The lack of any great selectivity by chemotherapeutic agents between cancer and normal cells is apparent when considering the adverse effect profiles of most chemotherapy drugs [18, 19]. Hair follicles, skin and the cells that line the gastrointestinal tract are some of the fastest growing cells in the human body, and therefore are most sensitive to the effects of chemotherapy. It is for this reason that patients may experience hair loss, rashes and diarrhea, respectively. As these agents do not possess favorable pharmacokinetic profiles to localize specifically into the tumor tissue, they become evenly distributed throughout the body, with resultant adverse side effects and other toxic reactions that greatly limit their dosage.

3.1.2.2 Anti-Angiogenic Therapeutics

The publication of Judah Folkman's imaginative hypothesis in 1971 launched the current research area of anti-angiogenic therapy for cancer [20], although more than three decades elapsed before the Food and Drug Administration (FDA) approved the first anti-angiogenic drug, bevacizumab (a humanized monoclonal antibody directed against VEGF) [21, 22]. The first clinical trials with this agent, when used in combination with standard chemotherapy, resulted in an enhanced survival of metastatic colorectal cancer and advanced non-small-cell lung cancers [23, 24]. Another group of anti-angiogenic therapeutics, also approved by the FDA, is based on small-molecule receptor tyrosine kinase inhibitors (RTKIs) which target VEGF receptors, platelet-derived growth factor (PDGF) and other tyrosine kinase-dependent receptors [25]. Examples of agents in this group are sorafenib and sunitinib; these orally administered medications have been shown to be effective in the treatment of metastatic renal cell cancer and hepatocellular carcinoma, when used as monotherapy [26–28]. When used as monotherapy, the survival benefits of these treatments are relatively modest (usually measured in months). Additionally, the treatments are also costly [29] and have toxic side effects [30–34].

3.1.2.3 Immunotherapy

While tumor cells are ultimately derived from normal progenitor cells, transformation to a malignant phenotype is often accompanied by changes in antigenicity. Antibodies are amazingly selective, possessing the natural ability to produce a cytotoxic effect on target cells. The immune system was first appreciated over 50 years ago for its ability to recognize malignant cells and defend against cancer, when Pressman and Korngold [35] showed that antibodies could distinguish efficiently between normal and tumor tissues. These results were confirmed by Burnet [36] during the 1960s, who also showed that neoplasms are actually formed only when lymphocytes lose the capability of differentiating between normal and malignant cells. These studies grounded the foundation for modern monoclonal antibody (mAb) -based cancer therapy. The expression of tumor-associated antigens can arise due to a variety of mechanisms, including alterations in glycosylation patterns [37], the expression of virally encoded genes [38], chromosomal translocations [39], or an overexpression of cellular oncogenes [40, 41]. The first challenge in the development of efficient mAb-based therapeutics is the detection of an appropriate and specific tumor-associated antigen. Some examples of mAbs used for cancer therapy are given below.

Hematologic malignancies, which possess fewer barriers capable of preventing mAbs from accessing their target antigens, are well suited for mAb therapy. Following intravenous injection and distribution throughout the vascular space, therapeutic antibodies may easily access their targets on the surface of blood malignant cells. Many of these B- and T-cell surface antigens, such as CD20, CD22, CD25, CD33 or CD52, are expressed only on a particular family of hematopoietic cells [42, 43]. These antigens are also expressed at high levels on the surface of various populations of malignant cells, but not on normal tissues or hematopoietic progenitor cells. The chimeric antibody which binds to CD20 B lymphocyte surface antigens, rituxan (rituximab; Genentech) was among the first of the mAbs to receive FDA approval for the treatment of nonHodgkin's lymphoma [44]. Alemtuzumab, which recognizes CD52 antigens present on normal B and T lymphocytes (Campath-1; Ilex Oncology) has also received FDA approval for the treatment of patients suffering from chronic lymphocytic leukemia.

The successful treatment of solid tumors with mAb therapeutics has proved to be more elusive compared to hematological malignancies, although some significant therapeutic benefits have been achieved. The failure of mAbs in the treatment of these malignancies is primarily attributable to an insufficient level of injected mAb that actually reaches its target within a tumor mass. The results of several studies using radiolabeled mAbs have suggested that only a very small percentage of the original injected antibody dose (0.01–0.1% g^{-1} tumor tissue) is able to ever reach target antigens within a solid tumor [45–47]. These low *in vivo* concentrations are due to the series of biobarriers (see above) that an intravenously administered mAb encounters *en route* to its specific antigens on the surface of cancer cells. Herceptin (trastuzumab; Genentech) is a humanized antibody marketed for the treatment of metastatic breast cancer. This mAb recognizes an extracellular epitope of the HER-2 protein, which is highly overexpressed in approximately 25–30% of invasive

breast tumors [40, 41]. It is noteworthy that HER-2 expression on breast cancer cells can be as high as 100-fold in comparison to normal breast epithelial cells. Clinical trials with herceptin have shown it to be well tolerated, both as a single agent for second- or third-line therapy or in combination with chemotherapeutic agents as a first line of therapy. A combination therapy resulted in a 25% improvement in overall survival among patients with HER-2-overexpressing tumors that are refractory to other forms of treatment [48, 49].

The levels of prostate-specific membrane antigen (PSMA), a transmembrane protein expressed primarily on the plasma membrane of prostatic epithelial cells [50], are elevated in virtually all cases of prostatic adenocarcinoma, with maximum expression levels observed in metastatic disease and androgen-independent tumors [50–53]. Due to this behavior, PSMA has become an important biomarker for prostate cancer, and antibodies to PSMA are currently being developed for the diagnosis and imaging of recurrent and metastatic prostate cancer, as well as for the therapeutic management of malignant disease [53–56].

Another mAb used for the treatment of colorectal cancer is elecolomab (panorex; GlaxoSmith-Kline), the anti-epithelial cellular adhesion molecule. Today, many other immunotherapeutics are being used in the clinic or are undergoing various stages of clinical trials. Beyond their pronounced therapeutic potential, these agents can be efficiently combined with nanovectors to enhance targeting of the latter to cancer tissues.

3.1.2.4 **Issues and Challenges**

As mentioned above, currently used conventional cancer therapies have several drawbacks that result in a pronounced toxicity and poor treatment efficacy. On the other hand, current diagnostic techniques do not allow for the competent detection of various malignancies, and do not reflect the vast clinical heterogeneity of the condition. Targeted approaches will ultimately increase the treatment efficiency, while decreasing toxicity to normal cells and tissues; thus, specific drug delivery in cancer treatment is of prime importance. As opposed to cancers of the blood, solid malignancies possess several unique characteristics, such as extensive blood vessel growth (angiogenesis), damaged vascular architecture and enhanced permeability, and impaired lymphatic flow and drainage. All of the above can serve as effective therapeutic targeting mechanisms, as well as for the passive homing of agents into the tumor tissue by means of various delivery systems.

To summarize, current issues and unmet needs in translational oncology include:

- Improved strategies for early cancer diagnostics and imaging.
- Advanced technologies to overcome the toxicity and adverse effects of chemotherapeutic agents.
- An accumulation of new knowledge on cancer biology, allowing for the design of more efficient therapeutics for more aggressive and lethal cancer phenotypes.

Progress in the above listed fields will sculpt the major cornerstones for a yet-to-come 'personalized' tumor therapy and early and predictive diagnosis of the disease.

Later in this chapter we will describe the currently available and under-development carriers and vectors from a 'nano-toolbox', and critically discuss the benefits and weaknesses of these systems for the design of specific, personalized and targeted medications. The benefits of rational design of the nanovectors to efficiently negotiate biobarriers and various aspects of a preclinical characterization for the nanoscale systems will be argued.

3.2
Nanotechnology for Cancer Applications: Basic Definitions and Rationale for Use

Nanoscience involves investigations to learn new behaviors and properties of materials on a submicron scale. Various important functions of living organisms and biological processes take place at the nanoscale. As an example, a typical protein such as hemoglobin, which carries oxygen through the bloodstream, is 5 nm (i.e. five-billionths of a meter) in diameter, while gamma-globulin accounts for a diameter of about 10 nm. For a comparison, the diameter of an erythrocyte – the smallest cell in the human body – ranges from 5 to 7 μm.

Research on the nanoscale has been a missing dimensional link, among an atomic scale which provides the basics for chemistry and physics, and micro-scale technologies, such as electronics. This issue was addressed by a Nobel Laureate Richard Feynman in his legendary lecture, "There is a plenty room in the bottom," in 1959 [57]. Almost four decades later, Richard Smalley, who received his Nobel Prize in 1996 for the discovery of the foundational in nanoscience and nanotechnology carbon-60 molecules, said "...human health has always been determined on the nanometer scale; this is where the structure and properties of the machines of life work in every one of the cells in every living thing." Nowadays, nanotechnology is a rapidly growing multidisciplinary field involving support from scientists in academia, industry and regulatory as well as federal sectors. As an example, the National Nanotechnology Initiative (NNI) program was established in 2001 to coordinate Federal Nanotechnology Research and Development [58]. The 2009 budget request provides US$ 1.5 billion for the NNI, with major investment in nanotechnology research and development over the past decade, reflecting a broad support of the US Congress for this program. Nanotechnology can offer impressive resolutions, when applied to medical challenges such as cancer, diabetes, Parkinson's or Alzheimer's disease, cardiovascular problems and inflammatory or infectious diseases.

Nanotechnology is more than simply throwing together a batch of nanoscale materials – it requires the ability to manipulate and control them in a useful way. The definition of nanotechnology pertains to synthetic and engineerable objects which are nanoscale in dimensions, or have critical functioning components of such a size, and that therefore possess special emergent properties [59]. This is a general and operational definition involving the following interrelated constituents: nanoscale dimensions of the whole system or its vital components; man-made nature; and the unique characteristics of new material that arise due to its nanoscopic size, with each element in this three-part description being equally essential for an object to be

defined as 'nanotechnological'. Another vital component in this definition is that the unique features and emerging properties of the nanomaterial must be backed up by the correct mechanism of action (e.g. mathematical modeling). Other definitions of nanotechnology can be found in the literature and, according to some agencies, the word 'nanoscale' should be interpreted to encompass the range of 1 to 100 nm. For example, the National Cancer Institute defines nanotechnology as

> "*The field of research that deals with the engineering and creation of things from materials that are less than 100 nanometers (one-billionth of a meter) in size, especially single atoms or molecules.*"

Nanotechnology has already occupied its niche for quite a few years in medicine, being known as 'nanomedicine', particularly in oncology [60–62]. The most studied and commercially available drug-delivery nanoparticle is the liposome, with liposomal doxorubicin having been granted FDA approval since 1996 for use against Kaposi's sarcoma. Later, it was also approved for use in metastatic breast cancer and recurrent ovarian cancer. Cancer-related issues of nanomedicine are supported by major funding programs; for example in 2005, the National Cancer Institute launched a US$ 144 million Alliance for Nanotechnology in Cancer.

The use of nanoparticles as carriers for therapeutic and imaging contrast agents is based on the simultaneous, anticipated advantages of drug localization at cancer lesions, and the ability to circumvent the biological barriers encountered between the point of administration and the projected target. Although physical localization at the tumor site is frequently defined as 'targeting' among the drug-delivery community, this term has a different scientific connotation, referring to the preferential activity of the agent on tumor-associated biological pathways. Due to this discrepancy, we will here use the term 'targeting' only when referring to the specific recognition between particles and the lesion (e.g., due to the presence of mAb on the particle's surface), while referring to passive concentration governed by physical laws as 'localization' or 'direction'.

A '*nanovector*' is a nanoscale particle or system having nanoscale components for the delivery of therapeutic or contrast agent. Currently used and investigated nanovectors can be generally organized into three main categories or 'generations' as shown schematically in Figure 3.1 [6, 8, 63]:

- The first generation (Figure 3.1a) comprises a delivery system that homes into the action site governed by passive mechanisms. In the case of liposomes as a nanovector, the mode of tumor localization is based on the enhanced permeation and retention (EPR) effect, which drives the system to localize into tumor through fenestrations in the adjacent neovasculature. Some of these carriers are surface-modified with a stealth layer [e.g. polyethylene glycol (PEG)] which prevents their uptake by the RES, and thus substantially prolongs the particles' circulation time [63].
- The second generation in this classification is thus defined as having specific additional functionalities on each individual particle, allowing for molecular recognition of target tissue (Figure 3.1b), or for the active or triggered release of the payload at the disease site. The best examples of the first subclass of nanovectors

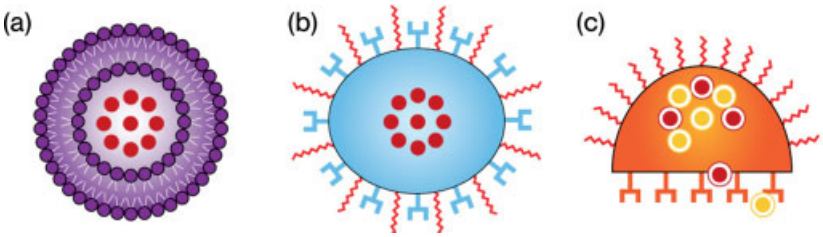

Figure 3.1 (a) First-generation nanovectors (e.g. clinical liposomes) comprise a container and an active principle, and localize in the tumor by enhanced permeation and retention (EPR), or the enhanced permeability of the tumor neovasculature; (b) Second-generation nanovectors further possess the ability to targeting their therapeutic action via antibodies and other biomolecules, remote activation, or responsiveness to environment; (c) Third-generation nanovectors (e.g. multistage agents) are capable of more complex functions, such as time-controlled deployment of multiple waves of active nanoparticles, deployed across different biological barriers and with different subcellular targets.

in this category are antibody-targeted nanoparticles, such as mAb-conjugated liposomes [64–69].

- Third-generation nanovectors, such as multistage agents, are capable of more complex functions which enable sequential overcoming of multiple biobarriers. An example is the time-controlled release of multiple payloads of active nanoparticles, negotiating different biological barriers and with different subcellular targets [7].

Later in this chapter we will focus on each of the three generations of nanovectors, discussing the 'pros' and 'cons', and presenting various examples of these technologies.

3.3
First-Generation Nanovectors and their History of Clinical Use

Today, the first-generation nanovectors that passively localize into tumor sites represents the only generation of nanomedicines broadly represented in the clinical situation. These systems are generally designed to achieve long circulation times for therapeutics and an enhanced accumulation of the drug into the target tissue. This is achieved through a pronounced extravasation of the carrier-associated therapeutic agent into the interstitial fluid at the tumor site, exploiting the locally increased vascular permeability, the EPR effect (Figure 3.2). An additional physiological factor which contributes to the EPR effect is that of impaired lymphatic function impeding clearance of the nanocarriers from their site of action [69–71]. The localization in this case is driven only by the particles' nanodimensions, and is not related to any specific recognition of the tumor or neovascular targets.

In order to prolong their circulation time, these systems are generally decorated on their surface by a 'stealth' layer (e.g. PEG) which prevents their uptake by phagocytic blood cells and organs of the RES system [63, 72, 73]. The most pronounced

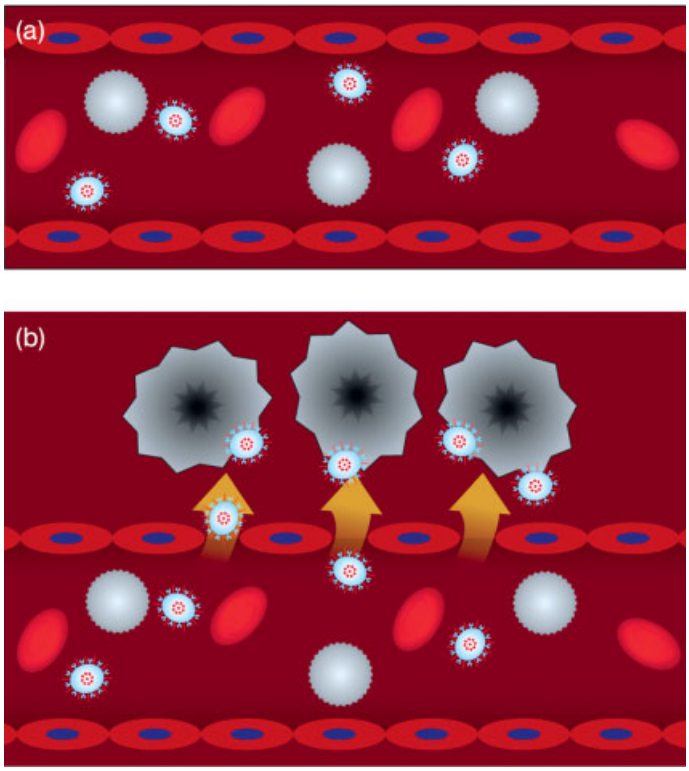

Figure 3.2 Mechanism of passive tumor targeting by enhanced permeation and retention (EPR).

representatives of this generation in clinical use are *liposomes*, which are the leaders among nanocarriers used in clinics. These self-assembling structures, which were first discovered by Bangham in 1965 [74], are composed of one or several lipid bilayers surrounding an aqueous core. This structure imparts an ability to encapsulate molecules that possess different degrees of lipophilicity; lipophilic and amphiphilic drugs will be localized in the bilayers while water-soluble molecules will concentrate into the hydrophilic core. The first drug to benefit from being encapsulated within this delivery system was doxorubicin. As of today, various companies market doxorubicin liposomal formulations, but Myocet (non-PEGylated liposomes) and Doxil (PEGylated liposomes) were among the first systems in clinical use [71, 75]. The pronounced advantages of liposomally encapsulated doxorubicin can be illustrated in its pharmacokinetic performance: an elimination half-life for the free drug is only 0.2 h, but this increases to 2.5 and 55 h, respectively, when non-PEGylated and PEGylated liposomal formulations are administered. Moreover, the area under the time–plasma concentration profile (the AUC), which indicates the bioavailability of an agent following its administration, is increased 11- and 200-fold for Myocet and Doxil, respectively, compared to the free drug [76]. Encapsulation into the liposomal carrier also causes a significant reduction in the most significant adverse side effect of doxorubicin, namely cardiotoxicity, as demonstrated in clinical trials [71, 75–77].

Liposomal doxorubicin is currently approved for the treatment of various malignancies, including Kaposi's sarcoma, metastatic breast cancer, advanced ovarian cancer and multiple myeloma. Other liposomal drugs which are either currently in use or are being evaluated in clinical trials include non-PEGylated liposomal daunorubicin (DaunoXome) and vincristine (Onco-TCS), PEGylated liposomal cisplatin (SPI-77) and lurtotecan (OSI-211) [78, 79].

Other systems in this category include metal nanoparticles for use in diagnostics, albumin paclitaxel nanoparticles approved for use in metastatic breast cancer, and drug–polymer constructs.

Nanoscale particles can act as contrast agents for all radiological imaging approaches. Iron-oxide particles provide a T_2-mode negative contrast for magnetic resonance imaging (MRI), while gold nanoparticles can be used to enhance the contrast in X-ray and computed tomography (CT) imaging, in a manner which is essentially proportional to their atomic number. Mechanical impendence disparity is the origin for the contrast in ultrasound imaging provided by the materials that are either more rigid (metals, ceramics) or much softer (microbubbles) than the surrounding tissue. The very existence of better contrast agents can drive the development of new imaging modalities. The emergence of nanocrystalline quantum dots has generated great interest in novel optical imaging technologies. The architecture and composition of quantum dots provide tunable emission properties that resist photobleaching. By concentrating preferentially at tumor sites following an EPR mechanism, nanoparticles which comprise a contrast material can provide an enhanced definition of anatomical contours and location, as well as the extent of disease. In addition, if coupled with a biological recognition moiety they can further offer molecular distribution information for the diagnostician [78].

Albumin-bound paclitaxel (Abraxane) was granted FDA approval in 2005. Paclitaxel is a highly lipophilic molecule that was previously formulated for injection with Cremophor, a toxic surfactant, under the trade name Taxol®. In a multicenter Phase II clinical trial involving 4400 women with metastatic breast cancer, Abraxane (30-min infusion, 260 mg m^{-2}) was proven to be more beneficial in terms of treatment efficiency and reduction in side effects than the free drug (3-h infusion, 175 mg m^{-2}) [80]. Albumin-bound methotrexate is currently being evaluated in the clinical situation.

Although the next group to be discussed does not have a particulate nature, these agents – drug–polymeric cleavable constructs – have also been considered as nanoengineered objects. In 1975, Ringdorf proposed a new concept of drug–polymer constructs that could be conjugated by using a linker with a certain degree of selectivity, and which would be stable in blood but cleaved in an acidic or enzymatic environment of a tumor site, or within an acidic intracellular compartment (e.g. endosomes) [81]. Some 20 years later, in 1994, doxorubicin conjugated to poly(*N*-(2-(hydroxypropyl)methacrylamide) (PHPMA), through an enzymatically cleavable tetrapeptide spacer (GFLG), was the first polymeric construct to enter clinical trials [70, 78]. This system significantly improved the therapeutic index of the drug, as indicated by a 45-fold higher maximum tolerated dose of the drug–polymer conjugate when compared to doxorubicin alone [82].

Other examples in this subcategory include PEG-L-asparaginase for lymphoblastic leukemia, PSMA-bound neocarcinostatin (which has been approved in Japan for the treatment of liver cancer), and PLGA-conjugated paclitaxel, which is currently undergoing Phase III evaluation for ovarian and non-small-cell lung cancer. In addition to such conventional polymer–drug, polymer–protein and protein–drug conjugates, several novel types of polymeric nanomedicines have also recently entered clinical trials, including cationic polyplexes for DNA and small interfering RNA (siRNA) delivery, dendrimers and polymeric micelles [71, 78, 79, 83].

3.4 Second-Generation Nanovectors: Achieving Multiple Functionality at the Single Particle Level

As defined above, the second generation of nanoparticles has specific additional functionalities on each individual particle, thus allowing for the molecular recognition of target tissues or for the active or triggered release of a payload at the disease site. The best examples of the targeting moieties utilized for homing the first subclass of nanovectors in this category (e.g. liposomes and other nanoparticles) are antibodies [64, 83–88]. Another example is the targeting through folate-receptors overexpressed on the membrane of some cancer cells.

Currently, a variety of targeting moieties besides antibodies are under investigation worldwide. These include ligands, aptamers and small peptides binding to specific target cell-surface markers or surface markers expressed in the disease microenvironment [89, 90].

By using active targeting, ligands can be attached to drugs to act as homing devices for binding to receptor structures expressed at the target site. Antibody–drug conjugates targeted to, for example, CD20, CD25 and CD33, which are (over) expressed in non-Hodgkin's lymphoma, T-cell lymphoma and acute myeloid leukemia, respectively, have been successfully used to deliver radionuclides (Zevalin), immunotoxins (Ontak) and antitumor antibiotics (Mylotarg) more selectively to tumor cells. Three platforms – immunoconstructs, immunoliposomes and immunopolymers – that utilize immune functional groups for targeting are presented schematically in Figure 3.3 [83].

A still unresolved question when targeting the solid tumor is the choice between high or low binding affinity of the ligand for its antigen or receptor. When the binding affinity is high, there is some evidence that the penetration of targeted therapeutics into a solid tumor is decreased due to the 'binding-site barrier'. In this case the targeted therapeutics binds strongly to the first targets encountered, but fails to diffuse further into the tumor. On the other hand, for targets in which most of the cells are readily accessible to the delivery system – for example, tumor vasculature and certain hematological malignancies – a high binding affinity might be desirable.

Another recently reported new system achieves targeting and detection based on PEGylated gold nanoparticles and surface-enhanced Raman scattering (SERS) (Figure 3.4a) [91]. These pegylated SERS nanoparticles have a significantly higher

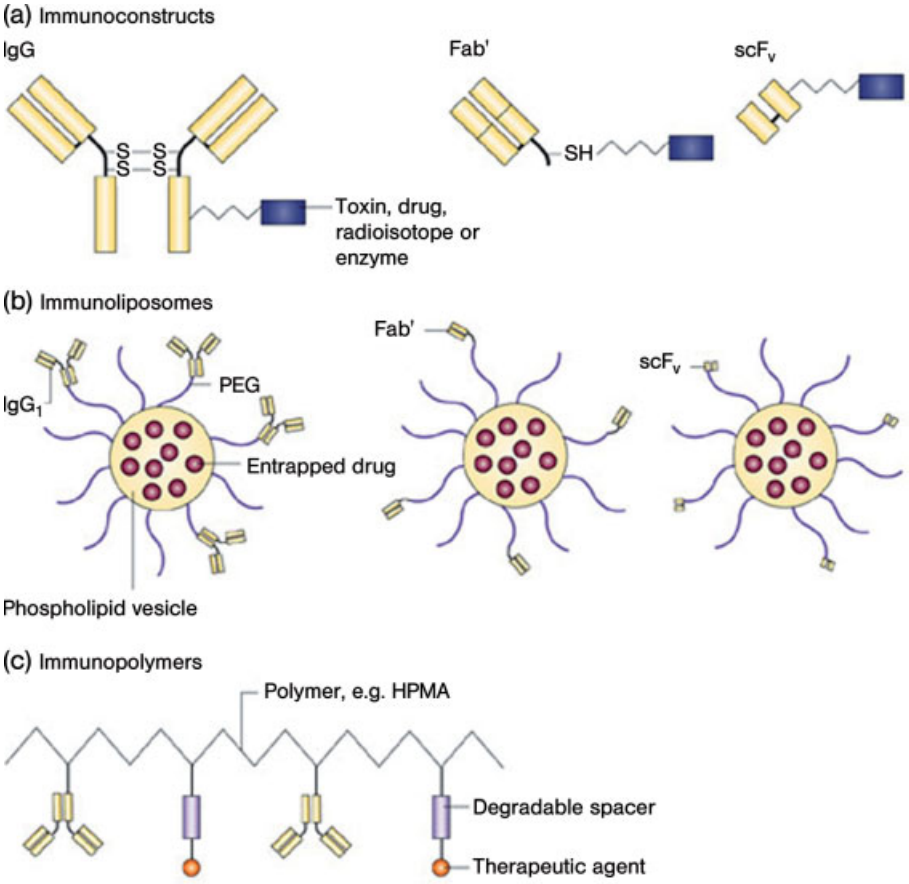

Figure 3.3 (a) Examples of targeted therapeutics constructs. Immunoconstructs are formed by the linking of antibodies, antibody fragments or nonantibody ligands to therapeutic molecules, such as toxins (immunotoxins), radioisotopes (radioimmunotherapy), drugs (immunoconjugates) or enzymes (ADEPT). Drug release, if required (immunotoxins and immunoconjugates), occurs through intracellular degradation of the peptide linker; (b) Immunoliposomes are formed by the attachment of multivalent arrays of antibodies, antibody fragments or nonantibody ligands to the liposome surface or, as in the example, to the terminus of hydrophilic polymers, such as polyethylene glycol (PEG), which are grafted at the liposome surface. The liposomes contain up to several million molecules of the therapeutic, the release of which occurs gradually by diffusion down its concentration gradient; (c) Immunopolymers are formed by linking both therapeutic agents and targeting ligands to separate sites on water-soluble, biodegradable polymers, such as hydroxypropylmethacrylamide (HPMA), with the use of appropriate degradable spacers to allow for drug release. ADEPT = antibody-directed enzyme–prodrug therapy; LTT = ligand-targeted therapeutic [83].

fluorescent intensity than quantum dots, with light emission in the near-infrared window, which is very appropriate for *in vivo* imaging. When conjugated to tumor-targeting ligands such as single-chain variable fragment (ScFv) antibodies, the conjugated nanoparticles were able to target tumor biomarkers such as epidermal

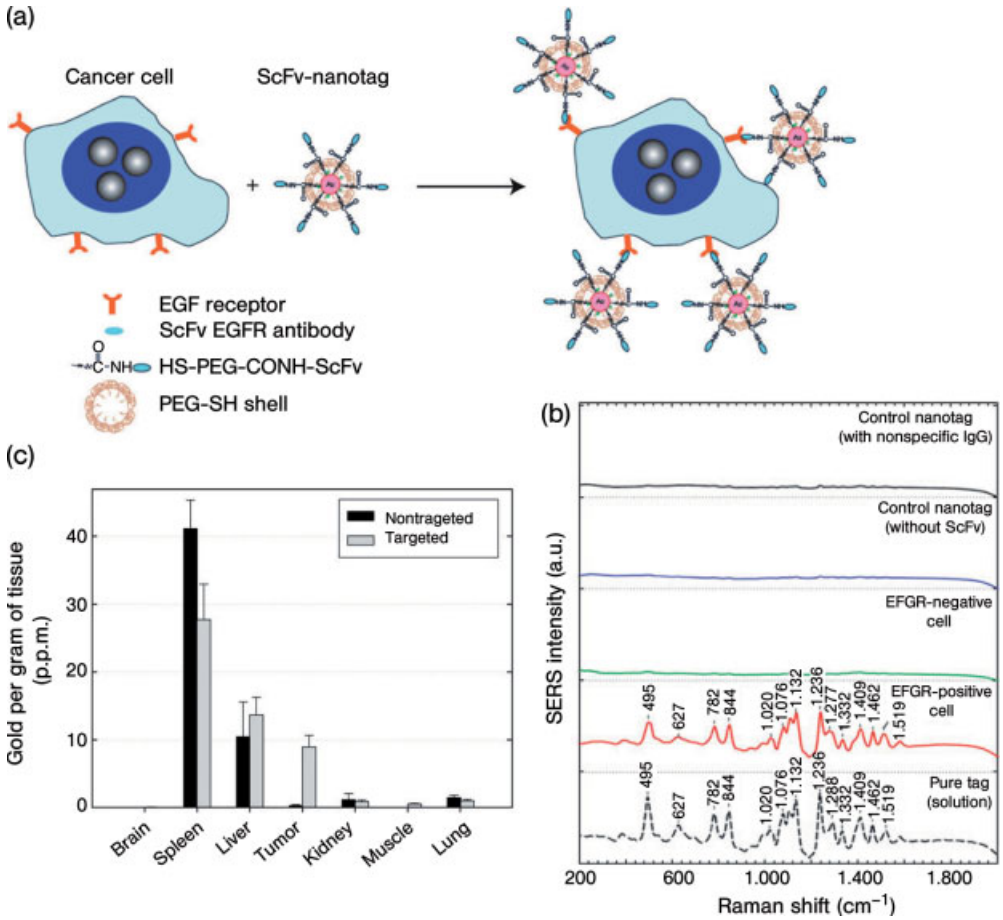

Figure 3.4 (a) Preparation of targeted SERS nanoparticles by using a mixture of SH-PEG and a heterofunctional PEG (SH-PEG-COOH). Covalent conjugation of an endothelial growth factor receptor (EGFR)-antibody fragment occurs at the exposed terminal of the heterofunctional PEG; (b) SERS spectra obtained from EGFR-positive cancer cells (Tu686) and EGFR-negative cancer cells (human non-small-cell lung carcinoma NCI-H520), together with control data and the standard tag spectrum. All spectra were taken in cell suspension with 785-nm laser excitation, and were corrected by subtracting the spectra of nanotag-stained cells by the spectra of unprocessed cells. The Raman reporter molecule is diethylthiatricarbocyanine (DTTC), and its distinct spectral signatures are indicated by wave numbers (cm^{-1}); (c) Biodistribution data of targeted and nontargeted gold nanoparticles in major organs at 5 h after injection, measured using inductively coupled plasma-mass spectrometry (ICP-MS). Reproduced with permission from Ref. [91].

growth factor (EGF) receptor on human cancer cells and in xenograft tumor models, with a 10-fold higher accumulation for targeted particles (see Figure 3.4b).

The nanovectors in the second subclass of this generation include responsive systems, such as pH-sensitive polymers or those activated by the disease site-specific enzymes, as well as a diverse group of remotely activated vectors. Among the most

interesting examples here are gold nanoshells that are activated by near-infrared light, or iron oxide nanoparticles triggered by oscillating magnetic fields [92, 93]. Other techniques used to remotely activate the second-generation particulates include ultrasound and radiofrequency (RF) [94–96]. Linking nanoshells to antibodies that recognize cancer cells enables these novel systems to seek out their cancerous targets prior to applying near-infrared light to heat them up. For example, in a mouse model of prostate cancer, nanoparticles activated with 2′-fluoropyrimidine RNA aptamers that recognized the extracellular domain of the PSMA, and loaded with docetaxel as a cytostatic drug, were used for targeting and destroying cancer cells [97, 98]. Another new approach is based on the coupling of nanoparticles to siRNA, used to silence specific genes responsible for malignancies. By using targeted nanoparticles, it was shown that the delivered siRNA can slow the growth of tumors in mice, without eliciting the side effects often associated with cancer therapies. Although the representatives of the second generation have not yet been approved by FDA, there are today numerous ongoing clinical trials involving targeted nanovectors, especially in cancer applications.

3.5
Third-Generation Nanoparticles: Achieving Collaborative Interactions Among Different Nanoparticle Families

The fundamental basis for the administration of drugs is to achieve a favorable therapeutic outcome in the treatment of a medical condition or disease, with minimal detrimental side effects. So far, we have described in detail the first- and second-generation nanoparticle therapeutic strategies. Although each generation has demonstrated incremental improvements relative to conventional intravenously administered chemotherapies, 'blockbuster' drug status has yet to be achieved by any nanobased construct. The second-generation nanoparticles offered new degrees of sophistication compared to their predecessors by employing additional complexities such as targeting moieties, remote activation, and environmentally sensitive components. However, these improvements predominantly represent simply a progressive evolution of the first-generation vectors; these subtle, yet augmenting, particle improvements do not fully address the primary challenge – or set of challenges – presented in the form of sequential biological barriers that continue to impair the efficacy of first- and second-generation nanoparticulates. This fundamental problem has given rise to a nanoparticle paradigm shift with the emergence of a third generation of particle that is specifically engineered to avoid biological barriers and to codeliver multiple nanovector payloads with tumor specificity.

The human body presents a robust bodily defense system that is extremely effective in preventing injected chemicals, biomolecules, nanoparticles and any other foreign agent(s) of therapeutic action from reaching their intended destinations. In addition to these natural biologic defenses, tumor-associated obstacles also exist. As a demonstration of the efficacy of these combined biological barriers, it has been calculated that only one out of every 100 000 molecules of drug successfully

reaches the intended site, permitting the overwhelming majority of the highly toxic, nondiscriminating, systemically disbursed poison to manifest in a number of undesirable side effects associated with cancer chemotherapy. This familiar scenario was quantitated in a study of Kaposi's sarcoma study that showed the percentage concentration of doxorubicin in Kaposi's sarcoma lesions to be ~0.001% [99]. This therapeutic phenomenon does not appear to be a tumor-specific challenge, however, and is therefore applicable to the lion's share of malignancies and tumor types [5, 100–102].

Some of the above-mentioned and most notable challenges include physiological barriers (i.e. the RES, epithelial/endothelial membranes, cellular drug extrusion mechanisms) and biophysical barriers (i.e. interstitial pressure gradients, transport across the ECM, expression and density of specific tumor receptors, and ionic molecular pumps). Biobarriers are sequential in nature, and therefore the probability of reaching the therapeutic objective is the product of individual probabilities of overcoming each and every one of them [8]. The requirement for a therapeutic agent to be provided with a sufficient collection of weaponry to conquer all barriers, yet still be small enough for safe vascular injection, is the major challenge faced by nanotechnology [14]. Once injected, nanoscale drug delivery systems (or 'nanovectors') are ideal candidates for the time-honored problem of optimizing the therapeutic index for treatment – that is, to maximize efficacy, while reducing adverse side effects.

The ideal injected chemotherapeutic strategy is envisioned to be capable of navigating through the vasculature after intravenous administration, to reach the desired tumor site at full concentration, and to selectively kill cancer cells with a cocktail of agents with minimal harmful side effects. Third-generation nanoparticle strategies represent the first wave of next-generation nanotherapeutics that are specifically equipped to address biological barriers to improve payload delivery at the tumor site. By definition, third-generation nanoparticles have the ability to perform a time sequence of functions which involve the cooperative coordination of multiple nanoparticles and/or nanocomponents. This novel generation of nanotherapeutics is exemplified through the employment of multiple nanobased products that synergistically provide distinct functionalities. In this chapter, the nanocomponents will include any engineered or artificially synthesized nanoproducts, including peptides, oligonucleotides (e.g. thioaptamers, siRNA) and phage with targeting peptides. Naturally existing biological molecules, such as antibodies, will be excluded from this designation, despite their ability to be synthesized.

Third-generation approaches have been developed to address the numerous challenges responsible for reducing the chemotherapeutic efficacy of earlier strategies. For example, surface modification of the exterior of nanoparticles with PEG has proven to be effective in increasing the circulation time within the bloodstream; however, this preservation tactic proves detrimental to the biological recognition and targeting ability of the nanovector [103]. In order to avoid such paradoxical approaches of employing debilitating improvements to therapeutic delivery systems, many research groups are combining multiple nanotechnologies to exploit the additive contributions of the constituent components. One example of third-generation nanoparticles is the biologically active molecular networks known as

'nanoshuttles'. These self-assemblies of gold nanoparticles within a bacteriophage matrix combine the hyperthermic response to near-infrared radiation of the gold with the biological targeting capabilities of the 4C-RGD sequence presented by the phage [104]. The nanoshuttles also collectively accommodate enhanced fluorescence, dark-field microscopy and surface-enhanced Raman scattering detection.

The next example of third-generation nanoparticles is the disease-inspired approach of the 'nanocell'. Newly emerging chemotherapeutic models utilize combinational therapies that are intended to inhibit tumor neovasculature growth and kill cancer cells. The coadministration of anti-angiogenic agents with conventional cytotoxic agents is a novel concept, but this practice has faced two critical problems. First, it has been shown that anti-angiogenic agents are capable of depleting blood flow to the tumor by interrupting new vessel growth. Unfortunately, however, this shutdown of tumor blood vessels has resulted in the prevention of chemotherapeutic agents from reaching the tumor site at sufficient concentrations. Furthermore, the decreased blood flow elicits intra-tumoral hypoxia which in turn increases the expression of hypoxia-inducible factor-1α (HIF1-α). HIF1-α overexpression is correlated to increased tumor invasiveness and chemotherapy resistance [105]. By using the same combinatorial chemotherapy approach, researchers have developed a nested nanoparticle construct that comprises a lipid-based nanoparticle enveloping a polymeric nanoparticle core called a 'nanocell'. Here, a conventional chemotherapeutic drug (doxorubicin) is conjugated to a polymer core and an anti-angiogenic agent (combretastatin) is then trapped within the lipid envelope. When the nanocells are accumulated within the tumor through the EPR effect, the sequential time release of the anti-angiogenic agent, followed by the cytotoxic drug, causes an initial disruption of tumor vascular growth and effectively traps the drug-conjugated nanoparticle core within the tumor to allow an eventual delivery of the cancer cell-killing agent.

The final example of third-generation nanoparticle technology utilizes a multistage approach that addresses many biological barriers experienced by an injec therapy. Currently, research groups are developing nanoporous silicon microparticles that utilize their unique particle size, shape and other physical characteristics in concert with active tumor biological targeting moieties to efficiently deliver payloads of nanoparticles to the tumor site. The ability to deliver a therapeutic agent to a tumor is analogous to the lunar voyage embarked upon by the Apollo 11 crew. This epic feat was not achieved simply by piloting a single vehicle to the moon and back; instead, it required a sequential execution of numerous steps, which included three stages of the Saturn V rocket to escape the Earth's atmosphere, a lunar module to descend and ascend to and from the lunar landscape, and finally a command module for re-entry and splashdown back to Earth. Similar mission-critical issues must also be addressed in a sequential manner when developing drug delivery systems to fight cancer.

The multistage drug delivery system is predicated upon a Stage 1 nanoporous silicon microparticle that is specifically designed (through mathematical modeling) to exhibit superior margination and adhesion properties during its negotiation through the systemic blood flow en route to the tumor site. Particle characteristics such as size, shape, porosity and charge can be exquisitely controlled with precise reproducibility through semiconductor fabrication techniques. In addition to its

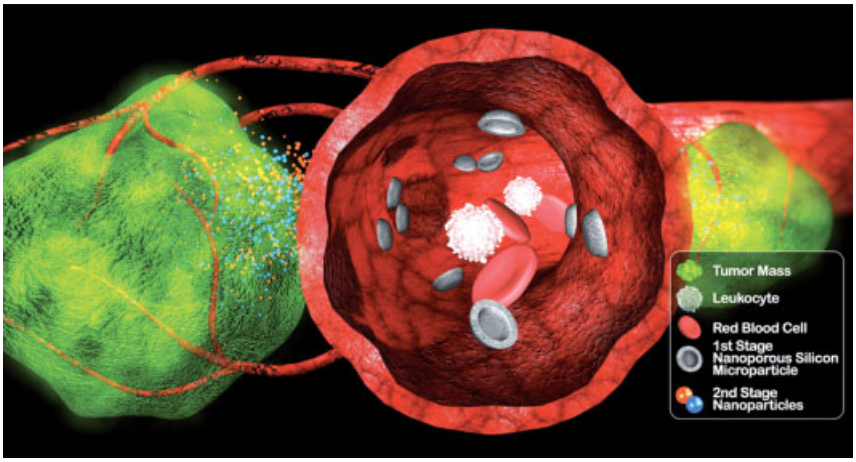

Figure 3.5 Multistage nanovectors. Stage 1 nanoporous silicon microparticles are engineered to exhibit an enhanced ability to marginate within blood vessels and adhere to tumor-associated endothelium. Once positioned at the tumor site, the Stage 1 particle can release its nanoparticle payload to achieve the desired therapeutic effect, prior to complete biodegradation of the carrier particle. The therapeutic outcome can be determined by selection of the nanoparticles loaded within the nanoporous structure of the Stage 1 particle.

favorable physical characteristics, the Stage 1 particle can be surface-treated with such modifications as PEG for RES avoidance and also equipped with biologically active targeting moieties (e.g. aptamers, peptides, phage, antibodies) to enhance the tumor-targeting specificity. This approach decouples the challenges of: (i) transporting therapeutic agents to the tumor-associated vasculature; and (ii) delivering therapeutic agents to cancer cells. The Stage 1 particles shoulder the burden of efficiently transporting a nanoparticle payload to the tumor site within the nanoporous structures of its interior (Figure 3.5). The nanoparticles called Stage 2 particles, generically represent any nanovector construct within the approximate diameter range of 5 to 100 nm. The Stage 1 particles have demonstrated the ability to rapidly load (within seconds) and gradually release (within hours) multiple nanoparticles (i.e. single-walled carbon nanotubes and quantum dots) during *in vitro* experiments, with complete biodegradation within 24–48 h, depending on the pore density [106]. Furthermore, unpublished preliminary data have demonstrated the ability to deliver liposomes and other nanovectors, as well as indications of the successful *in vivo* delivery of Stage 2 nanoparticles to tumor masses in xenograft murine models.

The multistage drug delivery system is emblematic of third-generation nanoparticle technology, since the strategy combines numerous nanocomponents to deliver multiple nanovectors to a tumor lesion. The Stage 1 particle is rationally designed to have a hemispherical shape to enhance particle margination within blood vessels, and to increase particle/endothelium interaction to maximize the probability of active tumor targeting and adhesion [107]. In addition to improved hemodynamic physical properties and active biological targeting by utilizing nanocomponents such as aptamers and phage, the Stage 1 particle can also present with specific surface

modifications in order to avoid RES uptake and exhibit degradation rates predetermined by nanopore density. Upon tumor recognition and vascular adhesion, a series of nanoparticle payloads may be released in a sequential order predicated upon Stage 1 particle degradation rates and payload conjugation strategies (e.g. environmentally sensitive crosslinking techniques, pH, temperature, enzymatic triggers). The versatility of this platform nanovector multistage delivery particle allows for a multiplicity of applications. Depending upon the nanoparticle 'cocktail' loaded within the Stage 1 particle, this third-generation nanoparticle system can provide for the delivery not only of cytotoxic drugs but also of remotely activated hyperthermic nanoparticles, contrast agents and future nanoparticle technologies.

3.6
Nanovector Mathematics and Engineering

Third-generation particles are transported by the blood flow and interact with the blood vessel walls, both specifically – through the formation of stable ligand–receptor bonds – and nonspecifically, by means of short-ranged van der Waals, electrostatic and steric interactions. If suitable conditions are met in terms of a sufficiently high expression of vascular receptors and sufficiently low hydrodynamic shear stresses at the wall, particles may adhere firmly to the blood vessel walls and control cell uptake, either by avoiding or favoring, based on their final objective. Such an intravascular 'journey' can be broken down into three fundamental events which form the cornerstone of the rational design, namely: the margination dynamics; the firm adhesion; and the control of internalization. The rational design of particles has the aim of identifying the dominating governing parameters in each of the above-cited events in order to propose the optimal design strategy as a function of the biological target (diseased cell or environment).

In physiology, the term 'margination' is conventionally used to describe the lateral drift of leukocytes and platelets from the core of the blood vessels towards the endothelial walls. This event is of fundamental importance as it allows an intimate contact between the circulating cells and the vessel walls, and in the case of leukocytes it is required for diapedesis. Similarly, the rational particle design should aim at generating a marginating particle, that can spontaneously move preferentially in close proximity to the blood vessel walls. Accumulating the particles in close proximity to the blood vessel walls is highly desirable both in vascular targeting and when the delivery strategy relies on the EPR approach. This occurs for two main reasons:

- The particles can 'sense' the vessel walls for biological and biophysical diversities, as for instance the overexpression of specific vascular markers (vascular targeting) or the presence of sufficiently large fenestrations through which they extravasate (EPR-based strategy).
- The particles can more easily leave the larger blood vessels in favor of the smaller ones, thus accumulating in larger numbers within the microcirculation (Figure 3.6) [108].

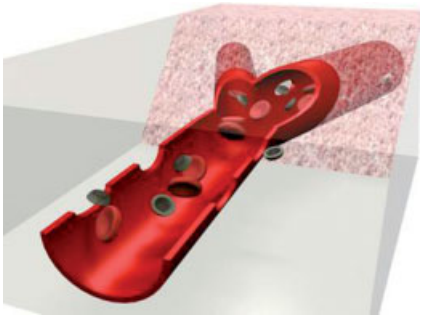

Figure 3.6 Marginating particles can more likely 'sense' the vessel walls for biological and biophysical diversity and more easily leave the vascular compartments through openings along the endothelium.

While leukocyte and platelet margination is an active process requiring an interaction with red blood cells (RBCs) and the dilatation of inflamed vessels with blood flow reduction [109], particle margination can only be achieved by proper rational design.

It should be noted that the RBCs – the most abundant blood-borne cell population – have a behavior opposite to margination, with an accumulation that occurs preferentially within the core of the vessels. This has long been described by Fahraeus and Lindqvist [110], and is referred to as the *plasma skimming* effect. An immediate consequence of this phenomenon is the formation of a 'cell-free layer' in the proximity of the wall, which varies in thickness with the size of the channel and mean blood velocity. For example, it may be as large as few tens of microns in arterioles ($\geq$100 μm in diameter) and a few microns in capillaries ($\geq$10 μm in diameter [111]). Particles designed to marginate should accumulate and move in a cell-free layer, which is also characterized by an almost linear laminar flow.

The motion of spherical particles in a linear laminar flow has been described by Goldmann *et al.* [112], who showed that the exerted hydrodynamic forces grow with the particle radius, and that no lateral drift would be observed unless an external forces such as gravitational or magnetic, or short-ranged van der Waals and electrostatic interactions were applied [113]. In other words, a neutrally buoyant spherical particle moving in close proximity to a wall can drift laterally only if an external force is applied. Here, it is important to recall that the gravitational force has been shown to be relevant even for submicrometer polystyrene beads (relative density to water of 0.05 g cm^{-3}), and that margination dynamics can be effectively controlled in horizontal channels by changing the size of the nonbuoyant nanoparticles [114]. On the other hand, nonspherical particles exhibit more complex motions with tumbling and rolling that can be exploited to control their margination dynamics, without any need for lateral external forces. The longitudinal (drag) and lateral (lift) forces, as well as the torque exerted by the flowing blood, depend on the size, shape and orientation of the particle to the stream direction, and change over time as the particle is transported. Considering an ellipsoidal particle with an aspect ratio of 2 (Figure 3.7a) in a linear laminar flow, the particle trajectory and its separation distance from the wall are shown in Figure 3.7b. Clearly, the particle motion is very complex,

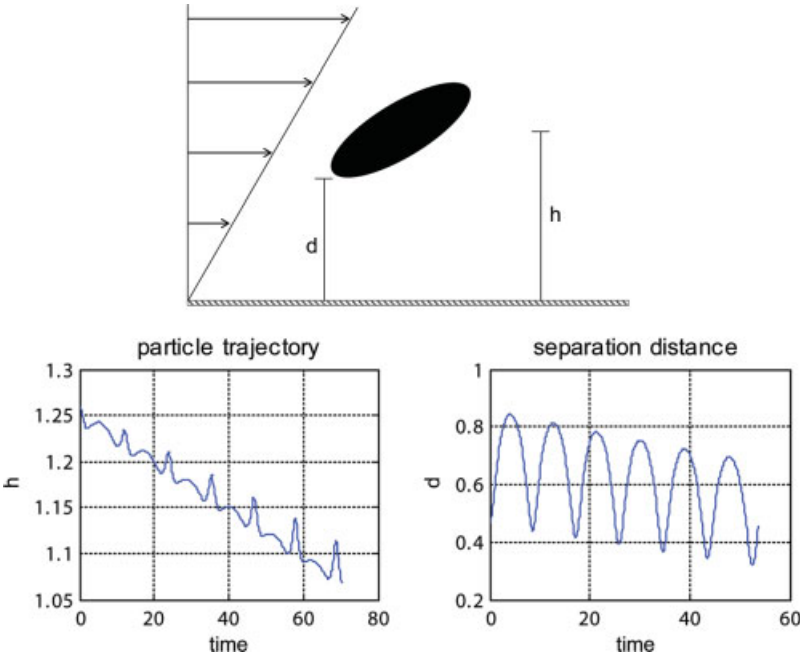

Figure 3.7 (a) An ellipsoidal particle transported within a linear laminar flow at a distance *d* from a rigid wall, as it would be in close proximity to the vessel walls; (b) The trajectory of the ellipsoidal particle with its characteristic oscillatory motion, and its separation distance from the wall reducing with time.

with periodic oscillations towards and away from the wall. Overall, however, the particle would approach the wall and interact with its surface.

For nonspherical particles, it has been shown that the lateral drifting velocity is directly related to their aspect ratio [115, 116], with a maximum between the two extremes: a sphere, with aspect ratio unity, and a disk, with aspect ratio infinity.

More recently, *in vitro* experiments have been conducted using spherical, discoidal and quasi-hemispherical particles with the same weight injected into a parallel plate flow chamber under controlled hydrodynamic conditions [117]. The experiments have shown that discoidal particles tend to marginate more than quasi-hemispherical and more than spherical particles in a gravitational field. Notably, these observations neglect the interaction of the particles with blood cells, in particular RBCs. However, this is a reasonable assumption as long as the particles are sufficiently smaller than RBCs and tend to accumulate within the cell-free layer.

Therefore, with regards to what concerns the design of marginating particles their size and shape, their geometric properties are of fundamental importance.

The marginating particle moving in close proximity to the blood vessels can interact both specifically and nonspecifically with the endothelial cells, and eventually adhere firmly to it. Firm and stable adhesion is ensured as long as the dislodging forces (hydrodynamic forces and any other force acting to release the particle from

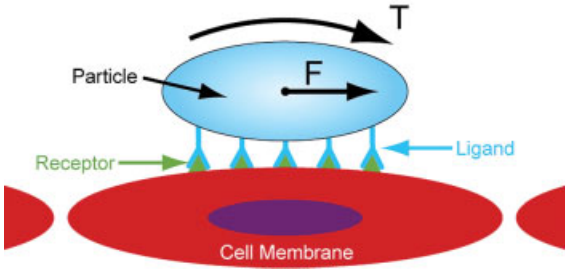

Figure 3.8 The longitudinal (drag) force (F) and the torque (T) exerted over a particle adhering to a cell layer under flow.

the target cell) are balanced by specific ligand–receptor interactions and nonspecific adhesion forces arising at the cell–particle interface (Figure 3.8).

The strength of adhesion must be expressed in terms of an adhesion probability factor, P_a, defined as the probability of having at least one ligand–receptor bond formed under the action of the dislodging forces. The probability of adhesion is decreased as the shear stress at the blood vessel wall μS and as the characteristic size of the particle increase; and grows as the surface density of ligand molecules m_l distributed over the particle surface and of receptor molecules m_r expressed at the cell membrane increases. However, for a fixed volume particle – that is to say, for a fixed payload – oblate particles with an aspect ratio γ larger than unity would have a larger strength of adhesion having fixed all other parameters [118]. Interestingly, for each particle shape, a characteristic size can be identified for which the probability of adhesion has a maximum, as shown in Figure 3.9. For small particles, the hydrodynamic forces are small but the area of interaction at the particle–cell interface is also smaller, leading consequently to a small number of ligand–receptor bonds involved which cannot withstand even a small dislodging force. For large particles, the number

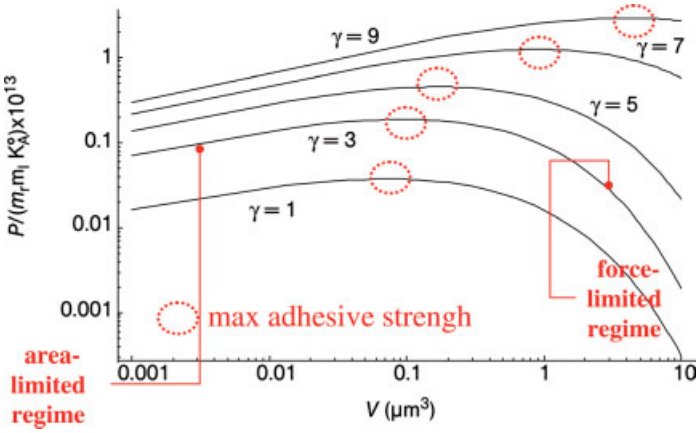

Figure 3.9 Variation of the normalized adhesive probability factor (P) with the volume V of the particle for different values of the aspect ratio γ [118].

of ligand–receptor bonds that can be formed grows, but the hydrodynamic forces grow even more. The optimal size for adhesion – that is, the size for which P_a has a maximum – falls between these two limiting conditions.

As an example, when considering a capillary with a shear stress at the wall of $\mu S = 1$ Pa and a surface density of receptors $m_r = 100\,\mu m^2$, the optimal radius for a spherical particle would be about 500 nm with a total volume of $0.05\,\mu m^3$, whereas the optimal volume for an oblate spheroidal particle with an aspect ratio $\gamma = 2$ would be more than 50 times larger ($3.5\,\mu m^2$) [118].

In particle adhesion, rational design should focus on the shape of the particle and the type and surface density of ligand molecules decorating the particle surface.

Once the particle has adhered to the target cell, it should be internalized if the aim is to release drugs or therapeutic agents within the cytosol or at the nuclear level (gene delivery). Alternatively, it should resist internalization if the target cell is used just as a docking site (vascular targeting) from which are released second-stage particles. The internalization rate is affected by the geometry of the particle and the ligand–receptor bonds involved.

Freund and colleagues [119] developed a mathematical model for receptor-mediated endocytosis based on an energetic analysis. This showed that a threshold particle radius R_{th} exists, below which endocytosis could never occur and, that an optimal particle radius R_{opt} exists, slightly larger than R_{th}, for which internalization is favored with the maximum internalization rate, thus confirming (in theory) the above-cited experimental observations. This analysis was then generalized to account for the contribution of the surface physico-chemical properties that may dramatically affect the internalization process, changing significantly both R_{opt} and R_{th} (Figure 3.10), as shown by Decuzzi and Ferrari [114].

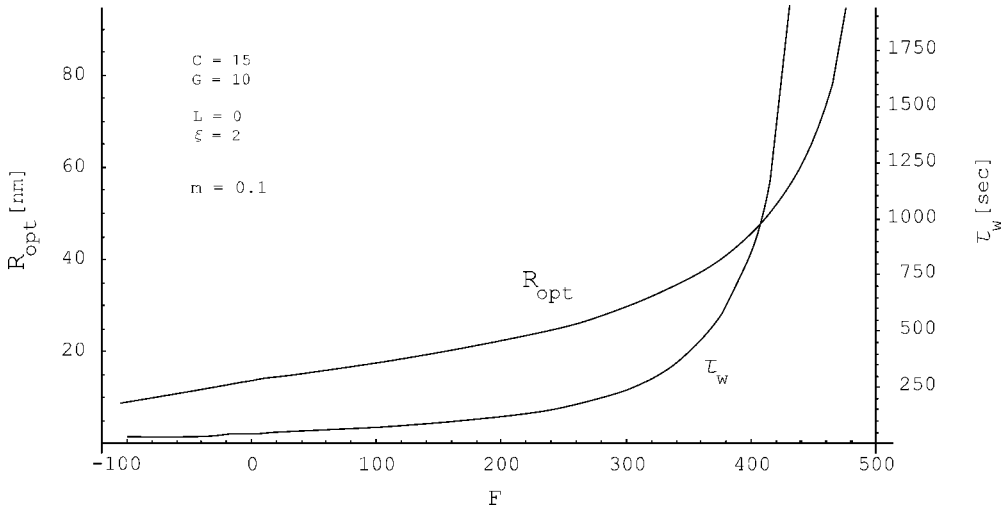

Figure 3.10 The optimal radius R_{opt} and the wrapping time τ_w as a function of the nonspecific parameter F, growing with the repulsive nonspecific interaction at the cell–particle interface.

A more recent theoretical model has been developed by Decuzzi and Ferrari for the receptor-mediated endocytosis of nonspherical particles [120]. This shows how elongated particles laying parallel to the cell membrane are less prone to internalization compared to spherical particles or particles laying normal to the cell membrane. The results show clearly how particle size and shape can be used to control the internalization process effectively, and that particles that deviate slightly from the spherical shape are more easily internalized compared to elongated particles that deviate severely from the classical spherical shape.

Even in the case of particle internalization, a judicious combination of surface physico-chemical properties and particle geometry would lead to a particle with optimized internalization rates, depending on the final biological applications.

Finally, a mathematical model has been recently developed [121] that allows one to predict the adhesive and endocytotic performances of particulate systems based on three different categories of governing parameters: (i) geometric (radius of the particle); (ii) biophysical (ligand-to-receptor surface density ratio; nonspecific interaction parameter; hydrodynamic force parameter); and (iii) biological (ligand–receptor binding affinity). This finding has led to the definition of *Design Maps* through which the three different states of the particulate system can be predicted: (i) no adhesion at the blood vessel walls; (ii) firm adhesion with no internalization by the endothelial cells; or (iii) firm adhesion and internalization (Figure 3.11) [121].

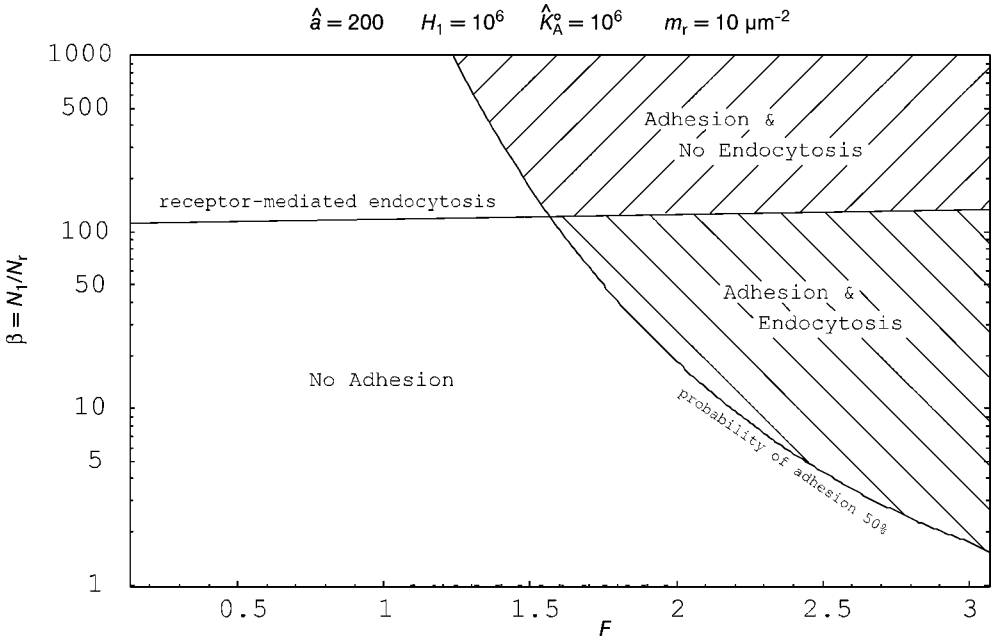

Figure 3.11 A typical design map showing areas for no adhesion; adhesion and no endocytosis; and adhesion and endocytosis [121].

3.7
The Biology, Chemistry and Physics of Nanovector Characterization

The small size, unique physico-chemical properties, and biological activity of nanoparticles create the need for extensive characterization prior to their use in biomedical applications. The National Cancer Institute has established the Nanotechnology Characterization Laboratory (NCL) to standardize and perform preclinical characterizations of nanomaterials designed for cancer therapeutics and diagnostics [122]. The objectives of the NCL are to speed the development of nanotechnology-based products for cancer patients, while reducing the risk to inventors, as well as encouraging private-sector investment. A further aim is to establish an analytical cascade of protocols for nanomaterial characterization. Challenges to creating standardized characterization techniques include the wide variety of materials used to construct nanomedicines. Thus, the characterization strategy is broad and includes physico-chemical characterization, sterility and pyrogenicity assessment, biodistribution (absorption, distribution, metabolism, excretion) and toxicity, both *in vitro* and *in vivo* in animal models [123]. An examination of the biological and functional characteristics of multicomponent/combinatorial platforms is also addressed.

NCL's standardized analytical cascade includes tests for preclinical toxicology, pharmacology and efficacy. The protocols include assays for physical attributes; *in vitro* testing for toxicity or biocompatibility; and *in vivo* testing for safety, efficacy and toxicokinetic properties in animal models (Figure 3.12).

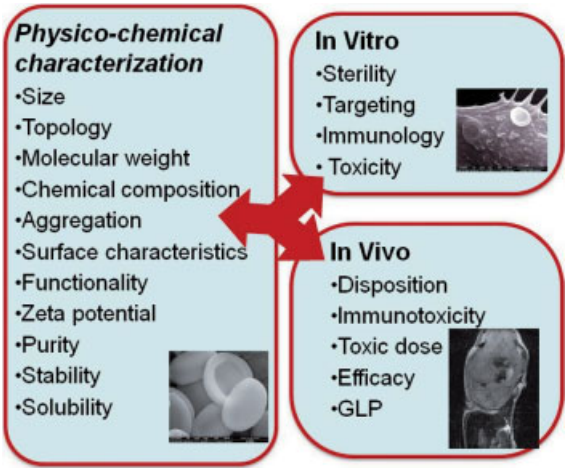

Figure 3.12 Preclinical characterization of nanoparticles involves physico-chemical, *in vitro* and *in vivo* characterization. The list includes assays outlined by the National Cancer Institute Nanotechnology Characterization Laboratory.

3.7.1 Physical Characterization

Physical characterization includes assays for particle size, size distribution, molecular weight, density, surface area, porosity, solubility, surface charge density, purity, sterility, surface chemistry and stability. The mean particle size – that is, the hydrodynamic diameter – is determined by batch-mode dynamic light scattering (DLS) in aqueous suspensions. Care must be taken with these measurements, because they can be affected by other parameters. For example, precautions include the cleaning of cuvettes with filtered, demineralized water; media filtering with 0.1 μm pore size membranes and pre-rinsing cuvettes multiple times; scattering contributions by media in the absence of analyte; optimized sample concentration; and filtering samples in conjunction with loading into the cuvette. The sample concentration should be optimized to avoid signal-to-noise ratio (SNR) deterioration at low concentration and particle interactions and scattering effects at high concentration. Another precaution is to add only small amounts of monovalent electrolyte in order to avoid salt effects on the electrical double-layer surrounding the particles in the media. Again, concentration optimization is necessary for optimal measurements. In order to evaluate instrument performance, latex size standards are commercially available. When analyzing these data, the absolute viscosity and refractive index for the suspending media is required to calculate the hydrodynamic diameter.

3.7.2 *In Vitro* Testing

In vitro testing includes the assessment of sterility, targeting, *in vitro* immunology and toxicity testing. Sterility testing for contaminates includes monitoring for the presence of endotoxins, bacteria, yeast, molds and mycoplasm. As an example, the LAL (limulus amoebocyte lysate) assay is commonly used to test for the presence of bacterial endotoxin. Although standard immunological *in vitro* assays exist, the preclinical immunotoxicity testing of nanoparticles has been hampered due to interference by the nanoparticles within the assay. Whilst a variety of mechanisms of interference exists, the most common occurrences are light absorbance by nanoparticles (which interfere with colorimetric methods) and the catalytic properties of nanoparticles creating false-positive effects in enzyme assays [122].

In vitro targeting assays measure cell binding and the internalization of particles (Figure 3.13). This is particularly relevant for drug delivery systems, as the route of internalization dictates the subcellular localization of nanoparticles. As an example, caveolar-mediated uptake leads to nanoparticles being localized into organelles with a nonacidic pH [124], whereas clathrin-mediated uptake favors their lysosomal entrapment [125], the latter leading to drug degradation. The uptake of larger particles (typically >500 nm) generally occurs by phagocytosis [126, 127]. Phagosomes typically fuse with endosomes, leading to lysosomal accumulation [126]. Common targeting assays include confocal microscopy, transmission and scanning electron microscopy, flow cytometric analysis and quantitative assessment assays (e.g. the BCA protein

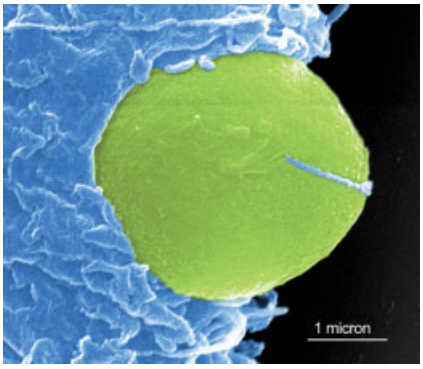

Figure 3.13 Pseudocolored scanning electron microscopy image of an endothelial cell internalizing a nanoporous silicon particle.

assay to assess PLGA uptake [128]). Both, fluorescence microscopy and flow cytometry rely on the attachment of fluorescent probes to the nanoparticle; alternatively, the latter technique may rely on changes in light scattering caused by the presence of internalized nanoparticles [127]. Controls are always essential to ensure that any intracellular fluorescence is not due to the uptake of dye that might have been released from the particles [128]. Factors affecting nanoparticle uptake include nanoparticle concentration, incubation time, nanoparticle size and shape and culture media.

For multicomponent systems, targeting may be difficult to access *in vitro*, especially for systems composed of nested particles, where each particle is targeting a specific and discrete population. Additional problems arise due to the modification of particles with imaging agents. For example, the conjugation of fluorescent probes to the surface of particles alters the surface charge density of the particle, and may also mask the binding of ligands on the particle surface. This in turn alters the ability of particles to bind to the cell-surface receptors that are responsible for their uptake. *In vitro* targeting assays also need to emphasize the impact of serum opsonization on particle uptake [127]. Serum components are signals for immune cells, and may either activate cells or serve as bridges attaching particles to cells. For example, antibodies found in serum may bind to particles and mediate their uptake via Fc receptors found on specific cell populations. The end result is dramatic, however, and may even completely alter which cell populations are able to internalize the particles.

To date, research investigations have shown that nanoparticles can stimulate and/or suppress the immune response [129]. Compatibility with the immune system is affected to a large degree by the surface chemistry. The cellular interaction of nanoparticles is dependent on either their direct binding to surface receptors or binding through the absorption of serum components to particles and their subsequent interaction with cell receptors [127]. Blood-contact properties of the nanomaterial and cell-based assays are used to determine the immunological compatibility of the device.

The blood-contact properties of nanoparticles are characterized by plasma protein binding, hemolysis, platelet aggregation, coagulation and complement activation.

- Plasma protein binding is achieved using two-dimensional gel electrophoresis, with individual proteins being evaluated by mass spectrometry. A drawback here is the need for 1 mg of nanoparticles to complete the assay.
- Hemolysis is assayed by a quantitative colorimetric determination of hemoglobin in whole blood, with the end result expressed as percentage hemolysis.
- Platelet aggregation is expressed as the percentage of active platelets per sample compared to a control baseline sample determined using a Z2 Coulter counter for the analysis of platelet-rich plasma.
- Multiple tests are used to assess the effect of nanoparticles on plasma coagulation, including prothrombin time.
- Complement activation is measured initially by the qualitative determination of total complement activation by Western blot. Anti-C3 specific antibodies recognize both native C3 and its cleaved product, which is a common product of all three complement activation pathways. Positive results elicit additional assays aimed at determining the specific complement activation pathway.

In vitro immunology assays also include cell-based assays including colony-forming units-granular macrophages (CFU-GM), leukocyte proliferation, macrophage/neutrophil function and cytotoxic activity of natural killer (NK) cells. The effect of nanoparticles on the proliferation and differentiation of murine bone marrow hematopoietic stem cells (HSC) is monitored by measuring the number of colony forming units (CFU) in the presence and absence of nanoparticles. The effect of nanoparticles on lymphocyte proliferation is determined in similar manner. The ability of nanoparticles to either induce or suppress proliferation is measured and compared to control induction by phytohemaglutinin. Macrophage/neutrophil function is measured by the analysis of phagocytosis, cytokine induction, chemotaxis and oxidative burst. Similar to earlier targeting studies, nanoparticle internalization is measured, but with respect to classical phagocytic cells rather than to the target populations. A current phagocytosis assay utilizes luminol-dependent chemiluminescence, although alternative detection dyes must be used for nanoparticles that interfere with measurements. Cytokine production induced by nanoparticles is measured using white blood cells isolated from human blood. Following particle incubation, the cell culture supernatants are collected and analyzed for the presence of cytokines, using cytometry beads. The chemoattractant capacity of nanoparticles is measured used a cell migration assay; here, cell migration through a 3 μm filter towards test nanoparticles is quantitated using a fluorescent dye. The final measure of macrophage activation is a measure of nitric oxide production using the Greiss reagent. NK-mediated cytotoxicity can be measured by radioactive release assays, in which labeled target cells release radioactivity upon cytolysis by NK cells. A new label-free assay known as 'xCELLigence' (available from Roche) is used to measure the electrical impedance of cells attached to the bottom of a microtiter plate containing cell sensor arrays. In this system, any changes in cell morphology, number, size or attachment are detected in real time.

3.7.2.1 *In Vitro* Toxicity Testing

Standard assays for toxicity assess oxidative stress, necrosis, apoptosis and metabolic stability. Oxidative stress is quantified as a measure of glutathione (GSH) reduction, lipid peroxidation and reactive oxygen species (ROS) in cells treated with nanoparticles. These are measured using colorimetric and fluorescence assays. Cytotoxicity can be measured by using two assays: reduction of 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT); and lactate dehydrogenase (LDH) release. The degree of caspase-3 activation is also used as a measure of cytotoxicity as it is an indicator of apoptosis. Assays for metabolic stability include cytochrome P450 (CYP450) and glucuronidation.

3.7.3 *In Vivo* Animal Testing

The final category of assays relies on *in vivo* animal testing. Under this umbrella are included disposition studies, immunotoxicity, dose-range-dependent toxicity and efficacy. The initial disposition of nanoparticles is dependent upon tissue distribution, clearance, half-life and systemic exposure. In the NCL regime, immunotoxicity is measured as a 28-day screen and by immunogenicity testing (repeat-dosing). Dose-dependent toxicity can be evaluated by monitoring blood chemistry, hematology, histopathology and gross pathology. Depending on the nature of the delivery system, the efficacy is measured either by imaging or by therapeutic impact.

One possible route of nanoparticle exposure within the work environment is that of *inhalation*, which in turn creates a need for additional studies that include animal inhalation and intratracheal instillation assays [130, 131]. These additional studies also illicit the need for even more characterization studies, such as determining the dispersion properties of nanoparticles. Hence, new methods to determine not only hazard and risk assessments but also therapeutic efficacy continue to be developed as new areas of concern arise. The careful characterization and optimized bioengineering of both nanoparticles and microparticles represent key contributors to the generation of nanomedical devices with optimal delivery and cellular interaction features.

3.8 A Compendium of Unresolved Issues

Unresolved issues and opportunities live in symbiosis. Programmatically, we welcome even the most daunting challenges, as their mere identification as such – not a simple task in most cases, and invariably one that requires the right timing and knowledge maturation – frequently happens when solutions are conceivable, or well within the reach of the scientific community. With this essentially positive outlook we will list in this section some questions that appear daunting at this time, but are starting to present themselves with finer detail and resolution, indicating in our mind that readers in a few years, if any, will find them to be essentially resolved, and the

value of this section, if any, to be basically that of a message in a bottle across the seas of time – and reading patience.

1. The key issue for all systemically administered drugs (nanotechnological, biological, and chemotherapeutical alike) is the management of biological barriers. Biological targeting is always helpful, under the assumption that a sufficient amount of the bioactive agent successfully navigates the sequential presentation of biological barriers. This is a very stringent and daunting assumption – essentially the success stories of the pharmaceutical world correspond to the largely serendipitous negotiation of a subset of biological barriers, for a given indication, and in a sufficiently large subset of the population. The third-generation nanosystems described above are but a first step toward the development of a general, modular system that can systematically address the biological barriers in their sequential totality. We certainly expect that novel generations, and refinements of nanovector generations 1–3 will be developed, to provide a general solution to the chief problem of biobarriers and biodistribution-by-design.

2. There is no expectation that any single, present or future biobarrier management vectoring system will be applicable to all, or even to most. Personalization of treatment is the focus of great emphasis worldwide – with overwhelming bias toward personalization by way of molecular biology. The vectoring problem, on the other hand, is a combination of biology, physics, engineering, mathematics, and chemistry – with substantial prevalence of the non-biological components of vector design. The evolution of nanotechnologies makes it conceivable, that personalization of treatment will develop as combination of biological methods, and vector design based on non-biological sciences. Foundational elements of mathematics-based methods of rational design of vectors were disclosed in the preceding chapters. The missing link to personalized therapy at this time is the refinement of imaging technologies that can be used to identify the characteristics of the target pathologies – lesion-by-lesion, at any given time, and with the expectation that a time evolution will occur – providing the basis for the synthesis of personalized vectors, which may then carry bioactive agents that may be further personalized for added therapeutic optimization. The word 'personalization' does not begin to capture the substance of this proposition; perhaps 'individualization' is a better term, with the understanding that treatment would individualize at the lesion level (or deeper) in a time-dynamic fashion, rather than at the much coarser level of a individual patient at a given time.

3. Hippocrates left no doubt that safety is first and foremost. The conjoined twin of personalized treatment by biodistribution design is the adverse collateral event by drug concentration at unintended location. Safety – and the regulatory approval pathways that are intended to ensure it – in a more advanced sense that the current observation of macroscopic damage requires an accurate determination of the biodistribution of the administered agents. This would be an ideal objective for all drugs, to be sure, but arguably an impossible one in general. Here is where a challenge turns into an opportunity for the nanomedicine: The ability of nanovectors

to be or carry active agents of therapy, while at the same time be or carry contrast agents that allow the tracking and monitoring of their biodistribution in real time provides the nanopharmaceutical world with a unique advantage. Alas reality at this time smiles much less than this vision would entail: In general it proves very difficult at this time to comprise or conjugate nanovectors with contrast agents or nuclear tracers in a manner that is stable in-vivo. Forming a construct that will not separate in their components once systemically administered is a difficult general conjugation chemistry proposition. Less than total success at it means that what is being tracked may be the label rather than the vector or the drug. The problem becomes combinatorially more complex with increasing numbers of nanovector components. Another facet of the same problem is that frequently the conjugation of labels, contrast agents or tracers dramatically alters biodistribution with respect to the construct that is intended for therapeutic applications. One strategic recommendation that naturally emerges for the immediate future is to prioritize nanovectors that are themselves easily traceable with current radiological imaging modalities.

4. Again in common with all drugs, the development and clinical deployment of nanomedicines would greatly benefit from the development of methods for the determination of toxicity and efficacy indicators from non-invasive or minimally invasive procedures such as blood draws. Serum or plasma proteomics and peptidomics are a promising direction toward this elusive goal. The challenge-turned-into-competitive advantage for nanomedicine is in the ability of nanovectors to carry reporters of location and interaction, which can be released into the blood stream and collected therefrom, to provide indications of toxicity and therapeutic effect.

5. Individualization by rational design of carriers together with biological optimization of drug – both informed by imaging and biological profiling – are a dimension of progress toward optimal therapeutic index for all. Another dimension is in the time dynamics of release: the right drug at the right place at the right time is the final objective. With their exquisite control of size, shape, surface chemistry and overall deign parameters, nanovectors are outstanding candidates for controlled release by implanted (nano)devices or (nano)materials; yet another case of challenge turned opportunity, and of synergistic application of multiple nanotechnologies to form a higher generation nanosystem.

6. The last and perhaps most important challenge ahead – and a wide, extraordinarily exciting prairie of opportunities for rides of discovery – is the generation of novel biological hypotheses. With the higher-order nanotechnologies in development, it is possible to reach subcellular target A with nanoparticle species X at time T, and in the same cell and from the same platform then reach subcellular target B with nanoparticle species Y at subsequent time T′. What therapeutic advantages that may bring, for the possible combinations of A, B, X, Y, T and T′ (and extensions-by-induction of the concept) is absolutely impossible to fathom at this time. There is basically little is any science on it – and of course that is the case, since the technology that permits the validating experiment is in its infancy at this time. The

growth of the infant must be accompanied by the co-development of the biological sciences that frame the missing hypotheses and turn their investigation into science. We respectfully suggest that this would change the course of medicine.

4.1
Introduction

Genome-sequencing projects continue to provide complete genetic descriptions of an ever-increasing number of model organisms [1–4]. Based on our current knowledge, it has been estimated that life depends on 200–300 core biological processes [5]. Individual gene products rarely function independently; to the contrary, large multicomponent protein assemblies are more often responsible for complex cellular functions. These assemblies are often dynamic and, in many cases, transient. As such, these assemblies are often termed 'molecular nanomachines', capable of carrying out a wide range of functions through often specific and highly intricate interactions [6–10].

Equally as complex as the nanomachines themselves, the individual components can adopt a wide variety of morphologies, functions and interactions. In addressing these complexities, structural genomics seeks to provide a description of all protein folds, where a fold is defined as the three-dimensional (3-D) structure of protein that relates the spatial arrangements and connectivity of secondary structure elements, such as α-helices and β-sheets. As such, the protein fold represents the basic 'building block' of much larger and more complex assemblies that carry out biochemical and cellular processes. To date, more than 51 000 individual protein structures are known [11]; however, far fewer unique folds are recognized.

It is generally accepted that the primary structure of a protein – the amino acid sequence – dictates its 3-D structure, or fold. As such, proteins with a similar primary sequence likely assume similar folds. However, the converse is not necessarily true; proteins with vastly dissimilar sequences can assume similar folds. Nonetheless, the protein fold is ultimately responsible for the necessary 3-D environment for protein function and intermolecular and intramolecular interactions. The description of these folds – and, in particular, their interactions within cellular complexes – is therefore paramount to the understanding of all molecular nanomachines and biological processes.

ISBN: 978-3-527-31736-3

Electron cryomicroscopy (cryo-EM) is an emerging methodology that is particularly well suited for studying molecular nanomachines at near-native or chemically defined conditions. Cryo-EM can be used to study nanomachines of various sizes, shapes and symmetries, including two-dimensional (2-D) arrays, helical arrays and single particles [12]. With recent advances, cryo-EM can now not only reveal the gross morphology of these nanomachines but also provide highly detailed models of protein folds approaching atomic resolutions [13–17]. In this chapter, we will present the methodology of single-particle cryo-EM, as well as its potential biomedical applications and future prospects.

Complementary to structural studies of nanomachines with cryo-EM, the application of cryo-tomography (cryo-ET) can depict the locations and low-resolution structures of nanomachines in a 3-D cellular environment. The power of cryo-ET comes from its unique ability to observe directly biological nanomachines *in situ*, without the need for isolation and purification. This approach has the potential to capture the structural diversity of nanomachines in their milieu of interacting partners and surrounding cellular context.

4.2
Structure Determination of Nanomachines and Cells

Figure 4.1 shows a series of typical steps in imaging nanomachines using cryo-EM or cryo-ET. The first steps are common to both techniques; biochemical preparation, specimen preservation via rapid freezing; and imaging the frozen, hydrated specimens by low-dose electron microscopy. Although the subsequent steps differ for the two techniques, they both include image processing to generate a 3-D reconstruction, interpreting the 3-D volume density together with other biological data and archiving the density maps and models. In this chapter we will not address how to perform each of the aforementioned mentioned steps, as numerous technical reports and books exist that describe them in detail [12, 18]. Rather, we will briefly summarize these steps and their applications to a few examples of molecular nanomachines and cells.

4.2.1
Experimental Procedures in Cryo-EM and Cryo-ET

In principle, most of these steps are rather straightforward, and the length of time taken to start from a highly purified nanomachine to obtaining a complete structure can range from a few days to months. However, as with any experimental method, various hurdles may be encountered that require further optimization before a reliable structure can be determined.

4.2.1.1 Specimen Preparation for Nanomachines and Cells

Specimen preparation is a critical step in single-particle cryo-EM, which necessarily requires high conformational uniformity while preserving functional activities. In X-ray crystallography, crystallization is a selective process through which only

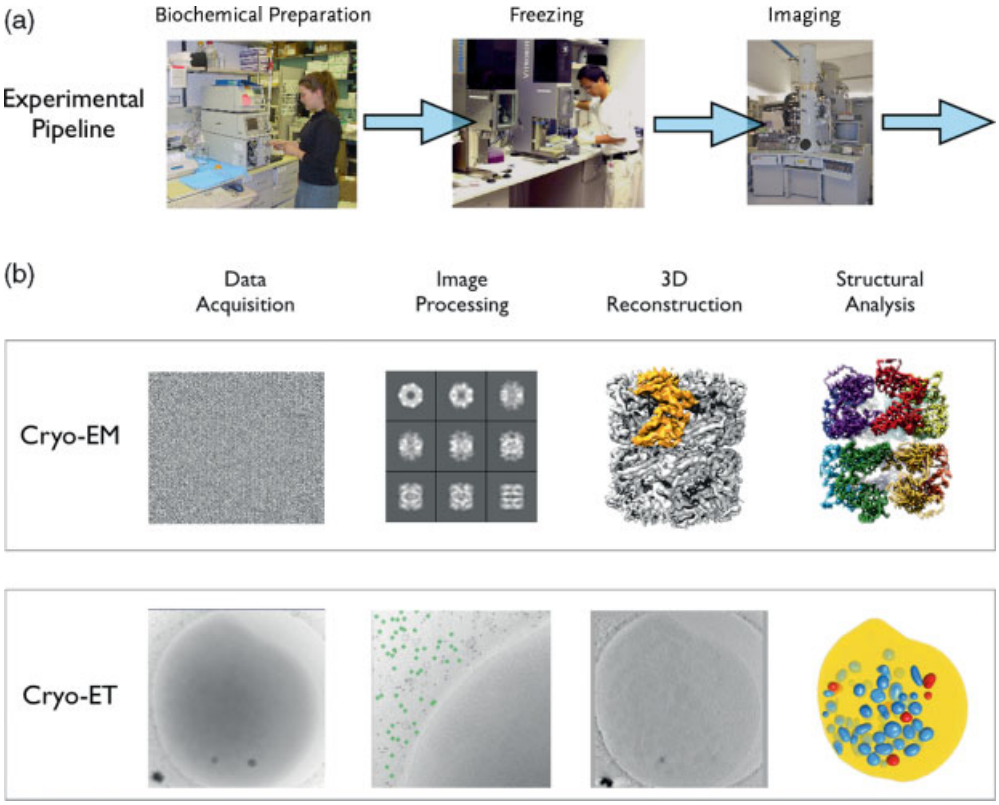

Figure 4.1 The experimental pipeline for cryo-imaging experiments. (a) The first steps of the experiment – specimen preparation, specimen freezing and microcopy – are common to both cryo-EM and cryo-ET; (b) The subsequent steps diverge and differ between the two types of experiments. For cryo-EM, these steps are illustrated with examples of the biological nanomachine GroEL. For cryo-ET, they are illustrated with a cell, the human platelet.

molecules of the same conformations nucleate and crystallize to form a diffracting object. In addition to chemical purification, crystallization also forces the molecules into specific, uniform spatial organization such that diffraction data can be averaged from over billions of molecules in identical conformations. However, cryo-EM experiments image one set of molecules at a time, regardless of their conformations, and thus possibly represents an ensemble of conformations of the molecules in a single micrograph. In order to obtain the highest possible resolution structures by cryo-EM, it is still necessary to computationally average from several hundreds to tens of thousands of a conformationally homogeneous set of particle images recorded in multiple micrographs. Nevertheless, computational methods are being developed to sort out images of particles with different conformations.

The nature of cryo-ET experiments differs substantially from single-particle cryo-EM experiments, and the resolution of the reconstructions is much lower. In contrast to the cryo-EM approach, where images of many conformationally

uniform particles are merged to yield a 3-D model, cryo-ET merges many images of the same specimen target, collected at different angles. With this approach, a reconstruction can be computed from the images of a single cell or nanomachine, and so conformational uniformity is not an issue in the most general case. The merging of whole cells or organelles such as single particles is not a reasonable goal, as uniformity can never realistically be expected; however, some subcelluar structures may be sufficiently uniform in conformation to warrant merging and averaging from the 3-D tomogram. Below, we consider such an example when discussing the bacterial flagella motor.

4.2.1.2 **Cryo-Specimen Preservation**

Following biochemical isolation and purification, the first step in a cryo-imaging experiment is to embed a biochemically purified nanomachine or cell under well-defined chemical conditions in ice on a cryo-EM grid [19]. This freezing process is extremely quick in order to prevent the formation of crystalline ice, and thus produces a matrix of vitreous ice in which the water molecules remain relatively unordered. The spread of the nanomachines on the grid should be neither too crowded, such that they would contact each other, nor too dilute as to only have a few nanomachines recorded in each micrograph. For cryo-EM, it is preferable to have the nanomachines situated in random orientations to allow sufficient angular sampling needed for the subsequent 3-D reconstruction procedure. The ideal thickness of the embedding ice is slightly greater than the size of the nanomachine or cell. Excessive ice thickness is detrimental because it diminishes the signal-to-noise ratio (SNR) of the images that can be acquired. Ice that is too shallow can be a problem for cryo-ET experiments, whereby flattening of the specimen can occur. The capillary forces of the solvent, in the fluid phase just prior to vitrification, can compress the sample; this has been reported in vesicles [20] as well as real cells where a 1 μm-thick cell can be reduced to 600 nm [21, 22].

Some specimens are very easy to prepare, while others are more difficult, which necessarily means optimization of the specimen preparation is a trial-and-error process. In general, this step – the preparation of the frozen, hydrated specimens, preserved in vitreous ice with an optimal ice thickness – is often a bottleneck. Analogous to the crystallization process in X-ray crystallography, there is no foolproof recipe for optimal specimen preservation. However, a computer-driven freezing apparatus has made this step more reproducible and tractable in finding optimal conditions for freezing a given specimen [23].

In principle, the frozen, hydrated specimens represent native conformations as they are maintained in an aqueous buffer. Fixation of the nanomachines in a specific orientation can occur prior to freezing. Specimen freezing can also be coordinated with a time-resolved chemical mixing reaction; prototype apparatuses have been built to perform such a time-resolved reaction [24, 25]. It is conceivable that a more sophisticated instrument can be built to allow all sorts of chemical reactions, including those that can be light-activated. Such an approach would allow cryo-EM to follow the structure variations in a chemical process with a temporal resolution of milliseconds [25].

4.2.1.3 Low-Dose Imaging

Once the sample has been frozen, the entire cryo-EM grid can be inserted into the electron cryo-microscope and imaged with electrons ranging from 100 to 400 keV. Electrons at these energies will damage the molecules during imaging [12]. Therefore, low-dose imaging is necessary to minimize the damage to the specimen before the image is recorded. To maintain the frozen, hydrated specimen in vitreous ice inside the electron microscope vacuum, the specimen is kept at low temperature, typically at or below liquid nitrogen temperature. If the specimen temperature is higher than $-160\,^{\circ}C$, the vitreous ice undergoes a phase transition to crystalline ice and denatures the nanomachines [19].

From a radiation damage perspective, the advantages and disadvantages of keeping biological specimens at different low temperatures have been studied [26–28]. High-quality images have been obtained using liquid helium temperature, and have resulted in high-resolution structures of 2-D crystals [29, 30], helical arrays [31, 32] and single particles [13, 14] where protein backbone traces were feasible. Imaging specimens at liquid nitrogen temperature has also been used successfully for the similar high-resolution structure determination of a broad spectrum of specimens [15, 17, 33, 34]. In the case of cellular cryo-ET, it has been suggested that liquid nitrogen is a preferred temperature [27, 35] because of a significant loss of contrast at liquid helium temperature [36].

4.2.1.4 Image Acquisition

Data collection differs significantly for cryo-EM and cryo-ET. For cryo-EM, images of a field containing multiple, randomly oriented specimens are recorded. Individual particles are recorded only once because of the radiation damage constraints for obtaining the highest possible resolution information. For cryo-ET, a series of images of the same specimen is acquired as the stage is iteratively tilted over an interval spanning approximately 130°. A typical tilt-series might include one image collected every 2° between -65° and $+65^{\circ}$. The resolution of the tomographic data is much lower because of the effects of cumulative radiation damage to the specimen throughout the data collection.

For cryo-EM and cryo-ET experiments, images have been traditionally collected on photographic film and subsequently digitized using a high-resolution film scanner. Recent advances in CCD cameras for electron microscopes have made direct digital recording feasible [37–39]. With a modern electron microscope equipped with specialized software for low-dose imaging, data collection is relatively simple and can be either partially or fully automated [40–43].

4.2.2 Computational Procedures in Cryo-EM and Cryo-ET

The recorded image of a nanomachine is essentially a projection (2-D) of its mass density along the path of the irradiating electrons. In order to retrieve its 3-D structure, the particle must be sampled in different angular views [44]. For cryo-ET, this sampling is carried out systematically whereby each image in the tilt-series

constitutes a separate angular view. With cryo-EM, the varied orientation of particles in the ice naturally provides an angular distribution of views. The number of views required for the reconstruction is proportional to the diameter of the particle and is inversely proportional to the desired resolution [45]. Because of the noisy nature of the image and the uneven angular distribution (in the case of cryo-EM) of the views, the actual number of the particles used to calculate a reconstruction at a certain resolution is much higher than the theoretical minimum [46, 47]. Ideally, the particles embedded in the vitreous ice are oriented randomly. However in some cases, the particles tend to assume a preferred orientation with respect to the surface of the embedding ice. This can often be overcome by varying the buffer or solvent by adding a small amount of detergent.

4.2.2.1 Image Processing and Reconstruction

During the image-processing phase, individual specimen images are aligned with respect to each other and then combined to form a 3-D density map [18, 48, 49]. For cryo-EM studies, the image processing is an iterative process. Several image-processing packages are available for single-particle cryo-EM, such as EMAN [50], SPIDER [51], IMAGIC [52] and Frealign [53]; these are multi-step procedures that can generally be broken into the following steps: (i) identify the locations of each particle; (ii) determine and correct the contrast transfer function and damping function for the particle images; (iii) classify the images according to their conformational identity and orientation parameters; and (iv) average the particle images in each classes and 3-D reconstruct to produce the final 3-D map. The specimen classification, particle averaging and reconstruction of the density map are iterated using the previous iteration as a reference. Iteration of these steps continues until no improvement in the 3-D density maps is made over the previous cycle of refinement. The final resolution of the map is typically assessed by a parameter referred to as Fourier shell correlation (FSC), in which two maps derived from two independent sets of image data are compared [54]. The FSC essentially measures a similarity and reproducibility of two structures in Fourier space; the final resolution is often determined using the 0.5 criterion.

Alignment and reconstruction differ for cryo-ET experiments. For cryo-ET, the nominal angular assignment is known for each image because the tilt-angle of the stage was recorded for each image of the tilt-series. Higher-precision angular assignments must be determined for reconstruction. Alignment processing is frequently simplified by including gold particles in the specimen; these particles have a strong contrast, even under low-dose imaging conditions, and serve as landmarks for registering images with respect to each other [55–57]. Once aligned, the images are then recombined directly by a reconstruction algorithm such as weighted back-projection [58, 59]. Many academically developed processing packages are available that will compute the alignment and reconstruction [60–63]. Although there is no community-accepted convention for assessing the resolution of tomographic reconstructions, a number of statistical approaches have been proposed [64].

4.2.2.2 Structure Analysis and Data Mining

In order to analyze the cryo-EM density maps of large, complex nanomachines, a number of tools have been developed that range from feature detection to domain localization. Perhaps the most well-developed set of tools for the analysis of cryo-EM density maps are those aimed at fitting known crystal or NMR structures to density maps. These tools range from simple rigid-body fitting to complex and dynamic flexible fitting algorithms (for reviews, see Refs [65, 66]). Regardless, each of these tools requires that the structures of a known domain or closely related domain are known.

Recent studies have also shown that cryo-EM density is sufficient for discriminating good models from a gallery of potential structures [67, 68]. In particular, cryo-EM density has been incorporated as a scoring function in a constrained homology modeling approach [69]. As with the aforementioned fitting routines, this approach relies on the availability of a known structure from which a sequence/structure alignment is produced. In the case where a suitable structural template is not known, a constrained *ab initio* modeling approach has also been developed in which the cryo-EM density can be used directly to screen a large gallery of potential models [67]. While no structural template is needed, this approach is restricted to relatively small (<200 amino acids), single-domain proteins.

At subnanometer resolutions, secondary structure elements become visible; α-helices appear as long density rods, while β-sheets appear as thin surfaces [70–73]. By using a variety of feature detection and computational geometry algorithms, secondary structure elements can be reliably identified and quantified [71, 72, 74, 75]. The spatial description of such elements has been used not only to describe protein structure, but also to infer structure and function of individual protein domains [70, 76].

Until recently, the resolution of cryo-EM density necessitated the use of the aforementioned approaches for understanding macromolecular structure and function. Several cryo-EM structures have now achieved resolutions better than 4.5 Å resolution, at which point the pitch of α-helices, separation of β-strands, as well as the densities that connect them, can be seen unambiguously with no reference to crystal structure [13, 14, 17]. In addition to these features, many of the bulky side chains could also be seen. However, it should be noted that these structures still do not have the resolution to utilize standard X-ray crystallographic methods for model construction. However, several *de novo* models have now been constructed directly from these high-resolution cryo-EM density maps using mostly manual assignment and visualization tools [13, 14, 17].

The annotation of cryo-ET maps is a different process because the goals of tomographic imaging are substantially different. Rather than trying to determine high-resolution protein structures, cryo-ET experiments are often focused on how the components of cells or nanomachines are spatially organized. *Segmentation* is a process by which the salient features of the reconstruction of an individual cell or nanomachine are traced. A segmented map hides the noisy data and highlights the structural findings. Tools for segmentation of tomograms include the academic IMOD package [60] and the commercial package Amira (Mercury Systems, Chelmsford, MA, USA). Unfortunately, this is a laborious manual process for which no suitable general-purpose automated routine has been advanced (for a review, see

Ref. [77]). Manual segmentation is applied by annotating one cell or nanomachine at a time. As a research study might require the annotation of many cells or nanomachines, this can drastically increase the time required to annotate the results. In cases where there are uniform nanomachines (e.g. ribosomes) present, these can be computationally identified, extracted and merged to improve the resolution (for a review, see Ref. [78]).

4.2.3 Data Archival

The result of a cryo-EM experiment is typically a 3-D density map with multiple domains and/or models used to annotate the structure and function of the molecular nanomachine. In reaching this model, multiple intermediate data sets and image processing workflows are produced. Databases, such as EMEN [79] and others [80, 81], function on a laboratory scale and can house the final 3-D density maps and model, as well as the original specimen images and all of the intermediate data and processes. The final density map, models and associated metadata can also be deposited in public repositories such as the electron microscopy databank (EMDB) and the protein databank (PDB) [82]. Individual cryo-EM structures are easily retrieved through accession numbers or IDs directly from publicly accessible websites.

4.3 Biological Examples

Cryo-EM is a powerful technique in that it can be used to image a wide variety of specimens under an equally wide array of conditions. Despite the lack of atomic resolution, these structures can provide unprecedented views of the structure and function of molecular nanomachines. In the following sections, we describe two very different samples, and how cryo-EM has provided us with a unique glimpse into their organization. It should also be noted that each of these samples are complex nanomachines that undergo dynamic structural and functional processes in carrying out their intended functions.

The resolution of cryo-EM models is considerably better than that of cryo-ET models, mainly because the heterogeneous cryo-ET particles are rarely suitable for averaging. Even when they are, the average may be the sum of tens to hundreds from extracted tomograms rather than the thousands to millions of asymmetric units in a single-particle reconstruction that contribute to a cryo-EM model. Despite the lower resolution, tremendous insight may still be gained from the cellular context, as evidenced by the two cryo-ET examples presented here.

Both, cryo-EM and cryo-ET offer unique views of nanomachines, and as such integrating the two approaches can generate multiresolution models where a tomogram establishes a low-resolution survey of a cell, and the individual machines in that model are the product of cryo-EM studies. This integrated approached is demonstrated in our last example.

4.3.1
Skeletal Muscle Calcium Release Channel

Ryanodine receptor (RyR1) is a 2.3 MDa homotetramer that regulates the release of Ca^{2+} from the sarcoplasmic reticulum to initiate muscle contraction (for a review, see Ref. [49]). Figure 4.2a shows the 9.6 Å resolution cryo-EM density map of RyR1 reconstructed from ~28 000 particle images (Figure 4.2b) [83]. In this map, the structural organization, including the transmembrane and cytoplasmic regions for each monomer, as well as domains within individual monomers can be clearly seen.

A structural analysis of the RyR1 map using SSEHunter [71] revealed 41 α-helices, 36 in the cytoplasmic region and five in the transmembrane region, as well as seven β-sheets in the cytoplasmic region of a RyR1 monomeric subunit (Figure 4.2c). Interestingly, a kinked inner, pore-lining helix and a pore helix in the transmembrane region bears a remarkable similarity to those of the MthK channel [84]. β-Sheets located in the constricted part that connect the transmembrane and cytoplasmic regions have been seen in the crystal structures of inward rectifier K^+ channels (Kir channels) [85, 86] and a cyclic nucleotide-modulated (HCN2) channel [87]. In Kir channels, this β-sheet has been proposed to form part of the cytoplasmic pore, which is connected to the inner pore. Therefore, this region in the RyR1 may play a role in regulating the ions by interacting with cellular regulators which are yet to be determined.

While there is no crystal structure from any domain or region of RyR1, a homologous domain from the IP3 receptor is known. Using the aforementioned cryo-EM constrained homology modeling approach [69], it was possible to derive three protein folds, based on the ligand-binding suppressor and IP_3-binding core domains from the type 1 IP_3 receptor, for the N-terminal portion (residues 12–565) of the RyR1 primary sequence [88] (Figure 4.2d). Interestingly, these models were localized to a region at the four corners of the RyR1 tetramer, a region that has also been implicated to interact with the dihydropyridine receptor (DHPR) during the

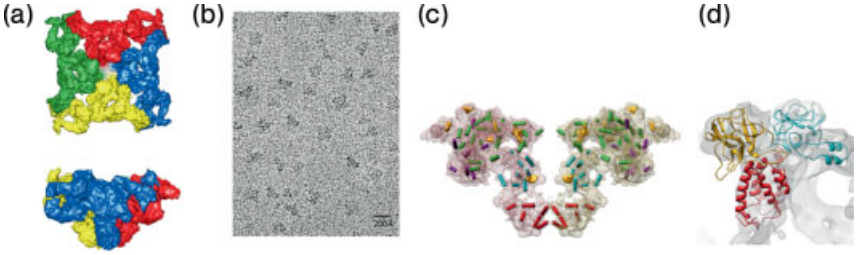

Figure 4.2 RyR1 at 9.6 Å resolution [88]. RyR1 at 9.6 Å resolution. The side and top views shown in (a) were reconstructed from ~28 000 individual particle images. The four subunits are annotated in different colors; (b) A representative view of the particle images; (c) The spatial dispositions of the α-helices (cylinders) and β-sheets (orange planes) in two of the homotetrameric subunits; (d) The three N-terminal models for RyR1 are shown fitted to the cryo-EM density. Model 1 is shown in cyan (residues Q12-S207), model 2 in yellow (residues G216-T407), and model 3 in red (residues A408-Y565). Models 2 and 3 are based on the aforementioned IP_3-binding core domain, while model 1 is based on the ligand-binding suppressor domain.

excitation–contraction coupling of the muscle [89–91]. Also of interest, several disease-related mutations in RyR1 occur within this region. As such, imaging of RyR1 with cryo-EM coupled to structural analysis has resulted into insight into the channels function and role in muscle contraction.

4.3.2
Bacteriophage Epsilon15

Epsilon15 is a 700 Å wide, 22 MDa nanomachine that infects *Salmonella* (Figure 4.3a) [92]. An icosahedral protein shell surrounds its dsDNA genome; at one vertex a large tail assembly protrudes from this shell. Without imposing any symmetry, a reconstruction of the native virion revealed at ~20 Å resolution all the molecular components of the virus, including the portal vertex (Figure 4.3b) [92]. When icosahedral symmetry was imposed during the reconstruction (effectively increasing the number of particle images, as there are 60 asymmetric units per particle), features of the nonicosahedral components such as the portal vertex were averaged out, but the icosahedral position shell proteins could be seen at a finer detail (4.5 Å resolution) [13]. In this high-resolution map, a complete annotation of the capsid components was possible.

While ~4.5 Å resolution is generally insufficient to construct a model by X-ray crystallographic standards, the aforementioned *de novo* model building tools for cryo-EM density maps make it possible with the existence of large α-helices which can be

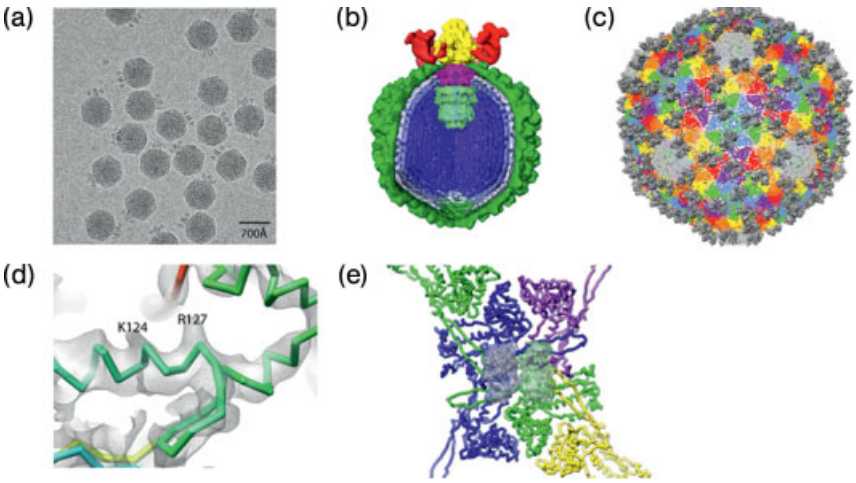

Figure 4.3 Bacteriophage epsilon15. (a) A 300-kV electron image of the phage particles embedded in vitreous ice; (b) A cut-away view of the 20 Å asymmetric reconstruction of epsilon15 [92] shows the molecular components of the portal vertex, the capsid shell protein and the viral DNA. The different molecular components are annotated in different colors; (c) 4.5 Å resolution structure [13], showing the backbone model of the Gp7 and the density of Gp10; (d) Side-chain density in the cryo-EM map; (e) A zoomed-in view of the capsid showing one gp10 spanning across four gp7 molecules, functioning as a 'molecular stapler'.

used to anchor the sequence-to-structure assignment. Gp7, a 420-amino acid protein that makes up the majority of the icosahedral capsid shell, was identified in the reconstruction and shown to have eight α-helices (>2.5 turns) and three β-sheets. Using these features, a complete *de novo* model was constructed (Figure 4.3c) to reveal a structure similar to that of the HK97 major capsid protein [93], despite the lack of detectable sequence similarity. In addition to the detection of a common fold, side-chain density could also be visualized in several regions throughout the map (Figure 4.3d).

Construction of the Gp7 model clearly revealed the presence of a previously undetected capsid protein. Biochemical analysis of the capsid later confirmed this protein to be Gp10 (12 kDa). In analyzing the sequence of this protein, potential structural homology to the PDZ domains [94] was identified. Taken together with the location of this protein of the capsid surface (along the icosahedral twofold symmetry axes), this small protein most likely acts like a molecular staple, bridging four adjacent gp10 molecules and thus assuring stability in the mature capsid (Figure 4.3e).

4.3.3
Bacterial Flagellum

The bacterial flagellum is an intricate biological nanomachine that transduces chemical energy into mechanical energy. The flagellar motor is a complicated assembly of approximately 25 unique polypeptide components that, when assembled correctly and operating under the proper electrochemical gradient, drives the rotary motor at speeds of nearly 300 Hz (for a review, see Ref. [95]). Models of the flagellar motor have been advanced through both single-particle and helical cryo-EM studies of the purified complexes from various spirochetes [96–98]. Cryo-ET has been used to complement these models; the *in situ* perspective derived from tomograms can reveal components of the structure that may be – and if fact, are – lost in the isolation and purification steps.

Recent studies have utilized cryo-ET to examine *in situ* the structure of the motor and the greater flagellar apparatus from the spirochete *Treponema primitia*. In their first report, Jensen and coworkers presented the structural details of the motor [99] in which 20 flagellar motors were computationally isolated from their positions in the cryo-ET reconstructions of 15 intact cells (each cell has two flagella, but not all tomograms captured both). These motors were subsequently merged to yield a ∼70 Å resolution model (Figure 4.4a). Like man-made motors, the flagellar motor consists of a rod attached to a rotor that rotates amidst an array of stationary stators; purified flagellar complexes lacked the stators altogether. This tomography-derived model was the first reconstruction to integrate the full motor with the stators, revealing the stators' 16-fold symmetry and their position with respect to the membrane. Besides accounting for the stator density, this model also revealed unexpected density above the stators in the peptidoglycan layer, including a new component termed the P-collar (Figure 4.4b). The P-collar and new findings about stator geometry raise new questions about the motor's mechanistic details.

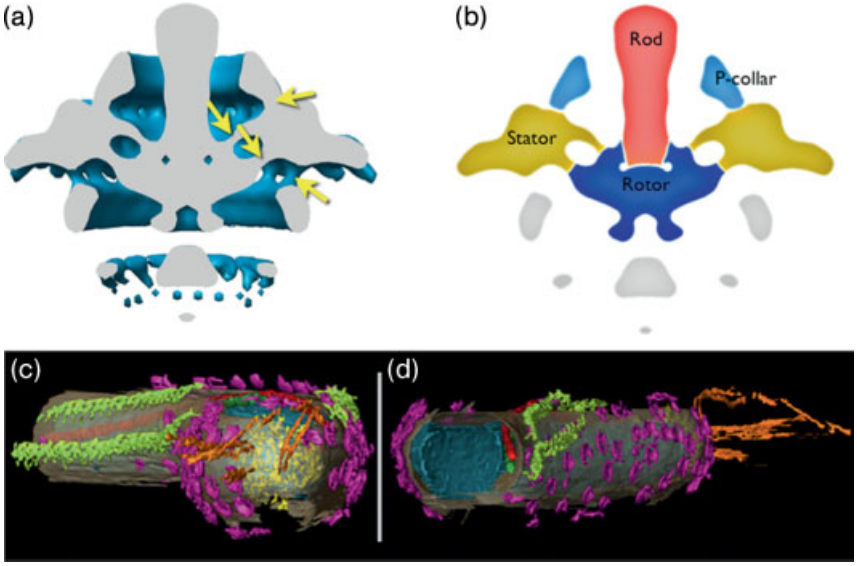

Figure 4.4 Cryo-ET findings on the flagellar motor and cellular features of spirochete *Treponema primitia*. (a) A cutaway surface rendering of the flagellar motor computed by averaging together 20 motors computationally isolated from tomograms. Novel findings included the surprising connectivity between the stator and other components of the motor, marked by yellow arrows; (b) Schematic of the motor organization as revealed through the analysis of the structure shown in (a). The position and geometry of the stator and the existence of the P-collar were missed by previous studies that examined biochemically purified flagellar motors; (c) Surface rendering of a *T. primitia* cell, showing many novel cellular structures, including surface bowls (magenta), the surface hook arcade (yellow) and tip fibrils (orange); the flagella are shown in green and red.

A subsequent cryo-ET study conducted by Jensen and coworkers revealed a plethora of novel structures in the *Treponema* cell, including outer-membrane bowls, polar fibrils, a polar cone and a surface hook arcade that sometimes tracks with the cellular position of flagella (Figure 4.4c and d) [100]. These findings beg new questions as to how, and if, these features relate to flagellar function. More importantly, two distinct periplasmic layers in *T. primitia* were revealed; this observation, when combined with video observations by light microscopy, affirms the rolling cylinder model of motility over the competing gyration model. The importance of this motility mechanism is underscored by the association between motility and pathogenicity in spirochetes such as those that cause Lyme disease and syphilis (for a review, see Ref. [101]).

4.3.4
Proteomic Atlas

Traditional cellular biology studies are frequently limited by carrying out experiments *in vitro* or investigating only fractions of cells. It is an obvious and tremendous

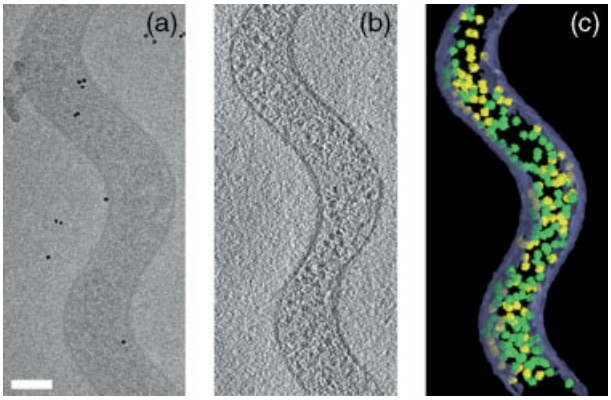

Figure 4.5 A map of ribosome location in the spirochete *Spiroplasma melliferum*. (a) The 0 (projection, an unprocessed cryo-ET image, showing a spirochete cell; (b) A slice of the reconstruction, which shows higher density at positions occupied by ribosomes; (c) A surface rendering of the reconstruction which has been filtered and segmented. High confidence ribosome matches are colored green; intermediate confidence matches are colored yellow.

advantage to integrate the structures and processes of all of the cellular space, enabling investigators to comprehend cells *in toto*. Today, Baumeister and colleagues continue to make strides towards this goal of visualizing a complete cell with all of its major nanomachines. Early proof-of-concept studies have shown that it is possible to identify and differentiate large complexes in the tomograms of synthetic cells [20]. Moreover, recent advances in data processing suggest that even similar assemblies with subtle differences in mass, such as GroEL and GroEL-GroES, can be differentiated [102]. The first application of mapping nanomachines in a cell showed that the total spatial distribution of ribosomes through an entire cell could be directly observed in the spirochete *Spiroplasma melliferum* (Figure 4.5) [103].

The archaebacteria *Thermoplasma acidophilum* is a relatively simple cell with only approximately 1507 open reading frames (ORFs) comprising considerably fewer subcellular assemblies [104]. As such, it is an attractive cryo-ET target for mapping the 3-D position of all major nanomachines – the 'proteomic atlas' – which, ultimately, will reveal unprecedented detail about the 3-D organization of protein–protein networks [105].

4.4 Future Prospects

Today, single-particle cryo-EM has reached the turning point where it is now possible to resolve relatively high-resolution structures of molecular nanomachines under conditions not generally possible with other high-resolution structure determination techniques. Due to the intrinsic nature of the cryo-EM experiment, it can also produce unique and biologically important information, even when a high-resolution

structure is already known. Cryo-EM structures of both the ribosome [106] and GroEL [14, 107, 108] have provided significant insight into structural and functional mechanisms, despite being extensively studied using X-ray crystallography.

One obvious challenge for cryo-EM is the pursuit of higher resolution (i.e. close to or better than 3.0 Å), at which point full, all-atom models could be constructed. On the other hand, cryo-EM is not aimed solely at high resolution. Rather, it offers the ability to resolve domains and/or components that are highly flexible at lower resolutions, as well as samples with multiple conformational states [108]. With further developments in the image-processing routines, both high-resolution structure determination and 'computational purification' of samples [108] will further allow for the exploration of complex molecular nanomachines in greater detail.

As with cryo-EM, improvements in data collection and image processing will allow cryo-ET to achieve more accurate and higher-resolution reconstructions of large nanomachines and cells. However – as alluded to in the proteomic atlas – the real strength of cryo-ET is its power to integrate known atomic structures and cryo-EM reconstructions to provide a complete model of *in vivo* protein function [105, 109]. Such integration will ultimately establish a true spatial and temporal view of functional nanomachines within the cell, which can systematically be investigated in either healthy or diseased states. In addition, there is a trend towards the integration of live cell observations made by light microscopy, followed by cryo-ET observations of the same specimens (e.g. [110]). Such hybrid approaches require not only new instrumentation to make sequential observations practical but also the computational tools to integrate the data. These integrated cellular views promise to enhance our understanding of cell structure and function relationships in normal and diseased states at higher spatial and temporal resolutions.

Acknowledgments

These studies were supported by grants from NIH (P41RR02250, 2PN2EY016525, R01GM079429) and NSF (IIS-0705474, IIS-0705644). We thank our collaborators Drs Irina Serysheva, Steve Ludtke, Yao Cong, Maya Topf, Andrej Sali and Susan Hamilton on the RYR1 project; Wen Jiang, Peter Weigele, Jonathan King, Joanita Jakana and Juan Chang on the epsilon15 phage project; and Jose Lopez on human platelet. We also thank Dr Grant Jensen at California Institute of Technology and Drs Wolfgang Baumeister and Julio Ortiz at the Max Planck Institute for providing the artwork for Figures 4.3 and 4.4, respectively.

Pushing Optical Microscopy to the Limit: From Single-Molecule Fluorescence Microscopy to Label-Free Detection and Tracking of Biological Nano-Objects

Philipp Kukura, Alois Renn, and Vahid Sandoghdar

5.1
Introduction

The fundamental goal of microscopic imaging is to visualize and identify small objects and to observe their motion. Many techniques based on a wide variety of approaches, including X-ray scattering, scanning probe microscopy, electron diffraction and various optical implementations, have been developed over the past century to improve upon the fundamental limitations of traditional optical microscopy. While each approach has its specific advantages, none by itself can provide a solution to all demands regarding spatial and temporal resolution, sensitivity and *in vivo* imaging capability, as are often desired in biologically motivated studies.

The ultimate resolution would allow one to detect, localize and visualize single molecules, or even atoms. Obtaining structural snapshots at molecular and atomic resolution has become routinely available through X-ray crystallographic techniques. Especially from a biological perspective, such detailed images of molecular and supramolecular structures regularly provide unique insights into their function [1–4]. Comparable resolution is attainable with scanning probe techniques such as scanning tunneling microscopy (STM) or atomic force microscopy (AFM) [5, 6]. While the former is generally limited to nonbiological samples, many biological AFM studies have been reported during the past decades [7, 8]. These experiments have been very informative, both due to their resolution and their ability to apply minute forces on single molecules or nano-objects. Various implementations of electron microscopy have also greatly contributed to biological imaging, due to its ability to provide spatial resolution in the nanometer region, thereby bridging the gap between the ultra high-resolution techniques mentioned above and standard optical imaging approaches [9].

Despite the many successes of these techniques, they all lack an ability to perform real-time, *in vivo* imaging. X-ray scattering experiments require high-quality crystals, which makes studies inside biological media intrinsically impossible. Scanning probe techniques are, by definition, limited to the study of surfaces and are relatively

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

slow, with acquisition rates rarely exceeding a few Hertz. Electron microscopy requires a vacuum and sometimes metal-coating or cryogenic conditions for high-resolution images, thus making it difficult to perform studies under biologically relevant conditions.

As a consequence, the method of choice for real-time, *in vivo* biological imaging has remained optical microscopy, despite its comparatively low resolution. The optical microscope was invented about 400 years ago, and improvements in resolution to about 200 nm had already taken place by the end of the nineteenth century, through advances in lens design. However, this is a factor of 100 larger than the size of single molecules or proteins that define the ultimately desired resolution, and represents the diffraction limit established by Abbe during the 1880s. Throughout most of the twentieth century, this fundamental limit prevented the optical microscope from opening our eyes to the molecular structure of matter. Nevertheless, numerous recent advances have been made to improve the resolution and, in particular, the contrast of images. In general, these contrast techniques can be divided into two categories, namely linear and nonlinear.

5.1.1 Linear Contrast Mechanisms

The central challenge in visualizing small objects is to distinguish their signals from background scattering, or from reflections that may be caused by other objects or the optics inside the microscope. One possible solution to this problem is provided by dark-field microscopy, which was first reported by Lister in 1830. Here, the design is optimized to reduce all unwanted light to a minimum by preventing the illumination light from reaching the detector [10, 11]. To achieve this, the illumination light is shaped such that it can be removed before detection through the use of an aperture. In general, there are two approaches to achieve dark-field illumination; these are illustrated schematically in Figure 5.1a and b. In Figure 5.1a, the illumination light is modified in such a way as to provide an intense ring of light, for example through the use of a coin-like object blocking all but the outer ring of the incident light. The illumination light can be then removed by an aperture after the sample. In this way, only the light that is scattered by objects of interest, and whose path is thereby deviated, can reach the detector. The other approach, shown in Figure 5.1b, is referred to as total internal reflection microscopy (TIRM) [12]. Here, the illumination is incident on the sample at a steep angle, and is fully reflected at the interface between the glass coverslip and the sample (e.g. water). There, an 'evanescent' region is created, where the light decays exponentially as it enters into the sample. When a particle is placed into this region it scatters energy out of the evanescent part of the beam into the objective. Thus, light will only reach the detector from scatterers that are located within 100 nm of the sample–substrate interface. This technique has been mostly used to detect very weak signals such as those from metallic nanoparticles, or to obtain surface-specific images [13, 14].

Another approach to minimize unwanted light is provided by confocal microscopy, which first appeared during the early 1960s (Figure 5.1c) [15, 16]. In contrast to the

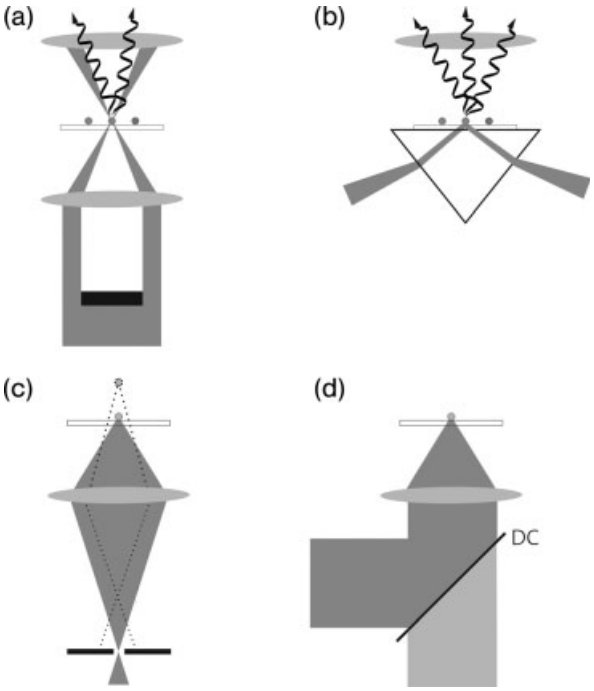

Figure 5.1 Illustration of the major linear contrast mechanisms in optical microscopy. (a) Dark-field illumination; (b) Total internal reflection microscopy (TIRM); (c) Confocal microscopy; (d) Fluorescence microscopy.

previous techniques, where the light from a relatively large sample area is collected ($\sim 20 \times 20\,\mu m$), only light from the focal region of the objective is allowed to reach the detector, thereby considerably reducing the background light. This is achieved through the use of a pinhole that is placed in the confocal plane of the objective. The size of the pinhole is usually chosen so as to match the size of the image of the focal spot. Collecting light in this fashion leads to optical sectioning – that is, the ability to provide three-dimensional (3-D) information by moving the focus in the z-direction through the sample. The major disadvantage of this approach is the need to scan the sample with respect to the illumination, which leads to relatively slow acquisition times.

An alternative for improving the contrast is to exploit the phase of the illumination light. Differential interference contrast (DIC) microscopy, which was introduced during the mid-1950s, takes advantage of slight differences in the refractive index of the specimen to generate additional information about the composition of the sample [17, 18]. For instance, the refractive index of water differs from that of lipids, so areas with a high water content will generate a different signal than those consisting mostly of organic material. The approach splits the illumination light

into two slightly displaced beams (<1 μm) at the focus that are recombined before detection. If the two beams travel through material with different indices of refraction, the phase of one relative to the other will change, and this will lead to a small degree of destructive interference after recombination of the two beams. Such areas will thus appear dark, while areas where the sample is homogeneous will appear bright.

So far, we have been only concerned with improving the contrast using scattered light. A different but powerful method is to use *fluorescence* as a contrast mechanism. The first such reports emerged during the early twentieth century, when ultra-violet light was used for the first time in microscopes. However, the breakthrough occurred during the 1950s, when the application of fluorescence labeling for the detection of antigens was demonstrated [19]. Rather than detecting the scattering of incident light, the illumination light is used to excite molecules, causing them to fluoresce. The advantage of this approach is that the excitation light can be reduced by many orders of magnitude by the use of appropriate filters, as the fluorescence is usually red-shifted in energy (Figure 5.1d). One can then observe the species of interest virtually against zero background because the only photons that can reach the detector must be due to fluorescence emission. Such contrast is virtually unachievable with scattering techniques, even when dark-field illumination is employed, because the background scattering cannot be extinguished to such a high degree. The major sources of contrast are biological autofluorescence, specific labeling of the objects of interest with fluorescent dye molecules, or use of the cellular expression system itself to produce fluorescent proteins [20]. Fluorescence can also be used to introduce specificity by spectrally 'coding' the sample. Examples are fluorescence recovery after photobleaching (FRAP) for studying fluidity [21], fluorescence lifetime imaging [22] or simply simultaneous labeling with different fluorophores.

The spectral resolution of fluorescence is, however, rather poor because the emission is usually very broad in energy. Techniques based on vibrational spectroscopy on the other hand, where the resonances are orders of magnitude sharper, provide a much more unique molecular fingerprint, but at the expense of much-reduced signal intensities. In particular, Raman and infrared microscopy yield information about the composition of the sample, without the need for any label [23]. The experimental set-up is very similar to that used for fluorescence microscopy, but is focused on detecting vibrational resonances rather than fluorescence emission. As a matter of fact, Raman experiments can only be successful when the background fluorescence is reduced to a minimum, because the cross-sections for Raman scattering are orders of magnitudes smaller than that of fluorescence. On the upside, every species has a unique Raman spectrum and can thus be identified without the need for any label. Because these experiments must be performed in a confocal arrangement to achieve a sufficiently high photon flux, they provide highly specific and spatially resolved information, even inside cells. The downside is that the intrinsically low Raman cross-sections require large illumination powers, and this might be problematic for live cell imaging, for reasons of phototoxicity.

5.1.2
Nonlinear Contrast Mechanisms

The recent availability of high-power laser sources producing ultrashort pulses on the order of a hundred femtoseconds (10^{-13} s) or less at high pulse powers (>mJ) has opened up completely new areas in microscopy. When such short and intense pulses are focused to a diffraction-limited spot, peak powers of terawatts per cm^2 and above can be achieved. At such high peak powers, nonlinear effects that involve the simultaneous interaction of multiple photons with the sample become observable. The main microscopy-related application that has emerged from this technological jump is that of *two-photon imaging* [24]. Here, rather than exciting a fluorophore with a single resonant photon, for example at 400 nm, two off-resonant photons at 800 nm are used to produce the same excitation. Although nonresonant two-photon cross-sections are negligible compared to their one-photon counterparts (10^{-50} versus 10^{-16} cm^2), the high peak powers coupled with high pulse repetition rates on the order of 100 MHz can compensate for these dramatically lowered cross-sections. The major advantage of this technique is that optical sectioning comes for free, because the high peak intensities are only produced at the focus of the illuminating beam, making confocal pinholes superfluous. Despite the fact that biological tissue is generally transparent in the near-infrared region, sample heating and the rapid destruction of two-photon fluorophores cannot be avoided due to the necessarily high peak intensities used.

Another prominent example of nonlinear microscopy is based on coherent anti-Stokes Raman scattering (CARS) [25], which is the nonlinear equivalent of Raman microscopy. Here, three incident photons are required to produce a single Raman shifted photon. Additional techniques based on second and third harmonic generation microscopies have also appeared [26, 27]. Finally, a very interesting recent development has been discussed in the context of RESOLFT (reversible saturable optically linear fluorescence transitions). Here, a nonlinear process such as stimulated emission is used to deplete the fluorescence to a subdiffraction-limited spot. As a result, the actual volume from which fluorescent photons are emitted is considerably reduced beyond $\lambda/50$ [28].

In this chapter, we will focus our attention on pushing both the sensitivity and resolution limits of state-of-the-art *linear* microscopic techniques. In particular, we will discuss the capabilities and limitations of single-molecule detection in the light of biological applications. After covering the fundamental aspects of resolution, we will outline recent advances in the detection and tracking of nonfluorescent nano-objects. Scattering based labels show much promise in eliminating many of the limitations of fluorescence microscopy. Yet, by going a step further, we will show how these techniques can be used to detect and follow the motion of *unlabeled* biological nanoparticles.

5.2
Single-Molecule Fluorescence Detection: Techniques and Applications

The fundamental question that arises from the previous discussion of current optical imaging methods is: Why is it so difficult, first to 'see' single molecules, and second to

achieve molecular resolution with optical microscopes? The former is particularly baffling because the fluorescence of single ions trapped in vacuum *can* be observed with the naked eye, as was shown 20 years ago [29].

5.2.1 Single Molecules: Light Sources with Ticks

To understand the intricacies of detecting single molecules in biological environments, it is useful to ask why it is so easy to observe single ions trapped in a vacuum. The answer is simply – the *absence of any background*. In a vacuum, the emitter is alone, with no other objects or molecules nearby that can either scatter the excitation light or fluoresce upon excitation. In this scenario, single-molecule detection simply becomes an issue of having a good enough detector (curiously, the human eye is one of the best light detectors available, being able to detect single photons with almost 70% efficiency [30]). However, the number of photons that any single molecule can emit via *fluorescence* is strictly limited by its intrinsic photophysics, and cannot be increased at will simply by raising the illumination power.

To understand this concept, it is useful to consider the dynamics that follow the absorption of a single photon by a single molecule. Population of the first excited electronic state is followed by an excited state decay which can take place via two major pathways: nonradiative and radiative decay. The former refers in this simple case to a transition from the excited to the ground state, without the emission of a photon. The excess energy is usually deposited in vibrational degrees of freedom, either of the molecule itself or of the surroundings. In the latter case, the energy is lost through the emission of a photon which is typically lower in energy (red-shifted) than the excitation photon due to the Stokes shift. To generate as many detectable photons per unit time as possible for a given excitation power, one requires: (i) a large absorption cross-section; and (ii) a high fluorescence quantum yield – that is, an efficient conversion of absorbed into emitted photons.

The former requirement brings with it a radiative lifetime on the order of nanoseconds, which can be related to the fundamental considerations of absorption and emission. This limits the total number of emitted photons, irrespective of the total incoming photon flux, because a single absorption–emission cycle takes about 10 ns. Thus, even in ideal circumstances no single molecule can emit more than 10^8 photons per second. The restricted collection properties of objectives, imperfect transmission and reflectivity of optics and limited quantum efficiencies of detectors result in typical effective collection efficiencies of $<10\%$. The corresponding count rates on the order of a few million counts per second can indeed be observed in single-molecule experiments at cryogenic temperatures [31]. Under ambient conditions, which are of relevance for biological investigations, photobleaching puts a limit on the applied excitation intensities. The cause of this bleaching is often the generation and further excitation of triplet states that are accessed through intersystem crossing from the first excited singlet state. Despite the low quantum efficiency of the process ($<1\%$), excitation powers must be chosen at the kW cm^{-2} level in order to avoid rapid

photobleaching. At these incident light levels, the observed count rates are below 10^5 photons per second [32].

Photobleaching is also the reason why single molecules usually emit a total of 10^5–10^7 photons before turning dark. The most likely cause of this 'sudden death' is triplet–triplet annihilation with molecular oxygen, which is a particular problem in biological environments. The highly reactive singlet oxygen that is generated attacks the dye and oxidizes it, greatly altering its electronic properties and thereby rendering it dark to the excitation photons [33, 34]. To make matters worse, triplet state formation is thought to be the main cause of phototoxicity [35, 36]. This situation can be improved somewhat by deoxygenating the system, or by using oxygen scavengers for *in vitro* experiments in solution [37].

5.2.2
The Signal-to-Noise Ratio Challenge

In addition to the saturation properties of single molecules discussed above, another difficulty arises from the fact that single molecules cannot be excited very efficiently. Even large single-molecule absorption cross-sections are only on the order of $10^{-16}\,\mathrm{cm}^2$, compared to focal areas that are no smaller than $\sim 10^{-9}\,\mathrm{cm}^2$. Therefore, only one in 10^7 photons that passes through the focus will cause electronic excitation of the molecule. What makes the situation even more problematic, is the fact that a typical focal volume contains on the order of 10^9 molecules. So, even if only one in 10^3 molecules emits a single fluorescence photon per second, the total emission background already matches the maximum fluorescence from the single molecule of about 10^6 photons, even at low temperatures.

As a consequence, initial attempts to detect single molecules used absorption [38], although these were swiftly followed by fluorescence detection [39]. The early studies were performed at cryogenic temperatures, where absorption cross-sections become large so that the saturation regime can be reached at much lower incident powers. At room temperature, however, the task appeared hopeless in the light of the numbers above. One possibility to improve this situation was to develop a technique that is: (i) only surface-sensitive; and (ii) somehow produces a much smaller excitation area. Scanning near-field optical microscopy (SNOM) provides exactly these properties [40, 41]. Here, the light is not focused as in a standard optical microscope, but rather is coupled into a metallized and sharpened tip of an optical fiber equipped with a subwavelength exit hole ($<50\,\mathrm{nm}$). The tip is then brought within tens of nanometers of the surface to be studied and scanned laterally. In this way, only molecules that are on the surface are excited by the evanescent field at the tip's aperture, and only in an area that is comparable to the aperture. Therefore, the number of molecules that can contribute to the background signal becomes considerably smaller compared to the confocal arrangement, making the detection of single molecules much more probable. Indeed, the first room-temperature observation of single molecules was achieved using SNOM [42].

The rather difficult experimental set-up necessary for performing SNOM, along with the limitations to study surfaces, motivated the development of far-field

single-molecule methods for biological studies. It was quickly realized that far-field methods are capable of generating much larger single-molecule signals than SNOM, with much-reduced experimental demands. Therefore, far-field detection has become the method of choice for detecting single molecules in biological environments [43, 44]. This advance was facilitated by the development of low autofluorescence microscope objectives and immersion oils, as well as improved excitation light rejection through the use of dielectric filters and highly efficient single photon detectors such as avalanche photodiodes. Today, single-molecule detection has become an almost standard technique in biology, chemistry and physics [45]. Single-molecule techniques have been used to directly observe the motion and function of single biological nano-objects such as enzymes, viruses or motor proteins in real time [37, 46, 47].

5.2.3
High-Precision Localization and Tracking of Single Emitters

In the previous section, we discussed the difficulties and current solutions to detecting single molecules. However, we are still faced with the problem, that single molecules are much smaller (~1 nm) than the best possible resolution of an optical microscope (~200 nm), which is linked to the wave nature of light [48]. The crucial point is that the image of a point-like emitter is itself not infinitely small but rather appears as an Airy diffraction image (Figure 5.2a), with the ripples originating from the diffraction at the edges of a circular objective, for example. Because these patterns, which are also known as the point spread functions (PSFs), are caused by the lens, the smaller the aperture of the lens the wider the PSF and the lower the resolution, and vice versa. Here, it is useful to define the term numerical aperture, $NA = n\sin(\varphi)$, where φ is defined as the half collection angle of the objective. Therefore, the larger the NA, the higher the resolution of the microscope. The distance from the central maximum to the first minimum is given by $d_{min} = 0.61\lambda/NA$ for a circular aperture, where λ is the wavelength of light and is a common measure of resolution also known as Rayleigh's limit (Figure 5.2b).

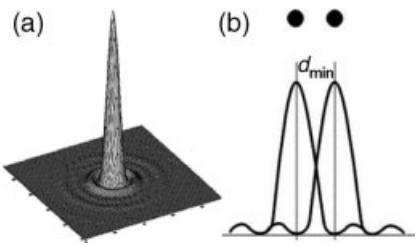

Figure 5.2 Point spread functions and their importance in determining resolution. (a) Surface plot of a typical Airy diffraction pattern; (b) Schematic representation of Rayleigh's criterion. The two graphs represent slices through the 2-D Airy function shown in (a).

Despite the fact that a single molecule smaller than 1 nm yields an image with a diameter of several hundred nanometers, it is possible to determine its location to within a few nanometers. This can be achieved by fitting the data to the theoretical PSF. Thus, the precision of this fit is only limited by the signal-to-noise ratio (SNR) of the acquired Gaussian profile, while the fit tolerance provides the uncertainty in x and y of the emitter's center [49]. To illustrate this, we have acquired confocal images of single rhodamine-labeled GM1 receptors adhered onto an acid-cleaned coverslip (Figure 5.3a). The observed single-step bleaching in Figure 5.3b for the spot highlighted in Figure 5.3a confirms that the image stems from a single molecule. The emission pattern (Figure 5.3c) and the corresponding Gaussian fit (Figure 5.3d) to the highlighted molecule result in a lateral localization accuracy of 10 nm. The high accuracy is due to the fact that all the information in two dimensions can be used for the fit. To illustrate this, three slices and the corresponding fits along the x axis of the spot are shown in Figure 5.3e–g. The center position fluctuates by >20 nm for these three fits due to the limited SNR. A two-dimensional fit, however, provides much higher accuracy, because one effectively fits all slices in every possible direction simultaneously. This approach has been employed in several recent investigations, including the study of lipid diffusion inside supported membrane bilayers [50], and of the mechanism of the molecular motor kinesin stepping along microtubules [51]. While the former study showed a maximum localization accuracy of $\sim$40 nm, the latter state-of-the-art measurements succeeded in realizing molecular resolution ($\sim$1.5 nm) with sub-second time resolution.

As can be seen from the previous discussion, the localization accuracy is critically dependent on the SNR with which the PSF can be measured. The limitation arises from the finite number of detectable photons per molecule. The longer the integration time, the higher the accuracy but also the lower the time resolution. As a rule of thumb, a SNR of 10 is required for a localization accuracy of $\sim$10 nm, which translates into roughly a time resolution on the order of several to tens of milliseconds [49, 52]. This makes tracking beyond video rates difficult if the object is to remain visible against the background, especially for *in vivo* imaging [47]. In addition, the total tracking time is limited to a few seconds because of photobleaching. These issues can only be addressed by using labels with no limitations on the number of emitted photons and on photostability. Nevertheless, single molecules have been used successfully to track individual biological nano-objects in real time. An excellent example is given in Figure 5.4, where single adenoviruses were labeled with single dye molecules and then observed before, during and after cell entry [47].

Inorganic quantum dots have become popular as labels in fluorescence microscopy because of their brightness and extreme photostability [53]. Their inherent toxicity is commonly deactivated through the use of protecting layers, and they have been used successfully in intracellular and *in vivo* studies [54]. A major disadvantage of these labels is that, so far, their emission switches off intermittently at unpredictable times and for unknown durations, a process known as *photoblinking*. In addition, once passivated, they can become as large as 15–20 nm.

Adapted from Ref. [47].

5.2.4
Getting Around the Rayleigh Limit: Colocalization of Multiple Emitters

While it may be possible to localize a single emitter with a precision comparable to its size, the fundamental problem defined by Rayleigh's criterion remains if identical objects that are separated by less than half the wavelength of light are to be resolved. This leaves a large gap between the achievable (~200 nm) and the desired molecular resolution (~1 nm). Several approaches have been explored over the past decades, many of which have closed this gap partially and are described in detail [55]. Here, we will focus on concepts that are particularly suited toward the study of single emitters.

One approach is based on the idea that if one emitter could be observed without the other, then the location of each could be pinpointed with high precision by using the methodology outlined above. One way to achieve this task would be to image spectrally orthogonal emitters, as demonstrated by Weiss and coworkers [56], through the use of two inorganic quantum dots fluorescing at different wavelengths. Each of the emitters can be observed independently by separating the emission of the two with a dichroic mirror. Unfortunately, this multicolor colocalization can only be applied to a few particles because fluorescence emission is generally broad, and it is not realistic to use more than two or three emitters simultaneously.

Rather than differentiating between emitters spectrally, another option would be to do this temporally. An early implementation of this approach involved the stepwise photobleaching of individual emitters, as demonstrated by Selvin *et al.* [57]. Here, two emitters (m_1 and m_2) are imaged continuously. The integrated intensity of the emission of both molecules as a function of time shows a two-step behavior due to

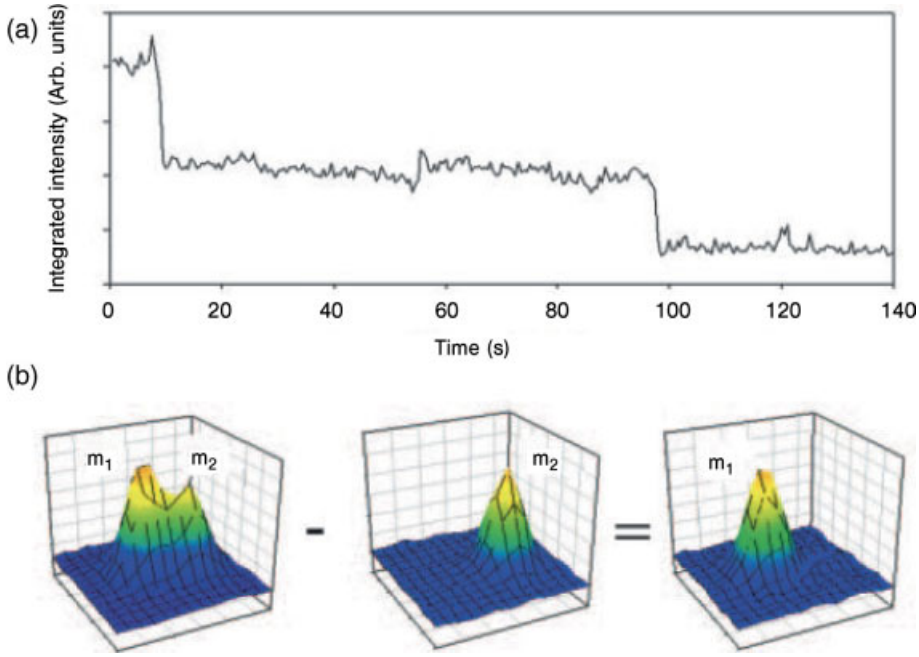

Figure 5.5 Subdiffraction localization through stepwise photobleaching. (a) Summed emission intensity showing clear two-step photobleaching; (b) Schematic representation of the localization procedure. Adapted from Ref. [57].

photobleaching, such as that shown in Figure 5.5a. After the first bleaching event, only m_2 is visible, and this can now be localized with high precision (as described previously). Subtracting the contribution of m_2 from the initial image, where both emitters are present, results in an image representative of m_1 (Figure 5.5b) which can again be localized with high precision. Thus, it is possible to determine the positions of several emitters with near-molecular resolution (down to 1.5 nm). This technique is extremely useful and precise for imaging fairly simple samples containing few fluorophores. However, for general applications such as those required for *in vivo* imaging where many labels are present, it quickly reaches its limit.

This barrier has recently been lifted by a recent approach proposed by Betzig and coworkers [58] and by Zhuang and colleagues [59], based on photoswitchable fluorophores. These methods have been named PALM (photoactivated localization microscopy) and STORM (stochastic optical reconstruction microscopy), respectively. Here, the problem of multiple fluorophores emitting simultaneously is eliminated by initially illuminating the sample in the near-UV (405 nm) at low light levels. This causes a small and stochastically distributed fraction of the total molecules to convert photochemically into an active state. Illumination of the sample in the yellow region (561 nm) then causes the photoactivated molecules to fluoresce.

By observing and fitting the emission pattern from each of these molecules, they can be localized with high precision. Those molecules are subsequently bleached and the process is repeated until the entire sample has been imaged. The resulting images are of spectacular clarity and resolution, especially when compared to standard confocal images, such as in Figure 5.6a–d. The main disadvantage of this approach is currently the low time resolution required by the stochastic activation of a small number of emitters and the reliance on the destruction of the activated signal.

