duration

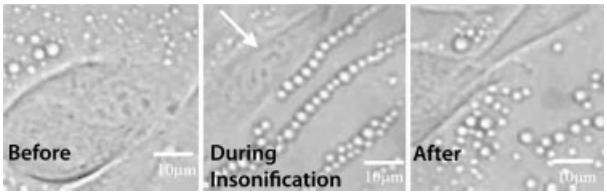

Figure 2.19 Still images of C32 melanoma cells with nanoparticles before, during and after insonification. These show primary and secondary radiation forces acting on the perfluorocarbon nanoparticles. The direction of acoustic insonification, as indicated by the arrow in the center panel, is the same in all three cases. Left panel: pre-insonification; the particles are arranged randomly. Center panel: during insonification, the particles line up on an axis perpendicular to the direction of insonification and move away from the source. Right panel: after insonification, the particle configuration is re-randomized by Brownian motion. During ultrasound exposure, the alignment of nanoparticles relative to the acoustic field (arrow) demonstrates conclusively that acoustic radiation forces (primary and secondary) influence the nanoparticles. This mechanism was observed to be a reversible and safe process; after ultrasound treatment the nanoparticles were no longer aligned, but had been neither destroyed nor altered.

of the lipid–surface interactions (see Figures 2.20 and 2.21). Spatial localization (via high-resolution ^{19}F-enhanced MRI) and quantification of the nanoparticles (via ^{19}F spectroscopy) permits the local therapeutic concentrations to be estimated. Thus, PFC nanoparticles can be used for detection, therapy and treatment monitoring.

As an example, *in vitro* vascular smooth muscle cells were treated with tissue factor-targeted PFC nanoparticles containing 0, 0.2 or 2.0 mol% doxorubicin or paclitaxel, or an equivalent amount of drug in buffer solution alone [83]. After targeting for only for 30 min, proliferation was inhibited for three days, while *in vitro* dissolution studies revealed that the nanoparticles' drug release persisted for more than one week. High-resolution MRI with a 4.7 Tesla field strength showed that the image intensity of the targeted vascular smooth muscle cells was twofold higher compared to nontargeted cells. In addition, the fluorine signal amplitude at 4.7 Tesla was unaffected by the presence of surface gadolinium, and was linearly

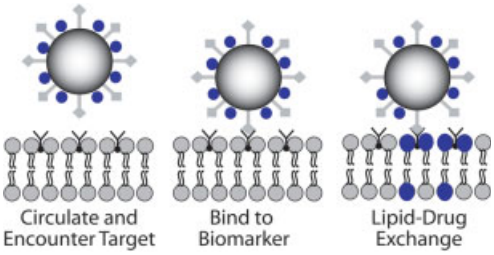

Figure 2.20 Schematic representation illustrating contact-facilitated drug delivery. The phospholipids and drugs within the nanoparticles surface-exchange with the lipids of the target membrane through a convection process, rather than diffusion, as is common among other targeted systems.

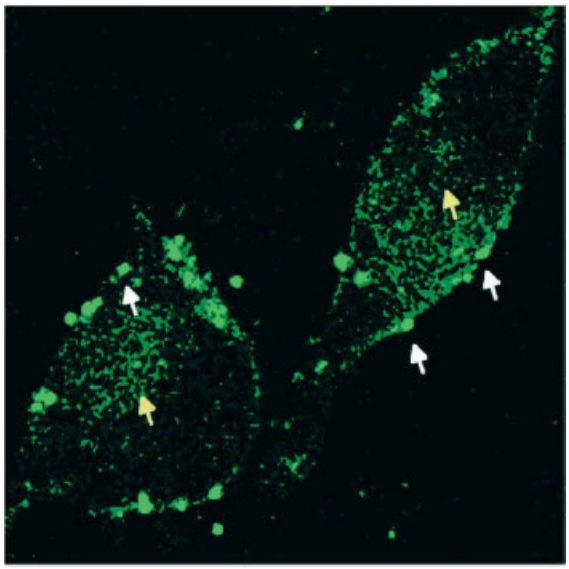

Figure 2.21 *In vitro* targeting of fluoroscein isothiocyanate (FITC)-labeled nanoparticles (white arrows) targeted to $\alpha_v\beta_3$ integrin expressed by C-32 melanoma cells. This illustrates the delivery of FITC-labeled surfactant lipids into target cell membranes (yellow arrows).

correlated to the PFC concentrations which, by direct inference could be related to the nanoparticles' number.

2.6 Conclusions

Targeted liquid PFC nanoparticles represent an extremely versatile platform which has been successfully employed in conjunction with ultrasound, single positron-emission tomography and MRI. These nanoparticles are capable of aiding in the detection of sparse biomarkers, such as integrins in angiogenesis, as well as high-density epitopes such as fibrin. They are unique in that they can be used to diagnose, treat and monitory therapy in a one-step process. Hence, their ongoing and future impact in the fields of cardiology and oncology are predicted to be substantial.