The highest spatial resolution in three dimensions has been achieved at cryogenic temperatures, taking advantage of spectral selectivity [60]. When cooled to a few Kelvin, the absorption and emission from single molecules becomes extremely narrow and highly sensitive to their local environment. Single molecules can then be excited individually and therefore localized with nanometer precision. Whilst, in

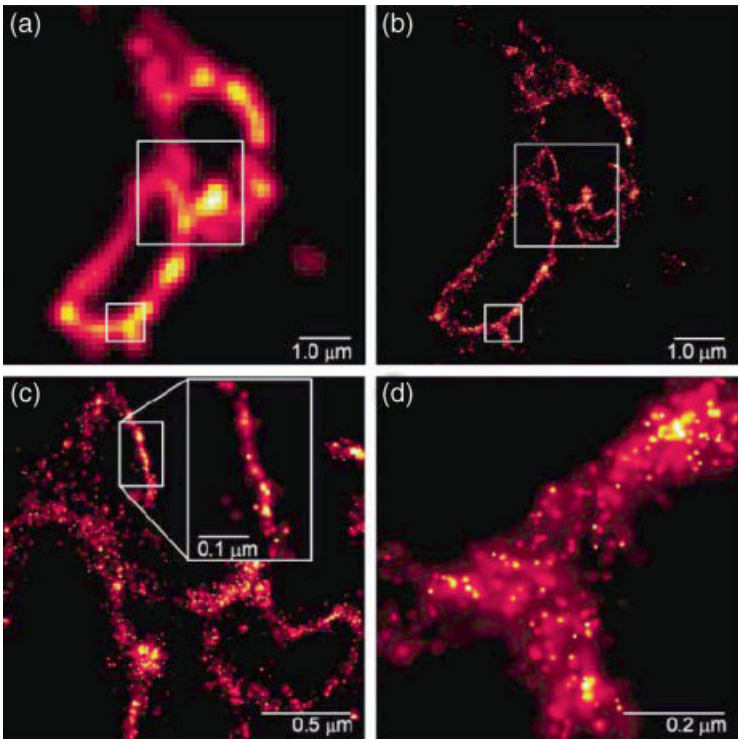

Figure 5.6 Near-molecular resolution using photoactivated localization microscopy (PALM). Comparison between summed molecule TIRF (a) and PALM (b) images from a thin, cryoprepared section of a fixed cell. An enlargement of the large boxed region in (b) reveals smaller associated membranes (c). The inset shows highly localized (10 nm) molecules. An enlargement of the smaller box in (c) shows the distribution of individual molecules within the membrane (d). Adapted from Ref. [58].

principle, this approach should be extendable to biological studies, none has so far been reported due to the high degree of experimental complexity compared to room-temperature studies.

One of the most successful and widespread approaches to achieve spatial information far below the Rayleigh limit involves taking advantage of fluorescence resonance energy transfer (FRET). The principle of this approach is depicted schematically in Figure 5.7. It uses two chromophores, a donor (D) and an acceptor (A), with overlapping absorption and emission bands (Figure 5.7b). When the two emitters are well separated, excitation of the donor will lead to observable emission only from the donor. However, when the two fluorophores are brought into close proximity of each other, the excitation energy originally placed in the donor is efficiently transferred to the acceptor due to the overlapping absorption and emission bands through Förster energy transfer (Figure 5.7c). This indirect excitation of the acceptor leads to fluorescence emission of the acceptor (i.e. far red-shifted compared to that of the donor). Commonly, the emission channels of both the donor and the acceptor are monitored simultaneously by the use of appropriate beam splitters. Thus, a dynamic system where the distance of the two

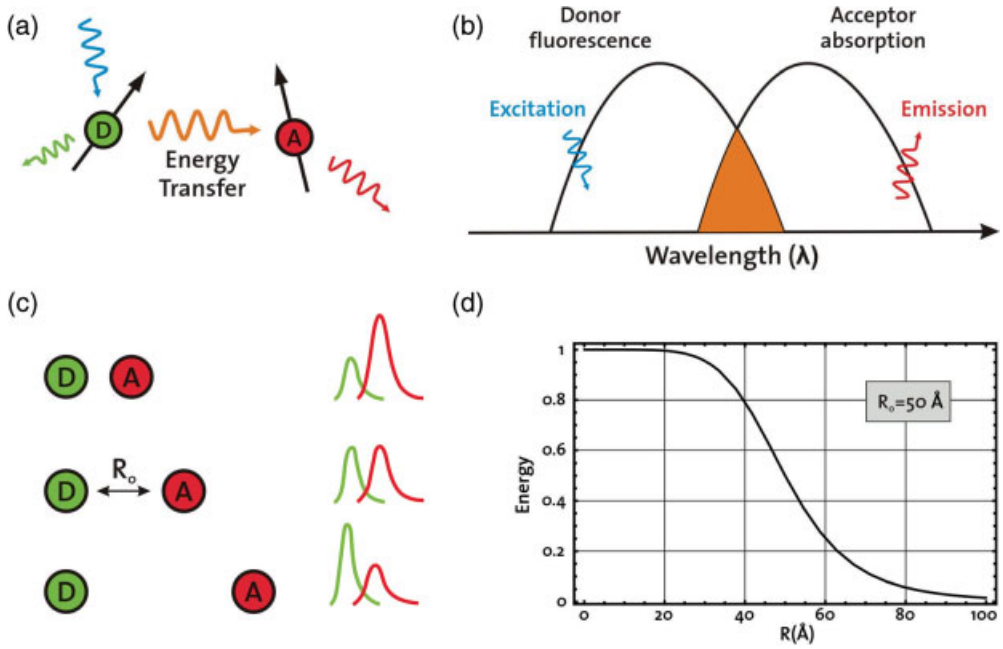

Figure 5.7 Fluorescence resonance energy transfer (FRET). (a) When a donor (D) and an acceptor (A) molecule with overlapping emission and absorption bands (b) are brought into close proximity, energy from the donor is transferred to the acceptor. In this case, red-shifted emission from the acceptor is observed; (c) When the two molecules are separated, donor fluorescence dominates; (d) The distance between the two molecules can be determined with high precision in the 2–8 nm range from the donor to acceptor emission ratio.

labels changes with time, for example due to conformational changes of a protein, will exhibit alternating emission from donor and acceptor [61]. The strong distance-dependence (R^6) of energy transfer efficiency makes FRET an excellent molecular ruler on the sub-10 nm length scale (Figure 5.7d).

5.3
Detection of *Non*-Fluorescent Single Nano-Objects

Despite the amazing capabilities of microscopy using single-molecule labels, two major limitations have become apparent. First, the total number of detectable photons is limited due to photobleaching, thus restricting the total observation times to a few seconds. Second, the saturation properties of single molecules limit the photon count rates to around $10^5\,s^{-1}$ or less. The requirement for a total of $\sim$100 detected photons for reasonable localization [52] results in a maximal time resolution on the order of milliseconds.

Many of the difficulties described above can be eliminated through the use of scattering rather than fluorescence as a contrast mechanism. Here, there is no limit on the number of detected photons because the amount of scattered photons depends only on the incident light level. As a result, an unlimited time resolution is theoretically possible. In addition, because a scattering object acts like a tiny 'mirror', neither bleaching nor blinking is an issue, providing indefinitely long unlimited observation times without dark periods. These advantages have led to the emergence of gold nanoparticles in biological applications with reported time resolutions down to $\sim$25 μs [62]. The downside associated with the use of gold nanoparticles as optical labels is the strong size dependence of the scattering cross-section, which results in a minimum label size on the order of $\sim$30 nm in dark-field detection [14, 63]. The fact that many biological nanoparticles of interest are either comparable (e.g. viruses) or much smaller (proteins) in size than this has restricted the applicability of these labels. In particular, such large labels may strongly perturb the motion of the entity under study.

5.3.1
The Difficulty of Detecting Small Particles Through Light Scattering

The ultimate goal is to detect a single molecule-sized scatterer, as this would combine the advantages of scattering detection and the minimal perturbation of the system. The question becomes: why is it so difficult to detect an object such as a 1 nm gold nanoparticle?

In many ways, the origin of this problem is very similar to that discussed earlier for single molecules. If a single-molecule-sized gold particle could be trapped in a vacuum, the light scattered by the particle could be observed by the naked eye. In a realistic environment, however, background scattering will easily overwhelm the tiny signal generated by the gold particle. For single-molecule fluorescence, one is limited by the maximum photon emission rate, background fluorescence and a small

absorption cross-section. For scattering detection, the situation is even worse because *every* object in the focal volume scatters light and the spectral selectivity available in fluorescence detection is lost, making low background measurements a true challenge.There are two possible sol utions to this problem: (i) the number of background scatterers from the focal volume is minimized; or (ii) the scattering signal from the particles of interest is somehow increased. The former has been the traditional approach to detecting small gold nanoparticles through dark-field or total internal reflection microscopy [14]. In this case, the scattered light intensity depends on the square of the polarizability of the particle which, in the electrostatic approximation, can be written as [64]:

$$\alpha(\lambda) = \frac{\pi d^3}{2} \frac{\varepsilon_p - \varepsilon_m}{\varepsilon_p + 2\varepsilon_m}$$

for a spherical particle of diameter d and dielectric constant ε_p inside a medium of dielectric constant ε_m. It easily follows, that the scattering intensity scales to the sixth power with the particle size; a 5 nm particle will therefore scatter light a million times less efficiently than a 50 nm particle! As a consequence, the signal from scatterers smaller than 30 nm drops below the background, even when a dark-field approach is used [14, 63].

Metallic nanoparticles such as those composed of gold or silver exhibit a so-called 'plasmon resonance'. As can be seen in the equation, such a resonance causes the denominator to approach zero in the specific case of $\varepsilon_p(\lambda) \rightarrow -2\varepsilon_m(\lambda)$, and therefore makes the scattering amplitude large. For spherical gold nanoparticles, this resonance occurs conveniently in the visible region of the spectrum at ~530 nm [65]. For biological nanoparticles, the scattering cross-sections are roughly a factor of three smaller than for gold because of the missing plasmon resonance [66].

To circumvent these difficulties, two approaches have emerged recently that allow the detection of gold nanoparticles down to 5 nm. One method involves taking advantage of the absorption of gold nanoparticles, which scales linearly with particle volume and therefore with the third power of the particle diameter. The resulting drop in the sensitivity of signal on the particle size has been utilized both in direct absorption measurements [67] and in the observation of a change in the refractive index through heating of the surrounding medium caused by the absorption of radiation [68]. We will focus here on an alternative method that measures the electric field directly, thereby achieving d^3 sensitivity without the need to heat the sample [69–71]. As we will show, this approach also brings with it the unique advantage of being able to detect biological nanoparticles *without any labels*.

5.3.2
Interferometric Detection of Gold Nanoparticles

To illustrate our approach, it is useful to consider the simple experimental set-up shown in Figure 5.8. Here, the incident laser beam is focused onto the sample, which in the simplest case consists of gold nanoparticles on a glass coverslip. As detection

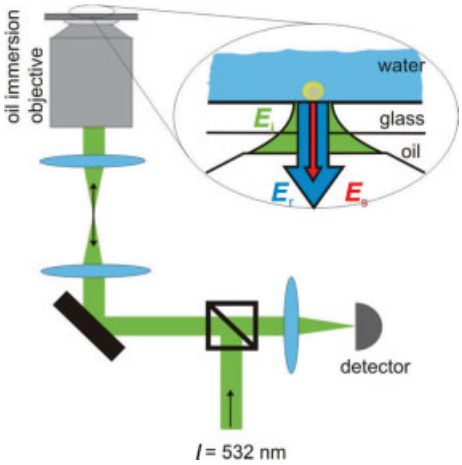

Figure 5.8 Simplified experimental set-up for the interferometric detection of nonfluorescent nanoparticles. The incident light, E_i, is reflected at the glass/water interface (E_r) and collected along with the scattered light from the particle, E_s, by the microscope objective. A portion of this light then passes through the beam splitter and reaches the detector.

occurs in the epi-direction, we are interested in the light returning through the microscope objective. The detector will therefore see the incident light (E_i) reflected at the interface between the glass and the medium. The reflected field reads $E_r = rE_i(\exp(-i\pi/2))$ where r is the field reflectivity and $\pi/2$ denotes the Gouy phase of the reflected focused beam. In addition, light scattered by the particle can be written as $E_s = sE_i = |s|\exp(i\varphi)E_i$ at the detector, where s is proportional to the particle polarizability and therefore to d^3. Here, ϕ signifies the phase change on scattering. The intensity, I_D, measured at the detector is thus

$$I_D = |E_r + E_s|^2 = |E_i|^2(r^2 + s^2 - |r||s|\sin\phi).$$

We can use this equation to illustrate some of the factors discussed above. Dark-field or total internal reflection detection are designed in such a way that $r \rightarrow 0$ and therefore only the scattering term, s^2, is detected. This signal drops very rapidly below the background level ($|rE_i|^2$) for particles <30 nm. In this case, the nature of the observed signal depends on the relative magnitudes of the three terms in the above equation. For large particles, the scattering term, s^2, dominates and the particles appear bright against the background (Figure 5.9). As the particle size decreases, s^2 becomes negligible compared to the other two terms, and only the reflection and interference terms contribute to the detected intensity. The particles appear dark against the background due to the destructive interference between the scattered and the reflected beams caused by a $-\pi/2$ Gouy phase shift of the reflected incident beam (Figure 5.10a and b) [71]. The change-over from bright to dark occurs according to the relative magnitudes of the scattering and interference terms, and therefore occurs

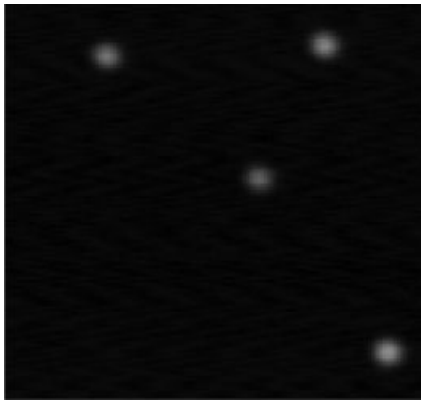

Figure 5.9 Confocal scan of 100 nm gold nanoparticles.

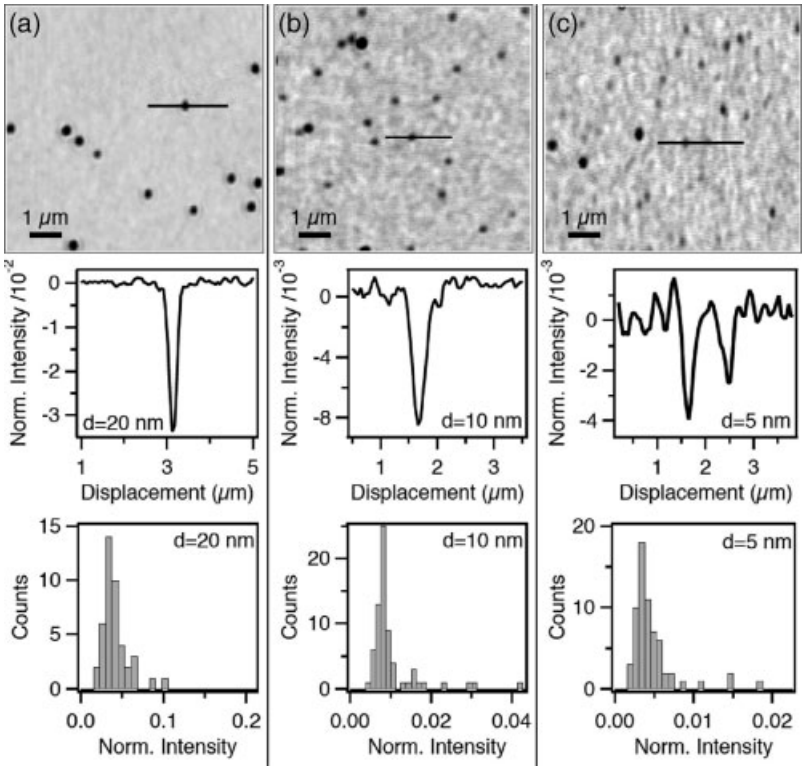

Figure 5.10 Interferometric images of gold nanoparticles spin-coated onto glass coverslips. (a) 20 nm; (b) 10 nm; (c) 5 nm diameter. Representative particle cross-sections, as well as intensity histograms, are provided in each case. Total acquisition time in each case = 10 s; incident power = 2 mW.

earlier for larger r: for example, at 40 nm for air as the surrounding medium, 30 nm for water, and 15 nm for oil that is index-matched fairly well to the glass coverslip.

5.3.2.1 Is it Possible to Detect Molecule-Sized Labels?

To explore the theoretical sensitivity limitations, it is useful to consider the origin of the true noise background that limits the detection sensitivity. This is governed mostly by the noise of the light source itself and the noise of the detector. Both will result in fluctuations in the detected reflected intensity, r, which is the major contributor to the overall detected signal at the detector. Other potential noise sources such as mechanical instabilities of the microscope or beam-pointing instability of the light source are comparatively small and easily corrected for in post-acquisition image processing.

An incident power of 1 mW on the sample will yield $\sim$3 μW of light reaching the detector, taking into account the reflectivity of the glass–water interface and losses due to the limited transmission of optics such as the microscope objective. The ideal detectors for such light intensities are photodiodes, which produce a corresponding photocurrent of 1 μA. The shot noise limit for this photocurrent is on the order of 500 fA $Hz^{-1/2}$, which is about an order of magnitude above the noise of available amplifiers with 10^7 V/A gain, suggesting that shot noise-limited detection is possible. At this amplification and a realistic detection bandwidth for mechanical scanning of 1 kHz, the electronic shot noise amounts to $\sim 1.5 \times 10^{-5}$ rms, which is a factor of $\sim$300 below the magnitude of the signal observed for 5 nm gold particles. A factor of three reduction in size on the other hand, which would lead to molecular sized labels on the order of 1.3 nm, brings with it a factor of 27 reduction in signal intensity. Thus, such molecular-sized labels should be observable with a SNR of 10 at kHz bandwidths with localization accuracies down to 10 nm!

The previous discussion has shown that neither shot noise nor detector noise limit the detectability of such small labels. One other critical noise source remains: the light source itself. Lasers used in confocal microscopes show optical noise on the order of a small percentage over a wide frequency range. Even state-of-the-art, solid-state, diode-pumped lasers rarely perform better than 0.1%. However, external stabilization using optical fibers, acousto-optic modulators and feedback loops has been shown to reduce laser noise from a small percentage to $\sim 5 \times 10^{-5}$ rms with kHz bandwidth [72], which is comparable to the electronic shot noise calculated above. In addition, the use of single-mode fibers in this stabilization scheme significantly reduces the effects of beam-pointing and mode instabilities, further contributing to the overall stability of the system. Given these simple calculations, it becomes evident that the rapid detection of molecular-sized gold scatterers should be possible. We are currently pursuing such experiments.

All of the images presented in Figure 5.10 have been obtained by scanning the sample across the focus using a piezo translation stage that requires 1–10 s per image. By using scanning mirrors rather than a piezo stage, we have shown previously that it is possible to detect 20 nm particles with up to MHz bandwidths – three orders of magnitude above what is possible using single molecules as labels [73]. In addition, rather than scanning the focus across the surface, the use of a feedback loop enables one to lock the focus to a particle and follow its movements rapidly. The feedback loop

is fed by the signal recorded on a four-quadrant detector, where the movement of the particle inside the focus leads to changes in the measured differential voltages. Using the same detector and amplifier combination above, which provide MHz detection bandwidths, the shot noise increases to $\sim 5 \times 10^{-4}$ with mW incident powers. In this way, the tracking of labels as small as 5 nm with MHz bandwidths should be possible.

The sensitivity limitations of the technique are illustrated in Figure 5.10c, which shows a confocal image of 5 nm particles spin-coated on a glass coverslip and covered by water. As can be seen in the image, the particles are visible against the background with a signal contrast on the order of 3×10^{-3}. The distribution width of the signal intensities is in agreement with the manufacturer's specifications with regards to the size of the gold particles, confirming that we are indeed observing single particles.

A close inspection of Figure 5.10b and c reveals the presence of a rather 'noisy' background as the size of the particles and thus their signal magnitude decreases. However, these features are *not* noise, as they are perfectly reproducible in sequential images. Rather, these patterns are due to the surface roughness of the glass coverslips used. Indeed, AFM measurements have shown that the surface roughness amounts to a few nanometers over a few microns. The reproducibility of such nanometer-sized surface roughness demonstrates the excellent sensitivity of this technique to nonmetallic species.

5.3.2.2 The Needle in the Haystack: Finding and Identifying Gold

So far, we have been concerned mostly with detecting and tracking the smallest possible gold nanoparticles. An interesting point to address is how such small labels can be detected in the presence of much larger scatterers, for example in intracellular imaging. Fortunately, gold nanoparticles have a type of 'built-in identification card' in the form of a plasmon resonance in the visible region of the electromagnetic spectrum (Figure 5.11a). As a result, one obtains roughly twice the scattering intensity in the green (532 nm) compared to the blue (488 nm) or red (>560 nm) regions. This wavelength-dependent scattering intensity is in contrast to the constituents of typical biological samples, where the scattering should be roughly identical for both wavelengths.

To demonstrate the possibility of using this interesting feature of gold nanoparticles, we have labeled microtubules with 40 nm gold particles and obtained scattering images simultaneously in the blue and green (Figure 5.11b and c). In the two images, both the nanoparticles and the microtubule are clearly visible. However, when the two images are subtracted from each other (Figure 5.11d), the microtubule disappears while the particles remain. One can thus use this form of differential spectral contrast to ensure that the observed particles are indeed the gold labels of interest and not other scatterers [69].

5.3.3 Combining Scattering and Fluorescence Detection: A Long-Range Nanoscopic Ruler

As yet, we have discussed the advantages and disadvantages of fluorescence and scattering as labels only in biological imaging applications. Now, we present an

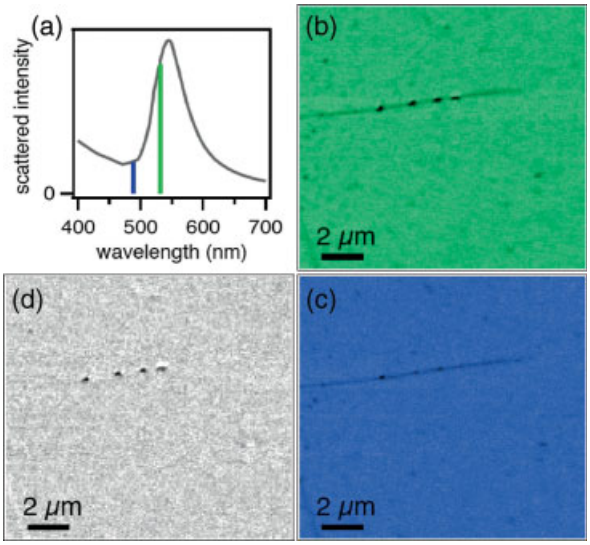

Figure 5.11 Identification of gold scatterers through spectral difference. (a) Plasmon resonance for a 40 nm gold particle; (b) Interferometric image of microtubules labeled with individual 40 nm gold particles acquired at 532 nm; (c) Identical image acquired simultaneously at 488 nm; (d) Subtraction of the blue from the green image. The microtubule with approximately identical scattering cross-sections at the two wavelengths disappears, while the gold particles remain visible.

example where the combination of the two leads to a potentially useful technique. It has been shown previously that nanostructures brought into close vicinity of single emitters can cause enhancement of luminescence and Raman scattering [75]. We have shown recently that a single gold nanoparticle can enhance the fluorescence of a single molecule and the decay rate of its excited state by a factor of 20 [76]. Furthermore, we demonstrated that this strong fluorescence modification is a function of the particle–emitter separation with nanometer sensitivity.

The mechanism of this effect can be intuitively explained as the near-field interaction of the molecular dipole moment, with its image dipole induced in the gold nanoparticle. The dipole–dipole character of this interaction gives rise to a strong distance-dependence much in the same way as in FRET (see also Figure 5.10). However, in this case the interaction range drops much more softly than the $1/r^6$ dependence observed in FRET. Thus, the modification of the fluorescence lifetime close to a nanoparticle can be used as a nanoscopic ruler for distances larger than that of FRET (>10 nm).

To demonstrate this, we have performed studies of systems where a single molecule is linked to a gold nanoparticle with DNA double strands of differing lengths [77]. The techniques of single-molecule detection and microscopy of gold nanoparticles were combined to locate such molecule–particle pairs. The corresponding confocal scans of single functionalized gold nanoparticles of 15 nm

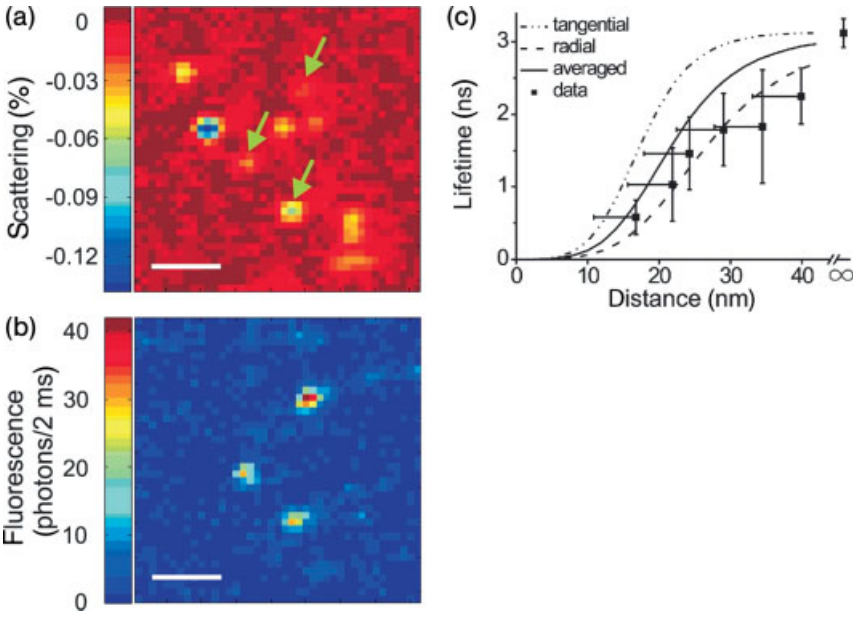

Figure 5.12 Combining scattering and fluorescence detection for a nanoscopic ruler. (a) Scattering image of single 15 nm gold particles functionalized with a single dye molecule via a DNA linker; (b) Simultaneously acquired fluorescence image. The arrows in (a) indicate gold particles that are functionalized with fluorescent markers; (c) Single-molecule fluorescence lifetime dependence on linker length. The dashed and dashed-dotted curves display the calculated fluorescence lifetime for the molecular dipole oriented radially or tangentially with respect to the gold nanoparticle. The solid curve shows the weighted average of the two orientations.

diameter are shown in Figure 5.12a (scattering) and b (fluorescence). As can be seen in the figure, only a fraction of the gold particles contains a fluorescent marker. Figure 5.12c demonstrates the dependence of fluorescence lifetime on linker length. In the absence of a gold nanoparticle, the fluorescence lifetime of the molecule was ~3 ns, but this was reduced to about 0.6 ns for a 15 nm-long DNA linker consisting of 44 base pairs. The interaction length and its slope can be tuned by choosing the particle size and emission wavelength of the dye molecule. The precision of such a nanoscopic ruler is on the order of 1 nm, and is limited by the accuracy with which the fluorescence lifetime can be determined [77].

5.3.4
Label-Free Detection of Biological Nano-Objects

Although we have focused mostly on gold as a scattering label, the previous discussion has also shown that interferometric detection is extremely sensitive to virtually any type of scatterer. This is demonstrated on the one hand by the

observation of nanometer surface roughness on glass coverslips, and on the other hand by the visibility of individual microtubules which are hollow shells of only 24 nm diameter. These results suggest that it may be possible to detect biological nano-objects *without the need for any label*. Such detection brings with it the aforementioned advantages of scattering detection, but more importantly eliminates any outside perturbation on the system which may be introduced by labels; moreover, it eliminates the need for labeling chemistry.

To illustrate the capabilities of the technique in this respect, we have obtained scattering images of unlabeled Simian virus 40 (SV40) virions bound to microscope coverslips. SV40 is a small, 45 nm-diameter, tumor-virus consisting of an outer protein shell of 720 copies of the VP1 protein, with a 5000 base-pair DNA-genome in its core (Figure 5.13a) [78]. As can be seen from the image in Figure 5.13b,

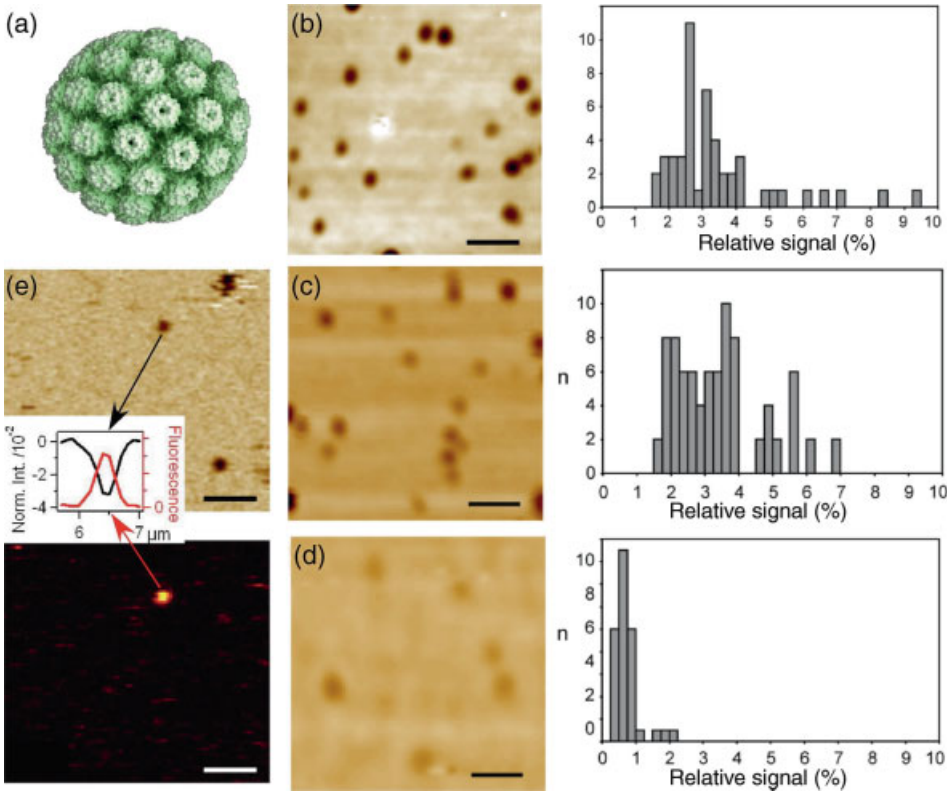

Figure 5.13 Label-free detection of biological nanoparticles. (a) Structure of the SV40 virus as determined from X-ray crystallography; (b) Interferometric images of SV40 adhered to glass and (c) on a supported membrane bilayer; (d) Virus-like particles on a supported membrane bilayer; (e) Simultaneous scattering and fluorescence images of single SV40 viruses labeled with multiple atto-565 fluorophores. The inset shows a cross-section of the particle for both images. Scale bars = 1 µm.

a 45 nm virus shows roughly the same scattering intensity as a 20 nm gold particle ($\sim 3 \times 10^{-2}$). The difference in the observed scattering intensity is due to the lacking plasmon resonance of the virus, and thereby to a reduced polarizability. To test the applicability of this approach in a biologically relevant environment, we have also obtained images of SV40 virions bound to supported lipid bilayer membranes (Figure 5.13c) [66]. Prior to addition of the virus, the membranes showed a homogeneous background signal and few detectable spots caused by unfused vesicles. Within seconds of adding the virus to the solution, Gaussian spots appeared in the image, corresponding to single viruses binding to GM1 pentasaccharide receptors that had been added to the membrane. The signal intensity was comparable to that of viruses bound to the glass coverslips (2.6×10^{-2}). To confirm the validity of the interpretation, we performed two further experiments. First, we acquired images of SV40 virus-like particles, which are identical to the virions, except that the DNA core had been removed. As might be expected, due to the reduced amount of material, the observed signal intensity was lower compared to the viruses at 0.75×10^{-2} (Figure 5.13d). Second, we checked our images by simultaneously acquiring fluorescence and scattering images of fluorescence-labeled SV40 viruses on a supported membrane bilayer (Figure 5.13e). As can be seen in the figure, the two images corresponded perfectly. The inset shows a slice along the virus, demonstrating the complementary nature of the two signals.

In addition, we have performed consecutive confocal scans to investigate diffusion of the virus on the membrane. The trace of the viral motion is superimposed on the image in Figure 5.14a. Computational analysis of the trajectories yielded linear mean square displacement plots, as would be expected for particles undergoing Brownian motion (Figure 5.14b), and exhibited a diffusion constant (D) of 0.0088 ± 0.0004 $\mu m^2\, s^{-1}$. These first results demonstrate the power of the interferometric detection of nano-objects, and its potential for the long-term tracking of unlabelled biological entities. The requirement for this is of course a well-defined sample where unwanted scattering has been eliminated, as in the case of the membrane studies presented here.

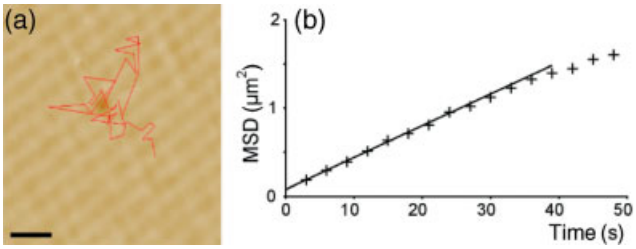

Figure 5.14 Label-free tracking of a single virus diffusing on a supported membrane bilayer. (a) Motion of the virus with 1 s time-resolution acquired over 50 s; (b) Corresponding mean square displacement as deduced from the observed motion in (a), indicating Brownian motion.

5.4 Summary and Outlook

We have discussed the capabilities and limitations of single-molecule fluorescence microscopy, with particular attention being paid to the critical parameters in biological imaging such as the SNR, time resolution and observation time. We have seen that, by detecting and localizing individual fluorescent molecules in a sample, the resolution in optical microscopy can be pushed down to the 1–10 nm regime. The resolution limit in this method is dictated by the noise of the fluorescence signal, and therefore, by the number of photons recorded from each emitter. Currently, problems such as photobleaching and photoblinking prevent an arbitrarily high resolution being achieved in realistic systems. Any efforts to suppress or minimize photobleaching are, therefore, of utmost importance to the future of high-resolution optical microscopy. One interesting possibility is to perform single-molecule detection at cryogenic temperatures where photochemistry is slowed tremendously.

For some imaging and real-time *in vivo* tracking applications, a very promising solution is offered by metallic nanoparticles as alternative labels. The lack of saturation, photobleaching and blinking in light scattering makes such labels ideal candidates to avoid many of the pitfalls of single-molecule spectroscopy. In particular, we have shown how recent advances in the interferometric detection of single gold nanoparticles enable the observation of such labels with sizes down to 5 nm. The ability to illuminate the sample at high power, without saturating the signal, allows a faster integration time and thus a much improved tracking speed, to more than three orders of magnitude above what is possible in single-molecule applications. Finally, we have shown how this interferometric detection technique can be used to observe dielectric objects *without the need for any labels*. Specifically, we have demonstrated label-free detection and the tracking of single SV40 viruses diffusing on artificial lipid bilayer membranes.

The 1990s were witness to a fantastic revival of optical microscopy for high-resolution imaging. Moreover, advances in laser spectroscopy, scanning microscopy, detector technology and photophysics have made it possible to interrogate matter at the single-molecule level, using light *in vitro* and even *in vivo*. In particular, various techniques have shown that the Rayleigh limit can be tackled for specific applications, and have demonstrated optical resolution at the 1–2 nm level. These improvements provide exciting new tools to study a wealth of biological questions at the subcellular level with a spatial resolution more than tenfold higher than can be achieved with conventional confocal microscopy. In other words, the resolution gap between optical microscopy and electron microscopy has been made much smaller. However, what is especially valuable is that this high optical resolution provides a major opportunity to open our eyes to the real-time life processes that occur within a functioning cell.

The road to the optical visualization of every single molecule in the sample, along with its trajectory in the time domain, remains long. However, if the rapid progress made during the past two decades continues then we will have good reason to feel that

this chapter will soon become somewhat of an 'antique'. In fact, since the first concept of this chapter, video rate fluorescence imaging with a focal spot of approximately 60 nm in living cells has been achieved using RESOLFT, and this has resulted in some impressive images of synaptic vesicle movement [79]. Furthermore, the initial 2-D studies with PALM and STORM have now been extended to 3-D imaging with a lateral resolution of 20–30 nm and an axial resolution of 50–60 nm [80]. Finally, single-molecule detection has been successfully extended to the investigation of single labels, such as semiconductor quantum dots, in *absorption* at room temperature. This will surely open the way to optical nanoscopy without a need for efficient fluorescent labels [74].

Nanostructured Probes for *In Vivo* Gene Detection

Gang Bao, Phillip Santangelo, Nitin Nitin, and Won Jong Rhee

6.1
Introduction

The ability to image specific RNAs in living cells in real time can provide essential information on RNA synthesis, processing, transport and localization, as well as on the dynamics of RNA expression and localization in response to external stimuli. Such an ability will also offer unprecedented opportunities for advancement in molecular biology, disease pathophysiology, drug discovery and medical diagnostics. Over the past decade or so, an increasing amount of evidence has come to light suggesting that RNA molecules have a wide range of functions in living cells, from physically conveying and interpreting genetic information, to essential catalytic roles, to providing structural support for molecular machines, and to gene silencing. These functions are realized through control of the expression level and stability, both temporally and spatially, of specific RNAs in a cell. Therefore, determining the dynamics and localization of RNA molecules in living cells will significantly impact on the molecular biology and medicine.

Many *in vitro* methods have been developed to provide a relative (mostly semi-quantitative) measure of gene expression level within a cell population, by using purified DNA or RNA obtained from cell lysates. These methods include the polymerase chain reaction (PCR) [1], Northern hybridization (or Northern blotting) [2], expressed sequence tag (EST) [3], serial analysis of gene expression (SAGE) [4], differential display [5] and DNA microarrays [6]. These technologies, combined with the rapidly increasing availability of genomic data for numerous biological entities, present exciting possibilities for the understanding of human health and disease. For example, pathogenic and carcinogenic sequences are increasingly being used as clinical markers for diseased states. However, the use of *in vitro* methods to detect and identify foreign or mutated nucleic acids is often difficult in a clinical setting, due to the low abundance of diseased cells in blood, sputum and stool samples. Further, these methods cannot reveal the spatial and temporal variation of RNA within a single cell.

Labeled linear oligonucleotide (ODN) probes have been used to study intracellular mRNA via *in situ* hybridization (ISH) [7], in which cells are fixed and permeabilized to increase the probe delivery efficiency. Unbound probes are removed by washing to reduce the background and achieve specificity [8]. In order to enhance the signal level, multiple probes targeting the same mRNA can be used [7], although fixation agents and other supporting chemicals can have a considerable effect on the signal level [9] and possibly also on the integrity of certain organelles, such as mitochondria. Thus, the fixation of cells (by using either crosslinking or denaturing agents) and the use of proteases in ISH assays may prevent an accurate description of intracellular mRNA localization from being obtained. It is also difficult to obtain a dynamic picture of gene expression in cells using ISH methods.

Of particular interest is the fluorescence imaging of specific messenger RNAs (mRNAs) – in terms of both their expression level and subcellular localization – in living cells. As shown schematically in Figure 6.1, for eukaryotic cells a pre-mRNA molecule is synthesized in the cell nucleus. After processing (including splicing and polyadenylation), the mature mRNAs are transported from the cell nucleus to the cytoplasm, and often are localized at specific sites. The mRNAs are then translated by

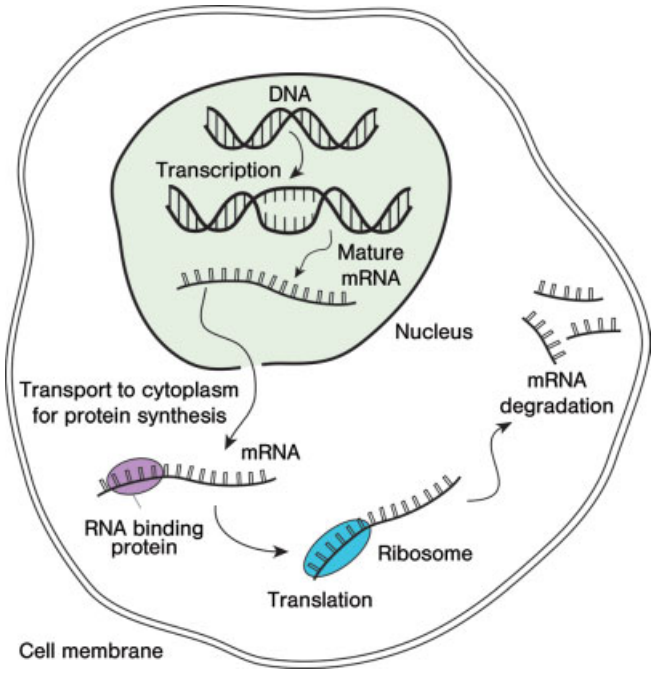

Figure 6.1 The mRNA life cycle. Messenger RNA (mRNA) encoding the chemical 'blueprint' for a protein is synthesized (transcribed) from a DNA template, and the pre-mRNA is processed (spliced) to produce a mature mRNA; this is then transported to specific locations in the cell cytoplasm. The coding information carried by mRNA is used by the ribosomes to produce proteins (translation). After a certain time the message is degraded. mRNAs are almost always complexed with RNA-binding proteins to form ribonucleoprotein (RNP) molecules.

ribosomes to produce specific proteins, and then degraded by RNases after a certain period of time. The limited lifetime of mRNA enables a cell to alter its protein synthesis rapidly, and in response to its changing needs. During the entire life cycle of an mRNA, it is always complexed with RNA-binding proteins to form a ribonucleoprotein (RNP). This has significant implications for the live-cell imaging of mRNAs (as discussed below).

To detect RNA molecules in living cells, with not only high specificity but also high sensitivity and signal-to-background ratio, it is important that the probes recognize RNA targets with high specificity, convert target recognition *directly* into a measurable signal, and differentiate between true and false-positive signals. This is especially important for low-abundance genes and clinical samples containing only a small number of diseased cells. It is also important for the probes to quantify low gene expression levels with great accuracy, and have fast kinetics in tracking alterations in gene expression in real time. For detecting genetic alterations such as mutations, insertions and deletions, the ability to recognize single nucleotide polymorphisms (SNPs) is essential. In order to achieve this optimal performance, it is necessary to have a good understanding of the structure–function relationship of the probes, the probe stability and the RNA target accessibility in living cells. It is also necessary to achieve an efficient cellular delivery of probes, with minimal probe degradation.

In the following sections we will review the fluorescent probes that are most often used for RNA detection, and discuss the critical issues in live-cell RNA detection, including probe design, target accessibility, the cellular delivery of probes, as well as detection sensitivity, specificity and signal-to-background ratio. Emphasis is placed on the design and application of molecular beacons, although some of the issues are common to other oligonucleotide probes.

6.2
Fluorescent Probes for Live-Cell RNA Detection

Several classes of molecular probes have been developed for RNA detection in living cells, including: (i) tagged linear ODN probes; (ii) oligonucleotide hairpin probes; and (iii) probes using fluorescent proteins as reporter. Although probes composed of full-length RNAs (mRNA or nuclear RNA) tagged with a fluorescent or radioactive reporter have been used to study the intracellular localization of RNA [10–12], they are not discussed here as they cannot be used to measure the expression level of specific RNAs in living cells.

6.2.1
Tagged Linear ODN Probes

Single fluorescently labeled linear oligonucleotide probes have been developed for RNA tracking and localization studies in living cells [13–15]. Although these probes may recognize specific endogenous RNA transcripts in living cells via Watson–Crick base pairing, and thus reveal subcellular RNA localization, this approach lacks the

ability to distinguish background from true signal, as both bound probes (i.e. those hybridized to RNA target) and unbound probes give a fluorescence signal. Such an approach might also lack detection specificity, as a partial match between the probe and target sequences could induce probe hybridization to RNA molecules of multiple genes. A novel way to increase the signal-to-noise ratio (SNR) and improve detection specificity is to use two linear probes with a fluorescence resonance energy transfer (FRET) pair of (donor and acceptor) fluorophores [13]. However, the dual-linear probe approach may still have a high background signal due to direct excitation of the acceptor and emission detection of the donor fluorescence. Further, it is difficult for linear probes to distinguish targets that differ by a few bases as the difference in free energy of the two hybrids (with and without mismatch) is typically rather small. This limits the application of linear ODN probes in biological and disease studies.

6.2.2 ODN Hairpin Probes

Hairpin nucleic acid probes have the potential to be highly sensitive and specific in live-cell RNA detection. As shown in Figure 6.2a and b, one class of such probes is that of '*molecular beacons*'; these are dual-labeled oligonucleotide probes with a fluorophore at one end and a quencher at the other end [16]. They are designed to form a stem–loop hairpin structure in the absence of a complementary target, so that the fluorescence of the fluorophore is quenched. Hybridization with the target nucleic acid opens the hairpin and physically separates the fluorophore from quencher, allowing a fluorescence signal to be emitted upon excitation (Figure 6.2b). Under optimal conditions, the fluorescence intensity of molecular beacons can increase more than 200-fold upon binding to their targets [16], and this enables them to function as sensitive probes with a high signal-to-background ratio. The stem–loop hairpin structure provides an adjustable energy penalty for hairpin opening which improves probe specificity [17, 18]. The ability to transduce target recognition *directly* into a fluorescence signal with a high signal-to-background ratio, coupled with an improved specificity, has allowed molecular beacons to enjoy a wide range of biological and biomedical applications. These include multiple analyte detection, real-time enzymatic cleavage assaying, cancer cell detection, real-time monitoring of PCR, genotyping and mutation detection, viral infection studies and mRNA detection in living cells [14, 19–32].

As illustrated in Figure 6.2a, a *conventional molecular beacon* has four essential components: loop, stem, fluorophore (dye) and quencher. The loop usually consists of 15–25 nucleotides and is selected to have a unique target sequence and proper melting temperature. The stem, which is formed by two complementary short-arm sequences, is typically four to six bases long and chosen to be independent of the target sequence (Figure 6.2a).

A novel design of hairpin probes is the *wavelength-shifting molecular beacon*, which can fluoresce in a variety of different colors [33]. As shown in Figure 6.2c, in this design, a molecular beacon contains two fluorophores (dyes): a first fluorophore that absorbs

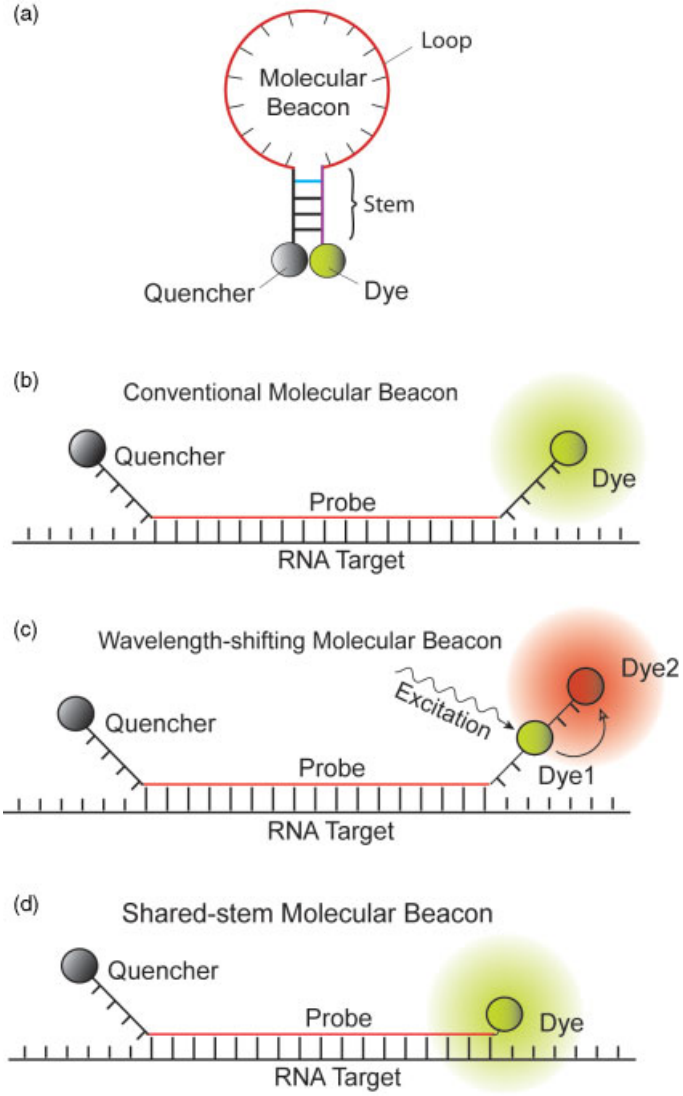

Figure 6.2 Illustrations of molecular beacon designs. (a) Molecular beacons are stem–loop hairpin oligonucleotide probes labeled with a reporter fluorophore at one end and a quencher molecule at the other end; (b) Conventional molecular beacons are designed such that the short complementary arms of the stem are independent of the target sequence; (c) Wavelength-shifting molecular beacons contain two fluorophores: one absorbs in the wavelength range of the monochromatic light source, and the other emits light at the desired emission wavelength due to FRET; (d) Shared-stem molecular beacons are designed such that one arm of the stem participates in both stem formation and target hybridization.

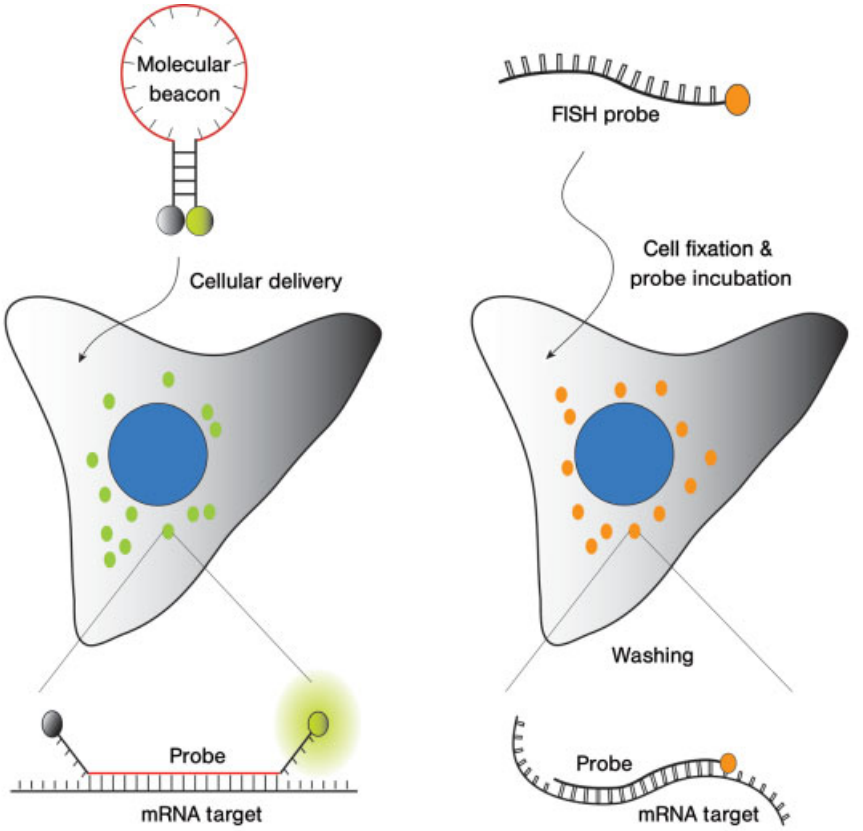
strongly in the wavelength range of the monochromatic light source, and a second fluorophore that emits at the desired emission wavelength due to fluorescence resonance energy transfer from the first fluorophore to the second fluorophore. It has been shown that wavelength-shifting molecular beacons are substantially brighter than conventional molecular beacons, which contain a fluorophore that cannot efficiently absorb energy from the available monochromatic light source.

One major advantage of the stem–loop hairpin probes is that they can recognize their targets with higher specificity than can linear ODN probes. The results of solution studies [17, 18] have suggested that, by using molecular beacons it is possible to discriminate between targets that differ by a single nucleotide. In contrast to current techniques for detecting SNPs – which are often labor-intensive and time-consuming – molecular beacons may provide a simple and promising tool for detecting SNPs in disease diagnosis.

The basic features of molecular beacon versus fluorescence *in situ* hybridization (FISH) are compared in Figure 6.3. Specifically, molecular beacons are dual-labeled hairpin probes of 15–25 nt, while FISH probes are dye-labeled linear oligonucleotides of 40–50 nt. The molecular beacon-based approach has the advantage of detecting RNA in live cells, without the need for cell fixation and washing. However, it does requires the cellular delivery of probes and has a low target accessibility (this is discussed below). The advantage of FISH assays is the ease of probe design due to a better target accessibility. Although FISH assays can be used to image the localization of mRNA in fixed cells, they rely on stringent washing to achieve signal specificity, and do not have the ability to image the dynamics of gene expression in living cells.

In the conventional molecular beacon design, the stem sequence is typically independent of the target sequence (see Figure 6.2b), although sometimes two end bases of the probe sequence, each adjacent to one arm sequence of the stem, could be complementary with each other, thus forming part of the stem (the light blue base of the stem shown in Figure 6.2a). Molecular beacons can also be designed such that all the bases of one arm of the stem (to which a fluorophore is conjugated) are complementary to the target sequence, thus participating in both stem formation and target hybridization (shared-stem molecular beacons) [34] (Figure 6.2d). The advantage of this shared-stem design is to help fix the position of the fluorophore that is attached to the stem arm, limiting its degree-of-freedom of motion, and increasing the FRET in the dual-FRET molecular beacon design (as discussed below).

A dual-FRET molecular beacon approach was developed [26–28] to overcome the difficult that, in live-cell RNA detection, molecular beacons are often degraded by nucleases or open due to nonspecific interaction with hairpin-binding proteins, causing a significant amount of false-positive signal. In this dual-probe design, a pair of molecular beacons labeled with a donor and an acceptor fluorophore, respectively are employed (Figure 6.4). The probe sequences are chosen such that this pair of molecular beacons hybridizes to adjacent regions on a single RNA target (Figure 6.4). As FRET is very sensitive to the distance between donor and acceptor fluorophores, and typically occurs when the donor and acceptor fluorophores are



Molecular beacon	FISH
Hairpin probe of 15–25 nt	Linear probe of 40–50 nt
Live cell assay	With fixed cells
Low target accessibility	Good target accessibility
Requires cellular delivery	Requires cell fixation & probe incubation

Figure 6.3 Comparison of molecular beacon and FISH approaches.

within ~10 nm, the FRET signal is generated by the donor and acceptor beacons only if both probes are bound to the same RNA target. Thus, the sensitized emission of the acceptor fluorophore upon donor excitation serves as a positive signal in the FRET-based detection assay; this can be differentiated from non-FRET false-positive signals due to probe degradation and nonspecific probe opening. This approach combines the low background signal and high specificity of molecular

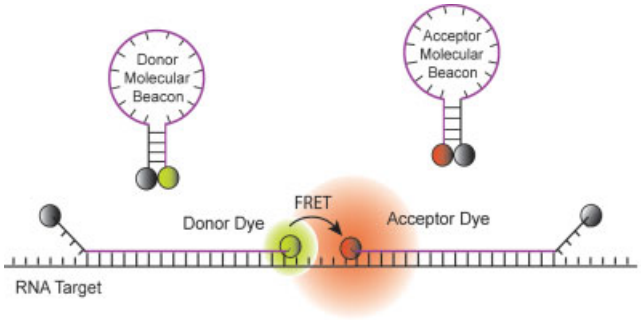


Figure 6.4 A schematic showing the concept of dual-FRET molecular beacons. Hybridization of the donor and acceptor molecular beacons to adjacent regions on the same mRNA target results in FRET between donor and acceptor fluorophores upon donor excitation. By detecting the FRET signal, fluorescence signals due to probe/target binding can be readily distinguished from that due to molecular beacon degradation and nonspecific interactions.

beacons with the ability of FRET assays in differentiating between true target recognition and false-positive signals, leading to an enhanced ability to quantify RNA expression in living cells [28].

6.2.3 Fluorescent Protein-Based Probes

In addition to oligonucleotide probes, tagged RNA-binding proteins such as those with green fluorescent protein (GFP) tags have been used to detect mRNA in live cells [35]. One limitation here is that it requires the identification of a unique protein, which only binds to the specific mRNA of interest. To address this issue, a coat protein of the RNA bacteriophage MS2 was tagged with GFP, after which a RNA sequence corresponding to several MS2 binding sites was introduced to the mRNA of interest. This allowed for the specific targeting of the *nanos* mRNA in live *Drosophila* eggs [36]. The GFP-MS2 approach has been used to track the localization and dynamics of RNA in living cells with single-molecule sensitivity [37, 38]. However, as unbound GFP-tagged MS2 proteins also produce a fluorescence signal, the background signal in the GFP-MS2 approach could be high, leading to a low signal-to-background ratio in live-cell imaging of RNA.

An interesting fluorescent protein-based approach that overcomes this problem is to utilize the fluorescent protein complementation [39, 40]. In this method (split-GFP), a RNA-binding protein is dissected into two fragments, which are respectively fused to the split fragments of a fluorescent protein. Binding of the two tagged fragments of the RNA-binding protein to adjacent sites on the same mRNA molecule (or two parts of an aptamer sequence inserted to the mRNA sequence) brings the two halves of the fluorescent protein together, thus reconstituting the fluorescent protein and restoring fluorescence [40]. Alternatively, two RNA-binding proteins that bind specifically to adjacent sites on the same mRNA molecule can be

tagged with the split fragments of a fluorescent protein, such that their binding to the target mRNA results in the restoration of fluorescence [39]. The advantage of this novel approach is that the background signal is low; there is no fluorescence signal unless the RNA-binding proteins (or protein fragments) are bound to the target mRNA. The split-GFP method, however, may have difficulties in tracking the dynamics of RNA expression in real time, as reconstitution of the fluorescent protein from the split fragments typically takes 2–4 h, during which time the RNA expression level may change. Transfection efficiency may also be a major concern in the GFP-based approaches, in that usually only a small percentage of the cells express the fluorescent proteins following transfection. This limits the application of the split-GFP methods in detecting diseased cells using mRNA as a biomarker for the disease.

6.3 Probe Design and Structure–Function Relationships

6.3.1 Target Specificity

There are three major design issues of molecular beacons: probe sequence; hairpin structure; and fluorophore/quencher selection. In general, the probe sequence is selected to ensure specificity, and to have good target accessibility. The hairpin structure, as well as the probe and stem sequences, are determined to have the proper melting temperature, while the fluorophore–quencher pair should produce a high signal-to-background ratio. To ensure specificity, for each gene to target, it is possible to use the NCBI BLAST [41] or similar software to select multiple target sequences of 15–25 bases that are unique to the target RNA. As the melting temperature of the molecular beacons affects both the signal-to-background ratio and detection specificity (especially for mutation detection), it is often necessary to select the target sequence with a balanced G-C content, and to adjust the loop and stem lengths and the stem sequence of the molecular beacon to realize the optimal melting temperature. In particular, it is necessary to understand the effect of molecular beacon design on melting temperature so that, at 37 °C, single-base mismatches in target mRNAs can be differentiated. This is also a general issue for detection specificity in that, for any specific probe sequence selected, there might be multiple genes in the mammalian genome that have sequences which differ from the probe sequence by only a few bases. Therefore, it is important to design the molecular beacons so that only the specific target RNA would produce a strong signal.

Several approaches can be taken to validate the signal specificity. For example, one could either upregulate or downregulate the expression level of a specific RNA, quantify the level using RT-PCR, and then compare the PCR result with that of molecular beacon-based imaging of the same RNA in living cells. However, complications may arise when the approach used to change the RNA expression level in living cells has an effect on multiple genes, as this would lead to some ambiguity, even

when the PCR and beacon results match. It is possible that the best way to down-regulate the level of a specific mRNA in live cells is to use small interfering RNA (siRNA) treatment, which typically leads to a >80% reduction of the specific mRNA level. As the effect of siRNA treatment varies depending on the specific probe used, the siRNA delivery method, cell type and optimization of the protocol (i.e. probe design and delivery method/conditions) is often needed.

6.3.2
Molecular Beacon Structure–Function Relationships

The loop, stem lengths and sequences are critical design parameters for molecular beacons, since at any given temperature they largely control the fraction of molecular beacons that are bound to the target [17, 18]. In many applications, the choices of the probe sequence are limited by target-specific considerations, such as the sequence surrounding a single nucleotide polymorphism (SNP) of interest. However, the probe and stem lengths, and stem sequence, can be adjusted to optimize the performance (i.e. specificity, hybridization rate and signal-to-background ratio) of a molecular beacon for a specific application [17, 34].

In order to demonstrate the effect of molecular beacon structure on its melting behavior, the melting temperature for molecular beacons with various stem–loop structures is displayed in Figure 6.5a. In general, the melting temperature was found to increase with probe length, but appeared to plateau at a length of ~20 nucleotides. The stem length of the molecular beacon was also found to have a major influence on the melting temperature of the molecular beacon–target duplexes.

While both the stability of the hairpin probe and its ability to discriminate targets over a wider range of temperatures increase with increasing stem length, it is accompanied by a decrease in the hybridization on-rate constant (see Figure 6.5b).

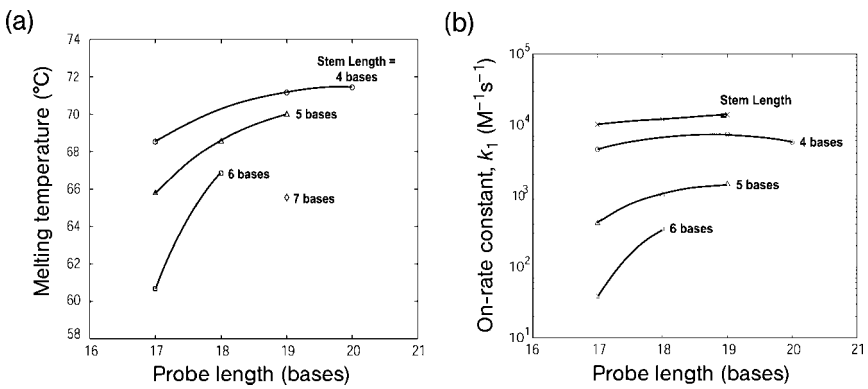

Figure 6.5 Structure–function relationships of molecular beacons. (a) Melting temperatures for molecular beacons with different structures in the presence of target; (b) The rate constant of hybridization k_1 (on-rate constant) for molecular beacons with various probe and stem lengths hybridized to their complementary targets.

For example, molecular beacons with a four-base stem had an on-rate constant up to 100-fold higher than did molecular beacons with a six-base stem. Changing the probe length of a molecular beacon may also influence the rate of hybridization, as shown in Figure 6.5b.

The results of thermodynamic and kinetic studies showed that, if the stem length was too large then it would be difficult for the beacon to open on hybridization. But, if the stem length was too small, then a large fraction of beacons might open due to the thermal force. Likewise, and relative to the stem length, whilst a longer probe might lead to a lower dissociation constant, it might also reduce the specificity, as the relative free energy change due to a one base mismatch would be smaller. A long probe length may also lead to coiled conformations of the beacons, resulting in reduced kinetic rates. Consequently, the stem and probe lengths must be carefully chosen in order to optimize both hybridization kinetics and molecular beacon specificity [17, 34]. In general, molecular beacons with longer stem lengths have an improved ability to discriminate between wild-type and mutant targets in solution, over a broader range of temperatures. This effect can be attributed to the enhanced stability of the molecular beacon stem–loop structure and the resulting smaller free energy difference between closed (unbound) molecular beacons and molecular beacon–target duplexes, which generates a condition where a single-base mismatch reduces the energetic preference of probe–target binding. Longer stem lengths, however, are accompanied by a reduced probe–target hybridization kinetic rate. On a similar note, molecular beacons with short stems have faster hybridization kinetics but suffer from lower signal-to-background ratios compared to molecular beacons with longer stems.

6.3.3
Target Accessibility

One critical issue in molecular beacon design is target accessibility, as is the case for most oligonucleotide probes for live-cell RNA detection. It is well known that a functional mRNA molecule in a living cell is always associated with RNA-binding proteins, thus forming a RNP. An mRNA molecule also often has double-stranded portions and forms secondary (folded) structures (Figure 6.6). Therefore, when designing a molecular beacon it is necessary to avoid targeting mRNA sequences that are double-stranded, or occupied by RNA-binding proteins, for otherwise the probe will have to penetrate into the RNA double strand or compete with the RNA-binding protein in order to hybridize to the target. In fact, molecular beacons designed to target a specific mRNA often show no signal when delivered to living cells. One difficulty in molecular beacon design is that, although predictions of mRNA secondary structure can be made using software such as *Beacon Designer* (www.premierbiosoft.com) and *mfold* (http://www.bioinfo.rpi.edu/applications/mfold/old/dna/), they may be inaccurate due to limitations of the biophysical models used, and the limited understanding of protein–RNA interaction. Therefore, for each gene to be targeted it may be necessary to select multiple unique sequences along the target RNA, and then to design, synthesize and test the corresponding molecular beacons in living cells in order to select the best target sequence.

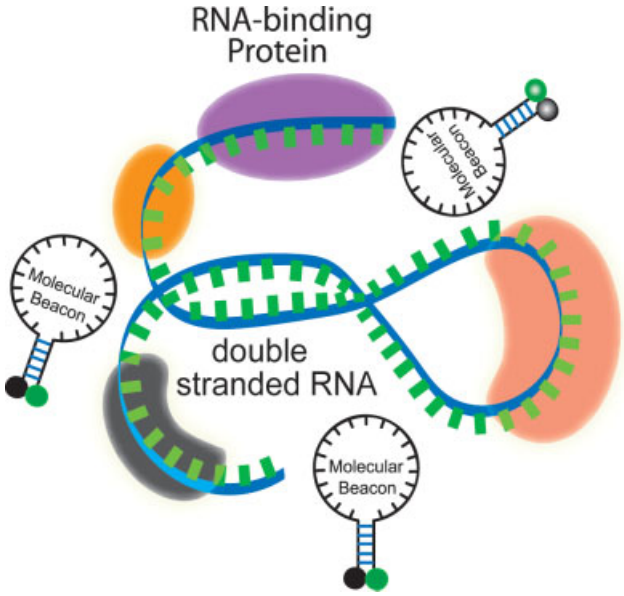

Figure 6.6 A schematic illustration of a segment of the target mRNA with a double-stranded portion and RNA-binding proteins. A molecular beacon must penetrate into the mRNA double strand or compete with the RNA-binding protein(s) in order to hybridize to the target.

In aiming to reveal the possible molecular beacon design rules, the accessibility of BMP-4 mRNA was studied using different beacon designs [42]. Specifically, molecular beacons were designed to target the start codon and termination codon regions, the siRNA and anti-sense oligonucleotide probe sites (which were identified previously) and also the sites that were chosen at random. All of the target sequences are unique to BMP-4 mRNA. Of the eight molecular beacons designed to target BMP-4 mRNA, only two were found to produce a strong signal: one which targeted the start codon region, and one which targeted the termination codon region. It was also found that, even for a molecular beacon which functioned well, shifting its targeting sequence by only a few bases towards the 3′ or 5′ ends caused a significant reduction in the fluorescence signal from beacons in a live-cell assay. This indicated that the target accessibility was quite sensitive to the location of the targeting sequence. These results, together with molecular beacons validated previously, suggest that the start and termination codon regions and the exon–exon junctions are more accessible than other locations in an mRNA.

6.3.4
Fluorophores and Quenchers

With a correct backbone synthesis and fluorophore/quencher conjugation, a molecular beacon can – in theory – be labeled with any desired reporter–quencher pair.

However, the correct selection of the reporter and quencher could also improve the signal-to-background ratio and multiplexing capabilities. The selection of a fluorophore label for a molecular beacon as reporter is normally less critical than for the hairpin probe design, as many conventional dyes can yield satisfactory results. However, the correct selection may yield additional benefits such as an improved signal-to-background ratio and multiplexing capabilities. As each molecular beacon utilizes only one fluorophore, it is possible to use multiple molecular beacons in the same assay, assuming that the fluorophores are chosen with minimal emission overlap [19]. Molecular beacons can even be labeled simultaneously with two fluorophores – that is with 'wavelength shifting' reporter dyes (see Figure 6.2c), allowing multiple reporter dye sets to be excited by the same monochromatic light source but to fluoresce in a variety of colors [33]. Clearly, multicolor fluorescence detection of different beacon/target duplexes may in time become a powerful tool for the simultaneous detection of multiple genes.

For dual-FRET molecular beacons (see Figure 6.4), the donor fluorophores typically emit at shorter wavelengths compared with the acceptor. Energy transfer then occurs as a result of long-range dipole–dipole interactions between the donor and acceptor. The efficiency of such energy transfer depends on the extent of the spectral overlap of the emission spectrum of the donor with the absorption spectrum of the acceptor, the quantum yield of the donor, the relative orientation of the donor and acceptor transition dipoles [43], and the distance between the donor and acceptor molecules (usually four to five bases). In selecting the donor and acceptor fluorophores so as to create a high signal-to-background ratio, it is important to optimize the above parameters, and to avoid direct excitation of the acceptor fluorophore at the donor excitation wavelength. It is also important to minimize donor emission detection at the acceptor emission detection wavelength. Examples of FRET dye pairs include Cy3 (donor) with Cy5 (acceptor), TMR (donor) with Texas Red (acceptor), and fluorescein (FAM) (donor) with Cy3 (acceptor).

By contrast, it is relatively straightforward to select the quencher molecules. Organic quencher molecules such as dabcyl, BHQ2 (blackhole quencher II) (Biosearch Tech), BHQ3 (Biosearch Tech) and Iowa Black (IDT) can all effectively quench a wide range of fluorophores by both FRET and the formation of an exciton complex between the fluorophore and the quencher [44].

6.4
Cellular Delivery of Nanoprobes

One of the most critical aspects of measuring the intracellular level of RNA molecules using synthetic probes is the ability to deliver the probes into cells via the plasma membrane, which itself is quite lipophilic and restricts the transport of large, charged molecules. Thus, the plasma membrane serves as a very robust barrier to polyanionic molecules such as hairpin oligonucleotides. Further, even if the probes enter the cells successfully, the efficiency of delivery in an imaging assay should be defined not only by how many probes enter the cell, or how many cells have probes internalized,

but also by how many probes remain functioning inside the cells. This is a different situation from both antisense and gene delivery applications, where the reduction in level of protein expression is the final metric used to define efficiency or success. For measuring RNA molecules (including mRNA and rRNA) in the cytoplasm, a large amount of the probe should remain in the cytoplasm.

Existing cellular delivery techniques can be divided into two categories, namely *endocytic* and *nonendocytic*. Endocytic delivery typically employs cationic and polycationic molecules such as liposomes and dendrimers, whereas nonendocytic methods include microinjection and the use of cell-penetrating peptides (CPPs) or streptolysin *O* (SLO). Probe delivery via the endocytic pathway typically takes 2–4 h. It has been reported that ODN probes internalized via endocytosis are predominantly trapped inside endosomes and lysosomes, where they are degraded by the action of cytoplasmic nucleases [45]. Consequently, only 0.01% to 10% of the probes remain functioning after having escaped from endosomes and lysosomes [46].

Oligonucleotide probes (including molecular beacons) have been delivered into cells via microinjection [47]. In most cases, the ODNs were accumulated rapidly in the cell nucleus and prevented the probes from targeting mRNAs in the cell cytoplasm. The depletion of intracellular ATP or lowering the temperature from 37 to 4 °C did not have any significant effect on ODN nuclear accumulation, thus ruling out any active, motor protein-driven transport [47]. It is unclear if the rapid transport of ODN probes to the nucleus is due to electrostatic interaction, or is driven by a microinjection-induced flow, or the triggering of a signaling pathway. There is no fundamental biological reason why ODN probes should accumulate in the cell nucleus, but to prevent such accumulation streptavidin (60 kDa) molecules were conjugated to linear ODN probes via biotin [13]. After being microinjected into the cells, the dual-FRET linear probes could hybridize to the same mRNA target in the cytoplasm, resulting in a FRET signal. More recently, it was shown that when transfer RNA (tRNA) transcripts were attached to molecular beacons with a 2′-*O*-methyl backbone and injected into the nucleus of HeLa cells, the probes were exported into the cytoplasm. Yet, when these constructs were introduced into the cytoplasm, they remained cytoplasmic [48]. However, even without the problem of unwanted nuclear accumulation, microinjection is an inefficient process for delivering probes into a large number of cells.

Another nonendocytic delivery method is that of *toxin-based cell membrane permeabilization*. For example, SLO is a pore-forming bacterial toxin that has been used as a simple and rapid means of introducing oligonucleotides into eukaryotic cells [49–51]. SLO binds as a monomer to cholesterol and oligomerizes into a ring-shaped structure to form pores of approximately 25–30 nm in diameter, allowing the influx of both ions and macromolecules. It was found that SLO-based permeabilization could achieve an intracellular concentration of ODNs which was approximately 10-fold that achieved with electroporation or liposomal-based delivery. As cholesterol composition varies with cell type, however, the permeabilization protocol must be optimized for each cell type by varying the temperature, incubation time, cell number and SLO concentration. One essential feature of toxin-based permeabilization is that it is reversible. This can be achieved by introducing oligonucleotides with SLO under

serum-free conditions and then removing the mixture and adding normal media with the serum [50, 52].

Cell-penetrating peptides have also been used to introduce proteins, nucleic acids and other biomolecules into living cells [53–55]. Included among the family of peptides with membrane-translocating activity are antennapedia, HSV-1 VP22 and the HIV-1 Tat peptide. To date, the most widely used peptides are HIV-1 Tat peptide and its derivatives, due to their small sizes and high delivery efficiencies. The Tat peptide is rich in cationic amino acids (especially arginine, which is very common in many CPPs); however, the exact mechanism of CPP-induced membrane translocation remains elusive.

A wide variety of cargos have been delivered to living cells, both in cell culture and in tissues, using CPPs [56, 57]. For example, Allinquant *et al.* [58] linked the antennapedia peptide to the 5′ end of DNA oligonucleotides (with biotin on the 3′ end) and incubated both peptide-linked ODNs and ODNs alone (as control) with cells. By detecting biotin via a streptavidin–alkaline phosphatase amplification, the peptide-linked ODNs were shown to be internalized very efficiently into all cell compartments compared to control ODNs. Moreover, no indication of endocytosis was found. Similar results were obtained by Troy *et al.* [59], with a 100-fold increase in antisense delivery efficiency when the ODNs were linked to antennapedia peptides. Recently, Tat peptides were conjugated to molecular beacons using different linkages (Figure 6.7); the resultant peptide-linked molecular beacons were delivered into living cells to target glyceraldehyde phosphate dehydrogenase (GAPDH) and survivin mRNAs [29]. It was shown that, at relatively low concentrations, peptide-linked molecular beacons were internalized into living cells within 30 min, with near-100% efficiency. Further, peptide-based delivery did not interfere with either specific targeting by, or hybridization-induced florescence of, the probes. In addition, the peptide-linked molecular beacons were seen to possess self-delivery, targeting and reporting functions. In contrast, the liposome-based (Oligofectamine) or dendrimer-based (Superfect) delivery of molecular beacons required 3–4 h and resulted in a punctate fluorescence signal in the cytoplasmic vesicles and a high background in

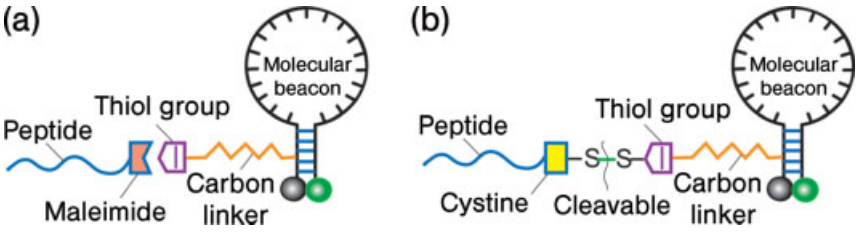

Figure 6.7 A schematic of peptide-linked molecular beacons. (a) A peptide-linked molecular beacon using the thiol–maleimide linkage in which the quencher arm of the molecular beacon stem is modified by adding a thiol group which can react with a maleimide group placed to the C terminus of the peptide to form a direct, stable linkage; (b) A peptide-linked molecular beacon with a cleavable disulfide bridge in which the peptide is modified by adding a cysteine residue at the C terminus; the cysteine then forms a disulfide bridge with the thiol-modified molecular beacon. This disulfide bridge design allows the peptide to be cleaved from the molecular beacon by the reducing environment of the cytoplasm.

both the cytoplasm and nucleus of cells [29]. These results showed clearly that the cellular delivery of molecular beacons using a peptide-based approach is far more effective than conventional transfection methods.

6.5 Living Cell RNA Detection Using Nanostructured Probes

Sensitive gene detection in living cells presents a significant challenge. In addition to issues of target accessibility, detection specificity and probe delivery (as discussed above), the achievement of a high detection sensitivity and a high signal-to-background ratio requires not only careful design of the probes and advanced fluorescence microscopy imaging, but also a better understanding of RNA biology and probe–target interactions. It is likely that different applications have different requirements on the properties of probes. For example, the rapid determination of RNA expression level and localization requires fast probe/target hybridization kinetics, whereas the long-term monitoring of gene expression dynamics requires probes with a high intracellular stability.

To demonstrate the capability of molecular beacons in the sensitive detection of specific endogenous mRNAs in living cells, dual-FRET molecular beacons were designed to detect K-ras and survivin mRNAs in HDF and MIAPaCa-2 cells, respectively [28]. K-*ras* is one of the most frequently mutated genes in human cancers [60]. A member of the G-protein family, K-ras is involved in transducing growth-promoting signals from the cell surface. Survivin, one of the inhibitor of apoptosis proteins (IAPs), is normally expressed during fetal development but not in most normal adult tissues [61], and thus can be used as a tumor biomarker for several types of cancer. Each FRET probe pair consisted of two molecular beacons – one labeled with a donor fluorophore (Cy3, donor beacon) and a second labeled with an acceptor fluorophore (Cy5, acceptor beacon). These molecular beacons were designed to hybridize to adjacent regions on an mRNA target so that the two fluorophores lay within the FRET range (~6 nm) when probe/target hybridization occurred for both beacons. BHQ-2 and BHQ-3 were used as quenchers for the donor and acceptor molecular beacons, respectively. One pair of molecular beacons targets a segment of the wild-type K-*ras* gene, the codon 12 mutations of which are involved in the pathogenesis of many cancers. A negative control dual-FRET molecular beacon pair was also designed ('random beacon pair'), the specific 16-base target sequence of which was selected using random walking, and thus had no exact match in the mammalian genome. It was found that detection of the FRET signal significantly reduced false-positives, leading to sensitive imaging of K-*ras* and survivin mRNAs in live HDF and MIAPaCa-2 cells. For example, FRET detection gave a ratio of 2.25 of K-*ras* mRNA expression in stimulated versus unstimulated HDF cells, which was comparable to a ratio of 1.95 using RT-PCR but contrasted to the single-beacon result of 1.2. The detection of survivin mRNA also indicated that, compared to the single-beacon approach, dual-FRET molecular beacons gave a lower background signal, which in turn led to a higher signal-to-background ratio [28].

6.5.1 Biological Significance

An intriguing discovery in detecting K-*ras* and survivin mRNAs using dual-FRET molecular beacons is the clear and detailed mRNA localization in living cells [28]. To demonstrate this point, a fluorescence image of K-*ras* mRNA in stimulated HDF cells is shown in Figure 6.8a, indicating an intriguing filamentous localization pattern. The localization pattern of K-*ras* mRNA was further studied and found to be colocalized with mitochondria inside live HDF cells [62]. As K-ras proteins interact with proteins such as Bcl-2 in the mitochondria to mediate both anti-apoptotic and pro-apoptotic pathways, it seems that cells localize certain mRNAs where the corresponding proteins can easily bind to their partners.

The survivin mRNA, however, is localized in MIAPaCa-2 cell very differently. As shown in Figure 6.8b, in which the fluorescence image was superimposed with a white-light image of the cells, the survivin mRNAs seemed to localize in a nonsymmetrical pattern within MIAPaCa-2 cells, often to one side of the nucleus of the cell. These mRNA localization patterns raise many interesting biological questions. For example, how are mRNAs transported to their destination, and how is the destination recognized? Also, to which subcellular organelle might the mRNAs be colocalized? And what is the biological implication of mRNA localization? Although mRNA localization in living cells is believed to be closely related to the post-transcriptional regulation of gene expression, much remains to be seen if such localization indeed targets a protein to its site of function by producing the protein 'right on the spot'.

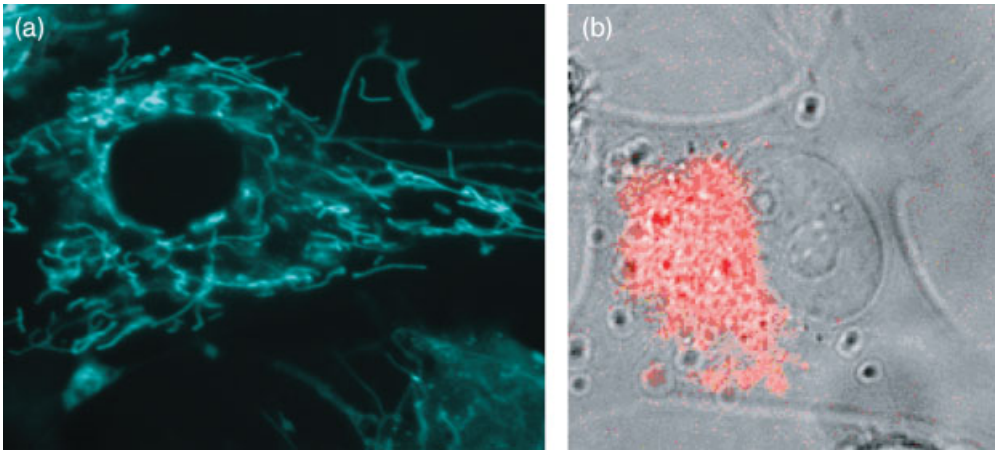

Figure 6.8 mRNA localization in HDF and MIAPaCa-2 cells. (a) Fluorescence images of K-*ras* mRNA in stimulated HDF cells. Note the filamentous K-*ras* mRNA localization pattern; (b) A fluorescence image of survivin mRNA localization in MIAPaCa-2 cells. Note that survivin mRNAs are often localized to one side of the nucleus of the MIAPaCa-2 cells.

The transport and localization of oskar mRNA in *Drosophila melanogaster* oocytes has also been visualized [26]. In these studies, molecular beacons with a 2′-*O*-methyl backbone were delivered into cells using microinjection, and the migration of oskar mRNA was tracked in real time, from the nurse cells where it is produced to the posterior cortex of the oocyte where it is localized. Clearly, the direct visualization of specific mRNAs in living cells with molecular beacons will provide important insights into the intracellular trafficking and localization of RNA molecules.

As another example of targeting specific genes in living cells, molecular beacons were used to detect the viral genome and characterize the spreading of bovine respiratory syncytial virus (bRSV) in living cells [63]. It was found that a molecular beacon signal could be detected in single living cells infected by bRSV with high detection sensitivity, and the signal revealed a connected, highly three-dimensional, amorphous inclusion-body structure not seen in fixed cells. Figure 6.9 shows the molecular beacon signal indicating the spreading of viral infection at days 1, 3, 5 and

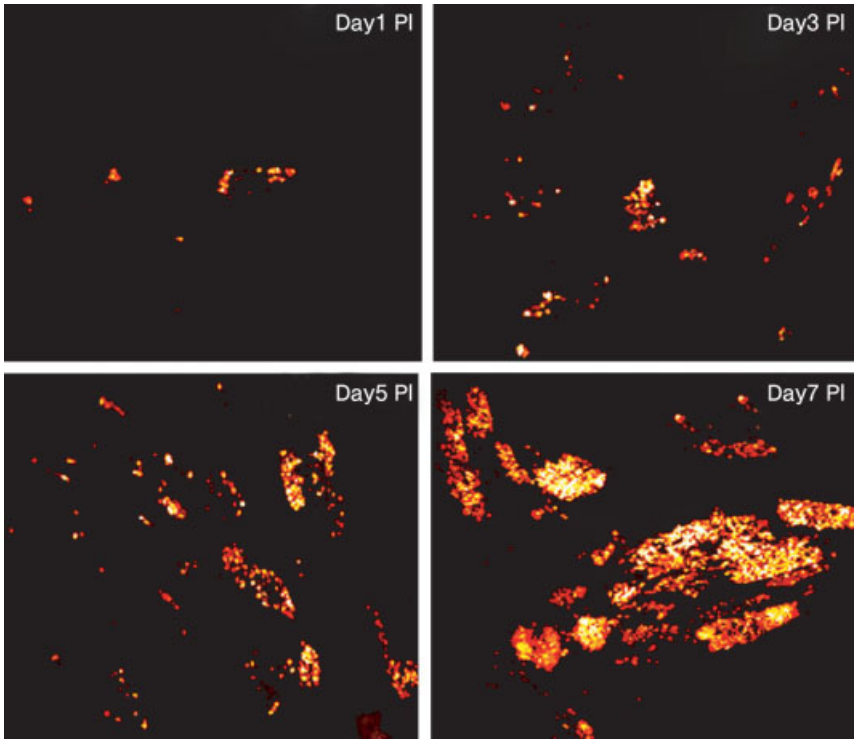

Figure 6.9 Live-cell fluorescence imaging of the genome of bovine respiratory syncytial virus (bRSV) using molecular beacons, showing the spreading of infection in host cells at days 1, 3, 5 and 7 post-infection (PI). Primary bovine turbinate cells were infected by a clinical isolate of bRSV, CA-1, with a viral titer of $2 \times 10^{3.6}\,TCID_{50}\,ml^{-1}$. Molecular beacons were designed to target several repeated sequences of the gene-end-intergenic-gene-start signal within the bRSV genome, with a SNR of 50–200.

7 post-infection, and demonstrates the ability of molecular beacons to monitor and quantify – in real time – the viral infection process. Molecular beacons were also used to image the viral genomic RNA (vRNA) of human RSV (hRSV) in live Vero cells, revealing the dynamics of filamentous virion egress, and providing an insight as to how viral filaments bud from the plasma membrane of the host cell [64].

6.6 Engineering Challenges in New Probe Development

Nanostructured molecular probes such as molecular beacons have the potential to enjoy a wide range of applications that require the sensitive detection of genomic sequences. For example, molecular beacons can be used as a tool for the detection of single-stranded nucleic acids in homogeneous *in vitro* assays [65, 66]. Surface-immobilized molecular beacons used in microarray assays allow for the high-throughput parallel detection of nucleic acid targets, while avoiding the difficulties associated with PCR-based labeling [65, 67]. Another novel application of molecular beacons is the detection of double-stranded DNA targets using PNA 'openers' that form triplexes with the DNA strands [68]. Further, proteins can be detected by synthesizing an 'aptamer molecular beacon' [69, 70] which, upon binding to a protein, undergoes a conformational change that results in the restoration of fluorescence.

The most exciting application of nanostructured oligonucleotide probes, however, is that of living cell *gene detection*. As demonstrated, molecular beacons can detect endogenous mRNA in living cells with high specificity, sensitivity and signal-to-background ratio, and thus have the potential to provide a powerful tool for both laboratory and clinical studies of gene expression *in vivo*. For example, molecular beacons can be used in high-throughput cell-based assays to quantify and monitor the dose-dependent changes of specific mRNA expression in response to different drug leads. The ability of molecular beacons to detect and quantify the expression of specific genes in living cells will also facilitate disease studies, such as viral infection detection and cancer diagnosis.

A number of challenges exist in the detection and quantification of RNA expression in living cells. In addition to the issues of probe design and target accessibility, quantifying gene expression in living cells in terms of mRNA copy-number per cell poses a significant challenge. For example, it is necessary to distinguish between true and background signals, to determine the fraction of mRNA molecules hybridized with probes, and to quantify the possible self-quenching effect of the reporter, especially when mRNA is highly localized. As the fluorescence intensity of the reporter may be altered by the intracellular environment, it is also necessary to create an internal control by, for example, injecting fluorescently labeled oligonucleotides with known quantity into the same cells and obtaining the corresponding fluorescence intensity. Furthermore, unlike RT-PCR studies – where the mRNA expression is averaged over a large number of cells (usually $>10^6$) – in the optical imaging of mRNA expression in living cells only a relatively small number of cells (typically

<1000) are observed. Therefore, the average copy number per cell may change with the total number of cells observed due to the (often large) cell-to-cell variation of mRNA expression.

Another issue in living cell gene detection using hairpin ODN probes is the possible effect of probes on normal cell function, including protein expression. As has been revealed in antisense therapy research, the complementary pairing of a short segment of an exogenous oligonucleotide to mRNA can have a profound impact on protein expression levels, and even cell fate. For example, tight binding of the probe to the translation start site may block mRNA translation. Binding of a DNA probe to mRNA can also trigger RNase H-mediated mRNA degradation. However, the probability of eliciting antisense effects with hairpin probes may be very low when low concentrations of probes (<200 n*M*) are used for mRNA detection, in contrast to the high concentrations (typically 20 μ*M*; [51]) employed in antisense experiments. Further, it generally takes 4 h before any noticeable antisense effect occurs, whereas the visualization of mRNA with hairpin probes requires less than 2 h after delivery. However, it is important to carry out a systematic study of the possible antisense effects, especially for molecular beacons with a 2′-*O*-methyl backbone, which may also trigger unwanted RNA interference.

As a new approach for *in vivo* gene detection, nanostructured probes can be further developed to have an enhanced sensitivity and a wider range of applications. For example, it is likely that hairpin ODN probes with quantum dot as the fluorophore will have a better ability to track the transport of individual mRNAs from the cell nucleus to the cytoplasm. Hairpin ODN probes with a near-infrared (NIR) dye as the reporter, combined with peptide-based delivery, have the potential to detect specific RNAs in tissue samples, animals or even humans. It is also possible to use lanthanide chelate as the donor in a dual-FRET probe assay and to perform time-resolved measurements to dramatically increase the SNR, thus achieving high sensitivity while detecting low-abundance genes. Although very challenging, the development of these and other nanostructured ODN probes will significantly enhance our ability to image, track and quantify gene expression *in vivo*, and provide a powerful tool for basic and clinical studies of human health and disease.

There are many possibilities for nanostructured probes to become clinical tools for disease detection and diagnosis. For example, molecular beacons could be used to perform cell-based early cancer detection using clinical samples such as blood, saliva and other body fluids. In this case, cells in the clinical sample are separated, while the molecular beacons designed to target specific cancer genes are delivered to the cell cytoplasm for detecting mRNAs of the cancer biomarker genes. Cancer cells having a high level of the target mRNAs (e.g. survivin) or mRNAs with specific mutations that cause cancer (e.g. K-*ras* codon 12 mutations) would show high levels of fluorescence signal, whereas normal cells would show just a low background signal. This would allow cancer cells to be distinguished from normal cells. When using this approach, the target mRNAs would not be diluted compared to approaches using a cell lysate, such as PCR. Thus, molecular beacon-based assays have the potential for the positive identification of cancer cells in a clinical sample, with high specificity and sensitivity. It might also be possible to detect cancer cells *in vivo*

by using NIR-dye-labeled molecular beacons in combination with endoscopy. Nanostructured probes could also be used for the cell-based detection of other diseases. As illustrated above, well-designed molecular beacons can rapidly detect viral infection in living cells, with high specificity and sensitivity. Another possibility might be to analyze the vulnerability of atherosclerotic plaques by designing nanostructured probes to image biomarkers (mRNAs or proteins) of vulnerable plaques in blood samples. Although there remain significant challenges, imaging methods using nanostructured probes possess a truly great potential to become a powerful clinical tool for disease detection and diagnosis.

High-Content Analysis of Cytoskeleton Functions by Fluorescent Speckle Microscopy

Kathryn T. Applegate, Ge Yang, and Gaudenz Danuser

7.1
Introduction

In 1949, Linus Pauling observed that hemoglobin in patients with sickle cell anemia is structurally different from that in healthy individuals [1]. This seminal discovery of a 'molecular disease' overturned a century-old notion that all diseases were caused by structural problems at the cellular level. Today, we know that disease can arise from aberrations in the expression, regulation or structure of a single molecule. Frequently, such aberrations interfere with one or more of the cell's basic morphological activities, including cell division, morphogenesis and maintenance in different tissue environments, or cell migration.

The advent of molecular pathology precipitated the rise of molecular biology and genomics, which in turn jump-started other large-scale '-omics' fields. In parallel, sophisticated imaging, quantitative image analysis and bioinformatics approaches were developed. These methods have enabled a quantum leap in our knowledge base about the molecular underpinnings of life, and what goes wrong during disease. Much has already been translated to the clinic. For example, mutation and gene expression profiles can be used to prescribe targeted drugs to breast cancer patients [2], and in the US many states have adopted metabolic screening programs to test newborns for a growing number of disorders [3].

Yet on the whole, the genomic era has failed to yield the 'goldmine of personalized interventions' that it first promised. Drug development pipelines rely heavily on high-throughput screens to identify compounds that have a desired effect on the biochemical activity of a particular drug target. These screens, however, cannot resolve whether a 'hit' will be active in living cells and specific to the pathway of interest. To avoid this limitation, high-content screens – also called 'phenotypic' or 'imaging' screens – use automated image analysis methods to detect desired changes in cells photographed under the light microscope [4]. Changes in gross cell morphology or the spatial activity of a protein of interest become apparent when analyzing a large population of cells. Although the identification of a molecular target causing a

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

phenotypic change can be rate-limiting, assays can often be designed with the drug target already in mind. The larger challenge is to derive meaningful, quantitative phenotypic information from images [4].

The problem of extracting phenotypic information is compounded by the fact that many phenotypic differences can only be resolved in *time*; the dynamics of molecules, not just their concentrations and localization, are important in disease development. In other words, a cell may look healthy in a still image, but an analysis of the underlying dynamics of cell-adhesion proteins, for example, may reveal that the cell has metastatic potential. Current phenotypic screens can only distinguish between coarse, spatially oriented phenotypes [5], while many diseases exhibit extremely subtle, yet significant, phenotypes. New methods are needed to extract and correlate dynamic descriptors if we are to design drugs and other nanomedical intervention strategies with minimal side effects.

In this chapter, we review quantitative fluorescent speckle microscopy (qFSM), a relatively young imaging technology that has been used to characterize the dynamic infrastructure of the cell. qFSM has the potential to become a unique assay for live-cell phenotypic screening that will guide the development of drugs and other nanomedical strategies based on the dynamics of subcellular structures. We begin by summarizing how regulation of the cytoskeleton contributes to important cell morphological processes that go awry in disease. We then describe how fluorescent speckles form to mark the dynamics of subcellular structures. Next, we illustrate critical biological insights that have been gleaned from qFSM experiments. We conclude with new applications and an outlook on the future of qFSM.

7.2 Cell Morphological Activities and Disease

The filamentous actin (F-actin), intermediate filament (IF) and microtubule (MT) cytoskeleton systems are key mediators of cell morphology (Figure 7.1). Each filament system is unique in its physical properties and extensive subset of associated proteins [6]. Endogenous and exogenous chemical and mechanical signals control the precise arrangement of these dynamic polymers, and defects in their regulation are seen in a wide variety of diseases [7].

7.2.1 Cell Migration

One of the most fundamental cell morphological functions is migration. Many cell types in the body are motile, including fibroblasts, epithelial cells, neurons, leukocytes and stem cells. Failure to migrate, or migration to the wrong location in the body, can lead to congenital heart or brain defects, atherosclerosis, chronic inflammation, neurodegenerative disease, compromised immune response, defects in wound healing and tumor metastasis [8].

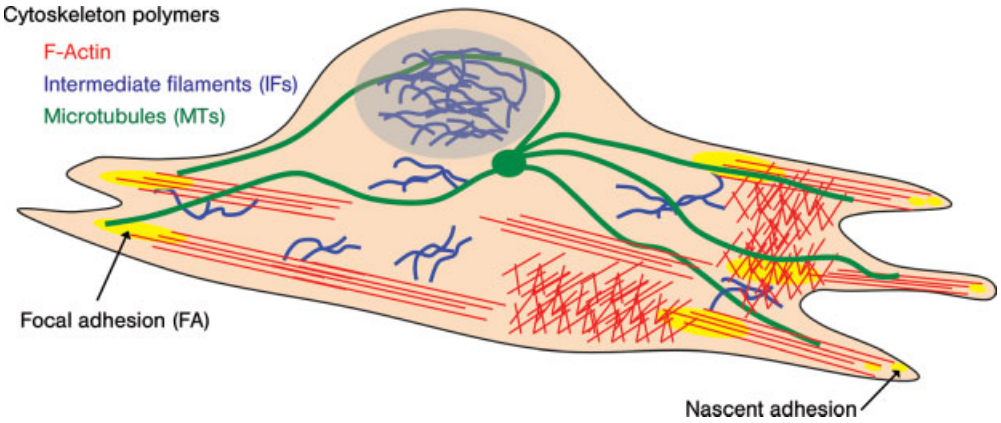

Figure 7.1 The F-actin, microtubule and intermediate filament cytoskeletons and adhesions in a migrating cell. A mesh-like F-actin network (red) at the leading edge drives the plasma membrane forward. Contractile F-actin bundles (red) linked to strong adhesions (yellow) in the front and weak adhesions in the back promote tail retraction. MTs (green) are implicated in cell polarization and adhesion regulation. The IFs (blue) are a heterogeneous group of filamentous proteins which help maintain cell structural integrity.

Cell migration is a remarkably complex behavior at the molecular level. Cell crawling involves three basic steps [9]: (i) leading edge protrusion; (ii) contraction of the F-actin polymer network; and (iii) tail retraction. Net movement of the cell cannot occur unless the F-actin network is anchored to the substrate. Otherwise, the protruding forces generated by F-actin polymerization at the leading edge plasma membrane and the contraction of the network by myosin molecular motors would simply deform the cell, without creating traction. Cells accomplish this via adhesion organelles located on the cell's ventral surface (Figure 7.1). In the case of uniform cell adhesion, actin network contraction would pull equally on the front and rear of the cell, resulting in zero movement. Directional movement thus requires an adhesion *gradient*, which is established by adhesions assembling at the protruding edge and weakening as they mature towards the cell rear [10]. The control of such a spatial gradient is extremely complex and involves many molecular components [11], the interactions of which are still poorly understood.

Like F-actin and adhesions, MTs are also important for migration in many cell types. They are implicated in polarizing the cell by delivering signaling molecules and regulating the turnover of adhesions [12]. In addition, mechanical interactions between MTs and F-actin may also contribute to the control of cell movement and morphology [13]. Tight spatial and temporal coordination between the F-actin, MT and adhesion systems is critical for cell migration.

7.2.2 Cell Division

Division is another cellular function that depends on a complex and highly regulated series of molecular events. Division is essential during embryogenesis and

development, and also occurs constantly in tissues of the adult body. In the intestines alone, approximately 10^{10} old cells are shed and replaced every day [14]. When DNA replication is complete, the pairs of chromosomes must be pulled apart symmetrically and segregated to opposite ends of the cell. Segregation is accomplished by a dynamic structure called the spindle, which is composed of MTs and motor proteins. In the final step of cell division – cytokinesis – the spindle elongates and a contractile actin structure develops to pinch off the membrane, partitioning organelles and cytoplasm into two daughter cells. While these processes progress with remarkable fidelity in healthy individuals, unchecked and faulty cell division are hallmarks of oncogenesis [15] and age-related disorders [16]. Cell cycling of adult neurons may be implicated in Alzheimer's disease [17]. Analysis of the architectural dynamics of the F-actin and MT structures involved in these steps is critical if we are to intervene with abnormal events in cell division associated with disease development.

7.2.3
Response to Environmental Changes

Cells also must be able to respond to physical changes in the environment. Almost 15 years ago, Wang *et al*. reported that applying a mechanical stimulus to integrin transmembrane receptors in adhesions caused the cytoskeleton to stiffen in proportion to the load [18]. The increased stiffness required the presence of intact F-actin, MTs and IFs. Such adaptation is central to the formation of multicellular tissues and functional organelles [19]. Recent studies have also provided evidence that mechanical cues relayed through the cytoskeleton systems dictate stem cell fate. Naïve mesenchymal stem cells cultured on a soft, brain-like matrix differentiate into neurons, while those cultured on a more rigid, bone-like matrix develop into osteoblasts [20]. When F-actin contraction by myosin motors is inhibited, lineage specification by elasticity is blocked. Mechanistic analyses of these differentiation-defining processes will require a quantitative analysis of the underlying cytoskeleton dynamics.

7.2.4
Cell–Cell Communication

Many diseases are directly linked to abnormalities in cell–cell or intracellular communication. For example, normal epithelial cells grow into organized, confluent monolayers because their growth is constantly monitored and controlled by cell–cell contacts. Carcinoma cells, on the other hand, lose this cue and grow into a mass. In addition to cancer, the loss of control over cell–cell contacts can result in embryonic death, severe developmental defects, neuropathy, skin-blistering diseases, diabetes, autoimmune disorders and atherosclerosis [21]. Besides the communication between cells in direct attachment, cells also communicate via a number of pathways, from the endo- or exocytosis of a few receptor-bound molecules to the uptake of large particles via phagocytosis [6]. Pathogens have managed to hijack these pathways to enter and exit cells [22]. In all of these communication pathways, the three cytoskeleton systems are on center stage. Analogously, the import of drugs or nanomedical

devices into defective cells requires the specific activation of one of these pathways in the right place, at the right time. Thus, our ability to understand disease and to precisely manipulate cells depends on our ability to analyze the cytoskeleton structure and dynamics *in situ* in living cells. We will now introduce qFSM as one of the emerging tools to achieve this goal.

7.3 Principles of Fluorescent Speckle Microscopy (FSM)

As reviewed by Danuser and Waterman-Storer [23], FSM enables quantitative analysis of the dynamics of subcellular structures *in vitro* and *in vivo*. Like many innovations in science, FSM was discovered by accident when Clare Waterman-Storer noticed that the microinjection of a small amount of X-rhodamine-labeled tubulin into cells gave rise to MTs with a speckled appearance [24]. Over the past ten years, sample preparation, speckle imaging and computational image analysis have been developed and improved to yield robust measurements of intracellular flow and assembly/disassembly dynamics for both MT and F-actin structures. Very recently, FSM has also been applied to measure interaction dynamics between molecular assemblies, such as transient F-actin and adhesion coupling in migrating epithelial cells [25] and F-actin and MT comovement in epithelial cells [26] and neurons [27]. Moreover, computational post-processing of FSM data has yielded indirect information, such as intracellular forces [28]. Thus, FSM is a prime imaging mode for interrogating the cytoskeleton's many roles in cell physiology and disease.

FSM is a twist on conventional live-cell fluorescence microscopy, where structures are visualized either by the expression of a fluorescent protein fused to the protein of interest, or by the microinjection of a covalently labeled protein into the cell. Typically in fluorescence microscopy, high expression levels or large amounts of injected fluorescent protein are necessary to achieve a high signal-to-noise ratio (SNR). This approach reveals protein localization and, to an extent, the movement of molecular structures in cells. However, the ability to report protein dynamics is limited due to the inherently high background fluorescence from out-of-focus incorporated and diffusing, unincorporated fluorescent protein. In addition, it is impossible to detect the movement or turnover of protein subunits within a larger, uniformly labeled structure. Laser photobleaching and photoactivation can help by marking structures in defined regions of the cell and allowing the measurement of recovery or movement in the local region at steady state [29–34]. Similar to these techniques is the ratiometric method of fluorescence localization after photobleaching (FLAP), which shows the diffusive and convective transport of unincorporated protein [35, 36].

In contrast to conventional fluorescence microscopy, FSM probes the dynamics of protein assemblies which contain very few (<1%) fluorescent subunits among a vast majority of unlabeled subunits. When imaged by high-resolution, diffraction-limited optics, the scattered distribution of fluorescence yields a punctate (speckled) pattern that reveals the motion of the entire structure, the reorganization of subunits within

the structure, and the association and dissociation of subunits. Thus, FSM provides the same information as the aforementioned photomarking techniques, but does so across much or all of the cell simultaneously. As FSM does not require active marking, it allows the continuous detection of nonsteady-state dynamics within protein assemblies, and reveals spatial and temporal relationships between these dynamic events at submicron and second resolution. FSM also reduces out-of-focus fluorescence and improves the visibility of fluorescently labeled structures and their dynamics in three-dimensional (3-D) polymer arrays, such as the mitotic spindle [37–39].

In the early years of its development, FSM used wide-field epifluorescence light microscopy and digital imaging with a sensitive, low-noise, cooled charge-coupled-device (CCD) camera [24]. Since then, FSM has been transferred to confocal and total internal reflection fluorescence (TIRF) microscopes [37, 40–42]. The development of fully automated, computer-based tracking and the statistical analysis of speckle behavior proved to be critical steps in establishing FSM as a routine method for measuring cytoskeleton architectural dynamics. Thus, FSM is an integrated technology in which sample preparation, imaging and image analysis are optimized to achieve detailed information about polymer dynamics.

7.4
Speckle Image Formation

7.4.1
Speckle Formation in Microtubules (MTs): Stochastic Clustering of Labeled Tubulin Dimers in the MT Lattice

MTs exhibit a variation in fluorescence intensity along their lattices when cells are injected with a small amount of labeled tubulin dimers, leading to a speckled appearance (Figure 7.2a and b). Several possibilities exist for how speckles arise in this situation:

- The fluorescent tubulin could form oligomers or aggregates on the MT.
- Cellular organelles or MT-associated proteins (MAPs) could be bound to the MT and conceal or quench the fluorescence in some regions.
- Random variation of the number of fluorescent tubulin subunits in each diffraction-limited image region along the MT could occur as the MT assembles from a pool of labeled and unlabeled dimers [43].

The first hypothesis was discounted by showing that labeled tubulin dimers sediment similarly to unlabeled dimers in an analytical ultracentrifugation assay. Next, it was shown that MTs assembled from purified tubulin *in vitro* exhibited similar speckle patterns to MTs in cells, where MAPs and organelles are present [43]. Thus, the most plausible explanation for MT speckle formation is that variations exist in the number of fluorescent tubulin subunits in each resolution-limited image region along the MT.

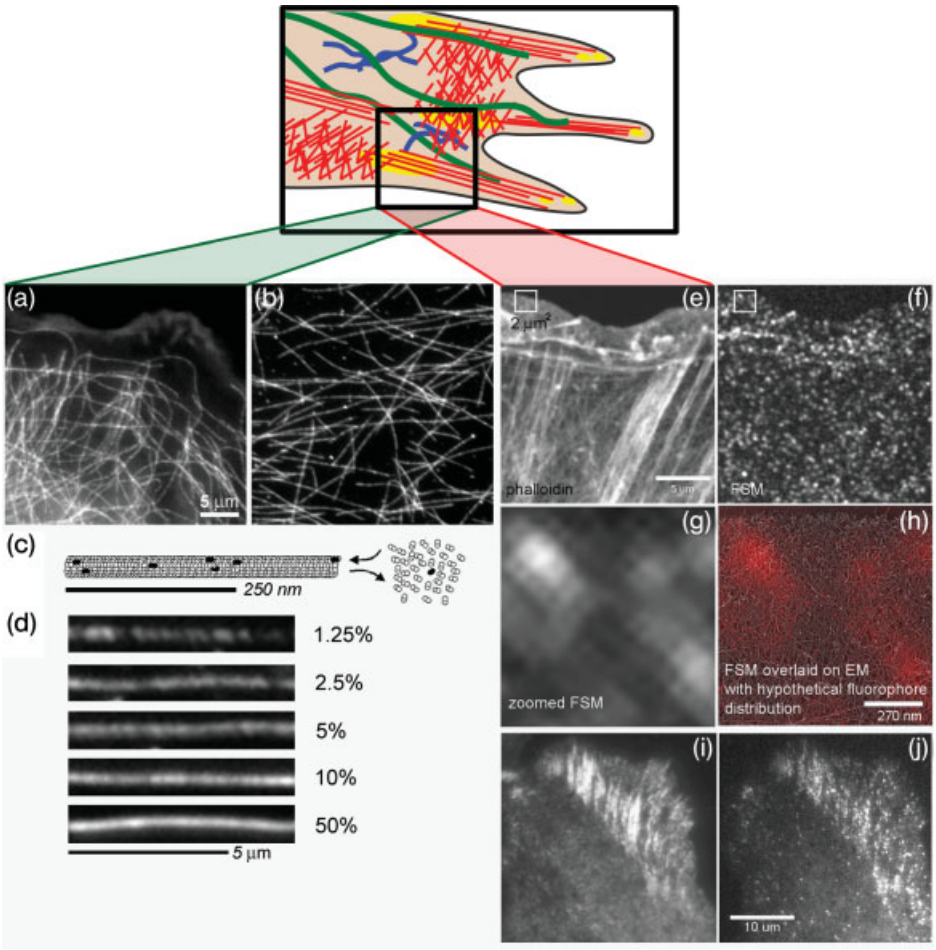

Figure 7.2 Speckle formation in microtubules, F-actin and FAs. The cartoon is an inset of Figure 7.1, showing that MTs (a) and F-actin (e, f) in cells can be imaged in separate channels. (a, b) Comparison of random speckle pattern of fluorescence along MTs for (a) a living epithelial cell microinjected with X-rhodamine-labeled tubulin and for (b) MTs assembled *in vitro* from 5% X-rhodamine-labeled tubulin; (c) Model for fluorescent speckle pattern formation in a MT grown from a tubulin pool containing a small fraction of labeled dimers; (d) Dependence of speckle contrast on the fraction of labeled tubulin dimers. (e, f) Speckle formation in actin filament networks. An epithelial cell was microinjected with a low level of X-rhodamine-labeled actin, fixed, and stained to show structure with Alexa-488 phalloidin. (e) Phalloidin image showing the organization of actin filaments in amorphous filament networks and bundles; (f) In the single FSM image, much of the structural information is lost, but time-lapse FSM series contain dynamic information of filament transport and turnover not accessible with higher-level labeling of the cytoskeleton; (g) Close-up of 2×2 µm window in panels e and f; (h) Colorized speckle signal overlaid onto a quick-freeze deep etch image of the same-sized region of the actin cytoskeleton in the leading edge of a fibroblast (kindly provided by Tatyana Svitkina). The hypothetical fluorophore distribution (red) could give rise to such a speckle pattern, indicating the scale of speckles in comparison with the polymer network ultrastructure. It also illustrates that a small proportion of the total actin fluoresces and that fluorophores from different filaments contribute to the same speckle; (i, j) Low-level expression of the GFP-tagged FA protein vinculin results in speckled FAs in TIRF images. A cell expressing GFP-vinculin was fixed and immunofluorescently stained with antibodies to (i) vinculin to reveal the position of FAs, which in the (j) GFP channel appear speckled because of the low level of incorporation of GFP-vinculin. Figure reproduced with permission from Ref. [23].

To understand how speckles originate, consider the incorporation of fluorescent subunits into the helical MT lattice, which consists of 1625 α/β tubulin dimers per micron (Figure 7.2c) [44]. The image of an individual MT under the light microscope results from a convolution of the fluorophore distribution along the MT with the point-spread function (PSF) of the microscope. Ignoring the vertical dimension, the in-focus slice of the PSF is given by the Airy disk. Given the emission wavelength λ of the fluorophore and the numerical aperture (NA) of the microscope objective, the first ring of the Airy disk with zero intensity has a radius $r = 0.61\,\lambda/\mathrm{NA}$ [45]. Objects separated by less than r cannot be resolved. For X-rhodamine-labeled MTs ($\lambda = 620$ nm) at a high NA (1.4), the Airy disk radius $r = 270$ nm, which corresponds to 440 tubulin subunits (270 nm × 1.625 subunits nm^{-1}). A given fraction of fluorescent dimers, f, produces a mean number of fluorescent dimers $n = 440 \cdot f$ per PSF. Variations in the number of fluorescent dimers per PSF relative to this mean produce the speckle pattern along the MT. The speckle pattern contrast in this example can be approximated by the ratio of the standard deviation and the mean of a binomial distribution with 440 elements: $c = \sqrt{440 \cdot f \cdot (1-f)}/(440 \cdot f)$. Accordingly, the contrast c can be increased by decreasing f (Figure 7.2d) or by making the Airy disk smaller – that is, effectively lowering the number of tubulin subunits per Airy disk. The latter is accomplished by using optics with the highest NA possible. Experiments have shown that fractions in the range of 0.5 to 2%, where speckles consisting of three to eight fluorophores are optimal for the speckle imaging of individual microtubules [46].

7.4.2
Speckle Formation in Other Systems: The Platform Model

Conventional fluorescence microscopy of the F-actin network reveals a variety of actin-based structures, such as stress fibers and filopodia, but this approach is not conducive to the observation of structural dynamics (see Section 7.3). When fluorescently labeled actin is injected into a cell at a low level relative to the amount of endogenous, unlabeled actin, actin-rich structures appear relatively evenly speckled (Figure 7.2e and f) [26, 47–50]. Importantly, while the speckle pattern reveals the local dynamics of actin structures the overall architectural organization of the cytoskeleton is no longer visible. Speckle formation can also be found when expressing green fluorescent protein (GFP)-fused actin at a very low level [48, 51] or by injecting trace amounts of the labeled actin-binding molecule phalloidin [52, 53]. In contrast to speckle formation in isolated MTs, labeled actin subunits bind within a highly cross-linked 3-D network of F-actin filaments [54–56]. The mesh size of an F-actin network in living cells is nearly always below the resolution limit of the light microscope (Figure 7.2g and h). Consequently, unless f is kept extremely low so that only one fluorophore falls into the PSF volume [48], most fluorescent speckles arise from subunits on multiple actin filaments.

The same concept applies to speckle formation within adhesion sites [40]. GFP-fusions to adhesion proteins, including vinculin, talin, paxilin, α-actinin, zyxin and $\alpha_v$integrin [57], have been expressed in epithelial cells from crippled promoters to achieve very low expression levels. Labeled proteins assembling with endogenous,

unlabeled proteins give the adhesions a speckled appearance (Figure 7.2i and j). As with F-actin networks, the speckles represent randomly distributed fluorescent adhesion proteins that are temporarily clustered in the adhesion complex within the volume of one PSF.

In summary, a speckle is defined as a diffraction-limited region that is significantly higher in fluorophore concentration (i.e. higher in fluorescence intensity) than its local neighborhood. For a speckle signal to be detected in an image, the contributing fluorescent molecules must be associated with a molecular scaffold, or 'speckle platform', during the 0.1–2.0 s exposure time required by most digital cameras to acquire the dim FSM image. Conversely, unbound, diffusible fluorescent molecules visit many pixels during the exposure and yield an evenly distributed background signal, instead of speckles [48]. The same idea was illustrated for the MT MAP ensconsin [58] and for the MT kinesin motor Eg5 [59]. Thus, association with the platform can occur when labeled subunits either *become* part of the platform, as with tubulin or actin, or simply *bind* to it, as in the case of cytoskeleton-associated proteins or adhesion molecules.

7.5
Interpretation of Speckle Appearance and Disappearance

7.5.1
Naïve Interpretation of Speckle Dynamics

Following the platform model, one would expect the appearance of a speckle to correspond to the local association of subunits with the platform. Conversely, the disappearance of a speckle would mark the local dissociation of subunits. In other words, FSM allows – in principle – the direct kinetic measurement of subunit turnover in space and time via speckle lifetime analysis. In addition, once a speckle is formed, it may undergo motion that indicates the coordinated movement of labeled subunits on the platform and/or the movement of the platform itself.

7.5.2
Computational Models of Speckle Dynamics

The interpretation of speckle dynamics becomes significantly more complicated when individual speckles arise from fluorophores distributed over multiple polymers. To examine how speckle appearance and disappearance relate to the rates of assembly and disassembly of F-actin, we performed Monte Carlo simulations of fluorophore incorporation into growing and shrinking filaments in dense, branched networks, and generated synthetic FSM time-lapse sequences [60]. The first lesson learned from this modeling was that the speckle density is independent of whether the network assembles or disassembles; it depends only on how many Airy disks can be resolved per square micron. With NA = 1.4/100× optics, this amounts to ∼4 (approximately 2 × 2), as confirmed by Figure 7.3a. The graph displays the mean

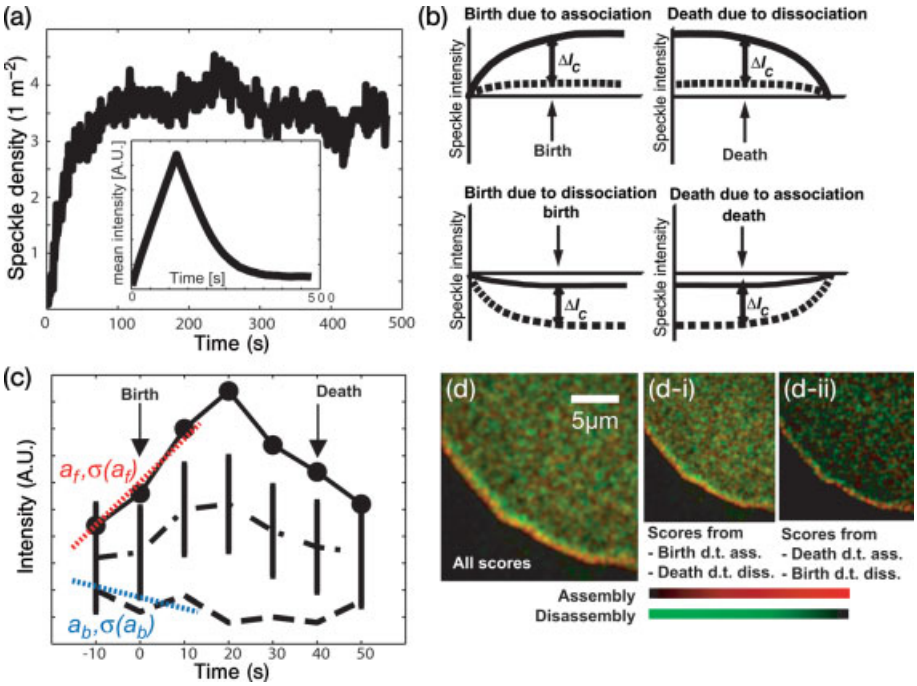

Figure 7.3 Relationship between speckle appearance (birth) and disappearance (death) and the turnover in the underlying macromolecular assembly. (a) Simulated speckle density in an actin filament network assembling for 120 s and disassembling for 360 s. Inset: Mean intensity indicating the overall change in bound fluorophore over time; (b) Classification of speckle birth and death due to monomer association and dissociation with the network. A speckle appears when the difference between foreground (solid line) and background (dashed line) is greater than a threshold ΔI_C, which is a function of the camera noise and the shot noise of the signal [60]; (c) Measurement of intensity changes in foreground (solid line) and background (dashed line) during a speckle birth. The entire lifetime of the speckle is shown (40 s). Dash-dotted line: Mean between foreground and background; error bars: ΔI_C computed in every time point. Birth and death are defined as the time points at which the intensity difference exceeds ΔI_C for the first and the last time. Red dotted line: Regression line to the foreground intensity values before, at and after birth. Blue dotted line: Regression line to the background intensity values. The cause of speckle birth is inferred by statistical classification of the two slopes and their standard deviations (see text). The statistically more dominant of the two slopes, if also significant relative to image noise, defines the score of the event (foreground slope in the example given); (d) Spatial averaging of scores accumulated over a defined time window of an FSM time-lapse sequence yields maps of net polymerization (red) and depolymerization (green). Scores from birth due to association and death due to dissociation (d-i) or from birth due to dissociation and death due to association (d-ii) reveal the same spatial distribution of polymerization and depolymerization. Figure in parts reproduced with permission from Refs [60, 83].

speckle density from five simulations of a network that starts with no fluorophores, assembles for 120 s (inset: mean fluorescence intensity increases), and disassembles for 360 s (inset: mean fluorescence intensity decreases) at equal rates. The density does not change after saturation at 100 s and remains constant, despite the further

addition of fluorophores for another 20 s. This suggests that monomer association can cause an equal number of speckle appearances and disappearances. The same holds true in the opposite sense during network disassembly.

Whereas, the NA of the optics defines the maximum number of resolvable speckles per unit area, the labeling ratio influences the speckle density indirectly. For multi-fluorophore speckles the ratio f is the main determinant of speckle contrast. When increasing this ratio, the speckle density drops because the difference between the peak intensity of a speckle and its surroundings is no longer distinguishable from intensity fluctuations due to noise. Similarly, at labeling ratios where speckles represent the image of single fluorophores ($f < 0.1\%$), a further decrease in f reduces the speckle density proportionally. Across the optimal range of ratios for multi-fluorophore speckles ($0.5\% < f < 3\%$) the density is almost constant. These model predictions were largely confirmed experimentally by Adams *et al.* [40].

The origin of constant speckle density in the range of $0.5\% < f < 3\%$ is illustrated in Figure 7.3b. A speckle represents a local image intensity maximum significantly above the surrounding background. The critical intensity difference ΔI_c depends on both the camera noise and the shot noise. The shot noise is by itself a function of the speckle intensity [60]. Speckles may appear (speckle birth) for two reasons: (i) the intensity of a local maximum becomes brighter because of the association of fluorescent subunits; or (ii) the intensity of the surrounding background becomes dimmer because of subunit dissociation in the neighborhood. In both cases, a speckle birth is detected when the peak-to-background intensity difference exceeds ΔI_c. Analogously, speckles may disappear (speckle death) either because of subunit dissociation in the location of a speckle or because of subunit association in the neighborhood.

7.5.3
Statistical Analysis of Speckle Dynamics

With the classification scheme in Figure 7.3b, speckles become time-specific, diffraction-limited probes of turnover of subcellular structures. The change in foreground or background intensity that causes the birth or death of a speckle is, on average, proportional to the net number of subunits Δm added to or removed from the PSF volume between two frames. This defines an algorithm for the local measurement of network assembly or disassembly kinetics [60]:

- Calculation of changes in foreground and background intensities. After detection of a speckle birth/death event, regression lines are fitted to the foreground and background intensities for one time point before, during and after the event (Figure 7.3c). Intensity values before birth and after death are extrapolated [60]. The line fits provide two estimates a_f and a_b of the slopes of foreground and background intensity variation. They also yield the standard deviations σa_f and σa_b of the slopes, which are derived from the residuals of the intensity values to the regression line. Noisy data, poorly represented by the regression model, generate large values of σ; intensity values in perfect match with the model result in small values of σ.

- Each of the two slopes is tested for statistical significance. Insignificant intensity changes are discarded.
- If both foreground and background slopes are significant, the one with the higher significance (lower *p*-value) is selected as the cause of the event. In the example in Figure 7.3c the foreground slope has the higher significance. The magnitude of the more significant slope is recorded as the score of the birth/death event. If neither foreground nor background slope is statistically significant, no score is generated.

Score values represent instantiations of a random variable with an expectation value $\mu = \alpha\Delta m{\cdot}f$ and variance $\sigma^2 = \alpha^2\Delta m^2{\cdot}f(1-f)$, where α denotes the unknown intensity of one fluorophore. In addition, the scores are perturbed by noise. However, assuming that the net rate Δm remains constant for a small probing window, the intrinsic score variation and noise are approximately eliminated by averaging all scores falling into the window. The choice of the window size depends on the density of significant scores and the demand for spatial or temporal resolution. The more scores averaged by time integration, the less spatial averaging is required, and *vice versa*.

Figure 7.3d displays rates of actin assembly (red) and disassembly (green) of the F-actin network at the edge of an epithelial cell. Score values were averaged over 10 min, reflecting the steady-state turnover. The two smaller panels indicate the rate distributions calculated from scores extracted from speckle births due to monomer association and from speckle deaths due to monomer dissociation only (Figure 7.3d-i), and from births due to monomer dissociation and from deaths due to monomer association only (Figure 7.3d-ii). Both panels display the same distribution of loci of strong assembly (for example, the cell edge) and disassembly but at different event densities. Figure 7.3d-i thus corresponds to the naïve interpretation of speckle appearance and disappearance. These events contribute ~70% of all scores; the other ~30% of significant scores is related to the counterintuitive cases of speckle birth and death, and neglecting these would significantly reduce the sample size. How many intuitive versus counterintuitive cases occur depends on the fraction of labeled monomers. The lower the fraction, the fewer counterintuitive cases are observed, with a lower boundary defined by the single-fluorophore speckle regime, where all speckle appearances are due to monomer association and all disappearances are due to monomer dissociation.

The processing of only short time intervals around speckle birth and death events focuses the analysis on image events that are more likely to have originated from monomer exchange rather than from intensity fluctuations due to image noise, bleaching and in- and out-of-focus speckle motion. In addition, the algorithm rejects ~60% of all speckle birth and death events as insignificant [61]. That is, these events are not classifiable as induced by monomer exchange with the certainty the user chooses as the confidence level for the analysis. Bleaching affects all speckle scores, and thus can be corrected based on global drifts in the image signal [60]. It has also been shown that, with a NA = 1.4 objective lens, focus drifts smaller than 100 nm over three frames (e.g. 30 nm per 1–5 s) have no effect on the mapping of network

turnover. Thus, the statistical model described in this section provides a robust method for calculating spatiotemporal maps of assembly and disassembly of subcellular structures such as F-actin networks.

7.5.4
Single- and Multi-Fluorophore Speckles Reveal Different Aspects of the Architectural Dynamics of Cytoskeleton Structures

Intuitively, it seems that FSM would be most powerful if implemented as a single-molecule imaging method, where speckle appearances and disappearances unambiguously signal association and dissociation of fluorescent subunits to the platform [48]. However, the much simpler signal analysis of single-molecule images is counterweighed by several disadvantages not encountered when using multifluorophore speckles. First, establishing that an image contains only single-fluorophore speckles can be challenging, especially when the signal of one fluorophore is close to the noise floor of the imaging system. Especially in 3-D structures a large number of speckles have residual contributions from at least one other fluorophore, and those mixtures must be eliminated from the statistics. Second, the imaging of single-fluorophore speckles is practically more demanding than multifluorophore FSM and requires longer camera exposures to capture the very dim signals, thus reducing the temporal resolution. Third, in addition to the lower temporal resolution, single-fluorophore FSM offers lower spatial resolution because the density of speckles drops significantly with the extremely low labeling ratio required for single-molecule-imaging conditions. In dense, crosslinked structures such as the F-actin network the intensity variation during appearance and disappearance events of multifluorophore speckles can distinguish between fast and slow turnover. In contrast, single-fluorophore speckles deliver on/off information only. Thus, in order to measure rates of the turnover of molecular structures on a continuous scale, single-fluorophore speckle analysis must rely on spatial and temporal averaging, which further decreases the resolution, while multifluorophore speckles provide this information at a finer spatial and shorter temporal scale.

On the other hand, multifluorophore speckles cannot resolve the dynamics of closely apposed individual units with subcellular structures. If the dynamics of the individual building blocks of a structure is of interest, and the lower density of spatial and temporal samples can be afforded, single-fluorophore speckles are adequate probes. If information about individual units *and* the ensemble of units is needed, single-fluorophore and multifluorophore speckle imaging can be combined in two spectrally distinct channels. This has been demonstrated in an analysis of the *Xenopus* spindle [62], where combined single- and multifluorophore qFSM revealed the overall dynamics of MTs in the spindle, as well as the dynamics and length distribution of individual MTs within densely packed bundles inside the spindle (see Section 7.9.2).

In summary, FSM can probe different aspects of the architectural dynamics of subcellular structures at different spatial and temporal scales via modulation of the

ratio of labeled to unlabeled subunits. Currently, the exact labeling ratio is difficult to control in a given experiment. Statistical clustering analysis of the resulting speckle intensity is required to identify the distribution of the numbers of fluorophores within speckles. In the near future, these mathematical methods will be complemented with sophisticated molecular biology that will allow relatively precise titration of the labeled subunits. Together, these approaches will be invaluable to a systematic mapping of the heterogeneous dynamics of complex subcellular structures such as the cytoskeleton.

7.6 Imaging Requirements for FSM

Time-lapse FSM requires the imaging of high-resolution, diffraction-limited regions containing one to ten fluorophores and the inhibiting of fluorescence photobleaching. This requires a sensitive imaging system with little extraneous background fluorescence, efficient light collection, a camera with low noise, high quantum efficiency, high dynamic range, high resolution, and the suppression of fluorescence photobleaching with illumination shutters and/or oxygen scavengers [49, 63, 64]. In addition, all fluorescently labeled molecules must be functionally competent to bind their platform; otherwise, they will contribute to diffusible background and reduce the speckle contrast [65]. The reader is referred to a review by Gupton and Waterman-Storer [66] for an in-depth discussion of the hardware requirements for obtaining FSM images.

Because FSM is achieved by the level of fluorescent protein in the sample, it is adaptable to various modes of high-resolution fluorescence microscopy, such that the specific advantages of each mode can be exploited in combination with the quantitative capabilities of FSM. For example, we have performed FSM on both spinning-disk confocal microscopy [41] and total internal reflection fluorescence microscopy (TIRFM) [40] systems to gain speckle data in two spectral channels with the specific image advantages of confocal and TIRFM. A comparison of FSM images of the actin cytoskeleton in migrating epithelial cells acquired by wide-field epifluorescence, spinning-disk confocal microscopy and TIRFM is shown in Figure 7.4a–c. Clearly, speckle contrast is improved by reducing out-of-focus fluorescence with either of the latter techniques. Contrast in TIRFM images is further improved over the spinning-disk confocal image because the evanescent field excitation depth is reduced to 100–200 nm into the specimen. When quantified, the effect of the reduced effective imaging volume on modulation and detectability of actin and focal adhesion (FA) speckles showed that TIRF-FSM indeed affords major improvements in these parameters over wide-field epifluorescence for imaging macromolecular assemblies at the ventral surface of living cells, both in thin peripheral and thick central cell regions [40]. Importantly, to date FSM has proved to be incompatible with all commercial laser-scanning confocal microscope systems. This is because these instruments use photomultipliers as detectors that are noisy and have a limited dynamic range compared to the

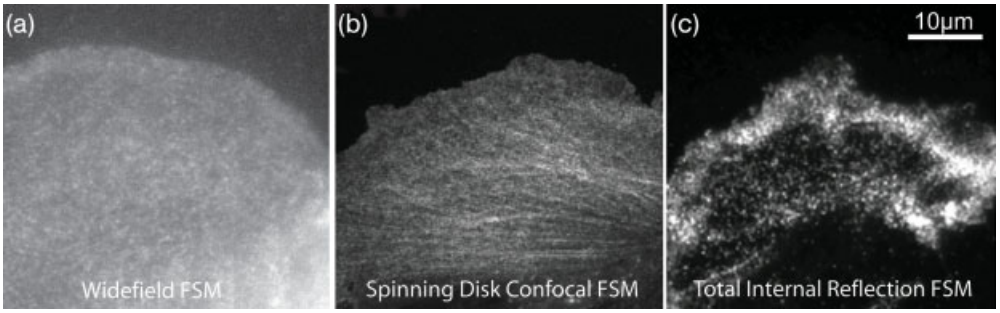

Figure 7.4 Comparison of X-rhodamine–actin FSM images of the edge of migrating Ptk1 epithelial cells using (a) wide-field epifluorescence, (b) spinning-disk confocal microscopy and (c) TIRF microscopy. Panels (a) and (b) were acquired using a Nikon 100 × 1.4 NA Plan Apo phase contrast objective lens and a 14 bit Hamamatsu Orca II camera with 6.7 micron pixels. Panel (c) was acquired with a Nikon 100 × 1.45 NA Plan Apo TIRF objective lens and a 14 bit Hamamatsu Orca II ER with 6.4 micron pixels. Note that speckle contrast and the ability to detect speckles in more central cell regions increases from panels (a) to (c). Note, however, in the TIRF image that speckles are very bright a few microns back from the edge, most likely where the cell is in closer contact with the substrate. Figure reproduced with permission from Ref. [23].

low-noise, high dynamic range CCDs used with spinning-disk confocal microscope systems.

7.7
Analysis of Speckle Motion

7.7.1
Tracking Speckle Flow: Early and Recent Developments

In addition to revealing the kinetics of association and dissociation of subunits to and from the molecular platform, speckles also show the movement of subunits within the platform and of the platform itself. In early applications of FSM, speckle motion was quantified by hand-tracking a few speckles – a tedious, error-prone and incomplete way of analyzing the wealth of information contained by these images [26, 27, 48]. Alternatively, kymographs provided average estimates of speckle velocities [37, 38, 49, 50, 59, 67–70].

Initial attempts to automate the extraction of more complete speckle flow maps from FSM time-lapse sequences of F-actin networks relied on correlation-based tracking. The speckled area of a source frame in the movie was divided into small probing windows, with each window being displaced until the normalized cross-correlation of the window with the signal of the next frame in the movie was maximized. This approach reported the average motion of all the speckles falling into the window. The window size pitted robustness in correlation against spatial resolution: the larger the window, the more unique was the speckle pattern to be

recognized in the target frame. On the other hand, larger windows increased the averaging of distinct speckle motions within the window.

Underlying the method of cross-correlation tracking is the assumption that the signal of a probing window, although translocated in space, does not change between source and target frame. In practice, this assumption is always violated because of noise. However, the cross-correlation of two image signals appears to be tolerant toward spatially uncorrelated noise, making it a prime objective function in computer vision tracking [71–73]. The many speckle appearances and disappearances in F-actin networks, however, introduce signal perturbations that cannot be tackled by the cross-correlation function [74]. Instead, we have developed a particle flow method, in which the movement of each speckle was tracked individually [74]. Speckles were linked between consecutive frames by nearest-neighbor assignment in a distance graph, in which conflicts between multiple speckles in the source frame competing for the same speckle in the target frame were resolved by global optimization [75]. An extension of the graph to linking speckles in three consecutive frames allowed enforcement of smooth and unidirectional trajectories, so that speckles moving in antiparallel flow fields could be tracked [74].

Surprisingly, cross-correlation-based tracking was successful in measuring average tubulin flux in meiotic spindles [76]. Simulated time-lapse sequences showed that if a significant subpopulation of speckles in the probing window moves jointly, then the coherent component of the flow can be estimated even when the rest of the speckles move randomly or, as in the case of the spindle apparatus, a smaller population moves coherently in opposite directions. However, the tracking result will be ambiguous if the window contains multiple, coherently moving speckle subpopulations of equal size. Miyamoto *et al*. [76] carefully chose windows in the central region of a half-spindle, where the motion of speckles towards the nearer of the two poles dominated speckle motion in the opposite direction and random components. The approach was aided further by several features of the spindle system: tubulin flux in a spindle is quasi-stationary; speckle appearances and disappearances are concentrated at the spindle midzone and in the pole regions, which were both excluded from the probing window; and the flow fields were approximately parallel inside the probing window.

Encouraged by these results, we returned to cross-correlation tracking of speckle flow in F-actin networks [77]. The advantage of cross-correlation tracking over particle flow tracking is that there is no requirement to detect the same speckle in at least two consecutive frames. Hence, speckle flows can be tracked in movies with high noise levels and weak speckle contrast [77]. In order to avoid trading correlation stability for spatial resolution, we capitalized on the fact that cytoskeleton transport is often stationary on the timescale of minutes. Thus, although the correlation of a single pair of probing windows in source and target frames is ambiguous (Figure 7.5b-i), rendering the tracking of speckle flow impossible (Figure 7.5c-i), time-integration of the correlation function over *multiple* frame pairs yields robust displacement estimates for probing windows as small as the Airy disk area (Figure 7.5b-ii, c-ii). Figure 7.5d presents a complete high-resolution speckle flow map extracted by integration over 20 frames ($\sim$3 min).

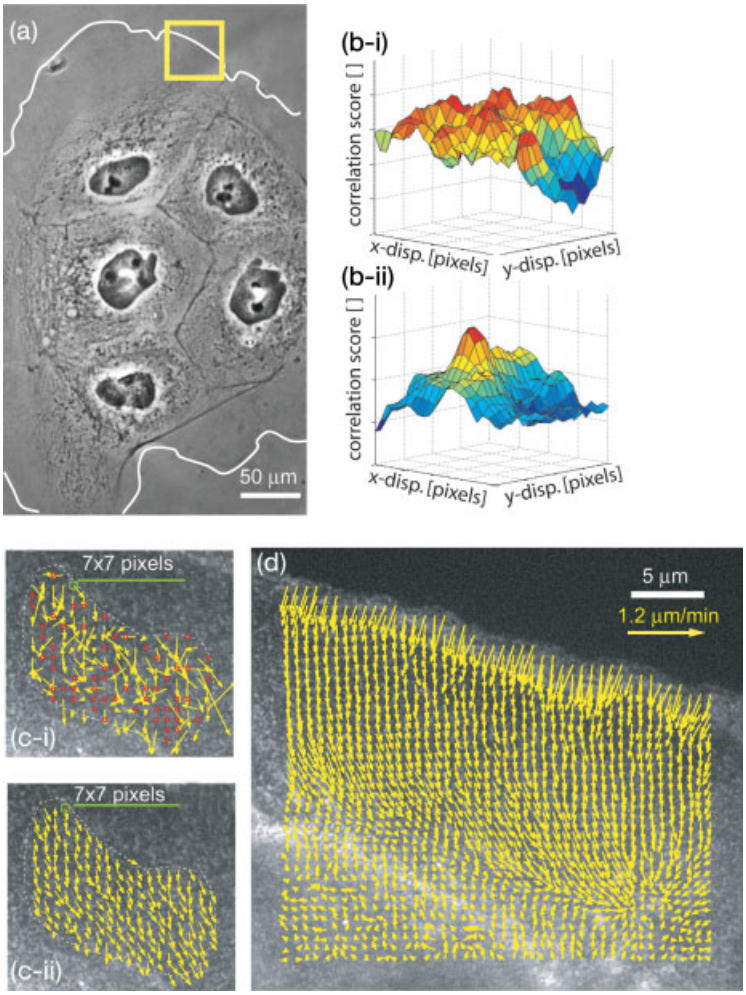

Figure 7.5 Tracking quasi-stationary speckle flow using multiframe correlation. (a) Island of epithelial cells; (b) Cross-correlation for a single frame pair (b-i) and integrated for 20 frame pairs (b-ii); (c) Region of a speckled actin network tracked with a probing window of 7×7 pixels (400×400 nm) using a single frame pair (c-i) and 20 frame pairs (c-ii); (d) Speckle flow map corresponding to the inset in (a) extracted by integration of the correlation score over 20 frame pairs. Speckle flow in this movie is almost stationary, justifying the time integration. Figure reproduced with permission from Ref. [77].

7.7.2
Tracking Single-Speckle Trajectories

The extraction of kinetic data according to Figure 7.3 requires the accurate localization of speckle birth and death events. For this, it was necessary to devise methods capable of tracking full trajectories at the single-speckle level. The large number

(>100 000) of dense speckles poses a significant challenge. Details of the current implementation of single-particle tracking of speckles are described by Ponti *et al.* [78]. Our approach follows the framework of most particle-tracking methods – that is, the detection of speckles as particles on a frame-by-frame basis, and the subsequent assignment of corresponding particles in consecutive frames. Assignment is iterated to close gaps in the trajectories created by the short-term instability of the speckle signal. Our implementation of this framework included two algorithms that address particularities of the speckle signal:

- Speckles are detected in an iterative statistical framework, which accounts for signal overlap between proximal speckles.
- Speckle assignments between consecutive frames are executed in a hybrid approach combining speckle flow and single-speckle tracking.

Speckle flow fields are extracted iteratively from previous solutions of single-speckle trajectories [78], or by initial correlation-based tracking [77]. The fields are then employed to propagate speckle motion from the source to the target frame, prior to establishing the correspondence between the projected speckle position and the effective speckle position in the target frame by global nearest-neighbor assignment [79, 80].

Motion propagation allows us to cope with two problems of FSM data. First, in many cases the magnitude of speckle displacements between two frames significantly exceeds half the distance between speckles. Hence, no solution to the correspondence problem exists without prediction of future speckle locations. Second, speckles undergo sharp spatial gradients in speed and direction of motion. A global propagation scheme discarding regional variations will thus fail, whereas an iterative extraction of the flow field permits a gradually refined trajectory reconstruction in these areas.