The field of engineered contrast agents continues to grow steadily and advance in line with the rapid developments in nanotechnology. At research centers worldwide, multidisciplinary teams have been assembled which combine expertise in the areas of physics, chemistry, biology, engineering and medicine, to focus on the challenges of creating this next generation of agents. Today, this field is progressing along a path that embraces the prediction summarized within the oft-quoted title of Richard Feynman's presentation, on the world of the nano-scale, to the American Physical Society on December 29th 1959: "There's plenty of room at the bottom."

The potential for significant contributions to paradigms of patient care have been reinforced in recent years via specific funding mechanisms from granting agencies, such as the US National Institutes of Health (NIH) initiatives creating the Programs of Excellence in Nanotechnology (NHLBI-PEN) and the Centers of Cancer Nanotechnology Excellence (NCI-CCNE). Currently, a number of agents are moving towards clinical trials under this aegis. In order to gain acceptance, the approval process by the US Food and Drug Administration is typically on the order of four to eight years for imaging agents (slightly longer for therapeutics). At the time of this writing, some agents have already advanced to Phase 1 and 2 clinical trials, and several new biotechnology start-up companies have also been launched that are devoted to the same goal.

3
Nanoparticles for Cancer Detection and Therapy

Biana Godin, Rita E. Serda, Jason Sakamoto, Paolo Decuzzi, and Mauro Ferrari

3.1
Introduction

3.1.1
Cancer Physiology and Associated Biological Barriers

Cancer is a major public health problem in developed countries, accounting for nearly one-fourth of deaths in the United States, exceeded only by heart diseases. According to a 2008 report by the American Cancer Society, estimated numbers for US cancer cases are 745 and 692 thousands for men and women, respectively [1, 2], with the lifetime probability of developing cancer higher in men (45%) than in women (38%). *Cancer* is a general term used to define any disease characterized by the uncontrolled proliferation of abnormal cells. Due to a widely used generalization of the condition, it is easy to overlook the fact that cancer is not a single disease, but rather a conglomerate of many diseases. During the past five decades, the complexity of cancer has been rendered more tangible by a large body of knowledge accumulated on the common principles of pathogenesis. It is now clear that cancer is a complex ailment caused by accumulation of multiple molecular alterations in the genetic material.

The disease can be divided into two broad categories of hematological malignancies (which affect circulating cells) and solid tumors. Solid tumors can be considered as an organ, and are divisible into three main subcompartments: vascular; interstitial; and cellular [3, 4]. Each of these subcompartments accounts for several biological barriers (or 'biobarriers') that a therapeutic agent should bypass to treat the disease effectively [5, 6]. Later in this section, we will describe the tumor compartments as well as related and other intrinsic 'biobarriers', which severely impede the localization of chemicals, biomolecules and particulate systems at their intended site of action. Biobarriers are sequential in nature, and therefore the probability of an active agent of reaching its therapeutic goal is the interrelated result of the individual probabilities of overcoming each one of the challenges it faces [7, 8].

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

The *tumor vasculature* is extremely heterogeneous, with necrotic and hemorrhagic areas neighboring regions with a dense vascular network formed as a result of angiogenesis triggered to sustain a sufficient supply of oxygen and nutrients necessary for tumor growth and progression [5, 9]. Tumor blood vessels are architecturally and structurally different from their normal counterparts. The vascular networks that are formed in response to tumor growth are not organized into definitive venules, arterioles and capillaries – as for the normal circulation – but rather share chaotic features of all of them. Furthermore, the blood flow in tumor vessels is irregular, sluggish, and sometimes oscillating. Angiogenic vessels possess several abnormal features such as a comparatively high percentage of proliferating endothelial cells, an insufficient number of pericytes, an enhanced tortuosity, and the formation of an atypical basal membrane. As a result, tumor vasculature is more permeable, with the pore cut-off size ranging from 380 to 780 nm in different tumor models [10, 11]. The hemoglobin in the erythrocytes is 'oxygen-starved', which makes the microenvironment profoundly hypoxic. The tumor environment is also nutrient-deficient (e.g. glucose), acidic (owing to lactate production from anaerobic glycolysis), and under oxidative stress [3, 9]. Although the molecular controls of the above abnormalities are not fully elucidated, these may be attributed to the imbalanced expression and function of angiogenic factors. Various mediators can affect angiogenesis as well as vascular permeability. Among these are vascular endothelial growth factor (VEGF), nitric oxide, prostaglandins and bradykinin. Macromolecules can traverse through neoplastic vessels using one of the following pathways: vasculature fenestrations; interendothelial junctions; transendothelial channels (open gaps); and vesicular vacuolar organelles [9]. The tumor vasculature, in being formed *de novo* during the angiogenic process, possesses a number of characteristic markers which are not seen on the surface of normal blood vessels, and can serve as therapeutic targets (these will be discussed later).