Figure 7.6a displays the single-speckle trajectories for speckles initiated in the first 20 frames of the same movie for which speckle flow computation is demon-

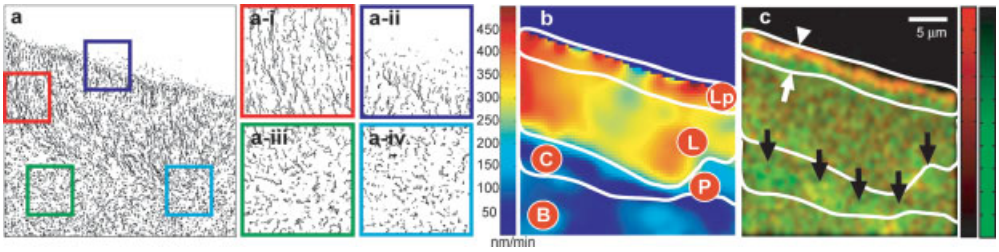

Figure 7.6 Tracking single-speckle trajectories. (a) Trajectories of speckles initiated in the first 20 frames of an actin FSM movie. (a-i to a-iv) Close-ups in different areas indicating regional variation in directional persistence, velocity and lifetime of the trajectories; (b) Speed distribution averaged over all 220 frames of the movie; (c) Distribution of polymerization (red channel) and depolymerization (green channel) calculated from scores averaged over 220 frames. Four regions of the actin network with distinct kinematic (motion) and kinetic (turnover) properties can be segmented (see text). Figure reproduced with permission from Ref. [23].

strated in Figure 7.5. The color-framed close-ups indicate regional differences between trajectories. Window (*a-i*) contains mostly straight trajectories with an average lifetime of 88 s; the trajectories in window (*a-ii*) are also straight, with an average lifetime of 60 s. In contrast, trajectories in windows (*a-iii*) and (*a-iv*) exhibit less directional persistence and have average lifetimes of 65 s and 59 s, respectively. It was concluded from such data that the F-actin cytoskeleton is regulated in a regionally variable fashion.

Figure 7.6b and c present the steady-state speed of actin network transport and turnover extracted from ∼100 000 trajectories. Three different patterns of turnover are recognized that correspond to regions with different average speeds. At the cell edge, a ∼1 μm-wide band of network assembly (red color; white arrowhead) abuts a ∼1 μm-wide band of disassembly (green color; white arrow). The yellow shade in the assembly band indicates that filament polymerization and depolymerization significantly overlap. This 2 μm-wide cell border, which is referred to as the lamellipodium (Lp), exhibits on average the fastest F-actin retrograde flow. Predominant disassembly is found ∼10 μm from the cell edge (black arrows), where the speed of F-actin flow is minimal. Here, the retrograde flow of the cell front encounters the anterograde flow of the cell body (B); this region is thus called the 'convergence zone' (C). Between the lamellipodium and the convergence zone is a region called the lamella (L), where assembly and disassembly alternate in a random pattern, accompanied by relatively coherent retrograde flow of moderate speed. The same pattern of network turnover is observed in the cell body.

7.7.3
Mapping Polymer Turnover Without Speckle Trajectories

It frequently occurs that a lower speckle contrast or a high image noise does not allow the precise identification of single-speckle trajectory endpoints. However, the trackable subsections of the trajectories are usually sufficient to extract the overall structure of speckle flow. In this case, an alternative scheme relying on the continuity of the optical density of the speckle field permits the mapping of turnover at lower resolution [81], as indicated in Figure 7.7 for the example of a crawling fish keratocyte, a cell system where the generation of clear fluorescent speckle patterns has proven difficult [52].

7.8
Applications of FSM for Studying Protein Dynamics *In Vitro* and *In Vivo*

Applications of FSM have thus far focused mostly on the study of F-actin and MT cytoskeleton systems, although other systems have also been analyzed in this way. A

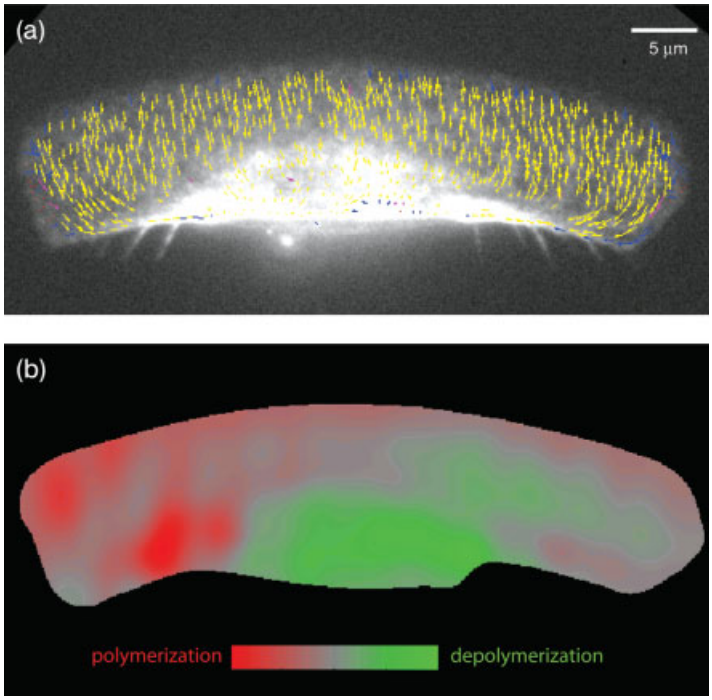

Figure 7.7 Reconstruction of F-actin network turnover from speckle flow in a fish keratocyte with poor speckle contrast. (a) Flow is calculated using multiframe correlation (as in Figure 7.5); (b) The calculated turnover map is based on conservation of image intensity. Without explicit identification of speckle births and deaths, essential details in the fine structure of the network turnover are lost.

summary of the FSM literature can be found in Table 7.1, where the major biological findings and technical advances in FSM made to date are listed. Most of the FSM data analysis has been limited to kymograph measurements of average speckle flow (see Section 7.7) and to the manual tracking of a few hundred speckles to extract lifetime information [48] and selected trajectories of cytoskeleton structures [26, 27, 69]. A systematic analysis of the full spatiotemporal information offered by FSM regarding transport and turnover in molecular assemblies is far from complete, although significant progress has already been made. In the following section, we describe comprehensive qFSM analyses both of F-actin cytoskeleton dynamics in migrating epithelial cells, and of the architectural dynamics of the spindle. Some of the most interesting results of these studies, showcasing the technical possibilities of qFSM, are also summarized.

Table 7.1 Selection of fluorescent speckle microscopy (FSM) general references and biological findings by subject.

Previous FSM Reviews and Methods Chapters

Previous reviews:

- Speckle image formation and the first FSM applications studying microtubule and F-actin dynamics *in vitro* and *in vivo*[a,b]
- Introduction to the 'platform concept' of FSM, where labeled subunit association with and dissociation from a macromolecular structure produces a stochastic signal indicative of turnover and movement of the structures[c]
- Algorithms development for quantitative FSM (through 2003)[d]
- FSM imaging of cytoskeleton dynamics in neurons[e]
- Comparison of the FSM signal in wide-field epifluorescence and total internal reflection fluorescence (TIRF) microscopy[f]
- FSM imaging and signal analysis, history of biological questions, and corresponding methodological advances[g]

Methods:

- Methods for microscope set-up and cell preparations for FSM imaging in living cells[h,i,j,k,j]
- Method of intracellular force reconstruction by FSM analysis[m]

FSM Analysis of Microtubule (MT) Motion and Assembly Dynamics

MTs assembled from pure tubulin (in vitro):

- MTs assembled from labeled and unlabeled pure tubulin *in vitro* exhibit fluorescent speckles, showing that cellular factors or organelles do not contribute to the speckle pattern[n]
- Speckles containing one fluorophore can be detected using conventional wide-field epifluorescence[o]
- For MTs *in vitro*, treadmilling is not unidirectional, suggesting that it is powered by differences in dynamic instability between plus and minus ends[p]
- The visualization of individual speckled MTs in a pool of tubulin, even when labeled at ratios <2%, requires a reduction of out-of-focus fluorescence by spinning-disk confocal microscopy[p]
- The KinI subfamily of kinesin-related proteins mediates depolymerization of MTs at both ends *in vitro*[q]

MT flux in meiotic spindles assembled from Xenopus laevis *egg extracts (in vitro):*

- FSM allows detailed analysis of dense polymers like the spindle[a]
- Spinning disk FSM reveals MT bundles, whereas in wide-field FSM those bundles are not detectable[r]
- MTs both polymerize and depolymerize at the kinetochores[r]
- Flux rates are different for kinetochore and nonkinetochore MT bundles[r,s]
- Monopoles do not exhibit MT flux during spontaneous bipolarization, and the onset of flux is correlated with the onset of bipolarity. This suggests that arrays of antiparallel MTs are required for flux generation[t]
- Disruption of depolymerization factors at the poles yields kinesin Eg5-dependent elongation of the metaphase spindle[u,v]
- MT flux is predominantly driven by ensembles of processive kinesin Eg5 motors[w]
- FSM and cross-correlation analysis reveal MT minus ends throughout the spindle, with more at the poles than at the spindle equator[x]
- MTs within bundles move at heterogeneous speeds, and FSM can be used to determine the length distribution of individual MTs in the spindle[y]

(*Continued*)

Table 7.1 (*Continued*)

MT flux in mitotic spindles in tissue culture cells (in vivo):
- The majority of poleward flux of kinetochore MTs in mammalian PtK1 epithelial cells is driven by a polar pulling-in mechanism, whereas Eg5, which plays a dominant role in *Xenopus* egg extracts, makes a minor contribution[z]

MT flux in spindles of other cell systems:
- MT flux makes a significant contribution to poleward chromosome movement during anaphase A in *Drosophila melanogaster* embryos[aa,bb]
- Three mitotic motors exhibit different roles in anaphase B in *Drosophila* embryos[cc]
- Two functionally distinct MT-destabilizing *Kin*I enzymes are responsible for normal chromatid-to-pole motion in *Drosophila*[dd]
- MT flux in crane-fly spermatocytes increases from metaphase to anaphase and is faster than chromosome poleward motion, suggesting that MT plus ends are still polymerizing[ee]

MTs in interphase tissue cells:
- In living cells, optimal speckle contrast occurs at fractions of labeled tubulin in the 0.1–0.5% range, where the fluorescence of each speckle corresponds to one to seven fluorophores per resolvable unit[n,o]
- Cytoplasmic dynein, a MT-associated motor, promotes the formation and growth of immobile MTs in organized astral arrays, as opposed to organizing the array by powering the motion of pre-existing polymers[ff]
- Overexpression of Ncd, a kinesin-14, in mammalian fibroblasts results in generation of sliding forces between adjacent MTs in bundles[gg]

MTs in neurons:
- In the axon shaft proximal to the cell body, individual MTs are stationary, suggesting that tubulin dimers are transported down the axon to promote axonal growth and branching[hh]
- In regions of axon growth (i.e. growth cones and interstitial branches), short segments of MTs move, suggesting that exploratory behavior of neurons is promoted by MT transport[ii]
- Measurement of MT growth and transport in growth cones reveals they grow towards the periphery while being transported towards the axon[jj,kk]

MT dynamics in S. cerevisiae *and* S. pombe*:*
- During mating of S. *cerevisiae*, the nucleus and spindle pole body are oriented and tethered to the shmoo tip by a MT-dependent search and capture mechanism, where MT growth and shrinkage are localized mostly to the shmoo tip[ll]
- Kinetochore MTs grow and shrink only at the plus ends and do not exhibit poleward flux[mm]
- Astral MT plus end growth and shortening at the cell cortex plays an important role in positioning the nucleus during interphase and the spindle during mitosis[nn]

MT dynamics in pathogens:
- Dynamics of MTs in the fungal pathogen *Ustilago maydis* determines cell polarity[oo]
- MT dynamics through the cell cycle alter morphogenesis in the fungal pathogen *Candida albicans*[pp]

FSM Analysis of Microtubule-Associated Protein (MAP) Dynamics

MT plus-end binding proteins:
- CLIP-170 binds at the growing MT end, stays stationary relative to the MT, and dissociates after some time[qq]
- MT assembly in meiotic *Xenopus* egg extract spindles is visualized by localization of speckle-like EB1 comets[rr]

MT motors:
- The motor protein Eg5 stays stationary in spindles despite the flux of MTs, suggesting that Eg5 may be bound to a putative non-MT spindle matrix[ss]

(*Continued*)

Table 7.1 (*Continued*)

Other MAPs:
- Co-imaging of full-length ensconsin or its MT-binding domain (EMTB) conjugated to GFP with fluorescent MTs suggests that dynamics of MAP:MT interactions is at least as rapid as tubulin: MT dynamics in the polymerization reaction[tt]
- Binding and unbinding of ensconsin generates a speckle pattern along the MT, the dynamics of which can be evaluated to study the phosphorylation-dependent regulation of the turnover[uu]
- Multi-GFP tandems on MAPs significantly increase the speckle contrast and stability[uu]

FSM Analysis of F-actin Dynamics in Migrating and Non-migrating Cells

Actin network dynamics in migrating tissue cells:
- F-actin in polarized cells is organized in four distinct zones: a lamellipodium with rapid retrograde flow and constant polymerization; a lamella with slower retrograde flow, a contraction zone with no flow, and a zone of anterograde flow. The spatial transition from retrograde to anterograde flow suggests the presence of a contractile belt powered by myosin II which may drive cell migration[vv]
- Single-fluorophore speckles can reveal F-actin turnover, as known from speckle analysis in MTs, despite the complex filamentous structure of the F-actin meshwork[ww]
- Statistical clustering analysis of single speckle dynamics reveals two kinetically and kinematically distinct, yet spatially overlapping, actin networks that mediate cell protrusion[xx]
- Spatiotemporal correlation of F-actin assembly maps and GFP-Arp2/3 clustering indicate that, in the lamellipodium, actin assembly is mediated by Arp2/3, while lamellar assembly is independent of Arp2/3 activity[yy]
- Arp2/3- and cofilin-regulated assembly of the lamellipodia is not required for epithelial cell protrusion[zz]
- Molecular kinetics of Arp2/3 and capping protein can be measured by single-molecule FSM[aaa]
- The dynamics of actin-binding proteins (capping protein, Arp2/3, tropomyosin) exhibit spatial differentiation in the lamellipodium and lamella of *Drosophila* S2 cells[bbb]

Actin network dynamics in neurons:
- Steady-state retrograde flow in neuronal growth cones depends on both myosin II contractility and actin-network treadmilling[ccc]

Actin networks in keratocytes and keratocyte fragments:
- Mechanical stimulation of keratocyte fragments activates acto-myosin contraction and causes directional motility[ddd]
- Keratocytes exhibit F-actin retrograde flow relative to the substrate[eee] in a biphasic relationship between flow magnitude and adhesiveness[fff]
- Actin and myosin undergo polarized assembly, suggesting force generation occurs at the lamellipodium/cell body transition zone[ggg]
- Directed motility is initiated by symmetry breaking actin-myosin network reorganization and contractility at the cell rear[hhh]

Actin in contact-inhibited epithelial cells:
- Unlike migrating cells, cortical actin in contact-inhibited cells is spatially stationary but undergoes rapid turnover[iii, jjj]
- The spatiotemporal mapping of F-actin network turnover from speckle signal analysis during appearance and disappearance events can be carried out at high resolution in contact-inhibited cells[jjj]

Actin dynamics in S. cerevisiae, *using GFP-tubulin:*
- FSM can be used to visualize bud-associated assembly and motion of F-actin cables in budding yeast[kkk]

Multi-Spectral FSM Analysis of F-actin and Other Macromolecular Structures

(*Continued*)

Table 7.1 (*Continued*)

Co-motion of the F-actin cytoskeleton and other structures, using spectrally distinct fluorescent analogues:

- FSM of MTs and F-actin in cytoplasmic extracts of *Xenopus* eggs confirms two basic types of interaction between the polymers: a cross-linking activity and a motor-mediated interaction[lll]
- Dynamic interactions between MTs and actin filaments are required for axon branching and directed axon outgrowth[mmm]
- Direction of MT growth is guided by the tight association of MTs with F-actin bundles[nnn]
- F-actin contraction may be involved in the breaking of MTs[vv,ooo]
- Rho and Rho effectors have differential effects on F-actin and MT dynamics during growth cone motility[ppp]
- In migrating epithelial cells, the dynamics of MTs and F-actin is coordinated by signaling pathways downstream of Rac1[qqq]
- FSM of F-actin and several focal adhesion (FA) proteins reveals a differential transmission of F-actin network motion through the adhesion structure to the extracellular matrix[rrr]

FSM Analysis of Protein Turnover in Focal Adhesions (FAs)

- FSM of low-level GFP-fusion protein expression, in combination with TIRF microscopy, allows quantification of molecular dynamics within FA protein assemblies at the ventral surface of living cells[f,rrr]

7.9
Results from Studying Cytoskeleton Dynamics

7.9.1
F-Actin in Cell Migration

Over the past few years, qFSM has critically driven our understanding of actin cytoskeleton dynamics in cell migration. It has provided unprecedented details of the spatial organization of F-actin turnover and the transport and deformation of F-actin networks *in vivo*. In the following sections, we review a few key discoveries, enabled by qFSM, that have defined a new paradigm for the functional linkage between actin cytoskeleton regulation and epithelial cell migration.

7.9.1.1 F-Actin in Epithelial Cells is Organized Into Four Dynamically Distinct Regions

Figures 7.5 and 7.6 indicate the steady-state organization of the F-actin cytoskeleton in four kinematically and kinetically distinct zones:

- The lamellipodium, characterized by fast retrograde flow and two narrow bands of assembly and disassembly resulting from the fast treadmilling of actin between its polymeric and monomeric states [54, 82].
- The lamella, characterized by reduced retrograde flow and assembly and disassembly in random punctate patterns.
- The cell body, characterized by anterograde flow and turnover patterns similar to those of the lamella.
- The convergence zone, where the flows of the lamella and cell body meet and where strong depolymerization suggests that the lamella and cell body are materially separate structures.

qFSM also delivers nonsteady-state measurements of flow and turnover, revealing distinct variations in the periodicity of turnover between these regions [78]. In combination with pharmacological perturbation, qFSM was used to dissect the mechanisms of retrograde flow. Thus, lamellipodium flow was found to be independent of myosin motor contraction, whereas lamella flow was blocked by the specific inhibition of myosin II activity [83]. The lamellipodium and the lamella also exhibited different sensitivity to the disruption of filament assembly, disassembly and severing, which suggested that these regional differences might be associated with differential molecular regulation [83]. This hypothesis has thus far been confirmed by immunostaining studies [83, 84] and by the expression of constitutively active and dominant-negative constructs of regulatory proteins [84, 85]. Here, qFSM provides a critical insight into cytoskeleton dynamic responses to shifted activation of regulatory factors.

In summary, these data demonstrate how qFSM can be used to quantify spatiotemporal modulations of the kinetics and kinematics of molecular assemblies and to identify dynamically distinct structural modules, even when they are composed of the same base protein.

7.9.1.2 Actin Disassembly and Contraction are Coupled in the Convergence Zone

A similar spatiotemporal correlation analysis was performed to examine the relationship of F-actin network depolymerization and contraction in the convergence zone [81]. It was first established that transient increases in speckle flow convergence are coupled to transient increases in disassembly. This begged the question whether the rate of speckle flow convergence increases because disassembly boosts the efficiency of myosin II motors in contracting a more compliant network, or because motor contraction mediates network disassembly. To address this question, we transiently perfused cells with Calyculin A, a type II phosphatase inhibitor that increases myosin II activity. Unexpectedly, we reproducibly measured a strong burst of disassembly long before flow convergence was affected. This evidence suggested that myosin II contraction can actively promote the depolymerization of F-actin, for example, by breaking filaments. The link between F-actin contractility and turnover has since been confirmed by fluorescence recovery after photobleaching measurements in the contractile ring required for cytokinesis [86]. In summary, these data demonstrate the correlation of two qFSM parameters to decipher the relationship between deformation and plasticity of polymer networks inside cells.

7.9.1.3 Two Distinct F-Actin Structures Overlap at the Leading Edge

The transition between the lamellipodium and the lamella is characterized by a narrow band of strong disassembly adjacent to a region of mixed assembly and disassembly and a sharp decrease in retrograde flow velocity (see Figure 7.6). Together, these features defined a unique mathematical signature for tracking the boundary between the two regions over time (Figure 7.8a). In view of the different speckle velocities and lifetimes between the two regions, it was speculated that the same boundary could be tracked by spatial clustering of speckle properties. It was predicted that fast, short-living speckles (class 1) would preferentially localize in the lamellipodium, whereas slow, longer-living speckles (class 2) would be dominant in the lamella. To test this hypothesis, we solved a multiobjective optimization problem in which the thresholds of velocity v_{th} and lifetime τ_{th} separating the two classes, as well as the boundary ∂Lp between lamellipodium and lamella, were determined subject to the rule $\{\partial \mathrm{Lp}, \tau_{th}, v_{th}\} = \max(N_1/(N_1 + N_2) \in \mathrm{Lp}) \& \min(N_1/(N_1 + N_2) \in \mathrm{La})$ (Figure 7.8b and c), where N_1 and N_2 denote the number of speckles in classes 1 and 2, respectively. The prediction was confirmed in the lamella, where class 1 speckles occupied a statistically insignificant fraction. However, class 2 speckles made up 30–40% of the lamellipodium, indicating that in this region speckles with different kinetic and kinematic behavior colocalize. This information was previously lost in the averaged analysis of single-speckle trajectories. When mapping the scores of class 1 and class 2 speckles separately (Figure 7.8di-dii), it was discovered that class 1 speckles define the bands of polymerization and depolymerization characteristic

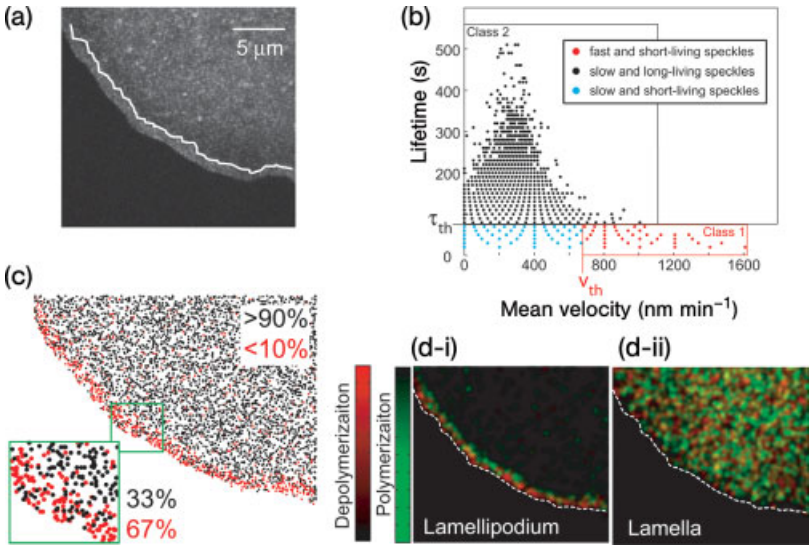

Figure 7.8 Distinction of two spatially overlapping actin networks based on heterogeneity of single-speckle properties. (a) Raw FSM image overlaid with the boundary between lamellipodium and lamella computed from spatial gradients in F-actin turnover and flow velocity; (b,c) Cluster analysis of speckle lifetime and velocity (see text); (d) Class 1 speckles constitute the rapidly treadmilling lamellipodium. Class 2 speckles constitute the lamella with a punctate pattern of random actin turnover. Both networks spatially overlap in the first 2 µm from the cell edge. Figure reproduced in parts with permission from Refs [83] and [23].

of the lamellipodium, and that class 2 speckles define the puncta of assembly and disassembly characteristic of the lamella, which reaches all the way to the leading edge. Subsequent experiments specifically disrupting actin treadmilling in the lamellipodium confirmed the finding that the lamellipodium and lamella form two spatially overlapping, yet kinetically, kinematically and molecularly different, F-actin networks [83, 84].

7.9.2 Architecture of *Xenopus laevis* Egg Extract Meiotic Spindles

During cell division, MTs form a spindle, which maintains stable bipolar attachment to chromosomes over tens of minutes. A sophisticated checkpoint system senses the status of attachment and generates a signal to progress with symmetric segregation of the replicated sister chromatids into the newly forming mother and daughter cells [6]. The minus ends of polar MTs are preferentially located at the spindle poles, whereas the plus ends continually switch between growth and shrinkage, a process known as 'MT dynamic instability' [87]. Strikingly, dynamic instability in vertebrate spindles occurs within a few tens of seconds, a time scale at least an order of magnitude shorter than the existence of the spindle [88]. In addition to MT dynamic instability at the MT plus end, individual MTs are transported toward the spindle poles, a behavior known as 'poleward flux'. Poleward flux has only been observed in higher eukaryotic

spindles, including the *Xenopus laevis* extract spindle system [89]. How the overall stability of spindle architecture is maintained under the much faster dynamics of its building blocks is largely unknown. qFSM has made several critical contributions to the mechanistic analysis of spindle architecture (Table 7.1). For example, it has revealed detailed maps of the organization of heterogeneous MT poleward flux (Figure 7.9a–c) [74, 90], and it was also used to show that MTs form distinct types of bundles with different flux dynamics, depending on whether they are attached to chromosomes (kinetochore fibers) or form a scaffold of overlapping fibers emanating from opposite poles (interpolar MT fibers) [38]. Together, these data have indicated an enormous architectural complexity, which requires fine regulation of the dynamics of each MT. However, the high MT density in the spindle has precluded measurement of the dynamics of individual MTs within bundles. Speckles generally consist of multiple fluorophores distributed over many different MTs.

Recently, this difficulty has been overcome by single-fluorophore speckle imaging of *Xenopus laevis* extract spindles [62]. As a cell-free spindle model, the extract spindle allows convenient control over fluorescent tubulin levels to achieve sparse labeling of MTs (Figure 7.9d). For low labeling ratios *f*, speckle intensities cluster in multiples of ~500 AU, indicating that speckles are composed of a discrete low number (e.g. one, two, three or four) of fluorophores (Figure 7.9e and f) [62]. At the lowest concentrations of labeled tubulin, only one intensity cluster with a mean value of ~500 AU was found. Furthermore, the average intensity of a detectable speckle remained constant over time at ~500 AU (Figure 7.9g), although the speckle number decreased due to photobleaching, Together, the cluster analysis of speckle intensities and the photobleaching analysis confirmed that >98% of the speckles reflected the image of a single fluorophore.

7.9.2.1 Individual MTs within the Same Bundle Move at Different Speeds

Single-fluorophore speckles were then used to investigate how individual MTs in close proximity move relative to one another. In order to avoid any *a priori* assumptions, the spatial organization of spindle MTs was mapped using the dense flow field measured in a spectrally distinct channel displaying multifluorophore speckles. Path integration of the flow field allowed the construction of equally spaced bands of uniform width (480 nm), which reflects the average position of MT bundles within the spindle (Figure 7.9h). The band width was chosen to match the diffraction limit of the microscope, and is consistent with electron microscopy studies which showed that MTs form bundles typically a few hundred nanometers wide, with individual MTs 20–50 nm apart [91, 92]. Next, the pairwise difference between the velocities of speckles located in the same band showed that MTs spaced at a distance comparable to the width of MT bundles exhibit remarkably heterogeneous movement (Figure 7.9i). Thus, individual MTs appear to slide past one another over very short distances, suggesting that the spindle is a MT scaffold that is continuously restructured at the scale of tens of seconds.

7.9.2.2 The Mean Length of Spindle MTs is 40% of the Total Spindle Length

Despite the heterogeneous movement of the majority of speckles within one band, a small percentage (~1% of all speckles) moved in synchronized pairs: not only did

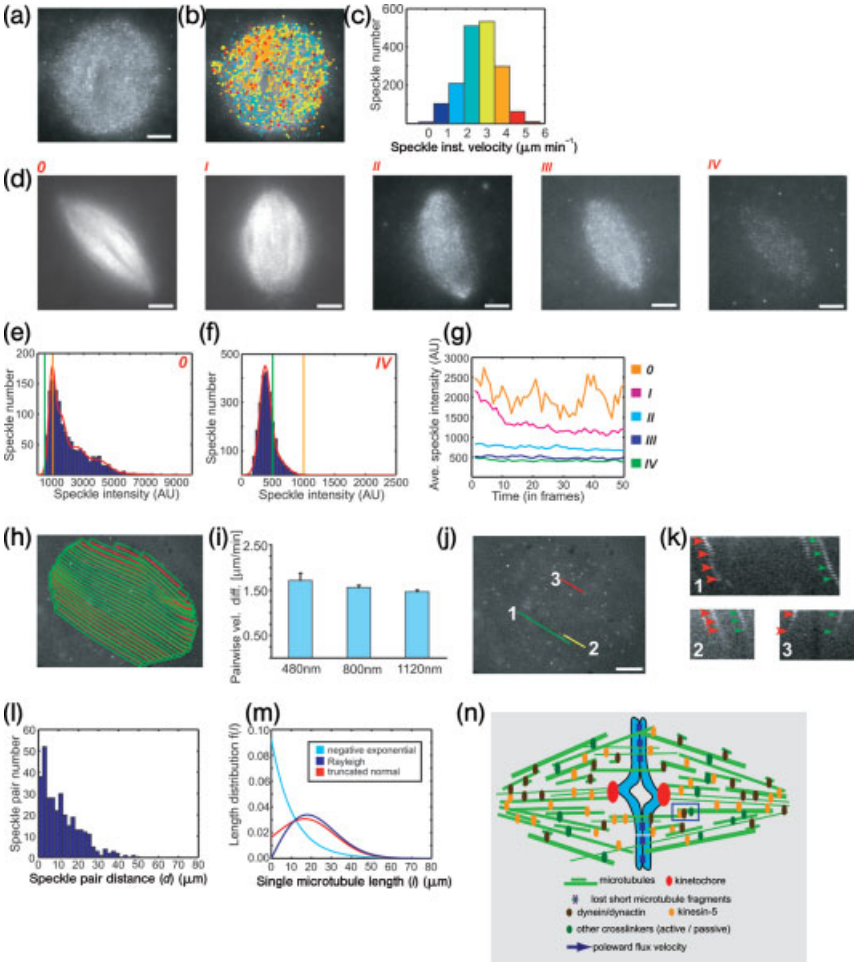

Figure 7.9 Analyzing the dynamic MT architecture of the *Xenopus laevis* egg extract spindle using single-fluorophore imaging. (a) Spindle imaged using multifluorophore tubulin speckles. Scale bar = 10 μm; (b,c) Speckle trajectories (b) overlaid onto the spindle from (a) were recovered using particle tracking. Color-coding by velocity range is specified in the velocity histogram (c). Average velocity mean ± SD = 2.68 ± 0.95 μm min^{-1} (n = 1699 tracks); (*d*) Single-fluorophore imaging conditions were determined by sequentially reducing labeled tubulin concentrations (***0***, 3.3 n*M*; ***I***, 1.1 n*M*; ***II***, 0.33 n*M*; ***III***, 0.11 n*M*; ***IV***, 0.033 n*M*; ***V***, 0.011 n*M*). Scale bars = 10 μm; (e, f) Speckle intensity distributions of spindles in (d) (concentrations ***0*** and ***V***), each fitted by a mixture of normal distributions (red lines) calculated from cluster analysis [103]. Lines mark 500 AU (green) and 1000 AU (brown); (g) Changes of average speckle intensity over time due to photobleaching within spindles in (d); (h) Based on two-color speckle imaging and path integration of the MT poleward flux vector field, uniform bands were generated at equal distances to trace MTs within the spindle [62]; (i) Difference in instantaneous velocities between pairs of speckles within bands constructed as in (h). Error bars represent standard errors of the mean (480 nm: n = 78 pairs; 800 nm: n = 659 pairs; 1120 nm: 1605 pairs); (j) Examples of synchronously moving speckle pairs identified within bands constructed as in (h). Each pair resided in the

they stay within the same band and move in the same direction at the same time (Figure 7.9j and k), but they also concurrently changed velocities (Figure 7.9k, 1–3). Clearly, these single-fluorophore speckle pairs must reside on the same MT. By applying stringent detection criteria on spatial colocalization, temporal overlap, relative distance change and relative velocity change, a total of 328 synchronous speckle pairs was identified from 13 spindles. Interestingly, 90% of the speckle distances were less than half the length of the spindle (Figure 7.9l). To estimate the lengths of spindle MTs from the measured distances between synchronously moving speckle pairs, a mathematical model was developed of the stochastic incorporation of labeled tubulin into a population of MTs with an *a priori* unknown length distribution $f(l)$ [62]. Assuming a hypothetical function $f(l)$, the model defined the expected cumulative distribution P of distances d between two speckles, given the event A that the speckles reside on the same MT:

$$P(D<d|A) = \frac{\int_0^d l^2 e^{-c\cdot l\cdot r} f(l)dl + \int_d^{+\infty}(2dl-d^2)e^{-c\cdot l\cdot r} f(l)dl}{\int_0^{+\infty} u^2 e^{-c\cdot u\cdot r} f(u)du}.$$

Here, l denotes the steady-state length of individual MTs in microns, c is the number of tubulin dimers per micron (1625), and r is the fraction of labeled tubulin ($\sim 2.86\times 10^{-6}$ for 0.066–0.033 nM labeled tubulin). Fitting the above formula for the expected cumulative distribution to the measured cumulative histogram of distances between speckle pairs made it possible to estimate parameters of $f(l)$ (Figure 7.9m). For instance, it was estimated that the ratio between the mean length of MTs and the spindle length is ~0.4.

In summary, by integrating single-fluorophore imaging with computational image analysis, it was found that spindle MTs in close proximity move at highly heterogeneous velocities, and that the majority have a length shorter than the spindle pole-to-metaphase plate distance. These results, along with molecular perturbation data (not shown), suggest that MTs in the vertebrate meiotic spindle are dynamically organized as a crosslinked 'tiled-array' in a way similar to how the actin network is organized in motile cells (Figure 7.9n) [62]. This model challenges longstanding textbook models, which assume that the majority of MTs emanate from the two poles. The mechanical stability of the tiled-array is maintained by dynamic crosslinks. Thus, a structure can be formed where the stability of the ensemble is much higher than the stability of its individual building blocks. It is speculated that the design of cytoskeleton structures

same band, coexisted over a time interval of at least 10 s, and varied synchronously in flux velocity. Scale bar = 10 µm; (k) Kymograph representation of the synchronous movement of the speckle pairs shown in (j); (l) Histogram of the measured distances between speckle pairs (328 pairs from $n = 13$ spindles); (m) Estimated length distributions under different models: exponential distribution (mean ± SD: 11.75 ± 11.75 µm) (light blue), Rayleigh distribution (mean ± SD: 22.00 ± 11.50 µm) (blue), truncated normal distribution (TND; mean ± SD: 20.11 ± 12.23 µm). TND was selected based on its minimal fitting error and statistically validated [62]. Spindle length: mean ± SD: 49.0 ± 5.0 µm ($n = 13$ spindles); (n) A tile-array architectural model of the *Xenopus* extract spindle. Figure reproduced with permission from Ref. [62].

follows the general principle of coupling many short and dynamic components into larger, longlasting ensembles to achieve both the flexibility and stability needed for cellular life under constantly changing conditions.

7.9.3
Hierarchical Transmission of F-Actin Motion Through Focal Adhesions

Cell migration requires a delicate spatial balance of cell adherence to the substrate. Dynamic structures called focal complexes assemble next to the leading edge and mature over time into FAs, macromolecular assemblies of more than 100 different proteins. Focal adhesions tether the F-actin network to integrin receptors, which in turn bind to the substrate. Forces generated by F-actin polymerization and/or contraction are transmitted to the extracellular matrix (ECM) via the coupling of F-actin to FAs. It has long been known that F-actin and FA proteins are coupled; many FA proteins bind directly or indirectly to F-actin [93–95] or integrin receptors [96–98], and the ends of contractile actin bundles often appear to be embedded in FAs [57, 99].

However, despite many years of intensive research aimed at identifying the molecular parts list of FAs, it has been impossible to determine the hierarchy of interactions between specific FA proteins and the F-actin cytoskeleton in living cells. Hu *et al*. used two-color total internal reflection fluorescent speckle microscopy (TIR-FSM) to simultaneously image X-rhodamine actin and various GFP-tagged FA proteins (Figure 7.10a) [25]. As expected, F-actin retrograde flow slowed down directly

Figure 7.10 Measuring the coupling between F-actin and FA proteins. (a) F-actin (red) and FA protein vinculin (green) in a live cell; (b) Simulated F-actin (red) and FA protein vinculin (green) from a Monte Carlo simulation. (c–e) Varying the association and dissociation rate constants of FA proteins in Monte Carlo simulations affects the speed of FA speckle motion and the coupling to F-actin. In these simulations, FA proteins switched between unbound (1), FA platform-bound (2) and F-actin-bound (3) states to allow coupling to F-actin flow. The VMCS and DCS were calculated using a simulation of F-actin flowing from left to right at $v = 0.25\,\mu m\,min^{-1}$; (c) Tracked motion of FA speckles (yellow vectors) for three representative FSM movies out of 25. VMCS increased from left to right as FA protein speckle flow became more aligned with F-actin speckle flow and more FA proteins were bound to the F-actin network; (d) Surface plot of VMCS determined by tracking 25 simulated FSM movies with the same dissociation rate constant ($k_{off} = k_{off21} = k_{off31} = 0.005$) and variable association rate constants to the FA platform (k_{on2}) and to F-actin (k_{on3}). For conditions $k_{on2} = k_{on3}$ (black diamonds), the VMCS was ~0.5, in agreement with the notion that half the FA proteins are stationary while the other half move at velocity v; (e) Scatter plot of VMCS versus $R_{kon} = k_{on3}/(k_{on2} + k_{on3})$. R_{kon} is a measure of the fraction of total FA proteins bound to F-actin. (f,g) Temporal variation of F-actin and vinculin speckle speeds, DCS, and VMCS within a stable (f) and a sliding (g) FA. The top left panels show graphs of average speeds of F-actin (red) and vinculin (green) speckles, vinculin-actin VMCS (blue) and vinculin-actin DCS (pink). The bottom left panels show kymographs of GFP-vinculin taken in the direction parallel to actin retrograde flow. The position of the cell edge (white) shows that the FA remains stationary in (f), whereas in (g) the FA initiates sliding at ~4 min (left arrow) and stops at ~12 min (right arrow). Right panels show maps of vinculin and actin speckle speeds and DCS. During retraction and FA sliding, vinculin alters its binding to F-actin. Times are shown as h:min:s. Figure reproduced with permission from Ref. [25].

over the FAs, suggesting that the latter may dampen flow by engaging F-actin to the ECM. Furthermore, when the motions of three classes of FA proteins were compared with F-actin, major differences in the speeds and visual coherence of the flow fields were observed. The ECM-binding α_V integrin exhibited slow, incoherent retrograde flow compared to actin, while the FA 'core' proteins paxilin, zyxin and focal-adhesion kinase (FAK), which do not bind F-actin or the ECM directly but have structural or signaling roles, moved slightly faster and more coherently. The third class, composed of the actin-binding proteins α-actinin, vinculin and talin, moved significantly faster (close to the speed of actin) and with the highest coherence.

The next step was to estimate coupling by quantifying the degree of correlated motion between FA and F-actin speckles. Correlated motion would strongly indicate that FA proteins help to transmit the force generated during actin polymerization and myosin II-mediated contraction to the ECM. To quantify this coupling, both speckle flow maps were interpolated to a common grid and two parameters were calculated: the direction coupling score (DCS) and the velocity magnitude coupling score (VMCS). The DCS measures the level of directional similarity between F-actin and FA speckle motion, while the VMCS measures the component of FA motion in the direction of actin, thus taking into account both direction and speed. The quantitative interpretation of these parameters, in terms of the kinetics of molecular interactions between F-actin and FA components, required mathematical modeling. Monte Carlo simulations were used to generate synthetic two-color movies of speckles associated with two transiently coupled protein structures (Figure 7.10b–d). Relating the binding/unbinding events at the molecular level to the relative movement of speckles in the two structures, along with an analysis of the noise characteristics of such movies, revealed that the VMCS is a linear reporter of the ratio between the time that the FA component is bound to F-actin alone and the time it is bound to both F-actin and the substrate (Figure 7.10e). Thus, the relative movement of two speckle fields directly reflects the degree of interaction between two protein structures in living cells.

When the DCS and VMCS were calculated for the three classes of FA proteins, integrin had the lowest coupling to actin, and F-actin-binding proteins the highest. The core proteins showed intermediate coupling. Such quantitative analysis provides even more insight when scores are compared over time. For example, coupling scores stayed constant for stationary FAs in a protrusive area of the cell edge, but F-actin–vinculin coupling increased in FAs that slid backwards in a retracting area of the cell edge (Figure 7.10f and g). Multicolor qFSM analysis therefore suggests a hierarchical molecular clutch model of force transmission, in which the efficiency of force transmission depends on the make-up of the FAs [25].

7.10
Outlook: Speckle Fluctuation Analysis to Probe Material Properties

Speckle trajectories probe different dynamic phenomena at different spatial and temporal scales. So far, by using the long-range directed components of speckle trajectories, qFSM has been used to measure the flow and deformation of F-actin and

MT networks. These movements are induced by molecular forces coordinated over several microns (e.g. by the activity of a large number of molecular motors or the concerted polymerization of many filaments). On a shorter spatiotemporal scale, speckle trajectories contain components associated with the microscopic deformations of polymer scaffolds that are induced by less-coordinated local actions of individual motors and thermal forces. The positional fluctuations of speckles can also be attributed to the sliding of locally decoupled filaments, to filament bending inside the network, and to photometric shifts of the speckle centroids due to local fluorophore exchange. These fluctuations occur at a length scale shorter than the mesh size of the polymer scaffold, and are independent between speckles. When calculating the cross-correlation of trajectories of two speckles separated by a distance greater than the mesh size, these fluctuations cancel out. However, even after directional components are eliminated, the cross-correlation between two-speckle trajectories decays with $1/r$, where r denotes the distance between them. The magnitude of the correlation indicates how much of the fluctuations are spatially transmitted through the material. Soft materials have a higher rate of transmission, and hence a higher correlation magnitude, than stiff materials. This is shown in Figure 7.11a for the example of a soft and a stiff F-actin network

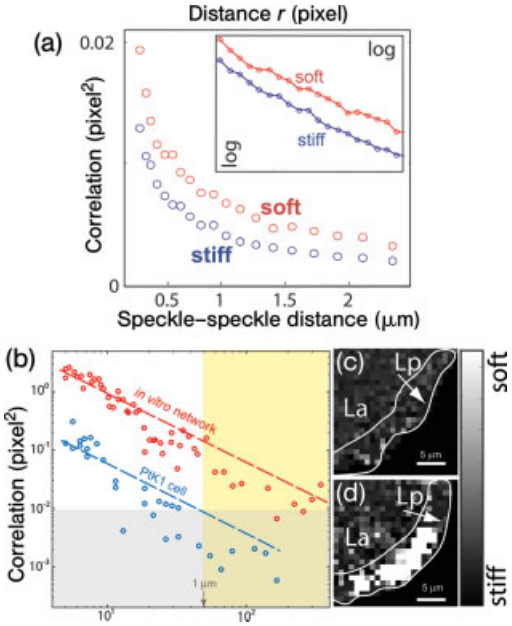

Figure 7.11 Probing stiffness of F-actin networks inside cells. (a) Correlation of random motion of two speckles as a function of their interspeckle distance r. The curves follow a $1/r$ decay (see inset), as predicted for a viscoeleastic medium; (b) Log-log plot of the correlation of random speckle motion as a function of r. *In vitro* networks are at least one order of magnitude softer than plated PtK1 cells. The gray area indicates the noise floor. Yellow area: for $r > 1\,\mu m$ the correlation is insignificant. Compliance of F-actin networks in a control cell (c) and in a cell expressing constitutively active cofilin (S3A) (d) which softens the lamellipodium network, most likely due to its selective severing activity on Lp filaments. Panel (a) reproduced with permission from Ref. [23].

measured *in vitro*. The $1/r$ decay of the fluctuation correlation is known from two-point microrheology, in which embedded beads instead of speckles are used to track thermal fluctuations in polymer networks [100, 101]. Thus, spatially correlated yet undirected components of speckle motion could be used to probe material properties of polymer networks inside a cell at the scale of the interspeckle distance. Figure 7.11b compares the stiffness between an *in vitro* network of entangled actin filaments and a cortical F-actin network in an epithelial cell. The marked difference originates in the dense crosslinking of *in vivo* networks, both intracellularly and extracellularly.

The stiffness of cellular networks is so high that correlations above noise are measurable only for speckles at a distance <1 μm (Figure 7.11b, gray zone). The possibility to extract meaningful information from speckle fluctuations over these short distances relies on recent enhancements of speckle tracking to an accuracy of approximately one-tenth of a pixel, even when speckles overlap. A module was also implemented that performs correlation analysis in small windows to map out the spatial modulation of material properties. Figure 7.11c and d compare the stiffness maps of a control epithelial cell and a cell expressing constitutively active cofilin(S3A). While the control cell has minimal spatial variation, the cell with cofilin(S3A) has a much softer lamellipodium (Lp) network but an unchanged lamella (La). These data show that cofilin – a severing factor and promoter of F-actin depolymerization – acts selectively in the lamellipodium network. High cofilin activity eventually eliminates the crosslink between the lamellipodium and lamella, resulting in a substantial softening of the lamellipodium network structure [85]. This example illustrates the potential of qFSM to derive spatial maps of the mechanical properties of cytoskeleton structures from speckle fluctuations.

7.11 Conclusions

Over the past few years, FSM has become a versatile tool for simultaneously probing the motion, deformation, turnover and materials properties of macromolecular assemblies. Despite the many exciting discoveries already made using FSM (see Table 7.1), it is a technology still in its infancy. In a next step, FSM measurements will be combined with correlational analyses to establish how assemblies operate as dynamic and plastic structures, enabling a broad variety of cell functions. In parallel, FSM will continue to go multispectral, so that these parameters can be correlated among different macromolecular structures. This requires major modifications to the current qFSM software to cope with the explosion of combinatorial data in two or more simultaneously imaged speckle channels.

With regards to future applications, FSM has the potential to uncover new biology outside the cytoskeleton field, and the analyses of FA dynamics have made some initial steps in this direction. Projects are also under way to apply qFSM to studies of the dynamic interaction of clathrin, dynamin and actin structures during endocytosis; of individual interphase MTs, MT-associated proteins and F-actin; and of DNA repair [102].

In addition to advancing basic research, FSM will hopefully become an important tool in drug discovery, particularly in the area of cancer. Already, by measuring MT dynamics in FSM-amenable cell lines transfected with patient-derived mutations in tumor suppressor genes, it has been observed that differential disease phenotypes are reproducibly replicated by different phenotypes of MT dynamics in nondividing cells (unpublished data). These subtle – but statistically highly significant – shifts in MT dynamics, that are not resolvable in static images of fixed cells, may disrupt the balance of the MT dynamics-mediated organization of signals within the cell and/or cell morphological functions. At the scale of multicellular tissues, these defects may result in detrimental responses that trigger tumor formation and metastatic behavior. Thus, FSM could enable the development of a screen for tumor-specific and patient-specific cancer drugs that would reverse the differences between cancer and control cells in terms of cytoskeleton dynamics. Such specific diagnostic tools at the subcellular scale may, at an early stage, allow the identification of efficient compounds and compound combinations with less harsh side effects than the current antimitotic chemotherapies.

Acknowledgments

These studies were supported by NIH through grants R01 GM67230 and NIH R01 GM60678 to the Danuser laboratory. Fellowship support from the Burroughs-Wellcome LJIS program (G.Y.) and the National Science Foundation (K.A.) is also acknowledged. We thank our collaborators, Clare Waterman-Storer, Edward Salmon, Tarun Kapoor, Julie Theriot, Paul Forscher and their laboratory members, for image data and uncountable discussions, without which the development of qFSM would not have been possible. We also thank James Lim and Dinah Loerke for sharing their unpublished data.

Harnessing Biological Motors to Engineer Systems for Nanoscale Transport and Assembly*

Anita Goel and Viola Vogel

By considering how the biological machinery of our cells carries out many different functions with a high level of specificity, we can identify a number of engineering principles that can be used to harness these sophisticated molecular machines for applications outside their usual environments. Here, we focus on two broad classes of nanomotors that burn chemical energy to move along linear tracks: assembly nanomotors and transport nanomotors.

8.1
Sequential Assembly and Polymerization

The molecular machinery found in our cells is responsible for the sequential assembly of complex biopolymers from their component building blocks (monomers): polymerases make DNA and RNA from nucleic acids, and ribosomes construct proteins from amino acids. These assembly nanomotors operate in conjunction with a master DNA or RNA template that defines the order in which individual building blocks must be incorporated into a new biopolymer. In addition to recognizing and binding the correct substrates (from a pool of many different ones), the motors must also catalyze the chemical reaction that joins them into a growing polymer chain. Moreover, both types of motors have evolved highly sophisticated mechanisms so that they are able not only to discriminate the correct monomers from the wrong ones, but also to detect and repair mistakes as they occur [1].

Molecular assembly machines or nanomotors (Figure 8.1a) must effectively discriminate between substrate monomers that are structurally very similar. Polymerases must be able to distinguish between different nucleosides, and ribosomes need to recognize particular transfer RNAs (tRNAs) that carry a specific amino acid. These well-engineered biological nanomotors achieve this by pairing complementary Watson–Crick base pairs and comparing the geometrical fit of the monomers to their respective polymeric templates. This molecular discrimination makes use of the

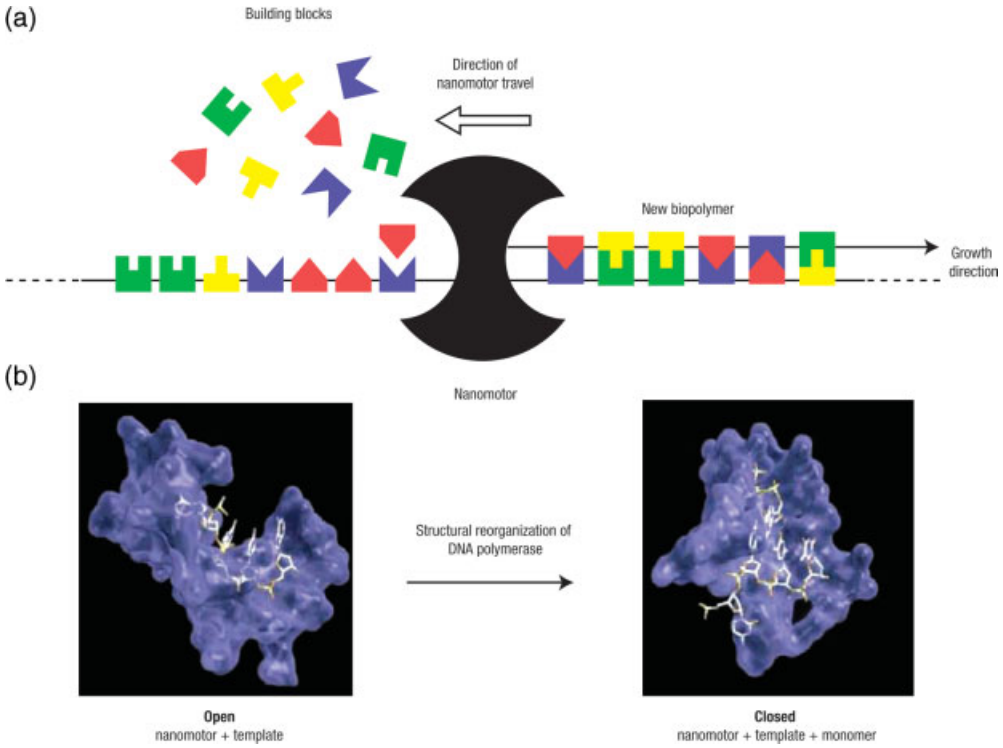

Figure 8.1 Molecular discrimination during sequential assembly. (a), The polymerase nanomotor discriminates between four different building blocks as it assembles a DNA or RNA strand complementary to its template sequence. Molecular discrimination between substrate monomers that are structurally very similar is achieved by comparing the geometrical fit of the monomers to their respective polymeric templates; (b), The T7 DNA polymerase motor undergoes an internal structural transition from an open state (when the active site samples different nucleotides) to a closed state (when the correct nucleotide is incorporated into the nascent DNA strand). Nucleotides are added to the nascent strand one at a time. This structural transition is the rate-limiting step in the replication cycle and is thought to be dependent on the mechanical tension in the template strand [2, 9, 107, 116, 121, 127, 128, 131]. Figure adapted from Ref. [127]; © 2001 PNAS.

differential binding strengths of correctly matched and mismatched substrates, which is determined by the complementarity of the base-pairing between them.

Figure 8.1b illustrates the assembly process used by the DNA polymerase nanomotor. A template of single-stranded DNA binds to the nanomotor with angstrom-level precision, forming an open complex. The open complex can 'sample' the free nucleosides available. Binding of the correct nucleoside induces a conformational change in the nanomotor, which then allows the new nucleoside to be added to the growing DNA strand [1]. The tight-fitting complementarity of shapes between the polymerase binding site and the properly paired base pair guarantees a 'geometric selection' for the correct nucleotide [2]. A similar mechanism is seen in *Escherichia coli* RNA polymerase, where the binding of an incorrect monomer inhibits the

conformational change in the motor from an 'open' (inactive) to a 'closed' (active) conformation [3].

Ribosome motors carry out tasks much more complex than polymerases. Instead of the four nucleotide building blocks used by polymerases to assemble DNA or RNA, ribosomes must recognize and selectively arrange 20 amino acids to synthesize a protein. This fact alone increases the chance of errors. Nevertheless, ribosomes obviously work (and do so along the same principles of geometric fit and conformational change as do polymerases) and are able to build amino acid polymers that are subsequently folded into functional proteins. But ribosomal motors can be tricked, much more easily than DNA motors, into building the 'incorrect' sequences when supplied with synthetic amino acids that resemble real ones [4].

8.1.1
Engineering Principle No. 1: discrimination of similar building blocks

Nanomotors used in the sequential assembly of biopolymers can discriminate efficiently between similar building blocks.

The structure of molecular machines can be visualized with angstrom-level resolution using X-ray crystallography, and the sequential assembly processes they drive can be probed in real time using single-molecule techniques [5–9]. By elucidating nanomotor kinetics under load, such nanoscale techniques provide detailed insights into the single-molecule dynamics of nanomotor-driven assembly processes. Techniques such as optical and magnetic tweezers, for example, have further elucidated the polymer properties of DNA [7, 10–12] and the force-dependent kinetics of molecular motors [13–18]. Single-molecule fluorescence methods such as fluorescence energy transfer, in conjunction with such biomechanical tools, are illuminating the internal conformational dynamics of these nanomotors [19–21].

As the underlying design principles of assembly nanomotors are revealed, it will become increasingly possible to use these biomachines for *ex vivo* tasks. Sequencing and PCR are two such techniques that already harness polymerase nanomotors for the *ex vivo* replication of nucleic acids. The polymerase chain reaction, or PCR, is a landmark, Nobel prize-winning technique [22] invented in the 1980s that harnessed polymerase nanomotors to amplify a very small starting sample of DNA to billions of molecules. Likewise, there are many conceivable future applications that either use assembly nanomotors *ex vivo* or mimic some of their design principles. Efforts are already under way to control these nanomotors better, and thus to improve such *ex vivo* sequential assembly processes for industrial use (see, for example, the websites www.cambrios.com; www.helicosbio.com; www.nanobiosym.com; www.pacificbiosciences.com).

In contrast, current *ex vivo* methods to synthesize block copolymers rely primarily on random collisions, resulting in a wide range of length distributions and much less control over the final sequence [23]. Sequential assembly without the use of nanomotors remains limited to the synthesis of comparatively short peptides, oligonucleotides and oligosaccharides [24–26]. Common synthesizers still lack both

the precision of monomer selection and the inbuilt proofreading machinery for monomer repair that nanomotors have. Building such copolymers with polymerase nanomotors *ex vivo* would yield much more homogeneous products of the correct sequence and precise length. Natural (e.g., nanomotor-enabled) designs could inspire new technologies to synthesize custom biopolymers precisely from a given blueprint.

Ribosome motors have likewise been harnessed *ex vivo* to drive the assembly of new bioinorganic heterostructures [27] and peptide nanowires [28, 29] with gold-modified amino acids inserted into a polypeptide chain. These ribosomes are forced to use inorganically modified tRNAs to sequentially assemble a hybrid protein containing gold nanoparticles wherever the amino acid cysteine was specified by the messenger RNA template. Such hybrid gold-containing proteins can then attach themselves selectively to materials used in electronics, such as gallium arsenide [28]. This application illustrates how biomotors could be harnessed to synthesize and assemble even nonbiological constructs such as nanoelectronic components (see www.cambrios.com).

Assembly nanomotors achieve such high precision in sequential assembly by making use of three key features: (i) geometric shape-fitting selection of their building blocks (e.g., nucleotides); (ii) motion along a polymeric template coupled to consumption of an energy source (e.g., hydrolysis of ATP molecules); and (iii) intricate proofreading machinery to correct errors as they occur. Furthermore, nanomotor-driven assembly processes allow much more stable, precise and complex nanostructures to be engineered than can be achieved by thermally driven self-assembly techniques alone [30–32].

We should also ask whether some of these principles, which work so well at the nanoscale, could be realized at the micrometer scale as well. Whitesides and coworkers, for example, have used simple molecular self-assembly strategies, driven by the interplay of hydrophobic and hydrophilic interactions, to assemble microfabricated objects at the mesoscale [33, 34]. Perhaps the design principles used by nanomotors to improve precision and correct errors could also be harnessed to engineer future *ex vivo* systems at the nanoscale, as well as on other length scales. Learning how to engineer systems that mimic the precision and control of nanomotor-driven assembly processes may ultimately lead to efficient fabrication of complex nanoscopic and mesoscopic structures.

8.2 Cargo Transport

Cells routinely use another set of nanomotors (i.e., transport nanomotors) to recognize, sort, shuttle and deliver intracellular cargo along filamentous freeways to well-defined destinations, allowing molecules and organelles to become highly organized (for reviews, see Refs. [35–44]). This is essential for many life processes. Motor proteins transport cargo along cytoskeletal filaments to precise targets, concentrating molecules in desired locations. In intracellular transport, myosin motors are guided by actin

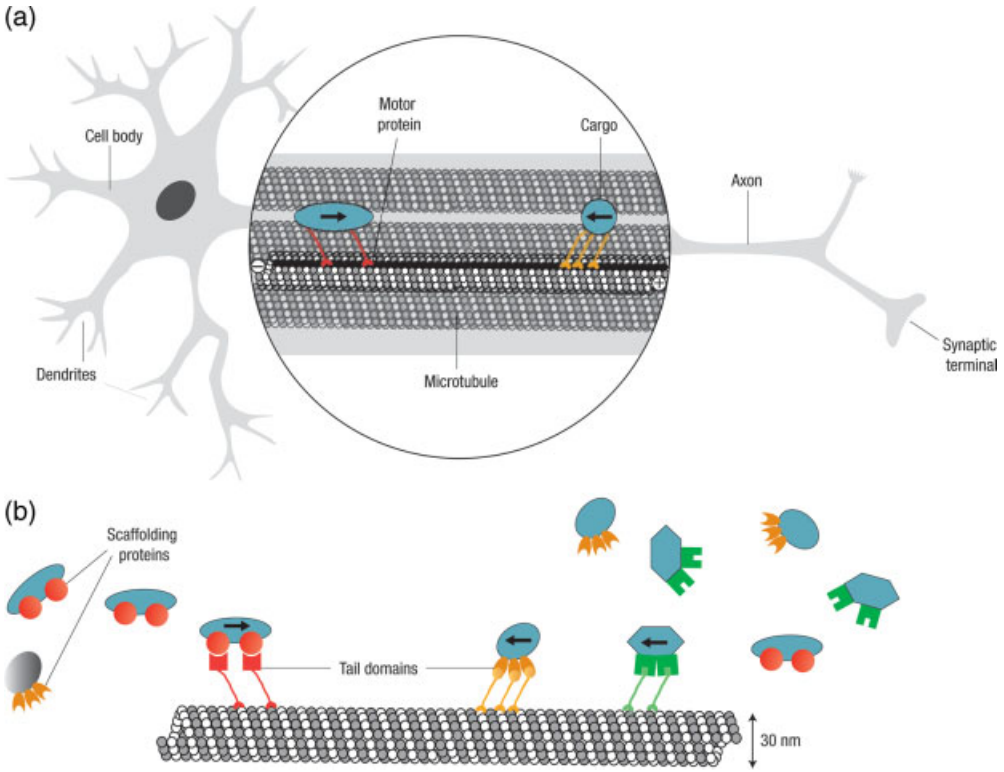

Figure 8.2 Motor-specific cargo transport in neurons. (a), The axon of neurons consists of a bundle of highly aligned microtubules along which cargo is trafficked from the cell body to the synapse and *vice versa*. Most members of the large kinesin family (red) transport cargo towards the periphery, while other motors, including dyneins (yellow), transport cargo in the opposite direction. Motors preferentially move along a protofilament rather then side-stepping (one randomly selected protofilament is shown in dark gray). Protofilaments are assembled from the dimeric protein tubulin (white and gray spheres) which gives microtubules their structural polarity. The protofilaments then form the hollow microtubule rod. When encountering each other on the same protofilament, the much more tightly bound kinesin has the 'right of way', perhaps even forcing the dynein to step sidewise to a neighboring protofilament [52–55]. (b), Each member of a motor family selects its own cargo (blue shapes) through specific binding by scaffolding proteins (colored symbols) or directly by the cargo's tail domains.

filaments, whereas dynein and kinesin motors move along rodlike microtubules. Figure 8.2a illustrates how conventional kinesins transport molecular cargo along nerve axons towards the periphery, efficiently transporting material from the cell body to the synaptic region [45]. Dyneins, in contrast, move cargo in the opposite direction, so that there is active communication and recycling between both ends (see reviews [42, 46]). In fact, the blockage of such bidirectional cargo transport along nerve axons can give rise to substantial neural disorders [47–50].

The long-range guidance of cargo is made possible by motors pulling their cargo along filamentous rods. Microtubules, for example, are polymerized from the dimeric

tubulin into protofilaments that assemble into rigid rods around 30 nm in diameter [36]. These polymeric rods are inherently unstable: they polymerize at one end (plus) while depolymerizing from the other (minus) end, giving rise to a structural polarity. The biological advantage of using transient tracks is that they can be rapidly reconfigured on demand and in response to changing cellular needs, or to various external stimuli. Highly efficient unidirectional cargo transport is realized in cells by bundling microtubules into transport highways where all microtubules are oriented in the same direction. Excessively tight bundling of microtubules, however, can greatly impair the efficiency of cargo transport, by blocking the access of motors and cargo to the microtubules in the bundle interior. Instead, microtubule-associated proteins are thought to act as repulsive polymer-brushes, thereby regulating the proximity and interactions between neighboring microtubules [51].

Traffic control is an issue when using the filaments as tracks on which kinesin and dynein motors move in opposite directions. Although different cargoes can be selectively recognized by different members of the motor protein families and shuttled to different destinations, what happens if motors moving in opposite directions encounter each other on the same protofilament (Figure 8.2b)? If two of these motors happen to run into each other, kinesin seems to have the 'right of way'. As kinesin binds the microtubule much more strongly, it is thought to force dynein to step sideways to a neighboring protofilament [52]. Dynein shows greater lateral movement between protofilaments than kinesin [52–54] as there is a strong diffusional component to its steps [55]. When a microtubule becomes overcrowded with only kinesins, the runs of individual kinesin motors are minimally affected. But when a microtubule becomes overloaded with a mutant kinesin that is unable to step efficiently, the average speed of wild-type kinesin is reduced, whereas its processivity is hardly changed. This suggests that kinesin remains tightly bound to the microtubule when encountering an obstacle and waits until the obstacle unbinds and frees the binding site for kinesin's next step [56].

8.2.1
Engineering Principle No. 2: various track designs

> *Various track designs enable motors to pull their cargo along filamentous tracks, whereas others allow motors bound to micro- or nanofabricated tracks to propel the filaments which can then serve as carriers.*

It is not a trivial task to engineer transport highways *ex vivo*, particularly in versatile geometries with intersections and complex shapes. Individual filaments typically allow only one-dimensional transport, as the motor-linked cargo drops off once the end of the filament is reached. Furthermore, conventional kinesin makes only a few hundred 8 nm-sized steps before dissociating from the microtubule [57, 58], further limiting the use of such a system for *ex vivo* applications.

Instead of having the motors transport their cargo along filaments, motors have been immobilized on surfaces in an inverted geometry that enables the filaments to

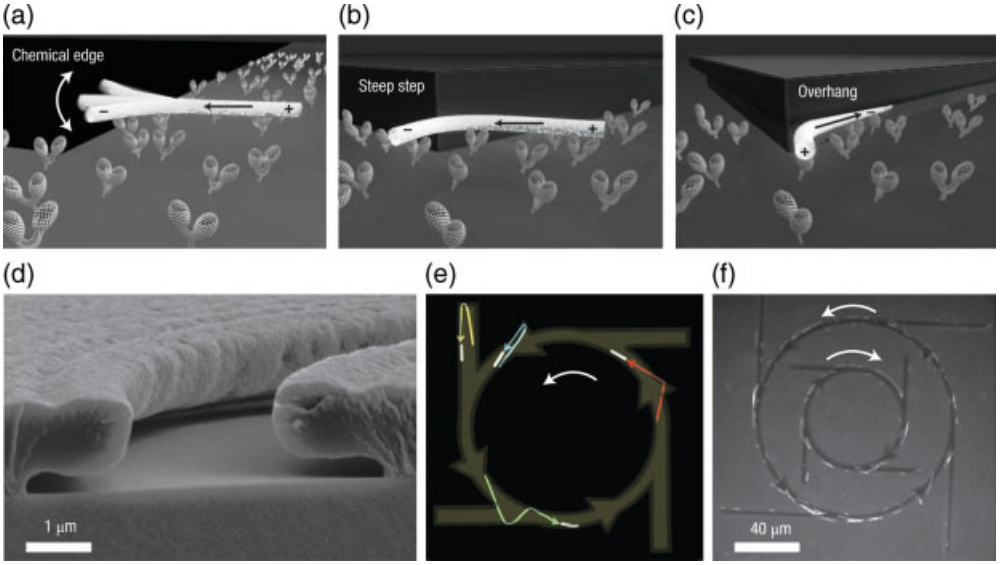

Figure 8.3 Track designs to guide nanomotor-driven filaments *ex vivo*. A variety of track designs have been used. (a), A chemical edge (adhesive stripes coated with kinesin surrounded by nonadhesive areas). The filament crosses the chemical edge and ultimately falls off as it does not find kinesins on the nonadhesive areas [61]; (b), Steep channel walls keep the microtubule on the desired path as they are forced to bend [61,65]; (c), Overhanging walls have been shown to have the highest guidance efficiency [64]; (d), Electron micrograph of a microfabricated open channel with overhanging walls [64]; (e), Breaking the symmetry of micropatterns can promote directional sorting of filament movement [63, 65, 69, 138]. The trajectories of four microtubules are shown: movement into reflector arms causes the tubule to turn around (yellow), an arrow-shaped direction rectifier allows those travelling in the desired direction to continue (red) and forces others to turn around (blue). At intersections, tubules preferentially continue straight on (green); (f), The complex microfabricated circuit analysed in (e) with open channels and overhanging walls, demonstrating unidirectional movement of microtubules.

be collectively propelled forward [45]. The head domains of the kinesin and myosin motors can rotate and swivel with respect to their feet domains, which are typically bound in random orientations to the surface. These motor heads detect the structural anisotropy of the microtubules and coherently work together to propel a filament forward [59, 60].

Various examples of such inverted designs for motor tracks have been engineered to guide filaments efficiently. Some of these are illustrated in Figure 8.3. Inverted motility assays can be created, for example, by laying down tracks of motor proteins in microscopic stripes of chemical adhesive on an otherwise flat, protein-repellent surface, surrounded by nonadhesive surface areas. Such chemical patterns (Figure 8.3a) have been explored to guide actin filaments or microtubules. The loss rate of guiding filaments increases exponentially with the angle at which they approach an adhesive/nonadhesive contact line [61]. The passage of the contact line by filaments at nongrazing angles, followed by their drop off, can be prevented by using much narrower lanes whose size is of the order of the diameter of the moving

object. Such nanoscale kinesin tracks provide good guidance and have been fabricated by nanotemplating [62].

Alternatively, considerably improved guidance has been accomplished by topographic surface features (Figure 8.3b). Microtubules hitting a wall are forced to bend along this obstacle and will continue to move along the wall [63–66]. The rigidity of the polymeric filaments used as shuttles thus greatly affects how tracks should be designed for optimal guidance. Whereas microtubules with a persistence length of a few millimeters can be effectively guided in channels a few micrometers wide as they are too stiff to turn around [61], the much more flexible actin filaments require channel widths in the submicrometer range [67, 68]. Finally, the best long-distance guidance of microtubules has been obtained so far with overhanging walls [64, 69] (Figure 8.3c). The concept of topographic guidance in fact works so well that swarms of kinesin-driven microtubules have been used as independently moving probes to image unknown surface topographies. After averaging all their trajectories in the focal plane for an extended time period, the image grayscale is determined by the probability of a surface pixel being visited by a microtubule in a given time frame [70].

But how can tracks be engineered to produce *uni*directional cargo transport? All the motor-propelled filaments must move in the same direction to achieve effective long-distance transport. When polar filaments land from solution onto a motor-covered surface, however, their orientations and initial directions of movement are often randomly distributed. Initially, various physical means, such as flow fields [71], have been introduced to promote their alignment. Strong flows eventually either force gliding microtubules to move along with the flow, or force microtubules, if either their plus or minus end is immobilized on a surface [72], to rotate around the anchoring point and along with the flow. The most universal way to control the local direction in which the filamentous shuttles are guided is to make use of asymmetric channel features. Figure 8.3d–f illustrates how filaments can be actively sorted according to their direction of motion by breaking the symmetry of the engineered tracks. This 'local directional sorting' has been demonstrated on surfaces patterned with open-channel geometries, where asymmetric intersections are followed by dead-ended channels (that is, reflector arms), or where channels are broadened into arrow heads. Both of these topographical features not only selectively pass filaments moving in the desired direction, but can also force filaments moving in the opposite direction to turn around [65, 69, 73, 74]. Once directional sorting has been accomplished, electric fields have been used to steer the movement of individual microtubules as they pass through engineered intersections [75, 76].

In addition to using isolated nanomotors, hybrid biodevices and systems that harness self-propelling microbes could be used to drive transport processes along engineered tracks. Flagellated bacteria, for example, have been used to generate both translational and rotational motion of microscopic objects [77]. These bacteria can be attached head-on to solid surfaces, either via polystyrene beads or polydimethylsiloxane, thereby enabling the cell bodies to form a densely packed monolayer, while their flagella continue to rotate freely. In fact, a microrotary motor, fuelled by glucose and comprising a 20 μm-diameter silicon dioxide rotor, can be driven along a silicon track by the gliding bacterium *Mycoplasma* [78]. Depending on the specific applica-

tion and the length scale on which transport needs to be achieved, integrating bacteria into such biohybrid devices (that work under physiological conditions) might ultimately prove more robust than relying solely on individual nanomotors.

8.3
Cargo Selection

To maintain intracellular contents in an inhomogeneous distribution far from equilibrium, the intracellular transport system must deliver molecular cargo and organelles on demand to precise destinations. This tight spatiotemporal control of molecular deliveries is critical for adequate cell function and survival. Molecular cargo or organelles are typically barcoded so that they can be recognized by their specific motor protein (Figure 8.4). Within cells, motors recognize cargo either from the cargo's tail domains directly, or via scaffolding proteins that link cargo to their tail domain [43].

8.3.1
Engineering Principle No. 3: barcoding

Engineered molecular recognition sites enable cargo to be selectively bonded to moving shuttles.

Although most cargo shuttled around by motors can be barcoded using the existing repertoire of biological scaffolding proteins, synthetic approaches are needed for all those *ex vivo* applications where the cargo has to be specifically linked to moving filaments. The loading and transport of biomedically relevant or engineered cargo has already been demonstrated (Figure 8.4) [79–83]. Typical approaches are to tag the cargo

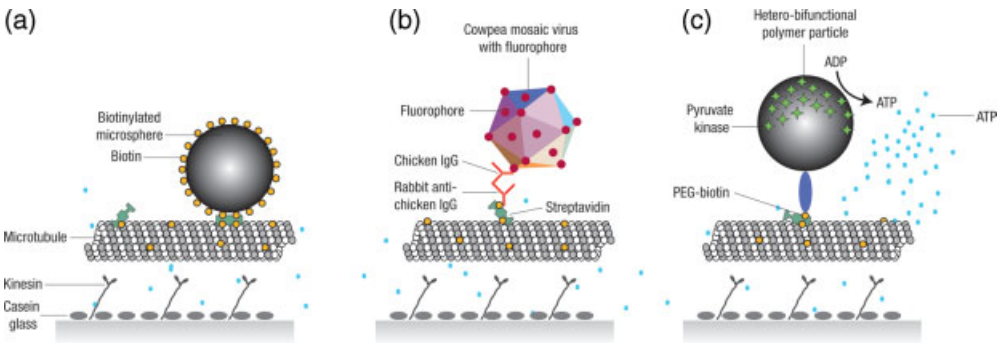

Figure 8.4 Selecting specific cargo by molecular recognition. A versatile toolbox exists by which synthetic and biological cargo can be coupled to microtubules. (a) Biotinylated objects are coupled via avidin or streptavidin to biotinylated microtubules. (b) Biological molecules, viruses [79, 81] or cells can be coupled by antibody recognition. (c) Backpacks of chemically or biologically active reagents can be shuttled around, including bioprobes [80] or tiny ATP factories [93] as shown here.

with antibodies or to biotinylate microtubules and coat the cargo with avidin or streptavidin (Figure 8.4) (for reviews, see Refs. [74, 79]), as done for polymeric and magnetic beads [84, 85] (Figure 8.4a), gold nanoparticles [86–88], DNA [87, 89, 90] and viruses [79, 81] (Figure 8.4b), and finally mobile bioprobes and sensors [80, 81, 91] (Figure 8.4c). However, if too much cargo is loaded onto the moving filaments and access of the propelling motors is even partially blocked, the transport velocity can be significantly impaired [92]. Finally, the binding of cargo to a moving shuttle can be used to regulate its performance. In fact, microtubules have recently been furnished with a backpack that selfsupplies the energy source ATP. Cargo particles bearing pyruvate kinase have been tethered to the microtubules to provide a local ATP source [93] (Figure 8.4c). The coupling of multiple motors to cargo or other scaffold materials can affect the motor performance. If single-headed instead of double-headed kinesins are used, cooperative interactions between the monomeric motors attached to protein scaffolds increase hydrolysis activity and microtubule gliding velocity [59].

At the next level of complexity – successful cargo tagging – sorting and delivery will depend on the engineering of integrated networks of cargo loading, cargo transport and cargo delivery zones. Although the construction of integrated transport circuits is still in its infancy, microfabricated loading stations have been built [88] (Figure 8.5). The challenge here is to immobilize cargo on loading stations such that it is not easily detached by thermal motion, yet to allow for rapid cargo transfer to passing microtubules. By properly tuning bond strength and multivalency, and most importantly by taking advantage of the fact that mechanical strain weakens bonds, cargo can be efficiently stored on micropatches and transferred after colliding with a microtu-

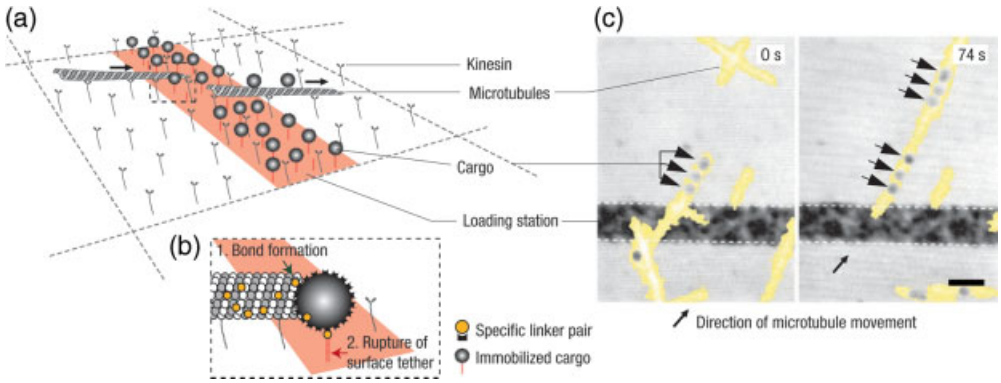

Figure 8.5 Cargo loading stations [93]; (a) Stripes of immobilized cargo are fabricated by binding thiolated oligonucleotides to micropatterned lines of gold. Hybridization with complementary strands exposing antibodies at their terminal ends allows them to immobilize a versatile range of cargos that carry antibodies on their surfaces. (b) The challenge is to tune the bond strength and valency to prevent thermal activation during cargo storage on the loading station. On collision with the shuttle (microtubule), the cargo must rapidly break off the bond it has formed with the station88. Fortunately, however, tensile mechanical force acting on a noncovalent bond shortens its lifetime; (c, d) These concepts are used in the design of the loading stations shown here, where a microtubule moves through a stripe of immobilized gold cargo and picks up a few beads.

bule [88]. Considerable fine-tuning of bond strength can be accomplished by using DNA oligomers hybridized such that the bonds are either broken by force all at once (a strong bond) or in sequence (a weak bond) [94].

As discussed above, filaments are most commonly used to shuttle molecular cargo in most emerging devices that harness linear motors for active transport. Alternatively, if the filamentous tracks could be engineered in versatile geometries, the motors themselves could be used to drag cargo coupled to the molecular recognition sites of their tail domains as in the native systems. We could thus make use of the full biological toolbox of already known or engineered scaffolding proteins that link specific motors to their respective cargoes [40, 43]. So far, assemblies of microtubules organized into complex, three-dimensional patterns such as asters, vortices and networks of interconnected poles [95, 96] have been successfully created in solution, and mesoscopic needles and rotating spools of microtubule bundles held together by noncovalent interactions have been engineered on surfaces [31]. All of these mesoscopic structures are uniquely related to active motor-driven motion, and would not have formed purely by self-assembly without access to an energy source.

To increase the complexity of microtubule track networks, densely packed arrays of microtubules have been grown in confined spaces, consisting of open microfabricated channels with user-defined geometrical patterns [97]. The key to achieving directed transport, however, is for all microtubules within each bundle or array to be oriented in the same direction. This has been accomplished by making use of directed motility in combination with sequential assembly procedures (Figure 8.6). First, microtubule seedlings have been oriented in open microfabricated and kinesin-

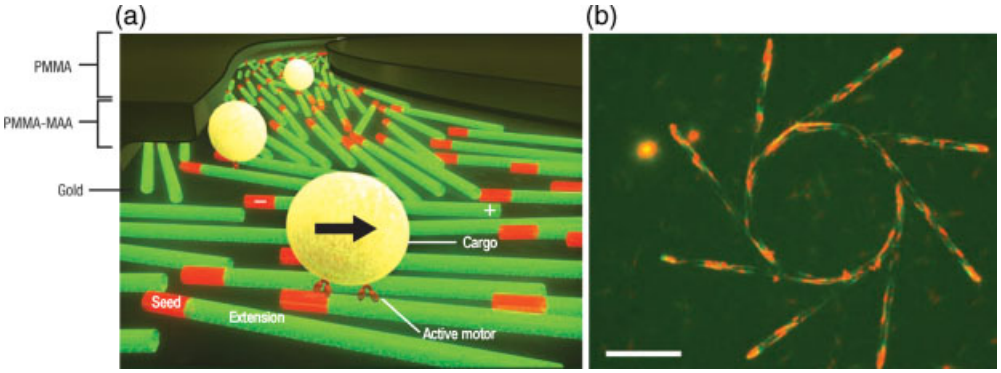

Figure 8.6 Filament tracks made from engineered bundles of microtubules [97]. Active transport is used to produce bundles of microtubules and confine them to user-defined geometries. (a) Sequential assembly procedure: first, microtubule seedlings (labelled in red) are allowed to orient themselves in open kinesin-coated microfabricated channels that contained reflector arms. Second, and after mild fixation, the oriented seedlings are polymerized into mature microtubules through the addition of tubulin into the solution (labelled green) which preferentially binds to the plus-end (polymerizing end) of the microtubules. (b) Fluorescence image of microtubules that have been grown in the confined space provided by the open channels until the channels were filled with dense networks of microtubules all oriented in the same direction [97]. Scale bar-40 μm.

coated channels that contain reflector arms. Once oriented by self-propelled motion, the seedlings were polymerized into mature microtubules that were confined to grow in the open channels until the channels were filled with dense networks of microtubules all oriented in the same direction [97]. Single kinesins take only a few hundred steps before they fall off, but the walking distance can be greatly increased if the cargo is pulled by more than one motor [98]. Such approaches to fabricating networks of microtubule bundles could be further expanded to engineer future devices that use either the full toolbox of native scaffolding proteins or new scaffolding proteins that target both biological and synthetic cargo.

Nanoengineers would not be the first to harness biological motors to transport their cargo. Various pathogens are known to hijack microtubule or actin-based transport systems within host cells (reviewed in Ref. [99]). *Listeria monocytogenes*, for example, propels itself through the host cell cytoplasm by means of a fast-polymerizing actin filament tail [100]. Likewise, the vaccinia virus, a close relative of smallpox, uses actin polymerization to enhance its cell-to-cell spreading [101], and the alpha herpesvirus hijacks kinesins to achieve long-distance transport along the microtubules of neuronal axons [102]. Signaling molecules and pathogens that cannot alter cell function and behavior by simply passing the outer cell membrane can thus hijack the cytoskeletal highways to get transported from the cell periphery to the nucleus.

8.3.2
Engineering Principle No. 4: active transport of tailored drugs and gene carriers

By taking advantage of the existing cytoskeleton, tailored drugs and gene carriers can be actively transported to the cell nucleus.

Indeed, many viruses [37, 103, 104] as well as nonviral therapeutic gene carriers, such as polyethylenimine/DNA or other polymer-based gene transfer systems (i.e., polyplexes) [105, 106] take advantage of nanomotor-driven transport along microtubule filaments to accelerate their way through the cytoplasm towards the nucleus. Nanomotor-driven transport to the nucleus leads to a much more efficient nuclear localization than could ever be achieved by slow random diffusion through the viscous cytoplasm. Active gene carrier transport can lead to more efficient perinuclear accumulation within minutes [37, 105, 106]. In contrast, nonviral gene carriers that depend solely on random diffusion through the cytoplasm move much more slowly and thus have considerably reduced transfection efficiencies. Understanding how to 'hijack' molecular and cellular transport systems, instead of letting a molecule become a target for endosomal degradation [37, 91], will ultimately allow the design of more efficient drug and gene carrier systems.

8.4
Quality Control

Nanomanufacturing processes, much like macroscopic assembly lines, urgently need procedures that offer precise control over the quality of the product, including

the ability to recognize and repair defects. Living systems use numerous quality control procedures to detect and repair defects occurring during the synthesis and assembly of biological nanostructures. As yet, this has not been possible in synthetic nanosystems. Many cellular mechanisms for damage surveillance and error correction rely on nanomotors. Such damage control can occur at two different levels as follows.

8.4.1
Engineering Principle No. 5: error recognition and repair at the molecular level

Certain motor proteins recognize assembly mistakes and repair them at the molecular level.

DNA replication represents one of the most complex sequential assembly processes in a cell. Here, the genetic information stored in the four-base code must be copied with ultra-high precision. Errors generated during replication can have disastrous biological consequences. Figure 8.7 illustrates the built-in mechanism used by the polymerase (DNAp) motor to repair mistakes made during the process of DNA replication [107]. When the DNAp motor misincorporates a base while replicating the template DNA strand, it slows down and switches gears from the polymerase to the exonuclease cycle. Once in exonuclease mode, it will excise the mismatched base pair and then rapidly switch back to the polymerase cycle to resume forward replication. Similar error correction mechanisms, known as 'kinetic proofreading', are conjectured to occur in RNA polymerases and ribosomal machineries [1, 13, 108–113].

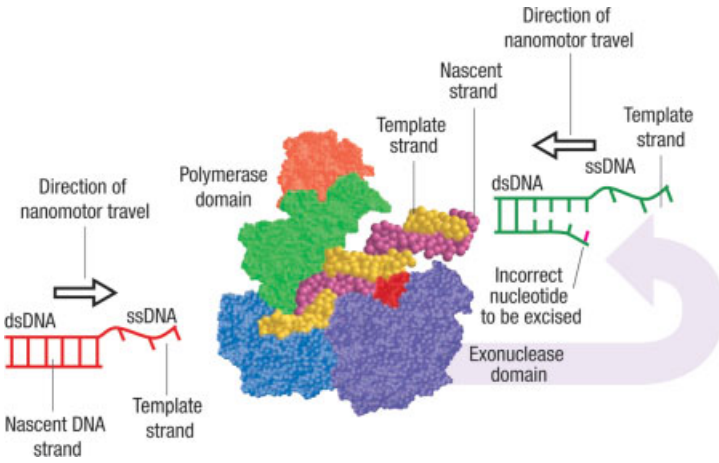

Figure 8.7 Quality control procedures for damage recognition and molecular repair. The DNA polymerase motor (DNAp) contains two active sites. It switches from polymerase (copying) to exonuclease (error correction) activity when it encounters a mismatched base. Mismatched bases are detected as they have weaker bonding interactions—the 'melting' temperature is lower—and this increases the chance of switching from the polymerase to the exonuclease active site [107]. In the exonuclease mode, the motor excises the incorrect base from the nascent DNA strand.

8.4.2
Engineering Principle No. 6: error recognition and repair at the system level

Integrated systems of motors and signaling molecules are needed to recognize and repair damage at the supramolecular level.

Nerve cells have evolved a highly regulated axonal transport system that contains an integrated damage surveillance system [114]. The traffic regulation of motors moving in opposite directions on a microtubule typically occurs in special 'turnaround' zones at the base and tip of an axon [43], but a zone for switching the organelle's direction can also be created when axonal transport is blocked at the site of nerve injury [46] (see Figure 8.2). When irreparable, such blockages are often signatures of neurodegenerative diseases. For example, amyloid precursor protein [47] or tau [115] can give rise to the accumulation of protein aggregates that inhibit anterograde axonal transport, a mechanism potentially implicated in Alzheimer's disease.

At present, there are no synthetic materials that can, in a self-regulated manner, recognize and repair defects at either the molecular or supramolecular level. Molecular recognition and repair is typically attributed to a tightly fitted stereochemical complementarity between binding partners. Nanoscale tools applied to the study of molecular recognition and repair are also elucidating the functional roles of the different structural conformations (and hence three-dimensional shapes) of the motors. For instance, the DNAp motor is in one particular conformation when it binds DNA in its copying (i.e., polymerization) mode and in an entirely different conformation (i.e., the exonuclease mode) when it binds DNA to proofread or excise a mistaken base from the replicated DNA strand [107]. In contrast, damage control at the supramolecular level (e.g., during axonal transport) is achieved by the trafficking of signaling molecules. Deciphering the underlying engineering design principles of damage surveillance and error correction mechanisms in biological systems will inevitably allow better quality-control procedures to be integrated into nanoengineered systems.

8.5
External Control

8.5.1
Engineering Principle No. 7: performance regulation on demand

As with macroscopic engines, external controls can regulate the performance of nanomotors on demand.

Learning how to control and manipulate the performance of nanomotors externally is another critical hurdle in harnessing nanomotors for *ex vivo* applications. By finding or engineering appropriate external knobs in the motor or its environment, its nanoscale movement can be tightly regulated, switched on and off, or otherwise manipulated on demand.

To achieve external control over the nanoscale movement of biological motors, it is important to identify the correct external parameters that can be used to control their dynamics. These external modulators of motor function ('handles') can be either naturally occurring or somehow artificially engineered into the motor to make it susceptible to a particular external control knob or regulator. Because the motion of nanomotors is typically driven by a series of conformational changes in the protein, mechanical load or strain on the motor molecule can also affect the dynamics of the motor. Nanomotors apply mechanical strain to their filaments or substrates as they go through various internal conformational changes. This mechanical strain is intimately related to their dynamics along the substrate and hence their functional performance. Certain interstate transition rates can depend, for example [107], on the amount of intramolecular strain in the motor protein. Applying a mechanical load to a motor perturbs key mechanical transitions in the motor's kinetic pathway, and can thereby affect rates of nucleotide binding, ATP hydrolysis and product release. Single-molecule techniques are beginning to elucidate how mechanical strain on a motor protein might be used to regulate its biological functions (e.g., nanoscale assembly or transport) [13, 55, 107, 116–120].

The single-molecule dynamics of the DNAp motor, as it converts single-stranded (ss) DNA to double-stranded (ds) DNA, has been probed, for example, through the differential elasticity of ssDNA and dsDNA (see Figure 8.8). The T7 DNA polymerase motor replicates DNA at rates of more than 100 bases per second, and this rate steadily decreases with mechanical tension greater than about 5 pN on the DNA template [9]. The motor can work against a maximum of about 34 pN of template tension [9]. The replication rates for the Klenow and Sequenase DNA polymerases also decrease when the ssDNA template tension exceeds 4 pN, and completely ceases at tensions greater than 20 pN [121]. Likewise, single-molecule techniques have allowed direct observation of the RNA polymerase (RNAp) motor moving one base at a time [122], and occasionally pausing and even backtracking [123]. Although RNAp motors are typically five- to tenfold slower than DNAp motors, the effects of DNA template tension on their dynamics are still being investigated [6]. Similarly, ribosome motors, which translate messenger RNA (mRNA) into amino acids at roughly 10 codons per second, have been found to generate about 26.5 ± 1 pN of force [124]. The underlying design principles by which these nanomotors operate are being further elucidated by theoretical models [107, 116, 125–128] that describe nanomachines at a level commensurate with single-molecule data. Furthermore, these molecular assembly machines can be actively directed, driven and controlled by environmental signals [107].

Consequently, an external load or force applied to the substrate or to the motor itself can be used to slow down a motor's action or stall its movement. The stalling forces of kinesin and dynein are 6 and 1 pN, respectively [58, 129]. For example, the binding of two kinesin domains to a microtubule track creates an internal strain in the motor that prevents ATP from binding to the leading motor head. In this way, the two motor domains remain out-of-phase for many mechanochemical cycles and thereby provide an efficient, adaptable mechanism for achieving highly processive movement [130]. Beyond stalling the movement of motors by a mechanical load, other types of perturbations can also influence the dynamics of molecular motors,

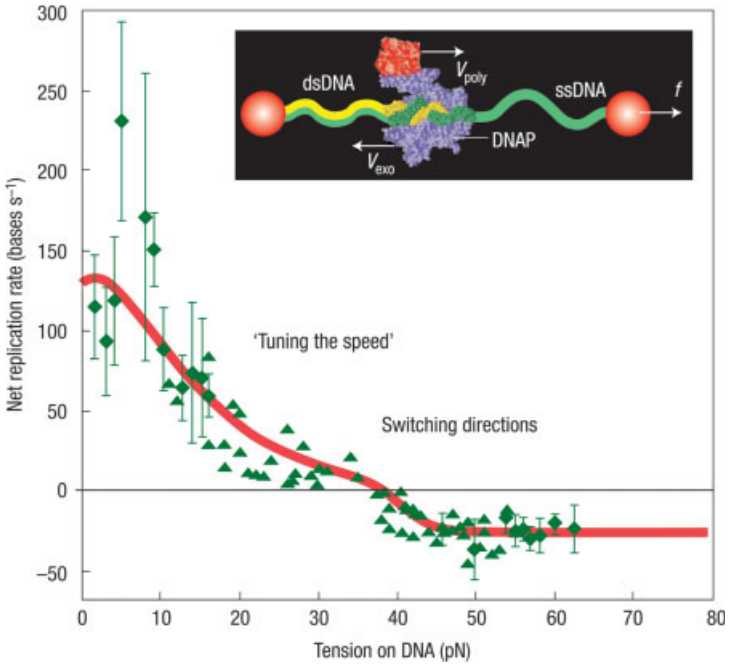

Figure 8.8 Precision control of nanomotors with external control 'knobs'. The net replication rate of a DN Ap motor can be controlled by the mechanical tension on the DNA template strand. Single-molecule data for the motor's force-dependent velocity (two sets of data—diamonds and triangles—are shown, relating to constant force and constant extension measurements) can be described by a network model (red curve) as shown here. The change in net replication rate shows how external controls can change the dynamics of the nanomotor. This model illustrates how environmental control knobs can tune the dynamics of the nanomotor by altering the rate constants associated with its various internal transitions [106]. Tensions between 0 and 35 pN control the net replication rate, whereas tensions above 35 pN actually reverse the velocity of the nanomotor. Inset, experimental setup: a single DNA molecule is stretched between two plastic beads as the motor catalyses the conversion of singlestranded to double-stranded DNA. Figure adapted from Ref. [106].

including the stretching of substrate molecules like DNA [13]. Although this external control over nanomotors has been demonstrated in a few different contexts *ex vivo*, a rich detailed mechanistic understanding of how such external control knobs can modulate the dynamics of the molecular motor is emerging from recent work on the DNA polymerase motor [9, 107, 116, 121, 127, 128, 131].

Remote-controlling the local ATP concentration by the photoactivated release of caged ATP can allow a nanomotor-driven transport system to be accelerated or stopped on demand [84]. External control knobs or regulators can also be engineered into the motors. For instance, point mutations can be introduced into the gene encoding the motor protein, such that it is engineered to respond to light, temperature, pH or other stimuli [43, 85]. Engineering light-sensitive switches into nanomotors enables the rate of ATPase [43, 132] to be regulated, thereby providing an alternate handle for tuning the motor's speed, even while the ATP concentration is

kept constant and high. When additional ATP-consuming enzymes are present in solution, the rate of ATP depletion regulates the distance the shuttles move after being activated by a light pulse and before again coming to a halt [84].

Future applications could require that, instead of all the shuttles being moved at the same time, only those in precisely defined locations be activated, on demand. Some of the highly conserved residues within motors help to determine the motor's ATPase rate [43]. Introducing chemical switches near those locations might provide a handle for chemical manipulation of the motor's speed. In fact, this has already been realized for a rotary motor [132] as well as for a linear kinesin motor, where the insertion of a Ca^{2+}-dependent chemical switch makes the ATPase activity steeply dependent on Ca^{2+} concentrations [133]. In addition to caged ATP, caged peptides that block binding sites could be used to regulate the motility of such systems. Caged peptides derived from the kinesin C-terminus domain have already been used to achieve photo control of kinesin-microtubule motility [134]. Instead of modulating the rate of ATP hydrolysis, the access of microtubules to the motor's head domain can also be blocked in an environmentally controlled manner. In fact, temperature has already been shown to regulate the number of kinesins that are accessible while embedded in a surface-bound film of thermoresponsive polymers [135].

The nanomotor-driven assembly of DNA by the DNA polymerase motor provides an excellent example of how precision control over the nanomotor can be achieved by various external knobs in the motor's environment [107, 116, 127, 128]. The DNAp motor moves along the DNA template by cycling through a given sequence of geometric shape changes. The sequence of shapes or internal states of the nanomachine can be denoted by nodes on a simple network [107, 116, 127, 128]. As illustrated in Figure 8.8, this approach elucidates how mechanical tension on a DNA molecule can precisely control (or 'tune') the nanoscale dynamics of the polymerase motor along the DNA track by coupling into key conformational changes of the motor [107].

Macroscopic knobs to precision-control the motor's movement along DNA tracks can be identified by probing how the motor's dynamics vary with each external control knob (varied one at a time). Efforts are currently under way to control even more precisely the movement of these nanomotors along DNA tracks by tightly controlling the parameters in the motor's environment (see www.nanobiosym.com). Concepts of fine-tuning and robustness could also be extended to describe the sensitivity of other nanomotors (modelled as simple biochemical networks) to various external control parameters [107]. Furthermore, such a network approach [107] provides experimentally testable predictions that could aid the design of future molecular-scale manufacturing methods that integrate nanomotor-driven assembly schemes. External control of these nanomotors will be critical in harnessing them for nanoscale manufacturing applications.

8.6 Concluding Remarks

We have reviewed several key engineering design principles that enable nanomotors moving along linear templates to perform a myriad of tasks. Equally complex

biomimetic tasks have not yet been mastered *ex vivo*, either by harnessing biological motors or via synthetic analogues. Engineering insights into how such tasks are carried out by the biological nanosystems will inspire new technologies that harness nanomotor-driven processes to build new systems for nanoscale transport and assembly.

Sequential assembly and nanoscale transport, combined with features currently attributed only to biological materials, such as self-repair and healing, might one day become an integral part of future materials and biohybrid devices. In the near term, molecular biology techniques could be used to synthesize and assemble nanoelectronic components with more control (www.cambrios.com; see also Ref. [29]). Numerous proof-of-concept experiments using nanomotors integrated into synthetic microdevices have already been demonstrated (for reviews, see Refs. [74, 136]). Among many others, these applications include stretching surface-bound molecules by moving microtubules [87, 90]; probing the lifetime of a single receptor–ligand interaction via a cantilevered microtubule that acts as a piconewton force sensor [85]; topographic surface imaging by self-propelled probes [70]; and cargo pick-up from loading stations [88] as illustrated in Figure 8.5.

Although much progress is being made in the synthesis of artificial motors (see Ref. [137]), it has been difficult, in practice, to synthesize artificial motors that come even close in performance to their natural counterparts (see Ref. [39]). Harnessing biological motors to perform nanoscale manufacturing tasks might thus be the best near-term strategy. Although many individual nanoparts can be easily manufactured, the high-throughput assembly of these nanocomponents into complex structures is still nontrivial. At present, no *ex vivo* technology exists that can actively guide such nanoscale assembly processes. Despite advances in deciphering the underlying engineering design principles of nanomotors, many hurdles still impede harnessing them for *ex vivo* transport and sequential assembly in nanosystems. Although the use of biological nanomotors puts intrinsic constraints on the conditions under which they can be assembled and used in biohybrid devices, many of their sophisticated tasks are still poorly mimicked by synthetic analogues. Understanding the details of how these little nanomachines convert chemical energy into controlled movements will nevertheless inspire new approaches to engineer synthetic counterparts that might some day be used under harsher conditions, operate at more extreme temperatures, or simply have longer shelf lives.

Certain stages of the materials production process might one day be replaced by nanomotor-driven sequential self-assembly, allowing much more control at the molecular level. Biological motors are already being used to drive the efficient fabrication of complex nanoscopic and mesoscopic structures, such as nanowires [31] and supramolecular assemblies. Techniques for precision control of nanomotors that read DNA are also being used to engineer integrated systems for rapid DNA detection and analysis (www.nanobiosym.com). The specificity and control of assembly and transport shown by biological systems offers many opportunities to those interested in assembly of complex nanosystems. Most importantly, the intricate schemes of proofreading and damage repair—features that have not yet been realized in any manmade nanosystems—should provide inspiration for those interested in producing synthetic systems capable of similarly complex tasks.

Acknowledgments

We thank Sheila Luna, Christian Brunner and Jennifer Wilson for the artwork, and all of our collaborators who contributed thoughts and experiments. At the same time, we apologize to all authors whose work we could not cite owing to space limitations.

Correspondence and requests for materials should be addressed to A.G. or V.V.

Mechanical Forces Matter in Health and Disease: From Cancer to Tissue Engineering

Viola Vogel and Michael P. Sheetz

9.1
Introduction: Mechanical Forces and Medical Indications

One of our earliest experiences showing that mechanical forces matter goes back to when we got our first blisters. Excessive friction causes a tear between the upper layer of the skin – the epidermis – and the layers beneath. When these skin layers – which in healthy skin are held together by cell–cell adhesion complexes – begin to separate, the resultant pocket fills with serum or blood. In some people, who have inherited skin diseases, the blistering occurs much more easily, and studies of point mutations that cause easy blistering have provided considerable insights into the underlying molecular mechanisms. Molecular defects can exist in different intracellular and extracellular proteins that are responsible for weakening the mechanical strength of cell–cell adhesions. The proteins implicated by genetic analysis include keratins, laminins, collagens and integrins [1–3]. Unfortunately, exactly how mutations in these proteins regulate the mechanical stability of the linkages that cells form with their environment remains unknown.

Mechanical forces acting on cells also affect our lives in many other, often unexpected, ways. Regular exercise, for example, not only strengthens our body tone but also offers protection against mortality by delaying the onset of various diseases. It is thought that physical training reduces the chance of chronic heart diseases, atherosclerosis and also type 2 diabetes [4]. But how can exercise have such a profound impact on so many diseases? Chronic low-grade systemic inflammation is a feature of these and many other chronic diseases that have been correlated with elevated levels of several cytokines [5–7]. By yet unknown mechanisms, it is suggested that regular exercise induces anti-inflammatory processes, thus suppressing the production of pro-inflammatory signaling proteins [5, 8].

Many more severe diseases for which we do not have cures also have a mechanical origin, or show abnormalities in cellular mechanoresponses. These range from cancer to cardiovascular disorders, from osteoporosis to other aging-related diseases. In the case of many cancers, the cells grow inappropriately and with the wrong mechanoresponse, which in turn destroys normal tissue mechanics and often also

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

tissue function [9–11]. While cardiovascular diseases have many forms, cardiac hypertrophy, plaque formation and heart repair are obvious cases where mechanosensory functions are important [12–14]. Abnormal mechanical forces can trigger an aberrant proliferation of endothelial and smooth muscle cells, as observed in the progression of vascular diseases such as atherosclerosis [15]. There is furthermore emerging evidence that immune synapse formation is a mechanically driven process [16]. Finally, damaged tissue is often repaired by new cells that differentiate from pluripotent cells to finally replace and regenerate the damaged regions. Successful healing includes re-establishing the proper mechanical tissue characteristics; even bioscaffolds that are used in reconstructive surgery heal best if they are mechanically exercised [14, 17]. Thus, from molecules to tissue, although the mechanical aspects are recognized as being critical, relatively little has yet been done to correlate mechanical effects with biochemical signal changes, and how these impact clinical outcomes.

There is, therefore, overwhelming evidence that physical and not just biochemical stimuli matter in tissue growth and repair in health and disease. But how do cells sense mechanical forces? A complete answer cannot yet be given as too few techniques have been available in the past to explore this question. However, the broad availability of nanoanalytical and nanomanipulation tools is beginning to have impact. This tool chest provides novel opportunities to decipher how physical and biochemical factors, in combination, can orchestrate the hierarchical control of cell and tissue functions (we will illustrate this point with some concrete examples later in the chapter). The diversity of biological forms in different organisms most likely belies a wide range of mechanosensing mechanisms that are specifically engineered to provide the desired morphology.

To summarize, based on the progress that has been made recently in the field of cell biomechanics, it is now clear that individual cells are dramatically affected in their functions, from growth to differentiation, by the mechanical properties of their environments and by externally applied forces (for reviews, see Refs [18–21]). But the question remains: How do cells sense mechanical forces, and how are mechanical stimuli translated at the nanoscale into biochemical signal changes that ultimately regulate cell function? A few examples are illustrated here of how physical junctions are formed between cells and their environment, how mechanical forces acting on molecules associated with junctions regulate their functional states, and what the downstream implications might be on cell signaling events. Considering the complexity of the puzzle, this chapter cannot provide a comprehensive review; rather, we will focus on describing a few selected molecular players involved in mechanochemical signal conversion, followed by a discussion of the associated signaling pathways and subsequent cellular responses, and then concluding on the role of physical stimuli in various diseases. Once the molecular pathways are identified, and the mechanisms deciphered by which force regulates diverse cell functions, the development of new drugs and therapies will surely emerge. In particular, it is expected that in the future, a number of diseases associated with altered mechanoresponses will be resolved more efficiently by treating the source of the problem, rather than the symptoms.

9.2
Force-Bearing Protein Networks Hold the Tissue Together

The search for proteins that are structurally altered if mechanically stretched, and which could thus serve as force sensors for cells, should start in junctions between cells and their environments. The focus should first be on the junctions that experience the highest tensile forces. The force-bearing elements in tissues are typically the cytoskeleton and extracellular matrix (ECM) fibers, and all the proteins that physically link the cell interior to the exterior. For different tissues, the major force-bearing elements can differ.

9.2.1
Cell–Cell Junctions

Some tissues such as epithelial and endothelial cell layers have barrier functions (Figure 9.1), where the majority of the force is born by the tight cell–cell junctions. These junctions couple the cell–cell adhesion molecules (cadherins) that hold the cells together to the cytoplasmic proteins that ultimately link cadherins to the actin, myosin and intermediate filaments in the cytoskeleton [22].

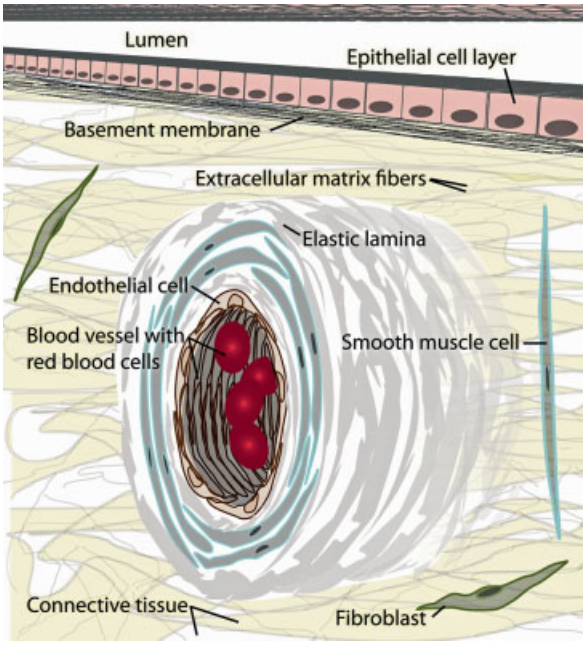

Figure 9.1 Schematic section through tissue, showing how layers of cells form a barrier that separates the connective tissue from the lumen of the lung or of the intestines (epithelial cells), or the blood vessels (endothelial cells). Within endothelial and epithelial cell layers, the cells are tightly connected to each other via cadherin junctions, while integrin junctions anchor cells to the basement membrane as well as to the extracellular matrix (ECM) of connective tissues.

Epithelial tissue lines both, the outside of the body (skin) and the cavities that are connected to the outside, such as the lungs and the gastrointestinal tract. Epithelial cells assume packing geometries in junctional networks that are characterized by different cell shapes, number of neighbor cells and contact areas. The development of specific packing geometries is tightly controlled [23].

Endothelial cells line the tight barrier between the circulating blood and the surrounding vessel wall. A synchronized migration of endothelial cells is required in order to grow blood vessels (the process of *angiogenesis*). When a new blood vessel is forming, for example in response to a lack of oxygen, the endothelial cells must maintain their cell–cell contacts, remain anchored to the basement membrane, and form curved continuous surfaces [24]; otherwise, the walls of the growing vessels would become leaky. Blood vessel formation is thus a tightly regulated process.

9.2.2 Cell–Matrix Junctions

In contrast to the tight cell–cell junctions, cells can also form junctions with surrounding extracellular fibers. The ECM, which is abundant in connective tissue, includes the interstitial matrix and basement membranes. The ECM provides structural support to the cells (Figure 9.1), in addition to performing many other important functions that regulate cell behavior. Cell–matrix contacts are formed by integrins; these molecules can link various ECM proteins, including fibronectin, vitronectin, laminins and collagens, via cytoplasmic adopter proteins to the cytoskeleton. During the formation or regeneration of tissue, major cell movements occur on or through the ECM, such that the cell–matrix junctions enable and facilitate integrin-mediated tissue growth, remodeling and repair processes. Integrins are also required for the assembly of the ECM (for reviews, see Refs [2]). The fibronectin matrix, the assembly of which is upregulated in embryogenesis and wound-healing processes, often serves as an early provisional matrix that is reinforced at later stages, for example, by collagen deposition [27]. Integrins thus mediate the regulatory functions of the ECM on cell migration, growth and differentiation. During wound healing, angiogenesis and tumor invasion, cells often change their expression profiles of fibronectin-binding integrins [28, 29]. Integrin–matrix interactions thus play central roles in regulating cell migration, invasion and extra- and intra-vasation (i.e. moving from the vasculature to the tissue, or *vice versa*), as well as in platelet interaction and wound healing [24, 29–36]. The functional roles of these interactions in health and disease will be discussed in much more detail below.

The forces acting on cell–cell or cell–matrix junctions can either be applied externally, or generated by the contractile cytoskeleton. Shear stresses due to the flow of blood, urine and of other body fluids impart forces on either the endothelial blood vessel linings, the linings of the epithelial urinary tract, as well as on bone cells, respectively, and are known to actively influence cell morphology, function and tissue remodeling (for reviews, see Refs [12, 37–41]). Lung expansion and contraction imposes great strain on lung tissue, and mechanical forces exerted on the lung epithelium are a major regulator of fetal lung development, as well as of the overall

pulmonary physiology [42]. Mechanical exercising of the lung also triggers the release of surfactants onto the epithelial surface [43]. Consequently, the levels of force generated and transmitted through cell–cell and cell–matrix junctions can change drastically with time, and between different organ tissues.

The forces that cells apply to their neighbors and matrices are furthermore dependent on the rigidity of their environment. Cell-generated tractile forces are lowest for soft tissues and increase with the rigidity of the organ. The brain is one of the softest tissues, whereas bone cells find themselves in one of the stiffest microenvironments of the body [18]. Yet, in all of these tissues the cells generate forces that provide the basis of active mechanosensing and mechanochemical signal conversion processes. The formation of force-bearing protein networks that connect the contractile cytoskeleton of cells with their surroundings is essential to prevent cell apoptosis of most normal cells.

What is missing is a mechanistic understanding of how the forces that are applied to cells are locally sensed and finally regulate a collective response of many cells to produce the proper tissue morphology and morphological transformations (Figure 9.2). Although it may be general for all tissues, in endothelia there is a

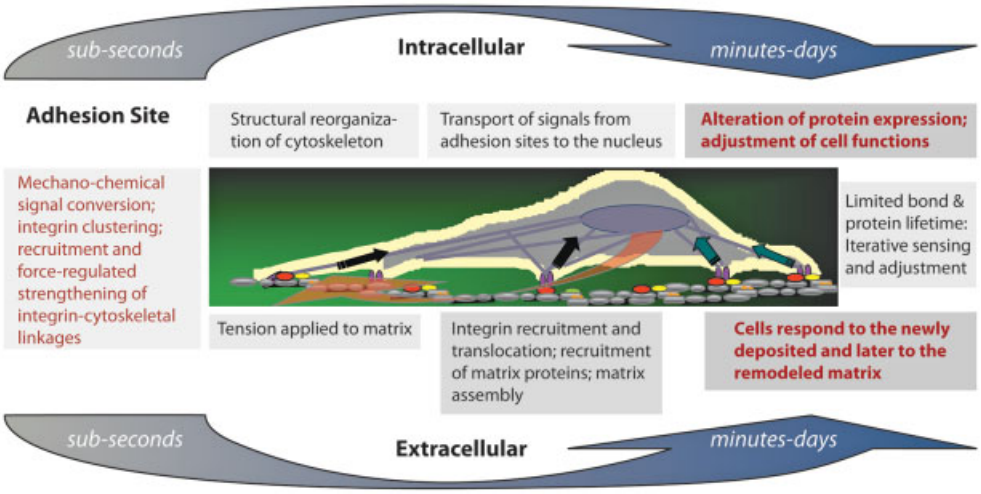

Figure 9.2 Sequential cellular processes of adhesion, mechanosensing and responses with the associated time scales. Initiated by cell adhesion, a cell responds to its environment by subsequent events that involve mechanosensing, reorganization of the cytoskeleton, adjustment of protein expression patterns and, in a secondary feedback loop, remodeling of the extracellular matrix. Initially, cells will sense the mechanical features of their environment, which will cause rapid motility and signaling responses. As the cell pulls on the environment, it will modify the extracellular matrix and create new signals, such as those originating from fibronectin stretching and unfolding. Intracellular signals will alter the expression pattern of the cell and, over time, the cellular forces and cell-generated matrices will change the cell shape. At any stage, extracellular signals, such as hormones or external mechanical stimuli, can cause acute changes that will set off a further round of cell and matrix modifications.

polarity and bending that must be controlled over many cell lengths. Studies of the development of fly wings and convergent extension in frogs have provided some important clues about mechanisms that can establish an axis in a tissue that would then result in axial contractions. In the fly wing, there are gradients of proteins that affect wing organization by influencing the physical properties [23, 44, 45], and some of those proteins are asymmetrically distributed in the hexagonal wing cells. In many tissues, however, the cells can move and change partners while they change tissue morphology in a stereotypical way, indicating that the multicellular coordination does not solely rely upon stationary protein complexes but rather is sensitive to intercellular forces or curvature.

To better understand the cellular nanomachinery by which cells sense mechanical stimuli, and how forces might synchronize cellular responses, it should be noted that the cellular nanomachinery is subjected both to exogenously applied forces and to cell-generated forces that the cells apply locally to the ECM and neighboring cells. As compressive forces on cells are primarily counterbalanced by the hydrostatic pressure of the cell volume that is contained by the plasma membrane, we will focus here entirely on the impact of tensile forces on proteins and protein networks and the subsequent changes in cell signaling.

When cells stretch their proteins, the protein structural changes may represent one important motif by which mechanical factors can be translated into biochemical signal changes in a variety of tissues and cell types (Figure 9.3). Many proteins are involved in force-bearing networks that connect the cell interior with the exterior, and they all are potential candidate proteins for mechanosensors (for reviews, see Refs [21, 26, 46–54]).

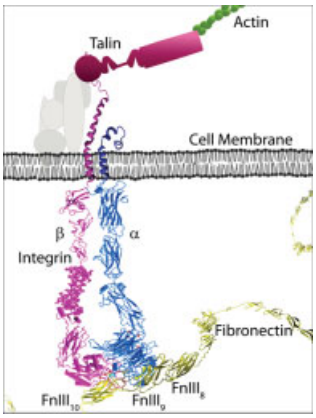

Figure 9.3 The integrin junction connecting the contractile actomyosin cytoskeleton with the extracellular matrix. In the schematic structure shown here, the integrin $\alpha_v\beta_3$ forms a complex with the extracellular matrix protein fibronectin via its cell binding peptide, RGD. In the cell interior, talin couples the cytoplasmic integrin tails to an actin filament. The stretching of talin leads to a reinforcement of the talin–actin linkage through the recruitment of further proteins that are subsequently involved in downstream cell signaling events. Particularly, the recruitment and stretching of p130cas regulates cell signaling events due to its phosphorylation, which is upregulated when stretched.

As cells actively bind, stretch and remodel their surroundings, they use a variety of specialized adhesion structures [25, 56], and their molecular composition will be discussed below (see Section 9.4). Once formed, the first contacts either mature rapidly or break (see Sections 9.5 and 9.7). These structures mechanically link the cell cytoskeleton and force-generating machinery within the cell to the ECM. Intracellular traction can thus generate large forces on the adhesive junctions – forces which are easily visualized as strain applied by cells to stretchable substrates [57–59], as discussed in Section 9.8. In addition, focal contacts are not passively resistant to force, but force actively induces focal contact strengthening through the recruitment of additional focal adhesion proteins, and finally initiates intracellular signaling events [60–64] (Section 9.6). Cell generated forces allow for rigidity sensing (Section 9.9), and causes matrix assembly and remodeling (Section 9.10). The matrix in turn regulates cell motility (Section 9.11). Ultimately, the structure and composition of the adhesions play regulatory roles in tissue formation and remodeling, and also control whether cells derail and evolve into cancer cells or cause other disease conditions (Section 9.12).

9.3
Nanotechnology has Opened a new Era in Protein Research

The advent of nanotech tools, particularly atomic force microscopy (AFM) and optical tweezers [65–67], followed by atomistic simulations of the force-induced unfolding pathways [68], were a major milestone in recognizing the unique mechanical properties of proteins and other biopolymers. The first force measurements on single multimodular proteins were performed on titin, and revealed that the modules cannot be deformed continuously but rather that they ruptured sequentially. But do cells take advantage of switching protein function mechanically? The first functional significance of unfolding proteins upon rapid tissue extension, for example when overstretching a muscle, was seen in them serving as mechanical shock absorbers.

Beyond muscle tissue, protein unfolding might be a much more common theme by which cells sense and transduce a broad range of mechanical forces into distinct sets of biochemical signals that ultimately regulate cellular processes, including adhesion, migration, proliferation, differentiation and apoptosis. The results of recent studies have shown that force-induced protein unfolding does indeed occur in cells and in their surrounding matrices [51–55, 69–71].

9.3.1
Mechanochemical Signal Conversion and Mechanotransduction

How, then, is force translated at the molecular level into biochemical signal changes (mechanochemical signal conversion) that have the potential to alter cellular behavior (mechanotransduction)? Despite all the experimental indications, only limited information is available on how mechanical forces alter the structure–function relationship of proteins and thus coregulate cell-signaling events. After a decade of new insights into single molecule mechanics, a new field is beginning to emerge:

How can the force-induced mechanical unfolding of proteins and other biomolecules switch their functions?

Through careful investigations of the conformational changes of isolated proteins that are mechanically stretched *in vitro*, and through computational simulations that have provided high-resolution structural information of the unfolding pathways of proteins, key design principles are beginning to emerge that describe how intracellular, extracellular and transmembrane proteins might sense mechanical forces and convert them into biochemical signal changes as discussed below (for reviews, see Refs [21, 26, 72, 73]). Stretch has been shown experimentally to expose cryptic phosphorylation sites, resulting in the onset of a major signaling cascade [51], to increase the reactivity of cysteines [52], and also to induce fibronectin fibrillogenesis (for a review, see Ref. [26]). Yeast two-hybrid measurements, crystallographic analyses and high-performance steered molecular dynamics (SMD) calculations all indicate that the exposure of amphipathic helices (e.g. talin, α-actinin) will cause binding to unstrained proteins (vinculin) or to the membrane, as detailed below. Thus, it seems that not a single mechanism can account for all the mechanical activities sensed by cells. Consequently, there is a need to develop a detailed understanding of the mechanical steps in each function of interest, in order to elucidate which of these mechanisms is responsible, or whether a new one must be formulated.

Design principles are also emerging by which such mechanosensory elements are integrated into structural motifs of various proteins, the conformations of which can be switched mechanically (for reviews, see Refs [26, 47, 74–79]). Multidomain proteins that are large and have many interaction sites constitute a major class of potentially force-transducing proteins [26, 80]. Both, matrix and cytoskeletal proteins fall into this class; for example, the cytoskeletal (titin, alpha actinin, filamin, etc.) and membrane skeletal molecules (spectrin, dystrophin, ankyrin) have series of between four and 100 repeat domains that can be stretched over a range of forces. An important feature here is that the repeats are often structurally homologous, but differ in their mechanical stability. Indeed, the differences in the mechanical stability of individual domains determines the time-dependent order in which their structure is altered by force, and consequently the sequence in which the molecular recognition sites are switched by force. Multimodularity thus provides for a mechanism not only for sensing but also for transducing a broad range of strains into a graded alteration of biochemical functionalities. Matrix molecules also have multiple domains and presumably exhibit similar characteristics. In both cases, the stretching of molecules can either reveal sites which can bind to and activate other proteins that could start a signaling cascade, or they can destroy recognition sites that are exposed only under equilibrium conditions [26].

9.3.2
Mechanical Forces and Structure–Function Relationships

As tensile force can stabilize proteins in otherwise short-lived structural intermediates, deciphering how the structure–function relationship of proteins is altered by

mechanical forces may well open totally new avenues in biotechnology, systems biology, pharmaceutics and medicine. In order to summarize our current understanding and future opportunities, we will first identify the critical molecules that are involved in linking the cell outside to the inside, and then discuss current knowledge on the effect of force on protein structure and associated force-regulated changes of protein function, and the downstream consequences. Cellular mechanotransduction systems can then transduce these primary physical signals into biochemical responses. More complex physical factors, such as matrix rigidity and the microscale and nanoscale textures of their environments, can be measured by cells through integrated force- and geometry-dependent transduction processes. Thus, it is important to differentiate between the primary sensory processes, the transduction processes and the downstream mechanoresponsive pathways that integrate multiple biochemical signals from sensing and transduction events over space and time, as shown schematically in Figure 9.2. It has also been postulated that cytoskeletal filaments can directly transmit stresses to distant cytoskeletal transduction sites [81, 82], which would involve additional distant mechanosensory and transductional components. Even in those cases, the forces would be focused on sites where primary transduction would occur.

Beyond the unfolding of stretched proteins, there are also other mechanisms in place by which force can alter many biochemical activities (see Box 9.1). The specific force-induced changes in motor protein velocity can lead to stalling their movement or buckling of their respective filaments [74, 83, 84]. Stretch-sensitive ion channels exist where the membrane pressure can regulate the ion current [20, 85–87]. Finally, even the lifetime of the strongest noncovalent bonds that last days under equilibrium, break down within seconds under the tensile force generated by a single kinesin [88, 89]. Not surprisingly, some adhesive bonds have evolved that are not weakened but are strengthened by force; these are also referred to as 'catch bonds' (as reviewed in Refs [90–93]). However, most of these force-regulated processes do not have an evident link to changes in cellular-level functions, or the links are currently not understood. For example, motor protein velocity is not generally linked to mechanically induced changes in cellular function, and neither are the ion currents that accompany the stretch activation of ion channels. Thus, it is unclear whether observed mechanochemical responses are products of the primary transduction of mechanical

Box 9.1
Activities altered by force-induced structural alterations:

- Motor protein velocity
- Stretch-sensitive ion channels (bacteria, hearing, touch)
- Catch bonds (bacterial and lymphocyte rolling and firm adhesion)
- Outside-in cell signaling through stretch-induced alterations of ECM binding sites
- Cytoskeletal protein stretching – phosphorylation by Tyr kinases of cryptic tyrosine repeat domains.

stimulation, or are just part of secondary downstream signaling cascades. Electrophysiological measurements reveal that distinct types of ion channels are mechanically activated [85, 87, 94, 95]; however, the biochemical consequences of channel opening are currently unclear – as are the relationships to downstream mechanoresponsive signaling pathways. Motor proteins will change the rate of movement and ATP hydrolysis in response to load (for a review, see Ref. [96]); however, the molecular pathway linking myosin mutations and cardiac hypertrophy is very unclear [13, 97]. Although catch bonds have a very clear role in enabling cells to adhere to surfaces under flow conditions, the link to subsequent infection or extravasation has not been determined. In any of the systems that employ specific mechanosensors, further investigations are required to determine whether – and/or how – these are functionally linked with specific steps in the cellular functions that are altered by mechanical force.

In the following section, which relates to mechanosensitive processes, we will discuss a few selected proteins that are part of the physical network through which force is transmitted bidirectionally from the cell exterior to the interior, and vice versa. Attention is focused here on the primary changes that have been shown to produce biochemical changes that lead in turn to general signals, although many more possible mechanisms clearly exist.

9.4
Making the Very First Contacts

9.4.1
Molecular Players of Cell–Extracellular Matrix Junctions

Cell motility is regulated by the polymerization of actin which drives the protrusion of the leading edge of the cell. Cells use lamellipodia and filopodia to 'feel' their environment and to identify locations to which they can adhere. Lamellipodia are flat, thin extensions of the cell edge that are supported by branched actin networks, while filopodia are finger-like extensions of the cell surface supported by parallel bundles of actin filaments [98]. Both are involved in sensing the environment through cycles of extension and retraction, in the attachment of particles for phagocytosis, in the anchorage of cells on a substratum, and in the response to chemoattractants or other guidance cues [99, 100]. When cells encounter a ligand bound to an extracellular surface, the ligand might bind to a transmembrane protein and ultimately induce coupling of the transmembrane protein to the cytoskeleton. *Integrins* are the key transmembrane proteins that mediate cell matrix interactions. Some integrins can recognize the tripeptide RGD, which is found for example in fibronectin, vitronectin and other matrix molecules, while other integrins bind specifically to collagens and laminins. Once a first bond (or set of bonds) is formed, a competition sets in between the time taken for a bond to break again and the cellular processes that can stabilize an early adhesion. The bond lifetime, however, is significantly decreased if a high tensile force is applied to it [101]. For example, without force, fibronectin can bind to $\alpha_5\beta_1$

integrin for minutes before releasing, whereas a force of approximately 40 pN will cause release in milliseconds [102, 103].

To illustrate some of the general concepts, rather than providing a detailed literature review, we will now briefly describe one of the force-bearing junctions that connects an ECM protein, via integrins, to the cytoskeleton (Figure 9.3).

9.4.1.1 Fibronectin

Fibronectin is a dimeric protein of more than 440 kDa (Figure 9.4), which is a pervasive component of the ECM during development and within healing wounds [24–26, 104, 105]. Fibronectin is composed of three types of repeating

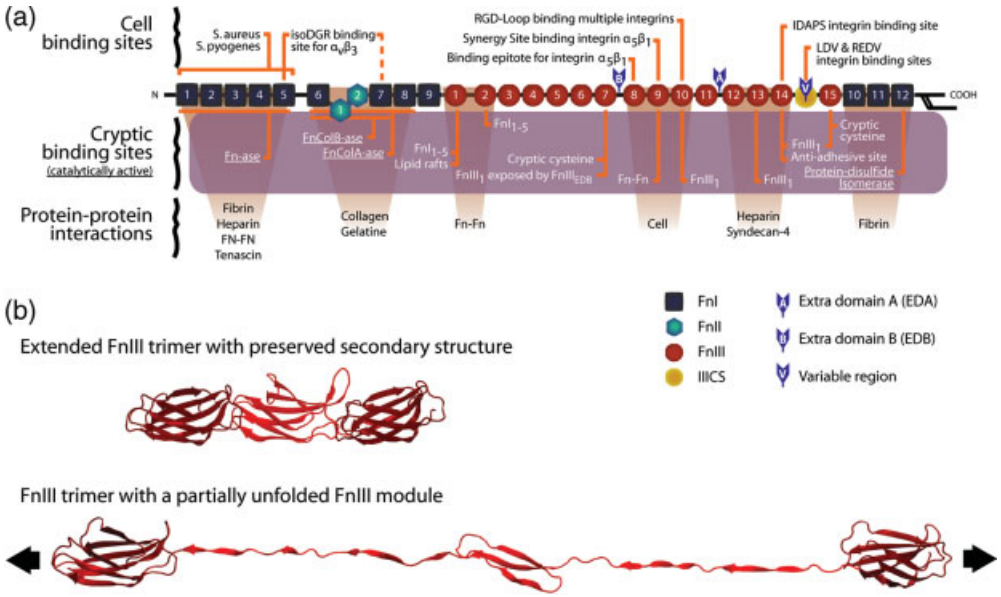

Figure 9.4 Fibronectin's major binding sites and an example of module unfolding under tensile stress [269]. Fibronectins are dimeric molecules composed of over 50 repeats of three different β-sheet modules (FnI, FnII and FnIII). (a) One monomer of as fibronectin found in blood plasma. Fibronectin produced by cells may contain additional alternatively spliced modules, as indicated. Fibronectins contain a large number of molecular recognition and cryptic sites, including the cell-binding site RGD, which is recognized by multiple integrins; the synergy site PHSRN, which is recognized by $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$ integrins; the sequence IDAPS at the FnIII13–14 junction in the heparin II binding region of fibronectin, which also supports $\alpha_4\beta_1$-dependent cell adhesion; and the NGR motif in FnI5, which is nonenzymatically converted to isoDGR and can then bind the $\alpha_v\beta_3$ integrin [249]. A similar, highly conserved NGR motif occurs in FnI7, but has not been extensively studied. The cryptic sites include various Fn self-assembly sites, the exposure of which is needed to induce fibronectin fibrillogenesis. Finally, there are two cryptic, nondisulfide-bonded cysteines on each monomer, in modules FnIII7 and FnIII15 which are utilized for site-specific labeling studies by fluorescence resonance energy transfer; (b) Tensile stress applied to Fn fibers causes changes in the quaternary, tertiary and secondary structure of Fn molecules. The figure shows three FnIII modules with intact secondary structure (upper) and with the partial unfolding of one module due to increased tensile stress (lower). (Reproduced with permission from Ref. [269].)

module, each of which has different structural folds, including 12 Fn type I domains, two Fn type II domains, and 15–17 Fn type III domains per Fn monomer. Both, FnI and FnII domains contain two intrachain disulfide bonds, while FnIII domains are not stabilized by disulfides and are hence more susceptible to force-dependent unfolding. Fibronectin displays a number of surface-exposed molecular recognition sites for cells, including integrin binding sites such as the RGD loop, PHSRN synergy site and LDV sequence, as well as binding sites for other ECM components, including collagen, heparin and fibrin. A number of cryptic binding sites and surface-exposed binding sites have been proposed to be exposed or deactivated, respectively, as a result of force-dependent conformational change (as reviewed in Ref. [26]). Interestingly, it is not only fibronectin that contains these modules; in fact, approximately 1% of all mammalian proteins contain FnIII domains that adopt a similar structural fold to the FnIII domains in fibronectin [80].

9.4.1.2 **Integrins**

Integrins – the major cell matrix adhesins – are transmembrane dimers composed of noncovalently bound α and β subunits which associate to form the extracellular, ligand-binding head, followed by two multi-domain 'legs', two single-pass transmembrane helices and two short cytoplasmic tails (Figure 9.5). Although integrins are not constitutively active, their activation is required to form a firm connection with RGD–ligands. Conformational alterations at the ligand binding site of the extracellular integrin head domains propagate all the way to the cytoplasmic integrin

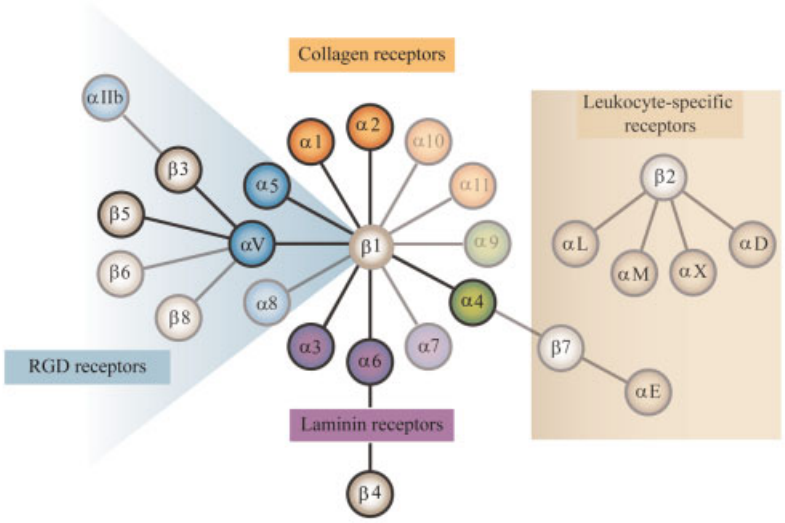

Figure 9.5 The integrin receptor family. Integrins are αβ heterodimers whereby the eight α subunits can assort with 18 β subunits to form 24 distinct integrins. Some integrins recognize the RGD-ligand (blue), while others bind to collagens (orange) or laminins (green), as further discussed in Refs [24, 31, 32]. (Adopted from Refs [31, 32].)

tails, and vice versa, by not-yet understood mechanisms (for reviews, see Refs [31, 32, 35, 106–108]). When a ligand binds to the integrin head, it becomes activated. The activation involves a conformational change that propagates through the extracellular integrin domains, finally forcing the crossed transmembrane helices of the integrin α- and β-subunits to separate, thereby opening up binding sites on their cytoplasmic tails. In contrast, if intracellular events force the crossed integrin tails to separate, then a conformational change will propagate to the extracellular headpiece, thereby priming the integrin head into the high-binding state, even in the absence of an RGD–ligand. This bidirectional conformational coupling between the outside and inside is remarkable, as the integrin molecule is approximately 28 nm long [35, 106–108]. Integrins, however, can also be constitutively activated, for example in the presence of Mn^{2+} ions, by point mutations and via activating monoclonal antibodies [48, 49, 109–111]. Integrin-mediated adhesion often occurs under tensile forces such as fluid flow or myosin-mediated contractions that cells exert to sample the rigidity of their surroundings. In fact, a dynamic mechanism has recently been proposed as to how mechanical forces can accelerate the activation of the RGD–integrin complex [112].

9.4.1.3 **Talin**

Talin is a cytoplasmic protein that can not only activate integrins [113], but also physically links integrins to the contractile cytoskeleton [114, 115], as depicted in Figure 9.6. The talin head has binding sites for integrin β-tails [116], PIP kinase

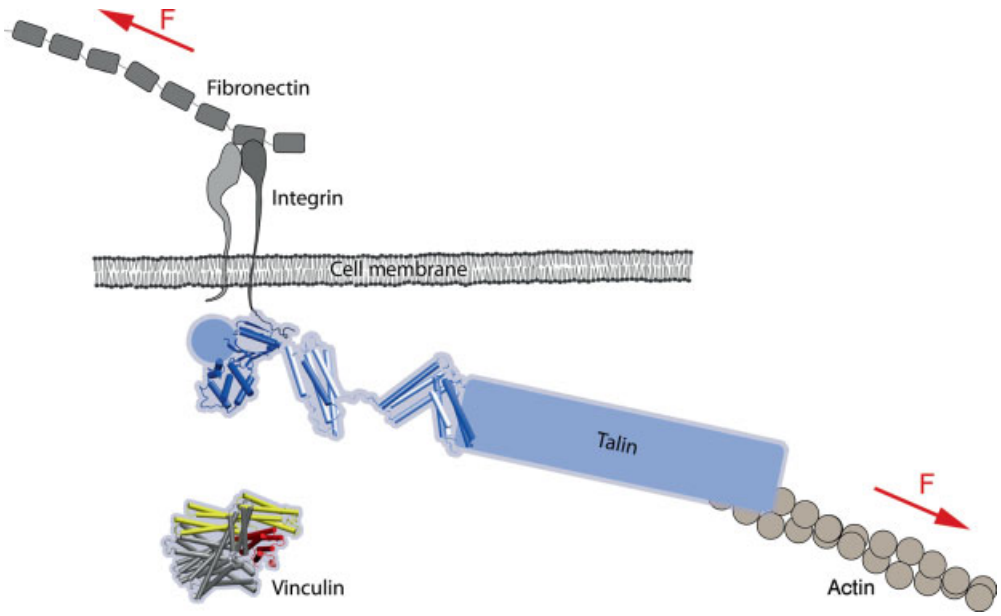

Figure 9.6 Schematic diagram showing how talin anchors integrins to an actin filament. The stretching and partially unfolding of talin (blue) exposes the vinculin binding helices.

γ [117], focal adhesion kinase (FAK) [118], layilin [118] and actin [119] (see also Figure 9.8 below). The 60 nm long talin rod is composed of bundles of amphipathic α-helices [120, 121]. The talin rod contains up to 11 vinculin binding sites (VBSs) [122], including five located within the helices H1–H12, residues 486–889. All of these five binding sites are buried inside helix bundles (native talin shows a considerably lower affinity for vinculin compared to peptide fragments isolated from talin). In addition to the VBSs, the talin rod has binding sites for actin [123] and for integrins [124].

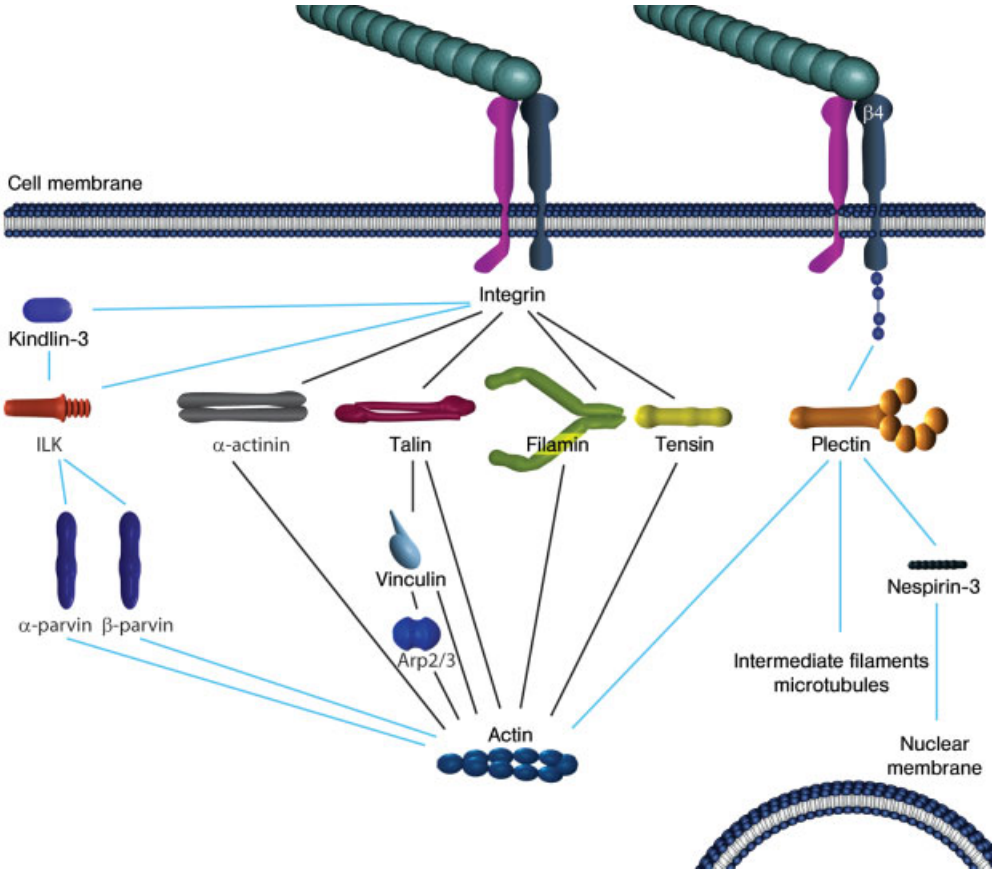

Figure 9.7 Scaffolding proteins that directly link various integrins to actin. Talin, tensin, plectin, filamin and α-actinin were reported to form a single bridge between the various integrins and actin [125–127, 334, 335]. Kindlin-3 was recently added to this list [128], while ILK binds via the formation of a ternary complex with PINCH and parvin [201]. The β_4 integrin has a highly unique intracellular tail which contains four FnIII modules. It can bind via plectin not only to actin, but also intermediate filaments and microtubules, as well as to the nuclear membrane via nesprin-3 [131, 319, 336].

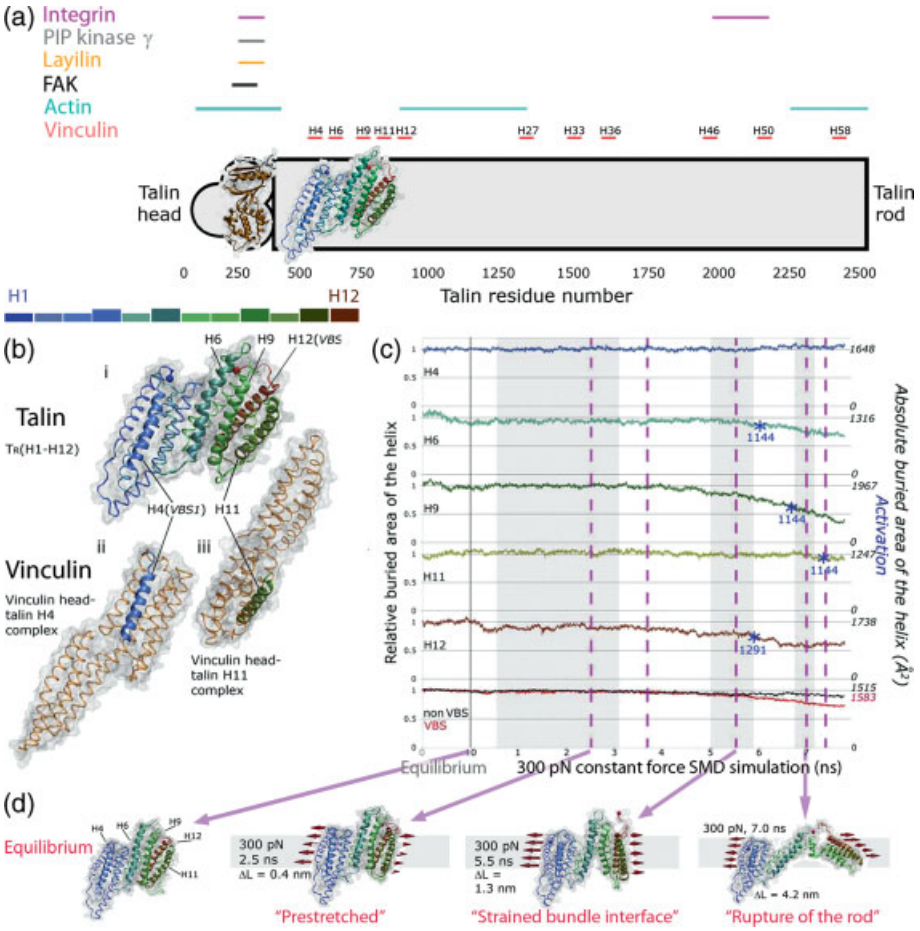

Figure 9.8 Structural mechanism showing how force alters the structure of the N-terminal talin rod comprising helices H1 to H12. (a) Structure of the α-helix bundle of talin, which includes five of the vinculin-binding helices (bold ribbons, namely H4, H6, H9, H11 and H12; (b) The vinculin-binding helices H4 (also referred to as (VBS1)) and H11 in complex with the vinculin head [149] (PDB 1SYQ). The molecular surface is presented in gray; (c) Steered molecular dynamic simulation of the force-induced exposure of the viculin-binding helices to water and the concomitant structural changes shown in (d). Change in the buried surface area of the viculin-binding helices during equilibration and when extended under 300 pN force. The buried areas are shown normalized to the average buried area obtained during equilibration. The respective points of 'activation' – that is, when the buried areas of helices H6, H9, H11 and H12 – in talin equal the experimentally found buried areas of isolated talin helices in complex with the vinculin head, are given as blue asterisks in (c). For H6 and H9, the buried area determined for the H11–vinculin complex is used as a reference because there is no available structure of those helices in complex with vinculin. The buried area of H4 was higher than the buried area of the VH–H4 complex for the whole simulation period. For more detailed information, see Ref. [150].

9.4.1.4 Other Scaffolding Proteins that Provide a Linkage Between Integrins and F-Actin

The physical linkage between integrins and actin can be formed independently by five cytosolic proteins (Figure 9.7). Talin, tensin, plectin, filamin and α-actinin were reported to form a single bridge between the various integrins and actin [125–127], and kindlin-3 was recently added to this list [128]. Talin binds the integrins beta 1, 2, 3 and 5, and weakly to 7 [113]. Tensin and filamin bind to integrins via the same NPxY motif that is recognized by talin [129, 130]. Plectin binds to the laminin-binding integrin β_4 [131], and α-actinin binds to β_1 and β_3 [132, 133]. In addition to integrins, there are ten other membrane-bound adhesion-receptor proteins which bind to either integrins and/or to other adhesion-plaque proteins. Recent data have suggested that certain receptors, for example syndecan [134], can synergize with integrins in adhesion formation [126, 127].

9.4.1.5 Cell Cytoskeleton

Cell–substrate and cell–cell forces are balanced by their interaction partners, except in the case of endothelial cells that experience high fluid flow rates. Thus, the cell cytoskeleton must transmit force across the cell to other sites. This has been observed in the studies of magnetic beads as the propagation of forces to distant substrate sites [135]. There are many ramifications of force propagation in that the cytoskeleton is constantly under tension. Although some of the contractile tension of the cytoskeleton is counterbalanced by the pressure in the cytoplasm, in most cases the intracellular pressure is relatively small (ca. 20 N per m^2) [136]. The majority of the tension is exerted on the actin cytoskeleton, however, we do not yet understand how the spatial distribution of force-bearing adhesions is determined.

9.5 Force-Upregulated Maturation of Early Cell–Matrix Adhesions

9.5.1 Protein Stretching Plays a Central Role

When the integrins latch on to their binding sites in the ECM, the cells apply force to these newly formed adhesion sites, ultimately promoting a rapid bond reinforcement through molecular recruitment. Such recruitment must occur within the lifetime of the initially labile adhesion bond. Key to the reinforcement is *integrin clustering*, followed or paralleled by protein recruitment [125, 137–139]. At least three integrins are needed to form an adhesion [140], and cells show a delayed spreading if the integrins are not sufficiently close [141]. The maturation of adhesion sites seems to involve the stretching and unfolding of proteins, since proteins that are part of such force-bearing linkages might change their structure and, therefore, also their function. One protein which is stretched early in the adhesion process is talin, which links integrins to the cytoskeleton. One of the many proteins that are recruited to newly formed adhesions is vinculin.

9.5.1.1 Vinculin is Recruited to Stretched Talin in a Force-dependent Manner

Upon cell adhesion, talin rapidly accumulates in focal contacts prior to vinculin recruitment [142]. In cases where integrin activation occurs without the application of force, and is thus not part of a force-bearing protein network [139], other adhesion proteins are not recruited. Indeed, the recruitment of vinculin to cell adhesion sites has been shown to be force-dependent [62–64] and to correlate with adhesion strengthening [143] and reduced focal adhesion turnover [144]. Even if not directly shown, this suggested that vinculin recruitment to focal adhesions is upregulated by force [62–64, 145, 146].

Since talin's vinculin-binding helices are buried in its native structure (Figure 9.8b), how might tensile mechanical forces activate them? Some key experimental observations [147–149], together with computational simulations [150] that provided high-resolution structural insights into the force-induced unfolding process of the N-terminal helix bundle of the talin rod which contains five of the vinculin binding sites, suggest the following model of activation.

As the vinculin head consisting of helix bundle is thermodynamically stabilized if it can recruit one additional helix, the vinculin head forms an auto-inhibited complex with its tail domain under equilibrium conditions [151] [PDB: 1TR2]. Instead of binding to itself, the head domain of vinculin can also be stabilized by recruiting other amphipathic helices. For example, isolated vinculin-binding helices of talin can activate vinculin by binding to the vinculin head if added to solution [147, 148, 152, 153]. The release of auto-inhibition is also needed to increase its affinity for actin [154].

Important for the force-activated mechanism is the fact that a larger hydrophobic surface area of talin's vinculin-binding helices can be shielded if they bury themselves in the talin rod rather than in complex with the vinculin head (Figure 9.8c). When mechanically strained, the tightly packed helix bundle of the talin rod breaks into fragments (Figure 9.8d), thereby gradually exposing the buried surface area of the vinculin-binding helices [150]. Once the buried surface area of the vinculin-binding helices in strained talin falls below that shielded if in complex with the vinculin head, the vinculin-binding helices can spontaneously switch their association, breaking off from the strained talin and associating with vinculin; this process is referred to as the *helix swap mechanism* [150]. It was suggested that a vinculin-binding helix would become 'activated' if the buried surface area in mechanically strained talin were to fall below the buried surface area if in complex with vinculin (Figure 9.8c). Vinculin recruitment to talin thus initially increases if talin is incorporated into a force-bearing network formed when a cell adheres to a surface or matrix fibrils [150]. However, as each of the vinculin binding helices is exposed to water at a different time point in the unfolding pathway of the talin (Figure 9.8c), talin can recruit vinculin in a graded response that is upregulated by force. As vinculin can bridge talin and actin, it may reinforce the talin–actin linkage that has been shown previously to be a rather weak bond, breaking at a force of 2 pN [115].

The mechanism described here might not be unique to the talin–vinculin bond, but may be more widespread among other intracellular proteins composed of α-helical bundles. First, when a force breaks away an amphipathic helix from a

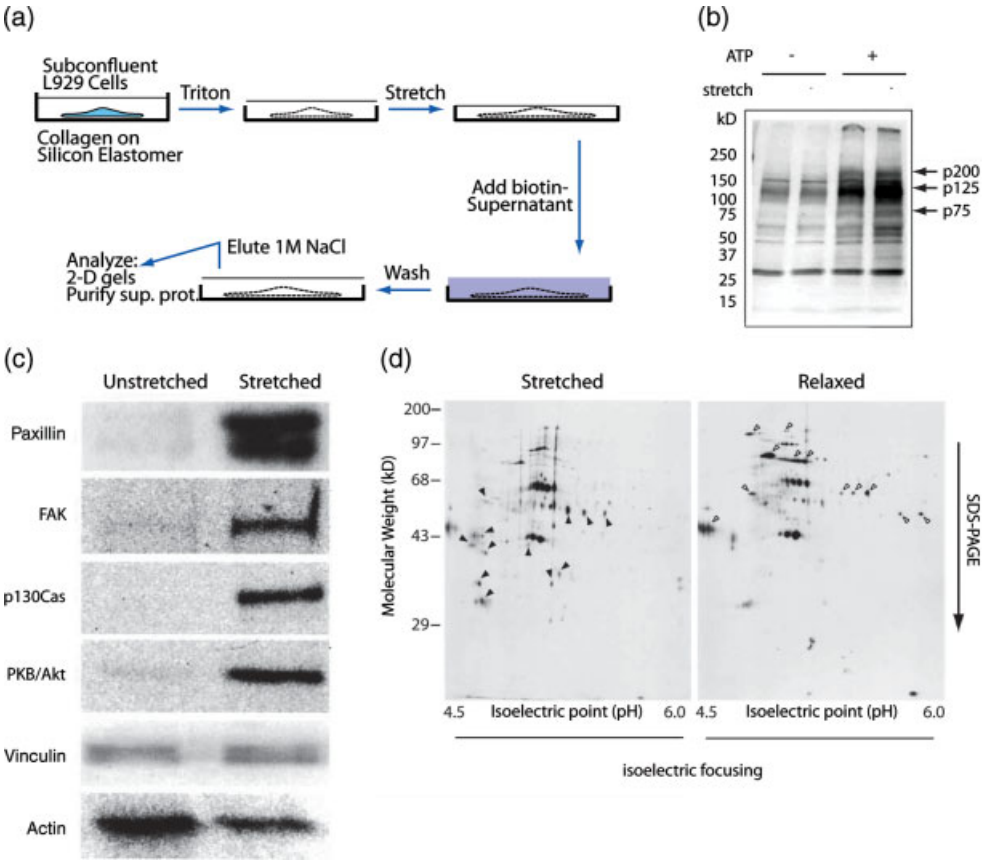
larger bundle, it might be stabilized by insertion into either the hydrophilic pockets of other proteins or even into the lipid bilayer [148]. Alternatively, other proteins that form helix bundles might also bind vinculin in a force-regulated manner. For example, α-actinin also has a vinculin-binding helix that can form a similar structural complex with vinculin [152, 153, 155, 156]. Similarly to talin, the VBS in α-actinin is buried in the native structure. Identifying the repertoire of mechanisms by which forces can upregulate adhesive interactions has led to the recent discovery of catch bonds, where a receptor–ligand interaction is enhanced when tensile mechanical force is applied between a receptor and its ligand (for reviews, see Refs [90, 93]). In contrast, the force-activated helix-swapping mechanism proposed here requires that the force is applied to just one of the binding partners, thereby activating bond formation with a free ligand. Also in contrast to catch bonds, the ligand need not necessarily form part of the force-bearing protein network at the time the switch is initiated. Thus, while force-induced helix swapping primarily upregulates the bond-formation rate, the catch bond mechanism primarily extends the lifetime of an already existing complex under tension.

9.6
Cell Signaling by Force-Upregulated Phosphorylation of Stretched Proteins

9.6.1
Phosphorylation is Central to Regulating Cell Phenotypes

While bond reinforcement is crucial for the cell to develop a stable adhesion site, the subsequent transformation of mechanical stimuli into biochemical signals is needed to alter cell behavior. But, which molecules act as the major mechanochemical signal converters? Although any experimental demonstration of the stretch-dependence of binding to the cytoskeleton had long been missing, there has always been some concern that the opening of stretch-activated ion channels was the cause of mechanosensation. By using matrix-attached, detergent-extracted cell cytoskeletons, it could

Figure 9.9 Stretch of cytoskeletons activates adhesion protein binding and tyrosine phosphorylation. (a) Diagram of protocol for stretch-dependent binding of cytoplasmic proteins to Triton X-100-insoluble cytoskeletons. L-929 cells were cultured on a collagen-coated silicone substrate, and cytoskeletons prepared by treating with 0.25% Triton X-100/ISO buffer for 2 min. Triton X-100-insoluble cytoskeletons were either left unstretched or stretched (or relaxed from prestretch) with ISO after washing three times. The ISO buffer was replaced with the cytoplasmic lysate solution, incubated for 2 min at room temperature, and washed four times with ISO (b) Tyrosine phosphorylation of many proteins increases upon cytoskeleton stretch. Detergent-extracted cell cytoskeletons showed dramatic increases in phosphotyrosine levels in many different proteins upon stretch. Because soluble kinases have been extracted, it is believed that much of the increased phosphorylation is due to stretch of substrate proteins, such as p130Cas. Thus, it appears that there are many additional proteins that could be involved in sensing stretch of cytoskeletally attached components. (Reproduced from Ref. [160]); (c) Focal contact proteins bind preferentially to stretched cytoskeletons. Western blots of focal contact proteins bound



to unstretched and stretched cytoskeletons. L-929 cytoplasmic proteins tagged with a photocleavable biotin (NHS-PC-LC-biotin) were added to Triton X-100-insoluble cytoskeletons of L-929 cells on a stretchable silicone dish [158], and cytoskeletons were stretched or left unstretched (see Figure 9.1). After washing, the bound cytoplasmic proteins were eluted with 1 ml 1 *M* NaCl in HYPO buffer, precipitated with avidin beads (immobilized neutravidin; Pierce Chemical Co.) after sevenfold dilution with HYPO buffer, and released from the bead complex by irradiation with 302 nm UV light (10 min). After photocleavage, proteins were eluted with 120 µl HYPO buffer, and 40 µl of the sample was subjected to 10% SDS–PAGE followed by immunoblotting with antibodies to paxillin, FAK, p130Cas, PKB/Akt (Transduction Laboratories), vinculin (Upstate Biotechnology) or actin (Santa Cruz Biotechnology). Scale bar = 10 µm; (d) 2-D gels of biotinylated proteins that were bound to stretched or relaxed cytoskeletons. The complex of the cytoskeleton with the biotinylated cytoplasmic proteins was solubilized with 1 ml of rehydration buffer (8 *M* urea, 2% CHAPS, 20 m*M* DTT, 0.5% IPG buffer) for isoelectric focusing (the first dimension of 2-D gel electrophoresis). Immobiline dry strip (pH 4–7; Amersham Pharmacia Biotech) was rehydrated with 350 µl of each sample and subjected to isoelectric focusing followed by SDS–PAGE. Biotinylated cytoplasmic proteins in 2-D gels were visualized with affinity blotting using horseradish peroxidase-conjugated streptavidin. Arrowheads mark the spots that were found specifically in Stretched or Relaxed samples. (Reproduced from Ref. [71].)

be shown that different sets of cytoplasmic proteins would bind to cytoskeletons, depending on the extension status (relaxed or stretched) of the cytoskeletons (Figure 9.9), and that binding of the focal adhesion proteins, paxillin, FAK and p130Cas to the cytoskeletons was increased by cytoskeleton stretching [71]. Any increased binding of the cytoplasmic proteins to stretched cytoskeletons would most likely result from the exposure of cryptic binding sites in the cytoskeleton. Whilst it was shown that the binding of another focal adhesion protein – vinculin – remained unchanged in L-929 cells on collagen [71], the force-dependent assembly of vinculin at fibronectin adhesion sites has been reported in other cells [58, 63]. Any specificity derived from the cell type and the substrate to which the cells adhere (including the ECM) appears to account for this discrepancy. In particular, there were no changes in the binding of vinculin to collagen adhesions in intact L-929 cells upon stretching. Subsequent analyses of the range of proteins that were bound to stretched cytoskeletons indicated that both heat-shock proteins and normal focal adhesion proteins would bind to cytoskeletons upon stretching. Both, heat-shock and adhesion stress signals could result from stretch, although the primary signal in the cellular environment is not clear.

9.6.1.1 Stretch-Dependent Binding of Some Cytoplasmic Proteins to Cytoskeletons

Stretch-specific binding studies (Figure 9.9d) indicate that some cytoplasmic proteins will be released from cytoskeletons upon stretching. For example, the binding of actin in a cytoplasmic extract to cytoskeletons was decreased upon cytoskeleton stretching [71]. It is likely that the increase in actin binding to triton (Triton-X-treated) cytoskeletons upon relaxation from a prestressed state is the result of an increase in actin filament assembly (Figure 9.9c), since in intact cells there is an increase in assembly upon relaxation – in that the cell edge becomes very active when a prestretched substrate is relaxed [157]. This indicates that some of the cellular enzyme pathways can be mechanically activated by relaxation, and that some of the binding to the cytoskeletons could result from the activation of enzyme pathways. In addition, cell relaxation-dependent signal activation was observed for Ras [158]. Alternatively, relaxation could enable the refolding of cytoskeletal proteins so that new binding sites would be formed. The binding of cytoplasmic proteins to cytoskeletons could then occur through the relaxation and refolding of cytoskeletal elements. In any case, the cyclic stretching and relaxation of cytoskeletons could play a significant role in controlling the local binding and release of cytoplasmic proteins to the cytoskeletons (Figure 9.9d). The cytoskeleton could thus act as a reservoir such that the mechanical strain would regulate the relative local concentrations of free proteins. This should have an additional impact on biochemical mechanotransduction processes.

Another class of proteins are the *scaffolding proteins* (p130Cas and other candidates that increase in phosphorylation upon cell stretching). These are able to associate with multiple cytoskeletal or signaling complexes through their N- and C-terminal ends, and have multiple phosphorylation sites in a central region (Figure 9.10). The scaffolding proteins appear to have more complex signaling roles, since both of their binding partners and the degree of stretching can change in response to hormone or

other signaling pathways. The phosphorylation of Cas requires both an active Src or Abl family kinase, as well as mechanical unfolding of Cas. The phosphotyrosine sites recruit other signaling molecules such as Crk that initiate signaling cascades. The primary transduction event is complicated, however, because the kinase activation step may occur through a force-activated pathway such as a receptor-like protein tyrosine phosphatase or through a hormone receptor. Consequently, primary and secondary force-sensing distinctions can become blurred and involve extrapolation from only a couple of incomplete examples (these are mentioned here only to stimulate further thought on these important mechanotransduction pathways).

9.6.1.2 **Tyrosine Phosphorylation as a General Mechanism of Force Sensing**

The reversible phosphorylation of intracellular proteins catalyzed by a multitude of protein kinases and phosphatases is central to cell signaling. The recently described phenomenon of substrate priming or stretch-activation of a tyrosine kinase substrate appears to be a major mechanism of force transduction [51]. Anti-phosphotyrosine immunostaining of individual fibroblasts has revealed that tyrosine-phosphorylated proteins are predominantly located at focal adhesions [159–161], where cell-generated forces are concentrated. Furthermore, an adhesion- or stretch-dependent enhancement of tyrosine phosphorylation was observed in many tyrosine phosphorylation sites in T cells [162], fibroblasts (Figure 9.9b) [160, 161] and epithelial cells (Y. Sawada, unpublished observations). In addition, receptor tyrosine kinases have been reported to be tyrosine phosphorylated (i.e. activated) by mechanical stimulation in a ligand-independent manner [163, 164]. These findings indicate that tyrosine phosphorylation plays a general role in adhesion and force-sensing [126, 127]. Due to their hydrophobic character, phosphorylatable tyrosines are typically 'buried' by intramolecular interactions under equilibrium conditions. When such proteins are subjected to stress, however, the buried tyrosines may be exposed, thus enabling them to become phosphorylated. Tyrosine-phosphorylatable proteins also very often carry more than one tyrosine that can be phosphorylated, as does Cas. Multiple repeats of structurally homologous domains are characteristic of many proteins with mechanical functions [26]. Progressive stretching of the molecule can then affect one domain after the other, thus gradually upregulating the response [51]. These observations indicate that substrate priming is a common mechanism for the regulation of tyrosine phosphorylation. As tyrosine phosphorylation appears to be generally involved in force-response (as mentioned above), substrate priming is most likely a universal mechanism of force sensing.

With regards to the force available for stretching molecules in the adhesion complex, the force exerted on one integrin molecule in the adhesion site is estimated to be on the order of 1 pN [58]; this is lower than the forces that allow refolding of many proteins in atomic force microscopy (AFM) experiments [165]. Consistently, the stretching of CasSD (p130Cas substrate domain, the central portion that contains 15 YXXP motifs and is phosphorylated upon stretch) by using AFM gave the appearance of stretching a random coil without any distinct barriers to unfolding (Y. Sawada, J.M. Fernandez and M.P. Sheetz, unpublished observations), suggesting that the Cas substrate domain could be extended by forces below

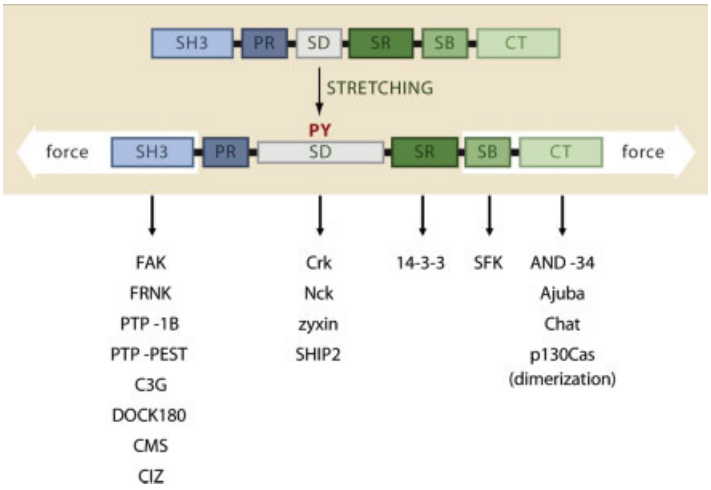


Figure 9.10 Mechanotransduction at focal adhesions through the stretch-dependent phosphorylation of p130cas. The domain structure of the p130CAS molecule is shown (top), before and after stretching. The domains include (from left to right): Src homology 3 (SH3) domain; the proline-rich region (PR); the substrate domain (SD); the serine-rich region (SR), the Src-binding domain (SB); and the C-terminal region. The extension of the substrate domain following stretching and subsequent tyrosine phosphorylation (PY) are indicated. p130Cas and its molecular binding partners are depicted (bottom), including adaptor ('scaffolding') molecules, tyrosine kinases, a serine/threonine kinase, GEFs and tyrosine phosphatases. (Reproduced with permission from Ref. [337].)

the detection limit of AFM (~10 pN). Further, it was observed that CasSD was significantly phosphorylated by Src-kinase with longer incubation times *in vitro*, and that the stretch-dependent enhancement of *in vitro* CasSD-phosphorylation (i.e. fold phosphorylation of stretched/unstretched) is attenuated in longer incubations with Src-kinase (Y. Sawada and M.P. Sheetz, unpublished observations). This indicated that thermal fluctuations of the Cas substrate domain were sufficient to expose tyrosine phosphorylation sites buried in the domain, and raises the possibility that proteins that bind to the native substrate domain like zyxin could stabilize it and inhibit phosphorylation. Thus, the unfolding of p130Cas and its phosphorylation appear to occur at very low applied forces, although the phosphatases that bind to p130Cas could rapidly remove the phosphates.

Finally, tyrosine phosphorylation of the adaptor protein, paxillin, functions as a major switch, regulating the adhesive phenotype of cells [126, 127]. Paxillin, which has binding sites for vinculin and p130cas, can be phosphorylated by tyrosine kinases (including FAK and ABL) and dephosphorylated by the phosphatase Shp2 [126, 127]. Whilst phosphorylated paxillin enhanced lamellipodial protrusions, nonphosphorylated paxillin is essential for fibrillar adhesion formation and for fibronectin fibrillogenesis. The modulation of tyrosine phosphorylation of paxillin thus regulates both the assembly and turnover of adhesion sites. Whilst the method by which force regulates paxillin recruitment and phosphorylation remains unknown,

enzymatic activities appeared to be unnecessary for the reversible, stretch-dependent binding of paxillin as the removal of ATP and inhibition of phosphatases did not block paxillin (Figure 9.9c) binding and release from stretched and relaxed cytoskeletons, respectively [71].

Other intracellular proteins have also been shown to be structurally altered by tensile forces. Some proteins (including nonmuscle myosin IIA, vimentin and spectrin), when mechanically stretched within a living cell [52], expose free cysteines, the functional significance of which is not yet known. Yet, key to all of these mechanisms – from force-induced exposure of otherwise buried residues to helix swapping – is that force induces a structural alteration that allows another protein to bind only if the binding partner is mechanically strained.

9.7
Dynamic Interplay between the Assembly and Disassembly of Adhesion Sites

9.7.1
Molecular Players of the Adhesome

It is essential that cells are able constantly to sense their environment and respond to alterations in mechanical parameters. Thus, while one set of cues and molecular players is required that will promote and drive the assembly of an adhesion complex, another set is responsible for regulating their disassembly. Cell adhesion to the ECM triggers the formation of integrin-mediated contacts and ultimately the reorganization of the actin cytoskeleton. The formation of matrix adhesions is a hierarchical process, consisting of several sequential molecular events during maturation (for reviews, see Refs [24, 125, 166–170]). The very first contacts are formed by matrix-specific integrins, and this leads to the immediate recruitment of talin and of phosphorylated paxilin [171]. This event of building the first integrin connection with actin filaments is followed by FAK activation and the force-sensitive recruitment of vinculin [58, 172–174] and the recruitment of α-actinin (α-actinin crosslinks actin filaments). Vinculin has binding sites for vasodilator-stimulated phosphoprotein (VASP) [175] and FAK [176], both of which coregulate actin assembly (via recruitment of profilin/G-actin complex to talin as well as Arp2/3, respectively). pp125FAK also functions as a key regulator of fibronectin receptor-stimulated cell migration events through the recruitment of both SH2 and SH3 domain-containing signaling proteins to sites of integrin receptor clustering [177, 178]. While the adhesions mature further, zyxin and tensin are recruited [167], and zyxin upregulates actin polymerization [179, 180]. The transition from paxillin-rich focal complexes to definitive, zyxin-containing focal adhesions, takes place only after the leading edge stops advancing or retracts [181]. A decrease in cellular traction forces on focal adhesions then leads to an increased off-rate for zyxin [182].

Tensin plays a central role in fibronectin fibrillogenesis which is upregulated by enhanced cell contractility [183]. As with talin, tensin binds to the NPxY

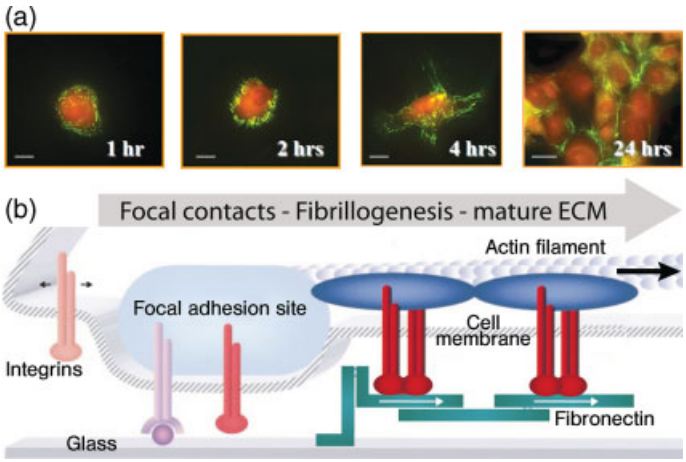

Figure 9.11 Sequential steps in the formation of fibrillar adhesions and fibronectin fibrillogenesis. (a) Time sequence of fibronectin fibril assembly for fibroblasts seeded on fibronectin-coated glass surfaces. (From Ref. [69].) The cells harvested photolabeled plasma fibronectin from solution and incorporated it into newly formed fibers (green). The autofluorescence of the cell bodies is shown in red; (b) Proposed mechanism by which fibronectin-bound integrins translocate out of the focal adhesion sites to form elongated fibrillar adhesions. This process is thought to initiate fibronectin fibrillogenesis. (Adopted from Ref. [167]).

motif of the cytoplasmic β-integrin tails. Fibronectin fibrillogenesis sets in when fibronectin-bound α5β1 integrins coupled via tensin to actin filaments are pulled out of the focal adhesions to form fibrillar adhesions [184] (Figure 9.11). $\alpha_5\beta_1$ integrins translocate along actin fibers, while the other integrins stay back in the adhesion contacts. Fibrillar adhesions translocate centripetally at a mean rate of 18 μm per hour in an actomyosin-dependent manner [56], and evidence is mounting that the stretching of fibronectin induces its polymerization into fibers [69, 70, 185–187]. While phosphorylation of the NPxY tyrosine disrupts talin binding, it has a negligible effect on tensin binding. This suggests that the tyrosine phosphorylation of integrins, which occurs during the maturation of focal adhesions, could act as a switch to promote the formation of fibrillar adhesions [130]. Tyrosine phosphorylation of paxillin regulates both the assembly and turnover of adhesion sites. Moreover, phosphorylated paxillin enhanced lamellipodial protrusions, whereas nonphosphorylated paxillin was essential for fibrillar adhesion formation and for fibronectin fibrillogenesis [126, 127].

The question is, therefore, how are all these processes linked to cell contractility? Rho family GTPases, the major substrates of which are myosin light chain and myosin phosphatase, upregulate myosin activity [15, 188–191], and thus play central roles in integrin signaling [192]. RhoA in particular has been linked with upregulated fibronectin fibrillogenesis [193, 194]. In this context, it is important to note that it is not the intracellular but the extracellular domain of integrin β_1 that controls RhoA activity [194, 195], potentially via its colocalization with syndecan-4 [134].

The formation of such adhesions depends on actomyosin contractility, matrix rigidity [58, 62, 196–198], and the spacing of the integrin ligands on the surface to which the cell adheres [140, 141]. Rigidity sensing is mediated through a mechanism which is further discussed below, where the receptor-like tyrosine phosphatase alpha (RPTPalpha) colocalizes with α_v-integrins at the leading edge of the cell and regulates the activation of Src family kinases [173, 174]. Src family kinases, particularly Fyn, phosphorylate p130Cas in a force-dependent manner [197]; thus, actomyosin contractility enables both fibronectin fibrillogenesis and rigidity sensing. Fibronectin fibrillogenesis, however, occurs via $\alpha_5\beta_1$ integrins, while rigidity sensing is mediated by α_v-integrins.

Finally, microfilament and microtubule networks are significantly reorganized by cyclic stretching, and the cytoskeletal reorganization plays an important role in stretch-induced gene transfer and expression [199]. Integrin-linked kinase (ILK) activity thereby plays an important role in Rac- and Cdc42-mediated actin cytoskeleton reorganization and gene transcription [200, 201]. ILK is a component in focal adhesions that interacts with the cytoplasmic domains of integrins, recruits adaptor proteins that link integrins to the actin cytoskeleton, and phosphorylates the serine/threonine kinases PKB/Akt and GSK-3beta [202]. Finally, the disassembly of adhesion sites is critical, especially at the rear of the cell to enable its forward locomotion [166, 203–205].

The fine-tuning of cell adhesion and detachment, however, requires far more proteins than the few discussed so far. The 'integrin adhesome' consists of a complex network of 156 so-far identified components that are linked in modular complexes and are modified by 690 interactions that have been identified to date [126, 127]. Three major protein families comprise the physical framework of the adhesome, the membrane-anchored adhesion receptors, adaptor or scaffolding proteins, and actin regulators (Figure 9.12). The remaining families consist of mostly enzymes that have roles in regulating the assembly and turnover of the adhesion sites, as well as signaling from the adhesion site into the cell [126, 127]. There are two proteolytic systems associated with the adhesome (ubiquitin E3 ligase protein (Cbl) and calpain), each acting on multiple substrates. Cbl is regulated by tyrosine kinases, and calpain by serine/threonine kinases [126, 127]. Calpain also degrades two tyrosine phosphatases – one of these, shp1, is a regulator of Cbl. Cbl is activated by tyrosine phosphorylation, whilst through its E3-ligase activity it downregulates tyrosine kinase signaling and promotes the proteasomal degradation of integrins [126, 127]. This regulation of binding interactions is very important. Anchoring of adhesion components through multiple links might suggest a robust scaffold structure. In contrast, it must be a highly dynamic, regulated structure that needs to respond to external stimuli and to support morphogenesis and cell migration [126, 127].

Several functional 'subnets' are involved in switching on or off many of the molecular interactions within the network, consequently affecting cell adhesion, migration and cytoskeletal organization. An examination of the adhesome network motifs reveals a relatively small number of key motifs, dominated by three-component complexes in which a scaffolding molecule recruits both a signaling molecule and its downstream target [126, 127]. The authors estimate that more than half of

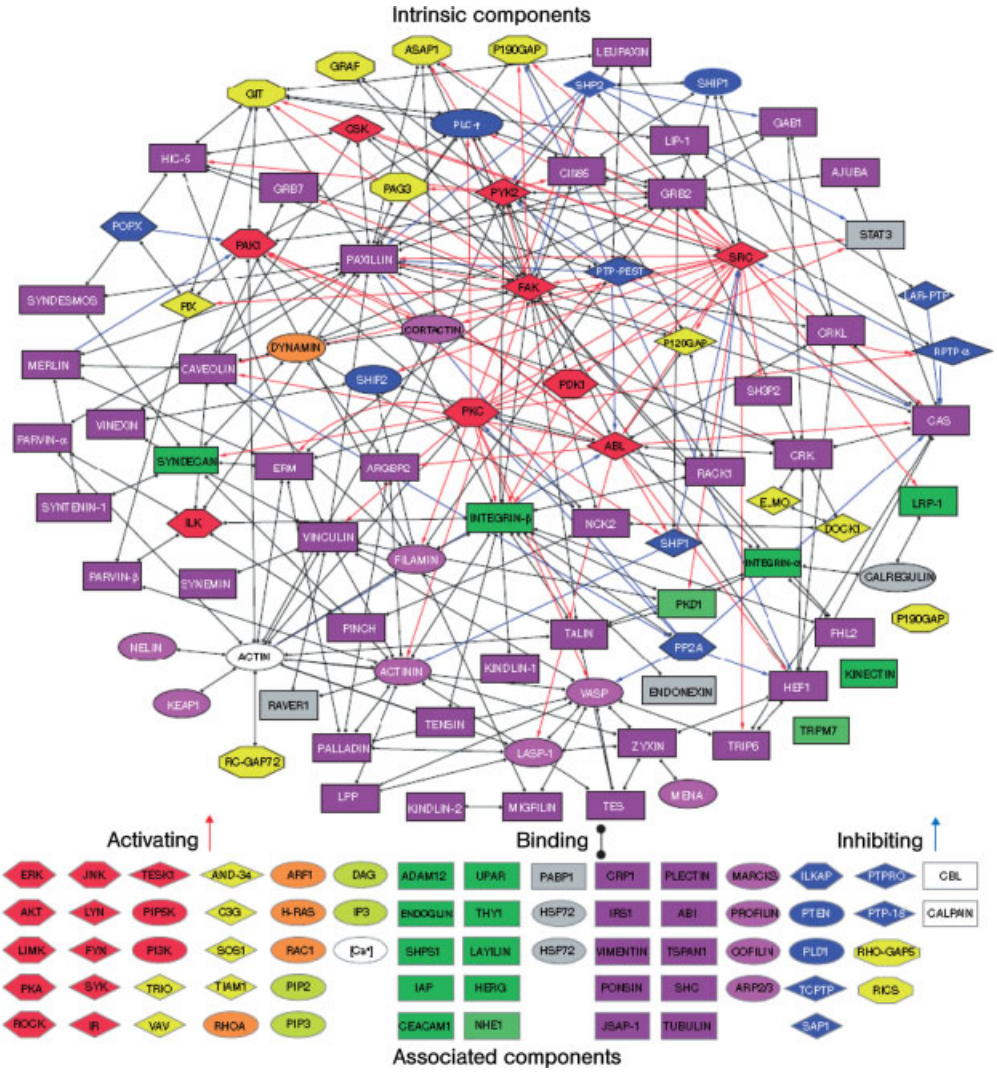

Figure 9.12 Interactions between all intrinsic components of the adhesome and a grouped list of the associated components [126, 127]. Black lines with full circles at their ends denote nondirectional binding interactions; blue arrows represent directional inhibition (e.g. dephosphorylation, G-protein inactivation, proteolysis); red arrows represent directional activation (e.g. phosphorylation, G-protein activation) interactions. The nodes are shape- and color-coded according to the function of the proteins. Intrinsic components are surrounded by a black frame and associated components by a gray frame. the links interconnecting different adhesome components can be switched on or off by signaling elements. There are several types of regulated interaction switches, including conformational switches, GTPase switches, lipid switches, proteolytic switches and PY–SH2 switches [126, 127].

9.8
Forces that Cells Apply to Mature Cell–Matrix and Cell–Cell Junctions

9.8.1
Insights Obtained from Micro- and Nanofabricated Tools

Major experimental tools were developed to probe, with high spatial and temporal resolution, the forces that cells apply to two-dimensional (2-D) surfaces [58, 59, 206–212]. For example, the deflection of microfabricated pillars makes it possible to observe the complete spatial pattern of actin–myosin-driven traction forces applied to the substrate, as shown in Figure 9.13 [59]. This and other tools enable research groups to determine how the linkage between the ECM and the cytoskeleton is stabilized by mechanical force [62, 115, 173, 174, 213–221].

If the force that cells apply to a newly formed junction is too high, the junction will break instantaneously. Thus, the generation and sensing of force is critical for the correct formation of the organism and functions of its tissues. First, however, we should define what is meant by the basic physical parameters of stress and strain in the cellular context, since the anchoring of a cell to an environment is critical for its survival. If firmly anchored to the ECM, the integrins couple the matrix to the contractile machinery of the cell; in this way the major cellular forces are generated by myosin II filaments pulling on actin in early spreading cells [222]. While the level of force orthogonal to the membrane plane that can be supported by the fluid lipid

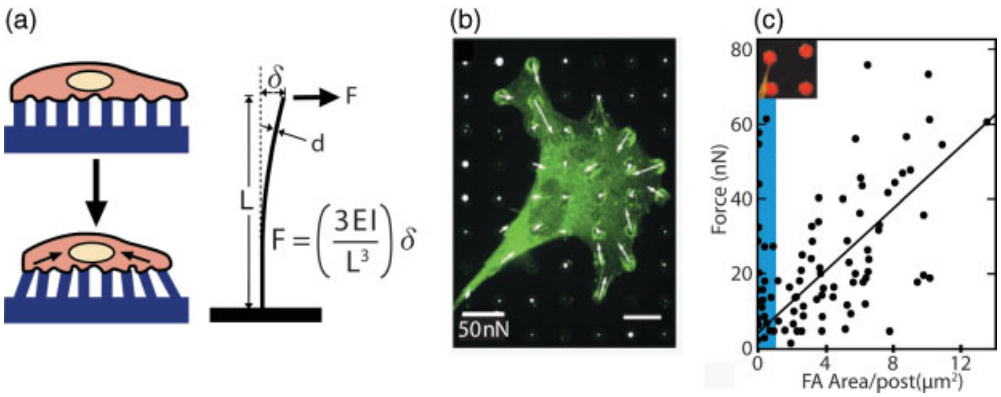

Figure 9.13 Measurement of contractile forces that cells apply to substrates [59]. (a) Cell culture on arrays of polydimethylsiloxane (PDMS) posts covered with fibronectin (as produced by microcontact printing); (b) Confocal images of immunofluorescence staining of a smooth muscle cell on posts. Cells deflected posts maximally during the 1–2 h period after plating, and were fully spread after 2 h. Scale bars indicate 10 μm. The positions of the tips of the posts were used to calculate the force exerted by cells (white arrows). The lengths of arrows indicate the magnitude of the calculated force (top right arrow indicates 50 nN); (c) Plot of the force generated on each post as a function of total area of focal adhesion staining per post. Each point represents the force and area of vinculin staining associated with each post; focal adhesions from five cells were analyzed. The shaded region (blue) indicates the adhesions smaller than 1 μm^2 (inset). (Reproduced with permission from Ref. [59].)

membrane alone is quite small (typically 10–20 pN for a circular area of 100 nm diameter; i.e. a membrane tether) for mammalian cells [223], the plasma membrane is supported by internal and external filamentous proteins that have links to the cytoskeleton. As discussed above, mechanical reinforcement of the very first contacts that a cell forms with the ECM is thus essential. When the adhesions have matured, they can typically withstand forces of a few nN per square micrometer (see Figure 9.13). Tensile forces are then transmitted to the cytoskeleton network in the cell, which can disseminate the force to many or a few sites, even on the opposite side of the cell [224]. Major cellular forces are generated by myosin II filaments pulling on actin throughout the cytoskeleton in early spreading cells, and in the periphery of epithelial cells, particularly around damaged areas in the tissue [160]. In mature epithelial cells, networks of intermediate filaments are generated that bear much of the force when the tissues are stretched.

Far more is currently known about the mechanical characteristics of cell–ECM contacts than about the mechanical properties of cell–cell contacts [21, 126, 127, 225]. The formation of tight cell–cell junctions, however, is critical for many developmental processes such as formation of the gut, kidney, breast and many other epithelial tissues, and is mediated by homologous cadherin–cadherin bonds [22]. These bonds must be dynamic because there are movements of cells relative to each other in epithelial monolayers [23, 226]. Further, when a cell dies, its neighbors rapidly close the gap by first forming an actomyosin collar around the hole; the collar then contracts to cover the hole [160]. Similarly, in the process of convergent extension during embryogenesis, cells converge along one axis while being able to move relative to one another. This is the major morphological movement responsible for organizing the spinal cord axis [227]. Many of the important morphological changes in development involve the contraction of epithelial cells, from the early formation of the gut to the later formation of kidney tubules. In all cases, there is evidence that although the individual cells can move independently, the whole tissue still acts as a unit to undergo a coordinated morphological change. The molecular basis of the mechanical coordination in epithelial or endothelial cell monolayers is not known, but the precision of movement implies that a rapid feedback mechanism is present. It is thus very interesting to note that when force-sensing micropillars were coated with cadherins rather than with fibronectin, the mechanical stresses transduced through cadherin-adhesions were of the same order of magnitude as those previously characterized for focal adhesions on fibronectin [225]. So, the question is, what is the relative importance of cell–cell and cell–matrix contacts in different tissues on transducing mechanical stimuli into altering the downstream behavior? In both tissue types, cell–cell interactions predominate. Endothelial cells require cell–cell contacts, while vascular endothelial cells utilize cadherin engagement to transduce stretch into proliferative signals [15]. Hence, stretch stimulated Rac1 activity in endothelial cells, whereas RhoA was activated by stretch in smooth muscle cells.

Finally, tissue remodeling often reflects alterations in local mechanical conditions that result in an integrated response among the different cell types that share – and thus cooperatively manage – the surrounding ECM and its remodeling. The question therefore is whether mechanical stresses can be communicated between different

cell types to synergize a matrix remodeling response. When normal stresses were imposed on bronchial epithelial cells in the presence of unstimulated lung fibroblasts, it could be shown that mechanical stresses can be communicated from stressed to unstressed cells to elicit a remodeling response. Thus, the integrated response of two cocultured cell types to mechanical stress mimics the key features of airways remodeling as seen in asthma: namely, an increase in production of fibronectin, collagen types III and V and matrix metalloproteinase type 9 (MMP-9) [228].

9.9
Sensing Matrix Rigidity

9.9.1
Reciprocity of the Physical Aspects of the Extracellular Matrix and Intracellular Events

As long as the cell–matrix and cell–cell linkages hold tight, intracellular motile activity will interrogate the matrix, and the subsequent cellular activity will depend on the physical properties of the extracellular fibrillar network, and vice versa. The interrogation involves a mechanical testing of the rigidity as well as the geometry of the environment through the normal cell motility processes (Box 9.2). When the rigidity is determined, the cell will respond appropriately. For example, the extracellular network structure is remodeled if it is of the same or a softer compliance than the intracellular network [18]. Rigidity is an important part of the environment of a cell, and different tissues have different rigidities as well as different levels of activity (this point will be discussed later). There is considerable interest in learning how this is achieved at a molecular level.

A number of reports have indicated that matrix rigidity is a critical factor regulating fundamental cell processes, including differentiation and growth. Discher's group recently showed that the differentiation of mesenchymal stem cells is heavily dependent on the rigidity of the matrix to which cells adhere [19]. The group reported that mesenchymal stem cells preferentially become neurogenic on soft substrates, while they preferentially commit to myogenic and osteogenic differentiation on intermediate and rigid substrates, respectively. The cellular response to rigidity has been seen at the time scale of seconds for submicron latex beads [213] and during cell spreading [229]. Fibroblast migration toward rigid substrates indicates further that the process has important ramifications for *in vivo* motile activities [230]. From the signal transduction point of view, these observations indicate that the sensing of different rigidities can be very rapid and may have profound effects on cell function at a variety of levels. Rigidity is a rather complicated parameter for the cell to sense because measurements of both force and displacement must be combined. In order for a cell to sense matrix rigidity, the cell must actively pull on the matrix; thus, the cell must actively test the rigidity of its environment. As a corollary, the cell in an inactive state will not be able to develop a rigidity response. Although these statements apply for single cells *in vitro*, the situation is more complicated in a tissue environment where neighboring cells and

Box 9.2
Cell Forces

- *Tensile Forces:* As the cytoskeleton of the cell is generally contractile, the transmembrane forces on cells are primarily tensile. Large forces in the movement of organisms or tissues are typically generated by linkages from the cytoskeleton to the ECM or neighboring cells through integrins or cadherins, respectively. In contrast, the lipid bilayer of the plasma membrane is fluid and can be distorted with relative ease. Forces are exerted typically on noncovalent protein–protein bonds (one exception is the transglutaminase linkage of lysines to glutamines on collagen or fibrin). Typical protein–protein bonds can sustain about 1 pN per bond (e.g. 1 pN per integrin–fibronectin bond in living tissue, where the bond holds for a matter of seconds). Although those forces seem low, they need to be maintained for long periods, and even the very high-affinity avidin–biotin bond only has a lifetime of about 5 s under a force of 5 pN. Typical forces that fibroblasts can exert on fibronectin-coated surfaces are on the order of 1–5 nNper μm cell edge.
- *Compressive Forces:* Compressive forces are primarily resisted by the hydrostatic pressure of the cytoplasm of the cell (particularly true in plant systems). The other type of compressive force is that generated as cells extend lamellipodia, filopodia or pseudopodia, and those processes push on neighboring cells or the environment.

Tissue Rigidity

- *Resting Rigidity:* A tissue at rest has a rigidity that is defined by the Young's modulus, E, which can be determined from the slope of the tensile stress versus the tensile strain curve:

$$E = \text{tensile stress}/\text{tensile strain} = \delta\sigma/\delta\varepsilon = \delta(F/A_0)/\delta(L/L_0)$$

where: E is the Young's modulus (modulus of elasticity) measured in Pascals; F is the force applied to the object; A_0 is the original cross-sectional area through which the force is applied; δL is the amount by which the length of the object changes; and L_0 is the original length of the object.

- *Rigidity Sensing:* To measure rigidity, cells develop force on matrix over time. This means that the mechanism of sensing rigidity must compare force and displacement during a given time period. If a cell pulls on an object, the total displacement is the sum of the matrix and of the intracellular displacements. Since the cell directly probes the relative molecular displacements in the adhesion site, it should not matter whether the force is applied from the outside or the inside. This statement, however, is true for soft surfaces only if the external force is applied rapidly before the cell has displaced the substrate. The time window is important since the cell does not pull with a constant force but gradually increases the force after making a first contact. The physiologically relevant time window in this context typically lasts for just 1–2 seconds. The real

question is whether the cell ramps up the force until a max force applied to the adhesion site is reached, or alternatively a maximal stress, or until a certain relative displacement of the intracellular rigidity sensors within adhesion sites is reached which might be in the order of 130 nm. If the latter is the case, the cells pull with larger forces on rigid objects attempting to reach the critical displacement of the intracellular rigidity sensors.

tissue modulation can produce stresses and strains on cellular components in a sustained manner. The complexity of the rigidity measurement can potentially be an important part of tissue assembly.

In terms of the mechanism by which cells can sense rigidity, they must measure the force needed for a given displacement (rigidity) or the displacement for a given force (compliance). The rigidity of tissues can be based upon the rigidity of either the matrix or of the cells themselves. Most of the focus of *in vitro* studies has been on the effect of matrix rigidity rather than cell rigidity, because that is easier to manipulate. By using elastic pillars of different rigidity as substrates, Saez *et al.* showed that the forces exerted by the cells increased linearly with rigidity of the pillars. Thus, the cells deform the pillars by the same amount (on the order of 130 nm) over an almost 100-fold change in rigidity (Figure 9.14) [231]. This observation suggests that cells can sense the displacement of the cell–substrate anchor sites and continue to develop higher forces on rigid substrates until the proper displacement is reached. Because displacement must be measured from the cell edge or the initial site of pulling, the sensor molecules must be anchored both at the edge (initial site of pulling) and at the integrin that is being pulled. In terms of a possible physical mechanism (see Figure 9.14), the movement of a component relative to a stationary component could produce a signal to stop further recruitment or further movement. As many molecules can easily span 130 nm, the movement of the actin (anchored to the integrin) past myosin or some other relative molecular displacement could be linked to a signaling process. If the displacements were less than 130 nm, then a signal for myosin filament contraction and/or assembly could be generated. If the displacements were greater than 130 nm, then further myosin activation would be blocked because the sensor would be physically separated from the enzyme that modifies it or the sensor could be fully stretched. Because the distance is molecular and yet micrometer-sized contacts were produced on rigid pillars, the measurement of rigidity must continually be made over time by activating new regions to contract and allowing old regions to relax. This can be compatible with a previously described model of rigidity sensing through p130Cas by assuming that force must increase until p130Cas is displaced from the kinase in (Figure 9.14) [21, 197]. However, other models, which are more closely linked to the movement of actin relative to myosin, may be used for longer-term rigidity sensing. Multiple mechanisms probably exist to enable different types of cells to properly sense rigidity in different environments. In many cases, there is a strong need for a local feedback between the level of actin and myosin recruited and the rigidity in the epithelial cells. Hence, additional experiments are required to identify possible molecules that could be the rulers in such a system. A consequence of the displacement sensing is that higher

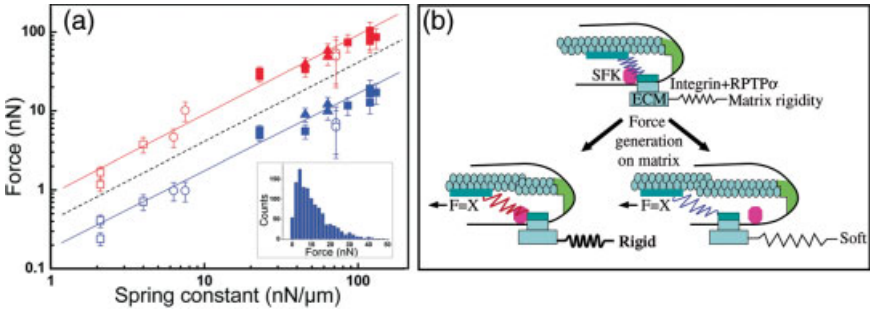

Figure 9.14 Rigidity sensing; evidence for a displacement sensor and one plausible molecular mechanism. (a) Linear relationship between rigidity and average force generated indicates that cells sense displacement [231]. Log-log plot of the force as a function of substrate rigidity. F (blue) and F_{max} (red) within an island of cells are represented for different surface densities: (ratio of the post surface over the total surface) 10% (circles); 22% (squares); 40% (triangles). Open and solid symbols correspond to pillars of 1 and 2 μm in diameter, respectively. The slope of the dashed line is 1. Inset: Typical histogram of force distribution (spring constant 64 nN μm^{-1}); (b) Relative displacement model for rigidity sensing by substrate priming. In this scheme, the displacement of the cytoskeleton–integrin–matrix complex from the active Src-family kinase (Fyn) is the signal to stop further phosphorylation. An initial force signal activates RPTPα at the leading edge that then recruits Fyn to a stationary lipid domain through its palmitoylation. Contraction of the cytoskeleton stretches Fyn substrates such as p130Cas, priming it for phosphorylation by Fyn. In rigid substrates, additional force-generating links are recruited by continued phosphorylation to develop the higher forces needed to displace the p130Cas from the kinase. (Adapted from Ref. [197], where the force needed to stretch p130Cas was emphasized; however, the results of Saez *et al.* [232] and other studies indicated that displacement was measured.)

rigidities will cause higher forces that will in turn enhance the intensity at upstream signals in mechanotransduction (e.g. tyrosine phosphorylation) [51] and may result in a greater activation of downstream signals on rigid substrates.

Another, possibly important, factor which affects the rigidity response is the distance between the cytoskeleton and cell–substrate anchor sites. As elasticity is defined by the magnitude of deformation (e.g. change of dimension) per unit force, cell–substrate anchor sites will be displaced by a larger distance on soft substrates for the same force (see Figure 9.14). If that is the case, the distance between cytoskeleton and cell–substrate anchor sites (the length of the matrix plus the integrin and the actin-binding molecules) would be larger on rigid substrates than on soft substrates [233, 234]. However, larger displacement of cell–substrate anchor sites has not yet been demonstrated, and the uniform cellular deformation of elastic substrates of vastly different rigidities [231] implies that the displacement of anchor sites is not necessarily larger on soft substrate.

9.9.1.1 Time Dependence and Rigidity Responses

When cells pull on the substrate to sense rigidity, they use the rearward movement of actin to generate the force. Actin moves rearward at a rate of 30–120 nm s^{-1}, which means that displacements of 130 nm will take more than 1 s. In the models of rigidity

sensing that have been discussed, a rapid rise in force that is sustained could elicit a rigid substrate response. *In vivo*, if the cell experiences tensile forces from the neighboring cells or the matrix during the period where it is pulling on the matrix, then the matrix can appear rigid because the force will rise rapidly. In experiments where the force was increased rapidly on fibronectin beads with a soft laser tweezers, the bead appeared to be in a rigid laser tweezers, as was predicted. Similarly, *in vivo* many tissues experience external forces on roughly a second time-scale that could develop a rigidity response. Thus, rigidity-dependent growth could be stimulated *in vivo* by tissue contractions.

The time dependence of the assembly of components in the integrin–cytoskeleton complex might affect the rigidity response, since different components bind and detach during the life cycle of an adhesion site [184, 235]. Primary connections between integrins and the cytoskeleton, and their reinforcement, depend on talin (which is probably one of the first proteins in adhesion sites) [64, 115], on α-actinin (which crosslinks actin filaments) and on zyxin (which enters the adhesion site during its maturation) [181, 236]. The transition from mature focal adhesion to fibrillar adhesion is characterized by the segregation of tensin and specific integrins [56]. Because the ECM–integrin–cytoskeleton connection is a viscoelastic material (i.e. it is not purely elastic) [237], the time required to reach the threshold force for rigidity responses probably differs depending on the stiffness of the ECM. Accordingly, a soft optical trap could mimic the effects of a rigid trap on the stabilization of the integrin–cytoskeleton linkages if externally applied forces rise rapidly [233]. In lamellipodia, the cytoskeletal-dependent radial transport of a contractile signal directs the timing of contraction and, probably, adhesion site initiation to stabilize protrusive events [229] (Figure 9.15). Consequently, the formation of cell contacts with the ECM is not a continuous process but rather involves cycles of contraction and relaxation.

9.9.1.2 **Position and Spacing Dependence of the Rigidity Responses**

The position dependence of rigidity responses is exemplified by the fact that structural and signaling proteins that are necessary for rigidity responses are placed at strategic locations – for example, at the cell edge during protrusive events and at early adhesion sites. Many proteins involved in rigidity responses and/or phosphotyrosine signaling, including talin [64, 115], integrins ($\alpha_v\beta_3$) [115, 238], paxillin [173, 174], α-actinin [173, 174, 229], RPTPα [173, 174], Rap1 [239] and p130Cas [240], are localized at the leading edge of the cell, ready to respond to any contraction generated by the cell or by the ECM. There is a position-dependent binding-and-release cycle of fibronectin–integrin–cytoskeleton interactions, with preferential binding occurring at the active edges of motile fibroblasts and release at 0.5–3 μm back from the edge [241]. Interestingly, reinforcement occurs preferentially at the edge in rigid tweezers [233], whereas weak connections that break easily are favored by nonrigid tweezers and at sites >1 μm back from the leading edge [115, 233]. At the molecular level, the reinforcement of integrin–cytoskeleton interactions are limited to linkages that have experienced force, and not those nearby (<1 μm) [213].

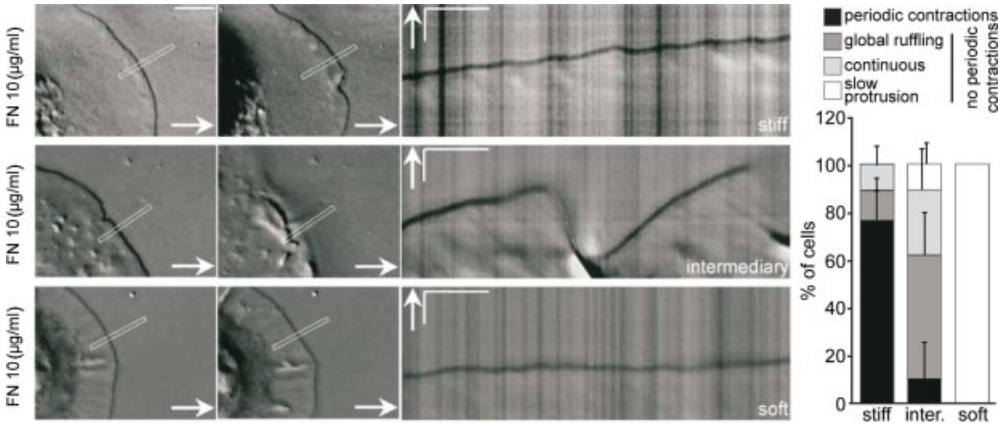

Figure 9.15 Contraction of spreading cells results in periodic contractions and further spreading on rigid surfaces, but no further spreading on soft surfaces. On intermediary stiff surfaces coated with the same concentration of covalently attached fibronectin, cells attempt to spread but lose adhesion. (Reproduced with permission from Ref. [229].)

Finally, many tissues experience periodic stretch *in vivo* during normal activity. When the tissue is inactive, it often experiences atrophy; this is obviously true for muscle, bone and connective tissue. The greatest problem for space travelers is that astronauts typically lose 1–2% of their bone mass for each month in space, even though they may exercise regularly [242]. Similarly, the skin on the feet or hands thickens with use or labor, and thins with disuse. Thus, force from activity or rigidity appears to be a global regulator of tissue function, and an understanding of the mechanisms whereby force is transduced into biochemical signals is an important area of future research.

At the subcellular level, there are many forces that must be regulated to produce normal cell morphology and the proper distribution of organelles. Although the protein composition of many genomes and even individual cell types is known, relatively little knowledge exists of how those proteins are assembled into functional complexes. Individual proteins, typically 5–20 nm in diameter, are assembled into larger functional complexes that can be considered as subcellular machines, controlling and regulating complex cellular functions, from reading and translating the genetic blueprint to the synthesis and transport of proteins, from cell migration to cell division, from cell differentiation to cell death. Those subcellular complexes range in size from ribosomes to the lamellipodial machines that drive ECM assembly and remodeling [243], including collagen fiber rearrangements [244]. It is important to be able to dissect the steps into these subcellular processes to enable greater understanding of the sequence of coherent molecular events [245] (Figure 9.16).

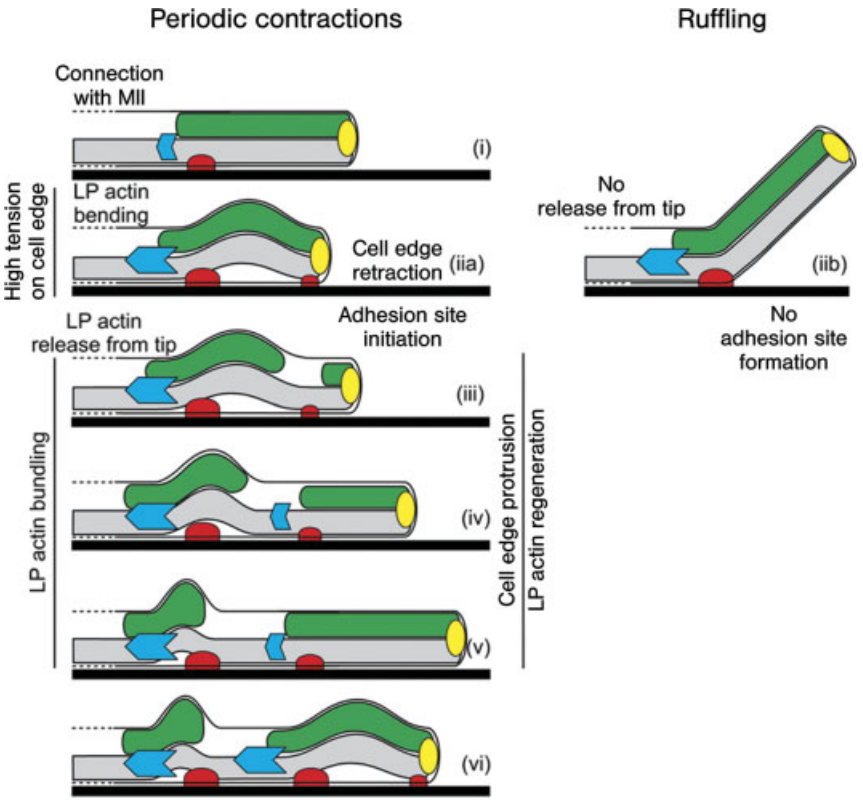

Figure 9.16 Schematic representation of lamellipodial (LP)–actin periodic regeneration. The LP actin (green) is above the LM (gray). Polymerization at the front of the LP actin network causes the back of the network to grow towards the back of the LP contractile module until it reaches an adhesion site (i) where a MII cluster (blue) forms. MII pulls the LP actin, generating high tension on the cell front, causing LP bending, edge retraction and initiation of new adhesion sites (red) on the extracellular matrix (ECM; black rectangle) (iia). The LP actin continues to be pulled until it is released from the tip (iii) and edge protrusion restarts. A new LP actin network immediately resumes growth, which suggests that the actin polymerization machinery (yellow) is still present at the cell tip (iv). The released LP actin, still pulled by MII, further condenses into a bundle at the back of the previous adhesion site (v), while the newly growing LP actin reaches the next adhesion site and the cycle begins anew (vi). LP ruffling (iib) occurred in the case when the total bond energy connecting LP actin to the edge was greater than the bond energy of nascent adhesion sites to the ECM. (Reproduced with permission from Ref. [245]).

9.10
Cellular Response to Initial Matrix Conditions

9.10.1
Assembly, Stretching and Remodeling of the Extracellular Matrix

Once the first contacts have been made by the cell with its surrounding, it will often soon begin to assemble its own matrix. Initially, cells build a provisional matrix which

is rich in fibronectin, which plays a particularly important role in early embryogenesis and in wound healing [104]. In order that the assembly process is started shortly after attachment – and even before the genetic machinery upregulates the expression of matrix proteins – the cells harvest fibronectin from body fluids or the cell medium. Only at later stages do the cells start to produce and secrete their own fibronectin, which has some structural and functional differences compared to plasma fibronectin [246]. The complex fibrillogenesis process begins when the cells apply force to fibronectin molecules (see Figure 9.11). Crucial to the assembly process is integrin $\alpha_5\beta_1$, which specifically recognizes only fibronectin among all other matrix proteins, due to fibronectin's unique synergy site that is sitting on the $FIII_9$ module adjacent to the RGD site (see Figure 9.4). Fibronectin fibrils then emerge as the fibronectin-bound $\alpha_5\beta_1$ integrin complexes are translocated along with actin fibers away from the cell periphery [25, 56, 126, 127, 184, 194]. The tensin-mediated $\alpha_5\beta_1$ integrin translocation thus initiates fibronectin fibrillogenesis on the cell surface. However, an integrin-mediated activation step is not the only way by which fibronectin fibrillogenesis can be initiated. While integrins serve as handles by which cells can apply force to fibronectin molecules, fibronectin fibrillogenesis can also be induced in the absence of integrins, as long as fibronectin molecules are stretched, for example by shear [247] or physical entrapment [248]. The RGD-sequence is thus not necessary for fibronectin fibrillogenesis [249]. It was shown recently that the fibronectin conformation in artificially pulled fibronectin fibers is similar to that found in cell-generated matrix fibers [53–55, 250, 251]. Artificially pulled fibronectin fibers can thus serve as physiologically significant model systems. Finally, src-kinase activity not only regulates rigidity sensing but is also essential in fibronectin fibrillogenesis. Src-induced phosphorylation of paxillin at Y118 is required for assembly of the FN matrix by fibroblasts, as well as for maintaining the attachment of FN matrix fibrils to the cell surface [252].

9.10.1.1 Switching the Biochemistry Displayed by the Matrix by Stretching and Unfolding of Matrix Proteins

When the cells have assembled the extracellular matrix fibers, a number of questions remain unanswered. First, do the cells respond only to the rigidity of the matrix fibers, or can the cell-generated tension alter the biochemistry displayed by the matrix proteins? Can molecular recognition sites that confer biochemical specificity to proteins be altered by stretching proteins? Is it possible that cell-generated tension is sufficient not just to strain but to mechanically unfold those proteins that form part of the force-bearing protein ECM networks in living tissue? Conclusive evidence that cell-generated forces are sufficient to unfold ECM proteins, and that the unfolding imparts new functional switches, rely most importantly on visualization techniques to probe protein conformations *ex vivo* and in cell culture.

Fluorescence resonance energy transfer (FRET) between multiple energy donors and acceptors (Figure 9.17) was indeed used to show that fibronectin in cell culture is exposed to cell-induced dynamic levels of stress which lead to partial fibronectin unfolding [53–55, 69, 70]. Fibronectin unfolding is hypothesized to mediate a variety of functions, ranging from altered mechanisms for cell binding

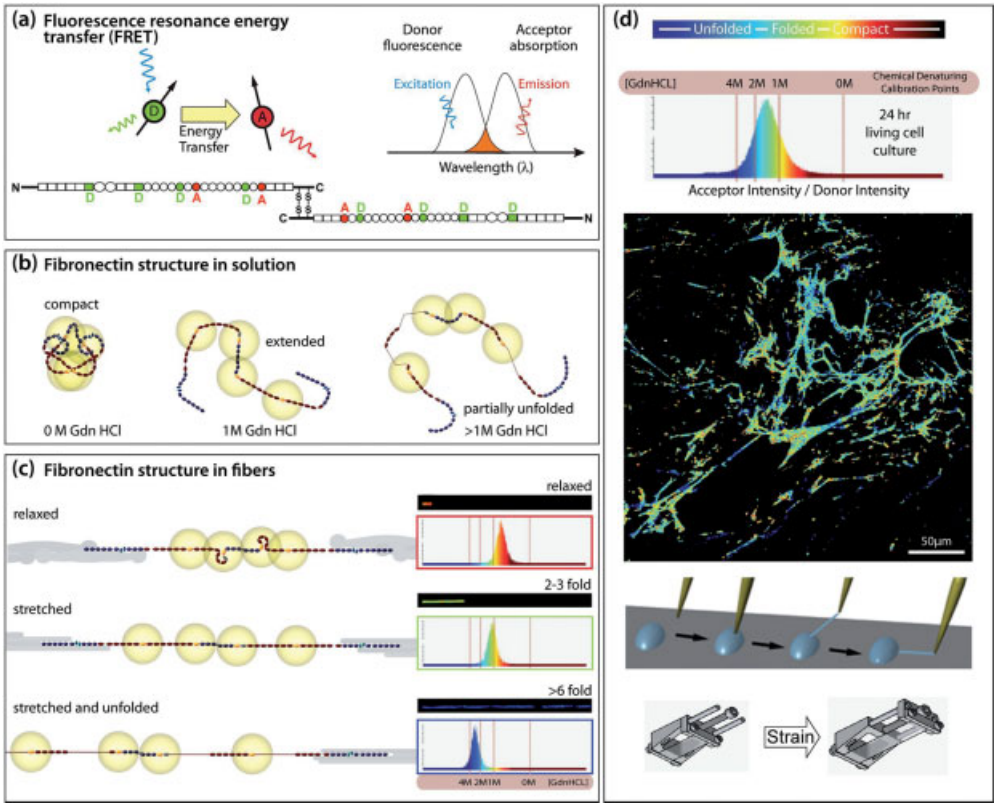

Figure 9.17 The use of fluorescence resonance energy transfer (FRET) to probe matrix stretching and unfolding in cell culture and artificially prepared fibronectin fibers. (a) The two free cysteines per fibronectin monomer, located on modules $FnIII_7$ and $FnIII_{15}$ (see Figure 9.4) are site-specifically labeled with the acceptors, while the donors are randomly distributed along the protein [69, 70]. The distance over which the acceptors can couple with potential energy donors are shown as yellow circles; (b) Schematic drawing of the fibronectin quaternary structure in solution and under denaturing conditions; (c) While the ultrastructure of fibronectin fibers remains unknown, FRET indicates that some quaternary structure is present when the fibers are fully relaxed. When the fibronectin fibers are stretched 200–300% of their equilibrium length, a first loss of secondary structure is observed [53–55, 250]; (d) Image of cell-made fibronectin matrix where trace amounts of FRET-labeled fibronectin were added to the cell culture medium. A broad distribution of different average fibronectin conformations can be seen. False colors have been used to visualize altered FRET ratios. Correlating FRET with mechanical strain was made possible by depositing fibronectin fibers onto stretchable PDMS sheets [250]. The fibers were therefore manually pulled out of a droplet of concentrated fibronectin solution. All of the conformations that can be seen in a broad range of strained artificial fibers coexist in every single field of view of a living cell culture.

to fibronectin to exposure of sites with enzymatic functions [21, 26, 53–55, 69, 70]. These cellular studies are important as they demonstrate that the nonequilibrium conformations of proteins can be stabilized by force and are thus physiologically relevant.

With regards to the translation of mechanical forces into biochemical signal changes, it should be noted that a wide variety of proteins (which are part of force-bearing protein networks linking the intracellular cytoskeleton and ECM) have multimodular structures where each individual module often carries one or more unique binding sites. However, what are the advantages of linking numerous modules equipped with different functionalities into macromolecules? The answer might be found in the following consideration. If domains of multimodular proteins were to possess similar mechanical stabilities, these domains would rupture in a stochastic sequence. But, if the domains have significantly different mechanical stabilities, as observed for fibronectin's FnIII modules [253–257], then sequential domain unfolding would lead to a well-defined graded sequence in which the various molecular recognition sites displayed by those domains would be altered as a function of mechanical strain. The significance of having a hierarchy of mechanical stabilities is thus central to mechanochemical signal conversion: as the mechanical hierarchy defines the sequence in which bonds or modules break, a sequence of stretching of different domains could be translated into a sequence of biochemical signal changes. This is also a likely explanation for why so many proteins contain buried cryptic sites in their hydrophobic interior that are only exposed when the protein unfolds [51, 52, 254, 256, 258–265]. Multidomain proteins are thus ideally suited to serve as mechanochemical signal converters to translate a large range of forces into sequential strain-specific functional changes [26].

Studies of the mechanical characteristics of proteins have thus revealed new insights into protein engineering principles. While fragments or a few domains of these molecules have often been employed in biotechnology or tissue engineering, mimicking only partial aspects of the whole molecule, engineers must ask what functional aspects might be missed if materials and surfaces were to be functionalized with peptides that contained only single molecular recognition motifs, as has been achieved for example with the cell-adhesive tripeptide RGD from the 450 kDa fibronectin molecule, instead of using the full-length protein. Such engineered systems would show a rather different mechanoresponse, and would not make it possible to translate a range of forces into a range of graded biochemical signal changes.

While the biochemistry of the quasi-equilibrium states of proteins is well understood, it is experimentally challenging to investigate how the structure–function relationship of proteins is altered when they are stretched. Deciphering the physiological significance of force-induced unfolding of fibronectin, and whether any of its versatile functions are up- or downregulated in a mechanoresponsive manner, however, has been hampered due to a lack of appropriate assays. In response to the growing need for quantitative biochemical and cellular assays that address whether the ECM acts as a mechanochemical signal converter to coregulate cellular mechanotransduction processes, we have developed a new assay where plasma fibronectin fibers are manually deposited onto elastic sheets, and force-induced changes in protein conformation are monitored using FRET (Figure 9.17). Our aim had been to develop a mechanical strain assays where the conformation of fibronectin can be adjusted externally on demand, while the force-induced protein extension is

monitored optically [250, 251]. To probe how the alterations of the structure of stretched Fn impact biochemical interactions and cellular behavior, such a strain assay needs to be amenable to cell culture environments. To tune the conformation of fibronectin, fibers were drawn manually from a concentrated fibronectin solution [266–268]. When adding trace amounts of FRET-labeled fibronectin into the solution, followed by a step where the freshly drawn fibers are deposited onto polymeric sheets that are mounted into stretch devices, fibers can be generated that have a far more narrow conformational distribution, as found in native matrix [250, 251]. Furthermore, the mechanical strain can be externally adjusted, which enabled protein-binding studies to be conducted as a function of the strain of fibrillar fibronectin [250, 251]. An image of conformationally tuned fibronectin fibers can be seen in Figure 9.17. These assays further open the doors to the question of whether – and how – cell phenotypes are regulated by force-induced alterations of fibronectin conformation.

9.10.1.2 Cell Responses to Initial Biomaterial Properties and Later to Self-Made Extracellular Matrix

While the differentiation of mesenchymal stem cells has been correlated with the rigidity of the substrate on which they were initially plated [19], does the rigidity response of the cell change as it assembles its own matrix hours or days after the cells have been seeded on a substrate with defined rigidity? For example, the initial rigidity of a substrate has been proposed to determine whether or not mammary epithelial cells upregulate integrin expression and differentiate into a malignant phenotype [145], and also to dictate whether mesenchymal stem cells differentiate into bone, muscle or neuronal tissue [19]. In those experiments, the macroscopic materials properties of the substrate were typically correlated with outcome after four to ten days of cell culturing. While the mechanical properties of a substrate or engineered scaffold have indeed been correlated with various aspects of cell behavior, the underlying mechanisms how substrate rigidity ultimately regulates the long-term responses have not yet been defined.

Once cells have been seeded onto synthetic matrices they rapidly begin to assemble their own matrix, and will ultimately touch, feel and respond to their self-made ECM. A few hours after cells have attached to surfaces and begun to assemble their matrix, the physical characteristics of the newly assembled matrix do indeed depend on the rigidity of the substrate. After 4 h of cell culture, the FRET data showed that the fibronectin matrix was indeed more unfolded on a rigid (33 kPa) compared to a soft substrate (7 kPa) (Figure 9.18a) [269]. Surprisingly, however, after only one day the fibroblasts that were initially seeded onto glass had produced sufficient matrix so as to sit on a much softer biopolymer cushion. The cells then assembled a matrix that was far less unfolded than the matrix they made during the first 4 h on glass, as probed by adding FRET-labeled fibronectin only during the last 23–24 h after seeding. This newly made matrix is comparable to the cells feeling a 7 kPa substrate [269]. Most interestingly, the aging matrix changes its physical properties. When the cells were seeded onto glass and allowed to assemble matrix for three days, the matrix deposited during the first 24 h was highly unfolded, while the younger matrix was far less

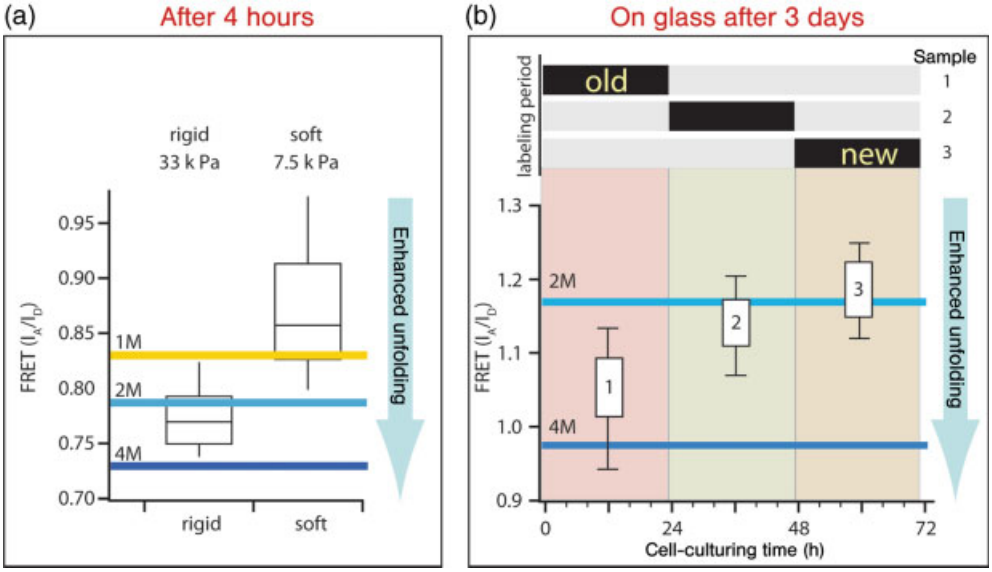

Figure 9.18 The tension of the extracellular matrix (and thus the mechanical strain of fibronectin) is upregulated with the rigidity of the substrate surface and changes as the matrix ages. (a) Fibronectin matrix assembly and unfolding on rigid and soft polyacrylamide surfaces 4 h after seeding the fibroblasts. The probabilities of finding certain FRET ratios are shown as boxes, where the maximum is given as the center line in the box, and the upper and lower ends of the boxes represent the 25th to 75th percentiles, and the 'whiskers' show the 2nd and 98th percentiles. FRET from fibrils on the rigid surface falls far below the FRET signature observed for fibronectin in solution at mild denaturing conditions (1 *M* GnHCl), thereby indicating that Fn is partially unfolded on rigid surfaces [53–55, 70, 250, 251]. FRET values on the soft surface indicate that the secondary structure of fibronectin is intact; (b) Three-day cell culture where FRET-labeled fibronectin was added for only limited time periods, as indicated in the upper bar graph. When the cells are seeded on glass and allowed to assemble matrix for three days, the matrix deposited during the first 24 h was highly unfolded, while the younger matrix was far less unfolded. Thus, the physical properties of matrix change as the matrix ages. (Adopted from Ref. [269].)

unfolded (Figure 9.18b). Thus, the matrix was progressively more unfolded as it aged, while the newly deposited matrix showed little unfolding. These data provided the first evidence that matrix maturation occurs, and that aging is associated with an increased stretching of fibronectin fibrils. Matrix assembly and remodeling involves at least partial unfolding of the secondary structure of fibronectin modules. Consequently, matured and aged matrix may display different physical and biochemical characteristics, and is structurally distinguishable from newly deposited matrix. A comparison of the conformation of Fn in these three-dimensional (3-D) matrices with those constructed by cells on rigid and flexible polyacrylamide surfaces suggests that cells in maturing matrices experience a microenvironment of gradually increased rigidity [269]. A future goal must be to understand the physiological consequences of matrix unfolding on cell function, including cancer and stem cell differentiation.

9.11
Cell Motility in Response to Force Generation and Matrix Properties

The relationship between force generation and motility is not simple. Fibroblasts that develop high forces on substrates do not move rapidly [222], whereas neutrophils that move at the highest rates reported for cells (about $40\,\mu m\,min^{-1}$ or $700\,nm\,s^{-1}$) generate very low forces on substrates [53–55]. There is considerable interest in the extravasation of cancer cells moving out of the bloodstream into tissues in the process of metastasis, although many of the steps in that process involve proteolysis of the matrix and deformation of the cell to pass through small gaps in the endothelium [270–272]. Although force generation is needed for motility, it is not the most important factor – indeed, cell polarization, matrix proteases, directional signals and the deformation of the cytoplasm are often as important.

Cell motility depends on substrate density and rigidity, and therefore also on the processes that respond to rigidity [273]. Many of the proteins involved in rigidity response have been linked to motility disorders, including cancer as well as malformations in development and neuronal connectivity. Src family kinases (SFKs) [274, 275], FAK [173, 174, 276]), the SH2 domain-containing phosphatase SHP-2 [173, 174] and RPTPs) [173, 174] are important components of the force-dependent signal transduction pathways that lead to the assembly of adhesion sites. The force-dependent initiation of adhesion sites and their rapid reinforcement occurs in protruding portions of cells, where adhesion sites can transmit cell propulsive forces [179, 277]. In extending regions of the cell, forces are generated on integrins by actin rearward flow rather than stress fibers. At the trailing end of the cell, mature focal adhesions create passive resistance during cell migration. To overcome this resistance, high forces must be generated by nascent adhesion sites [179]. However, in some static cells, higher forces are correlated with mature focal adhesions [58]. At the cell rear, traction stresses induce the disassembly instead of the reinforcement of focal adhesions and linked stress fibers [189, 278–280]; this is dependent on mechanosensitive ion channels and calcium signaling in keratocytes and astrocytoma cells. SFKs, FAK and PEST domain-enriched tyrosine phosphatase (PTP-PEST) are also crucial factors in adhesion site disassembly [229, 274, 281]. Recent studies have shown that the rigidity of 3-D matrices affects the migration rate differently from 2-D matrices, in that the less-rigid matrices cause an increase in migration rate [271]. At a biochemical level, the actin depolymerizing protein cofilin has been implicated in the motility of fibroblasts *in vitro*, and it is downstream in the biochemical signaling pathway of the integrins that have been activated at the leading edge [282–285]. These varying results indicate that different modalities of force generation and rigidity response at the cell front versus rear of the cell or in 3-D versus 2-D matrices can correlate with position-dependent regulation of phosphotyrosine signaling, and that different mechanisms of rigidity responses based on phosphotyrosine signaling can independently direct cell morphology as well as motility. Many observations point to tight links between morphology, migration, rigidity responses and tyrosine kinase activity.

9.12
Mechanical Forces and Force Sensing in Development and Disease

During the development and regeneration of tissues, forces act on and are propagated throughout most tissues. Such forces provide a local and global mechanism to shape cells and tissues, and to maintain homeostasis. Forces play a critical role by which cells interact with their environment and gain environmental feedback that regulates cell behavior. The signal for wound healing is often the loss of tissue integrity and the concomitant loss of force. Further, use of tissue and the periodic generation of force are often tied to the growth of that tissue, whereas inactivity is tied to the atrophy of the tissue. Bedridden patients suffer from a loss of muscle tissue and other aspects of atrophy. Similarly, with aging, osteoporosis, as well as many other cardiovascular diseases, mechanical changes and inappropriate responses of cells to mechanical changes, are critical and give rise to many symptoms. The size of the organism and its form are also set, at least in part, through a physical feedback between individual cells and their neighbors that is dynamic. As the cells grow and divide in development, they are constantly moving and even changing neighbors on occasion. The force-bearing cytoskeleton is actively remodeling and must clearly be responsive to changes in the level of force, or else the tissue would relax or contract too much. Contractile activity in individual cells can change the turgor of the tissue, and that parameter is under control of the signaling pathways that activate myosin contraction.

Consequently, forces play a critical role in health and disease in controlling the outcome of many biological processes (Figure 9.19). One obvious case is in cancer, where the cells ignore normal environmental cues and grow aberrantly, although there are many other examples (including problems with angiogenesis and tissue repair). Thus, it is speculated that in the future there will be an increasing emphasis

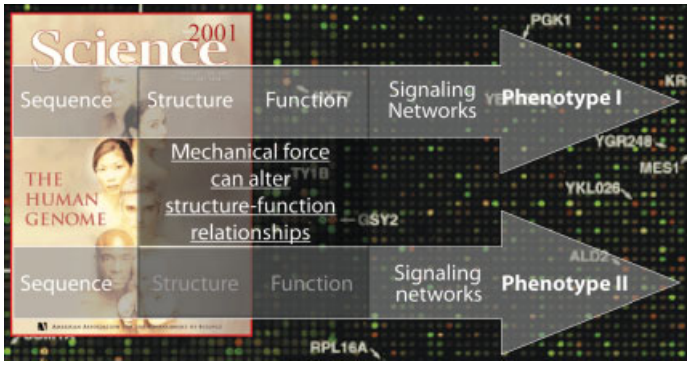

Figure 9.19 From the human genome to quantitative biology. The path is more complicated than originally thought, as mechanical force provides Nature with an additional dimension of regulating protein function. A switch in protein function might then alter cell signaling and thus the cell phenotype. The background shows the cover of *Science* announcing that details of the human genome had been resolved.

on the mechanical treatment of clinical problems and the targeting of therapeutics to mechanical response pathways. For the more effective treatment of diseases, there needs to be a greater recognition of the role that mechanical factors play in the development of the organism, as well as in the onset and progression of diseases. In other words, the genes code for a set of proteins that have developed the proper mechanical responses to shape the organism reproducibly. Similarly, disease-related alterations can result in alterations in mechanoresponsive pathways that are a major part of the disease. A much better understanding of those pathways is needed for proper treatment and therapy.

9.12.1
Cancer and Cell Transformation

Many cancer biologists have realized that cancer is inherently associated with a diseased mechanosensing and mechanoresponsive system. Many cancer cells ignore the normal environmental signals that regulate growth, and many of those cues are mechanical. For example, one of the early hallmarks of cancer cells is that they are often transformed, which was defined as the ability of those cells to grow on soft agar whereas normal cells required a rigid substrate [9–11]. Early observations linked transformation to uncontrolled cellular growth and to profound alterations in cell shape, as well as to the deregulation of tyrosine kinase and phosphatase activity. The first defined oncogene, *v-Src*, encodes an altered form of an important cellular tyrosine kinase, c-Src [286, 287]. In most studies on tumor cells, changes in morphology – but not cytoskeletal dynamics – have been reported.

The progression of cells from normal to a cancerous or even metastatic state is reflected in an increased softening of the cells, as probed by laser traps on suspended single cells [288]. Malignant fibroblasts, for example, have 30–35% less actin than normal cells. Transformed cells in culture often are rounder in morphology than primary cells. Tumor cells are also generally less adhesive than normal cells, and deposit less ECM [289], and the resulting loosened matrix adhesions may contribute to the ability of tumor cells to leave their original position in the tissue. In transformed cells, many aspects of nuclear and cell morphology as well as migration are altered. Focal adhesions can be replaced by podosomes and in addition, stress fibers can be absent [290]. Some transformed cells acquire anchorage independence – that is, they can grow without attachment to a substrate, suggesting a rigidity response deregulation. For example, transformed cells generate weak, poorly coordinated traction forces [291] but increased contractility. Thus, the one generality is that transformed cells can grow inappropriately, ignoring the mechanical cues of the environment that neighboring normal cells will follow to maintain appropriate tissue morphology. Although other factors, such as hormonal signals, form part of many cancers, the inappropriate mechanical responsiveness of cancer cells must also be considered as an important part of the process.

Cancer progression leads to a loss of tissue differentiation due to abnormal cell proliferation rates. Even if isolated malignant cells are associated with an increased softness of their overall cytoskeleton, it is equaly significant that tumors have a stiffer

ECM [145, 292, 293]. Malignant transformations of the breast, for example, are associated with dramatic changes in gland tension that include an increased ECM stiffness of the surrounding stroma [293]. Chronically increased mammary gland tension may influence tumor growth, perturb tissue morphogenesis, facilitate tumor invasion, and alter tumor survival and treatment responsiveness. However, changes in environmental factors (i.e. changes in ECM rigidity) and internal force generation (i.e. inappropriate rigidity responses) might be key factors in determining a transformed cell morphology and malignant phenotype [145]. For example, tumors are stiffer than normal tissue because they have a stiff stroma and elevated Rho-dependent cytoskeletal tension that drives focal adhesions, disrupts adherens junctions, perturbs tissue polarity, enhances growth, and hinders lumen formation [145]. Matrix stiffness thereby perturbs epithelial morphogenesis by clustering integrins to enhance ERK activation and increase ROCK-generated contractility and focal adhesions, thereby promoting malignant behavior [145].

Metastatic cells escape the tumor by invading the surrounding tissue, entering the circulation and finally attaching to previously unaffected tissues in often remote locations. In 1889, Stephen Paget published an article in *The Lancet* that described the propensity of various types of cancer to form metastases in specific organs, and proposed that these patterns were due to the "... dependence of the seed (the cancer cell) on the soil (the secondary organ)" [294]. This has often been linked to the chemical environment of the secondary organ, although recent results have indicated that it could also be a result of the mechanical environment in the secondary organ [295]. It was found that lung metastases from human breast cancer cells would grow better on soft fibronectin substrates than on hard, whereas bone metastases would grow better on hard than on soft (A. Kostic and M.P. Sheetz, unpublished results). Metastasis is an inefficient process, and many cancer cells are shed but few actually grow into a tumor at a new site. One reason for this is that the new site might not have the appropriate mechanical properties. At another level, tumor cells are generally less adhesive than normal cells and deposit less ECM [289]. The resulting loosened matrix adhesions, combined with the softened cytoskeleton, may contribute to the ability of tumor cells to leave their original position in the tissue and squeeze through tiny holes.

Many of the molecules discussed above play key roles in cancer progression, and also metastasis. Integrin-mediated cell adhesion leads to the activation of FAK and c-Src, after which the FAK–Src complex binds to and can phosphorylate various adaptor proteins such as p130Cas and paxillin. The results of recent studies have shown that the FAK–Src complex is activated in many tumor cells, and generates signals leading to tumor growth and metastasis (as reviewed in Ref. [296]). Tyrosine phosphorylation of paxillin regulates both the assembly and turnover of adhesion sites. Phosphorylated paxillin enhanced lamellipodial protrusions and thus promoted cell migration [126, 127]; the migration of tumor cells in 3-D matrices is then governed by matrix stiffness, along with cell–matrix adhesion and proteolysis [271]. As discussed above, the phosphorylation of p130Cas is upregulated when cells are located on a more rigid substrate.

The overall survival of breast cancer patients is inversely correlated with the levels of p130Cas (BCAR1) in the tumors [297] indicating that increased levels of p130Cas in

tumor cells contributed to patient death. It was subsequently found that cell migration was activated by p130Cas and the associated GEF (AND-34 or BCAR3), which indicated that metastasis was favored by elevated p130Cas [298]. Both, p130Cas and a p130Cas binding protein, AND34 (BCAR3), will increase the epithelial to mesenchymal transition when overexpressed [298]. p130Cas appears to have a central role in cell growth and motility; in many cases, it is dramatically altered in its phosphotyrosine levels in correlation with transformation [299–302] and metastasis [303]. In the specific case of lung tumors, metastasis was increased following removal of the primary tumor, and required p130Cas expression. Further, the substrate domain YxxP tyrosines were needed for both invasive and metastatic properties of the cells [304]. Even the invasion of Matrigel and the formation of large podosome structures required the YxxP tyrosines. Thus, it is suggested that the inappropriate growth of cancer cells may be partly due to changes in the normal force and rigidity-sensing pathways that can alter the cellular program. This means, in turn, that the protein mechanisms involved in controlling mechanical responses can be good targets for therapies in cancer. In addition, mechanical treatments can possibly alter the course of cancers. Several levels can be identified in the process of mechanosensing, transduction and response where alterations in cancer cells could result in abnormal growth control. For example, c-Src, Fyn and Yes knockout cells are each missing three important Src family kinases, and will grow on soft agar while not sensing any difference between soft and hard agar. However, the restoration of Fyn activity will enable the cells to sense rigidity, and they will no longer grow on soft agar [198]. Thus, an understanding of the mechanisms of force and rigidity sensing can provide an important perspective on cancer.

9.12.2 Angiogenesis

The growth of new blood vessels – that is, angiogenesis – is crucial not only in tissue growth and remodeling but also in wound healing and cancer. Vascular development requires correct interactions among endothelial cells, pericytes and surrounding cells [24]. Thus, the formation of new blood vessels might be compromised if any of these interactions – including cell–matrix interactions, both with basement membranes and with surrounding ECMs – are perturbed. Equally important, the injury-mediated degradation of the ECM can lead to changes in matrix–integrin interactions, causing an impaired reactivity of the endothelial cells that will lead to vascular wall remodeling. Consequently, alterations in integrin signaling, growth factor signaling, and even of the architecture and composition of the ECM, might all affect vascular development. As in other motility processes, angiogenesis involves a very stereotypical set of movements of the endothelial cells that result in the formation of capillary tubes.

The role and mechanisms by which mechanical forces promote angiogenesis remain unclear. It is notable, however, that angiogenesis is regulated by integrin signaling [305–308]. Angiogenesis is furthermore promoted by vascular endothelial growth factor (VEGF). As tumor neovascularization plays critical roles for the development, progression and metastasis of cancers, new therapeutic approaches to treat malignancies have been aimed at controlling angiogenesis by monoclonal

antibodies targeting VEGF, as well as with several tyrosine kinase inhibitors targeting VEGF-related pathways (for a review, see Ref. [309]).

VEGF binds to its transmembrane receptor by stimulated complex formation between VEGF receptor-2 and β_3 integrin. Prior studies have suggested, for example, that α_v-integrins ($\alpha_v\beta_3$ and $\alpha_v\beta_5$) could act as negative regulators of angiogenesis (as discussed in Refs [31, 32]). Neovascularization is impaired in mutant mice where the β_3 integrins were unable to undergo tyrosine phosphorylation [310]. The lack of integrin phosphorylation suppressed the complex formation with VEGF. Furthermore, the phosphorylation of VEGF receptor-2 was significantly reduced in cells expressing mutant β_3 compared to wild-type, leading to an impaired integrin activation in these cells. With its binding locations at both the N and C termini, VEGF also binds to fibronectin fibers [311, 312] and, when bound, has been shown to increase cell migration, proliferation and differentiation [311, 313, 314]. A reduced extracellular pH is one of the key signals that can induce angiogenesis. By demonstrating that VEGF binding to fibronectin is dependent on pH, and that released VEGF sustained biological activity, Goerges *et al.* [315] suggested that cells may use a lowered pH as a localized mechanism of controlled VEGF release [316]. Goerges and colleagues also suggested that VEGF might be stored in the ECM via interactions with fibronectin and heparan sulfate in tissues that are in need of vascularization, so that it can aid in directing the dynamic process of growth and migration of new blood vessels. If – and how – VEGF signaling is regulated by mechanical force, however, remains unclear.

Tumor blood vessels have an altered integrin expression profile, and both blood and lymphatic vessels have pathological lesions [28]. In contrast to healthy tissue, integrin β_4 signaling in tumor blood vessels promotes the onset of the invasive phase of pathological angiogenesis [317], while loss of the β_4 integrin subunit reduces tumorigenicity [318]. Integrin β_4 binds to laminin (Figure 9.5), which is enriched in basement membranes, but not to the RGD-ligand as exposed in fibronectin. Another difference from the RGD-binding integrins is that integrin β_4 connects to the cytoskeleton via plectin (not talin, as illustrated in Figure 9.7) [319], and little is known about the mechanoresponsivity of that linkage.

Another open question is whether degradation of the ECM is regulated by force. Exploring this question is of particular relevance since, in addition to serving as an anchoring scaffold and storage for growth factors, a group of angiogenesis regulators are derived from fragments of ECM or blood proteins. Endostatin, antithrombin and anastellin are members of this group of substances. Some of these compounds are currently undergoing clinical trials as inhibitors of tumor angiogenesis [320], as well as synthetic peptides modeled after these anti-angiogenic proteins, such as Anginex [321]. RGD-containing breakdown products of the ECM may also cause sustained vasodilation [87].

9.12.3
Tissue Engineering

Deciphering the mechanisms by which ECMs might sense and transduce mechanical stimulation into functional alterations of cell behavior and fate is also a critical

issue in advancing tissue engineering and regenerative medicine, as our abilities to interface synthetic materials with living soft tissue to promote angiogenesis and healing are still rather limited. Beyond artificial skin, few advances have been made when using synthetic scaffolds to grow functional soft organs or organ patches that can at least support some crucial physiological organ functions. The conventional thinking was that once surfaces are coated with the correct set of biomolecules, the cells might recognize them as 'biological'. If it will indeed be confirmed that cells have the ability to dynamically regulate the biochemical display of the surrounding matrix on demand by applying force, the currently pursued more 'static' approaches for designing tissue engineering scaffolds do neglect force as major regulatory factor of ECM function [322]. If the cells are in contact with synthetic surfaces, their ability to dynamically regulate the conformations of matrix proteins by stretching them might be compromised. A full appreciation of the engineering principles of adhesion molecules, and of the complexity by which ECM can respond to cell contractility [26], might thus lead to new approaches for how to better engineer the interface between cells and synthetic materials.

The engineering of scaffolds that can regenerate soft organs or support some soft organ functions remains a daunting task. Scaffolds derived from natural tissues or matrix proteins have so far shown significantly better clinical performance than their synthetic counterparts [323, 324]. The creation of a bioartificial heart, for example, requires the engineering of cardiac architecture, as well as of appropriate cellular constituents and pump function. A major breakthrough in bioartificial heart engineering has recently been reported [14]. While many approaches have been attempted in the past, some success was achieved by using decellularized organ-specific matrices as scaffolds. For this, hearts were first decellularized by coronary perfusion with detergents; this preserved the underlying ECM, the vascular architecture, competent acellular valves and an intact chamber geometry (Figure 9.20). After decellularization, collagens I and III, laminin and fibronectin remained within the thinned heart matrix. The fiber composition and orientation of the myocardial ECM were preserved, the ventricular ECM was retained, and the vascular basal membranes remained intact. In order to mimic cardiac cell composition, these decellularized heart matrices were reseeded first with cardiac and later endothelial cells [14], with macroscopic contractions being observed at day 4. By day 8, under physiological load and electrical stimulation, the constructs could generate a pump function (equivalent to about 2% of adult or 25% of 16-week fetal heart function). Notably however, perfusion and physiological stimulation were absolutely needed for tissue formation and to regain tissue function. The authors speculated that such organs, if matured even further, could become transplantable either in part (e.g. as a ventricle for congenital heart disease such as hypoplastic left heart syndrome) or as an entire donor heart in end-stage heart failure. The technique was subsequently applied to a variety of mammalian organs, including lung, liver, kidney and muscle. Ongoing studies are directed towards optimizing reseeding strategies to promote the dispersion of cells throughout the construct, *in vitro* conditions required for organ maturation, and the choice of stem or progenitor cells necessary to generate either autologous or off-the-shelf bioartificial solid organs for transplantation. In contrast,

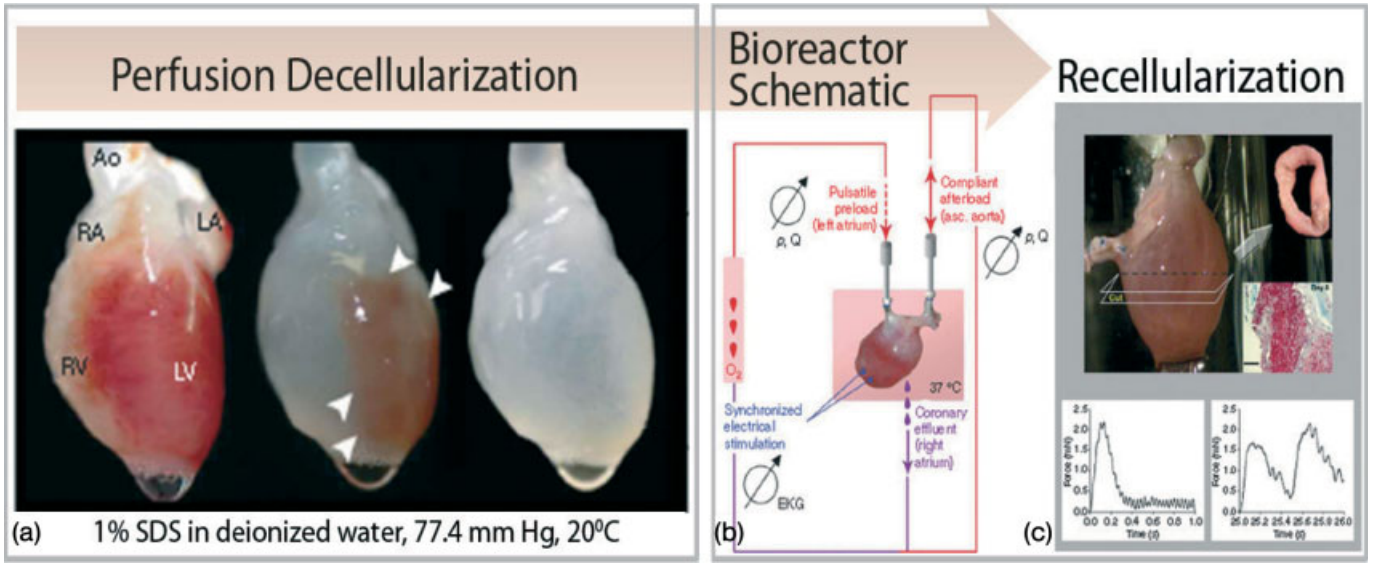

Figure 9.20 Decellularization and recellularization of a working heart-like construct. (a) Perfusion decellularization of whole rat hearts. Photographs of cadaveric rat hearts mounted on a Langendorff apparatus. Ao = aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. Retrograde perfusion of cadaveric rat heart using sodium dodecyl sulfate (SDS) over 12 h. The heart becomes more translucent as cellular material is washed out from the right ventricle, followed by the atria and finally the left ventricle; (b) Schematic of working heart bioreactor showing cannulation of the left atrium and ascending (asc.) aorta. The heart is exposed to physiological preload, afterload and intraventricular pressure, and electrically stimulated at 5–20 V. Oxygenated medium containing serum and antibiotics enters through the left atrium and exits through the aortic valve. Pulsatile distention of the left ventricle and a compliance loop attached to the ascending aorta provide physiological coronary perfusion and afterload. Coronary perfusate (effluent) exits through the right atrium; (c) Formation of a working perfused bioartificial heart-like construct by recellularization of decellularized cardiac extracellular matrix. Top, recellularized whole rat heart at day 4 of perfusion culture in a working heart bioreactor. Upper insert: cross-sectional ring harvested for functional analysis (day 8). Lower insert: Masson's trichrome staining of a ring thin section, showing cells throughout the thickness of the wall. Scale bar = 100 mm. Bottom: force generation in left ventricular rings after 1 Hz (left) and 2 Hz (right) electrical stimulation.

stem cells directly injected into scarred tissue, for example into an infarcted heart, are not properly directed by the matrix to form new myocardium [325]. Rather than injecting cells into rigidified scar tissue, tissue regeneration was far more effective when transplanting an entire monolayer sheet of mesenchymal stem cells [326]. The engrafted cell sheet gradually grew to form a thick stratum that included newly formed vessels, undifferentiated cells and few cardiomyocytes which might be promoted by the more favorable microenvironment that the cells would find if transplanted as sheets rather than being injected individually.

Early studies have already shown that matrix crosslinking would compromise the ability of tissue-derived matrices for use in functional reconstruction [327]. One of several reasons for this might be that crosslinking alters the rigidity of the matrix, and an upregulated rigidity response of the reseeded cells might interfere with regaining tissue function. Another – not necessarily exclusive – possibility is that crosslinking would inhibit the protein conformation changes caused by stretching the matrix fibers. It has been found that fibronectin fibers, for example, can be stretched on average more than five times their equilibrium length before they break [250, 251], whereas crosslinked fibers show a markedly decreased extensibility. Crosslinked cell-derived matrices cause an upregulated cellular rigidity response and alter the biophysical properties of the matrix that the newly seeded cells are generating [328]. Thus, force-induced protein unfolding in a newly deposited matrix is, at least in part, upregulated by crosslinking, with all the functional implications as discussed above. Another aspect of native matrix, that might be compromised by crosslinking, is its ability to serve as a scaffold for storing cytokines and growth factors and to release them upon demand. Integrins were also shown recently to play a central role in activating the matrix-bound cytokine transforming growth factor-beta 1 (TGF-β1) by cell-generated tension acting on the matrix [329]. TGF-β1 controls tissue homeostasis in embryonic and normal adult tissues, and also contributes to the development of fibrosis, cancer, autoimmune and vascular diseases. In most of these conditions, active TGF-β1 is generated by dissociation from a large latent protein complex that sequesters latent TGF-β1 in the fibronectin-containing ECM [330]. The studies of Wipff and colleagues might suggest that matrix stiffness could regulate the equilibrium between storage and release of a host of matrix-bound growth factors [331].

Finally, the fact that not only the intact ECM but also its breakdown products have regulatory functions, can be actively exploited in tissue engineering. Low-molecular-weight peptides derived from the ECM, for example, can act as chemo-attractants for primary endothelial cells [138]. ECM extracts were found to have antimicrobial activity [332], and fragments of ECM or blood proteins, including endostatin, antithrombin and anastellin, may serves as inhibitors of angiogenesis [321]. Moreover, these angiostatic peptides use plasma fibronectin to home to the angiogenic vasculature [321]. Finally, uncharacterized digestive products of the ECM seem to act as strong inflammatory mediators [333]. Extensive future investigations are required in order to provide a full comprehension of the multifaceted regulatory roles of the ECM and its constituents, and how forces might coregulate many of these functions.

Consequently, learning how to switch the structure–function relationship of proteins by force has far-reaching potential not only in tissue engineering but also

in biotechnology, and for the development of new drugs that might target proteins stretched into nonequilibrium states.

Acknowledgments

We gratefully acknowledge the many discussions with colleagues and our students, and thank in particular Sheila Luna for the graphics. Financial support was provided by the Nanotechnology Center for Mechanics in Regenerative Medicine (an NIH Roadmap Nanomedicine Development Center), the Volkswagen Stiftung, and various grants from NIH and ETH Zurich.

Stem Cells and Nanomedicine: Nanomechanics of the Microenvironment

Florian Rehfeldt, Adam J. Engler, and Dennis E. Discher

10.1
Introduction

Tissue cells in our body adhere to other cells and matrix and have evolved to require such attachment. While it has been known for some time that adhesion is needed for viability and normal function of most tissue cells, it has only recently been appreciated that adhesive substrates *in vivo* – namely other cells and the extracellular matrix (ECM) – are generally compliant. The only rigid substrate in most mammals is calcified bone. While the biochemical milieu for a given cell generally contains a wide range of important and distinctive soluble factors (e.g. neuronal growth factor, epidermal growth factor, fibroblast growth factor, erythropoietin), the physical environment may also possess very different *elasticity* from one tissue to another. It is well accepted that cells can 'smell' or 'taste' the soluble factors and respond via specific receptor pathways; however, it is also increasingly clear that cells 'feel' the mechanical properties of their surroundings. Regardless of the adhesion mechanism – that is, cadherins binding to adjacent cells or integrins binding to the ECM – cells engage their contractile actin/myosin cytoskeleton to exert forces on the environment, and this drives a *feedback* with responses that range from structural remodeling to differentiation. In this chapter, we aim to provide a brief overview of the diversity of *in vivo* micro/nano-environments in the human body, and also seek to describe some *mechanosensitive phenomena*, particularly with regards to adult stem cells cultured in *in vitro* systems and intended to mimic the elastic properties of native tissues.

10.2
Stem Cells in Microenvironment

10.2.1
Adult Stem Cells

Adult stem cells are distinct from embryonic stem cells (ESCs). Two properties are required for a stem cell: *self-renewal* and *pluripotency*. Stem cells must be able to

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

divide 'indefinitely' (or at least many times compared to other cells) and also maintain their undifferentiated state. They must be potent to differentiate into various lineages. The fertilized egg cell is *totipotent* because all possible cell types in the body are derived from it. Adult stem cells or somatic stem cells are *multipotent* and are not derived directly from eggs, sperm or early embryos, as are ESCs. Among the adult stem cells found in fully developed organisms, two classes are of paramount importance for both basic scientific inquiry and possible medical application: mesenchymal stem cells (MSCs) and hematopoietic stem cells (HSCs), both of which can be obtained from adult bone marrow (Figure 10.1).

For more than 50 years, it has been known that HSCs are present in the bone marrow and can differentiate into all of the different blood cell types. Becker and coworkers identified a certain type of cell in mouse bone marrow that, when transplanted into mice which had been heavily irradiated to kill any endogenous cells, would reconstitute the various HSCs: red blood cells, white blood cells, platelets, and so on [1]. Since then, the transplantation of HSCs has become a routine medical treatment for many blood diseases, such as leukemia. However, controversies persist regarding the differentiation and de-differentiation of HSCs, particularly whether or not they can become pluripotent, being able to differentiate into neurons, muscle or bone [2–5].

MSCs also reside in the bone marrow, and can certainly differentiate into various types of solid tissue cells such as muscle, bone, cartilage and fat. From human bone marrow, Pittenger and coworkers successfully isolated truly multipotent MSCs and also demonstrated *in vitro* differentiation into various lineages [6]. Using media cocktails – often composed of glucocorticoids such as dexamethasone – many other groups have since standardized their differentiation into different tissue lineages [7–13].

Unlike the adult stem cells, ESCs are derived from a newly fertilized egg that has divided sufficiently to form a blastocyst. Once isolated from the inner mass of the blastocyst, the ESCs are then cultured and expanded *in vitro* to produce a sufficient number of cells for study. These ESCs are pluripotent in that *all* organismal cell types in the developing embryo emerge from them. This cell type is therefore considered to be the most promising for cell therapy and regenerative medicine. On the other hand, major problems such as immune rejection are significant obstacles as ESCs will generally not be from the same organism.

Figure 10.1 *In vivo* microenvironments of adult stem cells: the physiological range of stiffness. (a) Range of physiological elasticity of native cells and tissue: mesenchymal stem cells (MSCs) reside in the bone marrow (see panel (b)), but can egress from their niche into the bloodstream and travel to different tissues and organs, facing new environments with a wide range of stiffness. Nerve cells and brain tissue (around and below 1 kPa) are softest, adipocytes are assumed to be slightly stiffer, while muscle has an intermediate stiffness (~10 kPa). The elasticity of chondrocytes is speculated to fall between myocytes and osteoids (precalcified bone precursors) that are very stiff ($E \sim 30$–50 kPa) prior to mineralization into bone (~MPa to GPa); (b) Hematopoietic stem cells (HSCs), as distinct from the MSC differentiation pathway, that also reside in the bone marrow niche are the precursor cells of all blood lineage-type cells. Within the bone marrow and between the marrow and the blood there are various gradients, for example, oxygen concentration, biochemical factors and, of course, viscoelasticity.

Stiffness

Regardless of the type of stem cell, it is essential to understand how the stem cell differentiates and in which ways it interacts with its environment, both within the niche and potential target tissues. Biochemical factors are key but not singular factors: mechanical cues in the microenvironment have only recently been recognized as contributing to the fate of MSCs.

In this chapter we focus on the nanomechanics of adult stem cells, as these cells interact with a substrate of well-defined stiffness. Stiffness – or, more formally, Young's elastic modulus, E (measured in Pascal (Pa)) – is a potential issue because of its physiological variation. That is, the only tissue in the body that is rigid is bone – all other solid tissues are soft, with elastic moduli in the range of 0.1 to 100 kPa (Figure 10.1a). Over the past decade, it has become particularly evident that the ability of an adherent cell to exert forces and build up tension reflects this elastic resistance of the surrounding microenvironment. This mechanosensitivity is based on the tension generated by ubiquitously expressed non-muscle myosins II (NMM II) which are the molecular motors that drive transduction. As with other class II myosins, such as skeletal muscle myosin (that moves all of our limbs against everyday), NMM II assembles into filaments. These NMM II minifilaments of ~300 nm length are bipolar with heads on either side that bind and actively traverse actin filaments [14]. In many situations involving moderately stiff substrates, actin–myosin assemblies are visible in cells as stress fibers, which is a prototypical contractile unit seen at least within cells grown on glass coverslips and other rigid substrates.

Of the three isoforms of NMM II (a–c), only non-muscle myosin IIa (NMM·IIa) appears prominent near the leading edge of crawling cells where cells probe their microenvironment, and is responsible for the bulk of force generation in non-muscle cells [15]. NMM IIa is also the only isoform that is essential in the developing embryo: [16] NMM IIa knockout mice fail to exhibit any functional differentiation beyond germ layers, in that they do not undergo gastrulation, and the null embryos die by day 7 *in utero*. Embryoid bodies grown in suspension culture also appear flat and flaccid, rather than spherical, which suggests weak and unstable cell–cell contacts, even though cadherins are clearly expressed. Such results highlight the fact that cell motors – as an active part of cell mechanics – are important even in the earliest stages of differentiation and development.

10.2.2
Probing the Nanoelasticity of Cell Microenvironments

Cells probe the elasticity of their microenvironment on the micro- and nanometer scale, whether the surroundings are tissue, ECM or an artificial culture substrate. Since this micro/nano-length scale is the range that cells can feel their surrounding, an appropriate experimental tool is needed to measure the elasticity on the same length scale. Perhaps the most suitable and pervasive technique for this is atomic force microscopy (AFM), which has been most widely used for imaging but can also make accurate force and elasticity measurements. The atomic force microscope exploits a microfabricated cantilever with a probe tip of well-defined geometry. This tip is pressed into the sample and the indentation depth as well as the required

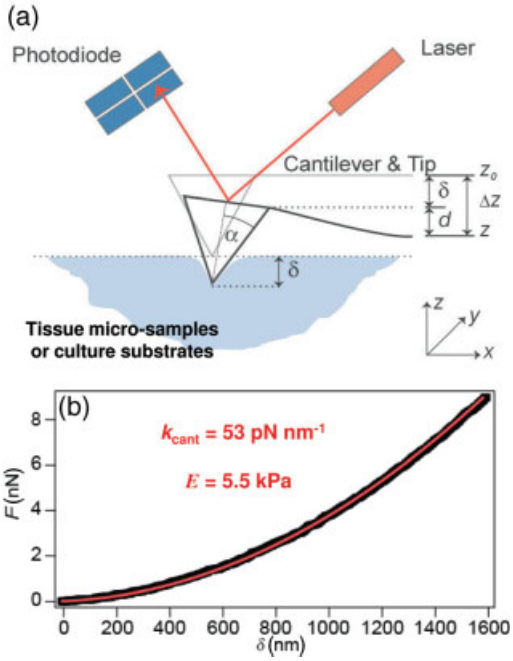

Figure 10.2 Probing the microelasticity by AFM. (a) Schematic of the measurement principle of Young's elastic modulus (E) of a hydrogel with AFM. A probe of well-defined geometry located at the tip of a cantilever with known spring constant k is pressed into the sample, and the deflection of a reflected laser beam is recorded with a four-quadrant photodiode. The required force F can be calculated by multiplying the deflection by the spring constant; (b) Force–indentation curve of a polyacrylamide gel with an elasticity of 5.5 kPa. The black points depict measured data; the solid red line represents the best fit of a modified Hertz model. (Reprinted with permission from Rehfeldt, F. *et al.* (2007) Cell responses to the mechano-chemical microenvironment – Implications for regenerative medicine and drug delivery. *Advanced Drug Delivery Reviews*, **59**, 1329–1339; © 2007, Elsevier.)

force is measured. The Young's elastic modulus E of the material surface can then be calculated from classical expressions and compared to bulk measurements, such as results from classic tensile tests.

AFM was developed during the 1980s by Binnig and coworkers [17], and was originally designed to investigate surfaces at the atomic scale with nanometer resolution. The instrument's ability to operate in a fluid environment has made it increasingly important for biological samples, and today it is used frequently to measure the nanomechanical properties of fre sh tissue samples [18], hydrogels for cell culture [18], and even living cells [19] as well as single proteins [20]. Many commercial AFM instruments allow for a precise measurement of forces, and have the ability to raster the sample at nanometer resolution, which permits mapping of a sample's elasticity.

The basic principle of AFM for determining the elasticity of a sample is sketched in Figure 10.2a. The cantilever's tip is pressed into the surface and the deflection of

the bent cantilever is monitored by a laser beam reflected onto a four-quadrant photodiode. The exerted force F can be calculated by multiplying the calibrated spring constant k of the cantilever with the measured deflection d.

$$F = k \cdot d$$

The fundamental problem of the deformation of two elastic solids was first described by Hertz in 1881 [21], and the classic Hertz model was subsequently refined and modified by Sneddon to take special geometries into account [22]. A pyramidal tip that is commonly used for imaging but also works for elasticity measurements is most simply approximated as a conical probe with an opening angle α. For this geometry, E can be calculated from

$$E = \frac{\pi(1-\nu^2)F}{\delta^2\, 2\tan\alpha}.$$

Here, F is the applied force of the tip, δ is the indentation depth of the probe into the sample, and ν is the Poisson ratio of the sample that is separately measured or can be estimated typically as 0.3–0.5.

Figure 10.2b shows a representative force indentation curve for a polyacrylamide hydrogel with a modulus of $E = 5.5$ kPa, an elasticity typical of soft tissues. The measured data points (black thick line) span a range of surface indentation (0–2000 nm) and surface forces (0–10 nN) that are typical of matrix displacements and cell-generated forces at focal adhesions [23]. AFM experiments involve measurements of the same surface THAT a cell would engage, and the results fit very well to a modified Hertz model (thin red line). The elastic modulus determined by this type of experiment only reflects the low frequency ($\sim$0.1–10 Hz) or quasi-static elasticity of the material, which is relevant to studies such as cardiac myocyte beating [23]. Additional techniques can address frequency-dependent viscoelasticity, which can be important for the interactions of cells and their surroundings. Several studies have shown a differential behavior of cells subject to an external static or oscillating force field, and a simple theoretical model seems to describe the cell response [24]. Though it seems unlikely that frequencies in the MHz range or higher will have an effect, timescales from milliseconds to hours are likely relevant when compared to processes of assembly and disassembly of actin filaments, microtubules, focal contacts and focal adhesions [25].

Frequency-dependent rheology measurements that not only encompass the static elasticity as a low-frequency limit but also measure dynamic viscous properties, are commonly performed with bulk samples using rheometers. Here, the hydrogel sample is placed between two parallel plates or a plate and a cone with very small angle (around 1°) and a well-defined stress is applied while the strain within the sample is measured. Using such a rheometer, Storm *et al.* investigated the complex rheology of several biopolymers (collagen, fibrin, neurofilaments, actin, vimentin) and polyacrylamide (PA) hydrogels, and found a nonlinear increase of the complex shear modulus with higher strain – so-called *strain-hardening behavior* [26]. In contrast to the biological gels, PA hydrogels exhibit a constant shear modulus over a large strain range. The nonlinear behavior found for biopolymers has clear, albeit unproven,

implications for cell–matrix interactions. With these instruments the bulk measures of the storage and loss modulus of the material can be determined, but they do not access the rheology on the cellular scale. AFM can be similarly used if, after the probe is indented into the sample (cells, gels, etc.), a sinusoidal signal is superimposed to measure the frequency-dependent viscoelasticty. Mahaffy *et al.* used this technique to determine the viscoelastic parameters for cells and PA gels, and found good agreement with bulk measurements, at least for PA gels [27]. Additional particle-based techniques include magnetic tweezers or magnetic twisting rheology, optical tweezers and two-particle passive rheology. Although beyond the scope of this chapter, Hoffman *et al.* have shown that the use of all these different microrheology tools converges towards a "...consensus mechanics of cultured mammalian cells" [28].

10.2.3
Physical Properties of *Ex-Vivo* Microenvironments

The microelasticity of freshly isolated tissue samples can also be determined using AFM, revealing tissue inhomogeneities vis-à-vis a lateral mapping of mechanical properties that macroscopic measurements cannot address. Thus, AFM serves as a mechanical analogue to histology as it could thus reveal microelasticity differences across diseased tissues, such as fibrotic regions.

At the whole-body scale, the elasticities of normal, soft tissue vary considerably (see Figure 10.1 and Table 10.1). Aside from bodily fluids such as blood, that obviously have zero elasticity, perhaps the softest solid tissue is the brain, with an elastic modulus of just $E \sim 0.1$–1 kPa [29–31]. Native mammary gland tissue has a similar elasticity ($E \sim 0.2$ kPa) [32]. The lateral elasticity of muscle, in its relaxed state, is significantly stiffer, with AFM probing yielding $E \sim 10$ kPa. Even at the subcellular level, myofibrils isolated from rabbit skeletal muscle have $E = 11.5 \pm 3.5$ kPa in the relaxed state [33]; this is consistent with the transverse stiffness of rat skeletal muscle measured under *in vivo* conditions ($E = 15.6 \pm 5.4$ kPa) [34], as well as the elasticity of both *ex-vivo* mouse *extensor digitorum longus* (EDL) muscle ($E \approx 12 \pm 4$ kPa) and one-week cultures of C2C12 myotubes ($E \approx 12$–15 kPa) [35]. Bone is of course the stiffest material in the body, with a modulus in the region of GPa after calcification; however, bone is a composite of protein plus mineral, and precalcified bone or 'osteoid' is

Table 10.1 Elastic modulus E of normal and diseased* tissues.

Type of tissue	Elastic modulus E [kPa]	Reference(s)
Brain (macroscopic)	0.1–1	[29–31]
Mammary gland tissue	~0.2	[32]
Muscle (passive, lateral)	~10	[33,34]
Osteoid (secreted film in culture)	30–50	[36–38]
*Mammary gland tumor tissue	~4	[32]
*Dystrophic muscle	~18	[39]
*Infarcted myocardium (surface)	~55	[42]
*Granulation tissue	~50	[41]

a heavily crosslinked network of collagen-I plus other matrix proteins such as osteocalcin [36–38] with an elastic modulus of 30–50 kPa. All of the measurements above indicate that the physiological range of the elasticity of soft solid tissues ranges from 0.1 kPa up to 100 kPa.

Abnormal or diseased tissue can exhibit an elasticity which is significantly different from normal tissue. 'Sclerosis' is Greek for 'hardening of tissue', and is a descriptor of many diseases, such as atherosclerosis, that refers to a hardening of the arteries. In the context of muscle, one AFM study has shown that the muscle of mice with dystrophy has an elevated stiffness of 18 ± 6 kPa in comparison to $E \approx 12 \pm 4$ kPa for healthy tissue [39], a difference which previously had only been described in bulk [40]. Commonly found granulation tissue after wound healing exhibits an elastic modulus of $E = 50 \pm 30$ kPa, which is three- to fivefold higher than that of normal tissue [41]. Following a myocardial infarction, the myocardium is also remodeled with fibrosis that stiffens the tissue significantly: AFM measurements have shown healthy rats with a normal myocardial $E = 10$–20 kPa that increases threefold to $E = 55 \pm 15$ kPa within the infarcted region [42]. Another significant increase in tissue stiffness from the native to the diseased state is observed in tumorigenesis. The average mammary gland tumor stiffens 20-fold to $E \approx 4 \pm 1$ kPa compared to 0.2 kPa for the normal tissue [32]. In addition to fibrosis, cell tension generally stiffens the cells and tissues; this is apparent even with isolated myofibrils that exhibit an order of magnitude increase in stiffness (relaxed: $E = 11.5 \pm 3.5$ kPa to rigor: $E = 84.0 \pm 18.1$ kPa) [33]. Whether hardening is part of the key initial causes, or simply a late after-effect of a disease, is presently unclear. Nonetheless, it seems reasonable to hypothesize that hardening contributes to the cycle of disease in many cases, with a likely basis in how cells feel normal soft tissue versus abnormally hard (sclerotic) tissue. Addressing tissue hardening in regenerative medicine would seem an important aspect of therapy.

10.3 *In Vitro* Microenvironments

Different tissue cells reside in a range of very different microenvironments *in vivo*. In order to assess biological questions in rigor, however, it is necessary to culture cells, and the first reports of culturing tissue cells *in vitro* date back to the start of the twentieth century. With time, techniques and protocols have become increasingly sophisticated, allowing the growth and maintenance of a wide variety of primary cells and cell lines. The introduction of serum-free media with well-defined soluble supplements during the 1970s opened up the possibility to investigate the effects of growth factors and other factors on cultured cells. Polystyrene (PS) cell culture flasks facilitated large-scale sterile cultures, while glass coverslips have allowed very high-resolution microscopy of live cells in culture. However, both types of material substrates – as ubiquitous as they are – are very rigid with an elastic modulus in the range of MPa or GPa, which is many orders of magnitude higher than the mechanical properties that cells encounter *in vivo* (see Figure 10.1 and Table 10.1). The difference

contributes to the distinct differences between cells cultured *in vitro* compared to those cultured *in vivo*. For example, cells grown on tissue culture plastic or glass very often exhibit 'stress fibers' that are not found *in vivo* and seem to reflect the mechanical stresses applied isometrically to rigid substrates. In the same way that more sophisticated media cocktails have been formulated and continue to be generated in order to dissect the different biochemical stimuli that affect tissue cells, there is growing effort with different substrates to better mimic the various physical and mechanical properties that cells encounter in soft tissues.

10.3.1
Cells Probe and Feel their Mechanical Microenvironment

In 1980, Harris and coworkers demonstrated that most cell types actively exert forces on their substrates [43]. The culture of 3T3 fibroblasts on thin silicone rubber films showed that these cells actively deform these films, generating a wrinkling pattern (Figure 10.3a). Opas demonstrated a decade later that chick retinal pigmented epithelial (RPE) cells exhibit a differential response to substrates that are rigid or viscoelastic, despite a similar surface composition [44]. On a thick compliant Matrigel substrate, the cells did not spread and remained heavily pigmented. In contrast, on the rigid glass substrate that was covalently coated with soluble basement membrane (Matrigel), the cells spread, developed stress fibers, vinculin- and talin-rich focal contacts, and expressed the dedifferentiated phenotype. These results were perhaps the first to suggest the mechanosensitivity of cells to substrate flexibility, although the study was far from conclusive: rather, it was limited to only two conditions with

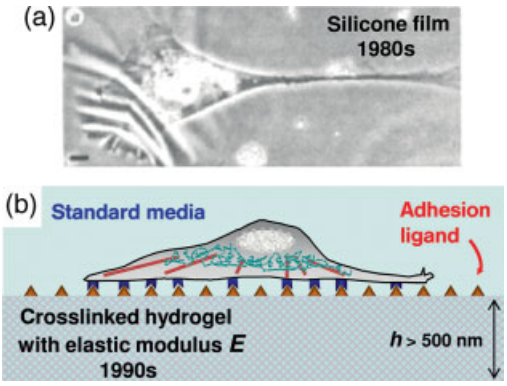

Figure 10.3 Cells pull and feel their mechanical environment. (a) 3T3 Fibroblasts cultured on a thin silicone rubber film exert forces that result in substrate wrinkling. Scale bar = 10 µm. (1981) Fibroblast traction as a mechanism for collagen morphogenesis. *Nature*, **290** (5803), 249–251; © 1981, Macmillan Publishers Ltd); (b) *In vitro* model system for cell culture on a flexible substrate. The elastic substrate with its Young's modulus *E* is coated with a ligand (e.g. collagen-I) for cell attachment. The cell attaches to this ligand and senses the elasticity via tension of actin–myosin complexes and/or stress fibers that are coupled to the substrate via integrins and other cell-surface receptors.

obvious compositional differences, namely rigid functionalized glass and soft Matrigel, and there were no quantitative measurements of substrate elasticity.

The study of cell mechanics on flexible substrates was significantly advanced in 1997 by Pelham and Wang, with their seminal studies on epithelial and fibroblast cell lines cultured on a range of collagen-I coated, elastic PA hydrogels [45]. An adhesive ligand in such studies is always needed because PA gels are not adhesive to cells (i.e. they do not engage integrins); collagen-I is a logical first choice for an ECM ligand because it is one of the most abundant proteins in mammals – which means of course that cells are very likely to encounter this protein in an organism. By using different crosslinker concentrations, a set of gels ranging in elastic modulus with an otherwise identical surface was generated. With this *in vitro* culture system, distinct differences were exhibited by cells on soft and stiff matrices: cells were seen to spread more on stiffer substrates, and also exhibited more typical focal adhesions on stiffer substrates. It was also clear that non-muscle myosin is a key player in generating force in the mechanosensitivity. When exposed to the common myosin inhibitors of the time (2,3-butanedione monoxime or KT5926), the cells could no longer distinguish between soft and stiff substrates. The effects on cell motility also have become clear: fibroblast cells that approached the transition from the soft side could easily migrate to the stiffer side, with a simultaneous increase in their spread area and traction forces [46]. In comparison, cells on the stiffer side of the gel often turned around or retracted as they reached the border. This dependence of cell movement on purely physical properties of the substrate has been termed *durotaxis*, and clearly shows that cells probe and feel the mechanics of their microenvironment.

Although these initial studies very elegantly demonstrated the differential responses of cells to substrate elasticity, the precise connections to *in vivo* microenvironments, as well as the role that diseases play in matrix stiffness, remained unclear and required further exploration. Measurements of elasticity were also only approximate: they were made by estimating indentations with steel balls of known weight. Different tissues often exhibit characteristic elasticities and can have significant alterations in disease (as discussed in Section 10.1). Engler and coworkers cultured myoblasts on the same collagen-I-coated PA gel systems with a wide range of AFM-determined elasticities, and showed that fusion into myotubes was not significantly affected, whereas myosin–actin striation was most prominent within cells grown on substrates with $E = 12 \pm 5$ kPa, which corresponds to the native muscle elasticity [39]. Gel substrates that were too stiff, as well as rigid glass, inhibited the formation of striated actin–myosin fibers. Striation was weak in myotubes on 18 kPa gels emulating dystrophic muscle, suggesting a significant counterinfluence against differentiation in disease.

In the context of wound healing, Goffin *et al*. examined fibroblast adhesion and cytoskeletal organization in cells on surfaces of different rigidity [41]. These cells play an essential role in wound healing and tissue remodeling as they migrate to wounded tissue and can develop stress fibers and tension to facilitate wound closure and healing. Using substrates that simulate normal soft tissue and stiffened wounded tissue, more contractile and differentiated myofibroblasts were only seen on the stiffer substrates. In addition, 'supermature' focal adhesions (suFAs) were found to develop only on rigid substrates and to exert a fourfold higher stress on the

matrix than was exerted under more typical focal adhesions formed on 11 kPa gels. It was proposed that this is a means by which the matrix influences the tension that the cells apply and therefore helps to steer the wound-healing process.

Similar findings were recently reported for liver-derived portal fibroblasts and their differentiation to myofibroblasts *in vitro* on PA substrates in the presence or absence of transforming growth factor-β (TGF-β) [47]. When these fibroblasts differentiate towards myofibroblasts – as occurs in response to an acute liver injury – they start to express α-smooth muscle actin (α-SMA) and form stress fibers on rigid surfaces (>3 kPa), but not on very soft (400 Pa) gels that resemble the elasticity of native rat or human liver tissue. When treated with 100 pM TGF-β the portal fibroblasts began to express α-SMA even on the soft matrix, although they did not develop organized stress fibers; stiffer matrices were required for cell spreading and stress fiber organization. Cells treated with 5 μ*M* TGF-β receptor kinase inhibitor did not differentiate on any of the substrates, which suggests that TGF-β functions as an essential contractile inducer in these cells (opposite to myosin inhibitors), leading to higher α-SMA expression and stress fiber organization as stiffer substrates. Both, biochemical and biophysical stimuli are thus part of the complex interplay of mechanosensing.

10.3.2
Cells React to External Forces

The responses of cells to physical cues in their microenvironment – namely elasticity and geometry – are not the only physical factors of importance. Cells also react to external forces, and forces are found throughout an organism. Muscles contract and relax, joints are compressed during standing, walking and running, and the average human heart beats 72 times each minute to keep our blood circulating, which leads to shear stresses on the surfaces of endothelial cells. The effects of external forces on cells have been widely studied, although it is often not clear to what extent the force-generation capabilities of cells are again part of the response.

Several studies have documented the influence of both static and dynamic strains on cells. For example, C2C12 mouse myoblasts cultured for several days on a substrate that is subject to a continuous, unidirectional stretching leads to alignment and elongation of the cells [35]. This applied static strain mimics the *in vivo* conditions of long bone growth and muscle development. Another investigation of fibroblast morphological changes in collagen matrices under a mechanical load [48] revealed cell alignment with the direction of the external force to minimize their exposure to the strain. In contrast to the parallel alignment in the case of static strain, several studies have also reported a more perpendicular orientation for rapidly oscillating external forces [49–52]. Experimental results such as these provide insight into potential mechanisms in development and repair of connective tissue.

Experiments are many, but theories are few and would benefit in understanding and predicting. Safran and coworkers have modeled the cell as a contractile dipole in an external force field [24]. This coarse-grain model of a cell aligns parallel to a static or quasistatic external oscillating force field, but it orients perpendicular to the field if the frequency is too high to follow. This is analogous to an electric dipole in an

oscillating electromagnetic field. The model not only agrees with experimental evidence but also demonstrates the applicability of basic physical concepts to cell mechanics.

10.3.3
Adult Stem Cell Differentiation

The impact of substrate elasticity on cell behavior is now evident in many studies. One last – but central – example for this chapter perhaps highlights the potent influence of elastic matrix effects, namely the differentiation of adult stem cells (MSCs) [53]. The usual method for inducing the differentiation of MSCs towards any particular lineage (e.g. adipocytes, chondrocytes, myocytes, osteocytes) is to use media cocktails based on steroids and/or growth factors [6–13]. Our approach has been to use a single, 10% serum-containing media and to vary only the stiffness of the culture substrate in sparsely plated cultures. These cells are exposed to serum *in vivo*, but during natural processes of emigration from the marrow to repair and maintain tissue, they also encounter different micromechanical environments. It is this latter aspect of environment that we sought to mimic.

MSCs were plated on collagen-I PA hydrogels of different elasticity E (Figure 10.3b) and found to exhibit after just 4 h a significantly different morphology that becomes even more pronounced over the next 24 to 96 h (Figure 10.4a). The cells spread more with increasing substrate stiffness, as found with other cells [45], but they also take on different morphologies. As the cells are multipotent, it was of further interest to assess whether substrate mechanics could also influence gene transcription, and therefore differentiation. Immunostaining for early lineage specific proteins indeed revealed that the neurogenic marker, β3 tubulin was only present on the softest 1 kPa gels, the myogenic transcription factor MyoD was most prominent on the 11 kPa gels, and an early osteogenic transcription factor, CBFα1, was detectable only on the stiffest 34 kPa substrates. Remarkably, these stiffnesses that induced differentiation correspond to the elasticities that the various lineages would experience in their respective native tissues: quantitative analyses of differentiation markers emphasizes the finding that adult stem cells adjust their lineage towards the stiffness of their surrounding tissues (Figure 10.4b).

Figure 10.4 (*Continued*) increase of any of the three proteins. Dashed green and orange curves depict the substrate-dependent upregulation of the markers for already committed cells [C2C12 (muscle) and hFOB (bone)] exhibiting the same qualitative behavior at a higher intensity due to their committed nature; (c) Transcription profiling array shows selective upregulation of several lineage-specific genes due to matrix elasticity. Values for MSCs cultured on PA gels for one week were normalized by β-actin and then further normalized with data obtained from naïve, undifferentiated MSCs before plating. Red depicts relative upregulation; green shows downregulation. Gene transcripts of the different lineages are upregulated only on the substrates with the appropriate stiffness; blebbistatin treatment inhibits this upregulation and thus differentiation. (Reprinted with permission from Engler, A.J. *et al.* (2006) Matrix elasticity directs stem cell lineage specification. *Cell*, **126**, 677–689; © 2006, Elsevier).

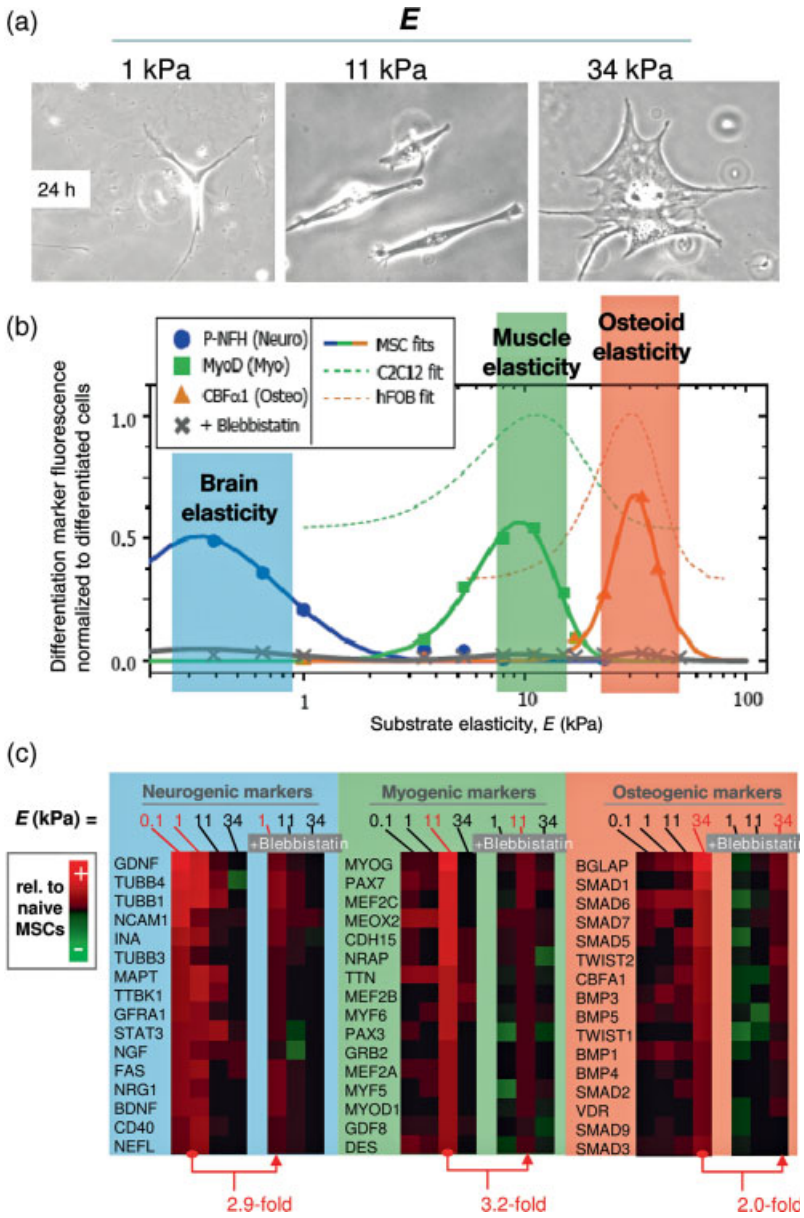

Figure 10.4 Differentiation of adult stem cells guided by matrix elasticity. (a) Mesenchymal stem cells (MSCs) on collagen-I coated PA gels with different elasticities ($E = 1$ kPa; 11 kPa; 34 kPa) show distinct morphology at 24 h after plating; (b) Quantitative immunofluorescence of the lineage markers (blue, P-NFH (neuro); green, MyoD (muscle); orange, CBFα1 (osteo)) reveals the stiffness-dependent differentiation of the MSCs. The multipotent stem cells upregulate differentiation markers only on substrates yielding a stiffness in the range of the native tissue, respectively. The gray curve of blebbistatin-treated cells shows no selective

Treatment of the MSCs with blebbistatin, a potent, recently synthesized NMM II inhibitor, largely blocked the expression of any of the differentiation markers, and again highlighted the key role of this motor in sensing the substrate in mechanoguided differentiation. Repeating the same experiment with two cell lines that were already committed (C2C12 mouse myoblasts and hFOB, human osteoblasts) showed a similar upregulation of the differentiation marker according to the tissue-level elasticity, but there was also a higher, baseline level of expression that reflected the fact that these cells were already committed. This led to a new hypothesis of differentiation mechanisms suggesting that both biochemical and biophysical stimuli influenced the differentiation of these *multipotent* adult stem cells.

Transcript profiling of some of the most commonly accepted lineage markers was used to more broadly assess lineage specification by matrix. The top-16 genes profiled for neuro-, myo- and osteo-genesis show selective upregulation of several relative to the naïve undifferentiated MSCs before plating (Figure 10.4c). Consistent with protein markers, it can be shown that β3 tubulin is the sixth-ranked gene on the softest 0.1–1 kPa gels, MyoD is the 14th-ranked gene on the 11 kPa gels, and CBFα1 is the seventh-ranked gene on the stiffest 34 kPa matrices. Also consistent with the downregulation of protein with blebbistatin treatment, the transcripts also exhibited a downregulation of about two to threefold.

Further examination of differentially expressed genes is revealing. Neural growth factors such as glial-derived neurotrophic factor (GDNF) and nerve growth factor (NGF) are upregulated on softer matrices. GDNF is interesting because its most prominent feature is its ability to support the survival of dopaminergic and motor neurons. The latter neuronal populations die during the course of amyotrophic lateral sclerosis (ALS). Myostatin (GDF8) is upregulated on the 11 kPa myogenic matrix and secreted by skeletal muscle cells; it is understood to circulate and act as a negative regulator of muscle mass, slowing down the myogenesis of muscle stem cells. Several bone growth factors (e.g. bone morphogenetic proteins: BMP 3, 4, 5) are upregulated on the stiffest osteogenic matrices. These proteins are interesting as potent osteoinductive growth factors belonging to the TGF-β superfamily, which was described in Section 10.2.1 as promoting stress fibers in fibroblasts on stiff matrices. This is very consistent with stress fiber assembly seen also in the MSCs [53]. Follow-up studies are certainly required to assess the secretion of these factors as well as autocrine–paracrine loops, although matrix elasticity is clearly the initiating factor throughout. Additionally, the many transcription factor genes listed (e.g. STATs, MYFs, MEFs and SMADs), as well as the many cytoskeletal and adhesion transcripts (e.g. NCAM, TTN and BGLAP (or osteocalcin)) make for a compelling story of how these MSCs physically interact with their microenvironment and reprogram their gene expression accordingly.

10.3.4
Implications for Regenerative Medicine

MSCs are believed to have considerable potential for cell therapies and regenerative medicine. Taking into account the impact of the microenvironment (as described

above), it perhaps becomes clear how important it is to carefully assess potential applications of these cells.

One application which currently is undergoing major exploration is the injection of purified and enriched MSCs into a stiffened infarct of the heart – a technique known as *cellular cardiomyoplasty*. The hope is that these adult stem cells will differentiate to cardiomyocytes and improve contractile function, although recent animal models and even clinical trials have yielded mixed results at best [42,54–56]. For example, in one rat infarct model, the injection of human-MSCs was found to marginally improve myocardial compliance as determined using AFM [42], but the MSCs did not regenerate the infarcted heart muscle tissue. Working strictly with a mouse model, Fleischmann and coworkers also injected MSCs into an infarcted myocardium [55] and, two to four weeks after injection, identified encapsulated calcifications and ossifications in the infarcted zone. These compartments were clearly restricted to the scarred region of the infarct where the elastic modulus E is much higher than that of native cardiac muscle. Interestingly, when MSCs were injected into intact non-infarcted hearts, calcifications and ossifications occurred only on the scar tissue along the injection channel. These findings were in excellent agreement with the *in vitro* studies of Engler *et al.* [53], where osteogenesis of MSCs was found on matrices having an elasticity in the range of 30–50 kPa (Figure 10.4) – that is, the stiffness of postinfarct scar tissue.