The *interstitial compartment* of solid tumors is mainly composed of a collagen and elastic fiber, crosslinked structure. Interstitial fluid and high-molecular-weight gelling constituents, such as hyaluronate and proteoglycans, are interdispersed within the above network. The characteristic feature of the interstitium, which distinguishes it from the majority of normal tissues, is the intrinsic high pressure resulting from the absence of an anatomically well-defined and operating lymphatic network, as well as an apparent convective interstitial fluid flow. These parameters present additional biobarriers towards the penetration of a therapeutic agent into the cancer cells, as the transport of an anticancer molecule or nanovector in this tumor subcompartment will be governed by physiological (pressure) and physico-chemical (charge, lipophilicity, composition, structure) properties of the interstitium and the agent itself [4, 5].

The *cellular subcompartment* accounts for the actual cancerous cell mass. The barriers directly related to the cellular compartment are generally categorized in terms of alterations in the biochemical mechanisms within the malignant cells making them resistant to anticancer medications. Among these biochemical shifts

are the P-glycoprotein efflux system, which is responsible for multidrug resistance and the impaired structure of specific enzymes (i.e. topoisomerase). Moreover, in order to efficiently treat the disease, a cytotoxic agent should be able to cross the cytoplasmic and nuclear membranes – a far from trivial deed for basic drugs that are ionizable within an acidic tumor environment [12, 13].

As mentioned above, following their administration, therapeutic agents encounter a multiplicity of biological barriers that adversely impact their ability to reach the intended target at the desired concentrations [5–8, 14]. This problem is considerably decoupled from the ability of agents to recognize and selectively bind to the target, that is, by the use of antibodies, aptamers or ligands. In other words, despite their high specificity these agents invariably present with concentrations at target sites that are vastly inferior to what is expected on the basis of molecular recognition alone. The biodistribution profiles for conventional chemotherapeutic agents are evenly adverse, if not worse, leading to a plethora of unwanted toxicities and collateral effects at the expense of the therapeutic action (i.e. a decreased 'therapeutic index'). The reticuloendothelial system (RES), which comprises immune cells and organs such as the liver and spleen, presents an important physiological biobarrier, causing an efficient clearance of the agent from the bloodstream. Other barriers of epithelial and endothelial nature, for example the blood–brain barrier, are based on tight-junctions, which significantly limit the paracellular transport of agents that owe their molecular discrimination to several mechanisms and proteins (occludin, claudin, desmosomes, zonula occludens).

To summarize, some of the most challenging biobarriers as the main cause for tumor resistance to therapeutic intervention, include physiological noncellular and cellular barriers, such as the RES, epithelial/endothelial membranes and drug extrusion mechanisms, and biophysical barriers, which include interstitial pressure gradients, transport across the extracellular matrix (ECM), and the expression and density of specific tumor receptors.

3.1.2
Currently Used Anticancer Agents

Since the pathology of cancer involves the dysregulation of endogenous and frequently essential cellular processes, the treatment of malignancies is extremely challenging. The vast majority of presently used therapeutics utilize the fact that cancer cells replicate faster than most healthy cells. Thus, most of these agents do not differentiate greatly between normal and tumor cells, thereby causing systemic toxicity and adverse side effects. More selective agents – which include monoclonal antibodies and anti-angiogenic agents – are now available, and the efficiency of these medications is still under evaluation in various types of tumor. Since cancer arising from certain tissues – including the mammary and prostate glands – may be inhibited or stimulated by appropriate changes in hormone balance, several malignancies may also respond to hormonal therapy. Various groups of anticancer therapeutics are exemplified below.

3.1.2.1 Chemotherapy

Chemotherapy, or the use of chemical agents to destroy cancer cells, is a mainstay in the treatment of malignancies. The modern era of cancer chemotherapy was launched during the 1940s, with the discovery by Louis S. Goodman and Alfred Gilman of nitrogen mustard, a chemical warfare agent, as an effective treatment for blood malignancies [15, 16].

Through a variety of mechanisms, chemotherapy affects cell division, DNA synthesis, or induces apoptosis. Consequently, more aggressive tumors with high growth fractions are more sensitive to chemotherapy, as a larger proportion of the targeted cells are undergoing cell division at any one time. A chemotherapy agent may function in only one phase (G_1, S, G_2 and M) of the cell cycle (when it is called cell cycle-specific), or be active in all phases (cell cycle-nonspecific). The majority of chemotherapeutic drugs can be categorized as alkylating agents (e.g. cisplatin, carboplatin, mechlorethamine, cyclophosphamide, chlorambucil), antimetabolites (e.g. azathioprine, mercaptopurine), anthracyclines (daunorubicin, doxorubicin, epirubicin, idarubicin, valrubicin), plant alkaloids (vinca alkaloids and taxanes) and topoisomerase inhibitors (irinotecan, topotecan, amsacrine, etoposide) [17–19].