For future experiments and clinical trials, it will be of paramount importance to clearly dissect all of the possible cell stimuli in order to at least avoid negative implications for the patient such as calcifications. Our cells live in a 'world' of biophysics and biochemistry, and it seems necessary to understand and control parameters of both sides.

10.4
Future Perspectives

This chapter could only highlight some of many studies on the implications of the *mechano*-chemical environment of cells, even this small selection underscores the importance of a better understanding of the interactions between cells and environment to improve the design of therapeutic applications. Adult stem cells are probably one of the most promising candidates for successful tissue regeneration, given their multipotency, availability and limited ethical considerations, although their interactions with the microenvironment must be taken into account. Further studies must elucidate the complex interplay of biochemistry and biophysics, and should identify ways to influence either side with stimuli from the other. As a prime example, approaches to repair the infarcted heart reveal how new strategies are needed to overcome the physical limitations of a fibrotic tissue. Perhaps it is possible to alter the cell's perception of the surrounding stiffness so that adult stem cells could develop towards a suitable myogenic lineage (instead of osteogenic)? This is clearly a large playground for future studies of what are ultimately diseases that couple to cell mechanics.

The Micro- and Nanoscale Architecture of the Immunological Synapse

Iain E. Dunlop, Michael L. Dustin, and Joachim P. Spatz

11.1
Introduction

In vivo, biological cells come into direct physical contact with other cells, and with extracellular matrices in a wide variety of contexts. These contact events are in turn used to pass an enormous variety of cell signals, often by bringing ligand–receptor pairs on adjacent cells into contact with each other. Whereas, some traditional outlooks on cell signaling arguably focused strongly on these individual ligation events as triggers for signaling cascades, it is now becoming clear that this is insufficient. Rather, in some cases where signal-activating ligands are found on cell or matrix surfaces *in vivo*, the properties of each surface as a whole need to be considered if the events leading to signaling are to be fully understood. That is, the strength of signaling – and whether signaling occurs at all – can depend on factors such as the spatial distribution of signaling-inducing ligands that are presented on a surface, the mobility of these ligands, the stiffness of the substrate, and the force and contact time between the surface and the cell being stimulated [1]. The effects of such surface properties on the activation of cell signaling pathways can often be studied by bringing the cells into contact with artificial surfaces, the properties of which can be controlled and systematically varied, so that the effects of such properties on signaling pathway activation can be observed. These studies have been successfully conducted in the context of signaling pathways associated with cell behaviors such as fibroblast adhesion to the extracellular matrix (ECM) [2, 3] and rolling adhesion of leukocytes [4, 5]. One important system in which cell–cell communication has been studied is the immunological synapse formed between T lymphocytes and tissue cells at multiple stages of the immune response.

We first introduce the role of T cells in the immune response and the concept of an immunological synapse (for an introduction to immunological concepts, see Ref. [6]). T cells are an important component of the mammalian adaptive immune system, and each of the billions of T cells in a mammal expresses a unique receptor generated by the recombination of variable genomic segments. This can then serve as a substrate

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

for the selection of pathogen-specific T cells suitable for combating only infections by identical or similar pathogens, the proteomes of which share a particular short peptide sequence, known as the T cell's *agonist peptide*. There are three main subclasses of T cell, classified according to their effector functions: helper-, killer- and regulatory T cells. Broadly speaking, helper T cells act to stimulate and maintain the immune response in the vicinity of an infection, whereas killer T cells are responsible for detecting and destroying virus-infected cells. Regulatory T cells play a role in the prevention of autoimmune disease. In this chapter we will concern ourselves almost entirely with the activation of helper T cells. As the number of possible pathogens is enormous, the body does not maintain large stocks of T cells of a wide variety of specificities, but rather maintains small numbers of inactive T cells of each possible specificity in locations such as the lymph nodes and the spleen. When a pathogen is detected in the body, specialist antigen-presenting cells (APCs) travel to these locations and locate the correct T cells to combat the infection. This causes the T cells to become *activated*, whereupon they proliferate, producing a large number of T cells that travel to the infected tissues to carry out their antipathogen roles. Activation of the T cell occurs during direct physical contact between the T cell and the APC, and proceeds via the formation of a stable contact region between the T cell and the APC, known as the immunological synapse. (The term 'synapse' was applied due to a number of shared features with neurological synapses, such as stability, a role for adhesion molecules and directed transfer of information between cells [7].) It is known that one of the central requirements for activation is the ligation of T-cell receptors (TCRs) on the T-cell surface by peptide-major histocompatibility complex protein (p-MHC) complexes on the APC surface. The MHC may be thought of as a molecule in which the APC mounts short peptides made by breaking down all proteins in the cytoplasm (MHC class I) or in the endocytic pathway (MHC class II), including both pathogenic and 'self' proteins. As MHC class II molecules are relevant for helper T cells, we will focus on these from here on. Each TCR molecule strongly binds MHC molecules that mount the agonist peptide, and weakly binds MHC molecules that mount a subset of self-peptides. These strong and weak interactions synergize to generate sustained signals in the T cell. Thus, the APC activates only the correct T cells to combat the particular infection that is under way due to the necessary role of the agonist peptide in T-cell activation, but does so with great sensitivity (early in infection) due to the contribution of the self-peptides [8].

In addition to the initial activation process, helper T cells may encounter other agonist p-MHC-bearing APCs later in the infection process with which they can also form immunological synapses. This is particularly important in the infected tissues, where helper T cells coordinate responses by many immune cell types. The signaling from these synapses effectively informs the T cells that the infection is still in progress, encouraging them to continue countering it locally. Although there are differences between the initial activation process and these subsequent restimulations, similar signaling methods may underlie them both, and we will usually not be concerned with such distinction in this chapter. Although most of the agonist peptide-specific T cells will die when the infectious agent has been eliminated from the body, a small subset will live on as 'memory' T cells and can facilitate the mounting of a response to

reinfection with the same or closely related agents at a later time [9–11]. In fact, memory T cells are the basis of vaccination, and the process by which they are reactivated is likely to be similar in its requirements for immunological synapse formation.

Although TCR–p-MHC ligation is necessary for T-cell activation, there is evidence that the structure of the T cell–APC contact zone on a wide variety of length scales from tens of micrometers down to one to a few nanometers plays a role in determining the strength of activation signaling. Artificial surfaces functionalized with p-MHC and other immune cell proteins have been used to study structures that arise in the contact zone, and their effect on the activation process.

In this chapter, we will review the emerging body of work in which surface functionalization and lithography techniques have been used to produce artificial surfaces that have shed light on the nature and dynamics of the immunological synapse. We will first consider the structure of the immunological synapse on the micrometer scale, including the so-called supramolecular activation clusters (SMACs). These are essentially segregated areas in which different ligated receptor species predominate. Although SMACs have been widely studied, it now seems unlikely that they are the critical structures in providing activation signaling, with smaller-scale microclusters consisting of around 5–20 TCR–p-MHC pairs bound closely together being of greater significance [12]; these microclusters will also be discussed. We will then describe experiments that demonstrate the importance of the spatial distribution of molecules on the nanometer scale – that is, one to a few protein molecules – using materials such as soluble p-MHC oligomers to stimulate T cells. By illustrating the importance of the nanoscale, these results should motivate future studies in which T cells are brought into contact with surfaces that are patterned on a nanometer scale with p-MHC and other immunological synapse molecules. We will then discuss an emerging nanolithography technique that could plausibly be used to perform such studies, namely block copolymer micellar nanolithography. Finally, we will consider the possibility of making direct therapeutic use of micro- and nanopatterned T-cell-activating surfaces, and conclude that the most likely application is in *adoptive cell therapy*. In this method, T cells are removed from a patient, expanded *in vitro*, and returned to the patient to combat a disease – most commonly a cancerous tumor. It has been suggested that the success of adoptive cell therapy can depend heavily on the detailed phenotype of the returned T cells; the use of micro- and nanopatterned surfaces for *in vitro* T-cell activation could help to control their phenotype.

11.2
The Immunological Synapse

11.2.1
Large-Scale Structure and Supramolecular Activation Clusters (SMACs)

The immunogical synapse is a complex structure, which features a number of important ligand–receptor interactions in addition to the crucial TCR–p-MHC

interactions. The artificial substrates discussed here are based on a simplified model of the synapse that includes two of the most significant ligand–receptor pairs: TCR with p-MHC, and lymphocyte function-associated antigen 1 (LFA-1) with intracellular adhesion molecule 1 (ICAM-1). LFA-1 is an integrin-family protein, the function of which is to control T cell to APC adhesion. LFA-1 is expressed on T cell surfaces and binds ICAM-1 on the APC surface.

A major contribution to the understanding of the immunological synapse has been derived from studies in which T cells are allowed to settle on glass substrates on which lipid bilayers have been deposited. These bilayers contain some lipid molecules that are bound to protein constructs containing the extracellular portions of p-MHC and ICAM-1, respectively. Due to the fluidity of the lipid bilayer, the p-MHC and ICAM-1 are mobile, creating a simplified model of the APC surface (see for example, Refs [12–15]). Although a simplified system, this model reproduces features of immunological synapses observed *in vivo* with some types of APC, for example the so-called *B cells*; differences between these synapses and those observed between T cells and so-called *dendritic cells* (another type of APC) may be due to the dendritic cell cytoskeleton's restricting and controlling of p-MHC and/or ICAM-1 motion [16].

On the largest length scales, the evolution of the synapse can be seen to proceed in three stages, as illustrated in Figure 11.1 [13]. In the first stage, the T cell is migrating over the model bilayer surface; this corresponds to an *in vivo* T cell forming transient contacts with passing APCs. A central core of adhesive LFA-1–ICAM-1 contacts forms, around which the cytoskeleton deforms to produce an area of very close contact between the cell and the substrate, in which TCR with agonist p-MHC pairs can readily form. This cytoskeletal deformation is important, as TCR and p-MHC molecules are both rather short and consequently easily prevented from coming into contact by abundant larger glycosolated membrane proteins [13]. Signaling arising from the formation of TCR–p-MHC pairs causes LFA-1 molecules to change their

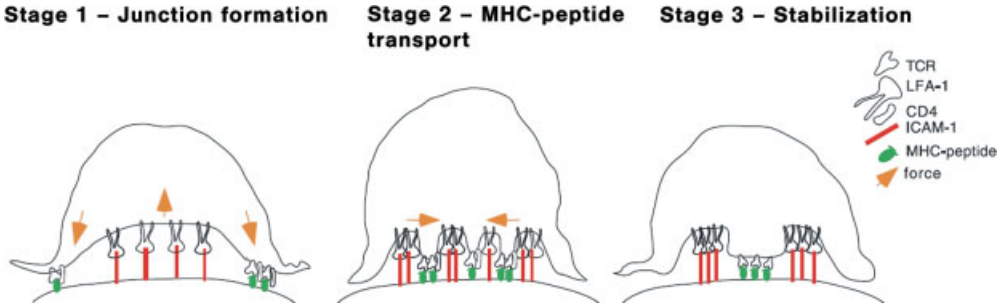

Figure 11.1 Schematic showing the three stages in the formation of the immunological synapse. A detailed description is provided in the text. Briefly, in stage 1, a central area of ICAM-1 ligating LFA-1 forms, around which the cytoskeleton rearranges to give a narrow zone in which p-MHCs can readily ligate TCRs. In stage 2, p-MHC-ligated TCRs move to the center of the contact zone, leading to stage 3, where a central area rich in TCRs and p-MHCs (the cSMAC) is surrounded by an annular area rich in ICAM-1-ligated LFA-1 (the pSMAC). (In the present chapter, to simplify the discussion, the role of CD4 is not described.) (Reproduced from *Science* **1999**, *285*, 221–227 [13]. Reprinted with permission from AAAS.)

shape so that they bind ICAM-1 strongly, which in turn causes the cell to stop migrating and thus stabilizes the synapse. *In vivo*, this mechanism enables the APCs to adhere strongly to T cells of the correct specificity, for the periods of up to several hours that may be necessary for full activation to take place. However, it simultaneously prevents the APCs from forming time-wasting, long-lasting contacts with other T cells.

In the second stage of immunological synapse evolution, p-MHC-ligated TCRs migrate to the middle of the contact zone, possibly due to actin-based transport, leading to the third stage, where a stable central region of bound TCR–p-MHC pairs, the central supramolecular activation cluster (cSMAC), is surrounded by a ring of ICAM-1 bound to LFA-1, the peripheral supramolecular activation cluster (pSMAC), which in turn is surrounded by an area of very close contact between the cell and the surface, suitable for the formation of new TCR–p-MHC pairs, the distal supramolecular activation cluster (dSMAC). As the primary purpose of the LFA-1–ICAM-1 bond is to bind the T cell to the APC, most of the lines of adhesive force between the cells pass through the dSMAC where these molecules are highly present, as shown by the arrows in Figure 11.1. Close examination of the structure and dynamics of cytoskeletal actin in the cell, as well as the distribution of LFA-1–ICAM-1 pairs, has shown that the dSMAC and pSMAC may be thought of as respectively analogous to *lamellapodium* and *lammella* structures that are exhibited by many motile cells [17], such as fibroblasts moving across the ECM. In the case of the fibroblast, $\alpha_v\beta_3$ integrin molecules (analogous to LFA-1) bind to the ECM surface in the lamellapodium, which is pushed out in the direction of desired motion. A characteristic feature is that the actin in the lamellapodium/dSMAC is organized into two stacked layers, whereas that in the lamella/pSMAC is organized into one layer only. By a combination of actin polymerization at the periphery and depolymerization at the cell center, the cell center effectively pulls on the anchored integrin molecules and thus moves towards them. In the case of the immunological synapse, the same actin polymerization and depolymerization occur, but because the dSMAC extends out in all directions, and because the ICAM-1 molecules are mobile in the APC lipid membrane (in contrast to integrin-binding elements of the ECM), the center of the T cell remains stationary, although there is a constant motion of actin towards the center of the cell [18]. Some important implications of this effect will be described in Section 11.2.2.

In a recent study conducted by Doh and Irvine, photolithographic methods were used to produce a substrate that encouraged T cells to form a cSMAC/pSMAC-like structure, but without using mobile ligands [19]. Rather, a surface was patterned with shaped patches of anti-CD3, a type of antibody that binds TCR and can thus simulate the effect of p-MHC, against a background of ICAM-1. This study employed a novel method for patterning surfaces with two proteins using photolithography, by using a photoresist that can be processed using biological buffers [20]. The photoresist used in this method is a random terpolymer with a methacrylate backbone, and methyl, *o*-nitrobenzyl and poly(ethylene glycol) (PEG) ($M_n \approx 600$ Da) side groups randomly distributed along the chain, where some of the PEG side chains are terminated with biotin. The PEG chains make the polymer somewhat hydrophilic, while the *o*-nitrobenzyl group can be cleaved to a carboxylic acid-bearing group by ultraviolet

(UV) light. The photoresist is spincoated onto a catonic substrate (in this case aminosilane-functionalized glass) so that, if the resist is exposed to UV light, and then rinsed with pH 7.4 buffer so that it contains negatively charged carboxylic acid groups, the negative charge of these groups causes the majority of the photoresist to be soluble and thus to be washed away. This will leave behind a thin layer of resist molecules, the negatively charged groups of which are ionically bound to positively charged amine groups on the glass surface. The sequence of events in preparing the patterned surface used in the T-cell studies [19] is shown in Figure 11.2. The photoresist layer was first exposed to UV through a photomask and then washed with pH 7.4 buffer to remove all but the thin residual polymer layer from the areas to be patterned with anti-CD3. After further UV irradiation of the whole surface, streptavidin followed by biotinylated anti-CD3 was deposited at pH 6.0 (at which the resist is stable) with the streptavidin binding the anti-CD3 to the biotin sites on the resist polymer surfaces. A second wash at pH 7.4 removed most of the resist from the non-anti-CD3 functionalized area, leaving a thin biotinylated polymer layer to which streptavidin followed by biotinylated ICAM-1 could be attached.

The T cells that were allowed to settle on surfaces bearing widely spaced circles of anti-CD3 6 μm in diameter against a background of ICAM-1 (prepared using this method) migrated until they encountered an anti-CD3 circle, and then formed a central cSMAC-like area of TCRs bound to anti-CD3, surrounded by a pSMAC-like ring of LFA-1 bound to ICAM-1 [19]. Molecules known to be associated respectively

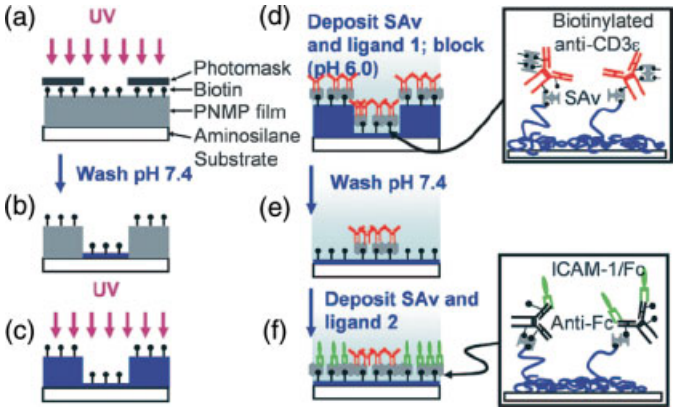

Figure 11.2 Schematic of the photolithographic production of surfaces patterned with two proteins on a micrometer scale, using a novel photoresist that can be processed in biological buffers [19]. A detailed description is provided in the text. Briefly: (a) A resist layer created by spincoating onto a cationic substrate was UV-irradiated through a photomask; (b) A wash at pH 7.4 removed all but a molecularly thin layer of resist from the irradiated areas; (c) The sample was uniformly UV-irradiated; (d) Biotinylated anti-CD3 was bound to the biotin functional groups in the resist layer via streptavidin (SAv); (e) Washing at pH 7.4 removed all but a molecularly thin layer of resist from the originally unirradiated areas; (f) ICAM-1-Fc was bound to the biotin functional groups in the resist layer via biotinylated anti-Fc and streptavidin. (Reproduced from *Proc. Nat. Acad. Sci. U.S.A.* **2006**, *103*, 5700 [19]. Copyright 2006 National Academy of Sciences, U.S.A.)

with LFA-1 (talin) and TCR (protein kinase C, θ isoform (PKC-θ)) signaling localized in the 'pSMAC'- and 'cSMAC'-like regions respectively, in accordance with some previous observations of T cell–APC contact zones [21]. T cells that formed these model 'cSMAC–pSMAC' structures showed elevated levels of intracellular free calcium (an early sign of activation), and eventually proliferated and showed increased cytokine production with respect to cells on control surfaces, thus confirming that full activation had taken place.

Although the cSMAC–pSMAC–dSMAC model corresponds well to *in vivo* images of some T cell–APC contacts (notably where a so-called B cell is used as the APC [21]), when the important dendritic cell APC type is used, a different structure is seen, which may be conceptualized as a multifocal pattern with several smaller cSMAC-like zones. This type of pattern, which could conceivably arise from the dendritic cell cytoskeleton's imposing constraints on the mobility of TCR [16], was reproduced by Doh and Irvine [19], by using their photolithographic technology to produce groups of four small anti-CD3 spots (spots 2 μm diameter, spot centers placed at corners of a ~5 μm cube). The T cells that encountered such groups indeed formed multifocal contacts.

Similar multifocal contacts have also been produced by Mossmann *et al.*, who used electron-beam lithography (EBL) to produce chromium 'walls' (about 100 nm wide and 5 nm high) on a silicon dioxide substrate on which a lipid bilayer containing ICAM-1 and p-MHC was then deposited. In this way, the ICAM-1 and p-MHC were able to move freely laterally up to, but not through, the walls. The p-MHC molecules could thus be confined to several large regions, resulting in the formation of a multifocal pattern with several miniature cSMAC-like regions [15, 16], as shown in Figure 11.3.

The T-cell structures produced on the anti-CD3-patterned substrates of Doh and Irvine [19] might be thought of as a good model of an activating T cell, with the cSMAC as the principal source of activation signaling from ligated TCR. However, as will be seen below, evidence has emerged which suggests that the cSMAC is not an important source of activation signaling, which rather comes primarily from TCR–p-MHC microclusters, and the physiological relevance of the model substrate of Doh and Irvine [19] may be questioned in this respect. It is possible that the interfacial line between anti-CD3- and ICAM-1-coated areas in the studies of Doh and Irvine [19] served the same function as the dSMAC in immunological synapses formed on B cells on supported planar bilayers. The important generalization is that T cells may be highly adaptable as part of their evolution to navigate a wide variety of anatomic sites and interact with essentially any cell in the body to combat continually evolving pathogens. Hence, one important role of nanotechnology may be to test the limits of adaptability and understand the fundamental recognition elements and how they may be manipulated.

11.2.2
TCR–p-MHC Microclusters as Important Signaling Centers

In the model shown in Figure 11.1, an early stage of immunological synapse formation was the ligation of TCR by p-MHC in the peripheral area around the

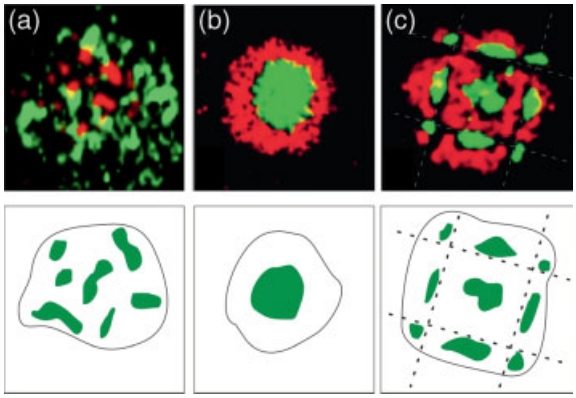

Figure 11.3 Fluorescence micrographs of immunological synapses, with TCRs labeled green (top row) and schematics (bottom row, green show TCR locations, solid back lines show cell outline). (a) A fixed synapse between a T cell and a dendritic cell (red shows PKC-θ, which is not important for our purposes here). TCRs gather at several separate focal points; (b) A synapse formed between a T cell and a supported lipid bilayer, where the lateral motion of p-MHC and ICAM-1 in the bilayer is unconstrained; red shows ICAM-1. TCRs gather in one large cluster, the cSMAC; (c) A synapse formed between a T cell and a supported lipid bilayer where the lateral mobility of p-MHC and ICAM-1 in the bilayer is constrained by chromium 'walls', indicated by dashed lines (white in micrograph, black in schematic) . (ICAM-1 is labeled red.) TCRs gather at several focal points. Note the presence of multiple TCR foci in (a) and (c), which suggests that a reduced lateral mobility of p-MHC on the dendritic cell surface might be responsible for the multifocal nature of the T cell with dendritic cell synapse (a). The central square formed by the chromium 'walls' in (c) has dimensions $2 \times 2\,\mu m$. (Micrographs reproduced from *Curr. Opin. Immunol.*, *18*, 512–516, M.L. Dustin, S.Y. Tseng, R. Varma, G. Campi, T cell-dendritic cell immunological synapses. Copyright (2006), with permission from Elsevier [16]; panels (b) and (c) are originally from **2005**, *310*, 1191–1193. Reprinted with permission from AAAS [15].)

central region of initial ICAM-1 adhesion, with the resulting TCR–p-MHC pairs then migrating to the center of the contact zone to finally form the cSMAC. A closer examination of this system in fact shows the TCR–p-MHC pairs combining to form microclusters throughout the contact zone, which then combine to form the cSMAC [22]. By using highly sensitive total internal reflection fluorescence microscopy (TIRFM), it has also proved possible to image a subsequent continuous 'rain' of microclusters, each consisting of between approximately five and 20 p-MHC–TCR pairs, that form in the peripheral dSMAC region, and then move radially inwards eventually joining the cSMAC [12, 23]. This motion is likely to occur because the TCR are indirectly connected to actin filaments, which are moving continuously inwards in the dSMAC and pSMAC (as discussed in Section 11.2.1). Experiments in which an antibody that disrupts TCR binding to p-MHC was added after the T cells had formed a stable cSMAC on a lipid bilayer surface (such that at early times the formation of new microclusters was prevented but the cSMAC was not yet disrupted) suggest strongly that activation signaling arises from the microclusters rather than from the cSMAC, as signaling almost completely ceased at a time when the cSMAC was still intact [12]. It therefore seems likely that, rather than functioning as a signaling device, the cSMAC in fact plays other roles. In particular, it has been observed that significant numbers of

TCR are endocytosed in the cSMAC. Some of these may be recycled through the cell for reincorporation into the dSMAC, ensuring a continuous supply of TCR and thus enabling signaling to continue for a long time, while others may be degraded [14, 24].

If TCR–p-MHC microclusters arising in the peripheral dSMAC give rise to activation signaling, which switches off as they join the cSMAC, there are two possible hypotheses: the initial signaling may decrease either with time, or with proximity to the center of the contact zone. It proved possible to distinguish between these hypotheses by using the chromium 'walls' of Mossmann *et al.* to divide the contact zone into many small areas, thus preventing microclusters from moving large distances. Using this approach, it was shown that, while the signaling from each microcluster has a finite lifetime, such lifetime decreased strongly with proximity to the center of the contact zone. This showed that spatial factors do play a role, and help to confirm the picture of the cSMAC as a non-signaling region [15].

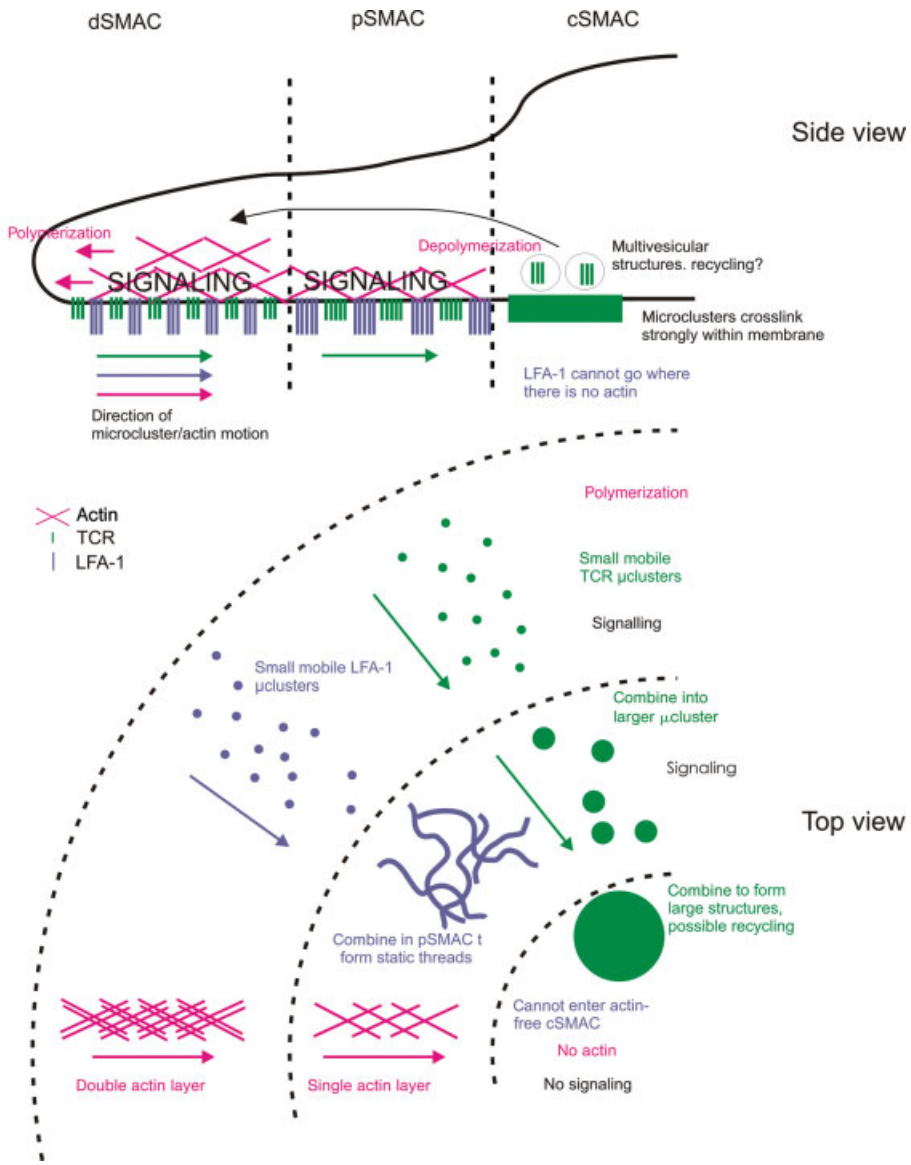
In contrast to the studies just mentioned, in which TCR–p-MHC microclusters formed spontaneously by the coming together or pulling together of mobile p-MHC molecules in a lipid bilayer [12, 15], Anikeeva *et al.* effectively created artificial TCR–p-MHC microclusters by exposing T cells to a solution of *quantum dots*. These are fluorescent semiconductor nanocrystals, to which p-MHC molecules have been bound, with the binding mechanism being the ligation of zinc ions on the semiconductor surfaces by carboxylic acid groups belonging to six histidine residues inserted at the base of the p-MHC molecule [25]. Approximately 12 p-MHC molecules were found per quantum dot, as determined by the measurement of nonradiative energy transfer between the quantum dot and fluorophores bound to the p-MHC molecules. This suggested that the number of ligated TCRs in the artificial microclusters might have been about six, comparable to the size of the smallest signaling microclusters observed in one of the previously mentioned bilayer studies [12]. The stimulation of T cells with appropriate p-MHC-functionalized quantum dots caused activation signaling to occur. Although this study does not relate directly to our theme of T-cell activation by artificial substrates, we mention it here because it is indicative of the potential value of studies performed using p-MHC molecules bound to nanospheres. In fact, it will be seen below that surfaces functionalized with nanospheres may play an important role in future studies.

In addition to TCR–p-MHC microclusters, LFA-1–ICAM-1 microclusters have also been observed; the latter seem to form in the dSMAC and to move inwards before eventually joining thread-like LFA-1–ICAM-1 structures in the pSMAC [18]. Figure 11.4 summarizes schematically the localization of TCRs, p-MHCs, LFA-1 and ICAM-1 in the three SMACs. The structure of the cytoskeletal actin in these regions, as discussed in Section 11.2.1, is also shown.

11.3
The Smallest Activating Units? p-MHC Oligomers

As discussed in Section 11.2, signaling from p-MHC-ligated TCRs seems to depend on the ligated TCRs coming together to form microclusters, rather than ligation alone

being enough for signaling. It transpires that activation signaling can indeed not be initiated by a single ligated TCR, but that the coming together of at least two ligated TCRs is necessary for signaling. This was demonstrated by Boniface *et al.*, who combined biotin-functionalized p-MHCs with naturally tetravalent streptavidin molecules to produce p-MHC monomers, dimers, trimers and tetramers. T cells exposed to the p-MHC monomer showed no activation signaling, whereas significant signaling was already present in the case of the dimer, and the strength increased



when trimer or tetramer was used [26]. This suggests that some degree of TCR 'clustering' is necessary for T-cell activation signaling. This could conceivably indicate that part of the signaling mechanism requires the close proximity of the cytoplasmic parts of neighboring TCRs.

Interestingly, doubt was cast on the finding that TCR clustering is required for the activation signal when, in an experiment using APCs in which all of the agonist p-MHC molecules had been fluorescently labeled, activation signaling was observed to be initiated by a T cell where the contact zone with the APC surface contained only one agonist p-MHC molecule [27]. This apparent contradiction may have been resolved by Krogsgaard *et al.*, who obtained a T-cell activation signal by stimulating cells with a synthetic heterodimer consisting of one MHC molecule with agonist peptide and one with self-peptide (i.e. peptide found within the proteome of the T cell-producing mammal, in this case a mouse) [28]. Krogsgaard *et al.* argued that such heterodimers may play a role in *in vivo* activation. This controversy and its resolution underlines the roles that molecules other than agonist p-MHC may play in *in vivo* T-cell activation; one of the principal advantages of experiments performed on artificial substrates is that 'clean' experiments can be performed, without the possible intrusion of unknown ligands. The ability of T cells to respond to mixed stimulations by agonist and self-peptide-loaded MHC molecules may be important for the functioning of the immune system, as it could increase the likelihood of T-cell activation by APC surfaces that present only small amounts of agonist peptide [8].

If TCR clustering is indeed required for T-cell activation, then it is interesting to ask how close together the TCRs need to be drawn in order for signaling to occur. A significant contribution towards answering this question was made by Cochran *et al.*, who used p-MHC molecules genetically engineered to contain free cystine residues to produce p-MHC dimers; the dimers were created by reacting the cystine residues

Figure 11.4 Summary of our current understanding of the structure of the immunological synapse. Schematic top and side views of the T cell only are provided here: it is assumed that all or most TCRs and LFA-1 molecules shown are ligated by p-MHCs or ICAM-1 on the opposing APC surface (not shown). In the top view, TCRs, LFA-1 and actin are shown in separate locations purely for visual clarity. In the dSMAC, which is analogous to a lamellapodium in a migrating cell, and thus contains two stacked layers of cytoskeletal actin, microclusters of TCR–p-MHC and LFA-1–ICAM-1 form and are transported towards the cell center by the inward motion of actin filaments, as indicated by arrows below the cell. The actin filament motion is caused by depolymerization at the edge of the cSMAC, and polymerization at the edge of the cell. The direction of actin filament growth is indicated by arrows within the cell. In the pSMAC, TCR–p-MHC microclusters merge to form somewhat larger microclusters, and continue migrating inwards, whereas LFA-1–ICAM-1 microclusters merge into a thread-like structure of mutually associated LFA–ICAM-1 pairs, and thus cease moving. The pSMAC is analogous to a lamella in a migrating cell, and thus contains only a single layer of cytoskeletal actin. In the cSMAC, TCR–pMHC pairs merge into a large mass of mutually associated TCR–pMHC pairs. Significant quantities of TCRs are endocytosed by the T cell, and some of these may be recycled through the cell back to the dSMAC, where the process can begin again, enabling signaling to be maintained over a long period of time. LFA-1–ICAM-1 pairs do not enter the actin-free cSMAC in significant quantities. TCR–pMHC microclusters in the dSMAC and pSMAC participate in T-cell activation signaling; there is no signaling due to TCR–p-MHC in the cSMAC.

with maleidomide groups on polypeptide crosslinkers of various lengths. The activation response from T cells decreased as the length of the spacer between the bases of the p-MHC molecules was increased from <1 to 9 nm [29].

11.4
Molecular-Scale Nanolithography

It can be seen from the above discussions that the clustering of p-MHC-ligated TCRs is critical to the initiation of T cell activation signaling. In this section, we describe possible future experiments aimed at further examining these effects, using the technology of *block copolymer micellar nanolithography*. This has recently become available, and enables surfaces to be patterned on the nanometer scale with single-protein molecules such as p-MHCs. Here, we will describe the technique in detail and review its previous uses in cell signaling studies. We will also discuss how the technique can be used, in combination with chemistry and protein engineering methods, to perform experiments to further our understanding of the immunological synapse.

11.4.1
Block Copolymer Micellar Nanolithography

The concept of block copolymer nanolithography is illustrated in Figure 11.5 [30–32]. Here, poly(styrene block 2-vinyl pyridine) forms a micellar solution in toluene with the hydrophilic 2-vinyl pyridine (2VP) block making up the micelle core. Hydrogen tetrachloroaurate (III) ($HAuCl_4$) is added, and complexes the 2VP, producing a gold-rich micelle core. When a flat substrate with a chemically suitable flat surface such as silicon oxide is immersed in the micellar solution and then withdrawn, the approximately spherical micelles form a two-dimensional (2-D) close-packed array on the substrate surface, with the capillary force due to the retreating toluene interface possibly playing a role in forcing them into this configuration. The micelle-coated surface is then exposed to a hydrogen plasma; this removes the polymeric material and reduces the gold ions, producing metallic gold particles at the former sites of the micelle cores. The result is a hexagonal array of gold particles on a (usually) silicon dioxide background. The size of the gold particles can be controlled between approximately 3 nm and 10 nm by varying the amount of added ($HAuCl_4$), while the spacing between adjacent particles can be controlled by varying the length of the styrene block of the original diblock copolymer, and to some extent also by varying the speed of withdrawal of the substrate from the micellar solution. Present investigations have produced interparticle spacings in the range of approximately 15–250 nm, although it seems likely that spacings below 15 nm should also be achievable.

For experiments to study the stimulation of biological cells, the gold nanoparticles can be functionalized with biological ligands using thiol chemistry, while the silicon dioxide surface in between the spheres can be differently functionalized using silane

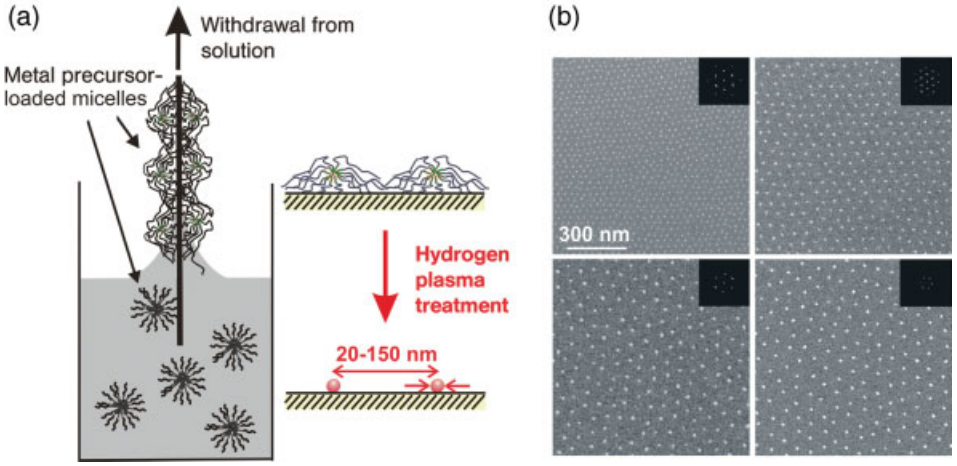


Figure 11.5 Block copolymer micellar nanolithography. Full details are provided in the text. Briefly: (a) Schematic: Micelles of which the cores are loaded with gold ions form a 2-D close-packed layer on a suitable substrate surface that is withdrawn at a suitable speed from the micellar solution. Treatment with a hydrogen plasma removes organic material, resulting in a hexagonally ordered array of gold nanoparticles, with the interparticle spacing being determined by the original polymer block molecular weights and the speed of withdrawal from the solution; (b) Scanning electron microscopy images of surfaces patterned with gold nanoparticles produced using diblock copolymers, where the two blocks have various different molecular weights: the variation in the lattice parameter can be seen. The ordered nature of the patterns is demonstrated by the sharp peaks in the numerically calculated 2-D Fourier transforms of the images (insets at top right of images). ((a) is from R. Glass, M. chemistry. The power of this technique is well illustrated by the studies of Arnold *et al.*, who functionalized the gold nanoparticles with cyclic arginine-glycine-aspartate (RGD) peptide molecules that were bound to the gold via a thiol-functionalized linker [2]. These RGD peptides bind strongly to $\alpha_v\beta_3$ integrins, which are membrane-bound receptors that play an important role in the initiation of adhesion by fibroblasts to the ECM. The large size of $\alpha_v\beta_3$ integrins ensured that only one integrin could bind to each gold particle, so that the interparticle spacing could be used as a measure of the minimum separation between adjacent ligated integrin molecules. Experiments showed that fibroblasts adhered readily to substrates with an interparticle spacing of 58 ± 7 nm or less, but did not adhere to substrates with an interparticle spacing of 73 ± 8 nm or more. This suggested that some clustering of ligated integrins is necessary for the initiation of adhesion signaling in fibroblasts, and that the critical spacing below which integrins may be considered to be 'clustered' lies between 58 nm and 73 nm. Additionally, actin-rich protein clusters known as *focal adhesions* that form at sites of $\alpha_v\beta_3$ integrin-mediated adhesion, and which may be considered

as local indicators of adhesion signaling, were observed to form only when the interparticle spacing was higher than this critical value.

It is important to note that, while other lithographic techniques such as EBL [3] and dip-pen nanolithography [33–35], have been used to immobilize biological ligands on surfaces, to the best of our knowledge, block copolymer micellar lithography is the only lithographic method that has thus far been used to spatially isolate individual ligand receptor interactions. This is most likely due to its ability to reliably produce particle sizes as small as 3 nm. This limit compares favorably with, for example, the lower size limit for reliable structure production using EBL with conventional poly (methyl methacrylate) (PMMA) resists, which is about 10 nm [36], and the smallest protein feature that has been created to date using dip-pen nanolithography, which is about 25–40 nm [33].

In view of the apparent requirement for the clustering of ligated TCRs if T-cell activation signaling were to occur, it would clearly be very interesting to perform an analogous experiment to that just described [2], but to study TCR rather than $\alpha_v\beta_3$ integrin clustering. In order to perform such an experiment, each gold nanoparticle would need to be functionalized with a single molecule of p-MHC, and the effect of the interparticle spacing on the activation signaling behavior of T cells brought into contact with such surfaces determined. If TCR clustering were indeed necessary for T-cell activation signaling, then one would expect to observe no signaling when the interparticle spacing was high, with signaling perhaps onsetting as the interparticle spacing was reduced below a critical value. Indeed, the above-mentioned studies of Cochran *et al.* suggested that this spacing should range between 1 and 15 nm [29].

The binding of p-MHCs to the gold dots could be achieved by creating a recombinant MHC construct containing an appropriately located free cystine residue that could react directly with the gold. Alternatively, protein constructs containing multiple consecutive histidine residues have been successfully bound to gold nanospheres on block copolymer micellar nanolithography-patterned surfaces by binding thiol-functionalized nitrilotriacetic acid (NTA) molecules, and allowing the carboxylic acid groups of the NTA and histidine to simultaneously coordinate the same nickel cation. Functionalization of the silicon dioxide surface between the gold nanospheres should also be considered. In the integrin-clustering experiments of Arnold *et al.*, the area between the gold nanoparticles was functionalized with protein-repellent PEG molecules that were end-functionalized with trimethoxysilane groups (this enabled them to bind covalently to the silicon dioxide surface). This PEG functionalization ensured that the cells under study interacted with the surface only via receptor interactions with ligand-functionalized gold particles, and not via nonspecific attractions, as well as resisting the deposition of cell-secreted proteins onto the silicon dioxide surface [2]. In the context of experiments to study T-cell activation, it might be advantageous to functionalize the area between the gold nanoparticles with a combination of PEG molecules to reduce the effect of nonspecific cell-surface attractions, and ICAM-1, to bring about the LFA-1-mediated cell adhesion that is a critical feature of the immunological synapse. This could be achieved by incor-

porating functional groups into the PEG layer that could be bound specifically to ICAM-1; an example would be to incorporate biotin groups into the PEG layer that bind via streptavidin to biotinylated ICAM-1 molecules. The incorporation of biotin into surface-grafted PEG layers has been achieved [37, 38]; I.E. Dunlop *et al.*, unpublished results], and its incorporation into the PEG layer between the gold nanoparticles should be readily achievable.

11.4.2
Micronanopatterning by Combining Block Copolymer Micellar Nanolithography and Electron-Beam Lithography

Surfaces that are structured on both the micrometer and nanometer scales can be produced using a method that combines block copolymer micellar nanolithography with EBL.

The principle of the method is shown schematically in Figure 11.6 [39]. After having deposited a close-packed monolayer of $HAuCl_4$-loaded block copolymer micelles onto the substrate, part of the layer is exposed to an electron beam, which causes the polymer molecules to become highly crosslinked. The substrate is then rinsed with acetone to remove all noncrosslinked polymer, leaving micelles behind only in the area that was exposed to the electron beam. These micelles are then exposed to a hydrogen plasma, which leads to hexagonally arranged gold nanoparticles in the normal manner. It is thus possible, by using a steerable electron beam (such as that in the scanning electron microscope) to pattern only parts of a surface using block copolymer micellar nanolithography, and thus to produce patches of patterning containing controlled numbers of gold nanoparticles (see Figure 11.6).

Surfaces prepared using this method could enable experiments that address questions relating to the number of p-MHC molecules or clusters required for T-cell activation signaling to be addressed. For example, if p-MHC-ligated TCR dimers are sufficient to cause T-cell activation signaling, then it is interesting to ask whether one dimer would be sufficient to produce a detectable activation signal, as suggested by the cell–cell contact experiments of Irvine *et al.* [27], and how the signaling strength would depend on the number of dimers with which a cell interacts. Additionally, the suggestion of Varma *et al.*, that signaling might arise primarily from microclusters of between roughly five and 20 p-MHC-ligated TCRs, suggests that it would be interesting to examine the effect on signaling intensity of the microcluster size, and the number of microclusters per cell. Simulated 'microclusters' containing precisely controlled numbers of molecules could be produced using patches of gold nanoparticles, similar to that shown in Figure 11.6; here, each gold nanoparticle could bear one p-MHC molecule and the interparticle spacing could be chosen sufficiently small that a T cell could 'see' the resulting ligated TCRs as being clustered. Alternatively, microclusters could be simulated by allowing several p-MHCs to bind to one larger nanosphere, as in the experiments of Anikeeva *et al.* mentioned above, in which p-MHCs were bound to soluble quantum dots [25].

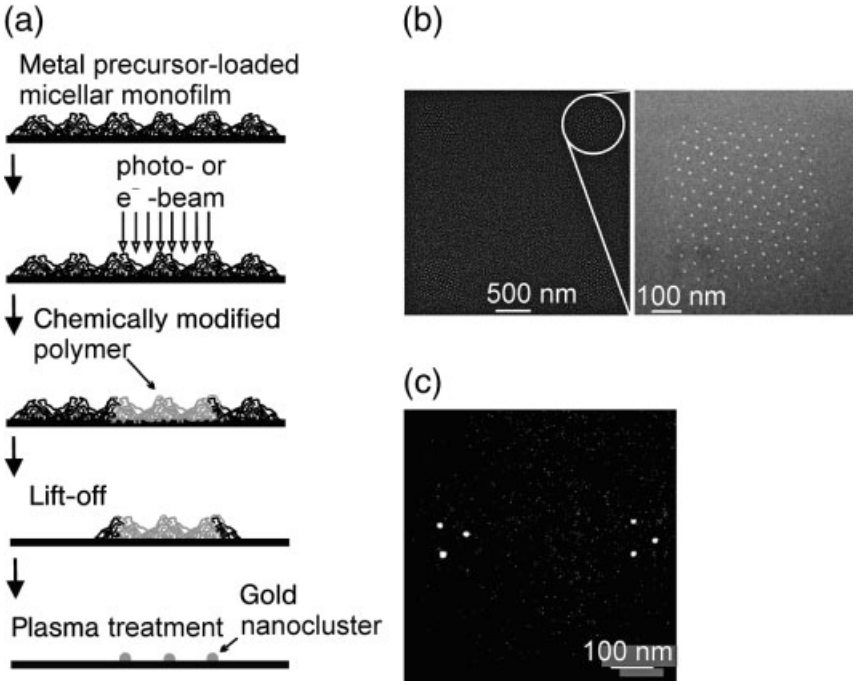

Figure 11.6 Block copolymer micellar nanolithography combined with electron beam lithography to produce patches of substrate nanopatterned with controlled numbers of nanoparticles. (a) Schematic: parts of a close-packed film of gold-loaded micelles are irradiated with a steerable electron beam. Washing in acetone 'lifts off' unirradiated polymer before plasma treatment produces hexagonal arrays of gold particles in the treated areas; (b) (c) Scanning electron microscopy images of different surfaces produced using this method, showing the possibility of producing widely spaced patches of patterned surface, where each patch contains a similar number of gold nanoparticles. 11.5
Therapeutic Possibilities of Immune Synapse Micro- and Nanolithography

So far, we have mostly considered the use of micro- and nanolithographically patterned T-cell-activating surfaces as tools to investigate the functioning of the immune synapse. It is also interesting to consider the potential of these technologies for direct use in clinical therapies. Although it is possible to imagine incorporating T-cell-activating surfaces into medical implants, in order to encourage a specific and local immune response (e.g. against a tumor), it is likely that the first therapeutic use of such surfaces will be in the context of *adoptive cell transfer*.

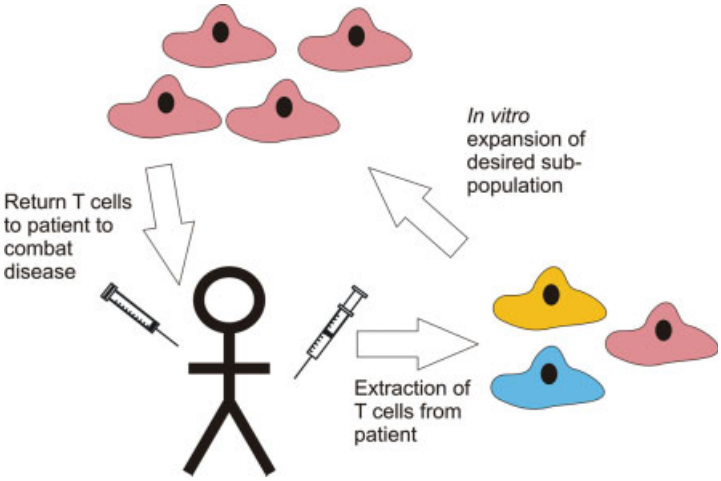

Figure 11.7 The principle of adoptive T-cell therapy.

The principle of the techniques is shown schematically in Figure 11.7. Here, T cells are removed from a patient and a selected subpopulation is deliberately activated, causing it to expand *in vitro*, before being returned to the patient's body. The returned T cells should then produce a strong immune response to the disease being treated. Although adoptive T cell transfer may prove useful in combating certain viral infections, much research has focused on the treatment of cancerous tumors, where the subpopulation of cells to be expanded should clearly be selected to be responsive to tumor-related antigens (for reviews, see Refs [40–42]). One approach is to use extracted tumor cells directly to selectively activate T cells of an appropriate specificity; this leads to a population of T cells that are specific for a variety of epitopes contained in the tumor [43]. Alternatively, epitopes that are known to be tumor-associated can be chosen, and T cells that are specific to those epitopes activated using artificial MHC–peptide constructs [40]. Here, we will focus on the second approach, as micro- and nanopatterned biomimetic surfaces functionalized with p-MHCs and costimulatory molecules might be of value in this context.

The identification of tumor-specific antigens is key if the adoptive cell therapy is to target a tumor, without damaging the healthy tissue: this approach is of particular value in tumors that are virus-induced, where antigens derived from viral proteins can be used [44]. Equally, many tumors express significantly mutated proteins that could be targeted, although the individual genetic analysis of a patient's tumor could prove expensive [41, 45]. Alternatively, antigens can be chosen from proteins that are known to be overexpressed in particular types of tumor, or even from healthy but tissue-specific proteins in tissues that are not necessary for survival, such as the prostate gland [41, 46].

In order to activate T cells using synthetic p-MHCs it is not necessary to use sophisticated spatially patterned substrates; the p-MHCs could simply be bound to a surface with no control of its spatial distribution. However, the results of recent studies of adoptive cell therapy have emphasized that T-cell activation is not a simple

on-off event; depending on the details of the activation method, as well as the prior history of the T cell, a huge variety of subtly different phenotypes can be obtained. Moreover, the differences between these phenotypes can determine the outcome of treatment [40]. An important factor here is the strength of T-cell stimulation with p-MHCs. T cells that are fairly strongly stimulated tend to differentiate to an *effector* or *effector memory* T-cell phenotype which will combat infection but not give rise to a long-lived population of T cells *in vivo*. In contrast, less-strongly stimulated cells tend to differentiate to longer-lived *central memory* T cells, which are more likely to act as progenitors of a large, long-lived T-cell population [40, 47]. It has been suggested that adoptive cell therapy can be more effective if central memory, rather than effector or effector memory, T cells are used [48]. P-MHC micro- and nanopatterned surfaces could clearly be used to control the activation 'dose' delivered to each T cell by, for example, producing spatially separated activating 'patches', each of which contains a given number of p-MHCs, along with appropriate adhesion molecules and cofactors. As discussed above, the spatial distribution of p-MHCs on an activating surface can play a role in determining immunological synapse structure and also the degree of T-cell activation; spatially structured p-MHC-functionalized surfaces may therefore be of use in controlling the phenotype of T cells used for adoptive cell therapy.

A number of other factors, in addition to the nature of the p-MHC stimulus, have been identified as important in the preparation of T cells for adoptive cell therapy [40]. For example, it may be necessary to selectively activate either helper or killer T cells, and it is certainly important not to activate regulatory T cells which act to suppress the immune response to the target epitope [42, 49]. Also, certain effects of *in vitro* culture may cause T cells to senesce in ways that resemble the weakening of the immune system on aging, thus reducing their therapeutic effectiveness [40, 50, 51]. Both of these issues have been addressed by activating T cells using costimulatory molecules simultaneously with p-MHCs. Given the spatial structuring of the immunological synapse, using lithographic methods to determine the relative positions of p-MHCs and costimulatory molecules (as described above for p-MHCs and ICAM-1) might well lead to a better control of the final T-cell phenotype. Recently, when using microcontact printing to generate patterns of costimulatory anti-CD28 and TCR-activating anti-CD3, it was shown that multiple peripheral anti-CD28 foci were better than one large central spot with the same amount of anti-CD28 for the stimulation of T-cell interleukin-2 production [52].

To summarize, adoptive cell therapy based on the *ex vivo* activation of T cells shows promise as an anti-cancer therapy, but better control of the detailed phenotype of the activated T cells is desired. Lithographic patterning of activating surfaces with p-MHCs and costimulatory molecules may contribute to attaining this control.

11.6 Conclusions

Studies performed by bringing T cells into contact with artificial surfaces that mimic aspects of the APC surfaces have contributed greatly to our understanding of the

immunological synapse, and such surfaces may be of therapeutic value in the future. Among the most informative experiments have been those performed using substrates bearing lipid bilayers that contain mobile ICAM-1 and p-MHCs. Photolithographic methods have been used to control the mobility of molecules within such bilayers, stimulating possible effects of the APC cytoskeleton and enabling the effects of reduced mobility on signaling by p-MHC-ligated TCR microclusters to be investigated. In separate studies, photolithographic methods that enable the patterning of surfaces with multiple proteins have been used to bring about artificial SMAC-like structures. The importance of studying p-MHC-ligated TCR clustering effects at the nanometer scale is attested to by evidence from several studies in which T cells were stimulated with soluble p-MHC oligomers, and substrates that are patterned with single p-MHC molecules on the nanometer scale will accordingly be required for the next generation of such studies. Block copolymer micellar nanolithography represents a suitable technique for generating such substrates and, when combined with EBL. will enable the production of surfaces patterned on both nanometer and micrometer length scales. T cell activation experiments performed on such substrates are likely to play a role in extending our understanding of the immunological synapse. Both, micro- and nanopatterned substrates may also be used for *ex vivo* T cell activation in the context of T cell adoptive immunotherapy, where T cells removed from a patient are activated and expanded *ex vivo* before being returned to combat disease, notably cancer. The use of these substrates may also help to gain close control of the phenotypes of *ex vivo*-activated T cells, leading to more effective treatments.

Acknowledgments

The authors thank Thomas O. Cameron and Rajat Varma for useful discussions. This chapter was partially supported by the National Institutes of Health through the NIH Roadmap for Medical Research (PN2 EY016586) (I.E.D., M.L.D., J.P.S.) and by the Max Planck Society (I.E.D., J.P.S.). 12
Bone Nanostructure and its Relevance for Mechanical Performance, Disease and Treatment

Peter Fratzl, Himadri S. Gupta, Paul Roschger, and Klaus Klaushofer

12.1
Introduction

The human skeleton not only serves as an ion reservoir for calcium homeostasis but also has an obvious mechanical function in supporting and protecting the body. These functions place serious requirements on the mechanical properties of bone, which should be stiff enough to support the body's weight and tough enough to prevent easy fracturing. Such outstanding mechanical properties are achieved by a very complex hierarchical structure of bone tissue, which has been described in a number of reviews [1–3]. Starting from the macroscopic structural level, bones can have quite diverse shapes, depending on their respective function. Long bones, such as the femur or the tibia, are found in the body's extremities and provide stability against bending and buckling. In other cases, for example in the vertebra or the head of the femur, the applied load is mainly compressive, and in such cases the bone shell is filled with highly porous cancellous bone (see Figure 12.1). Several levels of hierarchy are visible in this figure, with trabeculae or osteons in the hundred-micron range (Figure 12.1b and c), a lamellar structure in the micron range (Figure 12.1d), collagen fibrils of 50–200 nm diameter (Figure 12.1e), and collagen molecules as well as bone mineral particles with just a few nanometers thickness.

This hierarchical structure is largely responsible for the outstanding mechanical properties of bone. At the nanoscale, both collagen and mineral – and also their structural arrangement – play a crucial role. In this chapter we review the structure of bone at the nanoscale, and describe some recent findings concerning the influence of bone on deformation and fracture. We also outline some approaches to studying biopsy specimens in diseases and in treatments that are known to influence bone at the nanoscale.

12.2
Nanoscale Structure of Bone

At the nanometer scale, bone is a composite of a collagen-rich organic matrix and mineral nanoparticles made from carbonated hydroxyapatite. The structure and properties of bone have recently been reviewed [2]. The basic building block of the bone material is a mineralized collagen fibril of between 50 and 200 nm diameter (Figure 12.1e and f). Collagen type I is the organic constituent of these fibrils in bone and in many biological tissues, including tendon, ligaments skin and cornea. The collagen molecules are triple helices with a length of about 300 nm, and are assembled within the cell. After secretion, the globular ends of the molecules are cleaved off enzymatically and the (apart from short telopeptide ends) triple helical molecules [4, 5] undergo a self-assembly process that leads to a staggered arrangement of parallel molecules. This in turn creates a characteristic pattern of low-density gap zones that are 35 nm long and high-density overlap zones 32 nm long within the fibril [6]; hence, the effective periodicity (D) will be 67 nm (Figure 12.1f). The collagen fibrils are filled and coated by mineral crystallites [7, 8]; the latter are mainly flat plates [9] that are mostly arranged parallel to each other in a fibril, and parallel to the long axis of the collagen fibrils [10]; however, they may not always be parallel between different fibrils [7]. The crystallites have a periodicity in axial packing density along the fibrils of the same 67 nm dimension [11] by which adjacent collagen molecules are staggered (Figure 12.1f). Crystal formation is triggered by collagen or (more likely) other noncollagenous proteins which act as nucleation centers [12]. After nucleation, the plate-like crystals become elongated but extremely thin [7, 9, 13, 14],

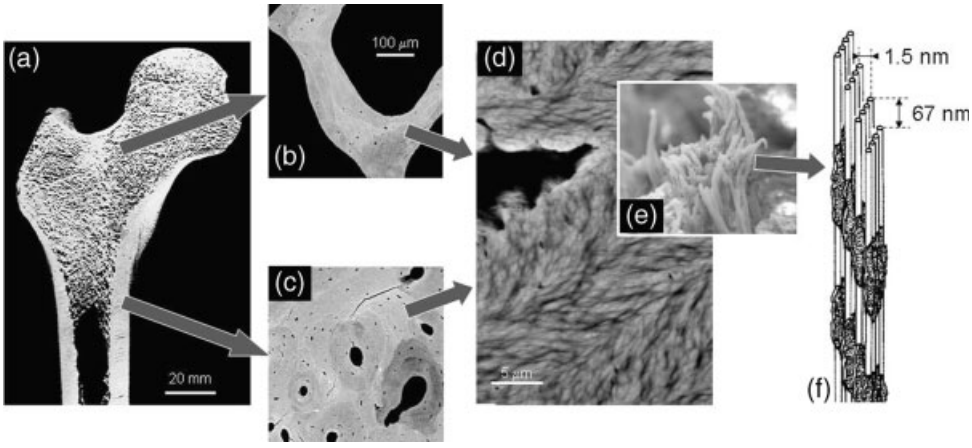

Figure 12.1 Hierarchical structure of a human femur. The femoral head (a) is filled with cancellous bone, consisting of individual trabeculae (b). The cortical bone shell contains osteons (c) where the central Haversian canal is surrounded by concentric lamellae of bone tissue. Lamellar bone (d) consists of thin layers of parallel collagen fibrils with rotating orientation similar to plywood. Collagen fibrils are constituted by parallel collagen molecules with a longitudinal stagger of 67 nm (e) and are reinforced with plate-like mineral particles located inside and on the surface of the fibrils.

and later grow in thickness [15, 16]. Among bone tissues from several different mammalian and nonmammalian species, the bone mineral crystals have thicknesses ranging from 1.5 to 4.5 nm [2, 7, 16–20]. While bone mineral is based mainly on hydroxyapatite ($Ca_5(PO_4)_3OH$), it also typically contains additional elements that replace either the calcium ions or the phosphate or hydroxyl groups; one of the most common such occurrences is replacement of the phosphate group by carbonate [1, 2].

12.3 Mechanical Behavior of Bone at the Nanoscale

The fracture resistance of bone results from the ability of its microstructure to dissipate deformation energy, without the propagation of large cracks leading to eventual material failure [21–23]. Different mechanisms have been reported for the dissipation of energy [24], including: the formation of nonconnected microcracks ahead of the crack tip [25, 26]; crack deflection and crack blunting at interlamellar interfaces and cement lines [27]; and crack bridging in the wake zone of the crack [28–30], which was attributed a dominant role [28].

One striking feature of the fracture properties in compact bone is the anisotropy of the fracture toughness, which differs by almost two orders of magnitudes between a crack that propagates parallel or perpendicular to the collagen fibrils [24]. This results in a zig-zag pattern of the crack path, when it needs to propagate perpendicular to the fibril direction (Figure 12.2a). This dependence of fracture properties on collagen orientation underlines the general importance of the organic matrix and

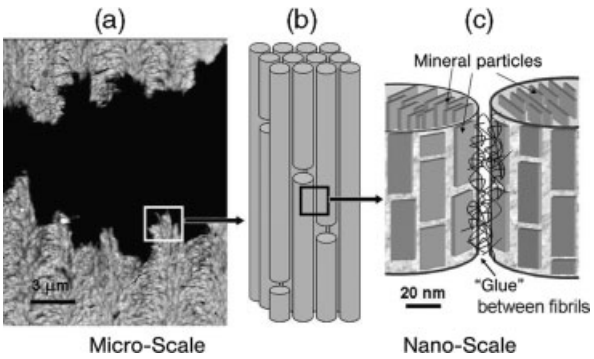

Figure 12.2 Some structural features of bone at the microscale and nanoscale that are responsible for dissipating energy during deformation and fracture. (a) Cracks propagating perpendicularly to the lamellar structure are forced into a zig-zag path, which increases the dissipated energy by about a factor of 30 [24]; (b) Each layer consists of parallel collagen fibrils arranged in a plywood-like structure where the fibril direction rotates along the direction perpendicular to the layer [47, 48]. About one-half of the deformation in a fibril bundle occurs in a glue layer between fibrils [40, 44, 45]. (c) The fibrils are stiffened by mineral particles inside and on the surface of fibrils. The 'glue' layer [43] may contain proteoglycans and phosphorylated proteins, perhaps coordinated by divalent ions, such as calcium [44].

its organization for bone toughness. The organic matrix varies with genetic background, age and disease, and this will clearly influence bone strength and toughness [2, 31–39].

The dominant structural motif at the nanoscale is the *mineralized collagen fibril*. Important contributions to the fracture resistance and defect tolerance of bone composites are believed to arise from these nanometer-scale structural motifs. In recent studies [40], it has been shown that both mineral nanoparticles and the mineralized fibrils deform at first elastically, but to different degrees, in a ratio of 12 : 5 : 2 between tissue, fibrils and mineral particles. These different degrees of deformation of different components arranged in parallel manner within the tissue can be explained by a shear deformation between the components [41]. This means that there is shear deformation within the collagen matrix inside the fibril to accommodate for the difference between the strain in mineral particles and fibrils. In addition, there must also be some shear deformation between adjacent collagen fibrils to accommodate the residual tissue strain. This shear deformation occurs presumably in a 'glue' layer between fibrils (Figure 12.2c), which may consist of proteoglycans and noncollagenous phosphorylated proteins [40, 42–45]. The existence of a glue layer was originally proposed as a consequence of investigations using scanning force microscopy [43]. Beyond the regime of elastic deformation, it is likely that the glue matrix is partially disrupted, and that neighboring fibrils move past each other, breaking and reforming the interfibrillar bonds. An alternative explanation could be the debonding between organic matrix and hydroxyapatite particles (Figure 12.2c) and a modification of the frictional stress between fibril structures [46].

The maximum strain seen in mineral nanoparticles (0.15–0.2%) can reach up to twice the fracture strain calculated for bulk apatite. The origin of this very high strength (~200 MPa) of the mineral particles may result directly from their extremely small size [49]. The strength of brittle materials is known to be controlled by the size of the defects, and of course it can be argued that a defect in a mineral particle cannot be larger than the particle itself. Under such conditions, the strength approaches the theoretical value determined by the chemical bonds between atoms rather than by the defects [49]. Although the nanoparticles in bone are still a way off this value ($\sim E/10$ or 10 GPa), it is believed that the trend towards higher strengths is related to their small size.

As a consequence, it must be concluded that the mechanical properties of bone material are determined by a number of structural features, including:

- the mineral concentration inside the organic matrix, the 'bone mineral density distribution (BMDD)
- the size of mineral particles
- the quality of the collagen, in terms of its amino-acid sequence, crosslinks and hydration
- the quality and composition of the extrafibrillar organic matrix between the collagen fibrils (consisting mostly of noncollagenous organic molecules)
- the orientation distribution of the mineralized collagen fibrils.

Assuming that these parameters are typically optimized in healthy bone material, it is likely that any variation from normal might affect the mechanical performance of the bone. Although these material characteristics cannot typically be determined in a noninvasive manner for patients, they are accessible when studying biopsies using different – and in some cases well-established – technology.

12.4
Bone Mineral Density Distribution in Osteoporosis and Treatments

The mineral concentration inside the organic bone matrix is a major determinant of bone stiffness and strength [2, 33, 50, 51]. However, the mineral content within both, the trabecular and the cortical bone motifs, is far from homogeneous (Figure 12.3). At least two processes that occur in bones over the whole lifetime of an adult individual are responsible for this situation [52]:

- Bone remodeling: The cortical and trabecular bone compartments are continuously remodeled. This means that, during a cycle of about 200 days, areas of bone are resorbed by specific bone cells (*osteoclasts*); this results in *resorption lacunae* which are re-filled with new bone matrix [53] produced by other bone cells (*osteoblasts*). Thus, the bone tissue of an individual adult is on average younger than that adult's chronological age, because the bone turnover time is about

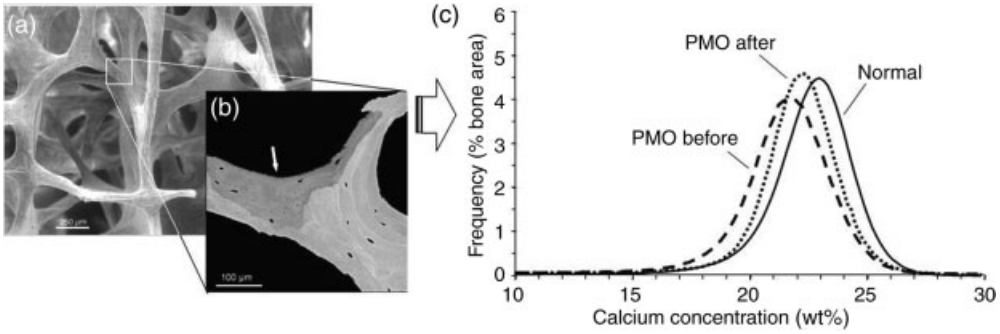

Figure 12.3 Bone is composed of packets of mineralized bone matrix with different mineral concentrations. The distribution of mineral is described by a histogram, called the bone mineralization density distribution (BMDD). (a) Scanning electron microscopy image (secondary electron emission) showing the 3-D structure of trabecular bone; (b) Backscattered electron image of a single trabecula in a bone section, revealing several bone packets with different mineral contents. The dark gray region indicates low mineralization, and the light gray high mineralization of the bone matrix. The arrow shows a newly forming bone packet with a lower mineral content than adjacent packets; (c) Examples of BMDD curves deduced from calibrated backscattered electron images of trabecular bone: NORMAL = healthy individual; PMO before = post-menopausal osteoporotic women before any treatment; PMO after = post-menopausal osteoporotic women after bisphosphonate treatment [57].

five years [54]. In addition, the more such remodeling sites act on the bone surface, the higher will be the bone turnover rate, and more bone packets will be present at a younger stage.

- Kinetics of matrix mineralization: The newly formed bone matrix is initially unmineralized (*osteoid*). However, after an initial maturation time of about 14 days the bone goes through a stage of rapid mineralization, where 70% of the full matrix mineral content is achieved in a few days (*primary mineralization*). Later on, the mineral content increases very slowly to reach full mineralization within years (*secondary mineralization*) [55, 56].

As a consequence of these processes, bone is composed of bone packets – also known as basic structural units (BSUs) – all of which have a different age and mineral content (Figure 12.3). The BSUs generate a characteristic mineralization pattern, sometimes referred to as the bone mineralization density distribution (BMDD) [57], which reflects the bone turnover status and the kinetics of mineralization in an individual [52].

The BMDD can best be measured and quantified using a backscattered electron method (quantitative backscattered electron imaging; qBEI), as described elsewhere [58] and recently reviewed [57]. In contrast to the noninvasive and widely used technique of dual X-ray absorptometry (DXA), which provides an estimate of the total amount of mineral in a scanned area of bone (BMD), the measurement of BMDD requires bone biopsies to be taken. However, the BMDD can also be determined using undecalcified resin-embedded bone blocks, as are prepared for histological examinations. The physical principle of the technique is based on a quantification of the intensity of electrons that are backscattered from a polished bone surface and yield a signal which is proportional to the local concentration of mineral (calcium). Thus, the resulting backscattered electron image visualizes regions of low and high mineral content in dark and light gray, respectively (Figure 12.3b). A suitable calibration of gray levels allows the deduction of frequency distributions of the Ca-concentrations that occur in the scanned bone area (BMDD) with a spatial resolution of 1–4 μm and a sensitivity of 0.17 wt% Ca (Figure 12.3c). The BMDD curve visualizes potential differences in mineralization status of bone between individuals with a high sensitivity (see Figure 12.3c).

With this technique at hand, it has become possible to study the mineral distribution in bone as well as its disease-related changes. The trabecular bone of normal (healthy) adults was found to exhibit minimal variations in BMDD between different skeletal sites, and due to other biological factors such as age, gender or ethnicity. Hence, the BMDD of adult trabecular bone may reflect an evolutionary optimum in bone matrix mineralization as a result of the bone cells' activity and mechanical loading, which most likely represents a compromise between optimum stiffness (which increases with mineral content) and toughness (which decreases with mineral content) of the bone material [2, 3]. It follows that deviations from the normal BMDD, as are observed for example in osteoporosis of post-menopausal women, are most likely of mechanical relevance.

12.4.1 Osteoporosis

Osteoporosis is a disease of enormous socioeconomic impact that is characterized by increased bone fragility [33, 59]. Such fragility is generally associated with an abnormal loss in bone volume, a deterioration in the quality of the bone microarchitecture, an increased bone turnover rate, and also a shift of BMDD towards a lower mineralization density (Figure 12.3c). Interestingly, basic treatment with Ca and vitamin D can have a beneficial effect on bone matrix mineralization and shift the BMDD curve back towards the normal peak position [60, 61]. Additional treatment with antiresorptive agents (e.g. bisphophonates such as alendronate, risedronate or zolendronate) results in a further increase in mineralization, as well as in a higher homogeneity of mineralization within three years of treatment [60, 62, 63]. A prolonged treatment with bisphosphonates over five and 10 years, for example, seemed to restore the BMDD to normal [64]. The treatment effect on BMDD can be explained by a reduction of the remodeling rate, together with a restoration of sufficiently high levels of Ca and vitamin D, thus allowing a more complete mineralization of the BSUs. A combined analysis of bone density (BMD), measured using DXA, and of BMDD as determined by qBEI, revealed that an 8% increase in BMD by bisphosphonate plus Ca/vitamin D treatment was due to a 5% contribution in the improvement of matrix mineralization and a slight (3%) increase in bone volume [61]. The beneficial effect on bone volume might indicate that the therapy also positively affects the negative net balance between bone formation and resorption, as characteristically is the case for osteoporosis. Both effects likely contribute to the sustained anti-fracture efficacy of about 30–50% provided by this anti-resorptive treatment.

Another therapeutic approach in the treatment of osteoporosis is to stimulate bone formation (anabolic treatment). Such an effect on bone can, in principle, be achieved by using sodium fluoride (NaF), which has been used at a daily dose level of 60 mg in several European countries, although it failed to exhibit any anti-fracture efficacy [65]. Interestingly, the BMDD showed a shift to a higher mineralization density with fluoride treatment, and the bone matrix was partly hypermineralized. Changes in the nanocomposite structure of bone (as described in Section 12.5) are most likely responsible for this [66]. Another anabolic agent, parathyroid hormone (PTH), when provided intermittently for a limited period of about 18 months, proved to be successful and has now been approved for the treatment of osteoporosis worldwide. The anabolic effect is clearly reflected in the changes of the BMDD [55], which shows a slight shift to a lower mineralization density and a remarkable broadening of the distribution peak, indicating an increased formation of new bone matrix. This therapy has proven especially useful when the bone loss is already severe. In order to preserve the bone mass gained in such anabolic treatment, possible combinations with anti-resorptive treatments are presently under investigation [67]. It is expected that this might also be beneficial to the mineralization status of the bone, as the prolonged time for secondary mineralization during the anti-resorptive treatment would also normalize the BMDD.

In summary, the BMD in a healthy bone matrix seems to approach an optimum which represents the best compromise between stiffness requiring a high mineral content and toughness, which decreases with mineral content. Biopsies may be used to assess the status of mineral concentration for individual patients at risk of bone fractures in a number of diseases.

12.5 Examples of Disorders Affecting the Structure of Bone Material

As discussed above, the mechanical performance of bone tissue depends on all levels of hierarchy, and several diseases are characterized by modifications at the nanostructural level. In this section, we will detail three examples: (i) *osteogenesis imperfecta*, which is based on mutations of the collagen gene; (ii) *pycnodysostosis*, which originates from a mutation of the cathepsin K gene; and (iii) *fluorosis*, which is caused by higher doses of fluoride. Whilst all three conditions are characterized by a modification at the nanoscale either of the organic matrix or of the mineral particles, adaptation processes during bone remodeling [3] may lead to a partial compensation of the original defect, sometimes at higher hierarchical levels. This means that the modification of bone structure may 'spread' over different hierarchical levels, making it more difficult to pin down the actual origin of the defect.

12.5.1 Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a genetic disease that generally affects the collagen gene and leads to brittle bone with different degrees of severity [68–70]. The origin of the brittleness of the tissue is not fully understood, but must be linked to a mutation of the collagen molecule and the resultant changes in tissue quality. Generally, OI also leads to a reduced bone mass and cortical thickness [70] which additionally increases bone fragility. It has been shown that anti-resorptive treatment of affected children with the bisphosphonate pamidronate leads to an increase in cortical thickness and to a concomitant reduction of fracture incidence [70]. At the nanostructural level, an increased mineral content was found in the bone matrix [71, 72], which leads to increased stiffness and hardness of the bone tissue [73]. However, the significance of bone fragility for this increased mineralization is not yet fully clear, as it is not affected by bisphosphonate treatment [73].

More detailed information on the bone matrix nanostructure and the disease-related changes of its properties were obtained in a mouse model of OI [74, 76–82]. This model, which is known as osteogenesis imperfecta murine (oim), is characterized by an absence of the α_2 procollagen molecule, leading to the formation of collagen α_1 homotrimers. The mechanical properties of bone tissue were found to be altered, with a reduced failure load [83] and toughness [82] in oim compared to controls. The mineral content was, however, increased in oim [75], leading to a stiffer matrix [75, 78] (see Figure 12.4). In agreement with observations in humans, this

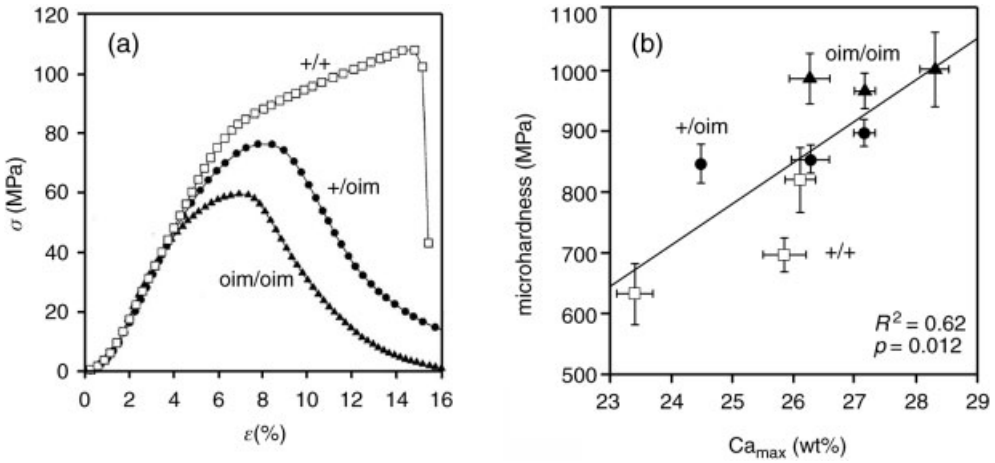

Figure 12.4 Collagen and mineral properties in the osteogenesis imperfecta murine (oim) model. Homozygote oim/oim (full triangles) and heterozygote + /oim (full circles) are compared to normal littermates + / + (open squares). (a) Stress–strain curve of collagen from the mouse tail (from Ref. [74]). The strength of collagen (the maximum stress σ) is reduced by half from + / + to oim; (b) Mineral content (Ca_{max}) and microhardness of bone tissue (from Ref. [75]). Both parameters increase from + / + to oim/oim.

increased tissue mineralization was preserved in treatment with bisphosphonates [84]. The increased brittleness of the tissue is most likely due to a weakness of the collagen-matrix, associated with an increase in mineralization. Indeed, the collagen fibrils seem to break at only half the load in oim homozygotes [74] (see Figure 12.4). The reason for this inherent weakness of collagen might be a modified crosslink pattern in the fibrils [81], due to the fact that normal crosslinks between α_2 and α_1 chains cannot form due to an absence of α_2.

12.5.2 Pycnodysostosis

Pycnodysostosis is an extremely rare human genetic syndrome characterized by an increased bone mass (osteosclerosis), short stature and high bone fragility. Despite very small numbers of cases (about 100), pycnodysostosis was best known for its suggested affliction of the French painter, Henri de Toulouse-Lautrec.

The disorder is caused by a mutation in the gene encoding for cathepsin K, a key enzyme of osteoclastic degradation [85]. Indeed, patients affected by the disease [86], as well as mice mutants lacking cathepsin K activity [87–89], have differentiated osteoclasts that are able to demineralize the bone matrix but not to degrade the remaining organic matrix. As a consequence, the loss of cathepsin K activity leads to a fundamental defect of bone resorption and, subsequently, to an increase in bone mass. The bone resorption is not completely inhibited, however, and can occur to a limited extent via an alternative pathway. The degradation of any unmineralized

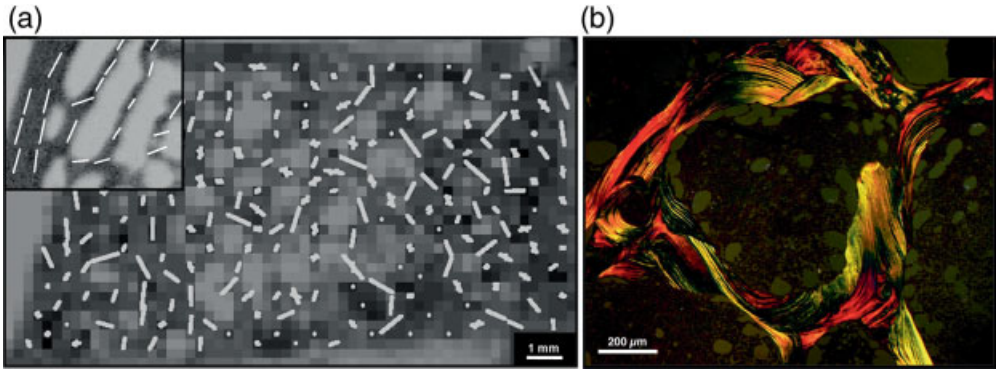

Figure 12.5 Disturbed lamellar organization in pycnodysostosis [92]. (a) The orientation of mineral particles in a biopsy is much less aligned than in normal bone (see inset (i)). The orientation and the length of the white bars indicate the direction and the local degree of alignment of the elongated plate-like mineral nanoparticles in bone, as measured with scanning small angle X-ray scattering; (b) Disturbed organization of the lamellar architecture of trabeculae, as revealed by polarized light microscopy.

collagen left by the dysfunctional osteoclasts may also be possible by the action of matrix-metalloproteinases synthesized by the bone lining-cells, which are members of the osteoblastic lineage [90]. It appears that these two pathways are not equivalent, however, as the lack of cathepsin K activity leads not only to a disturbed bone resorption [91] but also to a decreased bone formation activity [92, 93]. Bone tissue analyses of two affected patients also revealed defects at the nanostructural level, with mineral crystals being increased in size and reflecting a less-remodeled 'older' bone tissue. Moreover, the trabecular architecture appeared to be severely disturbed, with an unusually large variability in the orientation of the mineral particles and a highly disturbed lamellar organization, with the main collagen fibrils not oriented in the principal stress direction (see Figure 12.5). Thus, the absence of functional cathepsin K activity has a profound effect on bone quality at the nanoscale, and leads most likely to an observed increase in bone fragility.

12.5.3 Fluorosis

Fluoride has an anabolic effect on bone and is known to increase cancellous bone mass. During the 1980s and 1990s this led to fluoride being considered as a potential treatment of osteoporosis [94, 95], although clinical trials failed to confirm the anticipated anti-fracture efficacy [65, 96]. One reason for this is that fluoride clearly not only stimulates osteoblasts to form new bone but also has a direct effect on bone material quality. Studies involving small-angle X-ray scattering (SAXS) and back-scattered electron imaging [66, 97, 98] revealed that bone formed under the influence of fluoride has a quite different microscopic structure (see Figure 12.6). Moreover, the collagen–mineral nanocomposite was seen to be massively disturbed. Indeed, the

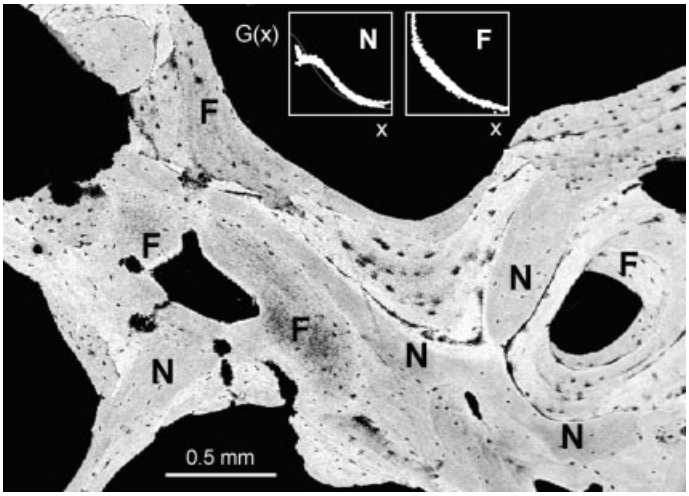

Figure 12.6 Bone biopsy after long-term fluoride treatment (3 years therapy; 50 mg NaF per day) [99]. 'N' indicates areas with normal bone and 'F' with fluorotic bone. The two insets at the top show the shape of the SAXS curves G(x) in normal and fluorotic bone [66, 98], indicating a severe modification of bone mineral nanoparticles during treatment.

strongly modified SAXS signal from bone areas newly formed under the influence of fluoride revealed the presence of mineral crystals much larger than in normal bone (Figure 12.6). This implied that the collagen and mineral in fluorotic bone did not form a well-organized nanocomposite, but that the large mineral crystals simply coexisted with the collagen fibrils. The result was a bone material of lower quality that would most likely be more brittle than usual. The images in Figure 12.6, which show a bone biopsy of a patient treated with sodium fluoride, also indicate that old bone with a normal structure coexists with newly formed fluorotic bone material. Due to a constant bone turnover, the old normal bone is gradually replaced by new bone with a fluorotic structure. This gradually compensates the positive mechanical effect of the bone mass increase and finally leads to a deterioration of bone stability against fracture [66, 97, 98].

12.6 Conclusions

Fractures – the clinical endpoint of disorders affecting the structure of bone material – are associated with increased morbidity, mortality and high socioeconomic costs [100, 101]. Today, due to an increased life expectancy for the general population, the incidence of fractures is also increasing, and the assessment of fracture risk and identification of those individuals who might benefit from the prevention and treatment of skeletal disorders represent major challenges in modern medicine.

New analyses of epidemiologic data provide strong evidence for the view that all (or better still, the overwhelming majority of) fractures – regardless of when they occur and of the level of trauma that precipitates them – may be based upon bone fragility [59], thus focusing all aspects of pathophysiology, diagnosis and treatment of skeletal diseases to the central question of mechanical competence and bone fragility. Following Robert Marcus' thoughts on ". . . the nature of osteoporosis" [102], 'bone fragility' might be defined most appropriately from the pathophysiological point of view as ". . . the consequence of a stochastic process, that is, multiple genetic, physical, hormonal and nutritional factors acting alone or in concert to diminish skeletal integrity."

Based on the fact that skeletal integrity is determined by the outstanding mechanical properties of bone at all hierarchical levels of its structure and organization [2], it becomes increasingly evident that a simple diagnostic parameter such as lumbar spine or hip BMD [103–105], although frequently used as a noninvasive diagnostic tool in clinical routine, does not have the diagnostic power to reflect the complex pathophysiological mechanisms that determine bone fragility. Thus, the availability of new diagnostic tools developed by materials scientists, coupled with a possible combinatorial approach using different methods to define the material qualities of bone from the micrometer to the nanometer scale, should introduce a renaissance of bone biopsies as diagnostic tools in clinical osteology. For example, the BMDD of trabecular human bone (as described above) was shown to be evolutionarily optimized within relative small variations (ca. 3%), independently of different skeletal regions for healthy adults aged between 25 and 95 years. Until now, no differences have been identified for BMDD-derived parameters with regards to gender or ethnicity. As shown in several examples, deviations from the normal BMDD seem to be associated with skeletal disorders, and in many examples indicate 'bone fragility' [57]. BMDD can be determined by using qBEI on a transiliac biopsy, as routinely occurs for histomorphometry, and combined with a variety of techniques based on spectroscopy, light scattering or biomechanical testing [2, 57].

When investigating the treatment of post-menopausal osteoporosis with the anti-resorptives alendronate [62] or risedronate [60] and the anabolic intermittent PTH [55], slight – but significant – deviations in BMDD indicated a lower mineralization for all placebo groups, and this was confirmed for idiopathic osteoporosis in pre-menopausal women. An example of learning from a materials science perspectives was that of fluorosis, and the fluoride treatment of post-menopausal osteoporosis [66, 97]. Yet, despite sodium fluoride being used widely to treat post-menopausal osteoporosis, no anti-fracture efficacy was reported. Rather, the bone quality revealed extensive and pathologic mineralization at both micro- and nanoscale, leading to a more brittle material with increased fragility.

Two classical genetic bone diseases – pycnodysostosis [92] and OI [68, 70, 71, 74–76, 78, 84] – point to a genetically related diminution of skeletal integrity. In OI, which often is fatal, the primary pathology was shown as brittle bones, inefficient repair mechanisms and a high bone turnover, whereas in pycnodysostosis the effects were caused by nonfunctioning osteoclasts due to mutations of the essential enzyme cathepsin K [85]. However, an inability to optimize structure by bone remodeling

results in a sclerosing bone disease with high bone mass and fragility fractures due to a disorganized structure at several hierarchical levels.

In conclusion, a wealth of evidence has been accumulated during the past years supporting the concept that the study of bone micro- and nanostructures will not only improve our understanding of the mechanisms that underlie bone fragility but also help to identify the effects of treatments. Nanomedicine, and its application to bone research, will in time undoubtedly broaden our knowledge of pathopysiology and improve the diagnoses, prevention and treatment of bone diseases. The availability of new techniques to investigate bone biopsies will surely challenge clinical osteologists and bone pathologists in the near future.

Nanoengineered Systems for Tissue Engineering and Regeneration

Ali Khademhosseini, Bimal Rajalingam, Satoshi Jinno, and Robert Langer

13.1
Introduction

In recent years, tissue engineering has emerged as a potentially powerful approach for the treatment of a variety of diseases by merging the principles of life sciences and engineering to generate biological substitutes that restore, maintain and enhance human tissue function [1]. In a typical tissue engineering approach, cells are seeded within biodegradable scaffolds. Then as the scaffolds degrade, the cells deposit their own matrices and self-assemble into tissue-like structures. This reassembly and degradation process eventually results in the formation of three-dimensional (3-D) tissue structures.

Over the past few years, tissue engineering has generated much excitement for fabricating a renewable source of transplantable tissues. Advances in the field have resulted in the engineering of clinically usable skin substitutes. In addition, other engineered tissues such as cartilage and bone are at various stages of clinical trials. Research groups have also attempted to engineer nerve tissue, pancreas, bladder and other organs. However, despite success in clinical studies, the dream of 'off-the-shelf' organs has eluded scientists and clinicians alike. This can be attributed to our inability to direct the behavior of cells in a desired manner, as well as to generate 3-D tissues with sufficient complexity and structural integrity to perform the function of the native tissues. Other concerns include the transmission of infection through the implanted tissue-engineered substrate, the possibility of immune reaction against the implanted cells, the variability of engineered products, the introduction of genetically modified, unwanted and potentially harmful cells into the body as well as regulatory and ethical aspects.

In order to generate functional tissues it is important to mimic the biological microenvironment by developing approaches and tools that can control materials and cells at the nanoscale. This is because many structural elements such as the extracellular matrix (ECM), as well as biological processes such as receptor clustering, are at the nanoscale. Thus, the ability to engineer the cellular environment and tissue

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

structure at the nanoscale is a potentially powerful approach for generating biomimetic tissues. These processes will be critical not only for generating tissue engineered constructs but also for engineering *in vitro* systems that can be used for various drug discovery and diagnostics applications.

Nanotechnology is an emerging field that is concerned with the design, synthesis, characterization and application of materials and devices that have a functional organization in at least one dimension on the nanometer scale, ranging from a few to about 100 nm [1]. Due to this ability to control features at small length scales, nanotechnology is becoming more commonly used in a number of biomedical endeavors ranging from drug delivery [2–5] to *in vivo* imaging [6].

In this chapter we will discuss the application of nanotechnology to tissue engineering as an enabling tool. Specifically, we will provide an overview of two different types of nanoengineered system that are used in tissue engineering. First, we will focus on various approaches that are used to generate nanoscale modifications to existing polymers and materials. These nanoengineered systems, such as nanopatterned substrates and electrospun scaffolds, provide structures that influence cell behavior and the subsequent tissue formation. Furthermore, we will discuss the use of other nanoscale structures such as controlled-release nanoparticles for tissue engineering. In the second part of the chapter we will discuss the use of nanotechnology for the synthesis of novel materials that behave differently as bulk compared to their nanoscale versions. Such materials include self-assembled materials, carbon nanotubes and quantum dots. Throughout the chapter we will discuss the use of nanomaterials for controlling the cellular microenvironment and for generating 3-D tissues. We will also detail the potential limitations and emerging topics of interest and challenges in this area of research. Clearly, the application of nanotechnology to tissue engineering and cell culture is an 'exploding' field, and hopefully in this chapter we will provide a glimpse into the various applications. Throughout the chapter, when applicable, the reader is directed to more extensive reviews to provide further detail regarding specific topics.

13.2
Nanomaterials Synthesized Using Top-Down Approaches

In 1959, Richard Feynman introduced the significant benefits associated with manipulating materials atom by atom. Since then, extensive research has been conducted in nanotechnology owing to the advances in technologies that enable the manipulation and characterization of nanoscale objects such as scanning tunneling microscopy (STM), atomic force microscopy (AFM) and other related technologies. Nanomaterials have generated interest in a variety of fields such as clinical medicine, defense, pharmaceuticals, aerospace, energy and biological research. Today, engineered nanomaterials are increasingly utilized for various tissue engineering applications due to their controllable and unique properties. Furthermore, nanostructures can aid in mimicking Nature, as many biological structures have features that are on the order of few to hundreds of nanometers. Nanoengineered materials

can be created by tailoring the properties of existing materials, for example by controlling the 3-D structure or surface roughness. In general, nanomaterials can be produced by either 'top-down' or 'bottom-up' approaches. Top-down approaches involve the miniaturization of materials to nano length scales, and have been enabled due to increased technological capability for miniaturizing materials either by using novel approaches or by making improvements to existing techniques. In this section, we will describe two techniques used to prepare nanomaterials using top-down approaches, namely the use of electrospinning and nanopatterned substrates to engineer cell behavior.

13.2.1 Electrospinning Nanofibers

Electrospinning is a technique that is used to generate nanofibrous scaffolds (Figure 13.1a). These scaffolds are highly porous (i.e. a large surface area-to-volume ratio), and thus mimic many of the properties of natural tissues and also provide cells with a pseudo 3-D environment [7]. Electrospinning is also relatively inexpensive and capable of producing nanofibers from a variety of biodegradable synthetic polymers, such as poly(lactic-*co*-glycolic acid) (PLGA) [8], polycaprolactone (PCL) [9] and poly(L-lactic acid) (PLLA) [10], as well as natural polymers such as collagen [11]. The nanoscale features of electrospun scaffolds promote cell proliferation and also guide cell growth. For example, aligned nanofibers have been shown to induce the growth and proliferation of cardiac cells into contractile spindle structures [12]. The seeding of neural stem cells (NSCs) on aligned PLLA nano/micro fibrous scaffolds has also resulted in neurite outgrowth along with the fiber direction for the aligned scaffolds [10]. Furthermore, fiber diameter and orientation have been shown to influence the cell morphology, while cell proliferation is not sensitive to the above-mentioned parameters. Goldstein and colleagues, while testing a range of diameters (0.14–3.6 μm) and angular standard deviations (31–60°), found that an increasing fiber diameter and degree of fiber orientation resulted in increased projected cell area and aspect ratio [8].

Electrospinning has been used to fabricate scaffolds for various tissues such as bone [9], cartilage [13–15] and cardiac muscle [16]. An example of bone tissue fabrication is shown in Figure 13.1b. These scaffolds have also been used to direct the differentiation of stem cells; for example, the coating of electrospun nanofibers composed of polyamide have been used to promote the proliferation and self-renewal of mouse embryonic stem cells (ESCs). These ESCs maintained their ability to differentiate into various lineages, which showed that such fibers could be used not only for *in vivo* applications as tissue engineered scaffolds but also as tools for *in vitro* cell culture. Electrospun nanofibers have also been shown to influence cell shape, actin cytoskeleton and matrix deposition, both *in vitro* [17, 18] and *in vivo* [19].

Despite its versatility, one disadvantage with electrospinning process is that the range of the resulting fibers is usually limited to the upper range of natural ECM fibers. In addition, it is difficult to control the complex architecture and intricate

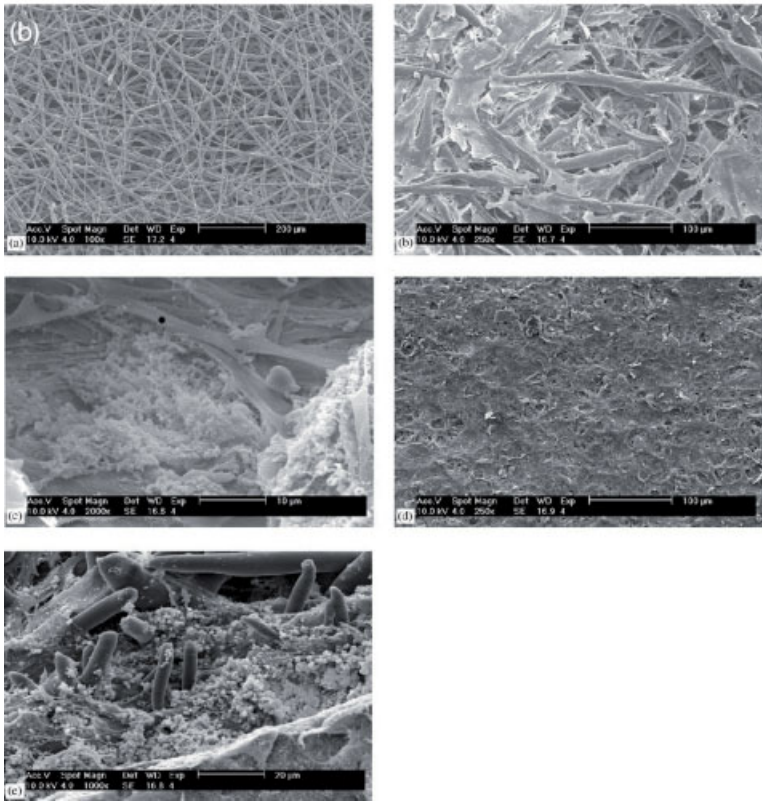
Fiber spray
Metal target
Ground



(b)

cell–cell, cell–ECM and cell-soluble factors in the resulting scaffolds. This has prompted the use of other techniques to fabricate nanofabricated scaffolds. For example, nanofabricated PLLA scaffolds that supported the differentiation and outgrowth of NSCs have been fabricated by a liquid–liquid phase separation method [20]. Yet, despite these limitations, electrospinning is a powerful technology for the fabrication of 3-D nanoscaffolds.

13.2.2
Scaffolds with Nanogrooved Surfaces

Both, micro- and nanotextured substrates can significantly influence cell behavior such as adhesion, gene expression [15] and migration [16]. This is because the interaction of cells with a biomaterial results in the localization of focal adhesions, actin stress fibers and microtubules [21]. Focal contacts are involved in signal transduction pathways which in turn can regulate a wide array of cell function [22] (Figure 13.2). As nanofiber scaffolds have a larger surface area, they have more potential binding sites to cell membrane receptors, thus affecting the cell behavior in unique ways. It has also been observed that the cells display more *filopodia* when they come in contact with the nanoscale surfaces, presumably to sense the external topography [23]. Although the mechanism of cellular response to nanotopography is not entirely understood, it is suggested that an interaction of the cellular processes and interfacial forces results in peculiar cellular behavior [7]. Both, micro- and nanotextured substrates can be engineered either on tissue culture substrates or within 3-D tissue scaffolds. Within tissue engineering scaffolds, nanotextures provide physical cues to seeded cells and regulate the interaction of host cells with the scaffold. For example, surfaces that have desired roughness have been shown to increase osteoblast adhesion for orthopedic replacement/augmentation applications [24].

Nanotextures can be generated using a variety of techniques, depending on the material as well as the dimension and shapes of the desired structures. For example, features less than 100 nm may be produced by a range of techniques including chemical etching in metals [25], the embedding of carbon nanofibers in composite

Figure 13.1 (a) Schematic of the electrospinning apparatus. The set-up for electrospinning consists of a spinneret with a metallic needle, a syringe pump, a high-voltage power supply and a grounded collector. By using the electrospinning apparatus, uniform fibers with nanometer-scale diameters can be fabricated. These scaffolds are highly porous (large surface area-to-volume ratio), thus mimicking many of the properties of natural tissues and providing cells with a pseudo 3-D environment. The nanoscale features of electrospun scaffolds promote cell proliferation and guide cell growth; (b) Panel (a) shows an electrospun poly(ε-caprolactone) scaffold, prior to cell seeding. Panels (b) and (c) are images of mesenchymal stem cells (MSCs) seeded on the scaffold after 7 days of culture, with low and high magnification, respectively. Panels (d) and (e) show the MSCs after four weeks of culture, again with low and high magnification, respectively. After 7 days, osteoblast-like cells developed, indicating bone-like formation. (Adapted from Ref. [9].)

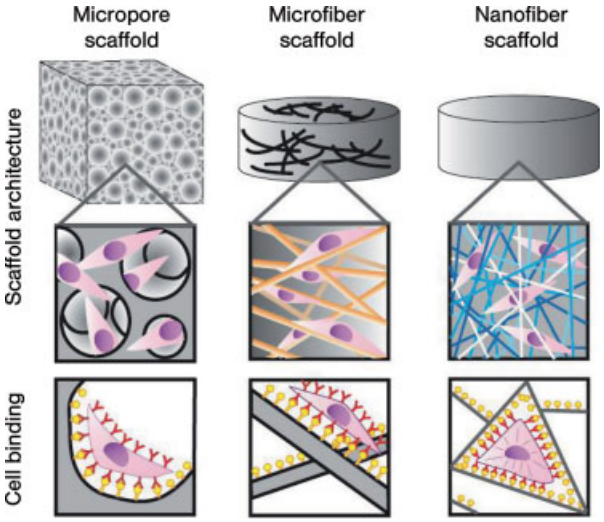


Figure 13.2 The influence of scaffold architecture on cell attachment and spreading. The attachment of cells on the micropore or microfiber scaffold is similar to that of cells cultured on flat surfaces. The larger surface area provided by the nanofiber scaffold results in many more binding sites to cell membrane receptors, thus influencing cell behavior and the subsequent tissue formation in unique ways. Focal contacts are involved in signal transduction pathways, which in turn can regulate a wide array of cell function. (Adapted from Ref. [7].)

materials [26], casting polymer replicas from ECM [27], or the embedding of constituent nanoparticles in materials ranging from metals to ceramics to composites [28–31]. Electron-beam lithography (EBL) technology has been used to fabricate well-defined nanostructures at sub-50 nm length scales [21, 32]. These tools can be used to form structures at the same length scales as the native ECM, and thus enable the systematic study of cell behavior (for a review, see Ref. [24]).

The shape of the nanostructures influences the cell behavior and phenotype. For example, nanogrooves [33–37] result in an alignment of cells parallel to the direction of the grooves [33, 38] as well as the alignment of actin, microtubules and other cytoskeletal elements [39–41]. Interestingly, both the pitch and depth of the grooves influence cell behavior. For example, typically the orientation increases with increased depth of the nanogrooves [42]. Another shape that has been shown to influence cell behavior is the natural roughness of tissues. For example, endothelial cells that were cultured on the ECM-textured replicas spread faster and had an appearance more like the cells in their native arteries than did cells grown on nontextured surfaces [27, 43]. Fibroblasts cultured on nanopatterned ε-PCL surfaces were also less spread compared to those on a planar substrate [44]. Furthermore, human mesenchymal stem cells (MSCs) and ESCs align on nanofabricated substrates and differentiate in a specific manner [45, 46]. Therefore, by controlling the nanotopography of tissue engineering scaffolds inductive signals can be delivered to enhance tissue formation and function.

13.3
Nanomaterials Synthesized using Bottom-Up Approaches

In this section we describe the synthesis and application of nanomaterials that are built by nanoscale assembly of molecules with properties that are often different from their individual components and their bulk material. These materials include self-assembled peptide hydrogels, quantum dots, carbon nanotubes and layer-by-layer deposited films.

13.3.1
Self-Assembled Peptide Scaffolds

A promising approach in tissue engineering is to use nanoengineered materials made from synthetic peptides or peptide amphiphiles (PA) that self-assemble. (An extensive review of this topic is provided in Chapter 14.) Self-assembled PA hydrogels can be generated by linking a carbon alkyl tail to functional peptides; these PA molecules then self-assemble based on hydrophobic interactions of the alkyl tail and thus form nanofibers that can form hydrogels either alone or by mixing with a cell suspension [47]. An example of a self-assembled peptide is shown in Figure 13.3. In addition, self-assembled peptide hydrogels made purely from peptides that self-assemble based on hydrophobic interactions have also been demonstrated [48–50]. In this approach, self-assembled beta-sheets are formed which can assemble into hydrogels. Both of these approaches have shown promising results in various tissue engineering, stem cell differentiation and cell culture applications [47, 51–54]. An example of this is the recent investigation of the proliferation and differentiation of MSCs in PA hydrogels. When rat MSCs were seeded into the PA nanofibers, with or without RGD, a larger number of cells attached to the PA nanofibers that contained RGD. Furthermore, upon examination of the osteogenic differentiation of MSCs, the alkaline phosphatase (ALP) activity and osteocalcin content increased for the PA nanofibers that contained RGD compared with those without RGD. In another study, the use of MSC-seeded hybrid scaffolds prepared from PAs and a collagen sponge reinforced with poly(glycolic acid) (PGA) fibers was examined to show increased osteogenic differentiation of MSCs and ectopic bone formation.

13.3.2
Layer-by-Layer Deposition of Nanomaterials

The ability to control the surface properties of biological interfaces is useful in various aspects of tissue engineering. One means of obtaining such controlled surfaces is by the layer-by-layer (LBL) deposition of the charged biopolymers. LBL deposition uses the electrostatic interaction between the surface and the polyelectrolyte solutions to generate films with nanoscale dimensions. LBL has been used extensively to control the cellular microenvironment *in vitro*. For example, we have generated patterned cellular cocultures using the LBL deposition of ionic biopolymers hyaluronic acid (HA), poly-L-lysine (PLL) [55] and collagen. In this approach, micropatterns of

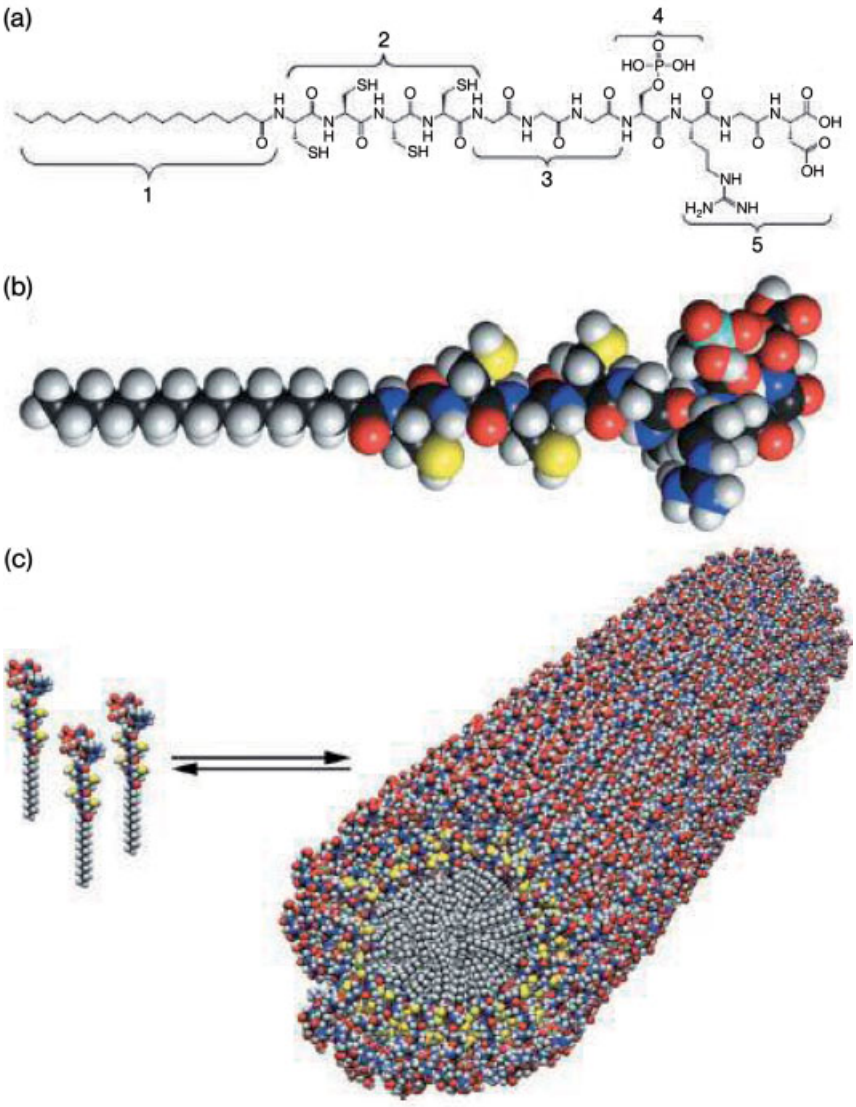

Figure 13.3 Self-assembled peptide scaffold. (a) The chemical structure of the peptide amphiphile. This is composed of a long alkyl tail (region 1), four consecutive cysteine residues (region 2), a flexible linker region of three glycine residues (region 3), a single phosphorylated serine residue (region 4) and cell adhesion ligand RGD (region 5); (b) The molecular model of (a); (c) These peptide amphiphiles are self-assembling into a cylindrical micelle. (Adapted from Ref. [47].)

nonbiofouling anionic HA were used to pattern cells on glass substrates. The subsequent adsorption of the cation PLL to HA pattern resulted in an adherent surface promoting the attachment of a second cell type. In order to minimize

toxicity, instead of PLL other positively charged molecules such as ECM components (i.e. collagen) have also been used (Figure 13.4) [56]. In a related experiment, cultured human endothelial cells have been patterned using LBL on a polyurethane surface. Here, it was observed that the cells did not spread on the negatively charged surface due to an electrostatic repulsion, whereas inversing the surface charge by adding positively charged collagen increased the cell spreading and proliferation. Thus, cell

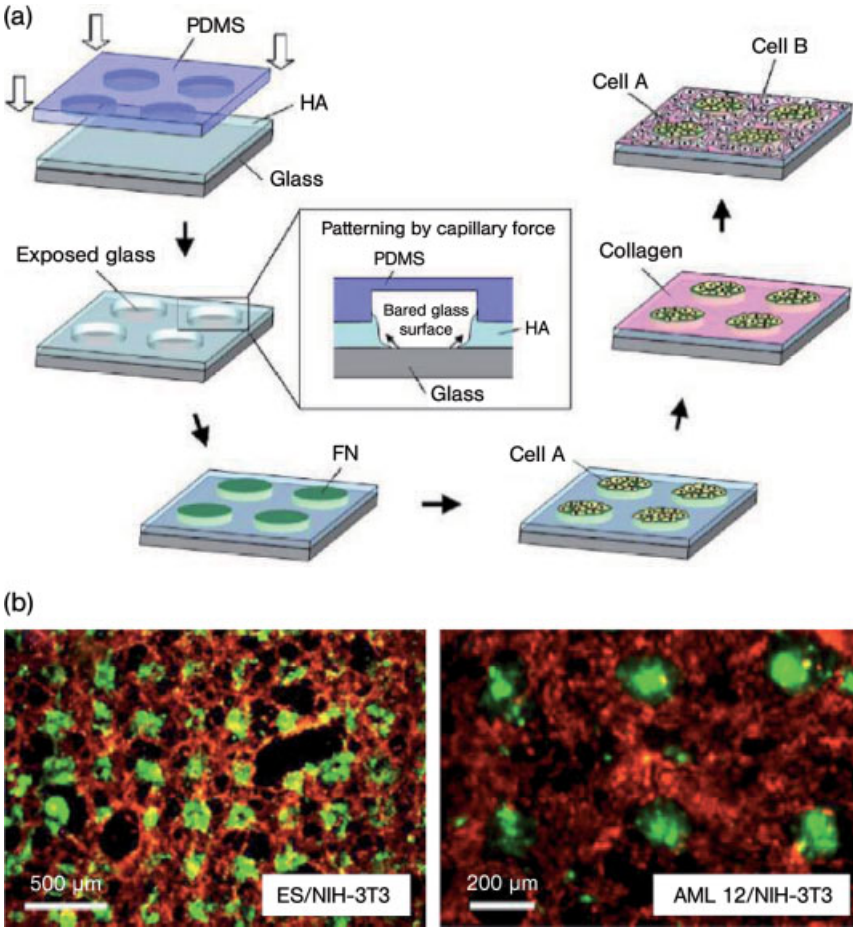

Figure 13.4 (a) The generation of cocultures using layer-by-layer deposition of the ECM materials, hyaluronic acid (HA) and collagen. A polydimethylsiloxane (PDMS) mold was placed on a glass slide coated with a thin layer of HA. Due to capillary forces, the HA in the exposed space of the PDMS mold receded, thus exposing the underlying glass surface. The exposed region of a glass substrate was coated with fibronectin (FN), where primary cells (cell A) could be selectively adhered. Subsequently, the PDMS mold was removed and collagen layered on the HA surface to make the surface adherent to secondary cells (cell B); (b) The fluorescent images of the patterned coculture after three days of culture, generated by a layer-by-layer coculture approach. The ESCs and hepatocytes (AML 12) were cocultured with the fibroblasts (NIH-3T3).

attachment on multilayer thin films may depend on the charge of the terminal polyion layer [57].

The number of layers in the LBL films may play a role in the cell attachment behavior. It was reported that increasing the number of layers of titanium oxide nanoparticle thin films increased the surface roughness, cell attachment and the rate of cell spreading. Although this may be due to the increased surface roughness, it also demonstrates the potential of this technology in controlling cell-surface properties [58]. Furthermore, the LBL assembly of PLL and dextran sulfate could be used to increase the rate of fibronectin deposition and the subsequent cell adhesion relative to the control substrates [59].

The LBL deposition of materials has been used in a variety of tissue engineering applications. For example, the LBL assembly of HgTe has been used to fabricate a hybrid device where the absorption of light by quantum nanoparticles stimulates neural cells by a sequence of photochemical and charge-transfer reactions [60]. These devices may be of potential use in tissue engineering applications in which it is desired to stimulate nerve cells using external cues. The LBL assemblies of nanoparticles have also been explored as a means of protecting arteries damaged during revascularization procedures. It has been reported that the deposition of self-assembled nanocoatings comprising alternating depositions of HA and chitosan onto aortic porcine arteries, led to a significant inhibition of the growth of thrombus on the damaged arterial surfaces. Clearly, this technique has the potential for clinical application to protect damaged arteries and to prevent subsequent restenosis [61]. Therefore, by properly choosing the LBL materials it is possible to modify the surface properties of materials for tissue engineering as well as for biosensing [62, 63] and drug delivery applications [64].

Mironov and colleagues have used the LBL technique for organ printing, with precise control over the spatial position of the deposited cell [65]. LBL deposition can also be used for the fabrication of immunosensors [66], islet cell encapsulation [67] and polyelectrolyte capsules for drug release [68].

13.3.3 Carbon Nanotubes

Carbon nanotubes are nanomaterials with unique mechanical and chemical properties. They have been used for cell tracking, for the delivery of desired molecules to cells, and as components of tissue engineering scaffolds [69]. Carbon nanotubes, depending on the number of carbon walls, can range from 1.5 to 30 nm in diameter and may be hundreds of nanometers in length.

Within tissue engineering scaffolds carbon nanotubes can be used to modify the mechanical and chemical properties. Furthermore, carbon nanotubes can be functionalized with biomolecules to signal the surrounding cells, or they may be electrically stimulated due to their high electrical conductivity to excite tissues such as muscle cells and nerve cells. One potentially powerful method of integrating carbon nanotubes into tissue engineering is by generating composite materials which comprise a biocompatible material such as collagen with embedded, single-

walled carbon nanotubes. As an example, smooth muscle cells (SMCs) have been encapsulated within collagen–carbon nanotube composite matrices with high cell viability (>85%) for at least 7 days [70]. Single-walled carbon nanotubes can also be used for culturing excitable tissues such as neuronal and muscle cells [71]. It has also been suggested that the growth of the neuronal circuits in carbon nanotubes might result in a significant increase in the network activity and an increase in neural transmission, perhaps due to the high electric conductivity of carbon nanotubes [72]. Furthermore, the electrical stimulation of osteoblasts cultured in nanocomposites comprising PLA and carbon nanotubes increased their cell proliferation and the deposition of calcium after 21 days. These data show that the use of novel current-conducting nanocomposites would be valuable for enhancing the function of the osteoblasts, and also provide useful avenues in bone tissue engineering [73].

Carbon nanotubes have also been used to delivery pharmaceutical drugs [74–76], genetic material [77–79] and biomolecules such as proteins [80, 81] to various cell types. For example, carbon nanotubes have been used to deliver Amphotericin B to fungal-infected cells. Here, the Amphotericin B was found to be bonded covalently to carbon nanotubes and was uptaken by mammalian cells, without significant toxicity, while maintaining its antifungal activity [82]. Thus, carbon nanotubes may be used for the delivery of antibiotics to specific cells.

The influence of carbon nanotubes on cells varies, depending on the type and their surface properties. For example, it has been reported that rat osteosarcoma (ROS) 17/2.8 cells, when cultured on carbon nanotubes carrying a neutral electric charge, proliferated to a greater extent than did other control cells [83]. Chemically modifying the surface of carbon nanotubes can also be used to enhance their cytocompatibility. For example, carbon nanotubes have been coated with bioactive 4-hydroxynonenal in order to culture embryonic rat brain neurons that promote neuronal branching compared to unmodified carbon nanotubes [84]. Despite such promise, however, the cytotoxicity of carbon nanotubes remains unclear. It is well known that various properties such as surface modifications and size greatly influence the potential toxicity of these structures. For example, long carbon nanotubes have been shown to generate a greater degree of inflammation in rats than shorter carbon nanotubes ($\sim$200 nm), which suggests that the smaller particles may be engulfed more easily by macrophages [85]. Other studies have also shown that carbon nanotubes may not only inhibit cell growth [86] but also induce pulmonary injury in the mouse model [87], when sequential exposure to carbon nanotubes and bacteria enhanced pulmonary inflammation and infectivity. Thus, more extensive and systematic studies must be conducted to ensure that the use of these nanomaterials in tissue engineering does not result in long-term toxicity.

13.3.4
MRI Contrast Agents

Nanotechnology may also permit the high-resolution imaging of tissue-engineered constructs. Specifically, the use of imaging contrast agents in magnetic resonance imaging (MRI) can be used to track cells *in vivo* and visualize constructs [88–90].

Although MRI contrast agents take many forms, nanoparticle systems have emerged in recent years as one of the most promising as nanoparticles not only provide an enormous surface area but can also be functionalized with targeting ligands and magnetic labels. Moreover, their smaller size provides an easy permeability across the blood capillaries.

Iron oxide nanoparticles have shown great promise for use in MRI to track cells, because they can be uptaken without compromising cell viability and are relatively safe. A wide variety of iron oxide-based nanoparticles have been developed that differ in hydrodynamic particle size and surface-coating material (dextran, starch, albumin, silicones) [91]. In general, these particles are categorized based on their diameter into superparamagnetic iron oxides (SPIOs) (50–500 nm) and ultrasmall superparamagnetic iron oxides (USPIOs) (<50 nm), with the size dictating their physico-chemical and pharmacokinetic properties. It has also been shown that clearance of the iron oxide nanoparticles in the rat liver depends on the outer coating [92].

Iron oxide nanoparticles have been used for imaging various organs, including the gastrointestinal tract, liver, spleen and lymph nodes. Furthermore, smaller-sized particles can also be used for angiography and perfusion imaging in myocardial and neurological diseases. Iron oxide particles can be coated with various molecules to increase their circulation and targeting. For example, dextran-coated iron oxide nanoparticles have been used for labeling cells, while anionic magnetic nanoparticles can be used to target positively charged tissues by using electrostatic interactions [93] (Figure 13.5). In addition, iron oxide nanoparticles can be used to track cells *in vivo* after transplantation. For example, MSCs and other mammalian cells labeled with SPIO nanoparticles were used to track cells in both experimental and clinical settings [94, 95]. Furthermore, green fluorescent protein (GFP^+) ESCs that were

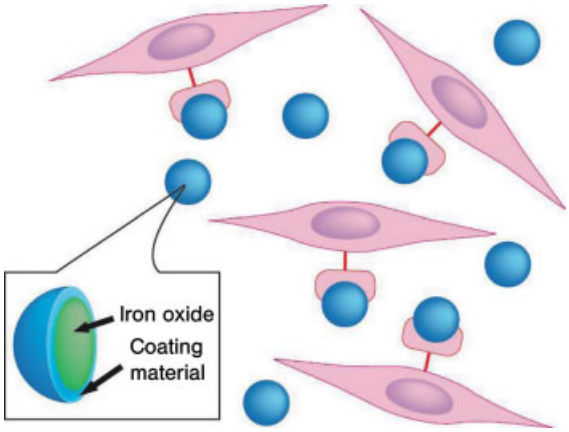

Figure 13.5 Schematic of the magnetic resonance molecular imaging. The tracking of magnetic nanoparticles to cancer cells is based on their static and dynamic magnetism, along with an ability to impart cell-specific functionality. The biocompatibility of coating materials (i.e., biscarboxyl-terminated poly(ethylene glycol)) allows for *in vivo* applications in animals and humans. Therefore, iron oxide nanoparticles show great promise for use in MRI to track cells *in vivo* and to visualize constructs, without compromising cell viability.

labeled with dextran-coated iron oxide nanoparticles and implanted into the brains of rats with brain stroke showed that the cells could be tracked for at least three weeks [96]. The *in vivo* tracking of iron oxide nanoparticle-labeled rat bone marrow MSCs and mouse ESCs and human $CD34^+$ hematopoietic progenitor cells in rats with a cortical or spinal cord lesion has also shown that cells may remain visible in the lesion for at least 50 days [97, 98]. Taken together, these and other results [99] indicate that magnetic nanoparticles are well-suited for the noninvasive analysis of cell migration, engraftment and morphological differentiation at high spatial and temporal resolution.

In order to target desired cells or to modify the rate of cellular uptake, nanoparticles may be engineered with specific molecules on their surfaces. For example, in order to increase their internalization, NSCs and $CD34^+$ bone marrow cells were labeled with superparamagnetic nanoparticles that were conjugated with short HIV-Tat peptides. This increased the internalization of the particles by the cells, without affecting their viability, differentiation or proliferation. The localization and retrieval of cell populations *in vivo* enabled a detailed analysis of specific stem cell and organ interactions that were critical for advancing the therapeutic use of stem cells [100]. In addition to iron oxide nanoparticles, other types of nanoparticle have also been used for tissue imaging, notably with applications in tissue engineering. As an example, fluoroscein isothiocyanate (FITC) -conjugated mesoporous silica nanoparticles (MSNs) have been used to label human bone marrow MSCs and 3T3-L1 cells. The FITC-MSNs were efficiently internalized into MSCs and 3T3-L1 cells, even with short-term incubation (2–4 h), without affecting cell viability [101]. Thus, it seems that nanoparticles can be used potentially not only to track cells but also to image tissues which may be useful for the noninvasive imaging of tissue-engineered constructs.

13.3.5
Quantum Dots

Nanoscale probes can also be used in tissue engineering applications for the study of various biological processes, as well as for real-time cell detection and tracking. Fluorescent dyes, which traditionally have been used to image cells and tissues, have several drawbacks including photobleaching and a lack of long-term stability. Quantum dots (QDs) are nanoparticles that have several advantages over conventional fluorophores for imaging, including tunable properties and a resistance to photobleaching [6]. QDs are semiconductor nanostructures that confine the motion of conduction band electrons, valence band holes or excitons in all three spatial directions. The band gap energy of the QD is the energy difference between the valence band and the conduction band. For nanoscale semiconductor particles such as QDs, the bandgap is dependent on the size of the nanocrystal, which results in a size-dependent variation in emission. A single light source can also be used for the simultaneous excitation of a spectrum of emission wavelength, which makes the method useful for multicolor, multiplexed biological detection and imaging applications.

QDs can be used for the ultrasensitive imaging of molecular targets in deep tissue and living animals (Figure 13.6). Here, they are used as specific markers for cellular structures [102, 103] and molecules [104], for monitoring physiological events in live cells [105–107], for measuring cell motility [108], and for monitoring RNA delivery and tracking cells [109] *in vivo*. As an example, QDs have been used for locating multiple distinct endogenous proteins within cells, thus determining the precise protein distribution in a high-throughput manner [110]. Peptide ligand-conjugated QDs have also been used for imaging G-protein-coupling receptors in both whole-cells and as single-molecules [111]. Cellular events such as the transport of lipids and proteins across membranes have also been tracked using QDs with molecular resolution in live cells [112]. Furthermore, QDs conjugated to immunoglobulin G (IgG) and streptavidin have been used to label the breast cancer marker Her2 on the surface of fixed and live cancer cells [113].

QDs have significant potential in analyzing the mechanisms of cell growth, apoptosis, cell–cell interactions, cell differentiations and inflammatory responses. For example, QDs have been used to study the signaling pathways of mast cells during an inflammatory response [114], as well as to quantify changes in organelle morphology during apoptosis [115]. In addition, the photostability and biocompatibility of QDs make them the preferred agents for the long-term tracking of live cells [116]. QDs are internalized into cells by endocytosis [117], by receptor-mediated uptake [118], by peptide-mediated transportation [119, 120] or microinjection [121]. An example of this was recently demonstrated in studies in which ligand-conjugated QDs were used to monitor antigen binding, entry and trafficking in dendritic cells [122]. QDs, when conjugated to a transporter protein, have also been used to label malignant and nonmalignant hematological cells and to track cell division, thus enabling lineage tracking [109].

Despite the remarkable potential for the application of QDs in clinical medicine, their toxicity and long-term adverse effects are still not clearly understood. The metabolism, excretion and toxicity of QDs may depend on multiple factors such as size, charge, concentration and outer coating bioactivity, as well as their oxidative, photolytic and mechanical stabilities and other unknown factors [123]. Importantly, these issues must be addressed before QDs can be used for *in vivo* applications in humans.

13.4 Future Directions

During a relatively short period of time, nanomaterials have spawned a number of new approaches to address important challenges in tissue engineering. These challenges range from understanding the mechanisms of stem cell differentiation to generating functional vasculature within tissue engineering constructs. Despite these advancements, further investigations are required to analyze the true potential and clinical viability of these technologies. Our current lack of knowledge regarding the long-term toxicity of many nanoengineered materials represents a

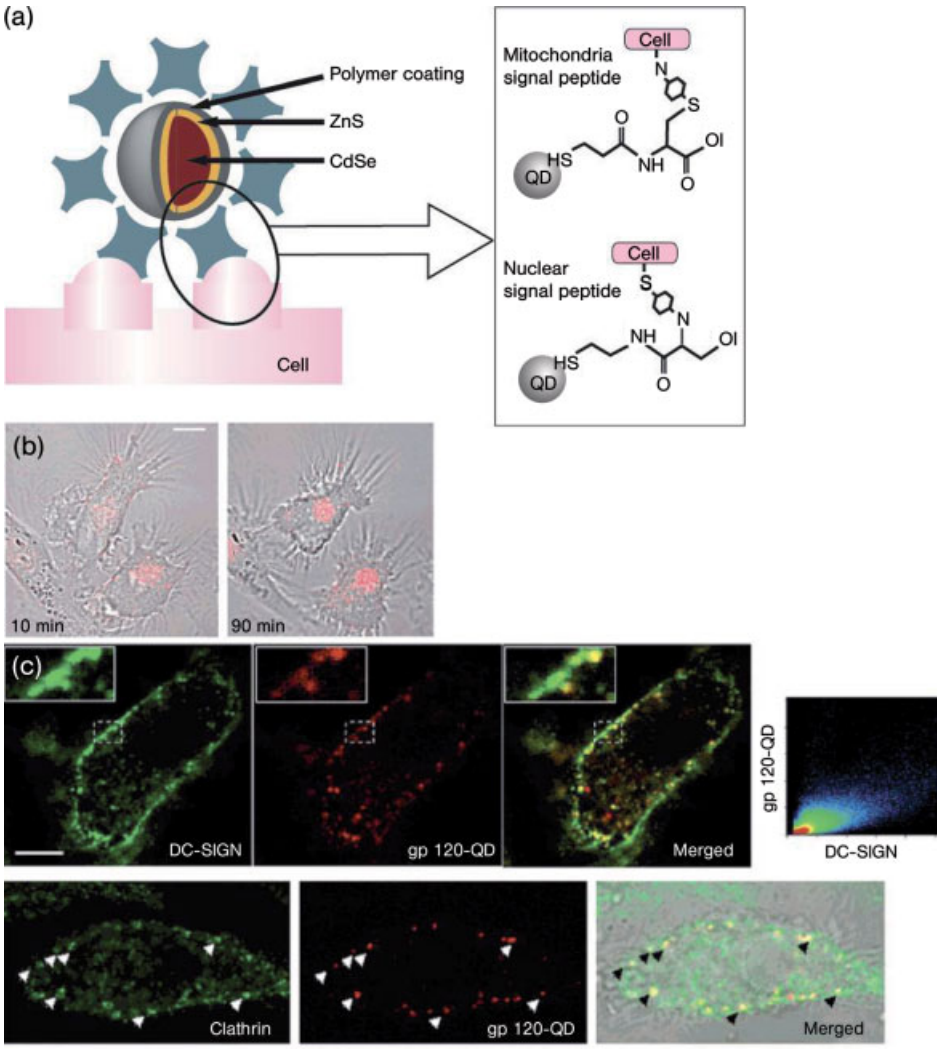

Figure 13.6 (a) Schematic of quantum dots (QDs). QDs are typically made from nanocrystals of a semiconductor material (CdSe), which has been coated with an additional semiconductor shell (ZnS) to improve the material's optical properties. This material is coated with a polymer shell that allows the materials to be conjugated to biological molecules and to retain their optical properties. These nanocrystals have been coupled to various biomolecules directly or indirectly. The inset at the right shows a schematic of peptide-conjugated QDs for organelle targeting and imaging. The amino acid-coated QDs are conjugated with target peptides by coupling. QDs can reveal the transduction of proteins and peptides into specific subcellular compartments as a powerful tool for studying intracellular analysis *in vitro* and even *in vivo*. (Adapted from Ref. [124].); (b) Ligand-conjugated QDs internalized by dendritic cells (DCs) via their specific binding protein (DC-SIGN). Ligand-coated QDs bind to DC-SIGN and are endocytosed into DCs; (c) DCs were incubated with the HIV-1 envelope glycoprotein gp120-QDs (red). After washing of unbound QDs, DCs were fixed and labeled with DC-SIGN marker (green). Data were obtained using confocal microscopy. The right-hand panel shows a 2-D histogram of DC-SIGN signal versus gp120-QDs signal. This result indicated that the small amount of dispersion leads to high colocalization. (Adapted from Ref. [122].)

critical barrier for their use in humans. Traditionally, tissue engineers have favored materials that have a long history of medical application (i.e. FDA approved), although many such materials have limitations to be overcome, perhaps through rational design enabled by nanotechnology. Thus, there remains a clear need to develop nanoengineered materials capable of addressing the various challenges of tissue engineering. In addition, systematic toxicity studies must be conducted in order to fully optimize and characterize not only the function but also the long-term behavior of nanomaterials *in vivo*. Yet, many of the traditional methods used to analyze previous generations of biomaterials do not apply to nanoscale materials, and a clear paradigm shift is required in these analytical and standardization procedures. This will range from how we study material–cell interactions *in vitro* and *in vivo*, to the standardization requirements of regulatory bodies such as the FDA. Clearly, these modifications will require extensive discussion amongst the scientists, the patients, the general public, the clinicians and the regulatory officers.

13.5 Conclusions

Today, nanotechnology offers a wide variety of tools in tissue engineering, biomedical imaging, biosensing, diagnostics and drug delivery. Nanotechnology-based applications are valuable in the research and development of viable substitutes that may restore, maintain or even improve the function of human tissues. Today, these materials have not only opened up novel applications but have also addressed a number of limitations associated with traditional approaches and materials. Nonetheless, much research is required to further demonstrate the long-term stability and clinical utility of nanoengineered materials.

Acknowledgments

The authors greatly appreciate the helpful discussions with Drs Hossein Hosseinkhani and Hossein Baharvand. They also acknowledge generous funding from the Draper laboratory, the CIMIT, NIH and Coulter Foundation.

Self-Assembling Peptide-Based Nanostructures for Regenerative Medicine

Ramille M. Capito, Alvaro Mata, and Samuel I. Stupp

14.1
Introduction

The goal of regenerative medicine is to develop therapies that can promote the growth of tissues and organs in need of repair as a result of trauma, disease or congenital defects. For most of the patient population this means regeneration of our bodies in adulthood, although there are also many critical pediatric needs in regenerative medicine. One specific target that would deeply impact the human condition is regeneration of the central nervous system (CNS). This would bring a higher quality of life to individuals paralyzed as a result of spinal cord injury, brought into serious dysfunction by stroke, afflicted with Parkinson's and Alzheimer's diseases, or those blind as a result of macular degeneration or retinitis pigmentosa. Another area that would benefit from regenerative medicine is heart disease, which continues to be one of the most dominant sources of premature death in humans. Here, the potential to regenerate myocardium would have a great impact on clinical outcomes. Many additional important targets exist. The regeneration of insulin-producing pancreatic β cells would bring a higher quality of life to individuals suffering from diabetes. Damage to cartilage – a critical tissue in correct joint function – is an enormous source of pain and compromised agility for many individuals, especially in societies that value a physically active life style for as long as possible. Other musculoskeletal tissues such as bone, intervertebral disc, tendon, meniscus and ligament all remain major therapeutic challenges in regenerative medicine. Another emerging target that could have an enormous impact is the regeneration of teeth, as this would prevent the need for dentures and other dental implants. All of these important targets in regenerative medicine would not only raise the quality of life for many individuals worldwide, but they would also have, for obvious reasons, a significant economic impact.

The development of effective regenerative medicine strategies generally includes the use of cells, soluble regulators (e.g. growth factors or genes) and

Nanotechnology, Volume 5: Nanomedicine. Edited by Viola Vogel

ISBN: 978-3-527-31736-3

scaffold technologies. In their natural environment, mammalian cells live surrounded by a form of solid or fluid matrix composed of structural protein fibers (i.e. collagen and elastin), adhesive proteins (i.e. fibronectin and laminin), soluble proteins (i.e. growth factors) and other biopolymers (i.e. polysaccharides), all of which have specific inter-related roles in the structure and normal function of the extracellular matrix (ECM). The creation of biomimetic artificial matrices represents a common theme in designing materials for regenerative medicine therapies, and stems from the idea that providing a more natural three-dimensional (3-D) environment can preserve cell viability and encourage cell differentiation and matrix synthesis. The nanoscale design of biomaterials, with particular attention to dimension, shape, internal structure and surface chemistry, may more effectively emulate the very sophisticated architecture and signaling machinery of the natural ECM for improved regeneration.

Strategies utilizing self-assembled supramolecular aggregates, macromolecules and even inorganic particles could be used to design a signaling machinery *de novo* that initiates regeneration events which do not occur naturally in mammalian biology. Self-assembly – a bioinspired phenomenon which involves the spontaneous association of disordered components into well-defined and functionally organized structures [1] – can play a major role in creating sophisticated and biomimetic biomaterials for regenerative therapies [2–7]. In molecular systems, self-assembly implies that molecules are programmed by design to organize spontaneously into supramolecular structures held together through noncovalent interactions, such as electrostatic or ionic interactions, hydrogen bonding, hydrophobic interactions and van der Waals interactions. Large collections of these relatively weak bonds compared to covalent bonds can result in very stable structures.

The first fundamental reason for a link between self-assembly and regenerative medicine is the potential to create multifunctional artificial forms of an ECM starting with liquids. Such liquids could contain dissolved molecules or pre-assembled nanostructures, and they could then be introduced by injection at a specific site or targeted through the circulation. Following self-assembly, a solid matrix could mechanically support cells and also signal them for survival, proliferation, differentiation or migration. Alternatively, the self-assembled solid matrix could be designed to recruit specific types of cells in order to promote a regenerative biological event, or serve as cell delivery vehicles by localizing them in 3-D environments within tissues and organs. These self-assembling molecules could also be used to modify the surfaces of solid implants in order to render them bioactive [1, 8, 9]. The 'bottom-up' approach that is possible using self-assembly can permit the creation of an architecture that multiplexes signals or tunes their concentration per unit area. This versatility makes self-assembling systems ideal for creating optimal materials for regenerative medicine therapies.

In this chapter, we focus on the use of self-assembling nanostructures – in particular, peptide-based molecules – which are currently being developed for regenerative medicine applications. Although many of these technologies are relatively new, much very promising biological data – both *in vitro* and *in vivo* – demonstrating

the promise of these systems in regenerative medicine is already available. Two currently important research areas in this field include:

- The development of self-assembling injectable bioactive scaffolds that have the ability to mimic the natural 3-D ECM of cells.
- The nanoscale surface modification of surfaces or 3-D tissue engineering scaffolds using self-assembling molecules to create bioactive implants and devices.

14.2 Self-Assembling Synthetic Peptide Scaffolds

Peptides are among the most useful building blocks for creating self-assembled structures at the nanoscale; they possess the biocompatibility and chemical versatility that are found in proteins, yet they are more chemically and thermally stable [10]. They can also be easily synthesized on a large scale by using conventional chemical techniques, and designed to contain functional bioactive sequences. A variety of short peptide molecules have been shown to self-assemble into a wide range of supramolecular structures including nanofibers, nanotubes, nanospheres and nanotapes. Some self-assembling nanostructures have been used successfully to generate injectable scaffolds with an extremely high water content and architectural features that mimic the natural structure of the ECM. These self-assembling scaffolds show great potential as 3-D environments for cell culture and regenerative medicine applications, and also as vehicles for drug, gene or protein delivery.

14.2.1 β-Sheet Peptides

Aggeli and colleagues demonstrated that the biological peptide β-sheet motif can be used to design oligopeptides that self-assemble into semi-flexible β-sheet nanotapes [11]. Depending on the intrinsic chirality of the peptides and concentration, these nanostructures can further assemble into twisted ribbons (double tapes), fibrils (twisted stacks of ribbons) and fibers (fibrils entwined edge-to-edge) (Figure 14.1a) [12]. The assembly process is principally driven by hydrogen bonding along the peptide backbone and interactions between specific side chains [13]. At sufficiently high peptide concentrations, these structures can become entangled to form gels, the viscoelastic properties of which can be altered by controlling the pH, by applying a physical (shear) stress, or by altering the peptide concentration. As in other peptide self-assembling systems, the hierarchical assembly can be altered by the addition and position of charged amino acids within the peptide sequence that is highly controlled by changes in pH [12] (Figure 14.1b and c). It has also been shown that mixing aqueous solutions of cationic and anionic peptides that have complementary charged side chains and a propensity to form antiparallel β-sheets, results in the spontaneous self-assembly of fibrillar networks and hydrogels that are robust to variations in pH and peptide concentration [14].

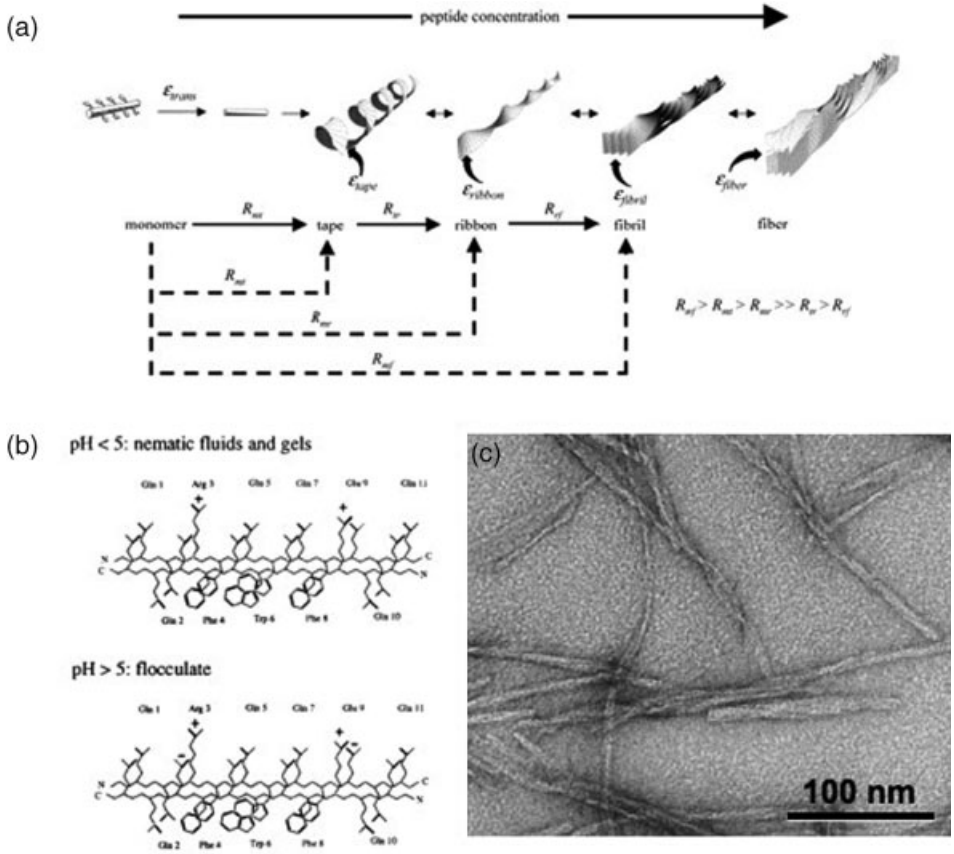

Figure 14.1 (a) The global equilibrium configurations obtained by the hierarchical self-assembly of β-sheet-forming peptides. The set of energy parameters ε_j correspond to the free energy differences per peptide molecule between successive structures. The 'critical' peptide concentrations at which each new configuration begins to appear is determined by the ε_j. The R_{ij} are the conversion rates both between and to the various configurations. The process depicted by solid arrows represents the dissolution route of lyophilized solid at constant pH, while the dashed arrows represent the direct and simultaneous conversion of monomer to tapes, ribbons, fibrils and fibers when the respective critical concentrations governing their self-assembly are instantaneously switched by pH change to values above the absolute peptide concentration in solution; (b) Electrostatic charge distribution on P11-2 dimer in an antiparallel β-sheet tape-like substructure: top, pH < 5; bottom, pH > 5; (c) Transmission electron microscopy image of a gel. (Reproduced with permission from Ref. [12]; © 2003, American Chemical Society.)

These β-sheet peptide nanostructures have been studied for the treatment of enamel decay [13]. *In vitro*, extracted human premolar teeth (containing caries-like lesions) were exposed to several cycles of demineralizing (acidic conditions) and remineralizing solutions (neutral pH conditions). Application of the self-assembling peptides to the defects significantly decreased demineralization during exposure

to acid and increased remineralization at neutral pH, resulting in a net mineral gain of the lesions compared to untreated controls [13]. Furthermore, when the peptide gels were incubated for one week in mineralizing solutions, *de novo* nucleation of hydroxyapatite by the nanostructures was observed [13].

In another application, these peptides were evaluated as an alternative injectable joint lubricant to hyaluronic acid (HA) for the treatment of osteoarthritis [15]. A β-sheet peptide designed to have molecular, mesoscopic and rheological properties that most closely resembled HA, performed similarly to HA in healthy static and dynamic friction tests, but not as well in friction tests with damaged cartilage [15]. The optimization of these peptides may result in a new alternative viscosupplementation treatment for degenerative osteoarthritis.

14.2.2 β-Hairpin Peptides

Another peptide design that exploits β-sheet nanostructure formation into a hydrogel network is composed of strands of alternating hydrophilic and hydrophobic residues flanking an intermittent tetrapetide [16–21] (Figure 14.2a and b). These peptides are designed so that they are fully dissolved in aqueous solutions in random coil conformations. Under specific stimuli, the molecules can be triggered to fold into a β-hairpin conformation that undergoes rapid self-assembly into a β-sheet-rich, highly crosslinked hydrogel. The molecular folding event – where one face of the β-hairpin structure is lined with hydrophobic valines and the other with hydrophilic lysines – is governed by the arrangement of polar and nonpolar residues within the sequence. Subsequent self-assembly of the individual hairpins occurs by hydrogen bonding between distinct hairpins and hydrophobic association of the hydrophobic faces. One such peptide was designed to self-assemble under specific pH conditions [16]. Under basic conditions, the peptide intramolecularly folds into the hairpin structure and forms a hydrogel. Unfolding of the hairpins and dissociation of the hydrogel structure can be triggered when the pH is subsequently lowered below the pK_a of the lysine side chains, where unfolding is a result of the intrastrand charge repulsion between the lysine residues [16]. Rheological studies indicate that these β-hairpin hydrogels are both rigid and shear-thinning; however, the mechanical strength is quickly regained after cessation of shear [16] (Figure 14.2a).

These gels can also be triggered to self-assemble when the charged amino acid residues within the sequence are screened by ions [22]. If a positively charged side chain of lysine is replaced by a negatively charged side chain of glutamic acid, the overall peptide charge is decreased and the peptide can be more easily screened, resulting in a much faster self-assembly [21]. The kinetics of hydrogelation were found to be significant for the homogeneous distribution of encapsulated cells within these types of self-assembling gels [21] (Figure 14.2c). Thermally reversible, self-assembling peptides were also synthesized by replacing specific valine residues with threonines to render the peptides less hydrophobic [17]. At ambient temperature and slightly basic pH, the peptide is unfolded; however, upon heating the peptide

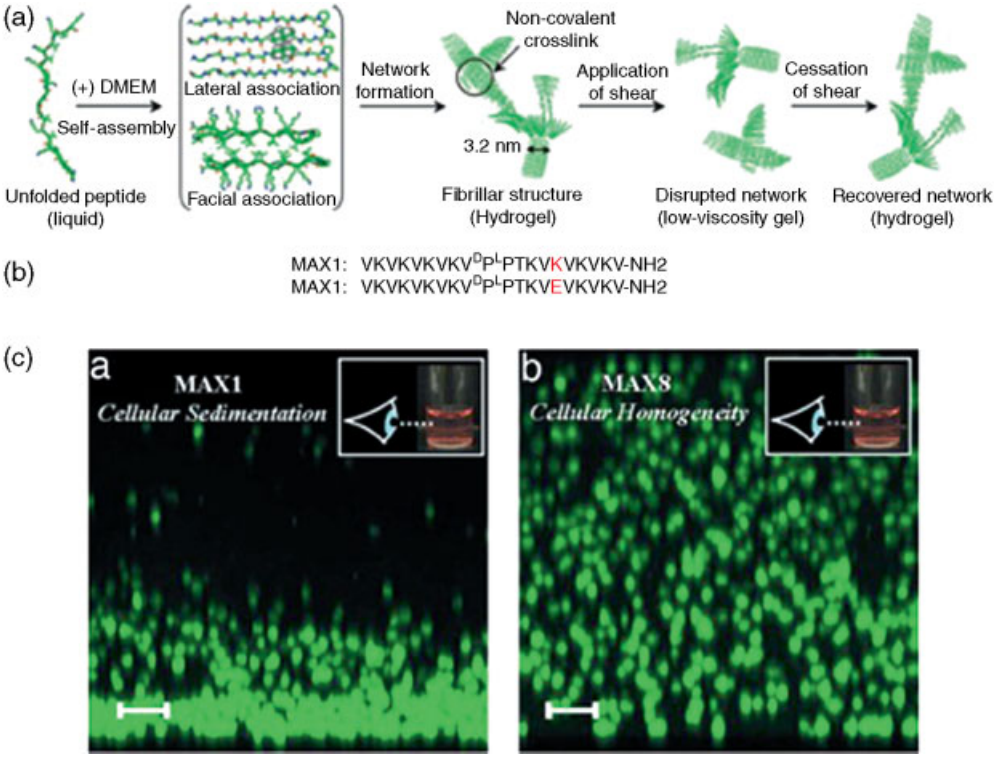

Figure 14.2 Self-assembly, shear-thinning and self-healing mechanism allowing rapid formation of β-hairpin hydrogels that can be subsequently syringe-delivered. (a) Addition of Dulbecco's modified Eagle medium (DMEM; pH 7.4, 37 °C) to a buffered solution of unfolded peptide induces the formation of a β-hairpin structure that undergoes lateral and facial self-assembly affording a rigid hydrogel with a fibrillar supramolecular structure. Subsequent application of shear stress disrupts the noncovalently stabilized network, leading to the conversion of hydrogel to a low-viscosity gel. Upon cessation of shear stress, the network structure recovers, converting the liquid back to a rigid hydrogel; (b) Peptide sequences of MAX8 and MAX1; (c) Encapsulation of mesenchymal C3H10t1/2 stem cells in 0.5 wt% MAX1 and MAX8 hydrogels. Shown are LSCM z-stack images (viewed along the *y*-axis) showing the incorporation of cells into a MAX1 gel leading to cell sedimentation (panel a) and into a MAX8 gel resulting in cellular homogeneity (panel b). folds and assembles via hydrophobic collapse as the temperature dehydrates the nonpolar residues within the peptide [17]. Yet another rendition of this peptide self-assembles via light activation [20]. In this design, a photocaged peptide is incorporated within the peptide sequence, with β-hairpin folding and subsequent hydrogelation occurring only when the photocage is released upon irradiation of the sample [20].

In vitro studies have shown that these types of β-hairpin hydrogels can support the survival, adhesion and migration of NIH 3T3 fibroblasts [20–22], and can be used to

encapsulate mesenchymal stem cells (MSCs) and hepatocytes [21]. Another study also showed that these gels have an inherent antibacterial activity, with selective toxicity to bacterial cells versus mammalian cells [23].

14.2.3 Block Copolypeptides

Deming and colleagues have developed diblock copolypeptide amphiphiles containing charged and hydrophobic segments that self-assemble into rigid hydrogels and can remain mechanically stable even at high temperatures (up to 90 °C) [24, 25] (Figure 14.3). These hydrogels were also found to recover rapidly after an applied stress, attributed to the relatively low molecular mass of the copolypetides, enabling rapid molecular organization. Their amphiphilic characteristics, architecture (diblock versus triblock) and block secondary structure (e.g. α-helix, β-strand or random coil) were found to play important roles in the gelation, rheological and morphological properties of the hydrogel [24–26]. One type of block copolypeptide consists of a hydrophobic block of poly-L-lysine and a shorter hydrophobic block of poly-L-leucine [26]. The helical secondary structure of the poly-L-leucine blocks was shown to be instrumental for gelation, while the hydrophilic polyelectrolyte segments helped to stabilize the twisted fibril assemblies by forming a corona around the hydrophobic core [26] (Figure 14.3).

In vitro studies using mouse fibroblasts revealed that, at concentrations below gelation, lysine-containing diblocks were cytotoxic to the cells, whereas glutamic

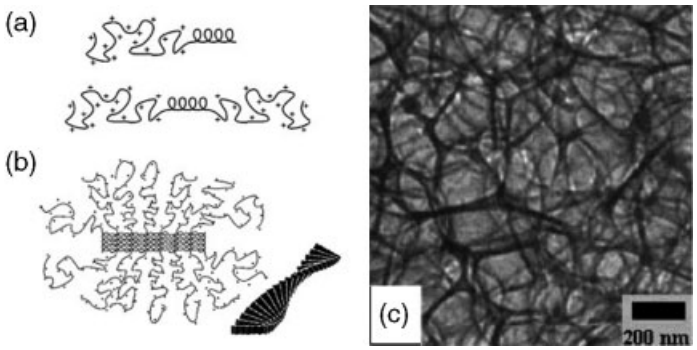

Figure 14.3 (a) Diblock (top) and triblock (bottom) copolypeptide architectures. The hydrophobic leucine block exhibits α-helical secondary structure, and the charged polyelectrolyte block has a stretched-coil configuration; (b) Packing of amphiphilic diblock copolypeptide molecule fibrils, the cross-section being shown in detail and the inset schematically depicting how the cross-sectional layers assemble into twisted fibers (for clarity, only the helices are drawn). acid-containing peptides were not cytotoxic [27]. In gel form, however, both lysine and glutamic acid-based diblocks were noncytotoxic, although the scaffolds did not support cell attachment or proliferation. This demonstrates how molecular design and charge can significantly affect the cytoxicity and biological activity of the resulting self-assembled material. Future research is directed towards covalently incorporating bioactive sites within these hydrogels in order to increase cellular attachment and enhance the biological response [27].

14.2.4 Ionic Self-Complementary Peptides

Another class of self-assembling peptide molecules developed by Zhang *et al*. was designed to include alternating positive and negative amino acid repeats within the peptide sequence [28, 29]. These oligopeptides associate to form stable fibrillar nanostructures in aqueous solution through β-sheet formation, due to their hydrophilic and hydrophobic surfaces and complementary ionic bonding between the oppositely charged residues. Upon addition of monovalent cations or physiological media, they form hydrogels composed of interwoven nanofibers (Figure 14.4a) [29, 30]. Studies have shown that oligopeptide length [31] and side-chain hydrophobicity [32] were important variables that affected the self-assembly and the resulting gel properties.

Several *in vitro* and *in vivo* studies have been conducted investigating the ability of these scaffolds to support cell attachment [29], survival, proliferation and differentiation for neural [30, 33–35], blood vessel [36–38], myocardial [39–42], liver [43], cartilage [44] and bone tissue regeneration [45, 46]. For the treatment of neural defects, primary mouse neuron cells encapsulated within the hydrogels were able to attach to the nanofiber matrix and showed extensive neurite outgrowth [30]. Furthermore, peptides implanted *in vivo* did not elicit a measurable immune response or tissue inflammation [30]. In a hamster model, the peptide scaffolds were shown to regenerate axons and reconnect target tissues in a severed optic tract that resulted in the restoration of visual function [33]. Likewise, the peptide scaffolds caused an effective promotion of cell migration, blood vessel growth and axonal elongation when implanted with neural progenitor cells and Schwann cells in the transected dorsal column of the rat spinal cord [47] (Figure 14.4b).

For the treatment of myocardial infarction, Davis *et al*. injected peptide scaffolds into rat myocardium and observed the recruitment of endothelial progenitor cells and vascular smooth muscle cells into the injection site that appeared to form functional vascular structures [40]. Biotinylated nanofibers were subsequently used to deliver insulin-like growth factor 1 (IGF-1) *in vivo* over prolonged periods (28 days) and were shown to significantly improve systolic function after myocardial infarction when delivered with transplanted cardiomyocytes [39]. Other *in vivo* studies, which delivered platelet-derived growth factor (PDGF)-BB with the self-assembling nanofibers in a rat myocardial infarct model, showed decreased cardiomyocyte death, reduced infarct size and a long-term improvement in cardiac performance after infarction, without systemic toxicity [41, 42].

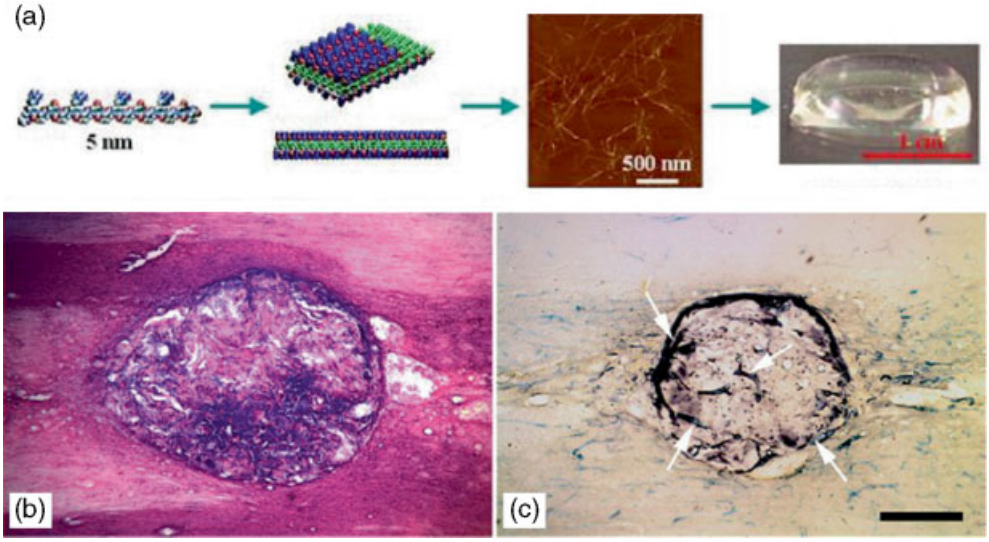

Figure 14.4 (a) Ionic self-complementary peptide consisting of 16 amino acids, ~5 nm in size, with an alternating polar and nonpolar pattern. These peptides form stable β-strand and β-sheet structures the side chains of which partition into two sides, one polar and the other nonpolar. These undergo self-assembly to form nanofibers with the nonpolar residues inside (green) and + (blue) and − (red) charged residues forming complementary ionic interactions, like a checkerboard. These nanofibers form interwoven matrices that further form a scaffold hydrogel with very high water content (>99.5%). (Reproduced with permission from Zhang, S. 14.2.5
Fmoc Peptides

A more recently developed class of self-assembling peptides that uses fluorenylmethyloxycarbonyl (Fmoc) -protected di- and tri-peptides have been shown to form highly tunable hydrogel structures (Figure 14.5a). The formation of these gels can be achieved either by pH adjustment [48] (Figure 14.5b) or by a reverse-hydrolysis enzyme action [49] (Figure 14.5c). Assembly occurs via hydrogen bonding in β-sheet arrangement and by π–π stacking of the fluorenyl rings that also stabilize the system [48] (Figure 14.5b). A number of sheets then twist together to form nanotubes (Figure 14.5d).

The results of *in vitro* studies indicated that these hydrogels can support chondrocyte survival and proliferation in both two and three dimensions [48]. It was also observed that cell morphology varied according to the nature of the molecular structure [48].

14.2.6
Peptide Amphiphiles

Peptide amphiphiles (PAs) are self-assembling molecules that also use hydrophobic and hydrophilic elements to drive self-assembly. There are different types of peptide amphiphiles that can assemble into a variety of nanostructures such as spherical micelles, fibrils, tubes or ribbons [50]. One unique PA design, which forms high-aspect ratio cylindrical nanofibers, has been exclusively studied during the past decade for regenerative medicine applications. These molecules are particularly distinguished from the other peptide systems described above, in that their amphiphilic nature derives from the incorporation of a hydrophilic head group and a hydrophobic alkyl tail, as opposed to molecules consisting of all amino acid residues with resultant hydrophilic and hydrophobic faces.

Stupp and colleagues have developed a family of amphiphilic molecules that can self-assemble from aqueous media into 3-D matrices composed of supramolecular nanofibers [4–6, 9, 51–59]. These molecules consist of a hydrophilic peptide segment which is bound covalently to a highly hydrophobic alkyl tail found in ordinary lipid molecules. The alkyl tail can be located at either the C or N terminus [51], and can also be constructed to contain branched structures [55]. In Stupp *et al.*'s specific design, the peptide region contains a β-sheet-forming peptide domain close to the hydrophobic segment and a bioactive peptide sequence (Figure 14.6a). Upon changes in

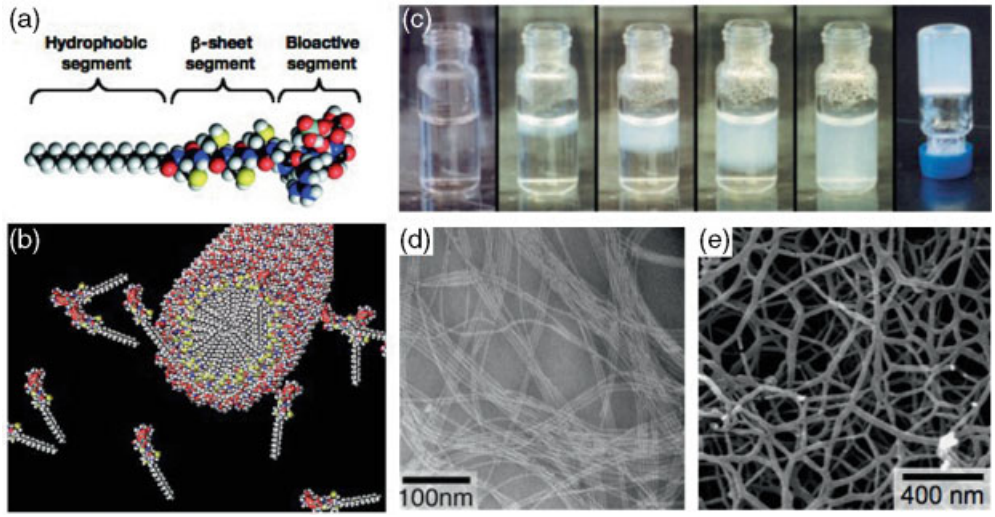

Figure 14.6 (a) General structure of PA molecules; (b) Illustrated self-assembly of PA molecules into nanofibers with hydrophobic cores; (c) Time sequence of pH-controlled PA self-assembly. From left to right: PA molecule dissolved in water at a concentration of 0.5% by weight at pH 8 is exposed to HCl vapor. As the acid diffuses into the solution a gel phase is formed, which self-supports upon inversion; (d) Transmission electron microscopy image of PA nanofibers. (Reproduced with permission from Ref. [5]; © 2002, National Academy of Sciences.); (e) Scanning electron microscopy image of PA nanofiber network. (Reproduced with permission from Ref. [7]; © 2005, Materials Research Society.)

pH or the addition of multivalent ions, the structure of these molecules drives their assembly into cylindrical nanofibers through hydrogen bonding into β-sheets and hydrophobic collapse of alkyl tails away from the aqueous environment to create nanofibers with a hydrophobic core (Figure 14.6b). This cylindrical nanostructure allows the presentation of high densities of bioactive epitopes at the surface of the nanofibers [6], whereas, if peptides were assembled into twisted sheets or tubes, this type of orientational biological signaling would not be possible [7]. These systems can also be used to craft nanofibers containing two or more PA molecules that can effectively coassemble, thus offering the possibility of multiplexing different biological signals within a single nanofiber [56].

The presence of a net charge in the peptide sequence ensures that the molecules or small β-sheet aggregates remain dissolved in water, inhibiting self-assembly through coulombic repulsion. Self-assembly and gelation is subsequently triggered when the charged amino acid residues are electrostatically screened or neutralized by pH adjustment, or by the addition of ions (Figure 14.6c–e). The growth of nanofibers can therefore be controlled by changing the pH or raising the concentration of screening electrolytes in the aqueous medium [7]. Growth and bundling of the nanofibers eventually lead to gelation of the PA solution. *In vivo*, ion concentrations present in physiological fluids can be sufficient to induce the formation of PA nanostructures [54]. Thus, a minimally invasive procedure could be designed

with these systems through a simple injection of the PA solution that spontaneously self-assembles into a bioactive scaffold at the desired site. Over time, the small molecules composing the nanofibers should biodegrade into amino acids and lipids, thus minimizing the potential problems of toxicity or immune response [54].

The results of both *in vitro* and *in vivo* studies have shown that these PA systems can serve as an effective analogue of the ECM by successfully supporting cell survival and attachment [60, 61], mediating cell differentiation [6] and promoting regeneration *in vivo* [57]. In efforts to address neural tissue regeneration for the repair of a spinal cord injury or treatment of extensive dysfunction as a result of stroke or Parkinson's disease, Stupp and colleagues have designed PAs to display the pentapeptide epitope isoleucine-lysine-valine-alanine-valine (IKVAV). This particular peptide sequence is found in the protein laminin, and has been shown to promote neurite sprouting and to direct neurite growth [6]. When neural progenitor cells were encapsulated within this PA nanofiber network, the cells more rapidly differentiated into neurons compared to using the protein laminin or the soluble peptide (Figure 14.7a and b). The PA scaffold was also found to discourage the development of astrocytes, a type of cell in the CNS which is responsible for the formation of glial scars that prevent regeneration and recovery after spinal cord injury. In this same study, the

density of epitopes displayed on the nanofibers proved to be a significant variable in the ability to induce rapid and selective differentiation of cells encapsulated within the PA gels. Furthermore, *in vivo* studies in which this self-assembling neural nanofiber scaffold was injected within a spinal cord injury in a rat model showed better functional improvement and axonal elongation through the injury site compared to controls [62] (Figure 14.7c and d).

Another PA molecule was designed to self-assemble upon the addition of heparin, a biopolymer that binds to angiogenic growth factors [57]. The resultant nanofibers displayed heparin chains on the periphery, which orient proteins on the surface for cell signaling. In an *in vivo* rabbit corneal model, the heparin-binding PA nanostructures, administered with only nanogram quantities of angiogenic growth factors, was sufficient to stimulate extensive neovascularization compared to controls (Figure 14.8). When using the same PA system, Kapadia *et al.*, was also able to create self-assembling nitric oxide (NO)-releasing nanofiber gels for the prevention of neointimal hyperplasia [63]. Using a rat carotid artery model, the group showed that the NO-releasing PA gels significantly reduced neointimal hyperplasia, inhibited inflammation and stimulated re-endothelialization compared to controls.

The value of this nanotechnology lies in its self-assembly code, which yields nanofibers that can be designed to have a great diversity of bioactive signals [64, 65]. For example, PAs have been successfully synthesized to contain binding groups for growth factors by phage display technology [51]. The inclusion of growth factor binding domains enables a greater retention of incorporated growth factors within the scaffold, or even the 'capture' of desired endogenous growth factors localized

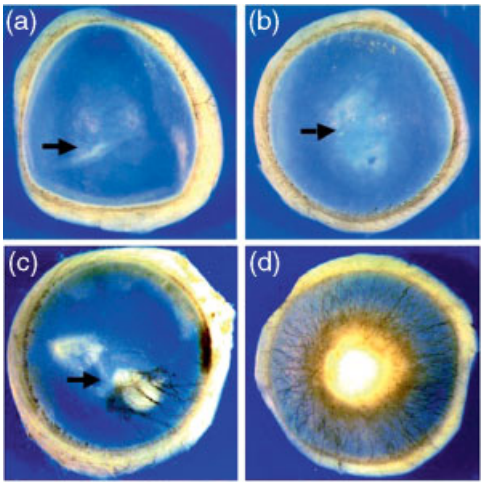

Figure 14.8 *In vivo* angiogenesis assay in a rat cornea 10 days after the placement of various materials at the site indicated by the black arrow. Growth factors alone (a) and heparin with growth factors (b) showed little to no neovascularization. Collagen, heparin and growth factors (c) showed some neovascularization; (d) Heparin-nucleated PA nanofiber networks with growth factors showed extensive neovascularization. at the implant site, thus eliminating the need for exogenous growth factor supplementation altogether. Hartgerink *et al.* synthesized PAs with a combination of biofunctional groups including a cell-mediated enzyme-sensitive site, a calcium-binding site and a cell-adhesive ligand [66]. The incorporation of an enzyme-specific cleavage site allows cell-mediated proteolytic degradation of the scaffold for cell-controlled migration and matrix remodeling. *In vitro* studies demonstrated that these PA scaffolds do degrade in the presence of proteases, and that the morphology of cells encapsulated within the nanofiber scaffolds was dependent on the density of the cell-adhesive ligand, with more elongated cells observed in gels with a higher adhesive ligand density [66].

To date, hundreds of peptide amphiphile nanofibers designs are known, including those that nucleate hydroxyapatite with some of the crystallographic features found in bone [4], increase the survival of cultured islets for the treatment of diabetes, bind to various growth factors [51], contain integrin-binding sequences [61], incorporate contrast agents for fate mapping of PA nanostructures [52], and have pro-apoptotic sequences for cancer therapy, among many others. Research investigating the development of hybrid materials using these versatile PA systems is also emerging. For example, PA nanofibers were integrated within titanium foams as a means to promote bone ingrowth or bone adhesion for improved orthopedic implant fixation (Figure 14.9) [1]. Preliminary *in vivo* results implanting these PA–Ti hybrids within bone defects in a rat femur demonstrated *de novo* bone formation around and inside the implant, vascularization in the vicinity of the implant, and no cytotoxic response [1]. Another type of hybrid system developed by Hartgerink *et al.* includes hydrogels that contain a mixture of PA and phospholipid (Figure 14.10) [67]. The phospholipid inclusions within the PA nanostructure were found to modulate

the peptide secondary structure as well as the mechanical properties of the hydrogel, with little change in the nanostructure. This composite system enables the optimization of mechanical and chemical properties of the hydrogel by simple adjustment of the PA to phospholipid ratios [67].

The ability to access new mechanisms to control self-assembly across the scales, and not just at the nanostructure level, offers new possibilities for regenerative therapies as bioactive functions can be extended by design into microscopic – and even macroscopic – dimensions. One system involves the self-assembly of hierarchically ordered materials at an aqueous interface resulting from the interaction between small, charged self-assembling PA molecules and oppositely charged high-molar mass biopolymers [68]. A PA–polymer sac can be formed instantly by injecting the polymer directly into the PA solution (Figure 14.11a). The interfacial interaction between the two aqueous liquids allows the formation of relatively robust membranes with tailorable size and shape (Figure 14.11b), self-sealing and suturable sacs (Figure 14.11c–f), as well as continuous strings (Figure 14.11g). The membrane structure grows to macroscopic dimensions with a high degree of hierarchical order across the scales. Studies have demonstrated that the sac membrane is permeable to large proteins, and therefore can be successfully used to encapsulate cells (Figure 14.11h). *In vitro* studies of mouse pancreatic islets (Figure 14.11i) and human MSCs (Figure 14.11j) cultured within the sacs showed that these structures can support cell survival and can be effective 3-D environments for cell differentiation. The unique structural and physical characteristics of these novel systems offer significant potential in cell therapies, drug diagnostics and regenerative medicine applications.

14.3
Self-Assembling Systems for Surface Modification

Implantable materials are the essence of today's regenerative medicine. The ability to control these materials at the nanoscale has moved them from simple inert materials to biocompatible and bioactive materials [69]. The surface of a biomaterial is particularly important in regenerative medicine as it is the first point of contact with the body. Whether it is presenting a biomimetic atmosphere, disguising a foreign body, or activating specific biological processes, the surface of an implant plays a crucial role and can determine its success or failure. One key advantage of self-assembly is the possibility to modify and tailor surfaces to elicit a specific biological response. In the following, we discuss the use of self-assembly to modify the properties of surfaces and 3-D structures.

14.3.1
Coatings on Surfaces

Within the scope of regenerative medicine, the molecular self-assembly of peptides represents a promising tool to modify the surfaces of medical implants or regenerative scaffolds. This technique facilitates the presentation of bioactive surface chemistries in a controlled, ordered fashion to mimic those of natural extracellular matrices. While the bioactivity of surfaces can be highly modulated by the presentation of specific ECM proteins, the effectiveness of this approach depends greatly on the appropriate conformation of the protein to expose the bioactive epitopes. Self-assembling materials offer the possibility to incorporate small peptide sequences as part of the self-assembling molecule. This approach avoids complications associated with intact proteins, such as undesirable protein folding and immune reactions, and also increases the specificity and efficiency of the bioactive epitope [70]. The use of small peptide sequences such as RGDS for cell adhesion [61] or IKVAV for neuronal differentiation [6], in combination with the capacity to self-assemble molecules in unique and specific conformations, makes this a powerful tool to modify and functionalize surfaces of materials used in regenerative medicine.

Self-assembled monolayers (SAMs) are single layers of molecules that react with and spontaneously order on solid surfaces. SAMs of alkanethiols on gold have been used extensively to study peptide and protein adsorption on surfaces [71, 72], as well as their effect on cell behavior [73, 74]. Recently, the modification of traditional SAM techniques has increased the level of surface chemistry manipulation and complexity that can be achieved. For example, the introduction of soft lithographic techniques such as microcontact printing has facilitated the use and significantly increased the potential of peptide-containing SAMs [70, 75]. This approach has been used to create self-assembled surface patterns to control and study a variety of cell behaviors such as cell adhesion, growth and apoptosis (Figure 14.12a) [76, 77]. Another approach that takes advantage of SAMs, and has been used in combination with soft lithographic techniques, consists of developing dynamically controlled and regulated surfaces,

which offer a unique opportunity to recreate and study dynamic biological processes. These types of surface can be achieved by controlling SAMs through different switching mechanisms (i.e. electrical, electrochemical, photochemical, thermal, and mechanical transduction [78, 79]) that organize specific ligands and peptides. By using these techniques, SAMs of peptides such as EG3- and RGD-terminated peptides have been used to study dynamic mechanisms controlling the adhesion and migration of bovine capillary endothelial cells [80] and fibroblasts [81], respectively (Figure 14.12b). Another modification of traditional SAM patterning takes advantage of dip-pen nanolithography (DPN), which uses atomic force microscopy (AFM) tips dipped into alkanethiol inks to transfer molecules by capillary force on

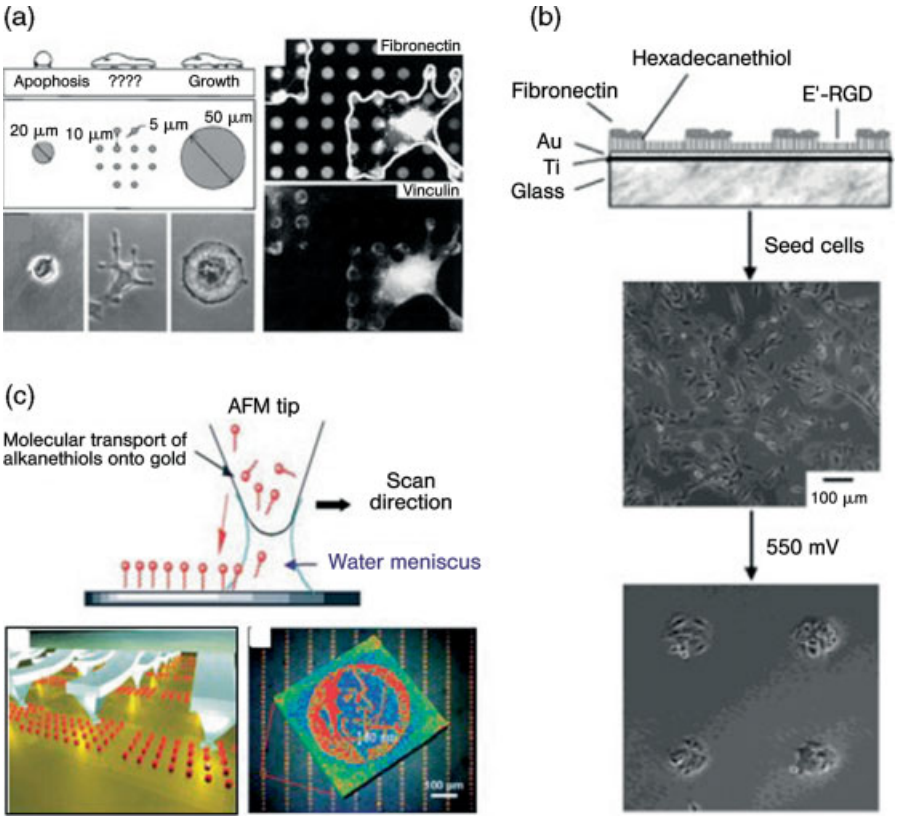

Figure 14.12 Approaches to create complex self-assembled monolayers (SAMs) including: (a) Micro-contact printing to create adhesive patterns of SAMs to study cell mechanisms such as growth and apoptosis. [82]; © 2007, Wiley-VCH Verlag GmbH & Co. KGaA.)

the gold surface (Figure 14.12c) [82, 83]. A major advantage of this technique is that it can create patterns of SAMs down to 15 nm in lateral dimension, significantly surpassing the resolution of soft lithographic techniques [82]. These types of studies not only provide reproducible tools to engineer biomimetic cell microenvironments, but also offer great promise for a deeper understanding of cell behaviors that could then be applied to the design of materials and implants in regenerative medicine [69].

While SAMs rely on individual molecules or peptides to create single-layer coatings, more complex self-assembled structures such as tubes or fibers are also being used as surface modifiers. One such example is a class of organic self-assembled fibers, referred to as helical rosette nanotubes (HRNs), that have been used to coat and functionalize bone prosthetic biomaterials (Figure 14.13). This approach was recently used to coat titanium surfaces, and caused a significant enhancement of osteoblast adhesion *in vitro* [84]. These molecules self-assemble from a single bicyclic block resulting from the complementary hydrogen-bonding arrays of both guanine (G) and cytosine (C). This C/G motif serves as the building block that self-assembles in water to form a six-membered supermacrocycle (rosette) maintained by 18 H-bonds. Subsequent assembly of these rosettes forms hollow nanotubes that are 1.1 nm in diameter and up to millimeters in length [85]. The outer surface of the G/C motif could further be modified to present specific physical and chemical properties.

(Reproduced with permission from Ref. [87]; © 2007, American Chemical Society.); (b) Optimum epitope presentation through specific molecular architectures. (Reproduced with permission from Ref. [61]; © 2007, Elsevier Limited.)

The self-assembly of PAs has also been used to functionalize two-dimensional (2-D) surfaces. As mentioned previously PAs are highly bioactive and biocompatible materials that have been used to develop 3-D scaffolds for tissue engineering and regenerative medicine. The diversity of design and robustness of these molecules has permitted a wide range of approaches for their use as surface-functionalizing coatings. For example, PAs containing cell-adhesive and triple-helical or α-helical structural motifs have been used to influence adhesion and signal transduction of human melanoma cells *in vitro* [86]. By utilizing microfluidic systems, Stroumpoulis *et al.* generated self-assembling patterns of RGD-containing PAs that directed mouse fibroblast adhesion (Figure 14.14a) [87]. In an attempt to optimize the presentation of PA coatings, Storrie *et al.* investigated the effect of PA molecular architecture and epitope concentration on nanofiber self-assembly, epitope presentation and fibroblast recognition for cell adhesion and spreading on surfaces (Figure 14.14b) [61].

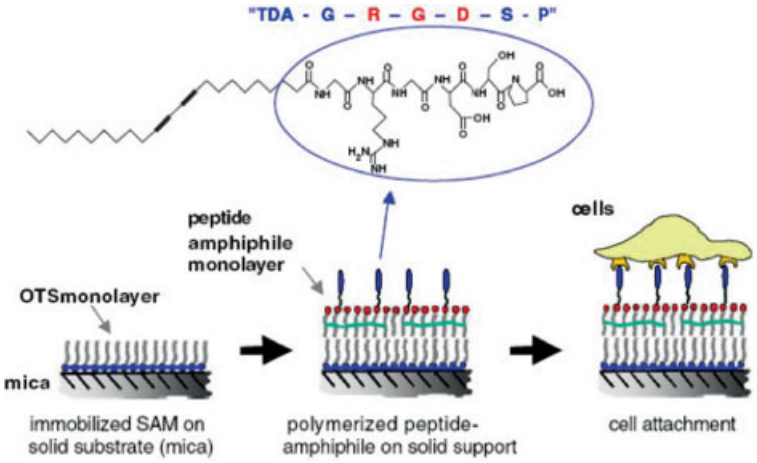

Figure 14.15 Peptide amphiphile (PA) molecules and self-assembling mechanism used to functionalize surfaces with improved molecular properties. A diacetylene-photosensitive segment in the hydrophobic tail promotes PA polymerization and subsequent monolayer stability. (Reproduced with permission from Ref. [89]; © 2006, Elsevier Limited.)

A number of strategies have been investigated to improve the chemical stability of PA coatings on implant surfaces. For example, Sargeant *et al.* has developed a method to covalently attach PA nanofibers to the surface of nickel–titanium (NiTi) shape memory alloys [88]. Here, the group used an RGDS containing PA and demonstrated its capacity to form robust PA coatings capable of promoting cell adhesion, proliferation and differentiation. This method significantly improves the potential of using PA materials for *in vivo* applications such as vascular stents, bone plates and artificial joints. Another approach used to improve PA stability was reported by Biesalski *et al.*, who developed a PA molecule comprising a diacetylene photosensitive segment, which promotes PA polymerization (Figure 14.15) [89]. This molecule was used to develop a stable polymerized monolayer of RGD-terminated PA molecules that significantly enhanced fibroblast adhesion.

The vast majority of investigations related to self-assembling peptides for surface modification has been dedicated to developing functional and bioactive surface chemistries to affect or elicit specific cell behaviors. However, in addition to surface chemistry, surface topography has also been shown to significantly affect cell and tissue behavior [90–92]. An ideal surface modification treatment for regenerative medicine would permit the fine-tuning of both surface chemistry and surface topography across different size scales. One approach to achieve this topographical/biochemical integration is to create SAMs of peptides on microfabricated surfaces comprising topographical features [93, 94]. The integration of microfabrication with molecularly designed self-assembling PAs also represents a unique opportunity to develop physical and biochemical environments with hierarchical

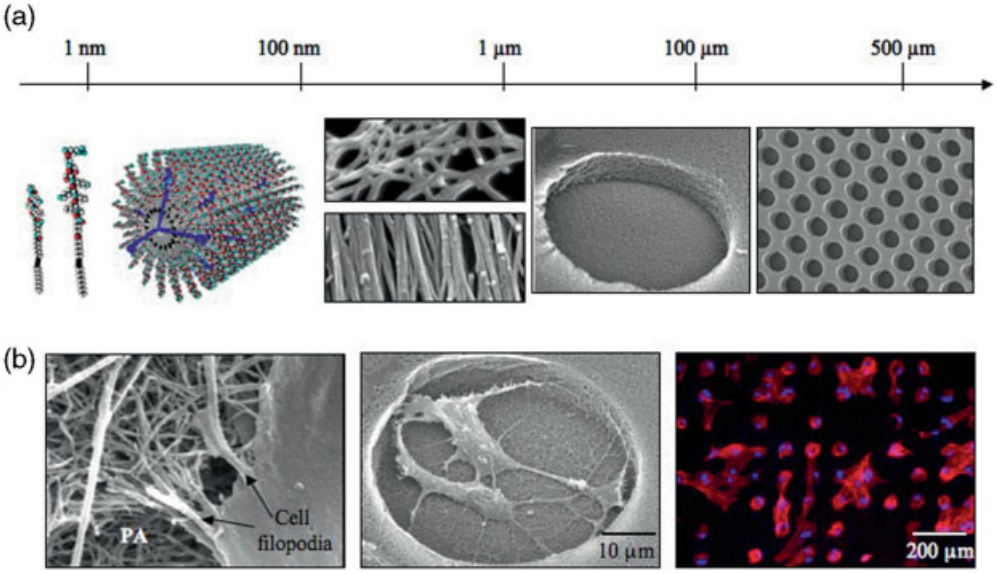

Figure 14.16 (a) Fabrication approach that combines bottom-up (self-assembling peptide-amphiphiles) with top-down (microfabrication) techniques to create biomimetic environments for stem cell manipulation. This method integrates precise topographical patterns and specific biochemical signals within a hierarchical structure that expands from the molecular to the macro scale; (b) Topographical patterns made from self-assembled PA nanofibers have demonstrated the capacity to guide the growth and differentiation of human mesenchymal stem cells (red = actin cytoskeleton, blue = cell nuclei). (with permission from *Soft Matter*, DOI:10.1039/b819002j).

organization (Figure 14.16a). With this approach, it may be possible to create biomimetic scaffolds made from PA molecules with the capacity to elicit specific cell behaviors using both topographical features and bioactive epitopes at different size scales (Figure 14.16b). Recent studies performed by Stupp *et al.* have demonstrated the capacity to promote osteoblastic differentiation of human MSCs by using topographical patterns made from self-assembled PA nanofibers. (*Soft Matter*, DOI:10.1039/b819002j).

14.3.2
Coatings on 3-D Scaffolds

Three-dimensional scaffolds prepared with synthetic materials such as poly(glygolic acid) (PGA) and poly (L-lactic acid) (PLLA) provide porous and biodegradable materials that have found extensive use in regenerative medicine applications [95]. The surface characteristics of these materials, however, do not have any specific or desired bioactivity. Therefore, self-assembling peptides may be used to functionalize surfaces to further improve bioactivity and tissue integration. For example, Harrington *et al.* used an RGDS-containing PA to self-assemble into well-defined

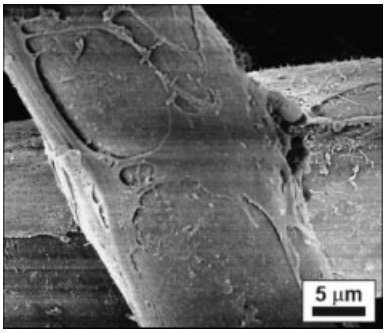

Figure 14.17 Osteoblasts growing on a fibrous poly(L-lactic acid) (PLLA) scaffold coated with molecules comprising cholesterol and lysine moieties. (Reproduced with permission from Ref. [8]; © 2004, Elsevier Limited.)

nanofibers on the surface of PGA porous scaffolds [95]. These RGDS-coated scaffolds significantly improved human bladder smooth muscle cell adhesion. Stendahl *et al.* self-assembled a triblock molecule comprising cholesterol and lysine moieties to coat and modify PLLA fiber scaffolds [8]. These amphiphilic molecules improved the adhesion and overall growth of osteoblastic cells (Figure 14.17). Another examples of a recent surface modification technique used within 3-D architectures includes studies conducted by Zhu *et al.*, who used poly(ethylenimine) (PEI) to activate the surface of poly(lactide) (PLA) scaffolds, which was subsequently modified with gelatin using electrostatic self-assembly [96, 97]. This treatment successfully promoted the growth of seeded osteoblasts.

14.4
Clinical Potential of Self-Assembling Systems

As discussed above, several preclinical studies have already shown great promise for the use of self-assembling biomaterials in regenerative medicine. Particularly, *in vivo* experiments using self-assembling peptide amphiphiles by Stupp and colleagues have shown that these bioactive matrices can be specifically designed to: (i) promote angiogenesis (rat cornea model); (ii) promote regeneration of axons in a spinal cord injury model (mouse and rat models), of cartilage (rabbit model), and of bone (rat model); (iii) promote recovery of cardiac function after infarct (mouse model); and (iv) show promise as treatments for Parkinson's disease (mouse models). It is expected that the self-assembly of supramolecular systems will, in time, lead to many effective regenerative medicine therapies providing an excellent platform to design for bioactivity, harmless degradation with appropriate half-lives after providing a function, and noninvasive methods for clinical delivery:

- Design for bioactivity: it is possible to engineer these peptide-based, self-assembling systems to include various combinations of amino acid sequences

that are bioactive and can enhance the regeneration process – that is, deliver growth factors, contain cell adhesion sequences, mimic the bioactivity of growth factors, and so on.

- Harmless degradation: peptide-based, self-assembling systems are capable of being degraded by enzymes in the body into basic amino acids that can be metabolized naturally, with appropriate half-lives after providing a function. Their degradation characteristics can be manipulated through molecular design. Ideally, such bioactive materials would provide a specific function (i.e. deliver growth factors, attract and adhere desired cell types, etc.) to enhance the regenerative process, and simultaneously degrade as the tissue starts to regenerate. Over time, what is left would be the completely regenerated tissue. The challenge would be to determine the 'appropriate' degradation rate for optimal regeneration.
- Noninvasive methods for clinical delivery: the ability of these peptide-based molecules to self-assemble spontaneously allows for the administration of materials through noninvasive methods. For example, a solution of the self-assembling molecules could be injected into the defect site, after which gelation in vivo could be triggered by ions within the body.

14.5 Conclusions

Today, research into the development of self-assembling biomaterials for regenerative medicine continues to expand–the main aim being to achieve real improvements in the quality of life for mankind. Without strategies for regeneration, genomic data and personalized medicine will not have the significant impact that is being promised. It is important that therapies for regenerative medicine must be not only highly effective and predictable, but also as noninvasive as possible, with the capacity to reach deep into problem areas of the heart, brain, skeleton, skin and other vital organs. It is for this reason that self-assembly at the nanoscale appears as the most sensible technological strategy, to signal and recruit the organism's own cells, or to manage the delivery of cell therapies to the correct sites after effective *in vitro* manipulation. The ability to design at both the nanoscale and macroscale will open the door to vast possibilities for biomaterials and regenerative medicine, with materials that can be designed to multiplex the required signals, can be delivered in a practical and optimal manner, and can reach targets across barriers via the blood circulation. In addition, molecular self-assembly on the surfaces of implants may enhance the bioactivity and predictable biocompatibility of metals, ceramics, composites and synthetic polymers. Self-assembly is at the root of structure versus function in biology and, in the context of regenerative medicine technology, is the 'ultimate inspiration from Nature'.

1
Spin-Polarized Scanning Tunneling Microscopy

Mathias Getzlaff

1.1
Introduction and Historical Background

Until the 1980s an idealized and rather unrealistic view was found in surface physics for a lack of techniques which allowed real-space imaging. During this time, surfaces were often assumed to be perfect – that is, imperfections such as step edges, dislocations or adsorbed atoms were neglected. Most of the important information was gained rather indirectly by spatially averaging methods or experimental techniques with insufficient resolution.

However, in 1982, with the invention of the scanning tunneling microscope by G. Binnig and H. Rohrer [1, 2], the situation changed dramatically. This instrument allowed, for the first time, the topography of surfaces to be imaged in real space with both lateral and vertical atomic resolution.

Subsequently, a number of different spectroscopic modes were introduced which provided additional access to electronic behavior, thus allowing the correlation of topographic and electronic properties down to the atomic scale.

In 1988, Pierce considered the possibility of making the scanning tunneling microscope sensitive towards the spin of tunneling electrons by using spin-sensitive tip materials as a further development [3], and this was also predicted – theoretically – by Minakov *et al.* [4]. As a step towards this aim, Allenspach *et al.* [5] replaced the electron gun of a scanning electron microscope with a scanning tunneling microscope tip. Thus, in field emission mode the electrons impinged on a magnetic surface, and the spin polarization of the emitted electrons was subsequently monitored; this, at least in principle, would allow magnetic imaging with nanometer resolution.

However, it was the first 'direct' realization by Wiesendanger *et al.* [6] that opened the possibility of imaging the magnetic properties at atomic resolution. Moreover, the importance of this proposal was not restricted only to basic studies but was also applicable to research investigations. Meanwhile, a rapidly increasing interest emerged from an industrial point of view, a concept which became even more

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

important when considering the need for dramatic increases in the storage density of devices such as computer hard drives. Clearly, further developments in this area will require tools that allow high spatial resolution magnetic imaging for an improved understanding of nanoscaled objects such as magnetic domains and domain wall structures.

In this chapter, we will describe the successful development and implementation of spin-polarized scanning tunneling microscopy (SP-STM), and will also show – by means of selected examples – how our understanding of surface magnetic behavior has vastly increased in recent years.

1.2
Spin-Polarized Electron Tunneling: Considerations Regarding Planar Junctions

First, let us assume that two ferromagnetically or antiferromagnetically coupling layers are separated by an insulator (Figure 1.1, left part). The following discussion can also be extended to ferromagnetic nanoparticles located within an insulating matrix (Figure 1.1, right part).

In order for an electric current to occur, there is the prerequisite that the thickness of the barrier should be small enough so as to allow quantum mechanical tunneling. It is also essential for this discussion that this process is assumed to conserve the spin orientation.

The dependence of the tunneling current on the relative magnetization is shown in Figure 1.2, assuming two ferromagnetic thin layers. The total resistivity for the parallel alignment is less than for the antiparallel orientation. This effect, which is known as tunneling magnetoresistance (TMR), represents a band structure effect that relies on the spin resolved density of states (DOS) at the Fermi level. In comparison, giant magnetoresistance (GMR) is caused by a spin-dependent scattering at the interfaces (further information is available in Ref. [7]).

In order to discuss the behavior of two ferromagnetic electrodes separated by an insulating barrier, the model of Jullière [8] is used; this employs the assumptions that the tunneling process is spin-conserving, and that the tunneling current is proportional to the density of states of the corresponding spin orientation in each electrode.

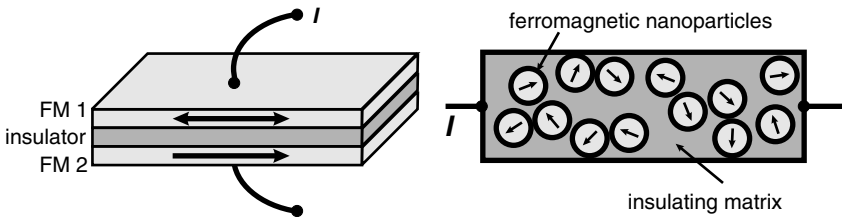

Figure 1.1 Tunneling magnetoresistance can occur when ferromagnetic thin films are separated by an insulating layer (left), and when ferromagnetic nanoparticles are embedded in an insulating matrix (right).

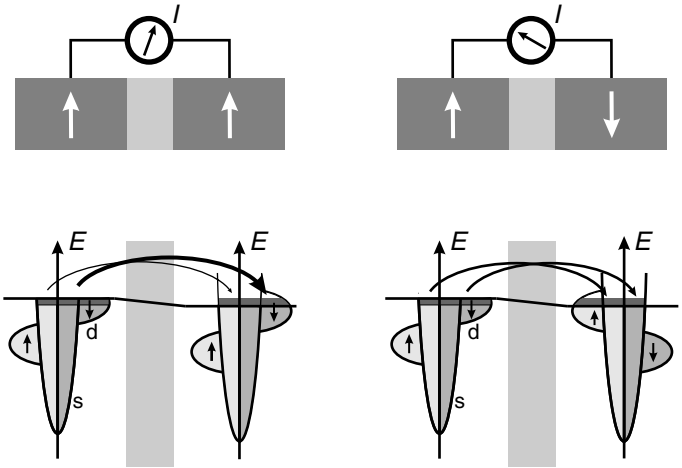

Figure 1.2 Dependence of the tunneling current on the relative magnetization of two ferromagnetic layers. For a parallel orientation a large quantity of spin down electrons at the Fermi energy can tunnel into empty down states; this results in a high tunneling current. In contrast, for an antiparallel orientation the quantity of empty down states is significantly lower, leading to a reduced tunneling current.

In this situation, the tunneling current for a parallel magnetization is given by:

$$I^{\uparrow\uparrow} \propto n_1^{\uparrow} n_2^{\uparrow} + n_1^{\downarrow} n_2^{\downarrow} \tag{1.1}$$

with n_i being the electron density of electrode i at the Fermi level E_F. For the antiparallel orientation, the tunneling current amounts to:

$$I^{\uparrow\downarrow} \propto n_1^{\uparrow} n_2^{\downarrow} + n_1^{\downarrow} n_2^{\uparrow} \tag{1.2}$$

With $a_i = n_i^{\uparrow}/(n_i^{\uparrow} + n_i^{\downarrow})$ being the part of majority electrons of electrode i, and $1-a_i = n_i^{\downarrow}/(n_i^{\uparrow} + n_i^{\downarrow})$ that of the minority electrons, the spin polarization P_i of electrode i is given by:

$$P_i = \frac{n_i^{\uparrow} - n_i^{\downarrow}}{n_i^{\uparrow} + n_i^{\downarrow}} = 2a_i - 1 \tag{1.3}$$

This allows the differential conductance for a parallel orientation to be expressed as:

$$G^{\uparrow\uparrow} = G_p \propto a_1 a_2 + (1-a_1)(1-a_2) = \frac{1}{2}(1 + P_1 P_2) \tag{1.4}$$

and for an antiparallel orientation as:

$$G^{\uparrow\downarrow} = G_{ap} \propto a_1(1-a_2) + (1-a_1)a_2 = \frac{1}{2}(1 - P_1 P_2) \tag{1.5}$$

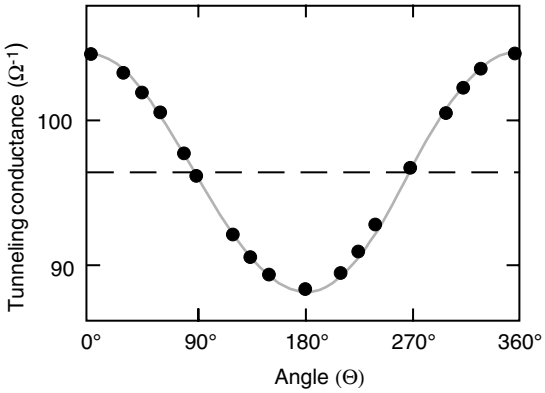

Figure 1.3 Dependence of the tunneling conductance (inverse resistance) of a planar Fe-Al_2O_3-Fe junction on the angle Θ between the magnetization vectors of both electrodes. (Data taken from Ref. [9]).

The magnitude of the TMR effect is given by:

$$\mathrm{TMR} = \frac{G^{\uparrow\uparrow} - G^{\uparrow\downarrow}}{G^{\uparrow\downarrow}} = \frac{G_\mathrm{p} - G_{ap}}{G_{ap}} = \frac{R_{ap} - R_\mathrm{p}}{R_\mathrm{p}} \tag{1.6}$$

where R_p (R_{ap}) is the resistance for the (anti)parallel orientation, respectively. By using the spin polarization, the TMR effect can be written as:

$$\mathrm{TMR} = \frac{\Delta R}{R_\mathrm{p}} = \frac{2P_1P_2}{1 - P_1P_2} \tag{1.7}$$

In the above considerations, it has been assumed that the magnetizations in both ferromagnetic electrodes are oriented parallel or antiparallel. However, the differential conductance also depends on the angle Θ between both directions of magnetization. This behavior is shown in Figure 1.3 for an Fe–Al_2O_3–Fe junction. Thus, until now the situation has been discussed for $\Theta = 0^\circ$ and $\Theta = 180^\circ$, respectively. For an arbitrary angle Θ, the differential conductance can be expressed as:

$$G = G_0 \cdot (1 + P_1P_2\cos\Theta) \tag{1.8}$$

with $G_0 = (G_\mathrm{p} + G_{ap})/2$ being the spin-averaged conductance.

1.3 Spin-Polarized Electron Tunneling in Scanning Tunneling Microscopy (STM): Experimental Aspects

The substitution of a ferromagnetic electrode (as discussed above) with a ferromagnetic probe tip represents the situation in SP-STM. The insulating barrier is realized by the vacuum between the sample and the tip, which are separated by a distance of several Ångstroms, thus allowing the laterally resolved determination of magnetic

properties. As a consequence, the zero bias anomaly – that is, the decrease in the TMR with increasing bias voltage in planar junctions – is not present for SP-STM investigations because the anomaly can be attributed to scattering of electrons at defects in amorphous barriers [10].

The following sections describe the two fundamental experimental aspects concerning spin-polarized electron tunneling in an STM experiment. Here, different probe tips and modes of operation are employed in order to obtain magnetic information from a sample.

1.3.1 Probe Tips for Spin-Polarized Electron Tunneling

In order to realize SP-STM, the probe tip should fulfill most of the following conditions:

- The higher the spin polarization of the apex atom, the more pronounced the magnetic information (cf. Equations 1.4–1.7) in comparison to electronic and topographic information. Due to the typical reduction of this spin polarization by adsorbates from the residual gas, even under ultra-high vacuum (UHV) conditions, a clean environment or an inert tip material is certainly advantageous [11].
- The sensitivity can also be improved by periodically reversing the magnetization direction, thus *directly* probing the local tunneling magnetoresistance.
- The interaction between tip and sample should be as low as possible because the stray field of a ferromagnetic tip may modify or destroy the sample's domain structure.
- Controlling the orientation of the magnetization axis of the tip parallel or perpendicular to the sample surface allows the domain structure of any sample to be imaged, independent of whether its easy axis is in-plane or out-of-plane.

1.3.1.1 Ferromagnetic Probe Tips

With regards to stray field minimization, bulk tips made from ferromagnetic 3*d* transition metals (see Refs. [12, 13]), with their high content of magnetic material and high saturation magnetization are an unfavorable choice. This mostly restricts their application to ferri- and antiferromagnetic samples [14], which are practically insensitive to external fields. Nevertheless, the stray field can be reduced either by using a material which exhibits a low saturation magnetization, or by using thin-film tips with a film thickness comparable to (or less than) the tip–sample separation [15]. The spin dependence of image potential states can also be used as a sensitive probe of surface magnetism [16], allowing high-resolution magnetic imaging at tip–sample distances larger than in normal tunneling experiments, and thereby reducing the stray field of the ferromagnetic tip.

The first path was realized by Wulfhekel and Kirschner [17–23], who periodically switched the magnetization direction of an amorphous CoFeNiSiB tip with a small coil wound around the tip (see Figure 1.4). Such a tip must exhibit a low coercivity, as this allows minimization of the coil size and thus the coil's stray field at the sample

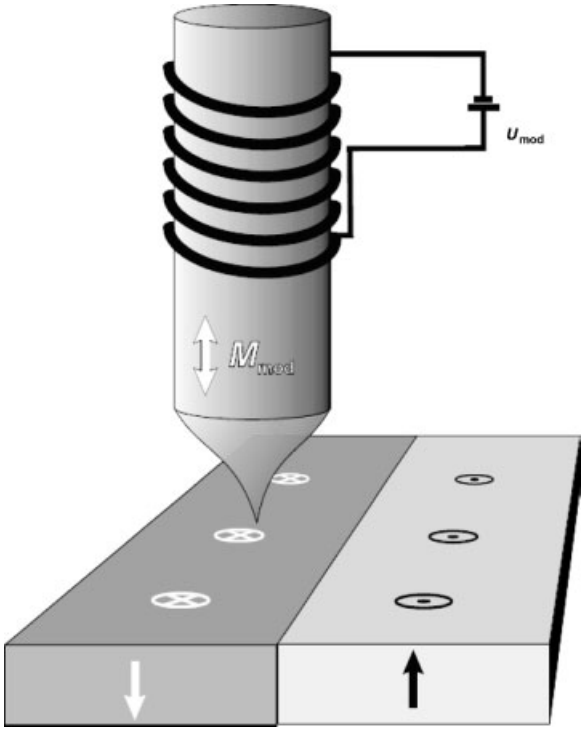

Figure 1.4 Schematic representation of the SP-STM as operated by Wulfhekel and Kirschner [17]. A soft magnetic tip is periodically magnetized in opposite directions along the tip axis by a small coil wound around the tip thus being sensitive to an out-of-plane magnetization. The resultant variation in tunneling current is measured using a lock-in technique. (From Ref. [24], with permission of IOP Publishing Ltd.)

position, as well as a low saturation magnetization. The most important precondition is an extremely low magnetostriction in order to suppress any modulation of the tip length due to the periodic remagnetization process. Consequently, the tips will be sensitive to the perpendicular component of the sample magnetization [21]. In order to realize an in-plane sensitivity, the same type of technique is applicable; however, the 'tip' would now consist of a ferromagnetic ring, the magnetization of which is also periodically switched by using a coil [25, 26].

In order to realize the second situation (see Ref. [27]), an *in situ* preparation of magnetic thin films is necessary. Typically, a polycrystalline tungsten (W) wire is electrochemically etched (this is important for tip stability). The W tip is heated to at least 2200 K upon introduction into the UHV chamber; otherwise, the magnetic coating material is frequently lost during the approach. This high-temperature flash removes oxides and other contaminants, thereby enhancing the binding between the

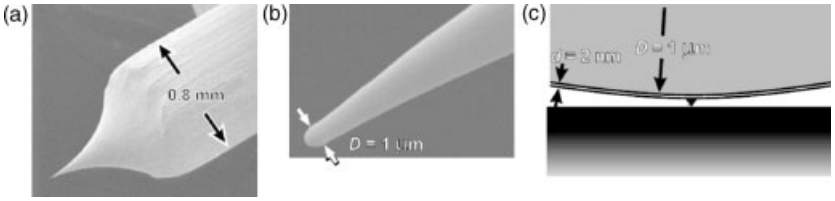

Figure 1.5 Scanning electron microscopy (SEM) images of an electrochemically etched, polycrystalline W tip after a high-temperature flash at $T > 2200$ K. (a) The overview shows the shaft of the tip, which exhibits a diameter of 0.8 mm; (b) High-resolution image of the very end of the tip. The tip apex has an angle of about 15° and the tip diameter amounts to approximately 1 µm; (c) Schematic representation of the tip apex (in scale). The magnetic film is very thin compared to the curvature of the tip. Most likely, a small magnetic cluster protrudes from the tip, and this is responsible for the lateral resolution of the SP-STM. (From Ref. [24], with permission of IOP Publishing Ltd.)

tip surface and the magnetic overlayer. While the overall shape of the tip [as shown in the scanning electron microscopy (SEM) overview image of Figure 1.5a] remains almost unaffected by the high-temperature treatment, the high-resolution SEM image shown in Figure 1.5b reveals that the tip diameter is increased to 1 µm, most likely due to melting of the tip apex. Following this high-temperature treatment, the tips are magnetically coated with a magnetic film exhibiting a thickness of several monolayers (MLs). In contrast to bulk tips, the magnetization direction is governed by the shape anisotropy. The anisotropy of thin film tips can thus be adjusted by selecting an appropriate film material. For example, while 3–10 ML Fe [27] and <50 ML Cr [28] are almost always sensitive to the in-plane component of the magnetization, 7–9 ML Gd [29], 10–15 ML $Gd_{90}Fe_{10}$ [30] and 25–45 ML Cr [30] are usually perpendicularly magnetized at low temperature. The well-known spin reorientation transition of Co films on Au (see Refs [31, 32]) which occur with increasing thickness of the magnetic material allows tuning of the magnetically sensitive direction of the tip with the *same* set of coating materials. For thin Co coverages (<8 ML) on a Au-coated W tip, an out-of-plane magnetic sensitivity is achieved, whereas for thicker Co films the in-plane component of the sample magnetization can be probed [33].

At least qualitatively, this observation can easily be understood. Two anisotropy terms are relevant: (i) the shape anisotropy which arises due to the pointed shape of the tip; and (ii) the surface and interface anisotropy of the film. The first term will always try to force the magnetization along the tip axis – that is, perpendicular to the sample surface. In contrast, the second term is material-dependent. Due to the rather large curvature of the tip as compared to the thickness of the coating film (see Figure 1.5c), the effective surface and interface anisotropy of a thin film can be deduced from an equivalent film on a flat W(110) substrate. For instance, in the case of 10 ML Fe the two anisotropy terms favor different directions. While the shape anisotropy still tries to force the magnetization along the tip axis, the ferromagnetic

film on W(110) exhibits a strong in-plane anisotropy [35] which obviously overcomes the shape anisotropy. An external field of 2 T is required to force the tip magnetization out of the easy (in-plane) into the hard (out-of-plane) direction [34]; this is consistent with results of Elmers and Gradmann [35] concerning thin film systems.

Even at room temperature magnetic thin film tips can be used for several days without losing their spin sensitivity. Initially, this is surprising as any surface is continuously exposed to the residual gas in the vacuum chamber which, depending on the reactivity of the sample under investigation, leads to a more or less rapid – but continuous – degradation of the surface spin polarization [36]. However, the geometry of the tunnel junction must be taken into account as it differs from that of an open surface. While residual gas particles may impinge onto a flat, uncovered surface from the entire half-space, the tip apex is almost completely shadowed by the sample, as shown schematically in Figure 1.5c. Thereby, gas transport onto the tip apex is dramatically reduced. Of course, the same argument can be applied to the sample surface which is, however, only valid for the particular location of the sample surface that is right under the tip apex. As this location varies when scanning the tip across the sample, the shadowing is only temporarily effective for any particular site of the sample surface, whereas the tip is shadowed at all times.

1.3.1.2 **Antiferromagnetic Probe Tips**

Despite the fact that the magnetic dipole interaction between the sample and the tip is considerably reduced for ferromagnetic ultrathin film coatings on a nonmagnetic tip, in comparison to thicker coatings or even bulk ferromagnetic tips, an additional influence cannot be ruled out. One straightforward and experimentally feasible solution, however, is to use an antiferromagnetically coated (see Ref. [30]) or a bulk antiferromagnetic tip consisting of, for example, a MnNi alloy [37–40]. The tip should exhibit no significant stray field, since opposite contributions compensate on an atomic scale, thus allowing the nondestructive imaging and investigation of spin structures even for magnetically soft samples. The spin sensitivity is determined solely by the orientation of the magnetic moment of the atom that forms the very end of the tip apex; the orientation of all other magnetic moments plays no role. Furthermore, the tip is insensitive to external fields, which allows direct access to intrinsic sample properties in field-dependent studies.

In order to demonstrate this insensitivity, we can refer to an investigation conducted by Kubetzka *et al.* [30]. Here, the response of an identically prepared system to an applied perpendicular magnetic field is shown using a ferromagnetic tip on the one hand, and an antiferromagnetic tip on the other hand. Figure 1.6a shows a series of dI/dU maps – that is, maps of the differential conductance, of 1.95 ML Fe on W(110) recorded with a ferromagnetic GdFe tip. Figure 1.6a(i) shows an overview of the initial state, while Figure 1.6a(ii) is taken at higher resolution, as indicated by the frame in Figure 1.6a(i). Because the coverage is slightly below 2 ML, narrow ML areas can be seen with a bright appearance at the chosen bias voltage. These ML areas efficiently decouple double layer (DL) regions on adjacent terraces. At 350 mT [see Figure 1.6a(iii)] the domain distribution is asymmetric; the bright domains have

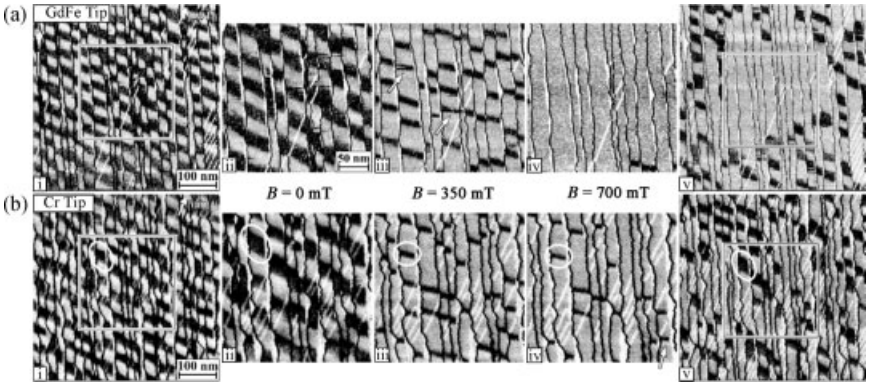

Figure 1.6 (a) d*I*/d*U* maps of 1.95 ML Fe/W (110) recorded with a GdFe tip (out-of-plane contrast): (i) $500 \times 500\,nm^2$ overview of magnetic initial state; (ii) $250 \times 250\,nm^2$ zoom-in; (iii) Asymmetry at B = 350 mT: dark domains are compressed and form 360° walls; (iv) saturation is observed within the field of view; (v) the influence of the tip's stray field becomes obvious in the overview recorded at $B = 0$ mT; (b) Analogous series of an identically prepared sample, recorded with a Cr-coated tip: (i, ii) magnetic initial state; (iii) asymmetry at B = 350 mT; (iv) a large fraction of the walls has survived at 700 mT, in contrast to (a); (v) the scanned area exhibits no significant difference in comparison to its surrounding. (Reprinted with permission from Ref. [30]; copyright (2002) American Physical Society.)

grown and the dark domains have shrunk. In some places the magnetic contrast changes abruptly from one horizontal scan line to the next (see arrows), this being the result of a rearrangement of the sample's magnetic state during the imaging process. At 700 mT [see Figure 1.6a(iv)] the sample has almost reached saturation within the field of view. However, it becomes obvious in the overview image, subsequently recorded at the same location in zero applied field [see Figure 1.6a(v)], that this field value does not reflect intrinsic sample properties. A large fraction of the dark domains has survived outside the region which was scanned previously at 700 mT. Thus, superpositioning of the applied field and the additional field emerging from the magnetic coating of the tip is much more efficient than the applied field alone.

Figure 1.6b shows an analogous series of images of a sample which was identically prepared but imaged with an antiferromagnetic Cr-covered tip. This exhibits an out-of-plane sensitivity, like the GdFe tips [30]. A dark domain is marked as an example to be recognized in all five images. The domain structure in Figure 1.6b(i)–(iii) displays no significant difference to the corresponding structures in Figure 1.6a. Since a rearrangement of the domain structure during imaging is not observed throughout this series, the occurrence of such events in Figure 1.6a can be attributed to the GdFe tip's stray field. As in Figure 1.6a(iii), the dark domains are compressed at 350 mT, which proceeds at 700 mT. At this field value, and in contrast to Figure 1.6a, a large fraction of the dark domains has survived. In the overview image of Figure 1.6b(v), which was taken again subsequently in a zero-applied field, the previously scanned area exhibits no significant difference in domain distribution in

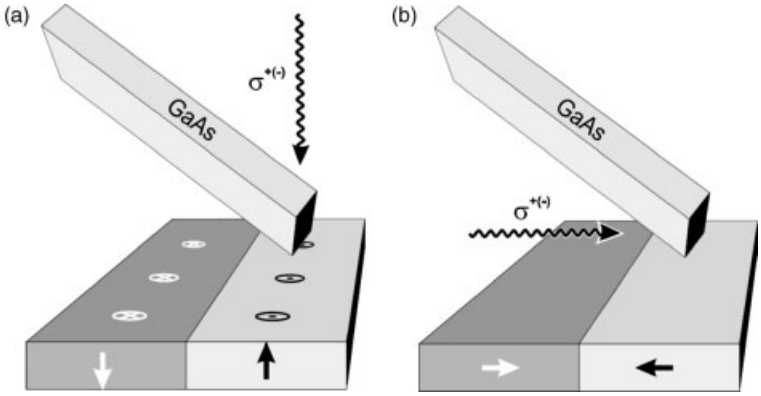

Figure 1.7 Schematic experimental set-up to realize spin-polarized electron tunneling using optically pumped GaAs tips, as proposed in Ref. [3]. (a) Spins aligned perpendicular to the sample surface can be detected by a GaAs tip excited by helical light incident along the surface normal; (b) When the incident light is along the sample surface the experiment is sensitive to electron spins parallel to the surface plane. (Reprinted from Ref. [24], with permission of IOP Publishing Ltd.)

comparison to its surrounding. This result directly demonstrates the advantage of a stray field free tip.

1.3.1.3 Optically Pumped GaAs Probe Tips

The concept of spin-polarized tunneling between a magnetic surface and an optically pumped GaAs tip (as discussed below) was first proposed by Pierce [3]. This experimental approach allows both the sign and the polarization direction of photoexcited electrons to be modified, simply by choosing an appropriate laser light helicity and experimental geometry. Varying the spin polarization of the tunneling electrons with a simultaneously constant intensity of the incident light enables the magnetic effects to be separated from the topographic and electronic effects. The corresponding schematic arrangement (see Figure 1.7) proves that the experiment can be made sensitive to either the out-of-plane or the in-plane magnetization direction by changing the direction of the incident light to be parallel and perpendicular to the sample surface, respectively.

Optically pumped *p*-type GaAs is widely used as a source to produce spin-polarized electrons close to the Fermi level. The physical principle is based on two properties of this material: (i) It is a direct band-gap semiconductor; and (ii) the degeneracy of the *p*-like valence band is lifted by spin–orbit interaction into a fourfold degenerate $p_{3/2}$ level (Γ_8 band edge) and a twofold degenerate $p_{1/2}$ level (Γ_7 band edge). The spin–orbit splitting amounts to $\Delta_{so} = 0.34$ eV. If circularly polarized light (σ^+ or σ^-) with an energy slightly above the energy gap of $E_{gap} = 1.52$ eV of p-GaAs is irradiated onto the sample, the electronic transition in GaAs must fulfill the optical selection rule $\Delta m_j = m_f - m_i = \pm 1$, where $m_{f,i}$ is the angular momentum of the final and initial states, respectively (see Figure 1.8). When using σ^+ light, the relative transmission probability into $m_j = -1/2$ states is threefold higher than that into $m_j = -3/2$ states

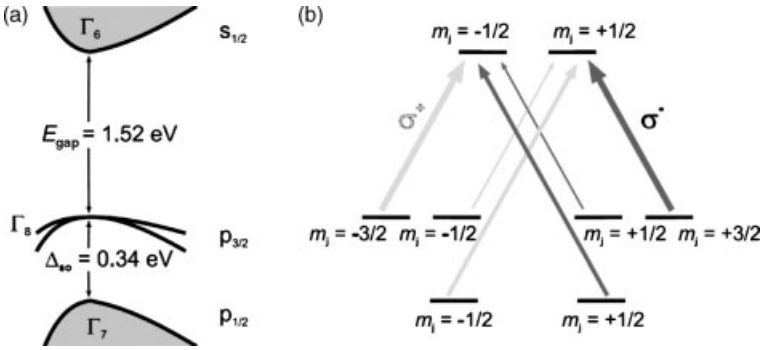

Figure 1.8 (a) Schematic band structure of GaAs in the vicinity of the Γ-point of the Brillouin zone. The width of the band gap between the conduction (Γ_6) and the fourfold degenerate $p_{3/2}$ valence band edge (Γ_8) amounts to 1.52 eV. Another 0.34 eV lower there is the twofold degenerate $p_{1/2}$ level (Γ_7); (b) Allowed transitions between different m_j sublevels for circularly polarized light of opposite helicity (σ^+ and σ^-). The transition probability is represented by the thickness of the arrows. (Reprinted from Ref. [24], with permission of IOP Publishing Ltd.)

(and vice versa for σ^- light). As a result, while the theoretical limit of the electron spin polarization in photoemission is $\pm 50\%$, values as high as 43% have been achieved experimentally [41].

The preliminary experiments on GaAs–insulator–ferromagnet tunnel junctions were reported in Ref. [42]. The specimen was prepared by cleaving a GaAs crystal in air along the (1 1 0) plane. A 20–40 Å layer of Al was then evaporated onto the GaAs (1 1 0) surface and subsequently oxidized. Onto this insulating barrier was then deposited a 150 Å thick Co film, which was itself protected by a 50 Å Au cap layer. The chosen experimental set-up required that the light would traverse the ferromagnetic layer and the insulator before reaching the semiconductor. After magnetization of the Co film perpendicular to the plane, a dependence of the tunneling current on the helicity of the light was measured, which suggested the existence of spin-polarized transport. However, an even stronger signal was detected when there was no tunneling barrier between the semiconductor and the ferromagnet' this was explained by "...an intensity modulation of the circularly polarized light upon transmission through the magnetically ordered layer, determined by the polar magneto-optic coefficients" [42]. The reduction of the helical asymmetry when using a tunnel barrier, compared to a situation without any barrier, was explained in a later analysis [43, 44] by a negative tunneling conductance. As this method to create spin-polarized electrons involves neither a magnetic material nor magnetic fields, it offers excellent conditions for application in SP-STM.

In spite of this favorable situation, GaAs tips have not yet been used successfully for the imaging of magnetic surfaces. Similar to the experiments performed with planar junctions, this may be caused by difficulties in separating spin-polarized tunneling from magneto-optical effects [45–49].

Compared to the proposal of Pierce [3] (as shown in Figure 1.7), the first successful observation of spin-polarized electron tunneling with the scanning tunneling

microscope, using a GaAs electrode [50], was obtained by exchanging the role of tip and sample – that is, by using a Ni tip and a GaAs(110) surface. Moreover, instead of optically pumping the GaAs sample and thereby producing spin-polarized charge carriers in the GaAs, the reverse process was used, with spin-polarized electrons being injected from the Ni tip into the conduction band of GaAs. Upon transition of the injected electrons from this metastable state in the conduction band into the final state in the valence band recombination, luminescence was seen to occur and the circular polarization of the emitted photons was analyzed.

Evidence for a second explanation for the failure of magnetic imaging with GaAs electrodes – namely an insufficient lifetime of the spin carriers at the tip apex – comes from analogous STM-excited luminescence experiments performed with single crystalline Ni(110) tips and a stepped GaAs(110) sample [51]. With the tip positioned above flat terraces, a high-spin injection efficiency was measured. However, the intensity of the recombination luminescence on the upper terrace was found to have decreased by a factor of 1000. Simultaneously, the polarization decreased by a factor of 6. This observation was explained by a reduction of either the spin injection efficiency or of the spin relaxation lifetime, and attributed to the metallic nature of the step edge caused by midgap states of the (111) surface. As a sharp tip must possess numerous step edges around the apex atom, it is a straightforward conclusion that the spin relaxation lifetime may be drastically reduced at the very end of the tip.

1.3.1.4 **Nonmagnetic Probe Tips**

Surprisingly, even nonmagnetic tips can be used to image certain magnetic sample properties, as demonstrated by Bode *et al.* [52, 53] and by Pietzsch *et al.* [54]. The images shown in Figure 1.9a and b [54] were taken for slightly less than 2 ML Fe on

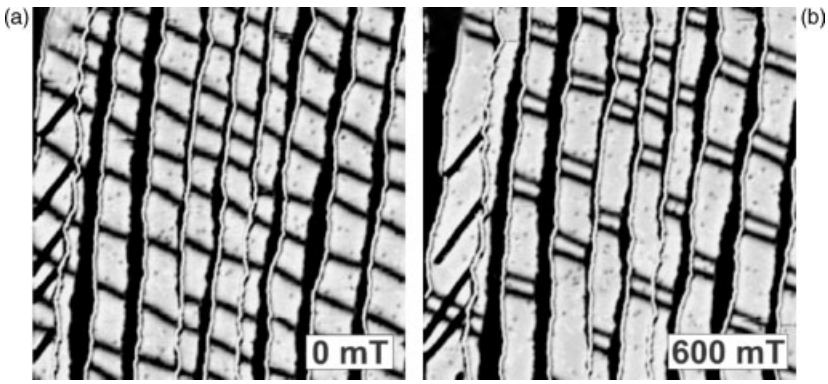

Figure 1.9 Domain walls as observed with a nonmagnetic W tip. (a) No external field applied; (b) Taken at 600 mT. The external field enforces pair formation. Sensitivity to the spin orientation inside the walls is lost, and all walls are imaged as dark lines. Thus, the image provides information on the magnetization lying along an easy or a hard direction. Note the five lines in the left stripe running in a direction bottom-left to top-right; these are not domain walls but are dislocation lines. (Reprinted from Ref. [54], with permission of Springer. Copyright (2004).)

W(110), which allows a comparison with the results shown in Figure 1.6 (which were obtained using a magnetic tip). However, a tungsten tip without any magnetic coating was now used, whereupon the dark lines revealed the presence of domain walls. The main difference between the two measurements was that the nonmagnetic tip did not provide sensitivity to the spin orientation inside the walls. Instead, both walls of a pair were imaged equally, in contrast to the observation made with the ferromagnetic tip [55] (cf. Figure 1.26). This is a consequence of the fact that the measurement made with the W tip does not involve spin-polarized tunneling; rather, it is the spin-averaged electronic structure of the sample that gives rise to the signal. The electronic structure of the DL stripes is locally modified due to the presence of a domain wall. In other words, the electronic structure is sensitive to whether the magnetization is in an easy or a hard direction. First-principle calculations have shown [52, 53] that the spin–orbit-induced mixing of different *d*-states depends on the magnetization direction, and changes the local density of those states that are detectable by non-spin-polarized STS.

As an important implication of this effect, the magnetic nanostructure of surfaces can be investigated with conventional nonmagnetic tips. This has the clear advantage that there is definitely no dipolar magnetic stray field from the tip that could interfere with the sample. In addition, the preparation of a magnetic tip is omitted.

1.3.2 Modes of Operation

In the following sections, different modes of operation enabling to achieve a magnetic contrast using magnetic probe tips will briefly be discussed from a theoretical point of view according to Ref. [56].

1.3.2.1 Constant Current Mode

In the situation when the tip and sample are magnetic, the tunneling current can be described as a sum of a spin-averaged I_0 and a spin-dependent term I_{sp} [56] (cf. Equation 1.8):

$$I(\vec{r}_t, U, \theta) = I_0(\vec{r}_t, U) + I_{sp}(\vec{r}_t, U, \theta) \tag{1.9}$$

$$= const. \cdot (n_t \tilde{n}_s(\vec{r}_t, U) + \vec{m}_t \tilde{\vec{m}}_s(\vec{r}_t, U)) \tag{1.10}$$

with n_t being the non-spin-polarized local density of states (LDOS) at the tip apex, $\tilde{n}_s$ the energy-integrated LDOS of the sample, and $\vec{m}_t$ and $\tilde{\vec{m}}_s$ the vectors of the (energy-integrated) spin-polarized LDOS with:

$$\tilde{\vec{m}}_s(\vec{r}_t, U) = \int \vec{m}_s(\vec{r}_t, E) \mathrm{d}E \tag{1.11}$$

and θ the angle between the magnetization direction of tip and sample. For a non-spin-polarized STM experiment – that is, using either a nonmagnetic tip or a nonmagnetic sample – the second term, I_{sp}, vanishes.

The constant current mode is restricted to some limited cases, which is partly due to the integral in Equation 1.11 and taken over all energies between the Fermi energy E_F and eU, with U being the applied bias voltage because I_{sp} becomes reduced if the spin polarization changes sign between E_F and eU. Furthermore, the magnetically induced corrugation is small compared to the topographic and electronic corrugation; this is due to the exponential dependence of the tunneling current on the distance between tip and sample. Nevertheless, it is still possible to obtain information of complex atomic-scale spin structures at ultimate magnetic resolution (as shown in Ref. [56]), although it is necessary to understand the influence of the tip [57, 58].

1.3.2.2 Spectroscopy of the Differential Conductance

The difficulties of separating the topographic, electronic and magnetic information can be overcome by measuring the differential conductance, $\mathrm{d}I/\mathrm{d}U$, with a magnetic tip [56]:

$$\mathrm{d}I/\mathrm{d}U(\vec{r}_t, U) \propto n_t\tilde{n}_s(\vec{r}_t, E_F + eU) + \vec{m}_t\tilde{\vec{m}}_s(\vec{r}_t, E_F + eU) \tag{1.12}$$

In this situation, the measured quantity no longer depends on the energy-integrated spin polarization, but rather on the spin polarization in a narrow energy window ΔE around $E_F + eU$.

The differential conductance is determined experimentally by adding a small ac-voltage to the dc-bias voltage at a frequency which is significantly above the cut-off frequency of the feedback loop that ensures a constant current. The amplitude of the ac-voltage is responsible for the width ΔE. The current modulation is amplified by means of a lock-in technique.

The electronically homogeneous surfaces maps of differential conductance reflect the magnetic behavior, since any variation of the signal must be due to the second spin-dependent term, I_{sp}. The situation becomes more complicated for electronically heterogeneous surfaces; nevertheless, a careful comparison between spin-averaged and spin-resolved measurements often allows a distinction to be made between topographic and electronic contrast compared to the magnetically induced information. However, this set of experiment requires measurements to be made with both nonmagnetic and magnetic probe tips.

The determination of differential conductance also provides access to the spin polarization of a surface which is *locally resolved* [59–61].

The recording of inelastic tunneling spectra (i.e. the second derivative of the conductance $\mathrm{d}^2I/\mathrm{d}U^2$) with a magnetic tip in an external magnetic field, it becomes possible to study directly – that is, without a separating insulating layer – magnon excitations in magnetic nanostructures [62].

1.3.2.3 Local Tunneling Magnetoresistance

As an alternative method, the local tunneling magnetoresistance $\mathrm{d}I/\mathrm{d}\vec{m}_t$ between the magnetic tip and magnetic sample can be determined by modulation of the tip magnetization direction and determining the variation of the tunneling current using a lock-in technique. This type of measurement was first proposed by Johnson

and Clarke [63] and later accomplished by Wulfhekel and Kirschner [17]. By taking the derivative of Equation 1.10 one obtains:

$$\mathrm{d}I/\mathrm{d}\vec{m}_t \propto \tilde{\vec{m}}_s \tag{1.13}$$

Thus, the signal is proportional to the energy-integrated spin-polarized LDOS. One significant advantage of this technique relates to the detailed knowledge of the magnetization of the probe tip. A nonvanishing signal is also obtained only if a local magnetization is present. Furthermore, this method allows the investigation of samples in a single domain state; this situation differs from the spectroscopy of differential conductance, which demands that different magnetic domains are simultaneously visible in a single image. Consequently, due to the direct detection of magnetic information, knowledge of the electronic properties is no longer required.

It must be borne in mind, however, that the interpretation of chemically heterogeneous surfaces (e.g. of alloys) remains difficult. Both, the sign and magnitude, of the element-specific spin polarization may vary, thereby avoiding any direct identification of the domain structure. Nonetheless, the chemical contrast plays an additional role.

1.4
Magnetic Arrangement of Ferromagnets

In this section, we will demonstrate the magnetic arrangement of ferromagnetic systems for systems which exhibit localized magnetic moments, and also which represent an itinerant or band magnet. A typical representative of the former group is the rare-earth metal gadolinium, while the transition metal cobalt is typical of the latter group.

1.4.1
Rare-Earth Metals: Gd/W(110)

In analogy to the low-temperature experiments performed with ferromagnet–insulator–superconductor planar tunneling junctions [64, 65], where the quasiparticle density of states of superconducting aluminum is split by a magnetic field into spin up and spin down parts, two spin-polarized electronic states with opposite polarization can be used to probe the magnetic orientation of the sample relative to the tip, thus enabling spin-polarized scanning tunneling spectroscopy (SP-STS) [60].

The principle of SP-STS is shown schematically in Figure 1.10, using a sample which exhibits an exchange split-surface state with a relatively small exchange splitting, Δ_{ex}. This situation is, for example, realized for the Gd(0001) [66–70], Tb (0001) [71] and Dy(0001) surfaces [72]. If Δ_{ex} is too large, then one spin component would be too far from the Fermi level and not accessible by STS, as for example in the case of Fe(001), where Δ_{ex} amounts to 2.1 eV and only the minority band appears as a

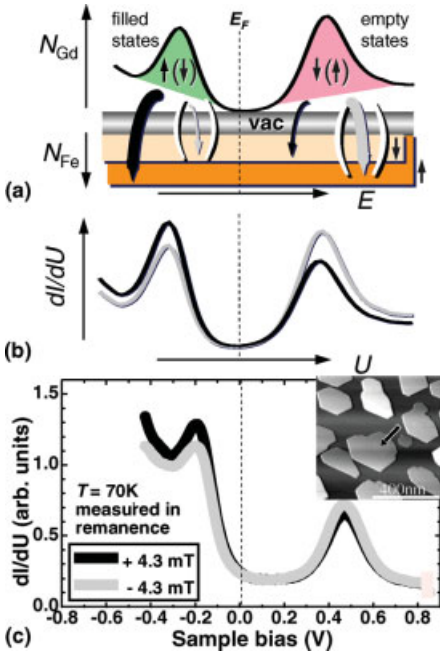

Figure 1.10 (a) The principle of SP-STS using a sample with an exchange split surface state, for example, Gd(0001), and a magnetic Fe tip with a constant spin polarization close to E_F. Due to the spin valve effect the tunneling current of the surface state spin component being parallel to the tip is enhanced at the expense of its spin counterpart; (b) This should lead to a reversal in the dI/dU signal at the surface state peak position upon switching the sample magnetically; (c) Exactly this behavior could be observed in the tunneling spectra measured with the tip positioned above an isolated Gd island (see arrow in the inset). (Reprinted with permission from Ref. [27]; copyright (1998), American Physical Society.)

peak in the dI/dU spectra just above the Fermi level [73]. In contrast, the majority (minority) part of the Gd(0001) surface state has a binding energy of −220 meV (500 meV) at 20 K [71]; that is, the exchange splitting only amounts to 700 meV, far below the Curie temperature of 293 K.

In the following section we consider vacuum tunneling between a Gd(0001) surface and a tip material; for simplicity, we assume a constant spin polarization (see Figure 1.10a, lower part). If the magnetization direction of the tip remains constant, then two possible magnetic orientational relationships occur between the tip and sample – parallel or antiparallel – under the assumption that the magnetization of the tip and sample is aligned. Since, however, both the majority and the minority component of the Gd(0001) surface state appear in the tunneling spectra, the spins of one component of the surface state will in any case be *parallel* with the tip, while the spins of the other component will be *antiparallel*. Therefore, the spin valve effect will act differently on the two spin components; due to the strong spin dependence of the density of states, the spin component of the surface state parallel to the tip magnetization is enhanced at the expense of its counterpart being antiparallel.

Consequently, by comparing tunneling dI/dU spectra measured above domains with opposite magnetization, one expects a reversal in contrast at the majority and minority peak positions (see Figure 1.10b).

Tunneling spectra measured in an external magnetic field with an in-plane sensitive ferromagnetic probe tip positioned above an isolated Gd(0001) island show exactly the expected behavior (see Figure 1.10c). The sample was magnetized in a magnetic field of $+4.3$ mT applied parallel to the sample surface, and the spectra were subsequently measured in remanence with the tip positioned above the Gd island (this is marked by an arrow in the inset of Figure 1.10c). The direction of the magnetic field was then reversed (to -4.3 mT) and further dI/dU spectra were monitored at the same location. Figure 1.10c shows the tunneling spectra measured in remanence after the application of a positive or negative field. A comparison of the spectra reveals that for a positive field, the differential conductance dI/dU measured at a sample bias which corresponds to the binding energy of the occupied (majority) part of the surface state, is higher than for negative field. The opposite is true for the empty (minority) part. Freestanding Gd islands on W(110) were chosen for this experiment, since it is known from Kerr effect measurements [74] that the coercivity is only 1.5 mT – that is, much lower than the applied field. Thus, it can be safely concluded that the magnetization of the sample was switched by the external field while the tip magnetization remained unchanged.

Further information relating to magnetic imaging of the Gd(0001) surface can be found in Refs [36, 68, 70], while data concerning the surface of another rare earth metal, Dy(0001), are available in Ref. [72].

1.4.2
Transition Metals: Co(0001)

The domain structure of the surface of a Co(0001) single crystal has been studied by Wulfhekel *et al.* [17–23]. The uniaxial magnetocrystalline anisotropy of hcp-Co points along the *c*-axis – that is, perpendicular to the (0001) surface. However, the total energy of the sample is minimized by the formation of surface closure domains where the magnetization locally tilts towards the surface plane, thereby reducing the dipolar energy. As the magnetocrystalline anisotropy energy and dipolar energy are similar in size, and the in-plane components of the magnetocrystalline anisotropy energy are almost degenerate, a complicated dendritic pattern is formed at the surface. Figure 1.11a shows the typical dendritic-like perpendicular domain pattern of Co(0001) as measured by Wulfhekel *et al.* [23]. Due to the fact that the tip magnetization is intentionally modulated by a small coil, the bright and dark locations in Figure 1.11a can be assigned to specific magnetic orientations, namely the magnetization vector points out of or into the surface, respectively. A sharp contrast can be recognized in Figure 1.11b, which is completely absent in the topographic image [21]. The absence of any correlation confirms that this contrast is not caused by different local structural or electronic properties; rather, it represents a domain wall separating two regions of different magnetization directions. This

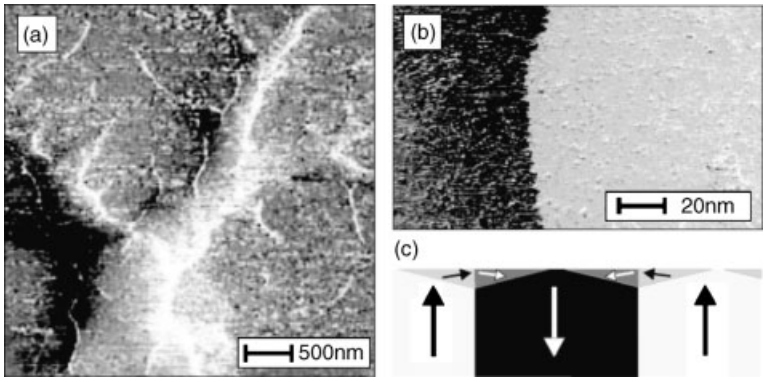

Figure 1.11 (a) Magnetic domain image on Co(0001) obtained by SP-STM; (b) A sharp domain wall at the end of a branch, at high magnification; (c) Schematic cross-section of the closure domain pattern of Co. (Reprinted with permission from Ref. [23]; copyright (2003), EDP Sciences.)

domain wall is found to correspond to the domain wall across two canted surface domains (see Figure 1.11c).

Further information concerning the ferromagnetic transition metal Fe on W(110) and Mo(110) is provided below. The spin-resolved electronic properties of dislocation lines that occur during thin film growth of Fe films on W(110) are described in Ref. [75], while details of the complex magnetic structure of Fe on W(001) are reported in Refs [76, 77]. The easy magnetization axis was shown to be layer-dependent, whereas the second and third Fe layers were magnetized along $\langle 110 \rangle$ or equivalent directions; the easy axis of the fourth layer was rotated by 45°.

1.5 Spin Structures of Antiferromagnets

The lateral averaging of magnetically sensitive techniques often fails in the imaging of antiferromagnetic surfaces because the overall detected magnetization is equal to zero. Here, we will show how SP-STM can be used to overcome this difficulty. The first example is the topological anti-ferromagnetism of Cr(001); a second example, namely the atomic resolution of magnetic behavior, will be demonstrated using the antiferromagnetic Mn monolayer on W(110) and Mn_3N_2 films on MgO(001).

The antiferromagnetic nature was additionally reported for the first monolayer of Fe on W(001) [77]. The antiferromagnetic coupling between a whole atomic layer and a ferromagnetic substrate was investigated for Mn on Fe(001) [25, 26, 78]; a Co layer on a Cu-capped Co substrate exhibits a ferromagnetic or antiferromagnetic coupling, depending on the interlayer thickness [79]. Magnetite Fe_3O_4 represents a ferrimagnet with a high spin polarization near the Fermi level. SP-STM was used to investigate the corresponding (001) [39, 40, 80–83] and (111) surfaces [40, 84].

1.5.1
Topological Anti-Ferromagnetism of Cr(001)

The Cr(001) surface for which the topological step structure is directly linked to the magnetic structure represents a topological anti-ferromagnet; that is, each terrace exhibits a ferromagnetic alignment of the magnetic moments, although between two adjacent terraces the magnetization possesses an antiparallel orientation that was predicted, on a theoretical basis, by Blügel *et al.* [85].

By using the scanning possibilities, the antiferromagnetic coupling between neighbored terraces of a Cr(001) surface can be imaged directly [70, 86–94]. The topography (see Figure 1.12a) presents a regular step structure with terrace widths of about 100 nm [88]. The line section in the bottom of Figure 1.12a shows that all step edges in the field of view are of single atomic height – that is, 1.4 Å. This topography should lead to a surface magnetization that periodically alternates between adjacent terraces and, indeed, this was observed experimentally (see Figure 1.12b). The line section of the differential conductance drawn along the same path as in Figure 1.12a indicates two discrete levels with sharp transitions at the positions of the step edges.

The typical domain wall width, as measured on a stepped Cr(001) surface, amounts to 120–170 nm [86]. In analogy to ferromagnetic domain walls (these are discussed in detail in Chapter 9), this value is determined by intrinsic material parameters – that is, the strength of the exchange coupling and the magnetocrystalline anisotropy. Clearly, the domain wall width cannot remain unchanged very close to a screw

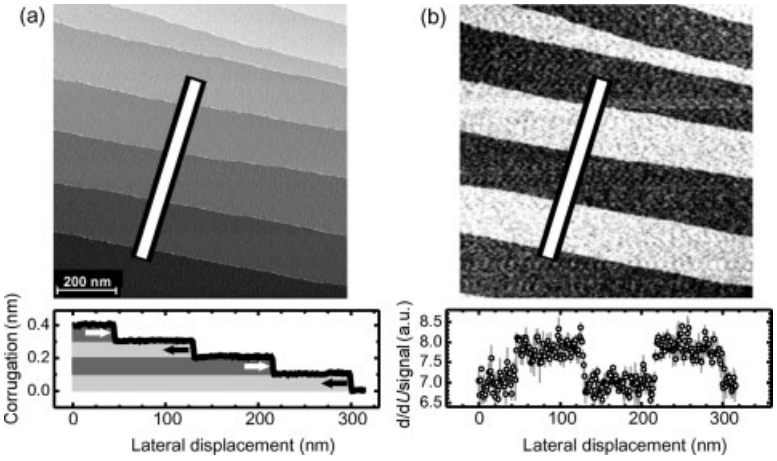

Figure 1.12 (a) Topography and (b) spin resolved map of the d*I*/d*U* signal of a clean and defect free Cr(0 0 1) surface as measured with a ferromagnetic Fe-coated tip. The bottom panels show averaged sections drawn along the line. Adjacent terraces are separated by steps of monatomic height. dislocation where the circumference becomes comparable with or smaller than the intrinsic domain wall width.

The dependence of domain wall width on the distance from the screw dislocation of the Cr(001) surface is shown in Figure 1.13a [88]. Here, approximately 100 nm from the next step edge, a single screw dislocation can be recognized in the upper left corner of the image. The magnetic d*I*/d*U* map of Figure 1.13b reveals that this screw dislocation is the starting point of a domain wall which propagates towards the upper side of the image. Starting at the tail of the arrow (zero lateral displacement), eight circular line sections are drawn counterclockwise around the screw dislocation at different radii r_{avg}, from 75 nm down to 7.5 nm; these data are plotted in Figure 1.13c. The domain walls were fitted using the model provided in Chapter 9. The results are shown as gray lines in Figure 1.13c; except for the smallest average

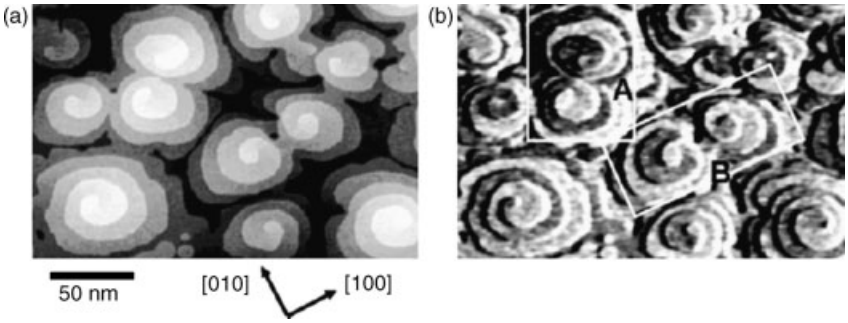

Figure 1.14 STM images of (a) the topography and (b) dI/dU magnetic signal obtained simultaneously from the same area of a 9 nm-thick Cr(001) film. (Reprinted with permission from Ref. [93]; copyright (2007), Elsevier.)

radius ($r_{avg} = 7.5$ nm), an excellent agreement with the experimental data was found. At an average radius $r_{avg} = 75$ nm, the domain wall width amounted to 125 nm, being in close agreement with the intrinsic domain wall width of Cr(001) as determined far away from screw dislocations. This was not surprising, as the circumference amounted to about 500 nm – much larger than the intrinsic domain wall width. However, as soon as r_{avg} was reduced below 60 nm a significant reduction in domain wall width was observed, although the circumference still exceeded the intrinsic domain wall width. The results showed clearly that the domain wall width was always considerably narrower than the circumference of the cross-section.

We can now discuss a more complex structure, namely the influence of the distance and chirality between two adjacent spiral terraces on magnetic structures on Cr(001) films [90, 93]. Figure 1.14a shows a topographic STM image of a 9 nm-thick Cr(001) film [93] where the feature of the surface morphology is that the Cr layers form high-density, self-organized spiral terraces. Each terrace is displaced by a monatomic step height, and a screw dislocation is clearly visible in the center of each spiral pattern. The typical diameter of these spiral terraces is 50 nm. A complex spin frustration and characteristic magnetic ordering is present, being restricted by the topological asymmetry of the spiral terraces. Figure 1.14b shows the dI/dU magnetic image obtained simultaneously in the same area of Figure 1.14a, exhibiting a magnetic contrast. A comparison of the two images of Figure 1.14a and b reveals that most parts of the observed magnetic contrasts are consistent with a topological antiferromagnetic structure. The maximum magnetic contrast corresponds to the topological antiferromagnetic order, and a deviation from the maximum magnetic contrast can be recognized as the spin frustration which appear in the region near the screw dislocations and between two spirals.

The magnetic structure can be deduced from the observed dI/dU magnetic signal intensity by assuming the orientation of the tip magnetization parallel to the bcc [100] direction. For example, the derived magnetic structures of two adjacent spirals (the regions A and B indicated in Figure 1.14b) are shown in Figure 1.15 by arrows. Although the two adjacent spirals have the same chirality, the sign is opposite

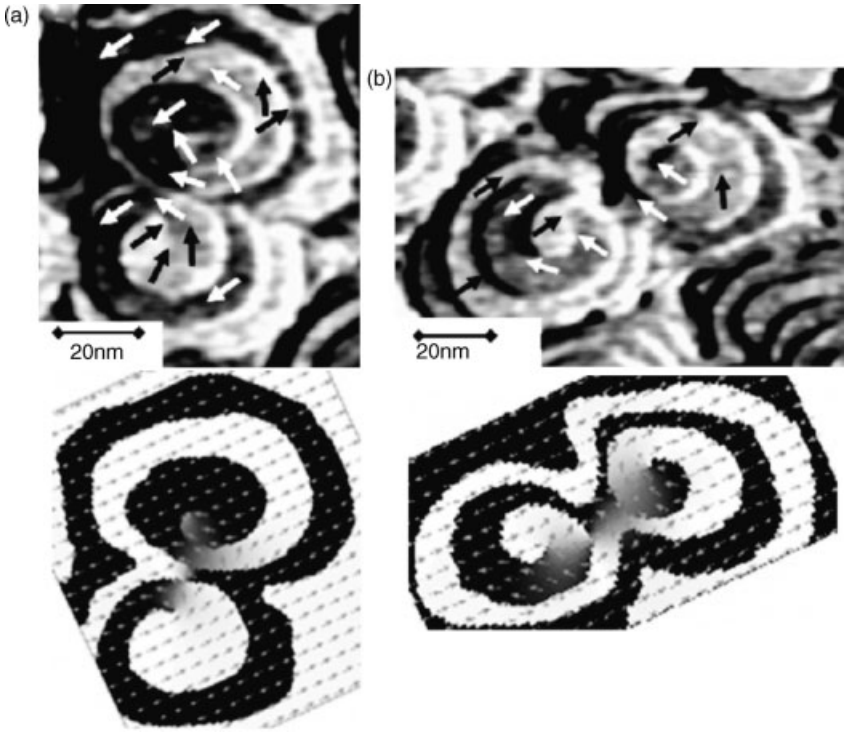

Figure 1.15 Observed (upper) and simulated (lower) magnetic structures of two adjacent spirals: (a) region A and (b) region B indicated in Figure 1.14b. The directions of the magnetization are represented by the arrows. The distance between the two screw dislocations is 20 nm (region A) and 32 nm (region B). (Reprinted with permission from Ref. [93]; copyright (2007), Elsevier.)

between regions A and B; the distance between the two screw dislocations d_s is 20 and 32 nm for the regions A and B, respectively. Although the magnetization rotates gradually around the center of the spiral in the case of $d_s = 75$ nm [90], this does not occur for $d_s = 20$ nm and 32 nm, which suggests that the spin-frustrated region decreases with decreasing d_s. There seems to be little difference in the sign of chirality of spirals.

In order to understand its origin, we can calculate the magnetic structure of these spiral terraces [93]; the result is shown in the two lower panels in Figure 1.15. The white (black) contrast represents the magnetization to be parallel (antiparallel) to the [100] direction. The topological antiferromagnetic order appears in a series of adjacent terraces, as well as in the most part of spiral terraces; the frustrated regions (the gray regions in the simulated figures) are evident between the center of adjacent spirals. It should be noted that the observed and calculated magnetic structures are clearly asymmetric with respect to the straight line connecting two screw dislocations, in spite of the different d_s-values. The simulated spin alignments are in good qualitative agreement with the observed results.

1.5.2
Magnetic Spin Structure of Mn with Atomic Resolution

The deposition of Mn on W(110) in the submonolayer regime results in a pseudomorphic growth; that is, Mn mimics the bcc symmetry as well as the lattice constant of the underlying substrate [95]. By using a clean W tip, atomic resolution could be achieved on the Mn islands, as demonstrated by Heinze *et al.* [96] (see Figure 1.16a). Additional information is provided in Refs [70, 97]. The diamond-shaped unit cell of the (1×1)-grown Mn ML is clearly visible. The line section drawn along the dense-packed $[1\,\bar{1}\,1]$ direction exhibits a periodicity of 0.27 nm, which almost perfectly fits the expected nearest-neighbor distance of 0.274 nm. The measured corrugation amplitude amounts to 15 pm. A calculated STM image for a conventional tip without spin polarization is given for comparison (see inset of Figure 1.16a). Clearly, the qualitative agreement between theory and experiment is excellent.

In a second set of experiments [96], different ferromagnetic tips were used. Since it is known from first-principles computations that the easy magnetization axis of the Mn ML on W(110) is in-plane [96], the experiment required a magnetic tip with a magnetization axis in the plane of the surface in order to maximize the effects. This condition is fulfilled by Fe-coated probe tips [27]. Figure 1.16b shows an STM image taken with such a tip, where the periodic parallel stripes along the [001] direction of the surface can be recognized. The periodicity along the $[1\,\bar{1}0]$ direction amounts to 4.5 Å, which corresponds to the size of the magnetic c(2×2) unit cell. The inset in Figure 1.16b shows the calculated STM image for the magnetic ground state, that is, the c(2×2)-antiferromagnetic configuration. Thus, theory and experiment give a consistent picture. Even the predicted faint constrictions of the stripes along the [001] direction related to the pair of second-smallest reciprocal lattice vectors are visible in the measurement. Again, experimental and theoretical data can be compared more quantitatively by drawing line sections along the dense-packed $[1\,\bar{1}1]$ direction (see Figure 1.16b). The result, which is plotted in Figure 1.16c, reveals that the periodicity, when measured with a Fe-coated probe, is twice the nearest-neighbor distance (i.e. 0.548 nm).

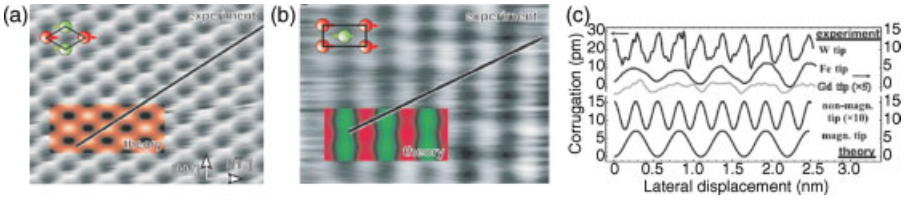

Figure 1.16 Comparison of experimental and theoretical STM images of a Mn ML on W(110) with (a) a nonmagnetic W tip and (b) a magnetic Fe tip; (c) Experimental and theoretical line sections for the images in (a) and (b). The unit cell of the calculated magnetic ground-state configuration is shown in (a) and (b) for comparison. The image size is 2.7×2.2 nm. (Reprinted with permission from Ref. [96]; AAAS.)

The pronounced dependence of the effect on the magnetization direction of the tip can be exploited to gain further information on the magnetization direction of the sample. This is done by using a tip that exhibits an easy magnetization axis that is almost perpendicular to the one of the sample surface. This condition is fulfilled by a W tip coated with about 7 ML Gd [29]. The gray line in Figure 1.16c represents a typical line section as measured with such a Gd-coated probe tip. Indeed, the corrugation amplitude was always much smaller than that for Fe-coated tips and never exceeded 1 pm, thus supporting the theoretical results that the easy axis of the Mn atoms is in-plane.

In the following section it will be shown, by reference to the studies of Yang *et al.* [98] and Smith *et al.* [99], that both magnetic and nonmagnetic atomic-scale information can be obtained simultaneously in the constant current mode for another Mn-based system which consists of Mn_3N_2 films grown on MgO(001) with the c axis parallel to the growth surface, which is (010). The surface geometrical unit cell, containing six Mn atoms and four N atoms (3 : 2 ratio), can be denoted as $c(1 \times 1)$, whereas the surface magnetic unit cell is just (1×1).

The bulk structure of Mn_3N_2 exhibits a face-centered tetragonal (fct) rock salt-type structure. The bulk magnetic moments of the Mn atoms are ferromagnetic within (001) planes, lie along the [100] direction, and are layerwise antiferromagnetic along [001]. Besides the magnetic superstructure, every third (001) layer along the c direction has all N sites vacant, which results in a bulk unit cell exhibiting $c = 12.13$ Å (six atomic layers).

Figure 1.17a presents a SP-STM image [98] of the surface acquired using a Mn-coated W tip thus being sensitive to the in-plane direction. Although the row structure with period $c/2$ is observed, a modulation with period c of the height of the rows is additionally obvious. The modulation shown in Figure 1.17b is evident for both domains D1 and D2 by the area-averaged line profiles taken from inside the boxed regions on either side of the domain boundary. For the domain D1 (red line), the modulation amplitude is about a factor of 2 larger than for the domain D2 (blue line). As the height modulation is proportional to $m_t m_s \cos\theta$, with m_t and m_s being the

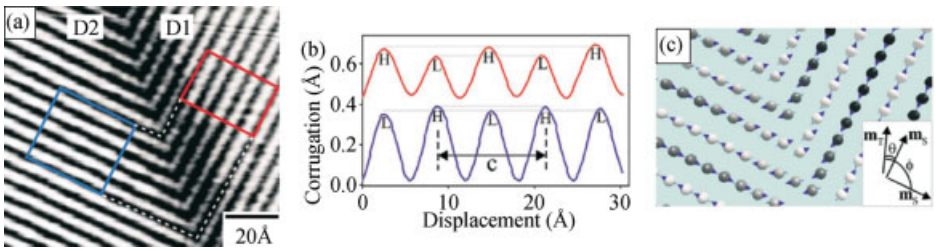

Figure 1.17 (a) SP-STM image acquired using a Mn-coated W tip; (b) Two area-averaged line profiles (red and blue) corresponding to the regions inside the red and blue rectangles in (a); (c) Simulated SP-STM map: contrast: white ↔ black ⇒ θ: 0 ↔ π. The inset shows the moments of tip ($\vec{m}_t$) and the sample ($\vec{m}_s$) for the two different domains and the angles between them. Each ball represents a magnetic atom. (Reprinted with permission from Ref. [98]; copyright (2002), American Physical Society.)

moment of the tip and sample, respectively, and θ the angle between them (cf. Equation 1.8), it is simple to show that $\theta = \arctan(\Delta z_2/\Delta z_1)$, where z_1 and z_2 are the height modulation in domains D1 and D2, respectively. In the case shown here, with $\Delta z_1 = 0.04$ Å and $\Delta z_2 = 0.02$ Å, θ amounts to ≈27°.

A high peak (H) on one side of the domain boundary converts to a low peak (L) on the other side. This inversion is simulated in Figure 1.17c by a simple antiferromagnetic model configuration of spin moments and a tip spin at the angle $\theta = 27°$. The gray scale for each magnetic atom is proportional to $m_t m_s \cos\theta$ (white: $\theta = 0$; black: $\theta = \pi$). Clearly, the inversion occurs when the difference $\phi - \theta = \pi/2$, where θ and φ are the two different angles between tip and sample moments in domains D1 and D2, respectively.

The data can now be used to separate the magnetic and nonmagnetic components. Beginning with the SP-STM image shown in Figure 1.18a [98], the average height profile $z(x)$ where x is along [001] (Figure 1.18b, dark blue line) and also $z(x + c/2)$ (Figure 1.18b, light blue line) are plotted. Clearly, by taking the difference and sum of these two functions, the magnetic component with periodicity c and the nonmagnetic component with period $c/2$ can be extracted: $m_t m_s \cos[\theta(x)] \sim [z(x) - z(x + c/2)]/2$. This is further justified if it is assumed that the bulk magnetic symmetry is maintained at the surface. When using this procedure, the resulting magnetic profile for the data of Figure 1.18 has a period of c and a trapezoidal wave shape, as shown in Figure 1.18c (violet line). The nonmagnetic profile is also shown in

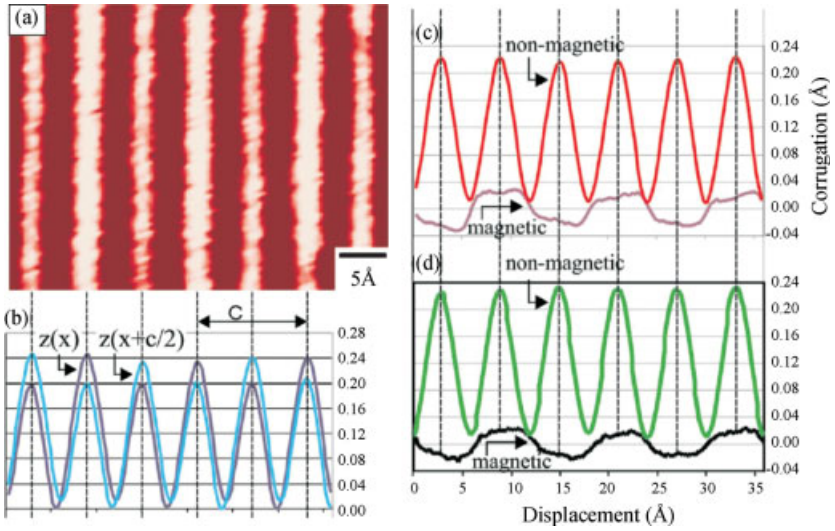

Figure 1.18 (a) SP-STM image acquired using a Mn-coated W tip; (b) Area-averaged line profile $z(x)$ of the whole image of (a) (dark blue), and $z(x + c/2)$ (light blue); (c) The resulting nonmagnetic component (red) and magnetic component (violet) for the Mn-coated tip; (d) Nonmagnetic (green) and magnetic (black) components for the Fe-coated tip on a similar sample region. The local coverage alternates between one and two atomic layers. White arrows symbolize the easy magnetization directions of the mono- and the double layer; that is, in-plane and perpendicular to the surface, respectively; (c) Adjacent perpendicularly magnetized DL stripes exhibit an antiparallel dipolar coupling. Within domain walls the Fe DL on W(110) locally exhibits an in-plane magnetization. (Reprinted with permission from Ref. [104]; Elsevier.)

Figure 1.18c (red line) exhibiting a period of $c/2$ and a sinusoidal shape, the same as for the average line profile acquired with a nonmagnetic tip. The magnetic component amplitude is about 20% of the nonmagnetic component amplitude.

1.6 Magnetic Properties of Nanoscaled Wires

The behavior of perpendicularly magnetized Fe double layer nanowires epitaxially grown on a stepped W(110) single crystal [29, 55, 69, 100–103] with an average terrace width of about 9 nm is presented as an example of magnetic wires exhibiting a width in the nanometer range (see Figure 1.19a) [104]. This study was carried out at low temperatures, below about 10 K. At higher temperatures a reorientation to an in-plane easy axis occurs with the spin reorientation temperature being coverage-dependent for samples with a coverage between 1.5 and 2.2 atomic layers [105]. The sample was prepared by the deposition of 1.6 ML Fe on the W(110) substrate held at elevated temperature of 450 K. This preparation procedure leads to step-flow growth of the second Fe ML on top of the closed first Fe layer, thereby creating a system of nanowires with alternating Fe ML and DL coverage elongated along the step edges of the substrate (this situation is shown schematically in Figure 1.19b, which also contains the line section corresponding to the line shown in Figure 1.19a). The coverage range between 1.4 and 1.8 ML Fe/W(110) is characterized by magnetic saturation at relatively low external perpendicular fields combined with the absence of a hysteresis – that is, zero remanence. As shown schematically in Figure 1.19c, this antiparallel order is a consequence of the dipolar coupling which reduces the

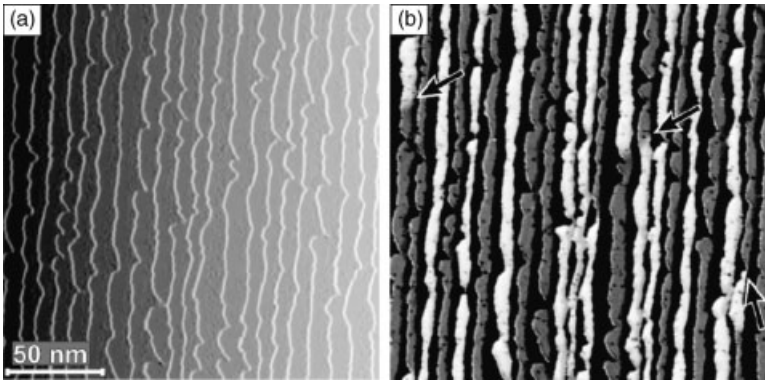

Figure 1.20 (a) STM topograph and (b) magnetic dI/dU image of Fe nanowires on W(110). Both images were measured simultaneously. The sample exhibits a demagnetized antiferromagnetic ground state which is energetically favorable due to flux closure between adjacent perpendicularly magnetized Fe nanowires [106]. (Reprinted with permission from Ref. [104]; Elsevier.)

magnetic stray field of the perpendicularly magnetized Fe DL. At domain walls the magnetization vector may locally be oriented along the hard magnetic axis – that is, in-plane.

Tunneling spectroscopy was used to image the corresponding magnetic domain structure. Since it is known from full dI/dU spectroscopy curves how the contrast must be interpreted (see Section 1.3.2), it is no longer necessary to measure the entire spectra at every pixel of the image as this is very time-consuming (about 10–20 h per image for the investigation discussed here [104]). Instead, the dI/dU signal at a fixed sample bias already gives a good contrast. Figure 1.20 shows the simultaneously recorded topography (panel a) and the dI/dU signal (panel b) of 1.5 ML Fe/W(110). The measurement time for this image was about 30 min. Due to its different electronic properties, the Fe ML appears dark, but this is not related to the magnetic properties. Instead, the ML is known to exhibit an in-plane magnetization [107] which cannot be detected using Gd-tips which are sensitive only to out-of-plane magnetization [29]. Clearly, the magnetic domain structure is dominated by DL nanowires which are magnetized alternately up and down, although exceptions from this model can easily be recognized. Several domain walls within single Fe nanowires are visible; some of these are marked with arrows in Figure 1.20b. There are also numerous adjacent nanowires which couple ferromagnetically rather than antiferromagnetically. It is likely that these DL nanowires approach very close to each other – or may even touch – so that the exchange coupling dominates.

Imaging by SP-STM can also be used to deduce macroscopic magnetic properties, a situation demonstrated by Pietzsch *et al.* [104, 108] for a system of Fe nanowires as just discussed above. These authors showed that spin-resolved dI/dU maps in a varying external field could be used to obtain the magnetic hysteresis curve of the

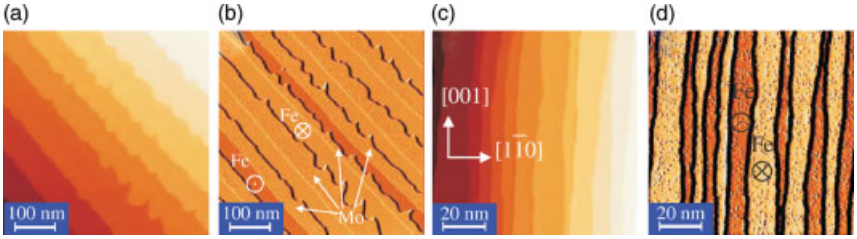

Figure 1.21 (a, c) Topographic STM images and (b, d) simultaneously measured differential conductance d*I*/d*U* maps of 0.5 ps-Fe (a, b) and of 1.0 ps-ML Fe (c, d) grown on Mo(110) at 700 K, respectively. Images (c, d) have been measured on the vicinal surface of the Mo substrate. Black and white lines in (b, d) located at step edges are artifacts due to scanning too quickly over the step edges. The black dots observed in (d) are due to adsorbates [24, 107]. Images and conductance maps were measured using a W/10 ML Au/4 ML Co magnetic tip. The Fe nanostructures reveal an out-of-plane magnetic contrast. (Reprinted with permission from Ref. [109]; copyright (2005), American Physical Society.)

surface area under investigation; that is, SP-STM enables the observation of magnetic hysteresis down to the nanometer scale.

Replacing W(110) with Mo(110) provides the unique possibility of observing the modification of magnetic properties of the Fe nanostructures, but leaving the structure and morphology almost unaffected [33, 109]. The magnetic easy axis is directed along the [001] direction for Fe/Mo(110) [110], while the easy axis is [1 $\bar{1}$0] for Fe/W(110) films [111]. The pseudomorphic ML (ps-ML) Fe/Mo(110) nanostructures are perpendicularly magnetized at low temperatures [112], whereas the ps-ML Fe/W (110) is magnetized in-plane along the [1 $\bar{1}$0] direction [113].

Figure 1.21a shows the topography and Figure 1.21b the simultaneously recorded d*I*/d*U* map of 0.5 ps-ML Fe deposited onto the Mo(110) single crystal at 700 K [109]. Monatomic Mo terraces decorated with the regular narrow Fe nanostripes grown by step-flow growth at the step edges are visible. The location of the Fe atoms on the Mo (110) surface is better visible on the d*I*/d*U* map (see Figure 1.21b) due to the element specific contrast resulting from the differences of the spin-averaged d*I*/d*U* signal which are connected with the local electronic surface properties that are different for Fe and Mo [112]. Uncovered Mo surfaces are indicated in Figure 1.21b by white arrows. The Fe nanowires show two different colors, representing two different values of the local d*I*/d*U* signal for equivalent surface regions (ML Fe/Mo(110)) for which the spin-averaged conductance signals should be the same [24]. All STM images and conductance maps shown in Figure 1.21 were measured using W tips covered by 10 ML Au and subsequently by 4 ML Co. It is known [114] that 4 ML Co prepared on W(110)/Au reveal an out-of-plane magnetic easy axis. Therefore, it may be expected that the magnetization of the tip would show perpendicular to the front plane of the tip – that is, along the tip axis – leading to an out-of-plane magnetic sensitivity of the tip. The contrast observed for the Fe nanostructures results from the perpendicularly magnetized Fe nanostripes, in agreement with Ref. [112].

The perpendicularly magnetized ML Fe nanostripes shown in Figure 1.21b are not antiferromagnetically ordered; that is, only two of the stripes are magnetized 'up',

whereas the orientation of the magnetization for the remaining stripes shows in the opposite direction ('down'). This means that the dipolar coupling between adjacent ML Fe nanowires is weak. The strength of the dipolar coupling between adjacent stripes increases with the stripe width and decreases with the distance between adjacent stripes [113]. The distance between adjacent ML Fe nanowires can be diminished down to a minimum by an increase of Fe coverage up to 1 ML. The topography of the 1 ML Fe deposited onto the vicinal surface of the Mo(110) crystal is presented in Figure 1.21c. Narrow ML Fe nanowires obtained on the vicinal surface are antiferromagnetically ordered, as demonstrated on the conductivity map (see Figure 1.21d).

1.7
Nanoscale Elements with Magnetic Vortex Structures

The domain structure of nanoscale magnetic elements has attracted considerable interest. The dependence of the domain structure on shape [115, 116], size [117] and edge structure [118] has been explored in many experiments. Further information on nanoislands gained by SP-STM are provided concerning Fe islands on W (110) [102, 119, 120], Fe islands on Mo(110) [112, 121], Co islands on Cu(111) [122, 123], Co islands on Pt(111) [124–126], Co islands on Au(11) [14], and FeAu alloy islands on Mo(110) [127, 128].

Due to their small dimensions, these elements are often superparamagnetic. This issue is addressed in Refs [112, 121], making use of time-dependent SP-STM studies. In a further development, Krause *et al.* showed [129] that superparamagnetic Fe nanoislands with typical sizes of 100 atoms could be addressed and locally switched using a magnetic probe tip. SP-STM thus provides an improved understanding of the underlying mechanism due to the feasibility to separate and quantify three fundamental contributions involved in magnetization switching, namely the current-induced spin torque, heating the island by the tunneling current, and Oerstedt field effects.

However, the influence of the thickness in conjunction with the magnetocrystalline anisotropy concerning nanoscale elements has rarely been studied [130]. Micromagnetic calculations have shown [131] that the lowest-energy domain configuration of permalloy rectangles depends critically on the thickness. With increasing thickness, a transition from the so-called C-state via the Landau-type or vortex configuration into a diamond state (double-vortex) was found. This behavior is caused by the thickness-dependent contribution of the magnetostatic energy, which must be paid wherever the magnetization is perpendicular to the element's rim. At a certain critical thickness it is energetically favorable to avoid the stray field by magnetizing the element along the edges throughout the entire particle, leading to a so-called *flux closure arrangement*.

This thickness-dependent behavior was corroborated experimentally by Bode *et al.* [120] using Fe islands on W(110). The left column of Figure 1.22 [120] shows the topography for different heights of the Fe islands, with the mean island height h

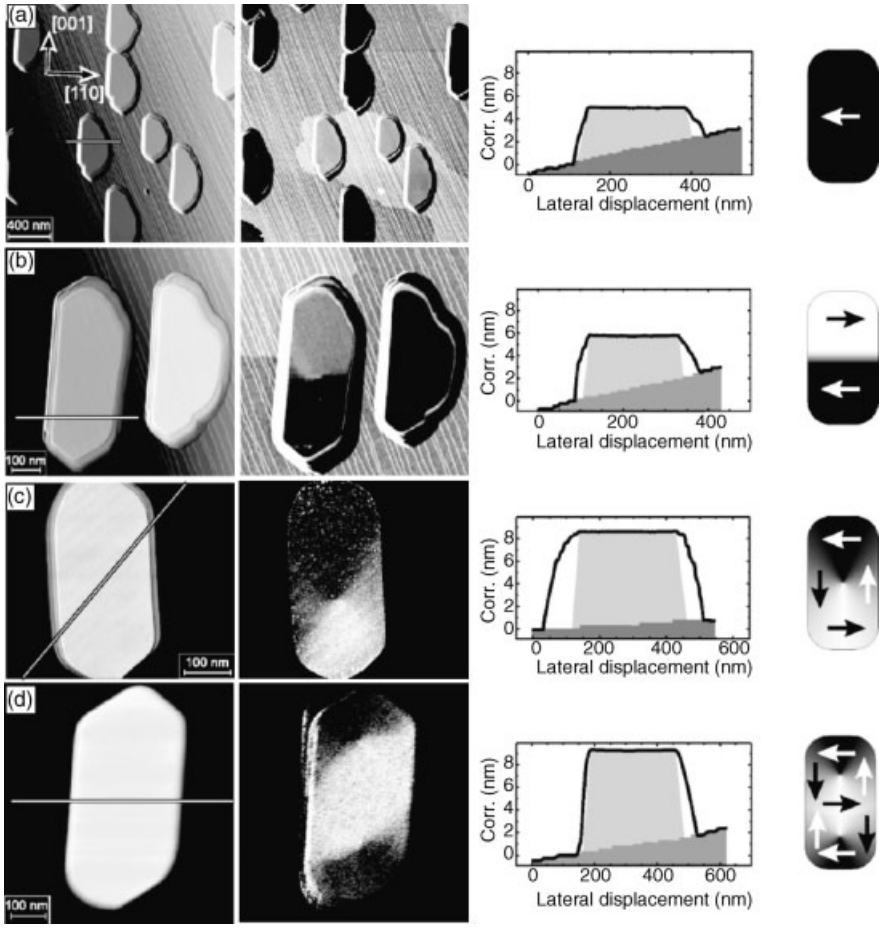

Figure 1.22 Topographic images (first column), spin-resolved dI/dU maps (second column) and topographic line sections (third column) of Fe islands on W(110) with different mean island heights h: (a) 53.5 nm, (b) 54.5 nm, (c) 57.5 nm, and (d) 58.5 nm. The data were obtained at $T = 14$ K. The resulting island domain configurations are schematically represented in the fourth column. (Reprinted with permission from Ref. [120]; copyright (2004), American Institute of Physics.)

varying between 3.5 and 8.5 nm. The lateral dimensions of the islands, irrespective of their height, are almost equal. The islands shown in Figure 1.22a exhibit an average height of approximately 3.5 nm (see line section). In the right-hand panel of Figure 1.22a the different magnetization states of islands can be distinguished by means of different dI/dU intensities. This variation results from spin-polarized tunneling between the magnetic STM tip (due to a coating with more than 100 ML Cr the tip is sensitive to the in-plane direction [28]) and the magnetic sample, and therefore represents different relative in-plane orientations of the magnetization in tip and sample. As no significant variation was found on top of the atomically flat

island surface, it would appear that these Fe islands are single domain, as shown schematically in the right-hand panel of Figure 1.22a. Evidently, there exists a close correlation between the magnetization direction of individual Fe islands and the surrounding Fe ML; dark (bright) Fe islands are always surrounded by a dark (bright) ML. With increasing thickness the magnetic pattern of the Fe islands becomes more and more complex such that, at $h = 54.5$ nm (see Figure 1.22b) a two-domain state is present. The island in Figure 1.22c exhibits a height h of 57.5 nm, while the corresponding spin-resolved dI/dU map shows the typical pattern of a single vortex state. A diamond state is found on the even higher island shown in Figure 1.22d ($h = 58.5$ nm).

Thus, the magnetic ground state is expected to be a vortex, as can be understood by the following consideration. If the dimensions of the particles are too small they do not form a single domain state, as this would require a relatively high stray field (or dipolar) energy. On the other hand, if the dimensions were too large, such domains would be formed such as those found in macroscopic pieces of magnetic material, because the additional cost of domain wall energy cannot be compensated by the reduction in stray field energy. By exhibiting a vortex configuration, the magnetization curls continuously around the particle center, drastically reducing the stray field energy and avoiding domain wall energy. Yet, the question arises as to the diameter of this core. An earlier investigation conducted by Shinjo *et al.* [132], using magnetic force microscopy, suggested an upper limit of about 50 nm caused by the intrinsic lateral resolution that was due to detection of the stray field. In the following section, it will be seen that an enhanced lateral resolution can be obtained using the technique of SP-STM, as shown by Wachowiak *et al.* [28, 102].

In order to gain a detailed insight into the magnetic behavior of the vortex core, a zoom into the central region was carried out where the rotation of the magnetization into the surface normal is expected. Maps of the dI/dU signal measured with different Cr-coated tips that are sensitive to the in-plane and out-of-plane component of the local sample magnetization are shown in Figure 1.23a and b, respectively [28]. The dI/dU signal as measured along a circular path around the vortex core (the circle in Figure 1.23a) exhibits a cosine-like modulation, indicating that the in-plane component of the local sample magnetization curls continuously around the vortex core. Figure 1.23b, which was measured with an out-of-plane sensitive tip on an identically prepared sample, exhibits a small bright area approximately in the center of the island. Therefore, the dI/dU map of Figure 1.23b confirms that the local magnetization in the vortex core is tilted normal to the surface (Figure 1.23c). The line section across the vortex core enables the width to be determined at about 9 nm, which is not restricted due to lateral resolution.

1.8 Individual Atoms on Magnetic Surfaces

The measurement of spin polarization states of individual atoms and understanding how atomic spins behave in a condensed matter environment, are essential steps

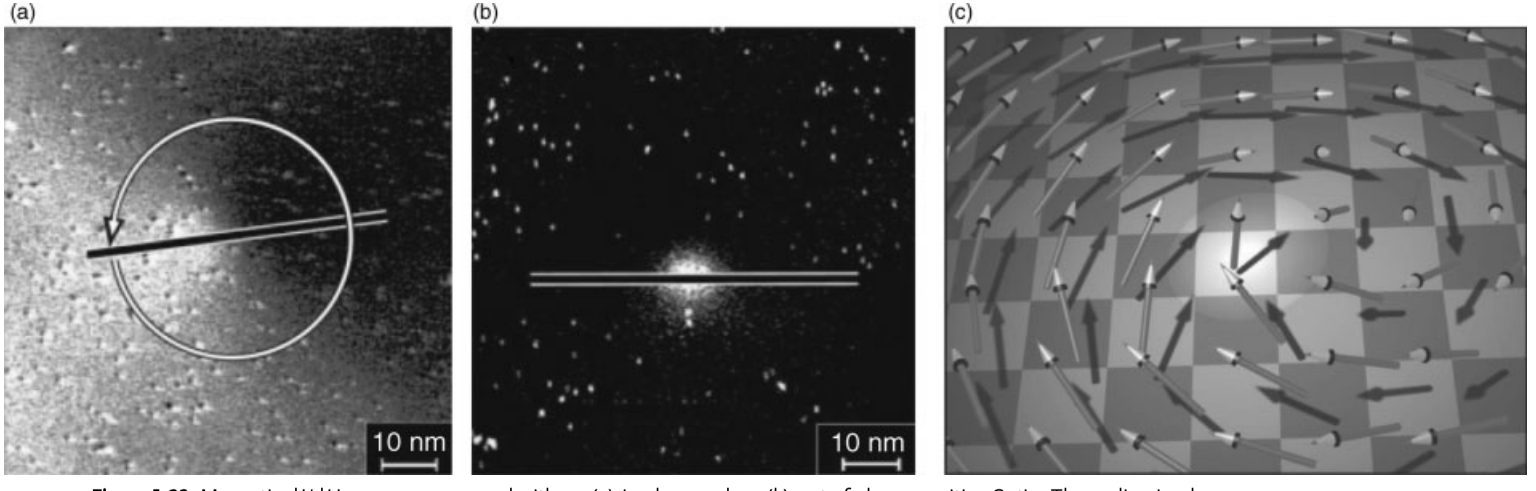

Figure 1.23 Magnetic dI/dU maps as measured with an (a) in-plane and an (b) out-of-plane sensitive Cr tip. The curling in-plane magnetization around the vortex core is recognizable in (a) and the perpendicular magnetization of the vortex core is visible as a bright area in (b); (c) Schematic arrangement of a magnetic vortex core. Far from the vortex core the magnetization curls continuously around the center with the orientation in the surface plane. In the center of the core the magnetization is perpendicular to the plane (highlighted). (Reprinted with permission from Ref. [28]; AAAS.)

towards the creation of devices, the functionality of which can be engineered at the level of individual atomic spins.

The direct observation of a spin polarization state of isolated adatoms remains challenging because isolated atoms have a low magnetic anisotropy energy that causes their spin to fluctuate over time due to environmental interactions. In the following section, measurements made by Yayon *et al.* [133] concerning the spin polarization state of *individual* Fe and Cr adatoms on a metal surface, are described. In order to fix the adatom spin in time, the adatoms were deposited onto ferromagnetic Co nanoislands, thereby coupling the adatom spin to the island magnetization through the direct exchange interaction.

Cobalt islands were chosen as a calibrated substrate where different magnetization states ('up' ↑ and 'down' ↓ with respect to the surface plane) are easily accessed [122]. The left-hand part of Figure 1.24 shows a representative topograph of Fe adatoms adsorbed onto triangular Co islands on the Cu(111) surface. The spatial oscillations seen on the Cu(111) surface are due to interference of surface state electrons scattered from the adatoms and Co islands [134].

In the right-hand part of Figure 1.24, panel (a) shows a color-scaled spin-polarized dI/dU map, together with topographic contour lines (measured simultaneously) for Fe and Cr atoms codeposited on two Co islands with opposite magnetization. The Fe and Cr atoms can easily be distinguished by their topographic signatures (Cr atoms

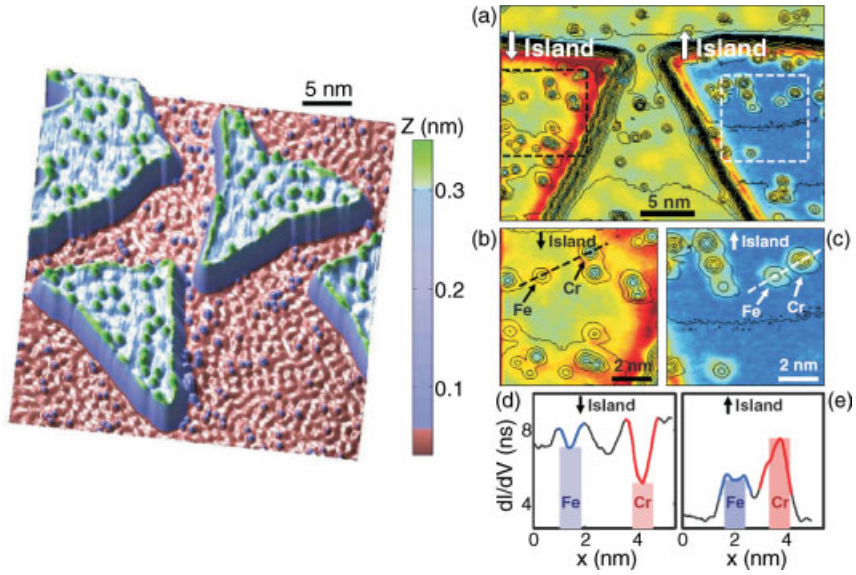

Figure 1.24 Left: Topograph of Fe adatoms adsorbed onto triangular Co islands on Cu(111) at $T = 4.8$ K. Fe adatoms are seen as green protrusions on the Co islands and blue protrusions on the bare Cu(111) surface. Right: (a) Spin-polarized dI/dU map of Fe and Cr adatoms on ↓ and ↑ Co islands on Cu(111); (b, c) Zoom-ins of areas marked by dashed lines on ↓ and ↑ islands in (a); (d, e) Line scans through the centers of Fe and Cr adatoms on ↓ and ↑ islands, respectively (marked by dashed lines in b and c). (Reprinted with permission from Ref. [133]; copyright (2007), American Physical Society.)

protrude 0.07 nm from the island surface, while Fe atoms protrude 0.04 nm). Spin-contrast between adatoms sitting on the two islands is seen as line cuts through Fe and Cr atoms (see Figure 1.24b–e). Fe atoms sitting on the ↓ island exhibit a larger dI/dU signal than those on the ↑ island, while Cr atoms on the ↓ island show a smaller dI/dU signal than those on the ↑ island. This confirms the parallel nature of the Fe/Co island spin coupling and the antiparallel nature of the Cr/Co island spin coupling over this energy range. SP-STS thus clearly reveals single adatom spin contrast: Each type of adatom yields a distinct spectrum, and over the energy range of the Co island surface-state Fe and Cr adatoms show opposite spin polarization. However, this measurement does not unambiguously determine the direction of the total spin of the adatom because the total spin is an integral over all filled states, whereas the spectra shown here were recorded over a finite energy range.

For a better understanding of the magnetic coupling between adatoms and islands, a density functional theory (DFT) calculation was also carried out [133]. The adsorption energies of Fe and Cr atoms on a ferromagnetic 2 ML film of Co on Cu(1 1 1) were calculated with the adatom moment fixed parallel and antiparallel to the magnetization of the Co film. The resulting values (see Figure 1.25) showed that Fe adatoms preferred a ferromagnetic alignment to the Co film, while Cr adatoms preferred an antiferromagnetic alignment. Comparison with the spin-polarized measurements implied that the Fe and Cr adatoms exhibit a negative spin polarization over the energy range of the Co island surface state.

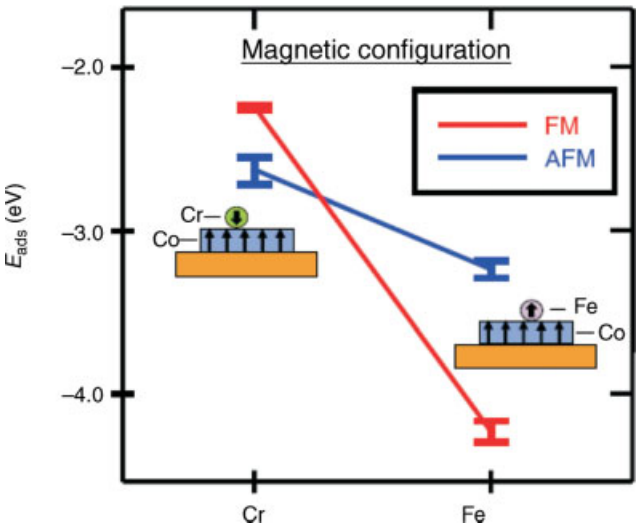

Figure 1.25 Calculated binding energies of ferromagnetic and antiferromagnetic configurations for Fe and Cr adatoms on a 2 ML high Co film on Cu(111). Error bars indicate the energy difference between hcp and fcc adatom adsorption sites. Cartoons depict the lowest-energy magnetic coupling configuration for Fe and Cr adatoms on the Co film. (Reprinted with permission from Ref. [133]; copyright (2007), American Physical Society.)

As discussed in Section 1.5.1, the Cr(001) surface exhibits a topological antiferromagnetic order. By increasing the number of adatoms, however, a small proportion of the Fe atoms on this surface will also exhibit an antiferromagnetic coupling to the underlying Cr(001) terraces [135, 136].

It is known from spin-polarized photoemission experiments that even nonmagnetic atoms such as oxygen (see Ref. [137] for O/Fe(110) and Ref. [138] for O/Co (0001)), sulfur [139] and iodine [140] become polarized upon chemisorption onto ferromagnetic surfaces. For each of these systems, SP-STM allows a deeper insight on the basis of its atomic resolution. For example, it was found that individual oxygen atoms on an Fe DL would induce highly anisotropic scattering states which were of minority spin character only [141]. This spin-dependent electron scattering at the single impurity level opens the possibility of understanding the origin of magnetoresistance phenomena on the atomic scale.

In the case of Fe islands, it has been reported that magnetic domains can be observed even after the deposition of a sulfur layer [142], and can act as a passivation species. These findings can be understood on the basis of the above discussion, also taking into account the fact that spin-polarized electrons from the interface with binding energies near the Fermi level are not fully damped but rather exhibit an attenuation length of at least several monolayers. Additionally, this mean free path is spin-dependent [143], such that an appropriate adsorbate layer may allow to extend the SP-STM to operate even under ambient conditions.

1.9 Domain Walls

The motion of domain walls is often hindered by lattice defects, leading to Barkhausen jumps in magnetic hysteresis curves. By using a high lateral resolution, the effective pinning of domain walls by screw-and-edge dislocations was first presented by Krause *et al.* [144] for Dy films on W(110).

Here, we will describe the details of two further aspects concerning domain walls which require an effective lateral resolution of SP-STM. First, we report on the behavior of domain walls in external magnetic fields, as investigated by Kubetzka *et al.* [103]; second, we will outline details of the widths of domain walls in nanoscale systems, referring to the studies conducted by Pratzer *et al.* [107].

The formation and stability of 360° domain walls plays a crucial role in the remagnetization processes of thin ferromagnetic films, with possible implications for the performance and development of magnetoresistive and magnetic random access memory (MRAM) devices. These are formed in external fields applied along the easy direction of the magnetic material when pairs of 180° walls with the same sense of rotation are forced together. Their stability against remagnetization into the uniform state is a manifestation of a hard axis anisotropy perpendicular to the rotational plane of the wall. This anisotropy may be of crystalline origin or – in films with an in-plane magnetic easy direction – due to the shape anisotropy.

Within Fe DL wires on W(110) that are separated by narrow regions with ML coverage (see Figure 1.26a [103]), two types of 180° walls can be distinguished using a ferromagnetic probe tip prepared by coating a W tip with several ML of Fe and therefore being sensitive to the in-plane magnetization component [27]. The wall width amounts to $w = 7$ nm. The intermediate $\mathrm{d}I/\mathrm{d}U$ signal (gray) corresponds to a perpendicular magnetization oriented either up or down. These two cases cannot be distinguished with a tip exhibiting a pure in-plane sensitivity unless the symmetry is broken by an external field. Figure 1.26 shows $\mathrm{d}I/\mathrm{d}U$ maps in an increasing perpendicular magnetic field of up to 800 mT. Areas magnetized parallel to the field direction grow at the expense of antiparallel ones, and pairs of 180° walls are forced together, which is equivalent to the formation of 360° walls. As expected, their lateral extension decreases with increasing field value. A closer inspection of these field-dependent measurements reveals that: (i) the magnetization rotates along every single nanowire with a defined chirality, and that (ii) the rotational sense is the same in each of the 12 wires within the imaged area. However, as the azimuthal angle of the tip magnetization is unknown, the absolute sense of rotation cannot be determined. For the same reason, it cannot be decided on the basis of these data alone whether the walls are of Bloch or Néel type, although the facts that the closed DL film is magnetized in-plane along $[1\,\bar{1}\,0]$ at elevated temperatures and the domain walls are oriented along the same direction, are indicative of their Bloch-type character. The first of the above observations is to be expected for stability reasons, as neighboring walls of opposite chirality (unwinding or untwisted walls [108]) will attract each other and can easily annihilate, in contrast to winding walls. As a consequence, the cooling process of the sample from above the Curie temperature to the measurement temperature of 14 K will result in a defined chirality within every individual wire, since such a structure is more stable against thermal fluctuations. The observed average distance between neighboring walls does not therefore necessarily reflect the magnetic ground state at low temperatures, as it might be a relic from the cooling process which is effectively frozen in a metastable state. The second of the observations will be discussed in Section 1.10.

With increasing external magnetic field, the tip's magnetization is successively rotated from in-plane towards the perpendicular direction. Its in-plane direction is also reversed during data acquisition at 400 mT (see Figure 1.26, black arrow), and this causes an inverted contrast for the remaining upper part of the image. At this field value a group of five 360° walls has formed a row (see ellipse), a correlation that might arise from their in-plane stray field. At 800 mT most of the 360° walls within the scanned area have been remagnetized by a rotation via the hard [001] in-plane direction.

Attention is now drawn to the Fe ML located in-between the Fe DL. Figure 1.27 [107] shows the topography (panel a) and the magnetic $\mathrm{d}I/\mathrm{d}U$ signal (panel b) of 1.25 ML Fe/W(110) grown at $T = 500$ K. Several domain walls separating dark and bright domains of the Fe ML can clearly be recognized in the overview of Figure 1.27b. Because of their different electronic properties, the DL stripes appear dark at this particular sample bias. At approximately the center of the white box in Figure 1.27b can be seen a bright spot; this is caused by a domain wall in this particular DL. The

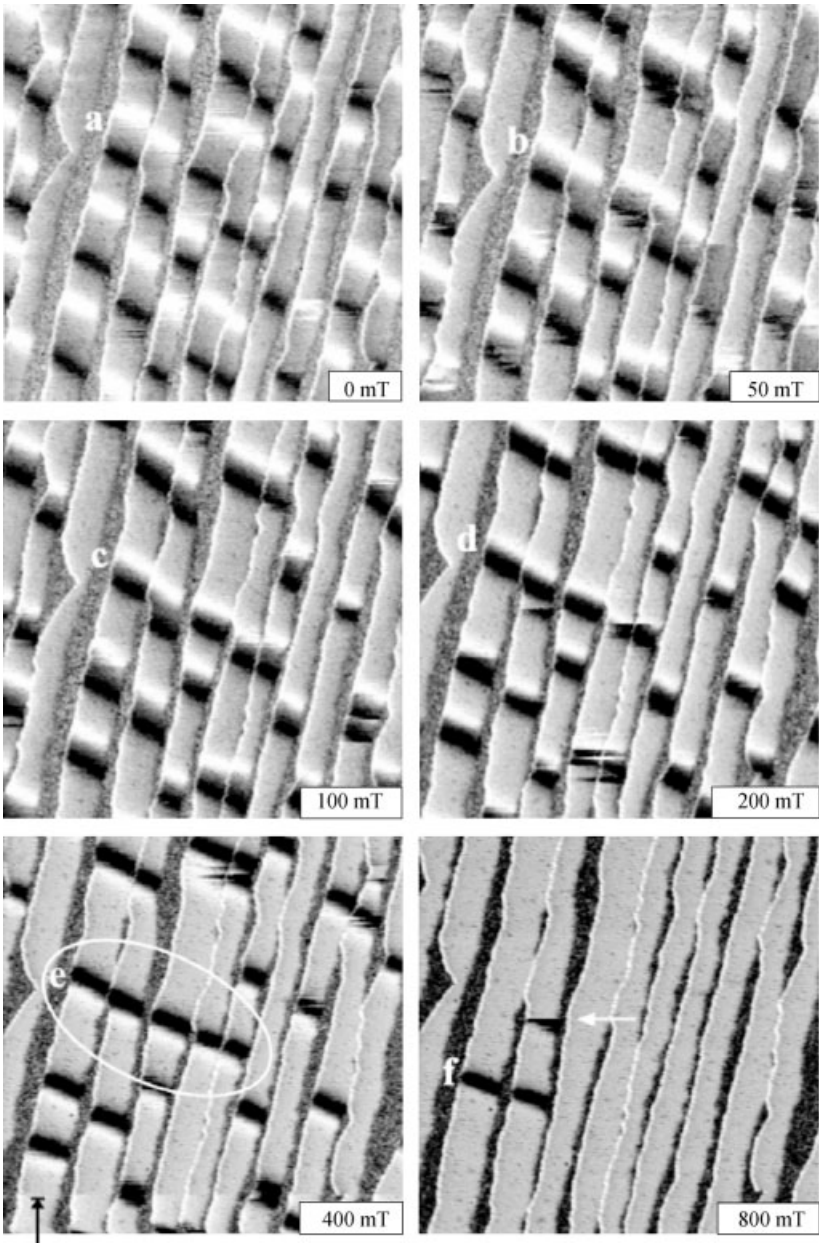

Figure 1.26 d*I*/d*U* maps of the surface area exhibiting Fe DL wires on W(110) imaged in an increasing perpendicular magnetic field. Pairs of 180° domain walls are gradually forced together, which is equivalent to the formation and compression of 360° walls. At 800 mT, most of these have vanished; that is, the Fe film is in magnetic saturation. With increasing external magnetic field the tip's magnetization is gradually forced from the in-plane towards the perpendicular direction. (Reprinted with permission from Ref. [103]; copyright (2003), American Physical Society.)

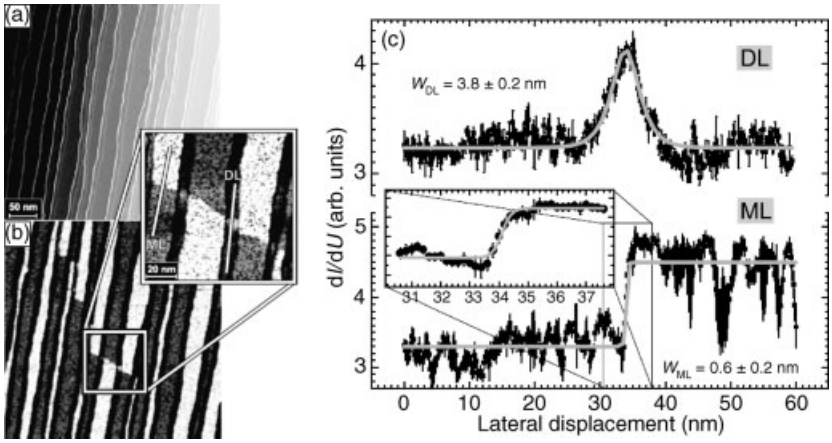

Figure 1.27 (a) Topographic and (b) spin-resolved dI/dU image showing the in-plane magnetic domain structure of 1.25 ML Fe/W (110). Several ML and DL domain walls can be recognized in the higher magnified inset; (c) Line sections showing domain wall profiles of the ML (bottom) and the DL (top). The inset shows that the ML domain wall width is on the atomic scale, with $w_{ML} = 6 \pm 2$ Å. (Reprinted with permission from Ref. [107]; copyright (2001), American Physical Society.)

inset of Figure 1.27b presents this location at higher magnification. Averaged line sections drawn along the white lines across domain walls in the ML and the DL are plotted in Figure 1.27c lower and upper, respectively, where clearly the ML domain wall is much narrower than the DL wall. The inset of Figure 1.27c shows the data in the vicinity of the ML domain wall in greater detail, and reveals a domain wall width $w < 1$ nm. In order to allow a more quantitative discussion the measured data have been fitted with a theoretical tanh function of a 180° wall profile [145]. This can be extended to an arbitrary angle between the magnetization axis of tip and sample ϕ [107, 146] by

$$\gamma(x) = \gamma_0 + \gamma_{sp} \cos\left\{\arccos\left[\tanh\left(\frac{x - x_0}{w/2}\right)\right] + \phi\right\} \tag{1.14}$$

where $\gamma(x)$ is the dI/dU signal measured at position x, x_0 is the position of the domain wall, w is the wall width, and γ_0 and γ_{sp} are the spin-averaged and spin-polarized dI/dU signals, respectively. Due to the Fe-coated tip which exhibits in-plane sensitivity, it is known that $\phi_{DL} = \pi/2$ and $\phi_{ML} = 0$. The best fit to the wall profile of the DL is achieved with $w_{DL} = 3.8 \pm 0.2$ nm. The profile of the ML domain wall is much narrower. If the fit procedure is performed over the full length of the line section $w_{ML} = 0.50 \pm 0.26$ nm, whereas $w_{ML} = 0.66 \pm 0.18$ nm is found if the fit is applied to the data in the inset of Figure 1.27c; this confirms the result of the analysis of the magnetization curves – that is, an almost atomically sharp domain wall.

A domain wall width of only six to eight atomic rows was also observed for an antiferromagnetic Fe monolayer on W(001) [147]. Such a narrow domain wall width can, in theory, be understood to arise from band structure effects, also taking into account intra-atomic noncollinear magnetism [148].

With regards to noncollinear effects it is important to distinguish between interatomic and intra-atomic magnetism. The first type is well known, and has been observed experimentally for small magnetic clusters [149] and in magnetic layers [150]; it has also been described on a theoretical basis [56, 151–157]. Interatomic magnetism can be understood within the Heisenberg model, taking into account *atomic* magnetic moments which are nonparallel for different atoms. Intra-atomic noncollinear effects arise from the tunneling current which flows through orbitals of the *same* atom, whilst that directly at the tip apex possesses a spin density orientation that is *noncollinear* [55].

1.10
Chiral Magnetic Order

Due to the inversion symmetry of bulk crystals, homochiral spin structures are unable to exist. However, as low-dimensional systems lack structural inversion symmetry, these single-handed spin arrangements may occur due to the Dzyaloshinskii–Moriya interaction [158, 159] arising from the spin-orbit scattering of electrons in an inversion asymmetric crystal field. This observation is now discussed with reference to the studies of Bode *et al.* [160], which were carried out in the same system Mn/W(110) for which atomic resolution of the magnetic properties had been demonstrated [96] (see Section 1.5.2).

In metallic itinerant magnets, spin-polarized electrons of the valence band hop across the lattice and exert the Heisenberg exchange interaction between magnetic spin moments $\vec{S}$ located on atomic sites i and j:

$$E_{exch} = \sum_{i,j} J_{ij}\, \vec{S}_i \cdot \vec{S}_j \tag{1.15}$$

As a consequence of a coulombic interaction, the exchange interaction is isotropic. Owing to the presence of a spin–orbit interaction, which connects the lattice with the spin symmetry, the broken parity of the lattice at an interface or surface gives rise to an additional interaction that breaks the inversion invariance of the Heisenberg Hamiltonian in Equation 1.15. This Dzyaloshinskii–Moriya interaction [158, 159]

$$E_{\mathrm{DM}} = \sum_{i,j} \vec{D}_{ij} \cdot (\vec{S}_i \times \vec{S}_j) \tag{1.16}$$

arises from the spin–orbit scattering of hopping electrons in an inversion asymmetric crystal field (where $\vec{D}_{ij}$ is the Dzyaloshinskii vector). In such an environment the scattering sequence of spin-polarized electrons, for example $i \rightarrow j \rightarrow i$ versus $j \rightarrow i \rightarrow j$, is noncommutative. The presence of this interaction has far-reaching consequences. Depending on the sign, the symmetry properties and the magnitude of $\vec{D}_{ij}$, uniaxial ferromagnetic or antiferromagnetic structures fail to exist and are instead replaced by a directional noncollinear magnetic structure of one specific chirality $\vec{C} = \vec{S}_i \times \vec{S}_{i+1}$, being either right-handed ($C>0$) or left-handed

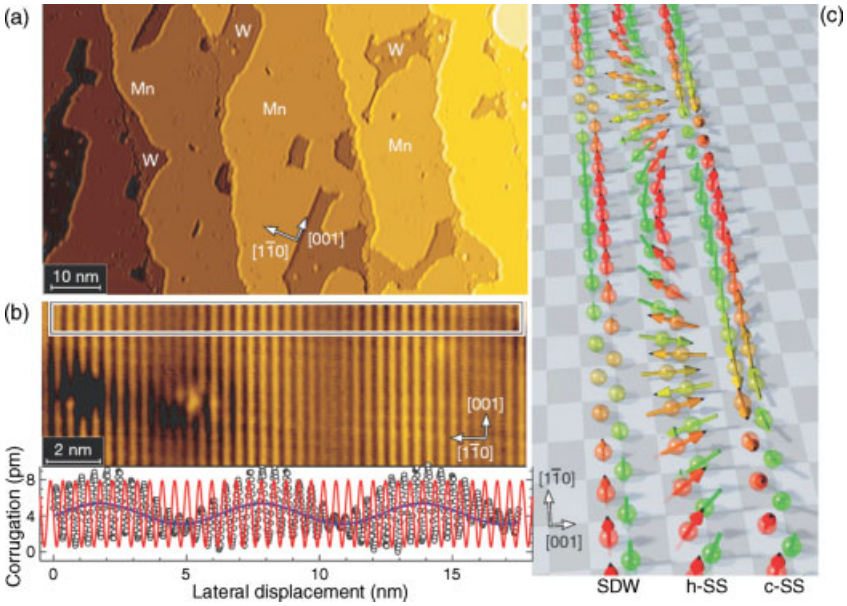

Figure 1.28 SP-STM of the Mn monolayer on W(110) and potential spin structures. (a) Topography of 0.77 atomic layers of Mn on W(110); (b) High-resolution constant-current image (upper panel) of the Mn monolayer taken with a Cr-coated tip. The stripes along the [001] direction are caused by spin-polarized tunneling between the magnetic tip and the sample. The averaged line section (lower panel) reveals a magnetic corrugation with a nominal periodicity of 0.448 nm and a long wavelength modulation. Comparison with a sine wave (red), expected for perfect antiferromagnetic order, reveals a phase shift of π between adjacent antinodes. In addition, there is an offset modulation (blue line) which is attributed to a varying electronic structure owing to spin–orbit coupling; (c) Artist's impression of the considered spin structures: a spin density wave (SDW), a helical spin spiral (h-SS) and a left-handed cycloidal spin spiral (c-SS). (Reprinted with permission from Ref. [160]; copyright (2007), MacMillan Publishers Ltd.)

($C<0$). In fact, J, D and also the anisotropy constants K, create a parameter space containing magnetic structures of unprecedented complexity [161], including 2-D and 3-D cycloidal, helicoidal or toroidal spin structures, or even vortices.

Figure 1.28a shows the topography of 0.77 atomic layers of Mn grown on a W(110) substrate [160]. The magnetic structure can be directly imaged with SP-STM using magnetically coated W tips. Figure 1.28b shows a high spatial resolution constant-current image measured on the atomically flat Mn layer using a Cr-coated probe tip which is sensitive to the in-plane magnetization [28]. The SP-STM data reveal periodic stripes running along the [001] direction, with an inter-stripe distance matching the surface lattice constant along the $[1\,\bar{1}\,0]$ direction (this was discussed earlier in Section 1.5.2). The additional important observation is, however, that the line section in the lower panel of Figure 1.28b, representing the magnetic amplitude, is not *constant* but is rather *modulated*, with a period of about 6 nm. Further, the magnetic corrugation is not simply a symmetric modulation superimposed on a

constant offset I_0. Instead, an additional long-wave modulation of I_0 (blue line) is present which is ascribed to spin–orbit coupling-induced variations of the spin-averaged electronic structure. When using in-plane-sensitive tips, the minima of the magnetic corrugation are found to coincide with the minima of the long-wave modulation of the spin-averaged local density of states. Within the field of view (see Figure 1.28b), three antinodes of the magnetic corrugation are visible. Comparing the experimental data with a sine function (red), representing perfect antiferromagnetic order, reveals a phase shift of π between adjacent antinodes.

The long wavelength modulation of the magnetic amplitude observed in Figure 1.28b may be explained by two fundamentally different spin structures: (i) a spin density wave (SDW) as it occurs, for example, in bulk Cr; or (ii) a spin spiral. Whereas, a SDW is characterized by a sinusoidal modulation of the size of the magnetic moments and the absence of spin rotation, the spin spiral consists of magnetic moments of approximately constant magnitude but whose directions rotate continuously. Spin spirals that are confined to a plane perpendicular or parallel to the propagation direction are denoted as either helical spirals (h-SS) or cycloidal spirals (c-SS). Figure 1.28c shows an artist's impression of a SDW, a h-SS and a c-SS. The magnetic contrast vanishes in either case twice over one magnetic period because: (i) the sample magnetic moments themselves vanish periodically; or (ii) the magnetic moments beneath the tip apex are orthogonal with respect to the tip magnetization m_t. The two cases can, however, be distinguished by addressing different components of the sample magnetization. Whereas, in case (i) a maximum spin contrast is always achieved at lateral positions where the magnetic moments are largest, and independent of m_t, in case (ii) a rotation of m_t can shift the position of maximum spin contrast.

Such a rotation of m_t can be achieved by subjecting an in-plane-sensitive Fe-coated tip to an appropriate external magnetic field (see sketches in Figure 1.29 [160]). For samples without a net magnetic moment, it is expected that the sample magnetization would remain unaffected. The SP-STM images and line sections of Figure 1.29 show data taken at a perpendicular field of 0 T (Figure 1.29a), 1 T (Figure 1.29b) and 2 T (Figure 1.29c). By using the encircled adsorbate as a marker, a maximum

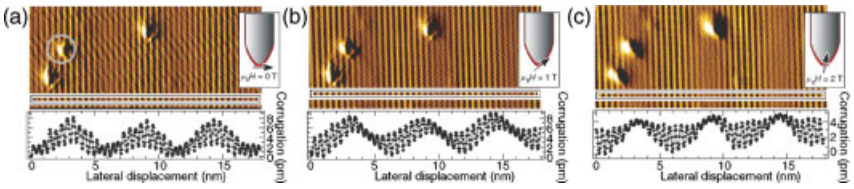

Figure 1.29 Field-dependent SP-STM measurements. Magnetically sensitive constant-current images of the Mn monolayer on W(110) (top panels) and corresponding line sections (bottom panels) taken with a ferromagnetic Fe-coated tip at external fields of (a) 0 T, (b) 1 T and (c) 2 T. As sketched in the insets, the external field rotates the tip magnetization from in-plane (a) to out-of-plane (c), shifting the position of maximum spin contrast. This proves that the Mn layer does not exhibit a spin density wave but rather a spin spiral rotating in a plane orthogonal to the surface. (Reprinted with permission from Ref. [160]; copyright (2007), MacMillan Publishers Ltd.)

magnetic contrast at this lateral position in zero field is observed, indicating large in-plane components of the sample magnetization here. This is also corroborated by the line section, which – in agreement with the in-plane-sensitive measurements of Figure 1.28b – shows a high magnetic corrugation at the maximum of the spin-averaged long-wave modulation. With an increasing external field the position of high magnetic corrugation shifts to the left (see Figure 1.29b) until a node reaches the adsorbate at 2 T (Figure 1.29c). The line sections reveal that the magnetic field shifts the position of high magnetic corrugation, but leaves the long-wave spin-averaged modulation unaffected. At 2 T – that is, with an almost perfectly out-of-plane magnetized tip – a maximum magnetic contrast is achieved and the spin-averaged signal exhibits a minimum (see line section of Figure 1.29c). Although this observation rules out a SDW, it provides clear proof of a spin spiral with magnetic moments rotating from in-plane (imaged in Figure 1.29a) to out-of-plane (imaged in Figure 1.29c).

The islands exhibit a spin spiral of only one chirality, as would be expected for a Dzyaloshinskii–Moriya interaction-driven magnetic configuration. The azimuthal orientation of the tip magnetization, however, cannot be reliably controlled, and consequently it is not possible to test experimentally whether the observed spin spiral is helical or cycloidal.

2
Nanoscale Imaging and Force Analysis with Atomic Force Microscopy

Hendrik Hölscher, André Schirmeisen, and Harald Fuchs

2.1
Principles of Atomic Force Microscopy

2.1.1
Basic Concept

The direct measurement of the force interaction between distinct molecules has been a challenge for scientists for many years. In fact, only very recently was a demonstration given that these forces can be determined for a single atomic bond, by using the powerful technique of atomic force microscopy (AFM). But how is it possible to measure interatomic forces, which may be as small as one billionth of one Newton?

The answer to this question is surprisingly simple: It is the same mechanical principle used by a pair of kitchen scales, where a spring with a defined elasticity is elongated or compressed due to the weight of the object to be measured. The compression Δz of the spring (with spring constant c_z) is a direct measure of the force F exerted, which in the regime of elastic deformation obeys Hooke's law:

$$F = c_z \times \Delta z. \tag{2.1}$$

The only difference from the kitchen scale is the sensitivity of the measurement. In AFM, the 'spring' is a bendable cantilever with a stiffness of 0.01 N m^{-1} to 10 N m^{-1}. As interatomic forces are in the range of some nN, the cantilever will be deflected by 0.01 nm to 100 nm. Consequently, the precise detection of the cantilever bending is the key feature of an atomic force microscope. If a sufficiently sharp tip is directly attached to the cantilever, it would be possible to measure the interacting forces between the last atoms of the tip and the sample through the bending of the cantilever.

In 1986, Binnig, Quate and Gerber presented exactly this concept for the first atomic force microscope [1]. These authors measured the deflection of a cantilever with sub-Ångström precision by a scanning tunneling microscope [2] and used a gold foil as the spring. The tip was a piece of diamond glued to this home-made cantilever

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

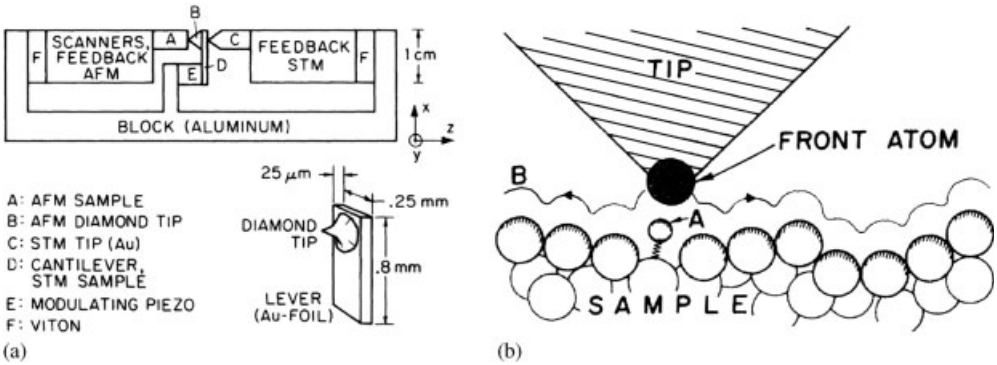

Figure 2.1 (a) The basic concept of the first atomic force microscope built in 1986 by Binnig, Quate and Gerber. A sharp diamond tip glued to a gold foil scanned the surface, while the bending of the cantilever was detected with scanning tunneling microscopy; (b) The ultimate goal was to measure the force between the front atom of the tip and a specific sample atom. (Reproduced from Ref. [1].)

(see Figure 2.1), and by using this set-up the group was able to image sample topographies down to the nanometer scale.

2.1.2 Current Experimental Set-Ups

During the past few years the experimental set-up has been modified while AFM has become a widespread research tool. Some 20 years after its invention, the commercial atomic force microscope is available from a variety of manufacturers. Although most of these instruments are designed for specific applications and environments, they are typically based on the following types of sensors detection method and scanning principles.

2.1.2.1 Sensors

Cantilevers are produced by standard microfabrication techniques, mostly from silicon and silicon nitride as rectangular or V-shaped cantilevers. Spring constants and resonance frequencies of cantilevers depend on the actual mode of operation. For contact AFM measurements these are about 0.01 to $1\,\mathrm{N\,m^{-1}}$ and 5–100 kHz, respectively. In a typical atomic force microscope, cantilever deflections ranging from 0.1 Å to a few micrometers are measured, which corresponds to a force sensitivity ranging from 10^{-13} N to 10^{-5} N.

Figure 2.2 shows two scanning electron microscopy (SEM) images of a typical rectangular silicon cantilever. When using this imaging technique, the length (l), width (w) and thickness (t) can be precisely measured. The spring constant c_z of the cantilever can then be determined from these values [3].

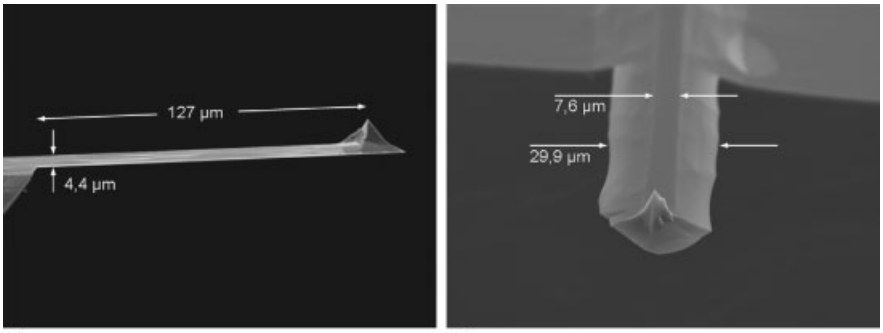

Figure 2.2 (a) Scanning electron microscopy image of a rectangular silicon cantilever with a width of 127 µm and a thickness of 4.4 µm; (b) A different view of the same cantilever reveals that the cross-section of the cantilever is trapezoidal and the cantilever has two geometric widths – a smaller one on the tip side and a broader one on the reverse side. Hence, most manufacturers provide a 'mean width', which for the cantilever shown is (7.6 + 29.9)/2 = 18.75 µm. The trapezoidal shape of the cantilever is caused by the anisotropic etching of the silicon during microfabrication of the cantilever. (Images courtesy of Boris Anczykowski, nanoAnalytics GmbH; used with kind permission.)

$$c_z = E_{\mathrm{Si}} \frac{w}{4} \left(\frac{t}{l}\right)^3 \tag{2.2}$$

where $E_{\mathrm{Si}} = 1.69 \times 10^{11}\,\mathrm{N\,m^{-2}}$ is the Youngs's modulus. The typical dimensions of silicon cantilevers are as follows: lengths of 100–300 µm; widths of 10–30 µm; and thicknesses of 0.3–5 µm.

The torsion of the cantilever due to lateral forces between tip and surface depends also on the height of the tip, h. The torsional spring constant can be calculated from [3]

$$c_{\mathrm{tor}} = \frac{G}{3} \frac{wt^3}{lh^2} \tag{2.3}$$

where $G_{\mathrm{Si}} = 0.68 \times 10^{11}\,\mathrm{N\,m^{-1}}$ is the shear modulus of silicon.

As the dimensions of cantilevers given by the manufacturer are only average values, the high-accuracy calibration of the spring constant requires the measurement of length, width and thickness for each individual cantilever. The length and width can be measured with sufficient accuracy using an optical microscope, but the thickness requires high-resolution techniques such as SEM. In order to avoid this time- and cost-consuming measurement one can determine the cantilever thickness from its eigenfrequency in normal direction [3–5]

$$t = \underbrace{\frac{4\sqrt{3}}{0.596861^2\pi} \sqrt{\frac{\rho_{\mathrm{Si}}}{E_{\mathrm{Si}}}}}_{\approx 7.23 \times 10^{-4}\ \mathrm{s/m}} l^2 f_0 \tag{2.4}$$

where the density of silicon $\rho_{\mathrm{Si}} = 2330\,\mathrm{kg\,m^{-3}}$.

The formulas presented above are only valid for rectangular cantilevers. Equations for V-shaped cantilevers can be found in Refs. [6, 7].

2.1.2.2 Detection Methods

In addition to changes in the cantilevers, the detection methods used to measure the minute bendings have also been improved. Today, commercial AFM instruments use the so-called *laser beam deflection* scheme shown in Figure 2.3. The bending and torsion of cantilevers can be detected by a laser beam reflected from their reverse side [8, 9], while the reflected laser spot is detected with a sectioned photo-diode. The different parts are read out separately. For this, a four-quadrant diode is normally used, in order to detect the normal as well as the torsional movements of the cantilever. With the cantilever at equilibrium the spot is adjusted such that the upper and lower sections show the same intensity. Then, if the cantilever bends up or down, the spot will move and the difference signal between the upper and lower sections will provide a measure of the bending.

The sensitivity can be improved by interferometer systems adapted by several research groups (see Refs [10–13]). It is also possible to use cantilevers with integrated deflection sensors based on piezoresistive films [14–16]. As no optical parts are

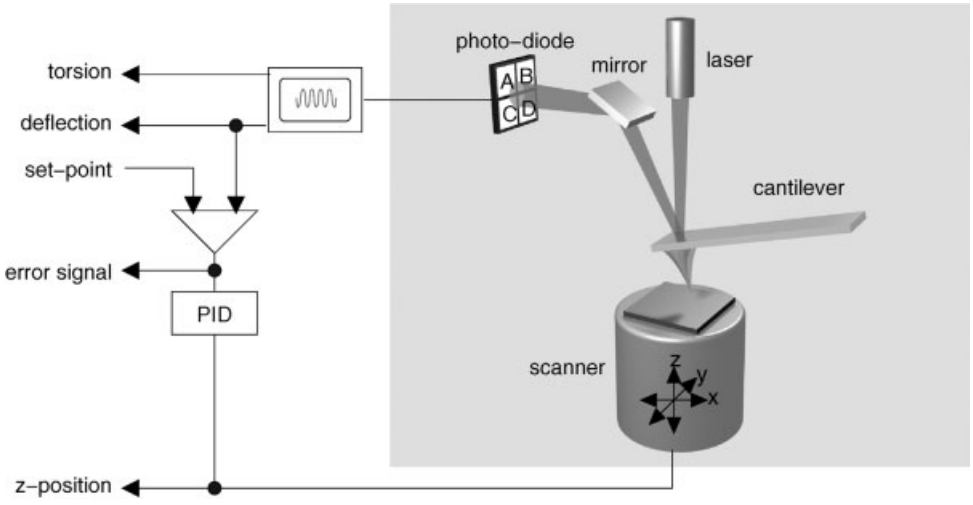

Figure 2.3 Principle of an atomic force microscope using the laser beam deflection method. Deflection (normal force) and torsion (friction) of the cantilever are measured simultaneously by measuring the lateral and vertical deflection of a laser beam while the sample is scanned in the x–y-plane. The laser beam deflection is determined using a four-quadrant photo diode. If A, B, C and D are proportional to the intensity of the incident light of the corresponding quadrant, the signal $(A + B) - (C + D)$ is a measure for the deflection, and $(A + C) - (B + D)$ is a measure of the torsion of the cantilever. A schematic of the feedback system is shown by the solid lines. The actual deflection signal of the photo-diode is compared with the set-point chosen by the experimentalist. The resultant error signal is fed into the PID controller, which moves the z-position of the scanner in order to minimize the deflection signal.

required in the experimental set-up of an atomic force microscope, when using these cantilevers the design can be very compact [17]. An extensive comparison of the different detection methods available can be found in Ref. [4].

2.1.2.3 Scanning and Feedback System

As the surface is scanned, the deflection of the cantilever is kept constant by a feedback system that controls the vertical movement of the scanner (shown schematically in Figure 2.3). The system functions as follows: (i) The current signal of the photo-diode is compared with a preset value; (ii) the feedback system, which includes a proportional, integral and differential (PID) controller, then varies the z-movement of the scanner to minimize the difference. As a consequence, the tip-sample force is kept practically constant for an optimal set-up of the PID parameters.

While the cantilever is moving relative to the sample in the x–y-plane of the surface by a piezoelectric scanner (see Figure 2.4), the current z-position of the scanner is recorded as a function of the lateral x–y-position with (ideally) sub-Ångström precision. The obtained data represents a map of equal forces, which is then analyzed and visualized by computer processing.

A principle of a simple laboratory class experiment – the imaging of a test grid – is shown in Figure 2.5. The comparison between the topography and the error signal shows that the PID controller needs some time at the step edges to correct the actual deflection error.

2.1.3 Tip–Sample Forces in Atomic Force Microscopy

A large variety of sample properties related to tip-sample forces can be detected using the atomic force microscope. The obtained contrast depends on the operational mode and

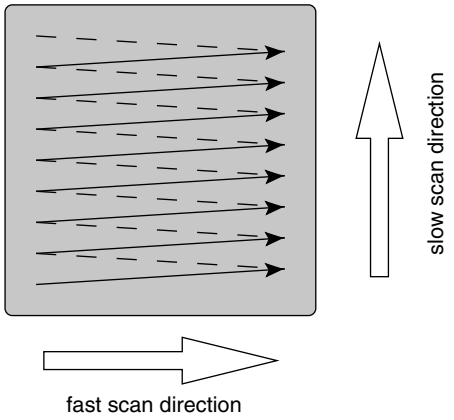

Figure 2.4 Schematic of the scan process. The cantilever scans the sample surface systematically in the x- and y-directions. Typical scan sizes ranging from less than 1 nm × 1 nm to 150 μm × 150 μm can be used.

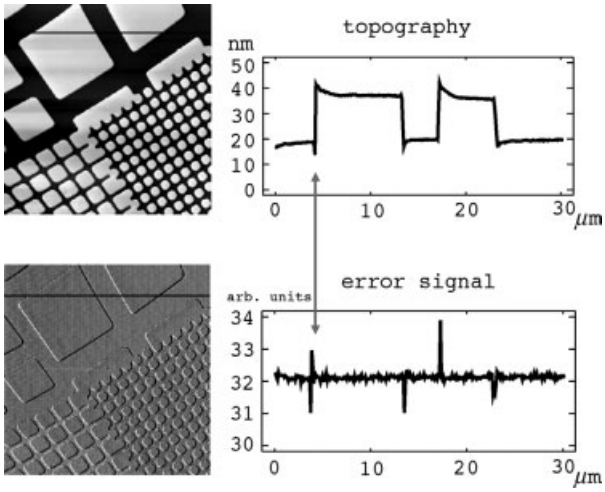

Figure 2.5 A simple laboratory class experiment demonstrating the scanning process of an atomic force microscope in contact mode. The cantilever is scanned over a simple test grid made of silicon. The feedback keeps the deflection (and therefore the force) constant, and the *z*-position of the scanner is interpreted as the topography of the sample. The resultant map is plotted as a gray-scale image (lighter areas correspond to higher topography, upper left graph). The simultaneously plotted error signal (lower graph) shows that the feedback fails to keep the deflection constant at the step edges.

the actual tip-sample interactions. Before discussing details of the operational modes of AFM, however, we must first specify the most important tip–sample interactions.

Figure 2.6 shows the typical shape of the interaction force curve that the tip senses during an approach towards the sample surface. Upon approach of the tip towards the

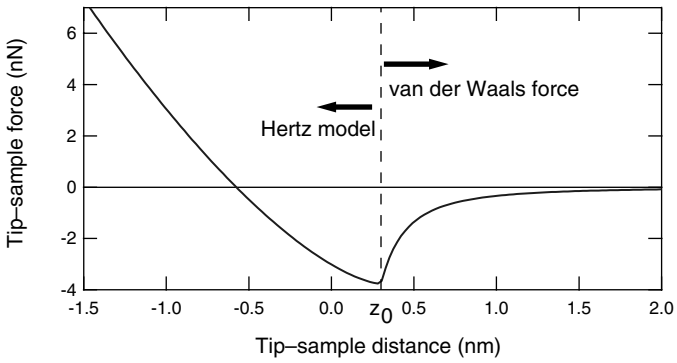

Figure 2.6 Tip–sample model force after the DMT-M model for air Equation 2.9, using the parameters described in the text. The dashed line marks the position z_0, where the tip touches the surface.

sample, the negative attractive forces (which represent, for example, van der Waals or electrostatic interaction forces) increase until a minimum is reached. This turn-around point is due to the onset of repulsive forces, caused by Pauli repulsion, which will start to dominate upon further approach. Eventually, the tip is pushed into the sample surface and elastic deformation will occur.

In general, the effective tip–sample interaction force is a sum of different force contributions, and these can be roughly divided into *attractive* and *repulsive* components. The most important forces are summarized as follows.

2.1.3.1 Van der Waals Forces

These forces are caused by fluctuating induced electric dipoles in atoms and molecules. The distance-dependence of this force for two distinct molecules follows $1/z^7$. For simplicity, solid bodies are often assumed to consist of many independent noninteracting molecules, and the van der Waals forces of these bodies are obtained by simple summation. For example, for a sphere over a flat surface the van der Waals force is given by

$$F_{vdW}(z) = -\frac{A_H R}{6z^2}, \tag{2.5}$$

where R is the radius of the sphere and A_H is the Hamaker constant, which is typically in the range of $\approx$0.1 aJ [18]. This geometry is often used to approximate the van der Waals forces between the tip and sample. Due to the $1/z^2$ dependency, van der Waals forces are considered long-range forces compared to the other forces that occur in AFM.

2.1.3.2 Capillary Forces

Capillary forces are important under ambient conditions. Water molecules condense at the sample surface (and also on the tip) and cause the occurrence of an adsorption layer. Consequently, the atomic force microscope tip penetrates through this layer when approaching the sample surface. At the tip–sample contact, a water meniscus is formed which causes a very strong attractive force [19]. For soft samples these forces often lead to unwanted deformations of the surface; however, this effect can be circumvented by measuring directly in liquids. Alternatively, capillary forces can be avoided by performing the experiments in a glovebox with dry gases, or in vacuum.

2.1.3.3 Pauli or Ionic Repulsion

These forces are the most important in conventional contact mode AFM. The Pauli exclusion principle forbids that the charge clouds of two electrons showing the same quantum numbers can have some significant overlap; first, the energy of one of the electrons must be increased, and this yields a repulsive force. In addition, an overlap of the charge clouds of electrons can cause an insufficient screening of the nuclear charge, leading to ionic repulsion of coulombic nature. The Pauli and the ionic repulsion are nearly hard-wall potentials. Thus, when the tip and sample are in intimate contact most of the (repulsive) interaction is carried by the atoms directly at the interface. The Pauli repulsion is of purely quantum mechanical origin, and semi-

empirical potentials are mostly used to allow an easy and fast calculation. One well-known model is the *Lennard–Jones* potential, which combines short-range repulsive interactions with long-range attractive van der Waals interactions:

$$V_{LJ}(z) = E_0\left(\left(\frac{r_0}{z}\right)^{12} - 2\left(\frac{r_0}{z}\right)^{6}\right) \tag{2.6}$$

where E_0 is the bonding energy and r_0 the equilibrium distance. In this case, the repulsion is described by an inverse power law with $n = 12$. The term with $n = 6$ describes the attractive van der Waals potential between two atoms/molecules.

2.1.3.4 Elastic Forces

Elastic forces and deformations can occur if the tip is in contact with the sample. As this deformation affects the effective contact area, knowledge about the elastic forces and the corresponding deformation mechanics of the contact is an important issue in AFM. The repulsive forces that occur during the elastic indentation of a sphere into a flat surface were analyzed as early as 1881 by H. Hertz (see Refs [20, 21]),

$$F_{\text{Hertz}}(z) = \frac{4}{3}E^*\sqrt{R}(z_0 - z)^{3/2} \quad \text{for} \quad z \le z_0, \tag{2.7}$$

where the effective elastic modulus E^*

$$\frac{1}{E^*} = \frac{(1-\mu_t^2)}{E_t} + \frac{(1-\mu_s^2)}{E_s} \tag{2.8}$$

depends on the Young's moduli $E_{t,s}$ and the Poisson ratios $\mu_{t,s}$ of the tip and surface, respectively. Here, R is the tip radius and z_0 is the point of contact.

This model does not include adhesion forces, however, which must be considered at the nanometer scale. Two extreme cases were analyzed by Johnson *et al.* [22] and Derjaguin *et al.* [23]. The model of Johnson, Kendall and Roberts (the JKR model) considers only the adhesion forces *inside* the contact area, whereas the model of Derjaguin, Muller and Toporov (the DMT model) includes only the adhesion *outside* the contact area. Various models analyzing the contact mechanics in the intermediate regime were suggested by other authors (see Ref. [24] for a recent overview).

However, in many practical cases it is sufficient to assume that the geometric shape of the tip and sample does not change until contact has been established at $z = z_0$, and that afterwards, the tip–sample forces are given by the DMT-M theory, denoting Maugis' approximation to the earlier DMT model [24]. In this approach, an offset $F_{\text{vdW}}(z_0)$ is added to the well-known Hertz model, which accounts for the adhesion force between tip and sample surface. Therefore, the DMT-M model is often also referred to as *Hertz-plus-offset model* [24]. The resulting overall force law is given by

$$F_{\text{DMT-M}}(z) = \begin{cases} -\dfrac{A_H R}{6z^2} & \text{for} \quad z \ge z_0\,, \\ \dfrac{4}{3}E^*\sqrt{R}(z_0 - z)^{3/2} - \dfrac{A_H R}{6z_0^2} & \text{for} \quad z < z_0\,. \end{cases} \tag{2.9}$$

Figure 2.6 shows the resulting tip–sample force curve for the DMT-M model. The following parameters were used, representing typical values for AFM measurements under ambient conditions: $A_H = 0.2$ aJ; $R = 10$ nm; $z_0 = 0.3$ nm; $\mu_t = \mu_s = 0.3$; $E_t = 130$ GPa; and $E_s = 1$ GPa.

2.1.3.5 Frictional Forces

Frictional forces counteract the movement of the tip during the scan process, and dissipate the kinetic energy of the moving tip–sample contact into the surface or tip material. This can be due to permanent changes in the surface itself, by scratching or indenting, or also by the excitation of lattice vibration (i.e. phonons) in the material.

2.1.3.6 Chemical Binding Forces

Chemical binding forces arise from the overlap of molecular orbitals, due to specific bonding states between the tip and the surface molecules. These forces are extremely short-ranged, and can be exploited to achieve atomic resolution imaging of surfaces. As these forces are also specific to the chemical identity of the molecules, it is conceivable to identify the chemical character of the surface atoms with AFM scans.

2.1.3.7 Magnetic and Electrostatic Forces

These forces are of long-range character and might be either attractive or repulsive; they are usually measured when the tip is not in contact with the surface (i.e. 'noncontact' mode). For magnetic forces, magnetic materials must be used for tip or tip coating. Well-defined electrical potentials between tip and sample are necessary for the measurement of electrostatic forces.

More detailed information on the intermolecular and surface forces relevant for AFM measurements can be found in the monographs of Israelachvili [18] and Sarid [25]. Details of the most important forces are summarized in Figure 2.7. Although, in principle, every type of force can be measured using the atomic force microscope, the actual sensitivity to a specific force depends on the mode of operation. Hence, the most important modes are introduced in the next section.

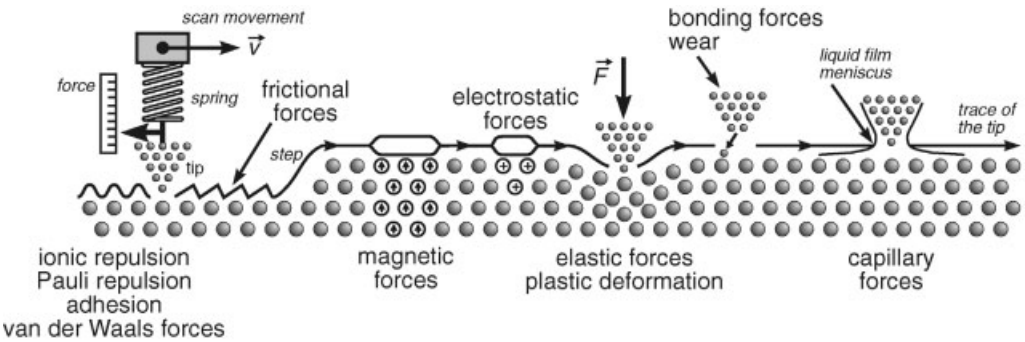

Figure 2.7 Summary of the forces relevant in atomic force microscopy. (Image courtesy of Udo D. Schwarz, Yale University; used with kind permission.)

2.2
Modes of Operation

Although an atomic force microscope can be driven in different modes of operation, we concentrate here on the two most important modes that are widely used to image sample surfaces down to the atomic scale.

2.2.1
Static or Contact Mode

The contact mode, which historically is the oldest, is used frequently to obtain nanometer-resolution images on a wide variety of surfaces. This technique also has the advantage that not only the deflection, but also the torsion of the cantilever, can be measured. As shown by Mate *et al.* [26], the lateral force can be directly correlated to the friction between tip and sample, thus extending AFM to friction force microscopy (FFM).

Some typical applications of an atomic force microscope driven in contact-mode are shown in Figure 2.8a and b. Here, the images represent a measurement of a L-α-

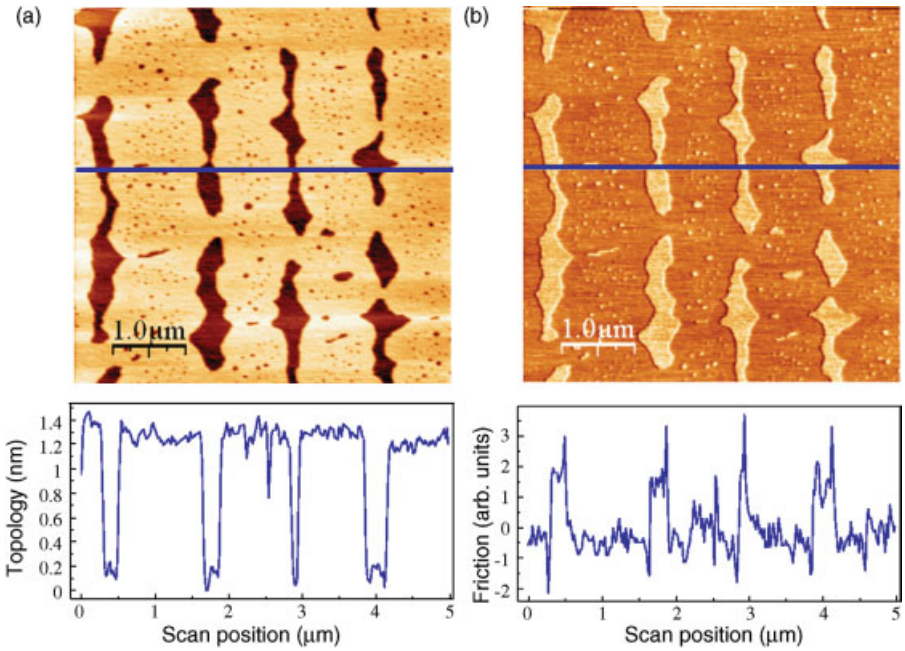

Figure 2.8 (a) Atomic force microscopy image obtained in contact mode of a monomolecular DPPC (L-α-dipalmitoyl-phophatidycholine) film adsorbed onto mica. The image is color-coded; that is, dark areas represent the mica substrate and light areas the DPPC film; (b) The simultaneously recorded friction image shows a lower friction on the film (dark areas) than on the substrate (light areas). The graphs represent single scan lines obtained at the positions marked by a dark line in the above images.

dipalmitoyl-phophatidycholine (DPPC) film adsorbed onto a mica substrate. The lateral force was simultaneously recorded with the topography, and shows a contrast between the DPPC film and the substrate. This effect can be attributed to the different frictional forces on DPPC and the mica substrate, and is frequently used to obtain a chemical contrast on flat surfaces [27, 28].

2.2.1.1 Force versus Distance Curves

So far, we have neglected one important issue for the operation of the atomic force microscope, namely the mechanical stability of the measurement. In static AFM the tip is allowed to approach very slowly towards the surface, and the attractive forces between the tip and sample must be counteracted by the restoring force of the cantilever. However, this fails if the force gradient of the tip–sample forces is larger than the spring constant of the cantilever. Mathematically speaking, an instability occurs if

$$c_z < \frac{\partial F_{ts}(z)}{\partial z}. \tag{2.10}$$

In this case the attractive forces can no longer be sustained by the cantilever and the tip 'jumps' towards the sample surface [29].

This effect has a strong influence on static-mode AFM measurements, as exemplified by a typical force-versus-distance curve shown in Figure 2.9. Here, the force

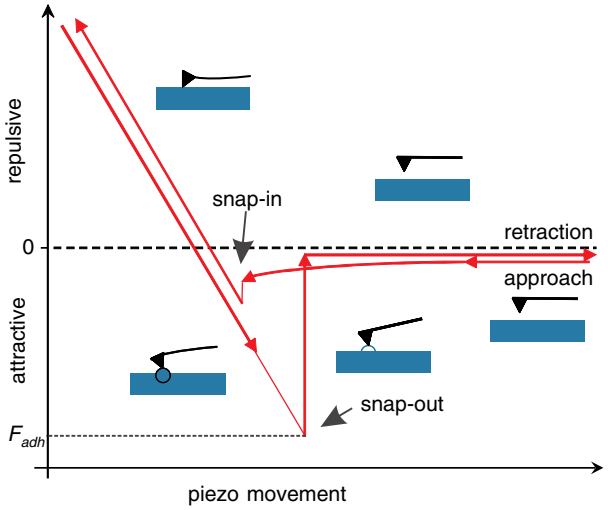

Figure 2.9 A schematic of a typical force versus distance curve obtained in static mode. The cantilever is approached towards the sample surface. Due to strong attractive forces it 'jumps' (snap-in) towards the sample surface at a specific position. During retraction, the tip is strongly attracted by the surface and the 'snap-out' point is considerably behind the 'snap-in' point. This results in an hysteresis between approach and retraction.

acting on the tip recorded during an approach and retraction movement of the cantilever is depicted. Upon approach of the cantilever towards the sample, the attractive forces acting on the tip bend the cantilever towards the sample surface. At a specific point close to the sample surface these forces can be no longer sustained by the cantilever spring, and the tip 'jumps' towards the sample surface. Now, the tip and sample are in direct mechanical contact, and a further approach towards the sample surface pushes the tip into the sample. As the spring constant of the cantilever usually is much softer than the elasticity of the sample, the bending of the cantilever increases almost linearly.

If the cantilever is now retracted from the surface, the tip stays in contact with the sample because it is strongly attracted by the sample due to adhesive forces, and the force F_{adh} is necessary to disconnect the tip from the surface. The 'snap-out' point is always at a larger distance from the surface than the 'snap-in', and this results in an hysteresis between the approach and retraction of the cantilever. This phenomenon of mechanical instability is often referred to as the *jump-to-contact*. Unfortunately, this sudden jump can lead to undesired changes of the tip and/or sample.

2.2.2 Dynamic Modes

Despite the success of contact-mode AFM, the resolution was found to be limited in many cases (in particular for soft samples) by lateral forces acting between tip and sample. In order to avoid this effect, the cantilever can be oscillated in a vertical direction near the sample surface. AFM imaging with vibrating cantilever is often denoted as dynamic force microscopy (DFM).

The historically oldest scheme of cantilever excitation in DFM imaging is the *external* driving of the cantilever at a *fixed excitation frequency* exactly at or very close to the cantilever's first resonance [30–32]. For this driving mechanism, different detection schemes measuring either the change of the oscillation amplitude or the phase shift were proposed. Over the years, the amplitude modulation (AM) or 'tapping' mode, where the oscillation amplitude is used as a measure of the tip–sample distance, has developed into the most widespread technique for imaging under ambient conditions and liquids.

In a vacuum, any external oscillation of the cantilever is disadvantageous. Standard AFM cantilevers constructed from silicon exhibit very high Q-values in vacuum, which results in very long response times of the system. Consequently, in 1991 Albrecht *et al*. [33] introduced the frequency modulation (FM) mode, which works well for high-Q systems and subsequently has developed into the dominant driving scheme for high-resolution DFM experiments in ultra-high vacuum (UHV) [34–37]. In contrast to the AM mode, this approach features a so-called *self-driven* oscillator [38, 39] which, when placed in a closed-loop set-up ('active feedback'), uses the cantilever deflection itself as the driving signal, thus ensuring that the cantilever instantaneously adapts to changes in the resonance frequency. These two driving mechanisms are discussed in more detail in the following section.

2.3
Amplitude Modulation (Tapping Mode)

2.3.1
Experimental Set-Up of AM-Atomic Force Microscopy

As an alternative to the contact mode, the cantilever can be excited to vibrate near its resonant frequency close to the sample surface. Under the influence of tip–sample forces the resonant frequency (and consequently also the amplitude and phase) of the cantilever will change and serve as the measurement parameters. This is known as the *dynamic* mode. If the tip is approached towards the surface, the oscillation parameters of amplitude and phase are influenced by the tip–surface interaction, and can therefore be used as feedback channels. A certain set-point (e.g. the amplitude) is given, whereby the feedback loop will adjust the tip–sample distance so that the amplitude remains constant. The controller parameter is recorded as a function of the lateral position of the tip with respect to the sample, and the scanned image essentially represents the surface topography.

The technical realization of dynamic-mode AFM is based on the same key components as a static AFM set-up. A sketch of the experimental set-up of an atomic force microscope driven in AM mode is shown in Figure 2.10.

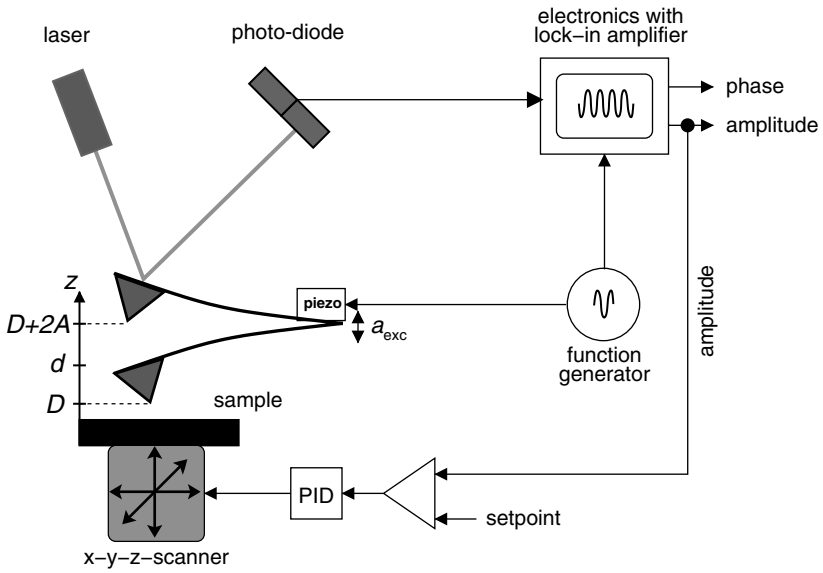

Figure 2.10 Set-up of a dynamic force microscope operated in AM or tapping mode. A laser beam is deflected by the reverse side of the cantilever, with the deflection being detected by a split photo-diode. The cantilever vibration is caused by an external frequency generator driving an excitation piezo. A lock-in amplifier is used to compare the cantilever driving with its oscillation. The amplitude signal is held constant by a feedback loop which controls the cantilever–sample distance.

The deflection of the cantilever is typically measured with the laser beam deflection method, as indicated [8, 9], but other displacement sensors such as *interferometric sensors* [12, 13, 30, 40] have also been applied. During operation in conventional tapping mode, the cantilever is driven at a fixed frequency with a constant excitation amplitude from an external function generator, while the resulting oscillation amplitude and/or the phase shift are detected by a lock-in amplifier. The function generator supplies not only the signal for the dither piezo; its signal serves simultaneously as a reference for the lock-in amplifier.

This set-up can be operated both in air and in liquids. A typical image obtained with this experimental set-up in ambient conditions is shown in Figure 2.11. For a direct comparison with the static mode, the sample is also DPPC-adsorbed onto a mica substrate. In contact mode the frictional forces are measured simultaneously with the topography, whereas in dynamic mode the phase between excitation and oscillation is acquired as an additional channel. The phase image provides information about the different material properties of DPPC and the mica substrate. It can be shown, that the phase signal is closely related to the energy dissipated in the tip–sample contact [41–43].

Due to its technical relevance the investigation of polymers has been the focal point of many studies (see Ref. [44] for a recent review). High-resolution imaging has been extensively performed in the area of materials science; for example, by using specific

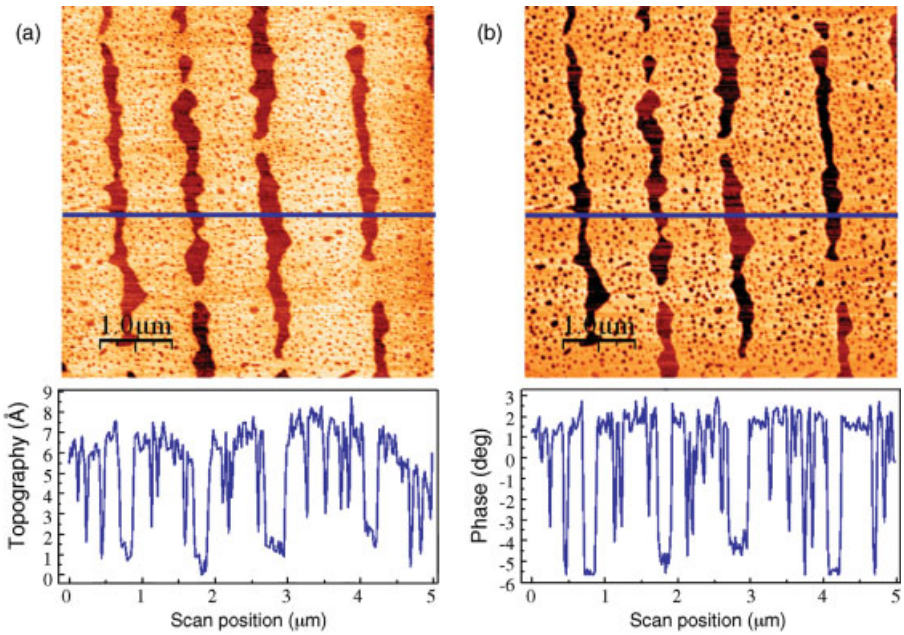

Figure 2.11 (a) A dynamic force microscopy image of a monomolecular DPPC film adsorbed onto mica; (b) The phase contrast is directly related to the topography; that is, the phase is different between the substrate and the DPPC film.

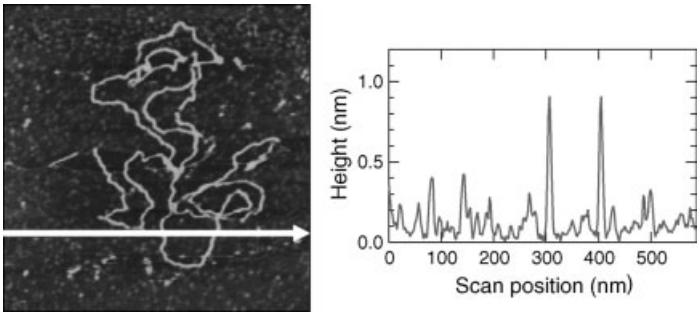

Figure 2.12 Topography of DNA adsorbed onto mica imaged in buffer solution by tapping mode AFM. The graph shows a single scan line obtained at the position marked by a white arrow in the image.

tips with additionally grown sharp spikes, Klinov *et al.* [45] obtained true molecular resolution on a polydiacetylene crystal.

Imaging in liquids opens up an avenue for the investigation of biological samples in their natural environment. For example, Möller *et al.* [46] have obtained high-resolution images of the topography of the hexagonally packed intermediate (HPI) layer of *Deinococcus radiodurans*, using tapping-mode AFM. A typical example of the imaging of DNA in liquid solution is shown in Figure 2.12.

2.3.1.1 Theory of AM-AFM

Based on the above description of the experimental set-up, it is possible to formulate the basic equation of motion describing the cantilever dynamics of AM-AFM:

$$m\ddot{z}(t) + \frac{2\pi f_0 m}{Q_0}\dot{z}(t) + c_z(z(t) - d) + = \underbrace{a_d c_z \cos(2\pi f_d t)}_{\text{external driving force}} + \underbrace{F_{ts}[z(t), \dot{z}(t)]}_{\text{tip-sample force}}. \tag{2.11}$$

Here, $\dot{z}(t)$ is the position of the tip at the time t; c_z, m and $f_0 = \sqrt{(c_z/m)}/(2\pi)$ are the spring constant, the effective mass, and the eigenfrequency of the cantilever, respectively. As a small simplification, it is assumed that the quality factor Q_0 combines the intrinsic damping of the cantilever and all influences from surrounding media, such as air or liquid (if present) in a single value. The equilibrium position of the tip is denoted as d. The first term on the right-hand side of the equation represents the external driving force of the cantilever by the frequency generator. It is modulated with the constant excitation amplitude a_d at a fixed frequency f_d. The (nonlinear) tip–sample interaction force F_{ts} is introduced by the second term.

Before discussing the solutions of this equation, some words of caution should be added with regards to the universality of the equation of motion and the various solutions discussed below. Equation 2.11 disregards two effects, which might become important under certain circumstances. First, we describe the cantilever by a spring-mass-model and neglect in this way the higher modes of the cantilever.

This is justified in most cases, as the first eigenfrequency is by far the most dominant in typical AM-AFM experiments (see Refs [41, 47–50]). Second, we assume in our model equation of motion that the dither piezo applies a sinusoidal force to the spring, but do not consider that the movement of the dither piezo simultaneously also changes the effective position of the tip at the cantilever end by $a_{\mathrm{exc}}(t) = a_d \cos(2\pi f_d t)$ [47, 51, 52]. This effect becomes important when a_d is in the range of the cantilever oscillation amplitude.

In a first step, we assume that the cantilever vibrates far away from the sample surface. Consequently, we can neglect tip–sample forces ($F_{ts} \equiv 0$), resulting in the well-known equation of motion of a driven damped harmonic oscillator.

After some time the external driving amplitude forces the cantilever to oscillate exactly at the driving frequency f_d. Therefore, the steady-state solution is given by the ansatz

$$z(t \gg 0) = d + A\cos(2\pi f_d t + \phi), \tag{2.12}$$

where ϕ is the phase difference between the excitation and the oscillation of the cantilever. With this, we obtain two functions for the amplitude and phase curves:

$$A = \frac{a_d}{\sqrt{\left(1 - \frac{f_d^2}{f_0^2}\right)^2 + \left(\frac{1}{Q_0}\frac{f_d}{f_0}\right)^2}}, \tag{2.13a}$$

$$\tan\phi = \frac{1}{Q_0}\frac{f_d/f_0}{1 - f_d^2/f_0^2}. \tag{2.13b}$$

The features of such an oscillator are well known from introductory physics courses.

If the cantilever is brought closer towards the sample surface, the tip senses the tip–sample interaction force, F_{ts}, which changes the oscillation behavior of the cantilever. However, as the mathematical form of realistic tip–sample forces is highly nonlinear, this fact complicates the analytical solution of the equation of motion Equation 2.11. For the analysis of DFM experiments we need to focus on steady-state solutions of the equation of motion with sinusoidal cantilever oscillation. Therefore, it is advantageous to expand the tip–sample force into a Fourier series

$$\begin{aligned} F_{ts}[z(t), \dot{z}(t)] \approx{}& f_d \int_0^{1/f_d} F_{ts}[z(t), \dot{z}(t)]dt \\ &+ 2f_d \int_0^{1/f_d} F_{ts}[z(t), \dot{z}(t)]\cos(2\pi f_d t + \phi)dt \times \cos(2\pi f_d t + \phi) \\ &+ 2f_d \int_0^{1/f_d} F_{ts}[z(t), \dot{z}(t)]\sin(2\pi f_d t + \phi)dt \times \sin(2\pi f_d t + \phi) \\ &+ \ldots, \end{aligned} \tag{2.14}$$

where $z(t)$ is given by Equation 2.12.

The first term in the Fourier series reflects the averaged tip–sample force over one full oscillation cycle, which shifts the equilibrium point of the oscillation by a small offset Δd from d to d_0. Actual values for Δd, however, are very small. For typical amplitudes used in AM-AFM in air (some nm to some tens of nm), the averaged tip–sample force is in the range of some pN. The resultant offset Δd is less than 1 pm for typical sets of parameters. As this is well beyond the resolution limit of an AM-AFM experiment in air, we neglect this effect in the following and assume $d \approx d_0$ and $D = d - A$.

For further analysis, we now insert the first harmonics of the Fourier series Equation 2.14 into the equation of motion (Equation 2.11), thus obtaining two coupled equations [53, 54]

$$\frac{f_0^2 - f_d^2}{f_0^2} = I_+(d, A) + \frac{a_d}{A}\cos\phi, \tag{2.15a}$$

$$-\frac{1}{Q_0}\frac{f_d}{f_0} = I_-(d, A) + \frac{a_d}{A}\sin\phi, \tag{2.15b}$$

where the following integrals have been defined:

$$\begin{aligned} I_+(d, A) &= \frac{2f_d}{c_z A}\int_0^{1/f_d} F_{ts}[z(t), \dot{z}(t)]\cos(2\pi f_d t + \phi)dt \\ &= \frac{1}{\pi c_z A^2}\int_{d-A}^{d+A} (F_\downarrow + F_\uparrow)\frac{z-d}{\sqrt{A^2-(z-d)^2}}dz, \end{aligned} \tag{2.16a}$$

$$\begin{aligned} I_-(d, A) &= \frac{2f_d}{c_z A}\int_0^{1/f_d} F_{ts}[z(t), \dot{z}(t)]\sin(2\pi f_d t + \phi)dt \\ &= \frac{1}{\pi c_z A^2}\int_{d-A}^{d+A} (F_\downarrow - F_\uparrow)dz \\ &= \frac{1}{\pi c_z A^2}\Delta E(d, A). \end{aligned} \tag{2.16b}$$

Both integrals are functions of the actual oscillation amplitude A and the cantilever–sample distance d. Furthermore, they depend on the sum and the difference of the tip–sample forces during approach ($E_\downarrow$) and retraction ($F_\uparrow$), as manifested by the labels '+' and '−' for easy distinction. The integral I_+ is a weighted average of the tip–sample forces ($F_\downarrow + F_\uparrow$). On the other hand, the integral I_- is directly connected to ΔE, which reflects the energy dissipated during an individual oscillation cycle. Consequently, this integral vanishes for purely conservative tip–sample forces, where $F_\downarrow$ and $F_\uparrow$ are identical. A more detailed discussion of these integrals can be found in Refs. [55, 56].

By combining Equations 1.13b and 1.16b we obtain a direct correlation between the phase and the energy dissipation.[1)]

1) The '−'-sign on the right-hand side of the equation is due to our definition of the phase ϕ in Equation 2.12.

$$\sin\phi = -\left(\frac{A}{A_0}\frac{f_d}{f_0} + \frac{Q_0 \Delta E}{\pi c_z A_0 A}\right). \tag{2.17}$$

This relationship can be also obtained from the conservation of energy principle [41–43].

Equation (2.15) can be used to calculate the resonance curves of a dynamic force microscope, including tip–sample forces. The results are

$$A = \frac{a_d}{\sqrt{\left(1 - \frac{f_d^2}{f_0^2} - I_+(d,A)\right)^2 + \left(\frac{1}{Q_0}\frac{f_d}{f_0} + I_-(d,A)\right)^2}}, \tag{2.18a}$$

$$\tan\phi = \frac{\frac{1}{Q_0}\frac{f_d}{f_0} + I_-(d,A)}{1 - \frac{f_d^2}{f_0^2} - I_+(d,A)}. \tag{2.18b}$$

Equation 2.18a describes the shape of the resonance curve, but it is an implicit function of the oscillation amplitude A, and cannot be plotted directly.

Figure 2.13 contrasts the solution of this equation (solid lines) with numerical solution (symbols). As pointed out by various authors (see Refs [47, 57–63]), the amplitude versus frequency curves are multivalued within certain parameter ranges. Moreover, as the gradient of the analytical curve increases to infinity at specific positions, some branches become unstable. The resulting instabilities are reflected by the 'jumps' in the simulated curves (marked by arrows in Figure 2.13), where only stable oscillation states are obtained. Obviously, they are different for increasing and decreasing driving frequencies. This well-known effect is frequently observed in nonlinear oscillators (see Refs [64, 65]).

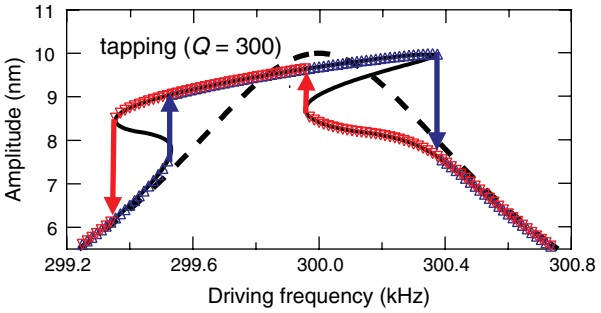

Figure 2.13 Resonance curves for tapping mode operation if the cantilever oscillates near the sample surface with $d = 8.5$ nm and $A_0 = 10$ nm, thereby experiencing the model force field given by Equation 2.9. The solid lines represent the analytical result of Equation 2.21, while the symbols are obtained from a numerical solution of the equation of motion, Equation 2.11. The dashed lines reflect the resonance curves without tip–sample force, and are shown purely for comparison. The resonance curve exhibits instabilities ('jumps') during a frequency sweep; these jumps take place at different positions (marked by arrows), depending on whether the driving frequency is increased or decreased.

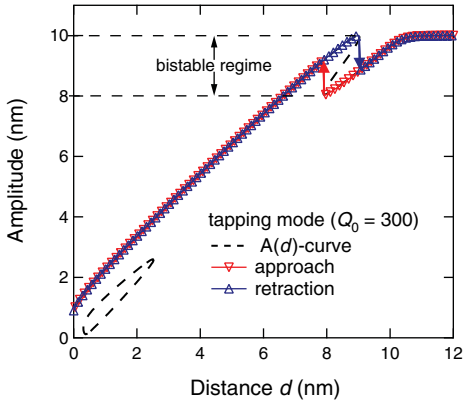

Figure 2.14 Amplitude versus distance curve for conventional ('tapping mode') AM-AFM for $A_0 = 10$ nm, $f_0 = 300$ kHz, and a tip–sample interaction force as given in Figure 2.6. The dashed lines represent the analytical result, while the symbols are obtained from a numerical solution of the equation of motion, Equation 2.11. The overall amplitudes decrease during an approach towards the sample surface in both cases, although instabilities (indicated by red and blue arrows) occur.

In AM-AFM, the cantilever might be oscillated at any frequency around the resonance peak. Here, we restrict ourselves to the situation where the driving frequency is set *exactly* to the eigenfrequency of the cantilever ($f_d = f_0$). With this choice – which is also very common in actual DFM experiments – we have defined imaging conditions leading to handy formulas suitable for further analysis. A discussion on the alternative cases of driving the cantilever slightly above or slightly below resonance can be found in the Refs [66–68].

From Equation (2.18a) we obtain the following relationship between the free oscillation amplitude A_0, the actual amplitude A, and the equilibrium tip position $\bar{d}$:

$$A_0 = A\sqrt{1 + (Q_0 I_+[\bar{d}, A])^2}. \tag{2.19}$$

In order to derive this formula, we used the approximation that the maximal value of the free oscillation amplitude at resonance is given by $A_0 \approx a_d Q_0$.

Solving this equation allows us to study amplitude versus distance curves for different effective Q-factors, as shown in Figure 2.14 for a Q-factor of 300. As observed previously in the resonance curves displayed in Figure 2.13, stable and unstable branches develop, which can be unambiguously identified by a comparison with numerical results (symbols).

Most noticeable, the tapping-mode curve exhibits jumps between unstable branches, which occur at different locations for approach and retraction. The resulting bistable regime then causes a hysteresis between approach and retraction, which has been the focus of numerous experimental and theoretical studies (see Refs [47, 61, 66, 67, 69–72]). As shown by various authors, the instability in conventional AM-AFM divides the tip–sample interaction into two regimes [47, 61, 70, 72]. Before the instability occurs, the tip interacts during an individual oscillation exclusively with the attractive part of

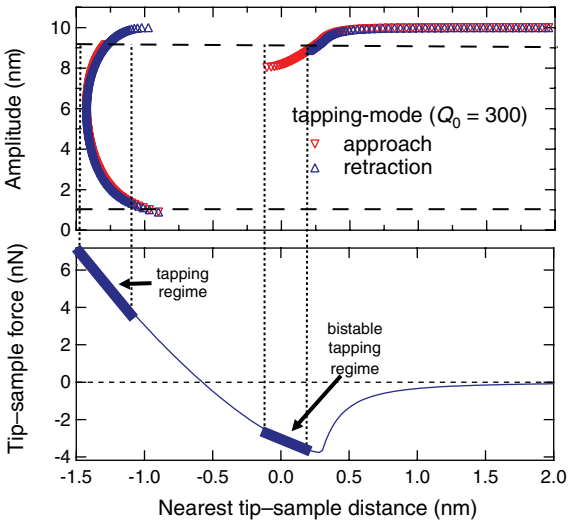

Figure 2.15 A comparison between the maximum tip–sample forces (tip–sample forces acting at the point of closest tip–sample approach/nearest tip–sample position *D*) experienced by conventional 'tapping mode' AM-AFM, assuming the same parameters as in Figure 2.14. The upper graph shows the nearest tip–sample position *D* versus the actual oscillation amplitude *A* for tapping mode. The lower graph shows the force regimes sensed by the tip. The maximal tip–sample forces in tapping mode are on the repulsive (tapping regime) as well as attractive (bistable tapping regime) part of the tip–sample force curve.

the tip–sample force. After jumping to the higher branch, however, the tip senses also the repulsive part of the tip–sample interaction.

In Figure 2.15 the oscillation amplitude is plotted as a function of the nearest tip–sample distance. In addition, the lower graph depicts the corresponding tip–sample force (cf. Figure 2.6). The origin of the nearest tip–sample position *D* is defined by this force curve. As both the amplitude curves and the tip–sample force curve are plotted as a function of the nearest tip–sample position, it is possible to identify the resulting maximum tip–sample interaction force for a given oscillation amplitude.

A closer look at the $A(D)$-curves helps to identify the different interaction regimes in AM-AFM. During the approach of the vibrating cantilever towards the sample surface, this curve shows a discontinuity for the nearest tip–sample position *D* (the point of closest approach during an individual oscillation) between 0 and −1 nm. This gap corresponds to the bistability and the resulting jumps in the amplitude versus distance curve. When the jump from the attractive to the repulsive regime has occurred, the amplitude decreases continuously, but the nearest tip–sample position does not reduce accordingly, remaining roughly between −0.8 nm and −1.5 nm. As a result, larger A/A_0 ratios do not necessarily translate into lower tip–sample interactions – a point which is important to bear in mind while adjusting imaging parameters in tapping mode AM-AFM imaging. In contrast, once the repulsive regime has been reached, the user's ability to influence the tip–sample interaction

strength by modifying the set-point for A is limited, thus also limiting the possibilities of improving the image quality.

For practical applications, it is reasonable to assume that the set-point of the amplitude used for imaging has been set to a value between 90% (= 9 nm) and 10% (= 1 nm) of the free oscillation amplitude. With this condition, we can identify the accessible imaging regimes indicated by the horizontal (dashed) lines and the corresponding vertical (dotted) lines in Figure 2.15. In tapping mode, two imaging regimes are realized: the *tapping* regime (left) and the *bistable tapping* regime (middle). The first can be accessed by any amplitude set-point between 9 nm and 1 nm, and results in a maximum tip–sample forces well within the repulsive regime. The second regime, belonging to the bistable imaging state, is only accessible during approach; here, the corresponding amplitude set-point is between 9 nm and 8 nm. Imaging in this regime is possible with the limitation that the oscillating cantilever might jump into the repulsive regime [68, 70].

2.3.1.2 Reconstruction of the Tip–Sample Interaction

Previously, we have outlined the influence of the tip–sample interaction on the cantilever oscillation, calculated the maximum tip–sample interaction forces based on the assumption of a specific model force, and subsequently discussed possible routes for image optimization. However, during AFM imaging, the tip–sample interaction is not known *a priori*. However, several groups [52, 73–75] have suggested solutions to this inversion problem. Here, we present an approach which is based on the analysis of the amplitude and phase versus distance curves which can easily be measured with most AM-AFM set-ups.

Let us start by applying the transformation $D = d - A$ to the integral I_+ in Equation 2.16a, where D corresponds to the nearest tip–sample distance, as defined in Figure 2.10. Next we note that, due to the cantilever oscillation, the current method intrinsically recovers the values of the force that the tip experiences at its lower turning point, where $F_\downarrow$ necessarily equals $F_\uparrow$. We thus define $F_{ts} = (F_\downarrow + F_\uparrow)/2$, and Equation 2.16a subsequently reads as

$$I_+ = \frac{2}{\pi c_z A^2} \int_D^{D+2A} F_{ts} \frac{z-D-A}{\sqrt{A^2-(z-D-A)^2}} dz. \tag{2.20}$$

The amplitudes commonly used in AM-AFM are considerably larger than the interaction range of the tip–sample force. Consequently, tip–sample forces in the integration range between $D + A$ and $D + 2A$ are insignificant. For this so-called 'large-amplitude approximation' [76, 77], the last term can be expanded at $z \to D$ to $(z-D-A)/\sqrt{A^2-(z-D-A)^2} \approx -\sqrt{A/2(z-D)}$, resulting in

$$I_+ \approx -\frac{\sqrt{2}}{\pi c_z A^{3/2}} \int_D^{D+2A} \frac{F_{ts}}{\sqrt{z-D}} dz. \tag{2.21}$$

By introducing this equation into Equation 2.15a, we obtain the following integral equation:

$$\underbrace{\frac{c_z A^{3/2}}{\sqrt{2}}\left[\frac{a_d\cos(\phi)}{A}-\frac{f_0^2-f_d^2}{f_0^2}\right]}_{\kappa}=\frac{1}{\pi}\int_D^{D+2A}\frac{F_{ts}}{\sqrt{z-D}}dz. \tag{2.22}$$

The left-hand side of this equation contains only experimentally accessible data, and we denote this term as κ. The benefit of these transformations is that the integral equation can be inverted [65, 76] and, as a final result, we find

$$F_{ts}(D)=-\frac{\partial}{\partial D}\int_D^{D+2A}\frac{\kappa(z)}{\sqrt{z-D}}dz. \tag{2.23}$$

It is now straightforward to recover the tip–sample force using Equation 2.23 from a 'spectroscopy experiment' – that is, an experiment where the amplitude and the phase are continuously measured as a function of the actual tip–sample distance $D=d-A$ at a fixed location. With this input, one first calculates κ as a function of D. In a second step, the tip–sample force is computed solving the integral in Equation 2.23 numerically.

Additional information about the tip–sample interaction can be obtained, remembering that the integral I_- is directly connected to the energy dissipation ΔE. By simply combining Equations 1.15b and 1.16b, we get

$$\Delta E=\left(\frac{1}{Q_0}\frac{f_d}{f_0}+\frac{a_d}{A}\sin\phi\right)\pi c_z A^2. \tag{2.24}$$

The same result was found earlier by Cleveland *et al.* [41], using the conservation of energy principle. However, in a further development of Cleveland's investigations we suggest plotting the energy dissipation as a function of the nearest tip–sample distance $D=d-A$ in order to have the same scaling as for the tip–sample force.

An application of the method to experimental data obtained on a silicon wafer is shown in Figure 2.16, where only the data points before the jump were used to reconstruct the tip–sample force and energy dissipation. As a consequence, the experimental force curve showed only the attractive part of the force between tip and sample, with a minimum of -1.8 nN. This result was in agreement with previous studies which stated that the tip sensed only attractive forces before the jump [66, 69, 78].

2.3.2
Frequency-Modulation or Noncontact Mode in Vacuum

In order to obtain high-resolution images with an atomic force microscope, it is very important to prepare clean sample surfaces that are free from unwanted adsorbates. Therefore, these experiments are usually performed in ultra-high vacuum with pressures below 1×10^{-10} mbar. As a consequence, most DFM experiments in

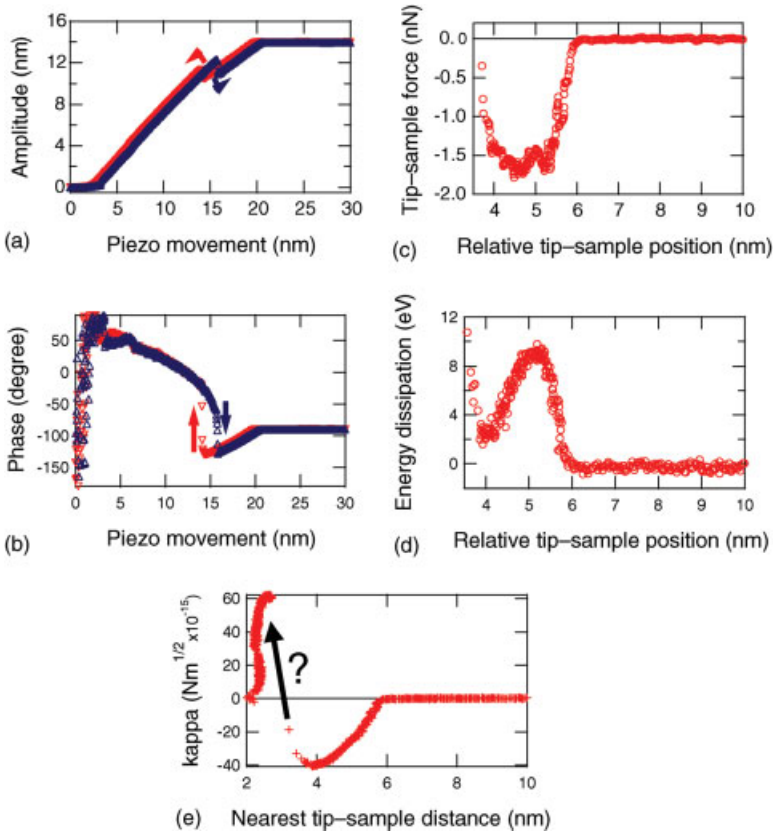

Figure 2.16 Dynamic force spectroscopy experiment on a silicon wafer in air (parameters of the cantilever: $f_d = f_0 = 328.61$ kHz, $c_z = 33.45$ N m^{-1}, $Q_0 = 537$). (a) A measurement of the oscillation amplitude as a function of the oscillation amplitude shows jumps at different positions during approach and retraction; (b) The jumps are also observed in the phase versus distance curves; (c) Using the algorithm described in the text, the tip–sample force can be reconstructed. This curve is calculated from the approach data. Only the data points before the jump are used for reconstruction of the tip–sample force; (d) The energy dissipation per oscillation cycle can be easily obtained from Equation 2.28; (e) This graph shows the $\kappa(D)$-values computed from the amplitude and phase versus distance curves plotted in panels (a) and (b). The jump in these curves results also in a jump in the κ-curve.

vacuum utilize the FM detection scheme introduced by Albrecht *et al.* [33]. In this mode, the cantilever is self-oscillated, in contrast to the AM- or tapping-mode discussed in Section 2.2.3. The FM technique enables the imaging of single point defects on clean sample surfaces in vacuum, and its resolution is comparable with that of the scanning tunneling microscope, while not restricted to conducting surfaces. During the years after the invention of the FM technique the term noncontact atomic force microscopy (NC-AFM) was established, because it is commonly believed that a repulsive, destructive contact between the tip and sample

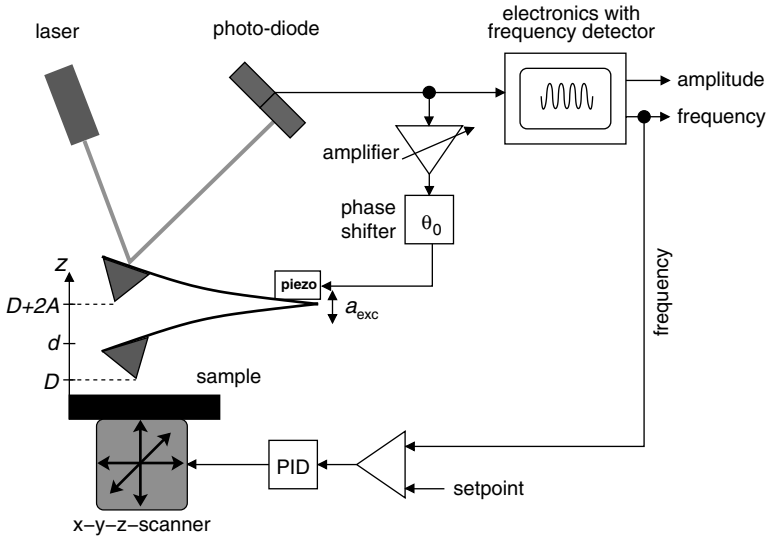

Figure 2.17 The schematic set-up of a dynamic force microscope using the frequency modulation technique. This experimental set-up is often used in UHV. A significant feature is the positive feedback of the self-driven cantilever. The detector signal is amplified and phase-shifted before being used to drive the piezo. The measured quantity is the frequency shift due to tip–sample interaction, which serves as the control signal for the cantilever–sample distance.

is prevented by this technique. In the following subsection we introduce the basic principles of the experimental set-up, explain the origin and calculation of the detected frequency shift, and present applications of this mode.

2.3.2.1 Set-Up of FM-AFM

In vacuum applications, the *Q*-factor of silicon cantilevers is in the range of 10 000 to 30 000. High *Q*-factors, however, limit the acquisition time (bandwidth) of DFM, as the oscillation amplitude of the cantilever requires a long time to adjust. This problem is avoided by the FM-detection scheme based on the specific features of a self-driven oscillator.

The basic set-up of a dynamic force microscope utilizing this driving mechanism is shown schematically in Figure 2.17. The movement of the cantilever is measured with a displacement sensor, after which this signal is fed back into an amplifier with an automatic gain control (AGC); the signal is subsequently used to excite the piezo oscillating the cantilever. The time delay between the excitation signal and cantilever deflection is adjusted by a time ('phase') shifter to a value $t_0 = 1/(4f_0)$, corresponding to $\approx 90^\circ$, as this ensures an oscillation at resonance. Two different modes have been established: (i) the *constant-amplitude mode* [33], where the oscillation amplitude A is kept at a constant value by the AGC; and (ii) the *constant excitation mode* [79], where the excitation amplitude is kept constant. In the following, however, we focus on the constant amplitude mode.

The key feature of the described set-up is the positive feedback loop which oscillates the cantilever always at its resonance frequency, f [39]. The reason for this behavior is that the cantilever serves as the frequency-determining element. This is in contrast to an external driving of the cantilever by a frequency generator, where the driving frequency f_d is not necessarily the resonant frequency of the cantilever.

If the cantilever oscillates near the sample surface, the tip–sample interaction alters its resonant frequency, which is then different from the eigenfrequency f_0 of the free cantilever. The actual value of the resonant frequency depends on the nearest tip–sample distance and the oscillation amplitude. The measured quantity is the *frequency shift* Δf, which is defined as the difference between both frequencies ($\Delta f = f - f_0$). The detection method received its name from the frequency demodulator (FM-detector). The cantilever driving mechanism, however, is independent of this part of the set-up. Other set-ups use a phase-locked loop (PLL) to detect the frequency and to oscillate the cantilever exactly with the frequency measured by the PLL [80].

For imaging, the frequency shift Δf is used to control the cantilever sample distance. Thus, the frequency shift is constant and the acquired data represents planes of constant Δf, which can be related to the surface topography in many cases. The recording of the frequency shift as a function of the tip–sample distance, or alternatively the oscillation amplitude can be used to determine the tip–sample force with high resolution (see Section 2.2.4.5).

2.3.2.2 Origin of the Frequency Shift

Before presenting experimental results obtained in vacuum, we will analyze the origin of the frequency shift. A good insight into the cantilever dynamics is provided by examining the tip potential displayed in Figure 2.18. If the cantilever is far away from the sample surface, the tip moves in a symmetric, parabolic potential (dotted line), and its oscillation is harmonic. In such a case, the tip motion is sinusoidal and the resonance

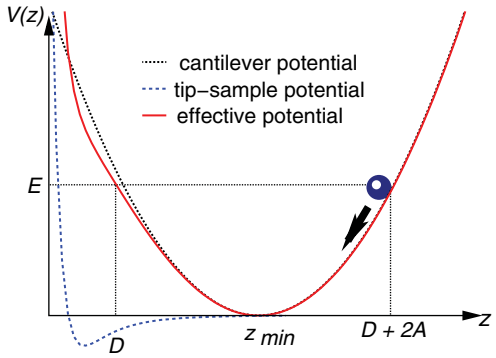

Figure 2.18 The frequency shift in dynamic force microscopy is caused by the tip–sample interaction potential (dashed line), which alters the harmonic cantilever potential (dotted line). Therefore, the tip moves in an anharmonic and asymmetric effective potential (solid line). z_{min} is the minimum position of the effective potential.

frequency is given by the eigenfrequency f_0 of the cantilever. If, however, the cantilever approaches the sample surface, the potential – which determines the tip oscillation – is modified to an effective potential V_{eff} (solid line) given by the sum of the parabolic potential and the tip–sample interaction potential V_{ts} (dashed line). This effective potential differs from the original parabolic potential and shows an asymmetric shape.

As a result of this modification of the tip potential the oscillation becomes anharmonic, and the resonance frequency of the cantilever depends now on the oscillation amplitude A. Since the effective potential experienced by the tip changes also with the nearest distance D, the frequency shift is a functional of both parameters ($\Rightarrow \Delta f := \Delta f(D, A)$).

Figure 2.19 displays some experimental frequency shift versus distance curves for different oscillation amplitudes. These experiments were carried out with

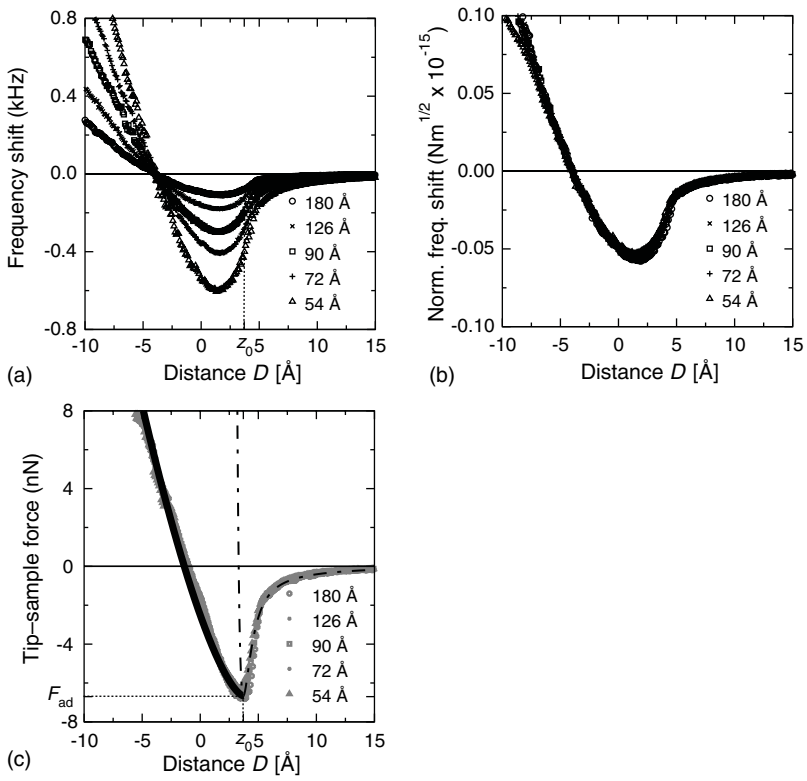

Figure 2.19 (a) Experimental frequency shift versus distance curves acquired with a silicon cantilever ($c_z = 38$ N m^{-1}; $f_0 = 171$ kHz) and a graphite sample for different amplitudes (54–180 Å) in UHV at low temperature ($T = 80$ K). The curves are shifted along the x-axes to make them comparable; (b) Transformation of all frequency shift curves shown in (a) to one universal curve using Equation 2.32. The normalized frequency shift $\gamma(D)$ is nearly identical for all amplitudes; (c) The tip–sample force calculated with the experimental data shown in (a) and (b), using the formula in Equation 2.33. The force F_{ts} (Equation 2.34) is plotted using a dashed-dotted line; the best fit using the force law F_c is displayed by a solid line. The border between 'contact' and 'noncontact' force is marked by the position z_0.

an atomic force microscope designed for operation in UHV and at low temperatures [10].

The obtained experimental frequency shift versus distance curves show a behavior expected from the simple model explained above. All curves show a similar overall shape, but differ in magnitude depending on the oscillation amplitude and the nearest tip–sample distance. During the approach of the cantilever towards the sample surface, the frequency shift decreases and reaches a minimum. With a further reduction of the nearest tip–sample distance, the frequency shift increases again and becomes positive. For smaller oscillation amplitudes, the minimum of the $\Delta f(z)$-curves is deeper and the slope after the minimum is steeper than for larger amplitudes – that is, the overall effect is larger for smaller amplitudes.

This can also be explained by the simple potential model: A decrease in the amplitude A for a fixed nearest distance D moves the minimum of the effective potential closer to the sample surface. Therefore, the relative perturbation of the harmonic cantilever potential increases, which increases also the absolute value of the frequency shift.

2.3.2.3 Theory of FM-AFM

As described in the previous subsection, it is a specific feature of the FM technique that the cantilever is 'self-driven' by a positive feedback loop. Due to this experimental set-up, the corresponding equation of motion is different from the case of the externally driven cantilever discussed in Section 2.2.3. The external driving term must be replaced in order to describe the self-driving mechanism correctly; therefore, the equation of motion is given by

$$m^*\ddot{z}(t) + \frac{2\pi f_0 m^*}{Q}\dot{z}(t) + c_z(z(t)-d) + \underbrace{g c_z(z(t-t_0)-d)}_{\text{driving}} = F_{ts}[z(t), \dot{z}(t)] \tag{2.25}$$

where $z := z(t)$ represents the position of the tip at the time t; and c_z, m and Q are the spring constant, the effective mass and the quality factor of the cantilever, respectively. $F_{ts} = -(\partial V_{ts})/(\partial z)$ is the tip–sample interaction force. The last term on the left describes the active feedback of the system by the amplification of the displacement signal by the *gain factor* g measured at the retarded time $t - t_0$.

The frequency shift can be calculated from the above equation of motion with the ansatz

$$z(t) = d + A\cos(2\pi f t) \tag{2.26}$$

describing the stationary solutions of Equation 2.25. As described in Section 2.2.3, it is assumed that the cantilever oscillations are more or less sinusoidal, such that the tip–sample force F_{ts} is developed into a Fourier-series, as in Equation 2.14. This procedure results in a set of two coupled trigonometric equations [38, 39]:

$$g\cos(2\pi f t_0) = \frac{f^2 - f_0^2}{f_0^2} + I_+ \tag{2.27}$$

$$g\sin(2\pi f t_0) = \frac{1}{Q}\frac{f}{f_0} + I_- \tag{2.28}$$

where the two integrals I_+ Equation 2.16a and I_- Equation 2.16b were defined in accordance to Section 2.2.3.2. These two coupled equations can be solved numerically, if one is interested in the exact dependency of the tip–sample interaction force F_{ts} and the time delay t_0 on the oscillation frequency f and the gain factor g.

Fortunately, a detailed analysis shows that the results of a FM-AFM experiment are mainly determined by the tip–sample force, and only very slightly by the time delay, if t_0 is set to an optimal value before approaching the tip towards the sample surface. These values of the time delay are specific resonance values corresponding to 90° (i.e. $t_0 = 1/4f_0$), and can be easily found by minimizing the gain factor as a function of the time delay. Therefore, it can be assumed that $\cos(2\pi f t_0) \approx 0$ and $\sin(2\pi f t_0) \approx 1$ and the two coupled Equations 1.27 and 1.28 can be decoupled. As a result, an equation for the frequency shift is obtained:

$$\Delta f \cong -\frac{f_0}{2} I_+ = \frac{1}{\pi c_z A^2}\int_{d-A}^{d+A} (F_\downarrow + F_\uparrow)\frac{z-d}{\sqrt{A^2-(z-d)^2}}dz \tag{2.29}$$

and the energy dissipation

$$\Delta E = \left(g - \frac{1}{Q}\frac{f}{f_0}\right)\pi c_z A^2. \tag{2.30}$$

As no assumptions were made about the specific force law of the tip–sample interaction F_{ts}, these equations are valid for any type of interaction as long as the resulting cantilever oscillations remain nearly sinusoidal.

As the amplitudes in FM-AFM are often considerably larger than the distance range of the tip–sample interaction, we can again make the 'large amplitude approximation' [76, 77] and introduce the approximation Equation 2.21 for the integral I_-. This yields the formula

$$\Delta f = \frac{1}{\sqrt{2}\pi}\frac{f_0}{c_z A^{3/2}}\int_D^{D+2A} \frac{F_{ts}(z)}{\sqrt{z-D}}dz \tag{2.31}$$

It is interesting to note that the integral in this equation is virtually independent of the oscillation amplitude. The experimental parameters (c_z, f_0 and A) appear as prefactors. Consequently, it is possible to define the *normalized frequency shift* [77]

$$\gamma(z) := \frac{c_z A^{3/2}}{f_0}\Delta f(z). \tag{2.32}$$

This is a very useful quantity to compare experiments obtained with different amplitudes and cantilevers. The validity of Equation 2.32 is nicely demonstrated by the application of this equation to the frequency shift curves already presented in Figure 2.19a. As shown in Figure 2.19b, all curves obtained for different amplitudes result in one universal γ-curve, which depends only on the actual tip–sample distance, D.

2.3.2.4 Applications of FM-AFM

The initial excitement surrounding the NC-AFM technique in UHV was driven by the first results of Giessibl [81], who was able to image the true atomic structure of the Si(1 1 1)-7 × 7-surface with this technique in 1995. In the same year, Sugawara *et al.* [82] observed the motion of single atomic defects on InP with true atomic resolution. However, imaging on conducting or semi-conducting surfaces is also possible by using scanning tunneling microscopy (STM), and these first NC-AFM images provided no new information on surface properties. The true potential of NC-AFM lies in the imaging of nonconducting surface with atomic precision, which was first demonstrated by Bammerlin *et al.* [83] on NaCl. A longstanding question about the surface reconstruction of the technological relevant material aluminum oxide could be answered by Barth *et al.* [84], who imaged the atomic structure of the high-temperature phase of α-Al_2O_3(0 0 0 1).

The high-resolution capabilities of NC-AFM are nicely demonstrated by the images shown in Figure 2.20. Allers *et al.* [85] resolved atomic steps and defects with atomic resolution on nickel oxide. Today, such a resolution is routinely obtained by various research groups (for an overview, see Refs [3, 34, 35, 86]). Recent efforts have also been concentrated on the analysis of functional organic molecules, since in the field of nanoelectronics it is anticipated that organic molecules in particular will play an important role as the fundamental building blocks of nanoscale electronic device elements. For example, atomic resolution on the highly curved surface of a nanotube [87] was achieved. The analysis of growth properties of thin films [88–90] with respect to their electronic properties has been investigated, while the intramolecular contrast of individual molecules has also been resolved [91], which might be directly related to the internal charge density distribution inside the molecules.

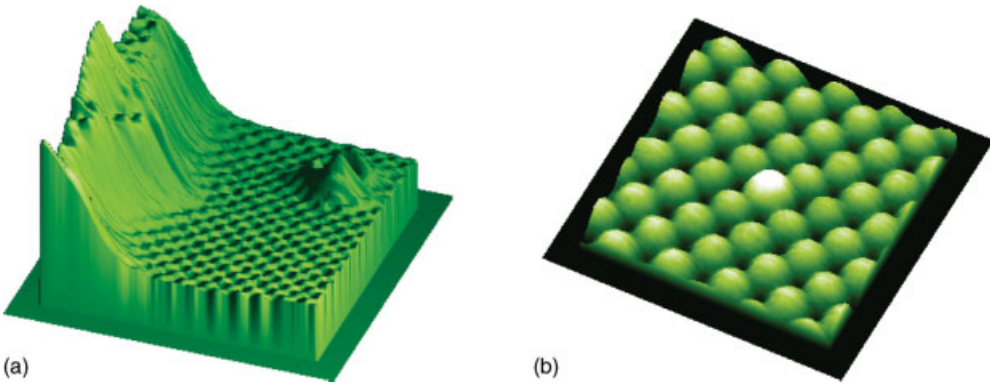

Figure 2.20 Imaging of a NiO(0 0 1) sample surface with a noncontact AFM. (a) Surface step and an atomic defect. The lateral distance between two atoms is 4.17 Å; (b) A dopant atom is imaged as a light protrusion about 0.1 Å higher than the other atoms. (Images courtesy of W. Allers and S. Langkat, University of Hamburg; used with kind permission.)

2.3.2.5 Dynamic Force Spectroscopy

Since its invention in 1986, the atomic force microscope has been used extensively to study tip–sample interactions for various material combinations. Unfortunately, in contact mode such investigations were often hindered close to the sample surface by a 'jump to contact' (see Section 2.2.1.1). In tapping mode, on the other hand, the force analysis is limited due to the instabilities in the amplitude and phase versus distance curves (see Section 2.2.3.3). Such problems, however, are avoided by using large oscillation amplitudes in the FM technique.

In Section 2.2.4.3 it was shown how the frequency shift can be calculated for a given tip–sample interaction law. The inverse problem, however, is even more interesting: *How can the tip-sample interaction be determined from frequency shift data?* Various mathematical solutions to this question have been presented by many research groups [76, 92–97], and this has led to the dynamic force spectroscopy (DFS) technique, which is a direct extension of the FM-AFM mode.

Here, we present the approach of Dürig [76], which is based on the inversion of the integral Equation 2.31 already presented in Section 2.2.4.3. This can be transformed to

$$F_{ts}(D) = \sqrt{2}\frac{c_z A^{3/2}}{f_0}\frac{\partial}{\partial D}\int_D^\infty \frac{\Delta f(z)}{\sqrt{z-D}}dz, \tag{2.33}$$

which allows a direct calculation of the tip–sample interaction force from the frequency shift versus distance curves.

An application of this formula to the experimental frequency shift curves already presented in Section 2.2.4.2 is shown in Figure 2.19c. The obtained force curves are almost identical, despite being obtained with different oscillation amplitudes. As the tip–sample interactions can be measured with high resolution, DFS opens a direct way to compare experiments with theoretical models and predictions.

Giessibl [77] suggested a description of the force between the tip and the sample by combining a long-range (van der Waals) and a short-range (Lennard–Jones) term (see Section 2.1.3). Here, the long-range part describes the van der Waals interaction of the tip, modeled as a sphere with a specific radius, with the surface. The short-range Lennard–Jones term is a superposition of the attractive van der Waals interaction of the last tip apex atom with the surface and the coulombic repulsion. For a tip with radius R, this assumption results in the tip–sample force:

$$F_{nc}(z) = -\frac{A_H R}{6z^2} + \frac{12E_0}{r_0}\left(\left(\frac{r_0}{z}\right)^{13} - \left(\frac{r_0}{z}\right)^{7}\right). \tag{2.34}$$

As this approach does not explicitly consider elastic contact forces between tip and sample, we call this the 'noncontact' force law in the following sections.

A fit of this equation to the experimental tip–sample force curve is shown in Figure 2.19c by a solid line; the obtained parameters are $A_H R = 2.4 \times 10^{-27}$ Jm, $r_0 = 3.4$ Å, and $E_0 = 3$ eV [98]. The regime on the right from the minimum fits well to the experimental data, but the deep and wide minimum of the experimental curves cannot be described accurately with the noncontact force. This is caused by the steep increase in the Lennard–Jones force in the repulsive regime ($\Rightarrow F_{ts} \propto 1/r^{13}$ for $z < r_0$).

The elastic contact behavior can be described with the assumption of the above-described DMT-M model (see Section 2.1.3), that the overall shape of tip and sample changes only slightly until point contact is reached and that, after the formation of this point contact, the tip–sample forces are described by the Hertz theory. A fit of the Hertz model to the experimental data is shown in Figure 2.19 by a solid line. The experimental force curves agree quite well with the contact force law for distances $D < z_0$. This shows that the overall behavior of the experimentally obtained force curves can be described by a combination of long-range (van der Waals), short-range (Lennard–Jones), and contact (Hertz/DMT) forces.

As Equation 2.31 was derived under the assumption that the resonance amplitude is considerably larger than the decay length of the tip–sample interaction, the same restriction applies for Equation 2.33. However, by using more advanced algorithms it is also possible to determine forces from DFS experiments without the large amplitude restriction. The numerical approach of Gotsmann *et al.* [94], as well as the semi-empirical methods of Dürig [92], Giessibl [93] and Sader and Jarvis [97], are applicable in all regimes.

The resolution of DFS can be driven down to the atomic scale. Lantz *et al.* [99] measured frequency shift versus distance curves at different lattice sites of the Si (1 1 1)-(7 × 7) surface, and in this way were able to distinguish differences in the bonding forces between inequivalent adatoms of the 7 × 7 surface reconstruction of silicon.

The concept of DFS can be also extended to three-dimensional (3-D)-force spectroscopy by mapping the complete force field above the sample surface [100]. A schematic of the measurement principle is shown in Figure 2.21a. Frequency shift versus distance curves are recorded on a matrix of points perpendicular to the sample

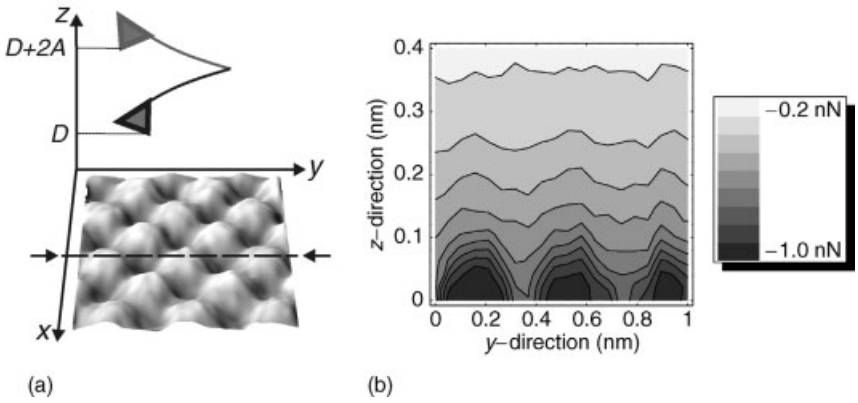

Figure 2.21 (a) Principle of 3-D force spectroscopy. The cantilever oscillates near the sample surface and measure the frequency shift in a *x*–*y*–*z*-box. The 3-D surface shows the topography of the sample (image size: 10 Å × 10 Å) obtained immediately before recording of the spectroscopy field; (b) The reconstructed force field of NiO(0 0 1) shows atomic resolution. The data are recorded along the dotted line shown in (a).

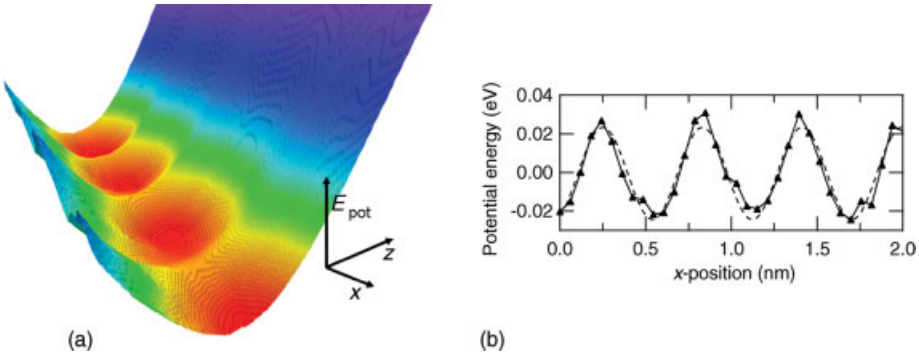

Figure 2.22 (a) A 3-D representation of the interaction energy map determined from 3-D force spectroscopy experiments on a NaCl(1 0 0) crystal surface. The red circular depressions represent the local energy minima; (b) Potential energy profile obtained from (a) by collecting the energy minimum values along the *x*-axis. This curve thus directly reveals the potential energy barrier of $\Delta E_{barrier} = 48$ meV which separates the local energy minima.

surface. By using Equation 2.33, the complete 3-D force field between the tip and sample can be recovered with atomic resolution. Figure 2.21b shows a cut through the force field as a two-dimensional (2-D) map.

The 3D-force technique has been applied also to a NaCl(1 0 0) surface, where not only conservative but also the dissipative tip–sample interaction could be measured in full space [101]. Initially, the forces were measured in the attractive as well as repulsive regime, allowing for the determination of the local minima in the corresponding potential energy curves (Figure 2.22). This information is directly related to the atomic energy barriers responsible for a multitude of dynamic phenomena in surface science, such as diffusion, faceting and crystalline growth. The direct comparison of conservative with the simultaneously acquired dissipative processes furthermore allowed determining atomic-scale mechanical relaxation processes.

If the NC-AFM is capable of measuring forces between single atoms with sub-nN precision, why should it not be possible to also exert forces with this technique? In fact, the new and exciting field of nanomanipulation would be driven to a whole new dimension, if defined forces could be reliably applied to single atoms or molecules. In this respect, Loppacher *et al.* [102] were able to exert pressure on different parts of an isolated Cu–TBBP molecule, which is known to possess four rotatable legs. Here, the force–distance curves were measured while one of the legs was pushed by the AFM tip and turned by 90°, and hence were able to measure the energy which was dissipated during the 'switching' of this molecule between different conformational states. The manipulation of single silicon atoms with NC-AFM was demonstrated by Oyabu *et al.* [103], who removed single atoms from a Si(1 1 1)-7 × 7 surface with the AFM tip and were able subsequently to re-deposit atoms from the tip onto the surface. This approach was driven to its limits by Sugimoto *et al.*, who manipulated single Sn-

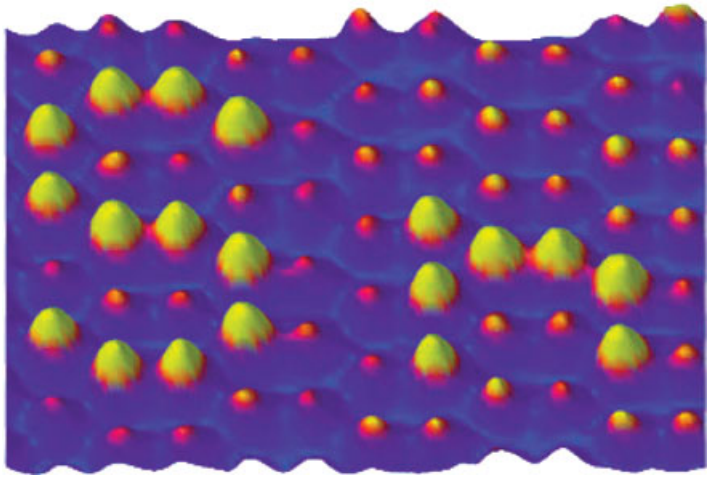

Figure 2.23 Final topographic NC-AFM image of the process of rearranging single atoms at room temperature. The image was acquired with a cantilever oscillation amplitude of 15.7 nm, using a Si cantilever. (Reproduced from Ref. [104].)

atoms on the Ge(1 1 1)-c(2 × 8) semiconductor surface. By pushing single Sn-atoms from one lattice site to another, they finally succeeded in writing the term 'Sn' with single atoms (Figure 2.23).

2.4 Summary

In summary, we have presented an overview over the basic principles and modern applications of AFM. This versatile technique can be categorized into two operational modes, static and dynamic. The static mode allows the simultaneous measurement of normal and lateral forces, thus yielding direct information about friction mechanisms of nanoscale contacts. The main advantage of the dynamic mode is the possibility to control tip–sample distances while avoiding the undesirable and destructive 'jump-to-contact' phenomenon. Two different excitation schemes for dynamic force microscopy were introduced, where the amplitude-modulation or tapping mode are in particular well-suited to high-resolution imaging under ambient or liquid conditions. The ultimate 'true' atomic resolution, however, is limited to vacuum conditions using FM or noncontact techniques. Nonetheless, the impact of AFM reaches far beyond the high-resolution imaging of surface topography: DFS allows the quantification of tip–sample forces, through the systematic acquisition of parameters such as amplitude, phase and oscillation frequency as a function of the relative tip–sample distance. Based on this approach, not only the bonding force of single interatomic chemical bonds can be measured, but also the full 3-D force field can be determined, at atomic resolution. Finally, the finding that atomic forces can

not only be measured but also exerted with atomic precision will open up the new and exciting field of nanomanipulation.

Acknowledgments

The authors would like to thank all colleagues who contributed to these studies with their images and experimental results, including Boris Anczykowski, Daniel Ebeling, Jan-Erik Schmutz, Domenique Weiner (University of Münster), Wolf Allers, Shenja Langkat, Alexander Schwarz (University of Hamburg) and Udo D. Schwarz (Yale University).

Probing Hydrodynamic Fluctuations with a Brownian Particle

Sylvia Jeney, Branimir Lukic, Camilo Guzman, and László Fórró

3.1
Introduction

The observation of Brownian motion has been a subject of interest since the invention of optical microscopy during the seventeenth century [1]. From then on, the understanding of its origin remained a subject of debate until 1905, when Einstein described a convincing model which, assumed that the fluctuations of a small-sized particle floating in a fluid were caused by momentum transfer from thermally excited fluid molecules. Einstein identified the mean square displacement of the particle as *the* characteristic experimental observable of Brownian motion, and showed that it grows linearly with time as $\langle \Delta x^2(t) \rangle = 2Dt$, thereby introducing the diffusion coefficient D [2]. In 1908, Langevin reformulated Newton's force balance equation by adding to the instantaneous Stokes' friction [3] a stochastic force term, representing the random impacts of surrounding medium molecules on the Brownian particle [4]. At the same time, Henri pointed out the limited nature of Stokes' formula for the friction force, when applied to neutrally buoyant, micron-sized particles [5], which is the case for most Brownian particles used in experiments. In such cases, correlations between friction and velocity are non-instantaneous, and the positions of the particle are expected to be correlated up to longer times. The origin of this effect comes from the non-negligible inertia of the fluid, and this must be accounted for in the description of Brownian motion. The expression for the mean square displacement using the noninstantaneous friction force was introduced by Vladimirsky and Terletzky in 1945 [6], but remained largely ignored, as their contribution was published in Russian. In 1967, Alder and Wainwright discovered, in numerical simulations, that the particle's velocity correlations (another characteristic observable of Brownian motion) display a power-law decay [7] instead of an exponential relaxation, as expected for instantaneous friction. These simulations led theoreticians during the 1970s to reconsider the contribution of fluid mechanics to Brownian motion [8–14], and to address its relevance in experiments. The idea of using a particle subjected to Brownian motion as a reporter of its local environment was settled. With this approach, any deviation

Nanotechnology: Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

from the normal diffusive behavior of the particle could be interpreted as a response to the material properties of its complex environment [15, 16]. To measure such behavior, a high spatial resolution down to the nanometer scale is needed. Experiments using dynamic light scattering in colloidal suspensions confirmed that the diffusion of colloidal particles is influenced by fluid mechanics, and hence is time-dependent [17–21]. However, in order to achieve a sufficiently high resolution, averaging over an ensemble of different particles was necessary. Nowadays, tracking a *single* particle in a fluid on time scales sufficiently short to detect hydrodynamic contributions can be realized by using optical tracking interferometry (OTI). This allows a *direct* measurement of Brownian motion at the same resolution as techniques averaging over many particles, and an individual particle comes to be the local Brownian probe. OTI utilizes a weak optical trap [22] and interferometric particle position detection. The trapping laser provides a light source for the position detection of the particle, and at the same time ensures that the particle remains within the detector range.

In this chapter we provide a complete picture of the measurements of a Brownian particle immersed in a viscous fluid and held by an optical trap. First, relevant theoretical insights are exposed and the different timescales of Brownian motion are summarized. Next, the technical aspects of OTI are described, and methodologies on data acquisition, analysis and interpretation provided. The influences of experimentally relevant parameters, such as the trapping force constant, the fluid properties and the Brownian particle itself, are presented. Finally, the overlap of the different measurable time scales of Brownian motion is quantified, and the consequences are discussed.

3.2
Theoretical Model of Brownian Motion in an Optical Trap

In general, the Brownian motion of a particle in a fluid is the result of thermal fluctuations of the surrounding fluid molecules. Collisions between a bath of fluid molecules at temperature T and the particle lead to an exchange of energy that allows the establishment of a thermal equilibrium between the particle and its environment. A simple model system to describe the phenomenon quantitatively in terms of statistical mechanics *as well as* hydrodynamics consists of a micrometer-sized sphere immersed in a viscous, so-called Newtonian fluid. Such a system can typically be observed in OTI. In this section, theoretical predictions on the motion of a Brownian sphere in a harmonic potential are discussed, starting from the Langevin equation, and including effects arising from hydrodynamic interactions with the viscous fluid. The section ends with an overview of different relaxation times related to the Brownian particle, the fluid and the optical trap.

3.2.1
The General Langevin Equation for a Brownian Sphere in an Incompressible Fluid

There are principally two, counteracting forces that govern the motion of a Brownian particle. First, the particle is driven through the thermal force $F_{th}(t)$, that arises from

random fluctuations of the fluid molecules excited by the thermal energy k_BT. Second, $F_{th}(t)$ is resisted by the friction force $F_{fr}(t)$, which (over-)damps the motion of the fluctuating particle. $F_{fr}(t)$ is the force exerted on the Brownian sphere by the surrounding viscous fluid, when the fluid is perturbed through the particle's fluctuations. Following from Newton's second law, the equation of motion can be written as the generalized Langevin equation:

$$m_s\ddot{x}(t) = F_{th}(t) + F_{fr}(t) + F_{ex}(t), \tag{3.1}$$

where m_s is the inertia of the Brownian sphere (s referring to the sphere's parameters), and $F_{ex}(t)$ represents the sum of any external forces, such as gravity or the force of the optical trap. For simplicity, we will discuss only the one-dimensional case for the axis x, even though OTI measurements give access to all three directions x, y and z.

3.2.1.1 The Random Thermal Force $F_{th}(t)$

The random force $F_{th}(t)$ represents the collisions of the fluid molecules on the particle. Its contribution in a homogeneous and isotropic medium varies so rapidly compared to the observable time scales, that $F_{th}(t)$ should be, on average, zero; $\langle F_{th}(t)\rangle = 0$.

Furthermore, as a very large number of collisions occurs during two successive measurements at times t and t', the correlation time of $F_{th}(t)$ is much shorter than the time interval between the two measurements [10]:

$$\langle F_{th}(t)F_{th}(t')\rangle = 2k_BT\gamma\langle\xi(t)\xi(t')\rangle$$

where k_B is the Boltzmann constant, γ is the viscous drag of the fluid on the particle and $\zeta(t)$ is a white noise term with no finite correlation time: $\langle\xi(t)\xi(t')\rangle = \delta(t-t')$.

$F_{th}(t)$ obeys the fluctuation–dissipation theorem, and has the expression:

$$F_{th}(t) = \sqrt{2k_BT\gamma}\xi(t) \tag{3.2}$$

In real systems the correlation time will not typically vanish instantaneously, because of the finite-size and finite-scale interactions which also exist between the fluid molecules themselves. Viscous and thermal forces will then become spatially and temporally correlated, through a time-dependent viscous drag γ (this is discussed next). It is worthy of note that $F_{th}(t)$ can only be described in terms of its statistical properties, and as its effect has already vanished on experimentally accessible time scales, $F_{th}(t)$ has never been measured [23].

3.2.1.2 The Friction Force $F_{fr}(t)$

An incompressible isotropic fluid with a viscosity $\eta_f(t)$ and density ρ_f (f refers to fluid parameters) generates a viscous drag $\gamma(t)$ on the thermally excited Brownian particle as it moves through the fluid, giving rise to the friction force $F_{fr}(t)$. A correct

expression of $\gamma(t)$ and the resulting $F_{fr}(t)$ is given by solving the Navier–Stokes equation, describing the hydrodynamic properties of the fluid [24]. Here, the molecular character of the viscous fluid is neglected, and the fluid is treated as a continuum, which is valid when the Brownian sphere with radius a_s and density ρ_s is much larger than the fluid molecules. Then, the average free path length of the molecules which compose the fluid is small compared to the dimension of, for example, the sphere immersed in it. Furthermore, we will only consider the sphere moving far away from any boundary, like an obstacle placed in its trajectory, which would make the fluid anisotropic. Two experimentally relevant solutions of the Navier–Stokes equation can then be distinguished, the first being a commonly used approximation of the second:

(i) $\rho_s \gg \rho_f$: If the sphere has a high inertia m_s, and hence a density much higher than the fluid's density ρ_f, it will move steadily and at very slow speeds through the fluid. The fluid's response to the particle's presence can then be considered as instantaneous, and the solution of the Navier–Stokes equation is simply the constant Stokes' drag [3]:

$$\gamma = 6\pi\eta_f a_s \tag{3.3}$$

and the friction force F_{fr} follows Stokes' law, which states that it is instantaneously linear with the sphere's velocity $\dot{x}$:

$$F_{fr} = -6\pi\eta_f a_s \dot{x} \tag{3.4}$$

It must be noted here that η_f, the dynamic viscosity of the fluid, is considered as time-independent, thus implying that correlations between successive collisions of the fluid molecules on the Brownian particle have already vanished. Motion can hence be observed as a Markovian process – that is, a random walk.

(ii) $\rho_s \approx \rho_f$: As noted by Lorentz [25], Equation 3.1, which includes Stoke's law (Equation 3.4), is only consistent with hydrodynamics when $m_s \gg m_f = (4/3)\pi a_s^3 \rho_f$. When the sphere has a density similar to its surrounding medium – which is usually the case for the neutrally buoyant particles used in optical trapping – the sphere's motion will be determined not only by its own inertia but also by the inertia m_f of the surrounding fluid. Then, Brownian motion theory needs to include frequency-dependent effects, and the time dependence of $\dot{x}$ should be accounted for when computing the drag γ.

As the particle receives momentum from the fluctuating fluid molecules, it displaces the fluid in its immediate vicinity. Although the fluid can still be considered as a continuum, and even with the conditions of a low Reynold's number, the fluid's flow field will be perturbed. The non-negligible inertia of entrained fluid $m_f = (4/3)\pi a_s^3 \rho_f$ will act back on the sphere. As a consequence, correlations in the fluid's fluctuations will persist up to time scales observable by OTI and become experimentally relevant. The Brownian sphere will move with a non-constant velocity and perform a non-random walk, which will depend heavily on the nature of the surrounding medium. This phenomenon is commonly called hydrodynamic memory. Such perturbations give rise to the Stokes–Boussinesq friction force that is

derived from the Navier–Stokes equation accounting for the inertia of the fluid, and given as [9]:

$$F_{fr} = -6\pi\eta_f a_s \dot{x} - \frac{2}{3}\pi a_s^3 \rho_f \ddot{x} - 6a_s^2 \sqrt{\pi\eta_f \rho_f} \int_0^t (t-t')^{-1/2} \ddot{x}(t')\mathrm{d}t' \tag{3.5}$$

The first term is the ordinary Stokes' friction from Equation 3.4, while the second term is connected to the mass m_f of the incompressible fluid displaced by the Brownian particle. In principle, this term defines an effective mass $M = m_s + m_f/2$ that should replace m_s on the left-hand side of the Langevin equation (Equation 3.1). The third term is time-dependent, stating that the friction force at time t is determined by the penetration depth of the viscous, unsteady flow around the sphere at all preceding times. Equation 3.5 confirms that, for a fluid with a density similar to the density of the Brownian particle, the terms containing ρ_f cannot be neglected, as they are of the same order of magnitude as the inertial term.

Consequently, an instantaneous disturbance of the fluid from the thermally excited Brownian sphere will spread, and its initial momentum will be shared with all of the molecules in a small volume around the sphere. The velocity field of this moving volume then grows by vorticity diffusion. In an incompressible liquid, this enforces a back flow at short times, which creates a vortex ring in three dimensions [12]. The diffusive spreading of this vortex carries the momentum into the fluid on a time scale $\tau_f = a_s^2 \rho_f / \eta_f$ – the time needed for vorticity to diffuse over the distance of one particle radius. Figure 3.1 shows a simplified scheme of the characteristic double-vortex structure of the velocity field caused by the initial displacement of the Brownian sphere in a simple liquid.

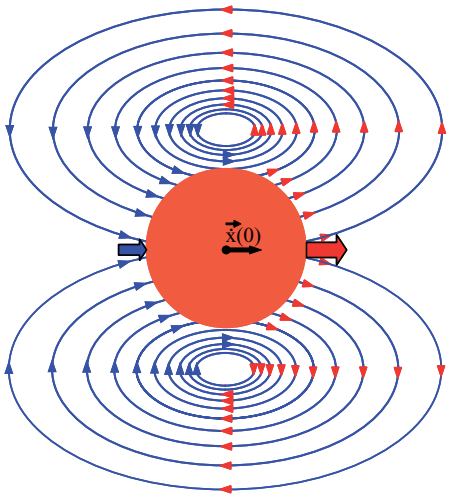

Figure 3.1 Schematic visualization of the velocity field of the fluid after the colloidal particle has been set in motion. (Inspired from computer simulations by Ref. [26].)

3.2.1.3 The External Force $F_{ex}(t)$

Only two different cases for $F_{ex}(t)$ will be considered for deriving the solutions of the Langevin equation:

(i) $F_{ex}(t) = 0$: When no additional force acts on the sphere and its motion is considered as free.

(ii) $F_{ex}(t) = -kx(t)$: Corresponding to the harmonic trapping potential with a force constant k created by the optical trap, which retains the sphere within the observation volume of the detector. The sphere's motion is then qualified as optically confined.

3.2.2 Solutions to the Different Langevin Equations for Cases Observable by OTI

From the solution of the Langevin equation for a Brownian sphere, the following measurable quantities of physical interest are derived for further studies in experiments (see Sections 3.3 and 3.4) the velocity autocorrelation function (VAF) $\langle \dot{x}(t)\dot{x}(0)\rangle$; the mean square displacement (MSD) $\langle \Delta x^2(t)\rangle$, which is related to the velocity autocorrelation function through:

$$\langle \Delta x^2(t)\rangle = 2\int_0^t (t-t')\langle \dot{x}(t')\dot{x}(0)\rangle \mathrm{d}t'; \tag{3.6}$$

and also the power spectral density (PSD) $\langle |\tilde{x}(f)|^2\rangle$, which mirrors the MSD through its Fourier transform as

$$\langle \Delta x^2(t)\rangle = 4\int_0^\infty \cos(2\pi f t)\langle |\tilde{x}(f)|^2\rangle \mathrm{d}f. \tag{3.7}$$

The following listing of all three measurables derived from the four discussed Langevin equations is meant to provide a summarizing overview of the theoretical models of Brownian motion derived in the literature by various authors. Each model can be picked accordingly to fit the data acquired by OTI, as discussed in Section 3.4. The most accurate expressions are also the most complex; however, a good understanding of the problem of Brownian motion in a viscous fluid is already gained by only considering the characteristic limiting behaviors in each situation.

3.2.2.1 Free Brownian Motion

Solving the Langevin Equation using Stokes Friction Solving the Langevin equation using the Stokes friction of Equation 3.4 and $F_{ex}(t) = 0$ results in a VAF:

$$\langle \dot{x}(t)\dot{x}(0)\rangle_{free} = \frac{k_B T}{m_s} e^{-t/\tau_s} \tag{3.8}$$

and in a MSD:

$$\langle \Delta x^2(t) \rangle_{free} = 2Dt\left[1 + \frac{\tau_s}{t}(e^{-t/\tau_s} - 1)\right] \tag{3.9}$$

that both decay exponentially with a characteristic time constant $\tau_s = m_s/\gamma = 2a_s^2\rho_s/9\eta_f$. This implies that, for a larger/heavier particle and/or a less viscous fluid, correlations will last longer. If $D = k_BT/\gamma$ is the diffusion constant, then the PSD will be:

$$\langle |\tilde{x}(f)|^2 \rangle_{free} = \frac{D}{\pi^2 f^2[(\gamma f/2\pi m_s)^2 + 1]} = \frac{D}{\pi^2 f^2[(f/\phi_s)^2 + 1]} \tag{3.10}$$

with $\phi_s = 1/2\pi\tau_s$, the corresponding characteristic frequency.

For short times ($t \to 0$), and respectively, high frequencies ($f \to \infty$), the particle moves with its initial velocity:

$$\dot{x}(0) = \sqrt{k_BT/m_s} \tag{3.11}$$

Then, the motion is ballistic with:

$$\langle \Delta x^2(t) \rangle_{free} = (k_BT/m_s)t^2 \tag{3.12}$$

and:

$$\langle |\tilde{x}(f)|^2 \rangle_{free} = (D\phi_s^2/\pi^2)f^{-4} \tag{3.13}$$

At long times ($t \to \infty$), and respectively, low frequencies ($f \to 0$), velocity correlations vanish exponentially with τ_s, the relaxation time of the particle's initial momentum. The particle has then lost all information about its initial velocity, and diffuses randomly with

$$\langle \Delta x^2(t) \rangle_{free} = 2Dt \tag{3.14}$$

and respectively

$$\langle |\tilde{x}(f)|^2 \rangle_{free} = (D/\pi^2)f^{-2} \tag{3.15}$$

Solving the Langevin Equation using the Stokes–Boussinesq Friction Force Solving the Langevin equation using the Stokes–Boussinesq friction force of Equation 3.5 and $F_{ex}(t) = 0$ results in more complex expressions [6, 11]:

$$\langle \dot{x}(t)\dot{x}(0) \rangle_{free} = \frac{k_BT}{2\pi a_s^3 \rho_f \sqrt{5 - 8\rho_s/\rho_f}}\left[\alpha_+ e^{\alpha_+^2 t} erfc(\alpha_+\sqrt{t}) - \alpha_- e^{\alpha_-^2 t} erfc(\alpha_-\sqrt{t})\right]$$

$$\text{with} \quad \alpha_\pm = \frac{3}{2}\frac{3 \pm \sqrt{5 - 36\tau_s/\tau_f}}{\sqrt{t}(1 + 9\tau_s/\tau_f)} \tag{3.16}$$

now also including the hydrodynamic effect, decaying with a fluid-dependent time constant $\tau_f = a_s^2\rho_f/\eta_f$, which represents the time needed by the perturbed fluid flow field to diffuse over the distance of one particle radius. For an incompressible fluid, the initial velocity is now given by $\dot{x}(0) = \sqrt{k_BT/(m_s + m_f/2)} = \sqrt{k_BT/M}$, and

τ_s should in principle be expressed as $\tau_s = (m_s + m_f/2)/\gamma = a_s^2(2\rho_s + \rho_f)/9\eta_f$. The MSD is given by:

$$\langle \Delta x^2(t) \rangle_{free} = 2Dt\left[1 - 2\sqrt{\frac{\tau_f}{\pi t}} + 4\frac{\tau_f}{t} - \frac{\tau_s}{t} + \Xi\left(\frac{\tau_s}{\tau_f}, \frac{t}{\tau_f}\right)\right]$$

$$\text{with} \quad \Xi\left(\frac{\tau_s}{\tau_f}, \frac{t}{\tau_f}\right) = \frac{3}{t\sqrt{5 - 36\tau_s/\tau_f}}\left[\frac{1}{\alpha_+^3} e^{\alpha_+^2 t} erfc\left(\alpha_+\sqrt{t}\right) - \frac{1}{\alpha_-^3} e^{\alpha_-^2 t} erfc\left(\alpha_-\sqrt{t}\right)\right]. \tag{3.17}$$

Equation 3.17 depends on the particle's inertia through τ_s and on the fluid's inertia through τ_f. The two times are connected by the relationship $\frac{\tau_s}{\tau_f} \approx \frac{2\rho_s}{9\rho_f}$.

The corresponding characteristic frequency $\phi_f = 1/2\pi\tau_f$ appears in the PSD as [27]:

$$\langle |\tilde{x}(f)|^2 \rangle_{free} = \frac{D}{\pi^2 f^2} \frac{\left(1 + \sqrt{f/2\phi_f}\right)}{\left[(f/\phi_s) + \sqrt{f/2\phi_f} + (f/9\phi_f)\right]^2 + \left(1 + \sqrt{f/2\phi_f}\right)^2} \tag{3.18}$$

The behaviors in the time and frequency limits of all three functions remain similar to the previously discussed case, meaning that, for very short times, the motion is ballistic and, for very long times, the motion is diffusive. However, the transition between the two regimes is algebraic and delayed to significantly longer times compared to the case of simple Stokes' friction. This translates into a slow algebraic decay in the MSD (Equation 3.12) and results in a VAF which is governed by a power-law rather than by an exponential tail [7]:

$$\langle \dot{x}(t)\dot{x}(0) \rangle_{free} \propto (t/\tau_f)^{-3/2}, \quad \text{for} \quad t \geq \tau_f \tag{3.19}$$

This power law is usually referred to in the literature as the 'long-time tail', and arises from the fluid vortices observed around the colloidal particle, as sketched in Figure 3.1.

The log-log plot in Figure 3.2a compares the VAF given by Equation 3.8 (red line) with that given by Equation 3.16 (blue line), both normalized by their respective initial velocity, for a sphere with radius $a_s = 1\,\mu m$, density $\rho_s = 1.51\,kg\,dm^{-3}$ immersed in water with viscosity $\eta_f = 10^{-3}$ Pa·s at $T = 22\,^\circ C$. It can be seen that the exponential relaxation resulting from the Stokes' friction changes to a power-law decay when the fluid's inertia is accounted for. In the same way, the log-log representations in Figures 3.2b and 3.2c show a comparison between Equations 3.9 and 3.17, as well as between Equations 3.10 and 3.18. Differences in the MSD and PSD are less visible in this representation, but the respective common limiting behaviors, translating to characteristic slopes are indicated. In Figure 3.2c, the discrepancies visible at high frequencies above 2 MHz (arrow) between both functions, arise from the differences in the displaced masses; m_s, and respectively M. The green bars on the abscissa highlight the time, and respectively, frequency regions accessible by OTI, as introduced in Section 3.3.

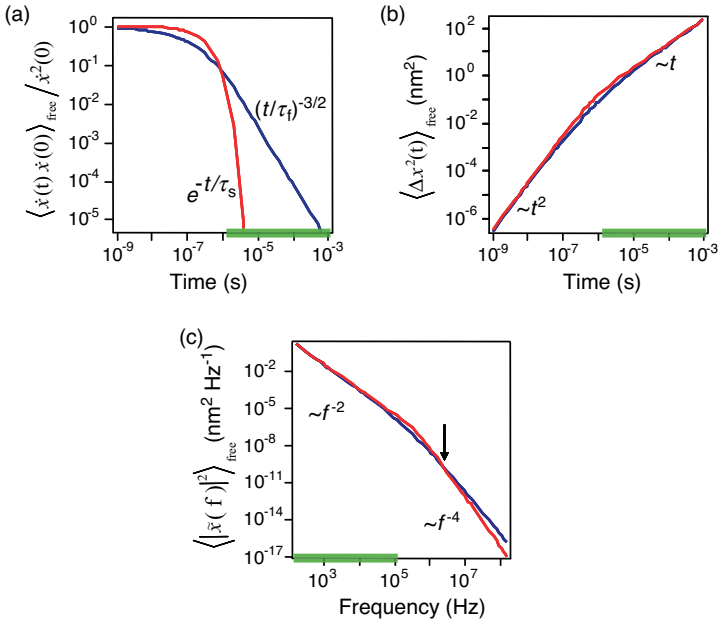

Figure 3.2 Log-log plots of (a) the normalized VAF given by Equation 3.8 (red line) and Equation 3.16 (blue line); (b) the MSD given by Equation 3.9 (red line) and Equation 3.17 (blue line); and (c) the PSD given by Equation 3.10 (red line) and Equation 3.18 (blue line) for a 2 µm-sized sphere in water. The chosen time span ranges from the short-time to the long-time limits of each function, which are indicated in each graph. The green bars on the abscissa highlight the regions accessible by OTI.

3.2.2.2 Optically Confined Brownian Motion

The Case of a Nonfree Particle In the case of a nonfree particle the situation becomes more complex. The diffusion of such a particle in an unbounded fluid was first described by Ornstein and Uhlenbeck [28]. The Langevin equation using the Stokes friction of Equation 3.4 gives then a velocity autocorrelation function:

$$\langle \dot{x}\ (t)\dot{x}(0)\rangle = \frac{k_B T}{m_s(\varsigma_+ - \varsigma_-)}\left[\varsigma_+ e^{-\varsigma_+ t} - \varsigma_- e^{-\varsigma_- t}\right]$$

$$\text{with} \quad \varsigma_\pm = \frac{1}{2\tau_s}\left(1 \pm \sqrt{1 - 4\tau_s/\tau_k}\right) \tag{3.20}$$

The VAF now has a positive part which decays exponentially to zero as $\langle \dot{x}(t)\dot{x}(0)\rangle \propto e^{-t/\tau_s}$ for $t \approx \tau_s$, and a negative part which decays exponentially as:

$$\langle \dot{x}(t)\dot{x}(0)\rangle \propto -e^{-t/\tau_k} \tag{3.21}$$

for $t \approx \tau_s$, a new characteristic time constant $\tau_k = 6\pi\eta_f a_s/k$ determined by the trap stiffness k. The MSD follows as:

$$\langle \Delta x^2(t) \rangle = \frac{2k_B T}{k}\left[1 + \frac{\varsigma_-}{\varsigma_+ - \varsigma_-}e^{-\varsigma_+ t} + \frac{\varsigma_+}{\varsigma_- - \varsigma_+}e^{-\varsigma_- t}\right] \tag{3.22}$$

and the PSD becomes Lorentzian [29]:

$$\langle |\tilde{x}(f)|^2 \rangle = \frac{D}{\pi^2 f^2 [1 + (\phi_k/f)^2]} \tag{3.23}$$

showing that the motion is also influenced by the trapping potential with the characteristic frequency $\phi_k = 1/2\pi\tau_k = k/12\pi^2\eta_f a_s$, corresponding to the corner frequency of the Lorentzian function.

In the short time limits, the behavior remains the same as introduced above, but in the long time limit it is now governed by the confining potential – that is, the optical trapping constant. Then, the velocity correlations still disappear, but Equation 3.22 approaches the time-independent limit:

$$\langle \Delta x^2(t) \rangle_{t \to \infty} = 2k_B T/k \tag{3.24}$$

and Equation 3.23 the limit:

$$\langle |\tilde{x}(f)|^2 \rangle_{f \to 0} = 4k_B T\gamma/\pi k^2 \tag{3.25}$$

The sphere's motion is now governed by the potential's restoring force with stiffness k.

Using the Stokes–Boussinesq Friction Force The most complete solution considered in this work is when the Stokes–Boussinesq friction force of Equation 3.5 and $F_{ex}(t) = -kx(t)$ are used to set up the Langevin equation. Then, the VAF is [14]:

$$\begin{aligned}\langle \dot{x}(t)\dot{x}(0) \rangle = {} & \frac{\zeta_1^3 e^{\zeta_1^2 t} erfc(\zeta_1\sqrt{t})}{(\zeta_1-\zeta_2)(\zeta_1-\zeta_3)(\zeta_1-\zeta_4)} + \frac{\zeta_2^3 e^{\zeta_2^2 t} erfc(\zeta_2\sqrt{t})}{(\zeta_2-\zeta_1)(\zeta_2-\zeta_3)(\zeta_2-\zeta_4)} \\ & + \frac{\zeta_3^3 e^{\zeta_3^2 t} erfc(\zeta_3\sqrt{t})}{(\zeta_3-\zeta_1)(\zeta_3-\zeta_2)(\zeta_3-\zeta_4)} + \frac{\zeta_4^3 e^{\zeta_4^2 t} erfc(\zeta_4\sqrt{t})}{(\zeta_4-\zeta_1)(\zeta_4-\zeta_2)(\zeta_4-\zeta_3)}\end{aligned} \tag{3.26}$$

where the coefficients ζ_1, ζ_2, ζ_3 and ζ_4 are the four roots of the equation:

$$\left(\tau_s + \frac{1}{9}\tau_f\right)\zeta^4 + \sqrt{\tau_f}\zeta^3 + \zeta^2 + \frac{1}{\tau_k} = 0.$$

Correspondingly, the MSD results in:

$$\langle \Delta x^2(t)\rangle = 2D\tau_k + \frac{2D}{\tau_s+\frac{\tau_f}{9}}\left[\frac{e^{\zeta_1^2 t}erfc(\zeta_1\sqrt{t})}{\zeta_1(\zeta_1-\zeta_2)(\zeta_1-\zeta_3)(\zeta_1-\zeta_4)}+\frac{e^{\zeta_2^2 t}erfc(\zeta_2\sqrt{t})}{\zeta_2(\zeta_2-\zeta_1)(\zeta_2-\zeta_3)(\zeta_2-\zeta_4)}\right] + \frac{2D}{\tau_s+\frac{\tau_f}{9}}\left[\frac{e^{\zeta_3^2 t}erfc(\zeta_3\sqrt{t})}{\zeta_3(\zeta_3-\zeta_1)(\zeta_3-\zeta_2)(\zeta_3-\zeta_4)}+\frac{e^{\zeta_4^2 t}erfc(\zeta_4\sqrt{t})}{\zeta_4(\zeta_4-\zeta_1)(\zeta_4-\zeta_2)(\zeta_4-\zeta_3)}\right] \tag{3.27}$$

and the PSD is given by [27]:

$$\langle|\tilde{x}(f)|^2\rangle = \frac{D}{\pi^2 f^2}\left[\frac{\left(1+\sqrt{f/2\phi_f}\right)}{\left[(\phi_k/f)-(f/\phi_s)-\sqrt{f/2\phi_f}-\left(f/9\phi_f\right)\right]^2+\left(1+\sqrt{f/2\phi_f}\right)^2}\right] \tag{3.28}$$

which is by far the most convenient formula of all three quantities to use for fitting data acquired in OTI experiments. Fortunately, despite their complexity, the limiting behaviors of all three expressions simplify in the same way as in the above-discussed cases.

3.2.3 Time Scales of Brownian Motion

All of the above considerations show that many different time scales (as outlined in Table 3.1) govern the physics of Brownian motion. To better appreciate these times, we can consider a sphere with radius $a_s = 1\,\mu m$ in water. The sphere is set into motion by random collisions with fluid molecules within $\tau_{col} = \bar{d}_{mol}\bar{v}_{mol} \approx 0.1$ ps, the correlation time of $F_{th}(t)$, estimated by the ratio of the mean solvent particle separation $\bar{d}_{mol}$ and fluctuation speed $\bar{v}_{mol}$ [30]. The momentum is then transferred from the particle to the fluid on very different time scales. If compressibility effects of the fluid are taken into account, one-third of the initial momentum is carried off

Table 3.1 Overview of the characteristic time scales of a Brownian particle in a harmonic potential.

Time constant	Origin	Typical value for our model system
$\tau_{col} = \bar{d}_{mol}/\bar{v}_{mol}$	Random molecular collisions	$\sim 10^{-13}$ s
$\tau_{sw} = a_s/c$	Sound wave propagation over the distance of a sphere's radius	$\sim 10^{-9}$ s
$\tau_s = m_s/\gamma = 2a_s^2\rho_s/9\eta_f$	Inertia of the Brownian particle	$\sim 10^{-6}$ s
$\tau_f = a_s^2\rho_f/\eta_f$	Inertia of the perturbed fluid surrounding the Brownian particle	$\sim 10^{-6}$ s
$\tau_k = 6\pi\eta_f a_s/k.$	Harmonic potential of the optical trap	$\sim 10^{-4}$ s

Typical values are calculated for a resin sphere ($a_s = 1\,\mu m$, $\rho_s = 1.51\,kg\,dm^{-3}$) in water ($\rho_f = 1\,kg\,dm^{-3}$, $\eta = 10^{-3}$ Pa·s).

rapidly by a spherical sound wave, the front of which leaves the sphere after a time $\tau_{sw} = a_s/c \approx 0.7$ ns, where c is the speed of sound in the fluid [31]. Equation 3.5, which was set for an incompressible fluid, has simply to be corrected to include a rapid change of the particle's inertial mass m_s to the combined mass $M = m_s + m_f/2$ [13]. Consequently, the velocity correlation function starts with the initial value given by the equipartition theorem, $\langle \dot{x}(0)\dot{x}(0)\rangle = k_B T/m_s$ and, after a short time, on the order of τ_{sw}, decays from $k_B T/m_s$ to $k_B T/M$ due to acoustic damping of the particle's velocity. When the sound wave has separated and the particle has relaxed with $\tau_s = m_s/\gamma \approx 0.9\,\mu$s or $\tau_{s+f} = (m_s + m_f/2)/\gamma \approx 0.7\,\mu$s, the vortex ring develops around the particle. The region of vorticity (see Figure 3.1) grows diffusively, as the remaining momentum is distributed over increasingly larger volumes, with the disturbance taking a time of order $\tau_f = a_s^2 \rho_f/\eta_f$ to leave the particle. Finally, the optical trapping force, $F_{ex}(t)$, sets in after a time $\tau_k = 6\pi\eta_f a_s/k$ and slows down the sphere, confining its motion around the potential minimum. The stronger the trap, the earlier optical confinement will reduce the particle's free motion.

For the model of a sphere in a harmonic potential with a typical spring constant $k = 10\,\mu\text{N m}^{-1}$, τ_s and τ_f are in the microsecond range, whereas τ_k is in the millisecond range. The relaxation time of the optical trapping potential is thus well separated from the others, and its separation can be adjusted by choosing suitable experimental parameters, that is, a_s, ρ_s, ρ_f, η_f and k. The diffusion constant D is on the order of $1\,\mu\text{m}^2\,\text{s}^{-1}$, and hence the time for the sphere to diffuse over its radius is on the order of 1 s. Correspondingly, within 1 μs, the sphere will have diffused about 1 nm, which is the time and distance range accessible by OTI. This will allow study of the interplay between τ_f and τ_k, as shown in detail in Section 3.4.

3.3
Experimental Aspects of Optical Trapping Interferometry

In OTI, optical trapping is combined with high-resolution interferometric position detection. The optical trap provides the linear external force $F_{ex}(t) = -kx(t)$ in the Langevin equation, which will maintain the studied microsphere within the detection range of the system. In general, the principles of optical trapping, as well as instrumental aspects, are well known and have been reported extensively in the literature [29, 32]. Therefore, at this point we will present only briefly the opto-mechanical and electronic components of the set-up. However, the data acquisition and analysis strategy deserves greater emphasis, as it allows the fine characterization of interactions between the Brownian probe and its environment.

3.3.1
Experimental Set-Up

The apparatus consists mainly of a custom-built inverted light microscope with a 3-D sample positioning stage, an infrared laser for trapping, and a quadrant photodiode for high-resolution 3-D and time-resolved position detection. The two main custom-made

Figure 3.3 Photograph of the experimental set-up on a vibration isolation table. The mechanical frame is made from titanium, steel and aluminum to achieve maximal mechanical and temperature stability. For details of abbreviations, see text and Figure 3.4. (Photograph courtesy of Daniel Gutierrez.)

circular base plates are made from the titanium alloy Ti-6AL-4V, on the basis of its high tensile strength, light weight, low thermal conductivity, low thermal expansion coefficient and corrosion resistance compared to steel or aluminum. The commercially available mechanical pieces are either made of aluminum or steel. In order to minimize mechanical vibrations, the whole set-up is mounted on a table with tuned damping (RS-4000, Newport, UK), supported by pneumatic isolators (I-2000, Newport). The main features of the instrument are shown in Figure 3.3.

3.3.1.1 Optical Trapping Interferometry and Microscopy Light Path

The optical paths can be divided into an infrared (IR) trapping and detection light path, and a visible illumination and imaging light path, as shown in Figure 3.4. The trapping beam is emitted by a diode-pumped, ultra-low-noise Nd:YaG laser with a wavelength of $\lambda = 1064\,\text{nm}$ (IRCL-500-1064-S; CrystaLaser, USA) and a maximal light power of 500 mW in continuous-wave mode. The choice of the near-IR wavelength satisfies the requirement of minimal water absorption to avoid heating of the sample in the laser focus [29]. A high-intensity gradient for good trapping efficiency is achieved by over-illuminating the high numerical back-aperture of the focusing lens (OBJ). Therefore, the effective laser beam diameter is expanded 20-fold by a telecentric lens system (EXP; Beam Expander, Sill Optics, Germany). In order to

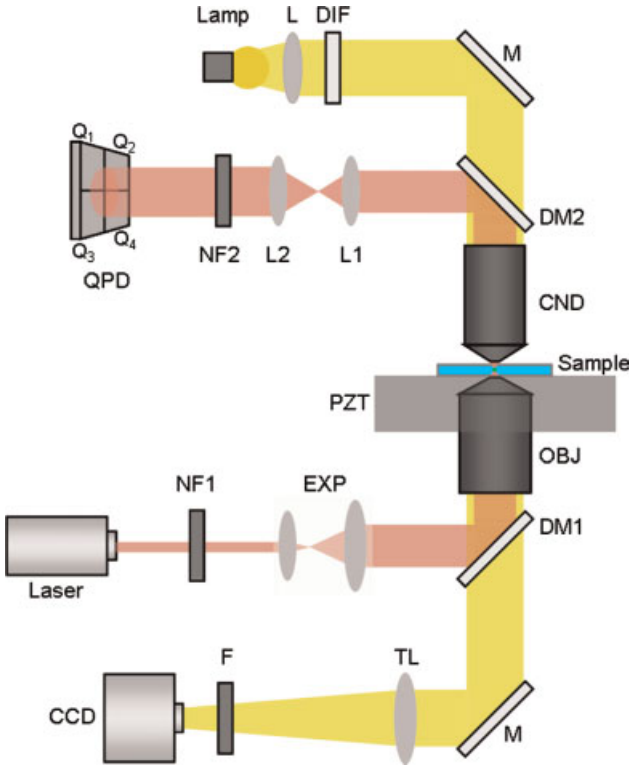

Figure 3.4 Schematic layout of the infrared (IR; red) and visible (yellow) light paths. The laser beam is expanded 20-fold by a beam expander (EXP), attenuated if necessary by a neutral density filter (NF1), and then reflected by a dichroic mirror (DM1) and focused by the objective lens (OBJ) into the sample chamber, which is mounted on a piezostage (PZT). The scattered IR light is collected by a condenser (CND), and directed by a second dichroic mirror (DM2) onto the quadrant photodiode (QPD). A second neutral density filter (NF2) is placed in front of the QPD, to avoid possible saturation of the detector. A 50 W halogen light source (Lamp) illuminating the object plane, through a lens (L) and diffuser (DIF), is reflected by the first mirror M, but transmitted through both dichroic mirrors (DM1 and 2). The image created by the CND and OBJ is reflected by the second lower mirror (M) and the 180 mm tube lens (TL) onto the charge-coupled device camera (CCD).

minimize noise, the laser is operated at high power, and its intensity is adapted after expansion by neutral density filters (NF1) with variable transmission coefficients ($T = 0.25$, 0.1, 0.01 or 0.001; OWIS, Germany). Increasing the transmission coefficient of NF1 will decrease the trapping stiffness, as this depends linearly on the laser power [33]. Next, the IR-beam is reflected by a dichroic mirror (DM1; AHF analysentechnik AG, Germany) into the high numerical aperture (NA = 1.2) of a $\times 60$ water-immersion objective (OBJ; UPLapo/IR, Olympus, Japan), which focuses the laser down to its refraction limit into the object plane of the microscope and creates the optical trap. The choice of a water-immersion objective lens offers a longer working distance of up to 280 µm compared to oil-immersion lenses. Such a long

working distance guarantees a stable space-invariant trap through the entire sample chamber. This is particularly essential when studies on Brownian particles far away from any surface boundary are of interest (as will be the case for the experiments discussed below).

The sample is mounted onto an *xyz*-piezo scanning table (PZT; P-561, Physikalishe Instrumente, Germany) for manipulation and positioning. The PZT with controller (E-710 Digital PZT Controller; Physikalishe Instrumente, Germany) has a travel range of 100 µm along all three dimensions, with a precision of 1 nm. The laser light focused by the objective lens is collected with a condenser (CND; 63X, Achroplan, NA = 0.9, water-immersion; Zeiss, Germany), and projected by a second dichroic mirror (DM2) and two lenses (L1 and L2, with focal lengths $f_1 = 30$ mm and $f_2 = 50$ mm) with a magnification of $f_1/f_2 \approx 1.67$ onto an InGaAs quadrant photodiode (QPD; G6849, Hamamatsu Photonics, Japan). The QPD is placed in the back focal plane of the condenser and fixed on an *x*–*y* translation stage (OWIS, Germany) for manual centering of the detector relative to the IR-beam. In order to avoid possible saturation of the QPD, a second neutral density filter (NF2) can be optionally placed in front of the QPD. For illumination in the visible range, a 50 W halogen lamp is diffused (DIF) and projected by a mirror (M) through the condenser, objective and a 180 mm tube lens (TL) that creates an image of the object plane onto a charge-coupled device camera (CCD; ORCA ER S5107, Hamamatsu Photonics, Japan). The image of the object plane is digitized (Hamamatsu Digital Controller ORCA ER), and can be further processed (HiPic, Hamamatsu Photonics, Japan).

3.3.1.2 Sample Preparation

The sample chamber consists of a custom-made flow cell. A coverslip (thickness ~130 µm) is stuck to a standard microscope slide using two pieces of double-sided tape, arranged in such a way as to form a ~5 mm-wide and ~70 µm-thick channel with a volume of ~20 µl. After loading with a suspension of microspheres, the flow-cell is mounted upside down on the 3-D piezo-stage. In the experiments presented in Section 3.4, either polystyrene ($\rho_s = 1.05\,\mathrm{kg\,dm^{-3}}$; Bangs Laboratories, USA), melamine resin ($\rho_s = 1.51\,\mathrm{kg\,dm^{-3}}$; Sigma-Aldrich, USA) or silica spheres ($\rho_s = 1.96\,\mathrm{kg\,dm^{-3}}$; Bangs Laboratories, USA) were used with radii (a_s) varying from 0.27 to 2 µm. To guarantee the manipulation and analysis of exclusively one particle, a particle concentration of 10^6 spheres per milliliter was used to maximize the average distance between two neighboring particles and minimize their mutual influence on their motions [34].

3.3.2 Position Signal Detection and Acquisition

When following the 3-D Brownian motion of the trapped particle, the scattering of the strongly focused trapping laser on the particle is measured by the QPD. The InGaAs Quadrant Photodiode (G6849, Hamamatsu Photonics, Japan) is 2.0 mm in diameter with a dead zone of 0.1 mm between the quadrants. The photosensitivity is 0.67 A W^{-1} at 1064 nm. The QPD signals are fed into a custom-built preamplifier (Pre-AMP;

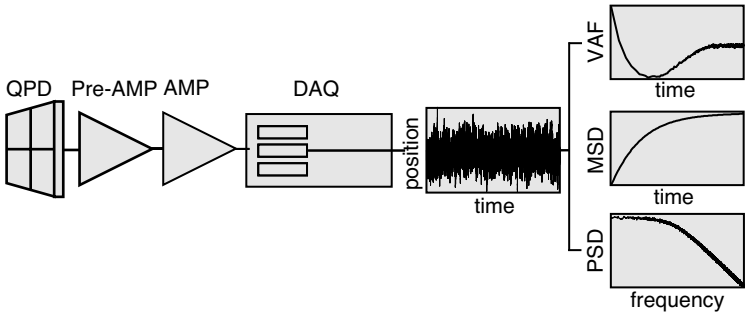

Figure 3.5 Position signal acquisition and data processing. Intensity fluctuations are recorded on the quadrant photodiode (QPD) and converted to volts (Pre-AMP). The signal is amplified (AMP) and digitized using the acquisition card (DAQ). The VAF, MSD and PSD are then calculated from the recorded position time trace.

Öffner MSR-Technik, Germany) which provides two differential signals between the segments and one signal that is proportional to the total light intensity (Figure 3.5). Preamplification of the quadrant photodiode signals at $20\,\mathrm{V\,mA^{-1}}$ with $0.67\,\mathrm{A\,W^{-1}}$ photosensitivity leads to a voltage of $13.4\,\mathrm{V\,mW^{-1}}$. Subsequently, differential amplifiers (AMP; Öffner MSR-Technik) adjust the preamplifier signals for optimal digitalization by the data acquisition board (DAQ) with a dynamic range of 12 bits (NI-6110, National Instruments, USA). Amplification of the QPD signal is chosen to span the maximal dynamic range of the acquisition card. The amplifier (Öffner MSR-Technik), with a maximal gain of 500, has a cut-off frequency around 1 MHz. The particle's position can be detected in all three dimensions. On the QPD, scattered and unscattered light generate an interference pattern that corresponds to the probe's position. A displacement of the particle near the beam focus modulates the optical power collected by the QPD. When the sphere moves perpendicularly to the optical axis – that is, along the x-direction – the current signal $S_x = (Q_1 + Q_2) - (Q_3 + Q_4)$ measured between both top segments (Q_1,Q_2) and both bottom segments (Q_3,Q_4) of the QPD changes correspondingly. The same holds for movements in the y-direction. Displacements along the z-axis instead affect the sum-signal $S_z = Q_1 + Q_2 + Q_3 + Q_4$ of the QPD, and so z displacements can be determined by the changes in total intensity. The full 3-D position information of the probe is thus encoded in the interference pattern of the forward-scattered and transmitted laser light recorded by the QPD. A detailed analysis of the detector response is given for fluctuations perpendicular to the optical axis in Ref. [35], and along the optical axis in Refs [36] and [37]. For small displacements from the trap center, the differential signals from the QPD are proportional to the lateral displacements of the particle in the optical trap, and the sum signal to the axial displacement.

The scanning stage, CCD camera and data acquisition are controlled and coordinated by a custom-made program written in VEE (Agilent, USA). Data are saved in binary format and analyzed with Igor 6.0 (WaveMetrics, USA).

The 3-D position–time traces of the Brownian motion of the probe can be acquired up to maximally $N = 10^7$ points (this limitation is set by the working memory of the

VEE). Data analysis also becomes very slow when the data files exceed 3.10^7 points per channel, and therefore the combination between data acquisition rate f_{acq} and total recording time t_{tot}, must be adjusted according to $N = f_{acq}t_{tot}$. A schematic overview of the signal acquisition and data processing schemes is shown in Figure 3.5.

3.3.3
Position Signal Processing

The three quantities of VAF, MSD and PSD, which were introduced in Section 3.2 can be calculated from the same experimental time trace $x(t)$, which is recorded in volts and converted to nanometers after fitting to the suitable theory of Brownian motion (as described in Section 3.4.1). An example of such a time trace, as well as the resulting VAF, MSD and PSD is shown on the right-hand side of Figure 3.5 for a 2 μm resin bead. For the sake of clarity, only one-dimensional time traces $x(t)$ will be presented through the remainder of this chapter, even though the developed data analysis strategy also applies to the y and z directions.

The velocity $\dot{x}(t) = \Delta x(t)/\Delta t$ of the studied sphere is derived from the steps $\Delta x(t) = x(t + \Delta t) - x(t)$ it performed, where Δt is the lag time related to the acquisition frequency as $f_{acq} = 1/\Delta t$. For the total number of acquired points N, the total recording time is expressed as $t_{tot} = N\Delta t$.

The velocity autocorrelation function $\langle \dot{x}(t)\dot{x}(0)\rangle$ is then defined as:

$$\langle \dot{x}(t)\dot{x}(0)\rangle = \frac{1}{(\Delta t)^2}\langle \Delta x(t)\Delta x(0)\rangle = \frac{f_{acq}^2}{N}\sum_i \Delta x(t + i\Delta t)\Delta x(i\Delta t) \tag{3.29}$$

with N the total number of acquired points.

$\langle \dot{x}(t)\dot{x}(0)\rangle$ can be normalized by its initial value in an incompressible fluid:

$$\langle \dot{x}^2(0)\rangle = k_B T/(m_s + m_f/2) \text{ at } t = 0.$$

The MSD is calculated from $x(t)$ as:

$$\langle \Delta x^2(t)\rangle = \frac{1}{N}\sum_i [x(t + i\Delta t) - x(i\Delta t)]^2 \tag{3.30}$$

The discrete Fourier transform of $x(t)$ is: $\tilde{x}(f) = (1/f_s)\sum_i e^{i2\pi tf/N}x(t)$, where $t = i\Delta t$ and $i = 0, \pm 1, \ldots, \pm N/2$ and the power spectral density follows as:

$$\langle |\tilde{x}(f)|^2\rangle = \frac{|\tilde{x}(f)|^2}{t_{tot}} \tag{3.31}$$

3.3.4
Temporal and Spatial Resolution of the Instrument

Apart from the signal arising from the particle's thermal fluctuations, anything that changes the intensity recorded by the quadrant photodiode will limit the resolution of the system. The main noise sources are the mechanical instabilities

of the microscope, and electronic noise combined with laser intensity fluctuations and pointing instabilities. Mechanical instabilities mainly cause low-frequency noise (drift). Laser intensity fluctuations may lead to temporal variations in the spring constants of the optical trapping potential, and pointing instabilities to unwanted drifting of the trapping focus in the specimen plane. To quantify the contribution of laser noise to the measured signal $x(t)$, it is decomposed in:

$$x(t) = x_s(t) + x_n(t)$$

where $x_s(t)$ is the particle's thermal fluctuations and $x_n(t)$ is the noise contribution to the signal. A subtraction of its contribution can increase the quality of the signal. With the assumption that position fluctuations of the sphere and the noise are uncorrelated – that is, $\langle x_s(t)x_n(t')\rangle = 0$ – the velocity autocorrelation function can be written as:

$$\langle \dot{x}(t)\dot{x}(0)\rangle = \langle \dot{x}_s(t)\dot{x}_s(0)\rangle + \langle \dot{x}_n(t)\dot{x}_n(0)\rangle$$

the MSD of the acquired signal as:

$$\langle \Delta x^2(t)\rangle = \langle \Delta x_s^2(t)\rangle + \langle \Delta x_n^2(t)\rangle$$

and similarly,

$$|\tilde{x}(f)|^2 = |\tilde{x}_s(f)|^2 + |\tilde{x}_n(f)|^2,$$

where $\tilde{x}_s(f)$ and $\tilde{x}_n(f)$ are the Fourier transforms of $x_s(t)$ and $x_n(t)$ respectively.

The calibrated (see Section 3.4.1) position fluctuations as a function of time of a trapped sphere (resin, radius $a_s = 1\,\mu\text{m}$ in water, $k \approx 5\,\mu\text{N m}^{-1}$, $f_{acq} = 5\,\text{MHz}$, $t_{tot} = 2\,\text{s}$) are shown in Figure 3.6a (red line). The blue line represents the recordings of the empty trap's noise signal $x_n(t)$ after the sphere has been released. $x_n(t)$ can be minimized by optimizing the illumination pattern of the incident laser spot on the QPD. The comparison between $x_s(t)$ and $x_n(t)$ indicates that the laser noise contribution in this configuration is very small, and its influence on the VAF, MSD and PSD are shown in Figure 3.6b–d, respectively. As expected, the velocity fluctuations of the laser spot without a scattering particle are uncorrelated and fluctuate around zero (Figure 3.6b, blue line). Correspondingly, $\langle \Delta x^2(t)\rangle_n$ is small and constant (Figure 3.6c, blue line), whereas $\langle \Delta x^2(t)\rangle$ increases with time (Figure 3.6c, red line). The resolution of the MSD of the sphere's position fluctuations can then be enhanced by subtracting $\langle \Delta x^2(t)\rangle_n$ from $\langle \Delta x^2(t)\rangle$. The spatial resolution of $\sim$8 Å achieved by the apparatus can be read from the first time points of the MSD (inset of Figure 3.6c, indicated by brackets).

In the frequency domain (Figure 3.6d), we define f_N as the frequency at which the power spectrum of the trapped bead (red line) drops to the noise level given by the power spectrum of the empty trap (blue line). The amplifier has a Butterworth-type low-pass filter with a cut-off frequency at 1 MHz, which is slightly above the frequency $f_N \approx 0.8\,\text{MHz}$. Therefore, in the following section we will analyze data in the frequency range up to a maximum of 0.5 MHz, setting the time resolution

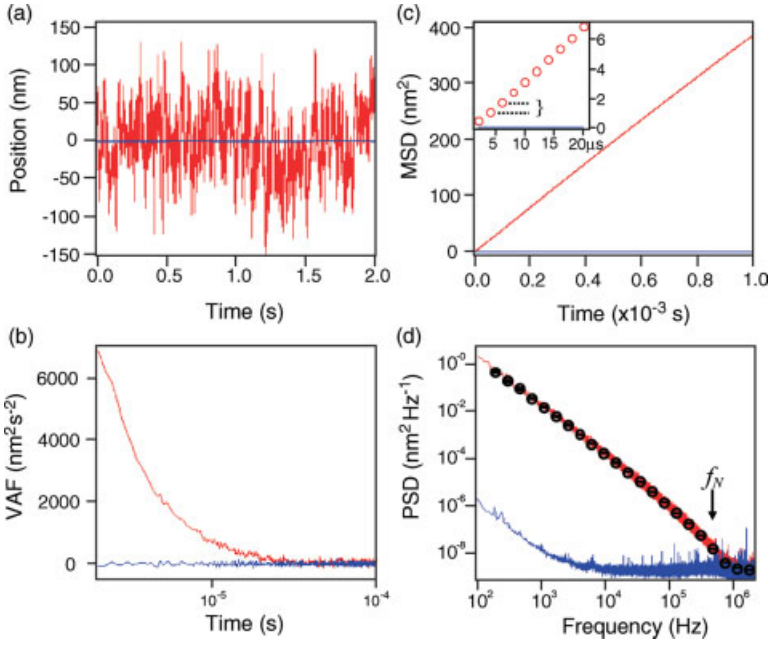

Figure 3.6 (a) Position signal of the sphere ($a_s = 2\,\mu m$) in the trap (red) and of the empty trap (blue) acquired during $t_{tot} = 2$ s at $f_{acq} = 5$ MHz; (b) VAF, (c) MSD and (d) PSD calculated from the position signal (the black circles represent the PSD blocked in five bins per decade). The frequency f_N, where the signal reaches the noise floor, is indicated by an arrow.

of the OTI system at 2 µs. Additionally, in order to avoid aliasing artifacts [38] from the data acquisition card, the acquired signal is oversampled by a factor of 2; $f_{acq} > 2f_N$.

When plotting the VAF and PSD on a log-log scale, further data processing can be made to enhance noisy data. As both functions are distributed exponentially, the number of points in a log-log plot will increase with, respectively, time or frequency. Therefore, data are commonly averaged from a 'block' of consecutive data points [39], resulting in equidistantly distributed points on the logarithmic scale. In the example discussed above, data were blocked in five bins per decade (Figure 3.6d, black circles). The data scattering around their average value gives the standard error, which remains within the size of the black circles. Together with improving the visibility of data, blocking allows fitting the data by the least-squares method, which assumes that the analyzed data points are statistically independent and conform to a Gaussian distribution [27]. Whilst the second assumption is satisfied by the VAF and PSD (as defined in Equations 3.29 and 3.31), the first assumption is satisfied only after blocking.

3.4 High-Resolution Analysis of Brownian Motion

After having characterized the performance of the OTI set-up, we can now present measurements on details in the Brownian motion of the model sphere. We demonstrate that the theory presented in Section 3.2 may be used for fitting and calibrating the data. The influence of experimentally relevant parameters on Brownian motion will be demonstrated, and the consequences of the presence of inertial effects in the data discussed.

3.4.1 Calibration of the Instrument

Position signal calibration consists of determining the detector sensitivity β and the spring constant k of the optical trapping potential. The term β has units of $\mathrm{V\,nm^{-1}}$, as the acquired position signal is recorded in volts, and the position of the particle is expressed in nanometers. Both, experimental and theoretical investigations [40] have shown that, close to the trap center, the optical trapping forces are well approximated by three orthogonal forces derived from a harmonic trapping potential. For a given wavelength of the laser beam, the spring constant along each direction depends mainly on the particle's size, the difference between refractive indices of particle and fluid, and the intensity of the trapping laser light. When the sphere's radius is known, the physics of Brownian motion in a harmonic potential (see Section 3.2.2.2) can be exploited to calibrate the optical trap [38]. Either of three quantities presented in Section 3.3.3 – namely the VAF, MSD or PSD – can be used to obtain β and k simultaneously. An overview is provided in Figure 3.7 for measurements of a resin sphere with radius $a_s = 0.5\,\mu\mathrm{m}$, $f_{acq} = 0.5\,\mathrm{MHz}$, $t_{tot} = 20\,\mathrm{s}$. For least-square fitting, the VAF (top graph) is normalized by its initial value, blocked in 10 bins per decade, and represented in a linear-log plot, whereas the PSD (bottom graph) is blocked in 10 bins per decade and plotted on a log-log scale. As can be seen by comparing Figures 3.2 and 3.6, the bandwidth of OTI allows the measurement of Brownian motion within a time range, during which it is greatly influenced by the hydrodynamic memory effect. Hence, the calibration must be made by using a theory that accounts for the fluid's inertia – that is, using Equation 3.26 instead of Equation 3.8 for fitting the VAF, Equation 3.27 instead of Equation 3.9 for fitting the MSD, and Equation 3.28 instead of Equation 3.10 for fitting the PSD. The black continuous line in each graph of Figure 3.7 therefore corresponds to Equations 3.26, 3.27and 3.28, respectively, being fitted to the data (red circles) with the two fitting parameters β and k. All three fits generally provide an accuracy of better than 6%, depending on the acquisition frequency and total acquisition time. The relative difference for all fitted values of β acquired by either of each equation is less than a small percentage [41]. The trapping force constant k (see Table 3.2 and next section) is obtained from the long-time and respectively low-frequency, limits of each function, according to Equations 3.21, 3.24 and 3.25, or from the corner frequency ϕ_k in Equation 3.23. The two main sources of error are uncertainties in the determination of the bead size and of the temperature

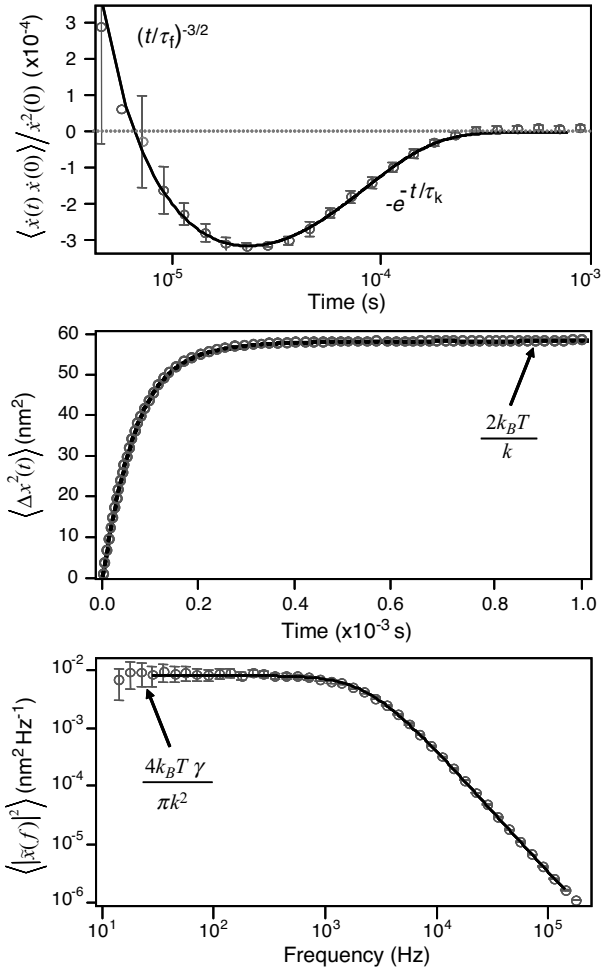

Figure 3.7 Measured VAF (raw data as red line, blocked values as red circles), MSD (circles, data points were removed for clarity) and PSD (only blocked values are shown as circles). The respective fits calculated from Equations 3.26, 3.27or 3.28 are plotted as black lines.

inside the laser focus. The latter can lead, in particular, to unwanted fluctuations in the fluid's viscosity and density [42].

3.4.2
Influence of Different Parameters on Brownian Motion

In this section we describe the influences of the trapping potential, the surrounding fluid's properties and the particle's properties on Brownian motion.

Table 3.2 Comparison of the three values k_1, k_2 and k_3 obtained from fitting the exponential relaxation time, the corner frequency, or the long time limits of the MSD and PSD.

	k_1	k_2	k_3
$\tau_k = \frac{6\pi\eta_f a_s}{k}$	$69\,\mu s \rightarrow 136\,\mu N\,m^{-1}$	$293\,\mu s \rightarrow 33\,\mu N\,m^{-1}$	$798\,\mu s \rightarrow 12\,\mu N\,m^{-1}$
$\phi_k = \frac{k}{12\pi^2\eta_f a_s}$	$2361\,Hz \rightarrow 140\,\mu N\,m^{-1}$	$547\,Hz \rightarrow 32\,\mu N\,m^{-1}$	$197\,Hz \rightarrow 12\,\mu N\,m^{-1}$
$\langle \Delta x^2(t)\rangle_{t\rightarrow\infty} = \frac{2k_BT}{k}$	$58.6\,nm^2 \rightarrow 139\,\mu N\,m^{-1}$	$243.3\,nm^2 \rightarrow 33\,\mu N\,m^{-1}$	$998\,nm^2 \rightarrow 8\,\mu N\,m^{-1}$
$\langle \lvert\tilde{x}(f)\rvert^2\rangle_{f\rightarrow 0} = \frac{96k_BT\eta_f a_s}{k^2}$	$10^{-2}\,nm^2\,Hz^{-1} \rightarrow 135\,\mu N\,m^{-1}$	$1.6\times10^{-2}\,nm^2\,Hz^{-1} \rightarrow 35\,\mu N\,m^{-1}$	$10^{-2}\,nm^2\,Hz^{-1} \rightarrow 7\,N\,m^{-1}$

3.4.2.1 Changing the Trap Stiffness

The influence of k on each quantity is shown in Figure 3.8 for the example of a resin sphere, with $a_s = 0.5\,\mu m$, held in three different potentials $k_1 = 140\,\mu N\,m^{-1}$ (red line), $k_2 = 32\,\mu N\,m^{-1}$ (blue line) and $k_2 = 12\,\mu N\,m^{-1}$ (green line). The variation of the trapping potential was achieved experimentally by changing the neutral density filter in front of the laser (NF1 in Figure 3.4). The acquisition frequency and time were chosen as: $f_{acq} = 0.5$ MHz, $t_{tot} = 20$ s. Changing k varies only τ_k, while τ_p and τ_f remain constant, as the particle's and the fluid's properties are fixed ($\tau_p = 0.084\,\mu s$, $\tau_p = 0.25\,\mu s$).

In the VAF (top graph, Figure 3.8), a distinction can be made between the three regimes in which the velocity correlations are either positive ($t < 10^{-5}$ s), negative ($10^{-5}\,s < t < 10^{-3}$ s), or vanish ($t > 10^{-3}$ s). As stated by Equation 3.16 and shown in Figure 3.2 (top, blue line), the velocity correlations of a free particle are always positive. However, a particle in an optical trap experiences an additional drift towards the trap center due to $F_{ext}(t)$. As the direction of the potential's restoring force $F_{ext}(t) = -kx(t)$ is opposite to the direction of the initial velocity $\dot{x}(0)$, the harmonic potential eventually introduces negative correlations, so-called anti-correlations in the VAF. As expected, the anti-correlations increase with k. The relaxation time τ_k describes the time scale for which $F_{ext}(t)$ makes the particle return from a displaced position to the trap center. For the stiffer trap in this example we find, from fitting, $\tau_{k_1} = 69\,\mu s$, while for the softer trap $\tau_{k_3} = 798\,\mu s$. As seen in the three data sets in Figure 3.8, $\langle \Delta x^2(t)\rangle_{t\rightarrow\infty}$ and, respectively, $\langle \lvert\tilde{x}(f)\rvert^2\rangle_{f\rightarrow 0}$ approach a constant value that is inversely proportional to k (Equation 3.24) or correspondingly k^2 (Equation 3.25). In Table 3.2 it can be seen that the values for k_1, k_2 and k_3 obtained from each relationship are consistent with each other, and vary by a maximum of 10%, except for k_3. A better precision for characterizing such soft trapping potentials can be obtained by acquiring data over longer times, as this increases the number of points in the time range of τ_k (data not shown).

The data in Figure 3.8 show that for $t < 10^{-5}$ s and, respectively, $f > 10^{-4}$ Hz, there is a time range during which the particle is free from any influence of the potential. As this time range is longer for weaker traps, in order to study the influences of the fluid and the particle on Brownian motion separately from the influence of an external

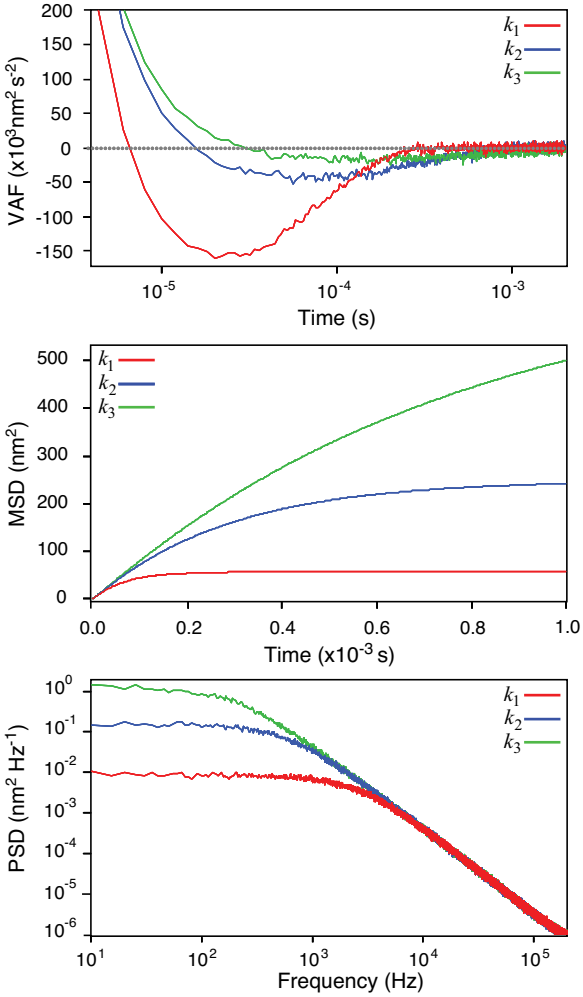

Figure 3.8 Measured VAF, MSD and PSD for three different force constants: $k_1 = 140\,\mu N\,m^{-1}$ (red line), $k_2 = 32\,\mu N\,m^{-1}$ (blue line) and $k_2 = 32\,\mu N\,m^{-1}$ (green line).

force, the trapping stiffness is minimized and the OTI configuration is used solely as a position detector for single particle tracking.

3.4.2.2 Changing the Fluid

In order to study the influence of the fluid's inertia and detect the long-time tail in the normalized VAF (see Figure 3.1 and Section 3.2.2.1), we track the Brownian motion of a larger resin sphere ($a_s = 1.5\,\mu m$, $\rho_s = 1.51\,kg\,dm^{-3}$, $f_{acq} = 0.5\,MHz$, $t_{tot} = 20\,s$) in three different solvents having different viscosities η_f and, unavoidably, different densities ρ_f (Figure 3.9). The resin beads are suspended either in a more viscous

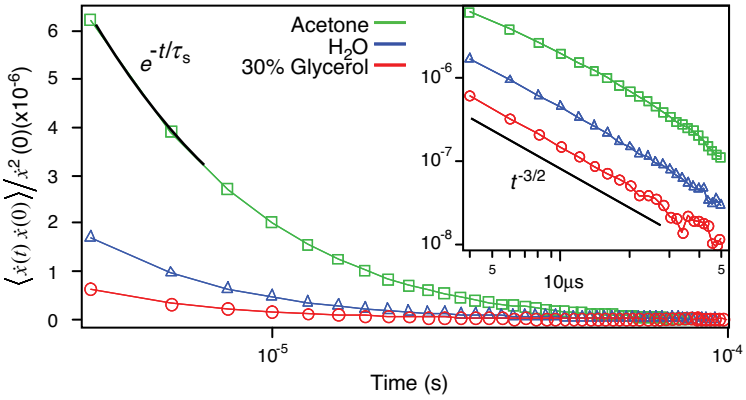

Figure 3.9 Log-linear representation of the measured normalized VAF of a resin sphere ($a_s = 1.5\,\mu m$, $\rho_s = 1.51\,kg\,dm^{-3}$, $f_{acq} = 0.5$ MHz, $t_{tot} = 20$ s) with $k \approx 10\,\mu N\,m^{-1}$, for three different fluids; 30% glycerol in H_2O ($\rho_f = 1.18\,kg\,dm^{-3}$, $\eta_{30\%glycerol} = 2.11 \times 10^{-3}$ Pa·s, ○), H_2O ($\rho_f = 1.118\,kg\,dm^{-3}$, $\eta_{H2O} = 10^{-3}$ Pa·s, △) and acetone ($\rho_f = 0.790\,kg\,dm^{-3}$, $\eta_{acetone} = 0.306 \times 10^{-3}$ Pa·s, □). Fits correspond to the continuous line with the respective color. Inset: log-log plot of the same VAFs. The $t^{-3/2}$ power-law is indicated by the black line.

solution of 30% glycerol in water ($\rho_{30\%Glycerol} = 1.18\,kg\,dm^{-3}$, $\eta_{30\%Glycerol} = 2.11 \times 10^{-3}$Pa·s, ○), in pure water with an intermediate viscosity ($\rho_{H_2O} = 1\,kg/dm^3$, $\eta_{H_2O} = 10^{-3}$ Pa · s, △), or in pure acetone ($\rho_{acetone} = 0.790\,kg\,dm^{-3}$, $\eta_{acetone} = 0.306 \times 10^{-3}$ Pa·s, □), the fluid with the lowest viscosity we could find. Decreasing η_f results in increasing not only τ_f as: $\tau_{30\%Glycerol} = 1.26\,\mu s$, $\tau_{H_20} = 2.25\,\mu s$ and $\tau_{acetone} = 5.8\,\mu s$, but also τ_s as: $\tau_{s_{30\%Gl}} = 0.36\,\mu s$, $\tau_{s_{H_20}} = 0.76\,\mu s$ and $\tau_{s_{ac}} = 2.48\,\mu s$. As $\tau_f$and τ_s depend on a_s^2, the use of a larger Brownian particle increases both time scales and places them closer to (or even within) the detection bandwidth of the instrument. The choice of a resin sphere in this particular experiment is motivated by the fact that resin, unlike polystyrene, is not soluble in acetone. Furthermore, the difference between the refractive indices of resin ($n = 1.68$) and acetone ($n = 1.36$) is still high enough to provide a good contrast and allow visualization of the particle by optical microscopy, which is not the case for example, with silica ($n = 1.37$).

In order to obtain anticorrelations that are negligible compared to the detection limit, the trap stiffness is reduced to $k \approx 10\,\mu N\,m^{-1}$, and hold this constant from one fluid to the other. However, this does not prevent τ_k from changing, as it is dependent on η_f as: $\tau_{k_{30\%Glyc}} \approx 5.9$ ms, $\tau_{k_{H2O}} \approx 2.84$ ms, $\tau_{k_{aceton}} \approx 950\,\mu s$. With such a weak trap the persistent positive correlations arising from the hydrodynamic back-flow introduced in Section 3.2.1.2 can be readily identified up to 50 μs. The data are best fitted by the normalized Equation 3.26 (continuous lines). In Figure 3.9, it can be seen that, as expected, for lower viscosities the correlations last longer (green line). Furthermore, the log-log representation in the inset allows recognizing of the $t^{-3/2}$ power law decay (black line) that is followed by all three fluids. In acetone, as $\tau_{s_{ac}} \approx 3\,\mu s$ is also within the detection range, it is possible to detect between 2 and 6 μs an exponential tendency arising from the combined fluid's and particle's inertia (Figure 3.9, green line).

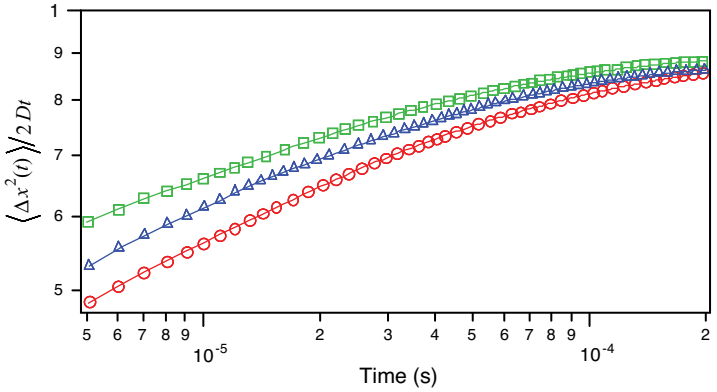

Figure 3.10 Comparison of the motion of particles with the same radius but different densities. Log-log representation of the measured normalized MSD for a silica sphere ($a_s = 1.97\,\mu m$, $\rho_s = 1.96\,kg\,dm^{-3}$, ○), of a resin sphere ($a_s = 2\,\mu m$, $\rho_s = 1.51\,kg\,dm^{-3}$, △) and a polystyrene sphere ($a_s = 1.94\,\mu m$, $\rho_s = 1.05\,kg\,dm^{-3}$, □). Fits correspond to the continuous line with the respective color.

3.4.2.3 Changing the Particle Density

The direct influence of the particle's inertia can be determined by comparing the motion of particles with approximately the same size but different densities. The MSD was calculated from the measured position fluctuations ($f_{acq} = 1\,MHz$, $t_{tot} = 10\,s$) of a silica sphere ($a_s = 1.97\,\mu m$, $\rho_s = 1.96\,kg\,dm^{-3}$, red line), of a resin sphere ($a_s = 2\,\mu m$, $\rho_s = 1.51\,kg\,dm^{-3}$, blue line) and a polystyrene sphere ($a_s = 1.94\,\mu m$, $\rho_s = 1.05\,kg\,dm^{-3}$, green line) in water with $\tau_f \approx 3.9\,\mu s$. The influence of the trap was again kept minimal at $k \approx 14\,\mu N\,m^{-1}$ for the three different beads. Hence, the MSD can be normalized by its long-time limit $\langle \Delta x^2(t) \rangle_{free} = 2Dt$ in the free regime, when $F_{ex}(t) \approx 0$, as shown in Figure 3.10. Equation 3.27 (continuous lines) corresponds to the best fit of the data (silica ○, resin △, polystyrene □). Here, the inertia of the perturbed fluid does not change, so that τ_f stays constant, while the inertias of the three particles are different and lead to different values of τ_s; $\tau_{s_{silica}} = 1.69\,\mu s$, $\tau_{s_{resin}} = 1.34\,\mu s$ and $\tau_{s_{PS}} = 0.88\,\mu s$. Even though differences in τ_s are in fact small compared to the time resolution of $2\,\mu s$, the contribution expected from the particle's mass can still be detected.

Changing the particle's radius a_s is equivalent to varying both τ_f and τ_s, while keeping τ_s/τ_f constant (data not shown) [34].

3.4.3 Implications of the Existence of Long-time Tails in Nanoscale Experiments

Having demonstrated agreement between Brownian motion theory and OTI data, and studied the influence of parameters which can be varied experimentally, we can derive a rule of thumb to estimate the time range during which the particle's motion

can be considered as effectively free from the influence of the trap. Furthermore, we can determine for how long the inertia of a Newtonian fluid will influence the Brownian probe's motion and prevent it from performing a diffusive random walk inside an optical trapping potential. This sets the bandwidth of OTI for high-resolution single particle tracking to probe locally many different media.

3.4.3.1 Single Particle Tracking by OTI

We define the time τ_{free} starting from which the optically confined MSD given by Equation 3.27 begins to deviate by at least 2% from the free MSD described by Equation 3.17. We record the motion of different polystyrene spheres of sizes $a_s = 0.27$, 0.33, 0.50, 0.74, 1.00 and 1.25 μm confined by potentials with a spring constant ranging from 1 to 100 μN m^{-1}. For stronger traps ($\tau_k < 1$ ms), the data are recorded at 500 kHz during 20 s and calibrated in the range between 2 μs and 1 ms. For softer traps ($\tau_k > 1$ ms), the data are recorded at 200 kHz for 50 s and calibrated between 5 μs and 10 ms. In Figure 3.11, τ_{free} is represented as a function of τ_k in a log-log scale, which allows us to formulate an approximate empirical relation between both time scales [41]:

$$\tau_{free} = \tau_k/20 \tag{3.32}$$

Hence, in the time range [2 μs, τ_{free}], which is limited on one side by the noise floor (see Figure 3.6) and on the other side by $\tau_k/20$, OTI can track the motion of a single free Brownian particle. Under these conditions, the sphere probes only its local environment, for up to three decades in time.

3.4.3.2 Diffusion in OTI

The next issue to address is the question of whether or not the Brownian probe has time to reach a purely diffusive behavior before it becomes confined by the potential of the trap. This is equivalent to studying the influence of inertial effects on the particle's motion in the optical trap at times shorter than τ_{free}. Therefore, we investigate the diffusion of a small sphere, which is expected to perturb the fluid less, and hence τ_f and the hydrodynamic memory effect are smaller. Furthermore, we adjust the trapping potential to be the softest possible, as the time region where the particle's motion is free from the influence of the trap lasts longer for high τ_k.

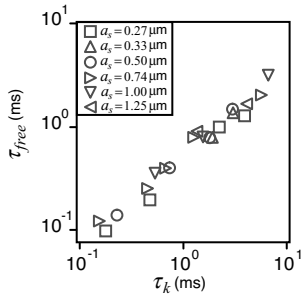

Figure 3.11 Log-log representation of τ_{free} versus τ_k for polystyrene spheres of different radii $a_s = 0.27$, 0.33, 0.50, 0.74, 1.00 and 1.25 μm.

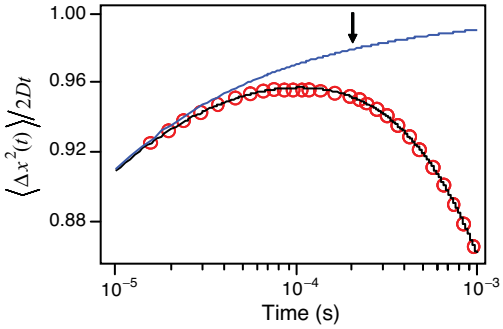

Figure 3.12 $\langle \Delta x^2(t) \rangle / 2Dt$ for the sphere with $a_s = 0.27\,\mu m$ and $k = 1.5\,\mu N\,m^{-1}$, $f_{acq} = 0.2$ MHz, $t_{tot} = 50$ s, fitted by Equation 3.34 (black line). The theory for the free particle is given by the blue line corresponding to Equation 3.24. The arrow indicates the time when $\langle \Delta x^2(t) \rangle_{free} / 2Dt$ reaches diffusive motion within 2%.

We introduce the dimensionless representation $\langle \Delta x^2(t) \rangle / 2Dt$ to distinguish between the free diffusive motion when $\langle \Delta x^2(t) \rangle / 2Dt = 1$ (see Section 3.2.2.1) and the motion influenced by inertial effects when the particle is either free or optically confined (see Section 3.2.2.1, parts (i) and (ii), respectively). In both cases motion is nondiffusive as $\langle \Delta x^2(t) \rangle / 2Dt < 1$.

The measured $\langle \Delta x^2(t) \rangle / 2Dt$ for a polystyrene sphere ($a_s = 0.27\,\mu m$, $k = 1.5\,\mu N\,m^{-1}$) is shown in Figure 3.12 (red circles), fitted to Equation 3.27 (black line) and compared to $\langle \Delta x^2(t) \rangle_{free} / 2Dt$ given by Equation 3.17 (blue line). Here, it can be seen that $\langle \Delta x^2(t) \rangle / 2Dt$ reaches a maximum of ~0.96, but never 1.

For the free particle, $\langle \Delta x^2(t) \rangle_{free} / 2Dt = 1$ would occur within 2% error after approximately 200 μs (Figure 3.12, arrow). Thus, in order to observe free diffusive Brownian motion, the optical trap would have to be so weak that $\tau_{free} > 0.2$ ms is satisfied, or equivalently $\tau_k > 4$ ms according to Equation 3.32. However, for all the combinations of particle sizes and spring constants studied, we could never adjust such a long relaxation time. In the particular case of the sphere with $a_s = 0.27\,\mu m$, a spring constant $k < 1$ nN/m would be needed to observe free diffusive motion for at least one decade in time. However, such a low spring constant does not allow us to trap and observe the particle for a sufficiently long period of time. Hence, in experiments using optical traps, the motion of a particle is influenced by either memory effects and/or by the harmonic potential [41]. This is in contradiction with assumptions commonly made in optical trapping experiments, where a normal diffusive behavior of the trapped particle is assumed and inertial effects from the fluid are ignored [38, 43].

The time-dependent diffusion coefficient can be derived from the VAF or the MSD as:

$$D(t) = \int_0^t \langle \dot{x}(t') \dot{x}(0) \rangle \mathrm{d}t' = \frac{1}{2} \frac{\mathrm{d}}{\mathrm{d}t} \langle \Delta x^2(t) \rangle \tag{3.33}$$

and approaches the diffusion constant D in the infinite time limit when $F_{ex}(t) = 0$:

$$D = \int_0^\infty \langle \dot{x}(t')\dot{x}(0)\rangle \mathrm{d}t' = \frac{k_B T}{6\pi\eta_f a_s} \tag{3.34}$$

3.4.3.3 Thermal Noise Statistics

According to our findings, the process of optically confined Brownian motion as observed by OTI is non-Markovian up to times $t > \tau_k$, when it becomes dominated by the trapping potential. Only from then on does motion become uncorrelated, $\langle \dot{x}(t)\dot{x}(0)\rangle = 0$, and can position data points be considered as statistically independent. It has been proposed that optical trapping data can be calibrated by thermal noise analysis using Boltzmann statistics [44]:

$$p(x)dx = ce^{-E(x)/k_B T} \tag{3.35}$$

which describes the probability $p(x)dx$ of finding the Brownian particle in the potential $E(x)$ (c normalizes the probability distribution).

From the calibrated time traces acquired with $f_{acq} = 0.5$ MHz, the probability distribution is represented in Figure 3.13 for two different resin spheres with $a_s = 0.5\,\mu$m (red histogram) and $a_s = 2\,\mu$m (green histogram) trapped in a similar potential with $k \approx 12.5\,\mu\mathrm{N\,m^{-1}}$ but obviously different τ_k: $\tau_{k_{small}} = 69\,\mu$s and $\tau_{k_{big}} = 798\,\mu$s. The position histograms, with a bin width of 1 nm, are compared for both spheres, and contain either $N = 400\,000$ data points, corresponding to an acquisition time $t_{tot} = 0.08$ s (top graph), $N = 400\,000$ points, corresponding to an acquisition time $t_{tot} = 0.8$ s (middle graph) or $N = 4\,000\,000$ points, corresponding to an acquisition time $t_{tot} = 8$ s (bottom graph).

Even though in each histogram there are apparently enough data points to perform statistical analysis, these points are clearly not statistically independent. Indeed, the upper histogram features only ~100 statistically independent points for the larger sphere and ~1000 for the smaller sphere. The smaller sphere will sample the trapping potential well more rapidly than the larger, which is translated in the differences between $\tau_{k_{small}}$ and $\tau_{k_{big}}$; therefore, the larger sphere will take ~10-fold longer to explore the potential and, consequently, for statistical analysis the trajectory should be acquired over longer times. The temporal resolution of the Boltzmann statistics method is determined by the time required to record uncorrelated data, and is heavily dependent on the particle's size and τ_k. The high acquisition rates used throughout these studies are not needed in this case.

3.5 Summary and Outlook

In this chapter we have shown how OTI can be used to study Brownian motion down to hydrodynamic time scales, where the response of the surrounding fluid becomes dominant. This is only possible due to the high bandwidth (up to 500 kHz) and

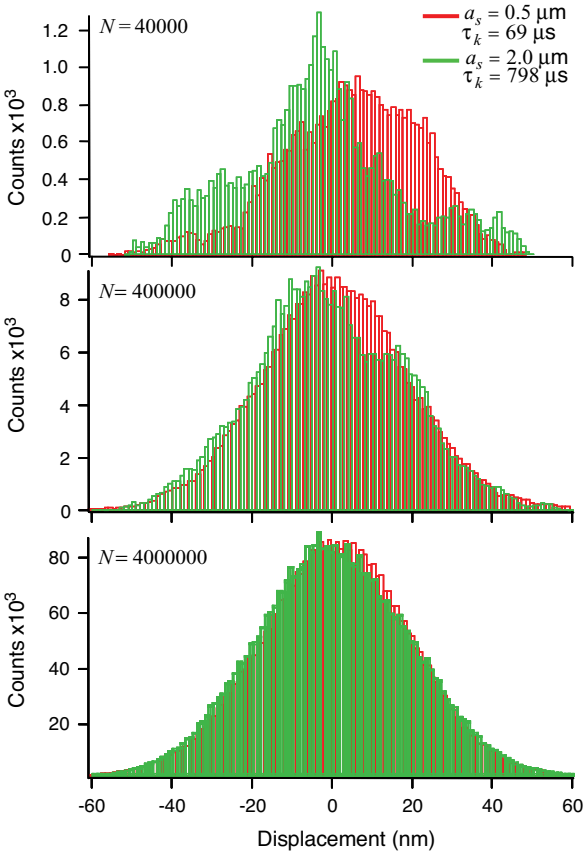

Figure 3.13 Histogram of position fluctuations (bin width of 1 nm) acquired with $f_{acq} = 0.5$ MHz for a sphere with $a_s = 0.5$ µm and $a_s = 2.0$ µm. The number of data points N in the histograms increases from top to bottom from 40 000 ($t_{tot} = 0.08$ s) to 4 000 000 ($t_{tot} = 0.08$ s). The trapping stiffness $k \approx 12.5$ µN m^{-1} is similar for both bead sizes.

subnanometer spatial resolution of the position detection configuration. The precision achieved allows us to detect not only the effects of the fluid's inertia but also the more subtle effects of the sphere's inertia.

The details in the motion of the trapped model sphere provide insight into the interplay between inertial effects and the optical trapping potential, as summarized by Figure 3.14. This shows in particular, the overlap of τ_f, the characteristic time of the

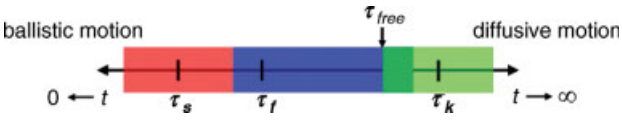

Figure 3.14 Overview of the characteristic times of a Brownian particle confined by a harmonic potential.

viscous fluid, with τ_k, the relaxation time of the restoring force of the trapping potential. The time τ_{free}, which separates τ_f from τ_k, was determined empirically and corresponds to $\sim\tau_k/20$. Below this time, OTI can be used solely as a position detector for *single particle tracking with unprecedented spatial and temporal resolution*.

At these time scales, the sphere performs a non-random walk, dominated by the nature of the surrounding medium [45]. The presented method is capable of providing new insights into the behavior of media that are more complex than just a simple viscous fluid, thus extending the bandwidth of microrheology by two decades in time [46]. For example, the high-frequency response of a viscoelastic polymer solution should provide information on the nanomechanical properties of the polymer molecules. In particular, highly dynamic polymers, such as those encountered in a living cell, should transmit their mechanical and dynamic signatures to the Brownian particle. Furthermore, an obstacle in the particle's trajectory such as a surface, with for example, various chemical functionalities, or a cell membrane, should influence Brownian motion in a characteristic way. Such studies for a variety of biopolymers and surfaces are currently in progress in our laboratory.

Nanoscale Thermal and Mechanical Interactions Studies using Heatable Probes

Bernd Gotsmann, Mark A. Lantz, Armin Knoll, and Urs Dürig

4.1
Introduction

Thermal properties such as thermal conductivity and diffusivity, although rather difficult to measure, are important properties for many applications. For example, in microelectronics, where power densities can be very high, the local generation of heat and its conduction away from the heated region are a major design issue. In general, the interplay between thermal and mechanical properties of solids is a fascinating topic of research, and is of immediate practical relevance in numerous applications. For example, the mechanical properties of soft matter – namely organic polymers – exhibit such a strong temperature dependence that in standard analysis techniques, such as dynamic mechanical thermal analysis (DMTA), both mechanical stress and temperature are varied. Often, the time scale is also varied, making the analysis rather complicated [1]. The local heating of materials is also used as a micromanufacturing technique. In all of these fields, there is a clear trend to extend research down to the nanoscale, and this is further nurtured by the necessity to understand nanoscale properties in order to tailor materials for nanoscale applications. The trend towards nanoscale opens up research fields and applications beyond conventional materials science. The very definition of temperature, which is a thermodynamic (i.e. statistical) concept based on local equilibrium, becomes vague on length scales smaller than the mean free path of heat carriers (typically in the range of 10–100 nm) [2–4]. On the nanoscale, it is commonly observed that interfaces become more predominant in determining materials properties. This is also true of thermal properties in general, and leads to fascinating concepts such as phonon engineering that promise tailored thermal conductance in nanostructures [5].

In order to study and exploit microscale and nanoscale thermal phenomena, a variety of scanning probe microscopy (SPM) -based techniques have been developed, most of which are based on contact scanning force microcopy (SFM). Two examples of exciting technological applications of these techniques are in the areas of nanoscale data storage [6, 7] and lithography [8]. In this chapter, experimental procedures and

results from the broad field of heated-probe SFM are addressed. Although the applications of these techniques are rather diverse, two common elements are the use of a sharp, temperature-sensitive tip and the use of SFM techniques to scan this tip over the surface and simultaneously measure the surface topography. Many of these applications also require a means to heat the tip, in turn to heat the sample, on a highly local scale. In the following sections we first describe the various types of probe that have been developed for thermal scanning probe microscopy, and outline the basics of probe-based imaging of thermal properties. Later, we analyze the various heat-loss mechanisms that play a role in the interpretation of thermal SPM data. Specific applications are discussed thereafter, including thermomechanical nanoindentation, data storage and nanopatterning and lithography.

4.2
Heated Probes

At the heart of all the techniques described in this chapter is a heatable probe with an integrated means of sensing the temperature of the probe tip. As with all scanning probe techniques, the resolution is limited at least in part by the geometry of the tip apex and the area of contact between the tip and the surface. The most widely used heated probe is a Wollaston wire probe. In this technique, a thin, bent platinum/rhodium wire is used to produce heat and detect temperature. For SPM-based applications, the wire is bent into the shape of a cantilever, as illustrated in Figure 4.1. Often, also a mirror is glued onto the back of the cantilever to improve optical detection of the cantilever bending. The temperature of the wire can be determined by measuring its electrical resistance and using the

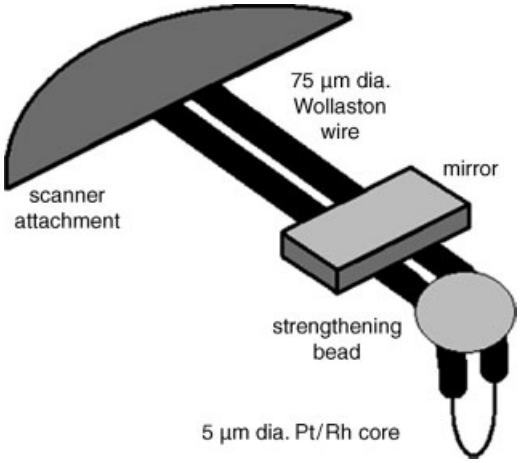

Figure 4.1 Schematic diagram of a thermal probe made from a Wollaston wire process. From Ref. [9].

known temperature dependence of the electrical resistance of the material. Although such probes are accurate and easy to handle, their spatial resolution is limited by the dimensions of the bent wire at the end that acts as the probing tip. To date, the spatial resolution reported using such probes is limited to about ~100 nm (see for example Figure 4.5).

The spatial resolution can be improved by using microfabrication techniques to produce cantilevers with very sharp, temperature-sensitive tips. Shi *et al.* [10] have made such probes using silicon nitride for the cantilever body and microfabricating a platinum tip with a junction to chromium near the tip apex (see Figure 4.2). This junction acts as a thermoelement and can be used to measure the temperature of the tip as it is being scanned over a heated surface, or to investigate local heat sources on a sample. Majumdar *et al.* have used such tips to image hot spots in a very-large-scale integration (VLSI) chip [11] and to image the heat generated by the current flowing through a carbon nanotube [12]. In the latter experiment, an impressive lateral resolution of 50 nm was demonstrated.

Another approach, developed by IBM, uses an all-silicon microfabricated cantilever with an integrated heater and tip (see Figure 4.3) [13]. Here, the largest part of the two-legged cantilever is made from highly doped silicon ($10^{20}\,\mathrm{cm}^{-3}$ As), whereas the part of the cantilever that supports the tip is lower-doped ($5 \times 10^{17}\,\mathrm{cm}^{-3}$) and serves as both heater and sensor. With dimensions of $4\,\mu\mathrm{m} \times 6\,\mu\mathrm{m}$ and a thickness of $\sim$200 nm, the heater has a resistance of few kΩ. The known temperature dependence of the resistivity of doped silicon can be exploited to sense the heater temperature. This type of thermal probe has been used in the majority of the experiments described in this chapter.

The temperature calibration of the heater can be carried out by measuring a current–voltage response curve (I–V curve) of the cantilever (Figure 4.4). For this, a resistor is typically placed in series with the cantilever. The measured voltage drop

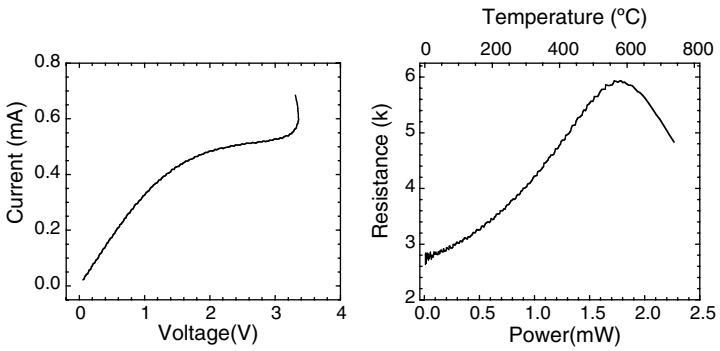

Figure 4.4 Current–voltage (I–V) curve and derived power–resistance (P–R) and temperature–resistance (T–R) curves of an integrated resistive heater.

across the resistor is used to determine the current flowing through the cantilever and, in combination with the measured voltage drop across the cantilever, can be used to calculate the electrical power dissipated in the cantilever. Initially, as the current flowing through the heater is increased, the dissipated power results in an increase in resistance due to increased scattering of the carriers. As the temperature rises, the number of thermally generated carriers also increases, which tends to reduce the rate at which the resistance increases with temperature. When the number of thermally generated carriers equals the number of dopants, the resistance reaches its maximum value, and begins to decrease with further increases in power and temperature. The temperature at which the maximum resistance occurs is a function of the doping density and is known from the literature [15]. The power needed to reach the maximum resistance, $P_{R\max}$, is determined from the measured I–V data. It is assumed that all of the power dissipated in the cantilever contributes to heating of the heater structure, and that the temperature change of the heater is a linear function of the dissipated power. We can then rescale a plot of resistance versus power to a plot of resistance versus temperature using two known values, namely, the resistance at room temperature measured at low very low power, and the temperature at which the maximum resistance occurs. For the doping values used here, the maximum resistance occurs at 550 °C, and the heater temperature can thus be calculated using

$$T_{\text{heater}} = \text{RT} + P(550^{\circ}C - \text{RT})/P_{R\max} = \text{RT} + R_{\text{th}}P,$$

where RT is room temperature.

The implicit assumption here is that the thermal resistance of the system, R_{th}, is independent of the heater temperature, T_{heater}. We find that R_{th} is typically on the order of $10^5\,\text{K}\,\text{W}^{-1}$ under ambient conditions. When checking all of these assumptions by measuring the temperature of the heater by independent means, we found that the resulting systematic error is far below the measurement errors, fabrication tolerances and scatter. Using this calibration method, we estimate an absolute error of about 30% for the temperature difference $\Delta T = T_{\text{heater}} - \text{RT}$. Relative measurements and temperature changes, however, can be conducted with a temperature resolution of ~0.1 K.

The time scale that these heaters are able to probe is related to the thermal equilibration time of the cantilevers. Although the dynamics is not a simple RC-type exponential [14, 16], it can be approximated by a simple exponential and a single time constant. For the cantilevers used in most of the examples discussed below, the time constant is on the order of 7 to 10 µs; this is then the time constant that limits fast thermal sensing. For a rapid application of heat, however, the heater can be operated in nonequilibrium on timescales down to 1 µs and lower [14]. The transient temperature can be sensed reliably at any time scale by means of the electrical resistance. By design, the time constant can be decreased to values below 1 µs, but there are trade-offs between power consumption, sensitivity, time constant, ease of fabrication and the mechanical stability of the cantilever [16, 17]. Therefore, the optimum design depends critically on the application envisaged. For a detailed study of cantilever designs and time constants, the reader is referred to Ref. [14].

4.3
Scanning Thermal Microscopy (SThM)

The thermal conductivity/diffusivity of a sample can be measured by scanning a heated tip on the sample surface of interest and monitoring the heat flow between probe and surface. The heater/tip is usually mounted on a cantilever so that the surface topography can be measured simultaneously with the thermal signal by applying atomic force microscopy (AFM) techniques. This so-called scanning thermal microscopy (SThM) method has recently been reviewed [10, 18–22].

In general, the heater is also used as a temperature sensor so that changes in the heat flow can be measured during scanning. In the Wollaston wire approach, this is achieved by measuring a thermo-voltage, whereas in the IBM approach the temperature-dependent heater resistance is measured; when the tip is in contact with the surface, the contact forms a heat-loss path. The corresponding thermal conductivity can be visualized by measuring changes in the tip temperature that result from changes in the thermal conductivity as the tip is scanned over the surface. However, to be able to sense this local heat loss, the conductivity must be large enough to produce a measurable signal if compared with the electrical noise in the transducer. An example of a local thermal conductivity map of a polymer blend by Reading *et al.* [18] is shown in Figure 4.5. In such a SThM image the color contrast depends on the local thermal conductivity.

Using this technique, it is relatively straightforward to produce a qualitative image of relative differences in thermal conductivity. Quantitative measurements, however, are significantly more challenging and require knowledge of both the tip–sample contact geometry and all of the various thermal resistances and parasitic heat-loss paths in the system (see Section 4.4). In contrast to the electronic case, heat paths

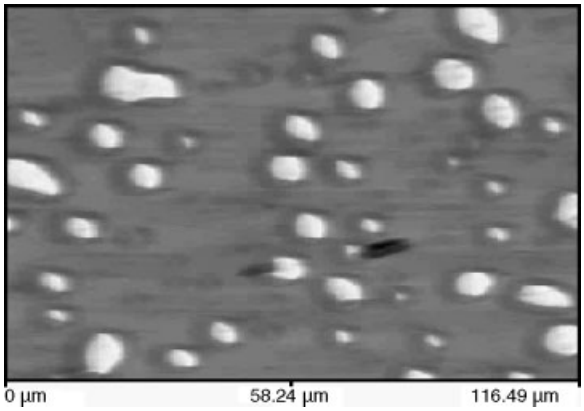

Figure 4.5 Scanning thermal microscopy image of a polymer blend. The two phases can be clearly distinguished in the thermal signal. (Reprinted from Ref. [18]; © 1998; International Scientific Communications, Inc.)

cannot easily be insulated, and therefore a heater typically has several heat-loss paths. The main heat-loss paths, which do not vary with the local sample conductivity, are conduction through the cantilever legs, nonlocal air conduction between heater and sample surface, and radiation cooling. Another potential heat-loss path is through a water meniscus that can form at the point of contact between tip and surface. This will effectively increase the heat-conduction cross-section, leading to a reduced lateral resolution. After performing experiments under ambient conditions, Shi *et al.* [10] have concluded that heat transfer between heater and sample is dominated by conduction through a water meniscus. The heat transfer paths are discussed in more detail in Section 4.4.

The method described above can be refined by modulating the heater drive voltage, which results in a modulation of the heat flow to the sample. The resulting ac component of the heater temperature can be measured using a lock-in amplifier and used to produce an ac thermal image. This ac heat-loss signal changes depending on how the modulation period compares with the diffusion time of heat in the tip-surface contact region – that is, lower-frequency signals diffuse further than do high-frequency signals. Thus, by varying the modulation frequency of the heater, the probing depth can be controlled. This can be seen in Figure 4.6, which shows two ac thermal images taken at 1 and 30 kHz. The sample consists of islands of high-thermal-conductivity material surrounded by low-thermal-conductivity material, both covered by a polymer layer. In the image taken at 1 kHz, the ac signal probes below the polymer layer and strong material contrast is observed, whereas at 10 kHz both probing depth and contrast are significantly reduced.

The limits of the SThM technology are not easily defined. There is a trade-off between time and temperature resolution on the one hand, and spatial resolution on the other hand. For example, increasing the contact area between the tip and sample increases the thermal conductivity, resulting in larger signals and therefore improved sensitivity – but at the expense of reduced lateral resolution. As will be shown below (Section 4.4), the high thermal impedance of the tip and the tip–surface interface make working on samples with high thermal conductivity challenging. Ideally, the

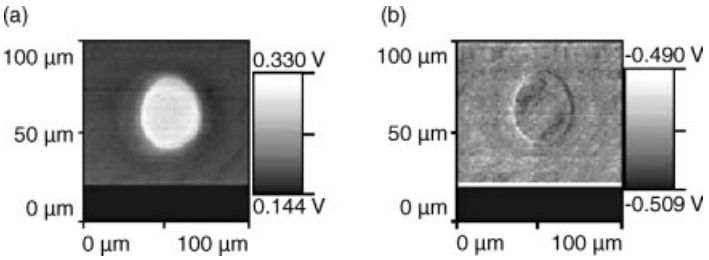

Figure 4.6 Two ac thermal images of a sample with an island of high-thermal-conductivity material within a matrix of low-thermal-conductivity material, both covered by a polymer coating. Image (a) was taken at 1 kHz and image (b) at 30 kHz. (Reprinted from Ref. [18]; © 1998, International Scientific Communications, Inc.)

thermal impedance of the tip and tip–surface interface should be comparable to, or smaller than, those of the sample. The tip and tip–sample interface impedances increase as the tip is made sharper and the contact area reduced, making high-spatial-resolution experiments challenging. Nevertheless, a spatial resolution in the range of some tens of nanometers is feasible on some samples. For example, Shi *et al.* have demonstrated a resolution better than 100 nm on metallic wires [10] and better than 50 nm when imaging a carbon nanotube [12]. A challenge for the quantitative analysis of SThM images is the unknown interaction volume under the probing tip [19]. Nevertheless, the method is very successful in the study of polymers and biological samples. For a recent review, see Ref. [19].

An example of high-lateral-resolution SThM is given in Figure 4.7. Here, the very small contrast between two materials of similar thermal conductivity (silicon oxide and hafnium oxide) is observed. The sample consisted of 2 nm-thick islands of SiO_2 surrounded by a 3 nm-thick film of HfO_2 on a single-crystal silicon substrate. Note that both materials have a considerably higher thermal conductivity than polymers. The measurements were performed in a high-vacuum environment using silicon probes with integrated silicon heaters (as described in Section 4.2). A lateral resolution of ~25 nm was achieved, and the previously unknown thermal conductivity of the 3 nm-thick HfO_2 film was determined. This example nicely demonstrates the potential of using SThM for quantitative measurements, even at high spatial resolution.

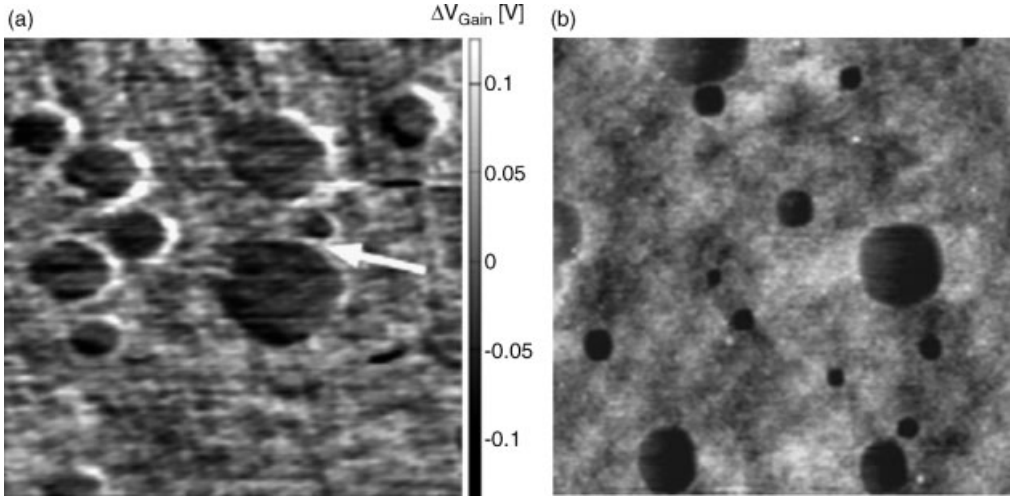

Figure 4.7 (a) Scanning thermal microscopy image (1.6 µm × 1.8 µm) and (b) topography image (2 µm × 2 µm × 5 nm) of a HfO_2 film on a Si substrate. The round holes are filled with 2 nm-thick SiO_2. From the image contrast between the HfO_2 and the SiO_2 regions, the thermal conductivity of HfO_2 can be determined quantitatively. (Images reproduced from Ref. [23].)

4.4
Heat-Transfer Mechanisms

Most of the applications described in this chapter use a sharp, heated probe to deliver heat to a surface on a highly localized scale. However, this process is often rather inefficient because of the high thermal resistance of nanometer-sharp tips and nanometer-sized contact areas, in combination with the other parasitic heat-loss paths present in the system.

In this section, we analyze the various heat-loss paths and mechanisms that can play a role in heated-probe experiments. The analysis in this section is taken from some unpublished results of U. Dürig and B. Gotsmann. The majority of heat-loss paths are undesirable in the sense that they do not contribute to the image contrast in SThM and reduce the efficiency of delivering heat to the sample in other applications. The various heat-loss mechanisms that can contribute to heat loss from a heated tip are illustrated in Figure 4.8 and described in more detail in the corresponding Sections 8.4.1–8.4.6. Which of these mechanisms contribute in a given experiment and the relative magnitudes of their contributions depend on the details of the cantilever design and the experimental conditions. The potentially undesirable heat-loss mechanisms include conductive heat loss through air and the cantilever (Section 4.4.1) and also thermal radiation (Section 4.4.2). Heat conduction through the tip is desirable, but the thermal resistance of the tip (Section 4.4.4) and conduction through a water meniscus (Section 4.4.3) that can form between the tip and sample limit the sensitivity and resolution. The thermal resistance of the tip–surface interface (Section 4.4.6) and the thermal spreading resistance in the sample (Section 4.4.5) are material-specific and determine the image contrast in SThM. The relative magnitudes of these resistances also play an important role in determining the efficiency of heat delivery to the sample. As a quantitative example, we calculate the thermal impedances of the various heat-loss paths for the microfabricated silicon cantilever with integrated silicon heater described at the end of Section 4.2. Finally, in Section 4.4.7, we describe a set of experiments designed to quantify the various thermal resistances.

4.4.1
Heat Transport Through the Cantilever Legs and Air

Microfabricated silicon heater structures integrated into a cantilever structure typically have a minimum size on the order of micrometers. Usually, they are integrated into 'u'-shaped cantilever structures that provide both mechanical support and electrical connections to the heaters. These cantilever structures result in additional heat-loss paths that, however, do not go through the tip but rather into the support structure and from there into the surrounding air. If the cantilever is close to a sample surface, then a fraction of this heat will be conducted through the air into sample, but will not lead to a significant temperature increase in the sample owing to the distributed nature of the heat transfer. The thermal coupling between cantilever and sample is relatively strong if the cantilever–surface distance is comparable to the

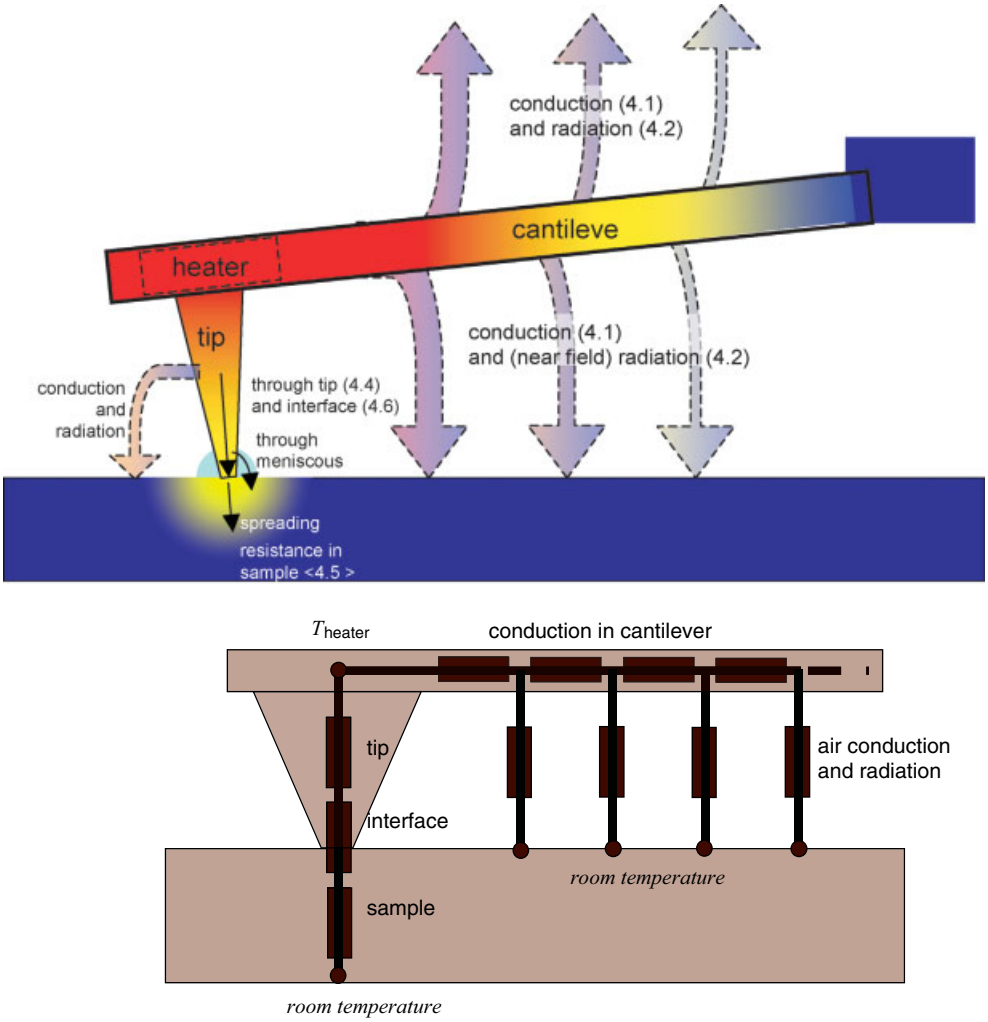

Figure 4.8 (a) Heat paths relevant for experiment using heated probes (numbers refer to text sections in which they are described); (b) Schematic representation as thermal resistances. Note that the distinction between tip, interface and spreading resistances is not possible in every case.

mean free paths of air molecules (~60 nm). For the cantilever design shown in Figure 4.3, the tip height is ~500 nm, resulting in a strong coupling to the substrate. For cantilevers that are long relative to the dimensions of the heater and to the cantilever–surface distance, most of the heat is conducted through the air and into the substrate. For the cantilever in Figure 4.3, the conductivity through cantilever allows the heat to spread along the cantilever by a distance on the order of a few tens of micrometers. Heat conduction along the cantilever and into the air is analogous to a

lossy transmission line. Thus, it can be modeled as a series of thermal resistances, describing conduction through the cantilever with a set of parallel resistances at each node that give the conduction through the air to the sample, as illustrated in Figure 4.8b. Earlier studies of the heat transfer through the cantilever–air gap and within the silicon cantilever/heater [14, 16] predicted that for typical dimensions (see Figure 4.3) – that is, a cantilever thickness of ~200 nm – a cantilever/heater–surface distance of 500 nm, a heater size ~5 × 5 μm and a cantilever width of ~5 μm, the thermal resistance of the combined air/cantilever heat loss path is on the order of $10^5\,\mathrm{K\,W^{-1}}$ and the thermal response times are approximately 10 μs. If the cantilever is operated in a vacuum environment, heat loss through the air is eliminated and heat flows directly through the cantilever to the thick silicon cantilever support structure. For the cantilever design shown in Figure 4.3, the thermal resistance of this heat loss path is on the order of $5\text{–}10 \times 10^5\,\mathrm{K\,W^{-1}}$.

4.4.2
Heat Transfer Through Radiation

Heat loss due to thermal black-body radiation, which involves the propagation of electromagnetic waves from a hot object, is described by the Stefan–Boltzmann equation

$$S = \frac{\pi^2 k_B^4}{60\hbar^3 c^2}\left(T_1^4 - T_2^4\right).$$

Here, the cooling power per area, S, is expressed in terms of the Boltzmann constant, k_B, the Planck constant, $\hbar$, the speed of light, c, the temperature of the heated body, T_1, and the temperature of the environment, T_2. For a heater temperature 100 K above the environment temperature, this corresponds to a thermal resistance of $\sim 6 \times 10^8\,\mathrm{K\,W^{-1}}$ for effective heater dimensions of $(9\,\mu\mathrm{m})^2$. Compared to the thermal resistance of the cantilever and air heat-loss paths of about $1\text{–}10 \times 10^5\,\mathrm{K\,W^{-1}}$, the contribution due to black-body radiation is negligible. In ambient conditions, the overall thermal resistance is dominated by air conduction and in vacuum by conduction through the legs to the support structure.

In heated-probe SPM experiments, the distance between the heater and sample is often less than 1 μm. In this case, the Stefan–Boltzmann equation is only an approximation, and near-field effects must be taken into account. Such effects have a long history of theoretical analysis (see for example Refs [24–28]). Experimentally, however, the effect appears difficult to pin down, and very few reports have been made [29–32]. It has been predicted on a theoretical basis that, compared with Stefan–Boltzmann's law, heat transport by evanescent thermal radiation will depend heavily on the materials involved, with a strong distance dependence ($1/d^2$ for most cases) and a weakened temperature dependence (T^2 for most cases) [25]. The effect is also heavily dependent on the dielectric constants of the heater and the sample material. According to theory, we can expect that the near-field effect for a polymer surface is very small. However, for a silicon surface it can be significantly higher, depending on the doping [26–28], but even in this case the effect is expected to be negligible when compared to the total thermal resistance of the cantilever.

Under ambient conditions, the distant-dependent cooling of the heater/cantilever is dominated by air cooling, and therefore it is not possible to observe near-field cooling effects. Under vacuum conditions, the contribution to cooling due to thermal radiation should become measurable – not so much because of the increased overall thermal resistance without air conduction but rather because we can use the distance dependence to demonstrate the existence of near-field cooling. In air, the distance dependence is dominated by air conduction, whereas in a vacuum the air conduction is of course eliminated and conduction through the cantilever legs does not depend on the heater–sample distance. Thus, on approaching a surface in vacuum, any variation in the thermal resistance that is observed prior to tip–surface contact can likely be attributed to near-field radiation effects.

4.4.3
Thermal Resistance of a Water Meniscus

Under ambient conditions, humidity in the air usually results in the formation of a water meniscus around the tip–sample contact. The size and thermal conductance of the meniscus are a function of both humidity and sample material, and therefore are difficult to control. Thermal conduction through such a water meniscus effectively increases the tip–sample contact area and thereby reduces lateral resolution. On the other hand, the meniscus improves thermal contact, especially on rough surfaces, and may even be necessary to make nanoscale measurements possible in the first place. In a groundbreaking report, Shi and Majumdar concluded that in experiments using a $\sim$100 nm-diameter metal tip on a metal surface, the influence of the water meniscus is of the same order of magnitude as the conduction through the solid–solid tip–sample contact [10]. Moreover, they also concluded that for relatively blunt tips under ambient conditions, thermal conduction through the air gap between the tip sidewalls [33] predominates, whereas for sharper tips, solid–solid and water–meniscus conduction dominate [10]. The effects of conduction through a water meniscus can of course be avoided by operating the heated tip in a low-humidity or vacuum environment.

4.4.4
Heat Transfer Through a Silicon Tip

The thermal resistance of the tip stems from the conductance of phonons in the silicon tip and from the layer of native oxide covering it. In the tip, the resistivity is larger than that of bulk silicon because of enhanced phonon scattering at boundary surfaces [3]. The thermal resistance of the silicon tip can be estimated using predictions for the thermal resistivity of silicon nanowires as a function of diameter [34]. Integrating the expression for the varying diameter of a cone-shaped tip with a typical opening angle of 50° down to the apex with a radius of 5–10 nm yields a thermal resistance on the order of 10^6 to 10^7 K W^{-1} because of phonon scattering. This is in agreement with finite-element calculations [35].

To develop a 'hands-on' feeling for this rather complex subject, we first derive a simple model for heat conduction in conical structures, in particular with regard to ballistic phonon transport. Let us initially consider a cylindrical rod with a cross-section $A = d^2\pi/4$ (d = rod diameter). Let us further assume that a constant current I_{th} of thermal energy flows through the rod, which is driven by a temperature difference along the rod axis (x-axis). For a temperature gradient $\Delta T/\Delta x$, the heat flow is)

$$I_{th} = \frac{\kappa A}{\Delta x}\Delta T, \tag{4.1}$$

where κ denotes the thermal conductance of the rod and ΔT is the temperature difference across a cylindrical slice of thickness Δx. In using Equation 4.1, we assume that the phonon mean free path is large compared with the diameter of the rod. For very thin rods, say $d < 100$ nm for crystalline Si, this assumption is no longer valid and one must account for phonon scattering at the boundaries by renormalizing the thermal conductance according to the so-called Mathiessen's rule [36, 37]:

$$\kappa' = \kappa\frac{1}{1+\frac{\lambda}{d}} \approx \kappa\frac{d}{\lambda}, \quad d \perp \lambda, \tag{4.2}$$

where λ denotes the phonon mean free path.

Let us now consider a rotational symmetric, conical conductor with opening angle Θ (see Figure 4.9). The diameter of a circular slice at distance x from the cone tip is thus $d(x) = 2x|\tan(\Theta/2)$. If $d \gg \lambda$, we can calculate the temperature profile along the cone axis by approximating the cone by a stack of short cylindrical rods of length $\Delta x \gg \lambda$ and diameter $d(x)$, yielding ($x_1 - x_2\ \pi\ \Delta x$):

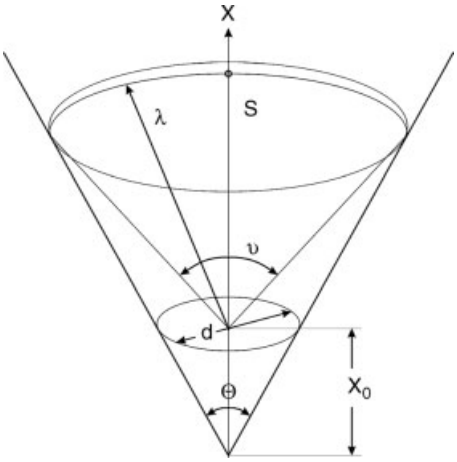

Figure 4.9 Schematic of the conical tip: Θ is cone angle, d the cone diameter at x_0, λ the phonon mean free path, and υ the opening angle for the intersection of the phonon mean free path with the surface of the cone.

$$T_1 - T_2 = I_{\text{th}} \frac{1}{\pi \tan\frac{\Theta}{2}} \int_{x_1}^{x_2} \kappa \frac{dx}{x^2}. \tag{4.3}$$

The cylindrical rod approximation has also been applied for d (λ by simply replacing the constant thermal conductivity κ by the renormalized value κ' [36]. However, it is not obvious that this approach is applicable because the cone cross-section changes significantly over a distance λ along the tip axis. Therefore, let us examine the problem in more detail.

Consider a point on the cone axis at a distance x_0 from the apex (see Figure 4.9). We assume that $d < \lambda$. Let S be the spherical cap defined by the intersection of the conical tip with a sphere of radius λ centered at x_0. A fraction of the phonons emanating from S arrive at x_0 in a direct path without interference from the tip surface. These unperturbed phonons impinge from a solid angle

$$\tan\frac{\upsilon}{2} = \frac{d(x_0+\lambda)}{2\lambda} = \frac{d(x_0)}{2\lambda} + \tan\frac{\Theta}{2}. \tag{4.4}$$

The fraction of the total heat transport seen at x_0 due to these direct phonons is

$$\begin{aligned} \eta^d &= \frac{I_{\text{th}}^d(\upsilon)}{I_{\text{th}}^d(\pi)} \\ &= \frac{2\pi \int_0^{\upsilon} \frac{T(x_0) - (x_0+\lambda)}{dT/dx \cdot \lambda} \cos\upsilon/2 \sin\upsilon/2 \, d\upsilon/2}{2\pi \int_0^{\pi} \cos\upsilon/2 \sin\upsilon 2 \, d\upsilon/2} \\ &= \frac{T(x_0) - T(x_0+\lambda)}{dT/dx \cdot \lambda} \sin^2\upsilon/2 \approx \frac{d(x_0)}{\lambda} \sin^2\upsilon/2. \end{aligned} \tag{4.5}$$

The factor $(T(x_0) - T(x_0 + \lambda))/(\lambda dT/dx)$ accounts for the reduced thermal energy carried by the impinging phonons with respect to the value calculated from the local thermal gradient at x_0. As the temperature difference $T(x_0) - T(x_0 + \lambda) \cong T(x_0) \propto 1/d^2$ (see below), the factor is equal to d/λ. Similarly, for the fraction of heat transported by the phonons scattered off the wall, one can write

$$\begin{aligned} \eta^d &= \frac{I_{\text{th}}^w(\upsilon)}{I_{\text{th}}(\pi)} \\ &= \frac{2\pi \int_0^{\pi} \frac{\Delta T^w(\upsilon')}{\Delta T(\upsilon')} \cos\upsilon'/2 / 2 \sin\upsilon'/2 \, d\upsilon'/2}{2\pi \int_0^{\pi} \cos\upsilon'/2 \sin\upsilon'/2 \, d\upsilon'/2} \\ &\approx \frac{d(x_0)}{\lambda} \cos^2\upsilon/2. \end{aligned} \tag{4.6}$$

As for the direct phonons, the factor $\Delta T^w/\Delta T$ denotes the fraction of heat carried by a phonon scattered from the wall with respect to a thermal equilibrium phonon. A calculation (A. Dürig, unpublished results) yields

$$\Delta T^w(\upsilon') \approx \Delta T(\upsilon') \begin{cases} \frac{d(x_0)}{\lambda} \; \frac{d(x_0)}{\lambda} < 1 \\ 1 \; \frac{d(x_0)}{\lambda} \geq 1 \end{cases}, \tag{4.7}$$

where the equality holds for $\upsilon = 0$ and deviations for $\upsilon > 0$ have been neglected. Hence, we obtain as final result

$$\kappa'(x_0) = \kappa(\eta^d + \eta^w) \approx \kappa \frac{d(x_0)}{\lambda}, \tag{4.8}$$

in exact agreement with Mathiessen's rule.

According to Equation 4.3, the thermal resistance of a conical heat conductor with an apex diameter $d_0 \perp \lambda$ can be written as

$$\begin{aligned} R &= \frac{1}{\kappa}\frac{4\lambda}{\pi} \int\limits_{d_0 \ll \lambda}^{\lambda} \frac{1}{d^3}\, dx \\ &\approx \frac{1}{\kappa}\frac{2\lambda}{\pi \tan\Theta/2}\frac{1}{d_0^2} \\ &= \frac{3}{8}\frac{1}{\tan\Theta/2} R_s, \end{aligned} \tag{4.9}$$

where

$$R_s = \frac{1}{\kappa}\frac{4\lambda}{3\pi}\frac{1}{(d_0/2)^2} \tag{4.10}$$

is the so-called Sharvin resistance for ballistic transport through a circular aperture (see e.g. Ref. [38]). It is interesting that, despite the short effective mean free path due to boundary scattering, the resistance of a conical conductor still retains the characteristics of ballistic transport expressed by the inverse d_0^2 dependence. Also, the length of the cone does not enter because more than 90% of the temperature change occurs over a distance on the order of three times the apex diameter. Substituting the corresponding values for the thermal conductivity $\kappa = 165\ \mathrm{W\,K^{-1}\,m^{-1}}$ and the mean free path $\lambda = 100\ \mathrm{nm}$, one obtains the following for the thermal resistance of a Si tip:

$$R \approx 3.86 \times 10^8\ \mathrm{KW^{-1}\,nm^2}\, \frac{1}{\tan\Theta/2 d_0^2}. \tag{4.11}$$

The cone angle dependence and explicit values of R for a representative set of Θ and d_0 values are tabulated in Table 4.1. Note that the tip resistance increases markedly if the cone angle is less than $\sim 45^\circ$.

Next, we investigate the influence of interface scattering at the apex for a tip in contact with a substrate surface. Specifically, let us assume that the substrate is a

Table 4.1 Normalized thermal resistance of a conical tip as a function of the cone angle and thermal resistance for $\Theta = 90^\circ$ as a function of apex diameter.

$R(\Theta)/R(90^\circ)$	1	1.73	2.41	3.73	7.60

R (90°) (KW^{-1})	3.86×10^{8}	9.65×10^{7}	1.54×10^{7}	3.86×10^{6}	9.65×10^{5}
d_0 (nm)	1	2	5	10	20

poorly conducting material, such as a polymer film, which has a correspondingly short phonon mean free path $\perp d_0$. The heat transmitted through the apex is carried away radially, where the temperature drop in the substrate is given by the spreading resistance (see e.g. Ref. [38] and Section 4.4.5):

$$R_{\mathrm{sp}} = \frac{1}{2\kappa_s d_0}. \tag{4.12}$$

Here, κ_s denotes the thermal conductance of the substrate.

Consider a heat current impinging on the interface. A fraction η is reflected back into the tip owing to scattering at the apex (see Figure 4.10a). Whether the scattering is elastic or inelastic is not important for the subsequent discussion. Because of the ballistic nature of the propagation, thermalization of the reflected phonon will occur far away from the interface, and therefore will not influence the local thermal equilibrium at the interface. Let T and I_{th} be the interface temperature and the thermal current in the absence of scattering, respectively. The heat transmitted into the substrate is thus $I^t_{\mathrm{th}} = (1-\eta)I_{\mathrm{th}}$. Correspondingly, the substrate temperature at the interface is $T_s = T - \eta(T - T_0)$, where T_0 is the substrate temperature far from the interface.

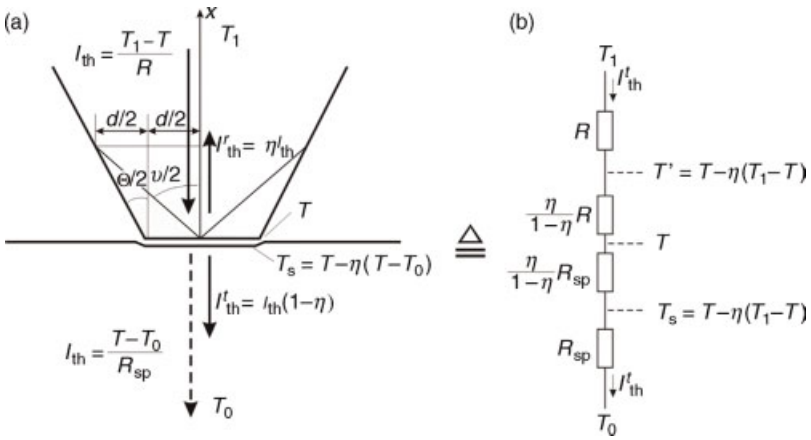

Figure 4.10 Schematic of boundary scattering at the tip apex.

The net heat current flow in the tip is $I^t_{\rm th} = I_{\rm th} - I^r_{\rm th}$, where $I^r_{\rm th} = \eta I_{\rm th}$ denotes the reflected current in the tip. As argued above, the tip temperature at the apex is not altered. Nevertheless, we introduce an effective temperature at a virtual tip interface $T' = T + \eta(T_1 - T)$, where T_1 is the tip temperature far from the interface (see Figure 4.10b). With this definition, the heat balance can be satisfied with regard to the net current, $T' = T_1 - I^t_{\rm th} R$, where the heat conduction in the tip is represented by the single resistive element, R. The virtual tip interface is connected to the substrate surface by means of a resistive element that must satisfy the equation $T' - T_s = I^t_{\rm th} R_b$. Hence, one obtains

$$R_b = \frac{\eta}{1-\eta}(R + R_{\rm sp}). \tag{4.13}$$

The scattering physics is captured in the reflection coefficient

$$\eta = a(1 - \cos\upsilon/2) \approx a\left(1 - \frac{1}{\sqrt{4\tan^2\Theta/2 + 1}}\right), \tag{4.14}$$

where $0 \leq a \leq 1$ is a type of accommodation factor for the back-scattering of the phonons into the tip and $(1 - \cos\upsilon/2$ accounts for the fraction of the solid angle covered by the back-scattered phonons that escape form the tip apex and thermalize in the heat bath. The particular choice for υ is heuristically motivated by the observation that the temperature gradient is roughly one order of magnitude lower at a distance above the apex that corresponds to a cone diameter of twice the aperture diameter.

The substrate temperature is one of the key parameters for studying thermomechanical material properties. It can be written as

$$T_s = \frac{R_{\rm sp}}{R + R_b + R_{\rm sp}}(T_1 - T_0) + T_0 = \frac{1-\eta}{1 + R/R_{\rm sp}}(T_1 - T_0) + T_0, \tag{4.15}$$

Note that already for rather weak back scattering the interface resistance accounts for a significant fraction of the total resistance, that is, $a = 0.3$ yields R_b λ0.5 $(R + R_{\rm sp})$ (see Equations 4.13 and 4.14). Figure 4.11 shows the substrate temperature as a function of tip cone angle for $a = 0.5$ and 0.75 and for various ratios of $R + R_{\rm sp} = (\kappa_s\lambda)/(\kappa d_0) < 1$ corresponding to cases in which the spreading resistance is dominating the tip resistance. Under such conditions, the substrate temperature is rather insensitive to the values substituted for the accommodation coefficient a and the cut-off angle υ.

As observed experimentally [8, 14, 35, 39, 40] and also described in Section 4.4.8, the simple model predicts that the temperature rise at the substrate interface is on the order of 0.4 to 0.7 times the total temperature difference between tip and substrate for parameters that correspond to typical experimental conditions. It is clear that the model cannot capture the complexities of phonon scattering in a predictive manner. Instead, a phenomenological parameter a must be introduced to match experimental observations with model predictions. However, the model provides a means for assessing the scaling properties and provides qualitative

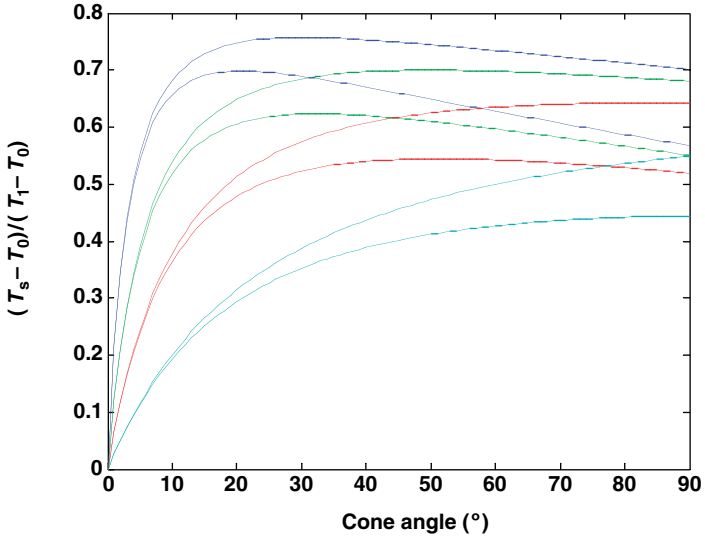

Figure 4.11 Substrate temperature at the tip apex: $a = 0.75$ (solid lines) and 0.5 (dashed lines) and $R/R_{sp} = (\kappa_s\, \lambda)/(\kappa\, d_0) =$ 0.025 (blue), 0.05 (green), 0.1 (red) and 0.25 (cyan).

insight based on intuitive physical arguments. A deeper discussion of physical mechanisms governing thermal transport of nanometer-scale tip–surface contacts is presented in Sections 4.4.5–4.4.8.

4.4.5
Thermal Spreading Resistance

The spreading resistance in the sample is probably the best understood of all the thermal resistances involved. Commonly, it is well approximated by Equation 4.12, which says that the resistance scales inversely with the contact diameter d_0. The scaling is borne out by the fundamental heat conduction Equation 4.1 by observing that the mean gradient $\Delta T/\Delta x$ scales as $1/d_0$ for diffusive transport in a half-space.

For a thin film on a substrate, one can account for the effect of the substrate by using an approximate solution proposed by Yovanovich *et al.* [41]:

$$R_{sp} = \frac{1}{2\kappa_s d_0} - \frac{1}{2\pi\kappa_s t}\log\left(\frac{2}{1+\kappa_s/\kappa_{sub}}\right). \tag{4.16}$$

Here, κ_s and t are the thermal conductance and the thickness of the film, respectively, and κ_{sub} denotes the thermal conductivity of the substrate on which the film has been deposited. In all experiments discussed below, the film thickness is at least one order of magnitude larger than the contact diameter, and we can disregard the finite-size correction term.

For polymer films, a value of $\kappa_s \sim 0.2$–$0.3\,\mathrm{W\,K{\cdot}m^{-1}}$ is typical. The thermal conductance can increase by up to a factor of 2 under a pressure of 1 GPa. As the

stress under the tip varies during an experiment and is transient within the tip–surface interaction volume, we must resort to estimating an effective pressure-increased thermal conductivity [42]. For the experiment described below, we use a value of k_{pol} of 0.3–0.6 $W K \cdot m^{-1}$. For a contact diameter of $d_0 = 10$ nm, we obtain an estimated R_{sp} of approximately $(0.8 - 1.6) \times 10^8 K W^{-1}$ for polymers, $\sim 10^6$–$10^7 K W^{-1}$ for oxides, $\sim 3 \times 10^5 K W^{-1}$ for silicon, and down to $10^4 K W^{-1}$ for metals.

4.4.6 Interface Thermal Resistance

As discussed in Section 4.4.4, the thermal resistance of the interface R_{int} defies accurate prediction. The situation is further complicated because the interface resistance usually depends heavily on the quality of the interface and the contact pressure. For most of the cases described in this chapter, we can assume a single-asperity contact characterized by a contact diameter d_0. Contact mechanics models can be invoked to estimate d_0. For a tip with a radius of 10 nm and applied loads of a few tens of nanoNewtons, d_0 is on the order of a few nanometers.

On the other hand, the values of the interface resistance reported in the literature were measured on macroscopically large areas (rather than a tip–surface contact). Typical values for silicon–polymer interfaces are in the range of 10^{-8} to $10^{-7} Km^2 W^{-1}$ [43, 44]. For a silicon–silicon interface, the corresponding value obtained for phonon scattering is $2.1 \times 10^{-9} Km^2 W^{-1}$. The subject of interface scattering has been extensively reviewed by Swartz and Pohl, who discuss the thermal interface (or boundary) resistance between various materials as well as related models [45].

Returning to the nanoscale tip contact, it is not immediately clear how to relate the macroscopic data to the nanoscale interface resistance. One simple approach adopted by King [35] is to treat the interface as a scattering site for phonons in silicon and to assume that the total interface resistance is inversely proportional to the contact area, which yields $R_{int} = 2.1 \times 10^{-9} Km^2 W^{-1} \times 4/(\pi \ d_0^2) \sim 2.7 \times 10^7 K W^{-1}$ for $d_0 = 10$ nm. Alternatively, if we substitute the measured value for the polymer–silicon interface resistance, we obtain $R_{int} = 10^{-8}$ to $10^{-7} Km^2 W^{-1} \times 4/(\pi \ d_0^2) \sim 1.3 \times 10^8$ to $10^9 K W^{-1}$ for $d_0 = 10$ nm.

Alternatively, it is shown in Section 4.4.4 that the resistance due to boundary scattering at the tip apex is proportional to the sum of the thermal resistances associated with the conduction paths through substrate and tip. Therefore, this has two components: one scaling as $1/d_0$ and corresponding to the spreading resistance in the substrate; and the other scaling as $1/d_0^2$ and corresponding to the tip resistance. The question then arises how this is to be reconciled with the $1/d_0^2$ scaling suggested by extrapolating from the macroscopic scale.

The interface resistance is a somewhat artificial construct, which bridges the gap in the conduction path where the temperature of the phonon gas cannot be defined unequivocally. The temperature is well defined only if the phonons thermalize by means of mutual scattering. Therefore, the gap typically extends over a distance on the order of the phonon mean free path on either side of the interface. For consistency with the concept of a thermal resistance, the interface resistance is defined as the tempera-

ture difference divided by the net heat flux across the gap, as measured by an imaginary observer with an apparatus that is in thermal equilibrium with the phonon gas. Note, however, that unlike a regular thermal resistor, the interface resistance cannot be broken up into a string of series resistors to calculate the temperature at any point along the gap. In fact, such temperatures have no meaning and merely serve as a mathematical concept. The interface temperature of the tip, T' (which was introduced in Figure 4.10b), is an example of such a fictitious temperature. Moreover, the ballistic tip resistance, R (see Equation 4.9 in Section 4.4.4) constitutes part of the overall interface resistance. Therefore, we must write the following for the interface resistance:

$$R_{\text{int}} = R_b + R, \tag{4.17}$$

which spans the entire ballistic propagation path of the phonons through the conical tip, including boundary scattering at the tip–substrate interface up to their thermalization in the substrate. It is also clear from the above discussion that we cannot simply extrapolate from macrosopic results to nanoscale thermal contacts without accurately accounting for the conduction path. What one can do, however, is to extract a mean backscattering probability from macroscopic experiments. Using the same type of reasoning as in Section 4.4.4, one obtains the following for the interface resistance for a unit area of a planar contact:

$$r_{\text{int}} = \frac{\eta}{1-\eta}\frac{\lambda}{\kappa}. \tag{4.18}$$

With $\eta \sim a$, and assuming $\lambda \sim 1$ nm and $\kappa \sim 0.3\ \text{W Km}^{-1}$ for the mean free path and the thermal conductance of polymers, respectively, one must substitute $a \sim 0.75$ to 0.97 in order to obtain the experimentally observed values of $r_{\text{int}} \sim 10^{-8}$ to $10^{-7}\ \text{Km}^2\ \text{W}^{-1}$ [43, 44]. The upper bound for the measured interface resistance yields a somewhat unrealistically high value of 0.97 for the backscattering probability. However, it must be borne in mind that it is difficult to obtain good contact uniformity in a large-scale experiment, and therefore the experimental values must be seen as upper bounds.

4.4.7
Combined Heat Transport Through Tip, Interface and Sample

We define the *heating efficiency c* (similar to – but a simplification of Equation 4.15 and Figure 4.11) as the increase in the sample surface temperature divided by the total temperature difference between heater and substrate:

$$c = \frac{R_{\text{sp}}}{R_{\text{tip}} + R_{\text{int}} + R_{\text{sp}}}. \tag{4.19}$$

Here, R_{tip} denotes the nonballistic, diffusive component of the tip resistance (the ballistic part is captured in R_{int}, as explained in Section 4.4.6). This definition is useful for understanding sensitivity issues when using heated probes. The heating efficiency c is a strong function of tip size – that is, of the lateral resolution. Small values of c imply that also the measured signal will be small, indicating that achieving high lateral resolution becomes increasingly difficult.

As outlined in Section 4.4.4 and inferred experimentally [8, 14, 35, 39, 40], typical values for c range from 0.3 to 0.7 for polymer samples. In the case of better thermal conductors, c can be much lower; for example, on metals we estimate $c \sim 10^{-3}$–10^{-4}, for semiconductors $c \sim 10^{-2}$–10^{-3}, and for oxides $c \sim 10^{-1}$. This points to the challenges expected when extending the SThM method to both the nanoscale (e.g. $a = 5$ nm in the above calculations) and to sample materials having a higher thermal conductivity than the commonly used polymers or oxides.

We note that, although the heating efficiency reflects the temperatures, it does not reflect how efficient a probe is in terms of *heating power*. For the cantilever type shown in Figure 4.3 operating in air, the ratio of power going through the tip to that lost to other heat paths is approximately $10^5/10^8$ (K/W) $= 0.001$. Thus, from a power consumption point of view, the delivery of heat to the sample through the tip is very inefficient. Improving the efficiency requires either a reduction in the interface and the tip thermal resistances or an increase in the air/cantilever thermal resistance. The tip and interface resistances can of course be decreased by using a blunter tip, but at the expense of lateral resolution. Increasing the cantilever thermal resistance requires a decrease in the heater and lead cross-sections and/or an increase in the cantilever length. Among the design issues that restrict the freedom to reduce the heater/lead cross-sections are the mechanical stability, cantilever stiffness, mechanical response time, power consumption of the heater, electrical resistance and noise, thermal response time and fabrication tolerances.

4.4.8
Heat-Transport Experiments Through a Tip–Surface Point Contact

The sheer number of heat-transport paths described above renders an understanding of heat transport in heated probes challenging, let alone the direct measurement of individual components of heat transport. In order to distinguish between different heat paths, we have chosen a threefold approach:

- Bringing the tip into and out of contact with the sample opens and closes heat channels.
- Operation in a vacuum removes the distance-dependent cooling path through the air, which tends to dominate the small change in cooling that occurs when the tip is brought into contact with the sample in ambient conditions and completely eliminates conduction through the water meniscus.
- By varying the contact area, a, only some of the contributions will be affected (interface and spreading part).

The total thermal resistance of the heater, R_{th}, is given by

$$R_{\mathrm{th}} = (T_{\mathrm{heater}} - \mathrm{RT})/P, \tag{4.20}$$

where T_{heater} is the temperature of the heater, RT is the room temperature, and P the heating power. The thermal resistance due to conduction through the cantilever legs

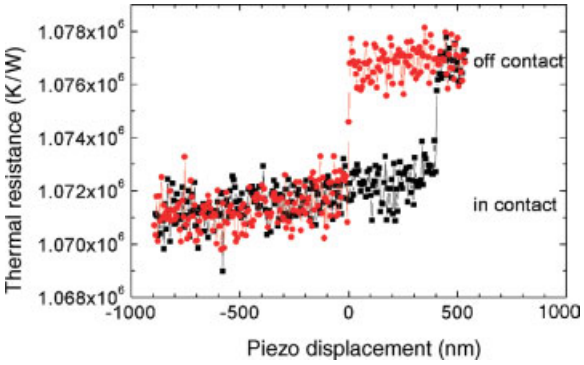

Figure 4.12 Thermal resistance of heated cantilever/tip as a function of displacement and contact with an 80 nm-thick SU8 film on a silicon substrate. (Reproduced from Ref. [14]; © Springer-Verlag.)

and radiation can be determined from the data obtained before the tip contacts the sample. The tip–surface thermal conductance can then be determined by subtracting this value from the data measured with the tip in contact with the sample. Figure 4.12 shows an example of such an experiment performed using a thermal probe similar to that shown in Figure 4.3 and a sample consisting of 80 nm of SU8 (an epoxy-based photoresist) on a silicon substrate. Out of contact, the displacement translates into a distance change between heater and sample. In contact, the displacement translates into a load force as the tip is pressed against the polymer. In this experiment, the average T_{heater} was approximately 315 °C, and the change in T_{heater} resulting from contact was about 1.5 K. From the difference between the thermal resistance out-of-contact ($\sim$1.077 MK W^{-1}) and the thermal resistance in-contact (1.071–1.073 MK W^{-1}), the thermal resistance due to heat transport through the tip–surface contact was calculated to be $2 - 3 \times 10^8$ MK W^{-1} (see Figure 4.14).

The tip–sample resistance is given by

$$R_{\text{ts}} = R_{\text{tip}} + R_{\text{int}} + R_{\text{sp}}, \tag{4.21}$$

as illustrated in Figure 4.13, where R_{tip} is the diffusive thermal resistance of tip, R_{int} is the tip–sample interface resistance, and R_{sp} is the spreading resistance in the polymer.

To experimentally quantify the different contributions to R_{ts}, we can vary the individual contributions by varying the sample material and the applied force. As the contributions depend on the contact radius, 0.5 d_0, it is useful to vary this parameter. To study the contact area dependence of the overall thermal resistance of the tip–polymer contact, we vary the force during an approach experiment. The contact area is calculated using the JKR model [46]. For this purpose, the applied force, the pull-off force and the tip radius need to be known. The applied force and pull-off force are determined from the cantilever spring constant and the known motion of the tip holder relative to the sample surface. The tip radius is measured *ex situ* by means of

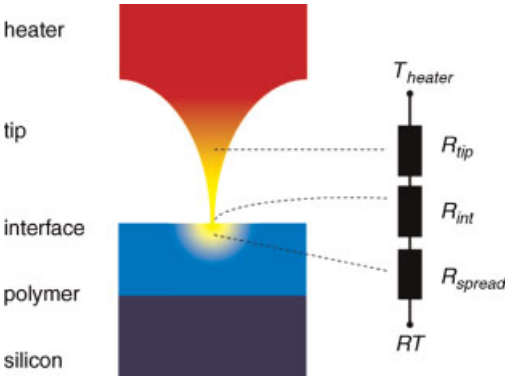

Figure 4.13 Schematic representation of the thermal resistances involved in heat transfer between the heater and a polymer sample. (Reproduced from Ref. [14]; © Springer-Verlag.)

scanning electron microscopy. The data shown in Figure 4.14 were obtained for a tip with $R_{tip} \cong 13.5$ nm corresponding to a variation of the contact diameter from 7 nm just before the contact breaks at a pull-off force of −15 nN to 13 nm at the maximum load of 35 nN.

Clearly, the thermal resistance depends on the tip force and hence on the contact diameter. Motivated by the above discussion, we propose the following ansatz for the thermal resistance:

$$R_{ts} = A_0 + A_1/d_0 + A_2/d_0^2. \tag{4.22}$$

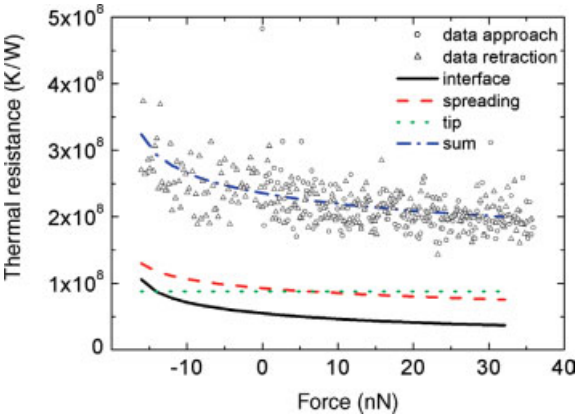

Figure 4.14 Experimental thermal resistance R_{th} of a typical tip–sample contact on a polymer (SU8) film and fit (blue, dash-dotted line) containing the three components R_{tip} or A_0 (green, dotted), R_{int} or A_2 (black, solid) and R_{sp} or A_1 (red, dashed). (Reproduced from Ref. [14]; © Springer-Verlag.)

Indeed, a good fit to the data is obtained with this second-order ansatz. In Figure 4.14, the individual contributions are shown as a green dotted line for the A_0 term, a red dashed line for the A_1/d_0 term, and a solid black line for the A_2/d_0^2 term.

Recalling the results from Sections NaN.2.4–NaN.2.6, it is surprising that there is a significant A_0 term ($\sim 9 \times 10^7$ MK W^{-1}). All components – tip, interface and spreading – should have an explicit dependence on d_0. We attribute the contribution A_0 to the thermal resistance of the tip R_{tip}. This may appear as a rather strong assumption, because we argued in Section 4.4.4 that the thermal resistance of the tip is predominated by ballistic conduction, and therefore the diffusive (nonballistic) thermal resistance of the tip should be vanishingly small in comparison. However, in practical applications the inner structure of the tip may play a role. In particular, the oxide cap covering silicon tips can contribute decisively to the thermal resistance of the tip. The value of this contribution can be estimated on its own as an independent thermal resistance by using approximate dimensions or as a mesoscopic link enabling 'phonon tunneling' between the silicon cone and the sample [47]. The uncertainty remains large, and we estimate 10^7–10^8 MK W^{-1} for the oxide cap. Accordingly, the total value of R_{tip} might be dominated by the value for the oxide cap, and we therefore also expect 10^7–10^8 MK W^{-1} for R_{tip}. This interpretation is supported by control experiments using the same tip on a silicon sample.

The A_2/d_0^2 term is an unequivocal sign for ballistic transport, and therefore it must be assigned to the interface resistance R_{int} (see Section 4.4.6). The A_1/d_0 term stems from the spreading resistance in the polymer sample. As discussed in Sections 4.4.4 and 4.4.6, it is composed of a real diffusive component and an interface contribution. It is difficult to assess the magnitude of the latter without detailed knowledge of the tip structure at the interface, which would allow one to make realistic assumptions on the scattering efficiency at the interface to the polymer. We note, however, that the magnitude is consistent with the diffusive spreading resistance for polymers (see Section 4.4.5). Hence, most likely the interface scattering contribution is rather small. It is interesting to note that all three terms contributing to the overall thermal resistance are of similar magnitude, namely, on the order of 10^8 MK W^{-1}, which results in a heating efficiency of $c \sim 40\%$ in this example (assuming that the A_1/d_0 term corresponds to a purely diffusive spreading resistance).

4.5 Thermomechanical Nanoindentation

Thermomechanical nanoindentation can be viewed as a powerful nanoscale extension to the existing methods of indentation (hardness testing) and dynamic thermomechanical analysis (modulus testing). The process involves pressing a heated tip into a sample using a defined tip temperature, load/heat duration, and load force. The indentation dynamics and the yield of the sample can be used to understand its material properties. Apart from the metrology discussed in this section, the technique has applications in data storage and in nanoscale patterning and lithography.

The indentation process yields considerable insight into the thermomechanical properties of materials – in particular of polymers – on the nanometer scale [48–52]. Traditionally, indentation processes are used to determine the hardness of a material [53], in which experiments an indenter produces a permanent deformation at the surface of the material under investigation. The hardness is determined by the size of the indentation with respect to the loading force. As the geometry of the indenter plays a fundamental role, common hardness definitions are based on individual, defined geometries, such as a ball (Brinell) or a pyramid (Vickers) [53]. In the experiments, typically a specific load is applied for specific time durations to yield comparable results.

Although it has not been widely used in traditional hardness testing, temperature is an additional important parameter in indentation experiments [14, 52]. As the mechanical properties of materials typically depend largely on temperature, the control of this parameter opens up interesting new areas of investigation. Heated probes provide an easy means to vary the temperatures on any given surface. In addition, controlling the probe temperature is relatively straightforward, and the low heat capacity of the probes allows the temperature of the probe to be switched at relatively high rates.

Polymers are one class of materials in which the mechanical and viscoelastic properties change dramatically with temperature, for example, at the polymer's glass transition temperature, T_g [1, 54]. At this temperature, the internal configurational changes within the polymer chain (which are linked to the translational motion of the chain) become slow compared to the typical experimental observation time scale of 1–100 s. As a result, the material drops out of equilibrium into a so-called 'glassy' state, and its materials properties change dramatically. The elastic modulus, for example, increases by orders of magnitude.

Heated probes are ideally suited to investigate the mechanical properties of polymers on a nanometer scale over a wide range of temperatures, from room temperature to several hundred degrees Celsius, and time scales varying over orders of magnitude down to the microsecond regime.

As an example, Figure 4.15 shows the result of an indentation experiment using heated probes. The indentations were written as a function of the load force, F, and the tip temperature, T, for indentation times of 10 µs using a tip having a radius of about 10 nm. The image shows the topography measured in contact mode after writing the indentations using the same tip. Whereas, in the lower left part of the image, no permanent indentations were formed, they appeared very clearly in the upper right part at high temperatures and forces. Clearly, in order to produce permanent indentations a certain minimum force and/or temperature must be applied. The corresponding characteristic line at the onset of indentation formation is called the *writing threshold* (see shaded region in Figure 4.15). For practical purposes, this dividing line can be defined as the load/temperature combination that leads to indentations of 1 nm depth: $T(F)_{d\,=\,1\,\mathrm{nm}}$.

Figure 4.16 exemplifies the threshold behavior of writing indentations with increasing temperature at a given load of 50 nN and a pulse duration of 10 µs. Whereas, below the threshold temperature T_h, no permanent indentations can be formed, above T_h their depth increases linearly with temperature.

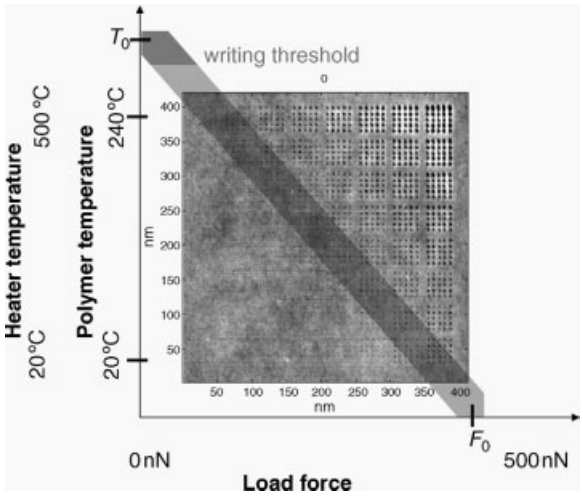

Figure 4.15 Atomic force microscopy image of indentations written into a polymer film at various combinations of load forces and tip temperatures using an indentation time of 10 µs. Blocks of 5 × 5 indentations spaced 36.6 nm apart are written using the same parameters. The blocks are written with increasing force and temperature along the *x*- and *y*-axis, respectively. The heater temperature is determined as described in the text. The polymer temperature under the tip is estimated using the results of the heat-transfer experiments described in Section 4.4.

Before turning to the physical interpretation of such temperature–load plots, let us briefly see how they can be used in practice. Of particular interest are the well-defined intersections of the writing threshold curves with the axes – that is, the writing temperature in the limit of no load force applied, T_0, and the load force in the limit of

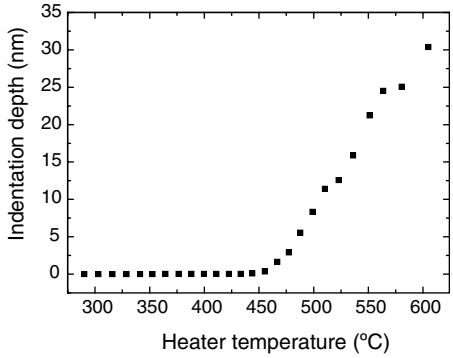

Figure 4.16 Depth of indentations in a polymer film (polymethylmethacrylate, PMMA) as a function of heater temperature for a load of 50 nN and heat- and force-pulse durations of 10 µs. Above a threshold heater temperature T_h of ~450 °C, the indentation depth increases linearly with the heater temperature. For the parameters applied, T_h is therefore closely related to the glass-transition temperature, T_g, of the polymer.

no heat applied, F_0. The quantities T_0 and F_0 are a function of both indentation time and tip geometry.

T_0 is the writing temperature needed in the limit $F \rightarrow 0$, which is also the limit of zero stress. In this limit the T_g is defined and therefore, for a given tip radius and indentation time, T_0 is a measure of the T_g.

For a given heater temperature, the temperature reached in the polymer underneath the tip depends on the geometry of the tip (see Section 4.4). Whereas, the opening angle of the tip cone has relatively little effect, the contact area – and therefore the heat transport from the tip to the polymer – differ for blunt and for sharp tips.

To reach more quantitative statements about the T_g of a polymer, we must normalize the effects of the tip geometry. There are two possible solutions to this:

- First, to obtain comparable results, one can use the same tip for all samples being studied. Assuming that the tip shape stays constant over the range of experiments, this procedure yields comparable results that can be correlated to traditionally measured T_g values of polymers.
- The second approach is to pick one of the polymers as a reference sample and to normalize the results on the other polymers with respect to this reference polymer.

Clearly, the first approach is prone to difficulties relating to the necessary constant geometry of the tip, is restricted to the use of a single tip, and therefore cannot be applied as a general method. In the second method, the T_g values measured are rescaled with respect to a reference tip on the reference sample, which cancels to first order the relative difference in heat-transfer properties resulting from the use of different tips.

By using these two approaches, a correlation to T_g measured by conventional means can be made [6, 14], as shown in Figure 4.17. All experimental data were either

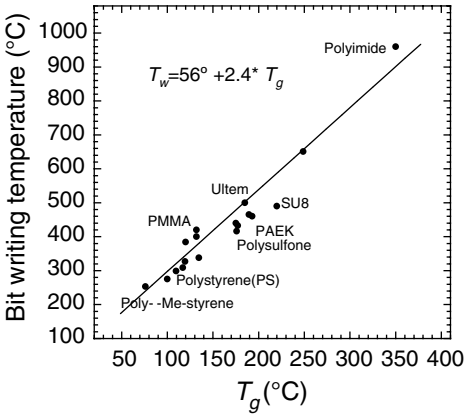

Figure 4.17 Indentation-writing temperature T_0 as a function of the conventionally determined T_g for various polymers. The indentation-writing temperature has been normalized to a reference tip, as described in the text. All data points are within 10% of the linear fit to the data.

obtained with a tip of approximately 10 nm radius or rescaled using reference samples [poly(methylmethacrylate) (PMMA) and polystyrene] to the case of a particular tip with specific opening angle and tip radius ($R_{tip} = 10$ nm), which yielded T_h at 400 °C for 10 µs-long heat pulses. The writing temperatures measured correlate very well with the respective T_g values of the polymers. This holds for uncrosslinked polymers, such as PMMA or Poly-a-Me-styrene, as well as for highly crosslinked polymers, such as the epoxy-resist SU8. In fact, the largest deviation of the data from the linear fit is less than 10%.

The excellent correlation of the indentation-writing and T_g values demonstrates the applicability of the method for determining T_g for unknown samples. This is insofar surprising as the T_g values for the given samples were determined using macroscopic bulk methods of dynamic mechanical analysis (DMA) or differential scanning calorimetry (DSC) and, in particular, also because these methods work on much longer time scales (1–100 s).

The second parameter obtained from the threshold curve, F_0, can be used to determine the hardness of the materials. As a demonstration, measured indentation-writing threshold curves are shown in Figure 4.18 for a class of similar polymers. The samples are thin films (120 nm thick) of polystyrene crosslinked using benzocyclobutene (BCB) as crosslinking groups [55]. This system is an ideal system to study the effects of the crosslink density on the thermomechanical properties of polymers. Increasing the crosslink density by incorporating a larger amount of BCB monomers increases both the hardness and T_g [56].

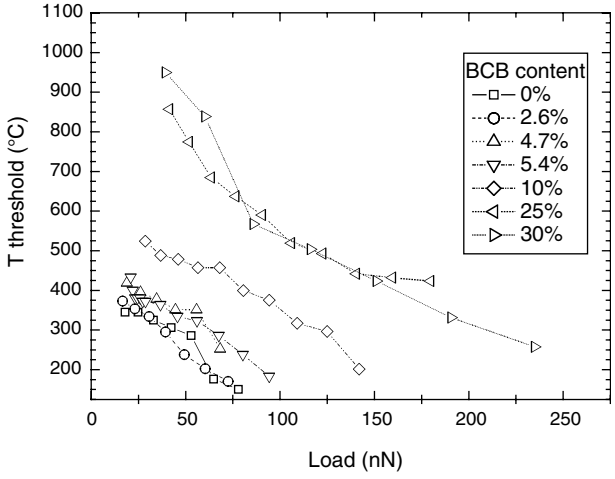

Figure 4.18 Indentation-writing threshold plots determined by writing indentation arrays, as shown in Figure 4.15. Each datum point refers to the temperature needed to write an indentation of 1 nm depth at a given load. Here, thins films of polystyrene that have different crosslink densities are compared. The percentage values in the inset refer to the relative amount of crosslinking benzocyclobutene (BCB) monomers with respect to styrene monomers in the polymer.

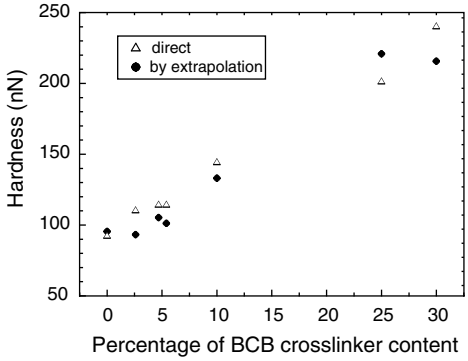

Figure 4.19 Comparison of two methods to determine sample hardness by nanoindentation. In the first method, the value (solid circles) is obtained by extrapolating the writing-threshold data from Figure 4.18 to room temperature. The second method (open triangles) measures the hardness in a more conventional manner: the minimum force required to obtain an indentation of 1 nm is determined, with tip and sample at room temperature. Within experimental uncertainty, the two methods yield identical results.

To a good approximation, the temperature needed to write an indentation decreases linearly with the writing load applied. This linearity can be used to extrapolate T_0 and F_0 from data taken in a limited force/temperature range. For example, in Figure 4.18 the writing-threshold curves reach neither T_0 nor F_0. Nevertheless, both values may be determined by extrapolation to zero force and room temperature, respectively. To verify the validity of this extrapolation, direct measurements of F_0 were performed at room temperature using the same tip. A comparison of the extrapolated and the directly measured hardness values for the polymers is shown in Figure 4.19.

A well-known issue in hardness testing is the wear of the indenter. This poses a problem in particular in the case of nanoindentation because, in order to draw valid conclusions, the indenter geometry must be known. Typically, this issue is circumvented by choosing indenters having relatively blunt apexes and/or using diamond materials. For true nanoscale applications using indentations that are confined in both the normal and the lateral direction, the wear of the probe is an unsolved issue.

The writing-threshold experiment as depicted in Figure 4.15 can be a workable solution, because the forces acting on the tip can be minimized. A grid with limited writing forces and subsequent extrapolation to room temperature can be applied to minimize tip wear. Thus, measuring the temperature dependence of writing permanent indentations is an elegant way to measure the real hardness data by extrapolation.

The indentation experiments shown above demonstrate how sensitively thermomechanical nanoindentation depends on the load and temperature. Underlying, of course, are the material properties of the polymer, such as hardness and the T_g, as well as the tip geometry and heat-transfer properties of the cantilever/tip. All of these govern the indentation formation. As discussed above, the indentation-writing

threshold experiment results in a relationship of $T_{\mathrm{thresh}}(F)$ (or $F(T_{\mathrm{thresh}})$) that is linear within the uncertainties given.

One explanation of the existence of a defined threshold for the force needed to write a permanent indentation is to argue that the stress build-up in the polymer has to overcome a critical stress, the yield stress of the polymer. It has been found macroscopically that the yield stress σ_y [57, 58] of polymers is a function of temperature. More precisely, around T_g, σ_y varies linearly with temperature, with $\sigma_y \sim 0$ for $T = T_g$, which is consistent with our observation of the linear shape of the writing-threshold curves. Hence, we can write $F(T_{\mathrm{thresh}}) \propto \sigma_y(T)$. This model of yielding is also supported by the analysis of the indentation shapes as a function of indentation parameters [59] (T. Altebaeumer, unpublished results).

A model that explains the observed indentation behavior simply as a yielding phenomenon, however, is not fully satisfactorily. Yield implies a permanent deformation of the material. In polymers, such a permanent change is linked to a change in the topology of the material, which proceeds via chains sliding with respect to each other. In the case of yielding, this sliding is forced by the external stress, which has to overcome the inherent monomer-sliding friction in the polymer [60].

In macroscopic yield experiments, two types of yield behavior are generally observed, namely *shear yielding* and *crazing*. Shear yielding occurs in partially crystalline and tough polymers (such as polycarbonates) which can extend to a multiple of their initial lengths. Just above a critical yield stress, the polymers often form shear bands on a macroscopic scale. Crazing is observed in brittle polymers such as polystyrenes; these polymers can elongate by only a small percentage before they rupture, and therefore the stress–strain curve is only slightly bent just before fracture. At the same time, one often observes elongated voids in the material called 'crazes'.

Clearly, both macroscopic phenomena encounter difficulties at the nanometer scale. Both typically have a length scale much larger than the length scale of the nanoindentation experiments. Moreover, in many of the materials studied here such mechanisms should be largely constrained by the high crosslink density. Therefore, we note that the macroscopic definition of yielding must be applied with care on the nanometer scale.

In an alternative model, the material is not assumed to undergo yielding but rather a viscoelastic deformation (like rubber) in the heated state at a temperature above T_g. Elastic deformation in this regime still proceeds via the deformation of polymer chains, which implies a relative movement of polymer chains. In contrast to yielding, the chains in rubbery deformation are almost free to slide and are only held in place by entanglement or crosslink sites. The monomer relaxations in the polymer backbone, which couple to the translational motion of the polymer chains, are fast, and the friction between the monomers is reduced to very low values. Polymer motion is mainly limited by the chain-like nature and the network constraints of the material. In viscoelastic deformation, the external force is mainly needed to deform the polymer network because monomer friction is low.

After cooling to temperatures below T_g, monomer relaxations in the backbone become orders of magnitude slower and limit the translational motion of the polymer

chains: the indentation is 'frozen in' and the 'loaded rubber springs' are kinetically hindered from relaxing.

This picture of rubbery indentation is more compliant with our nanoscopic length scales because no macroscopic changes in the material are involved. In addition, as has been argued [14, 61], this picture of 'rubbery indentation' also captures some apparent physics better than the yield picture. For example, it works much better at ultrafast indentation times, which are possible experimentally. Moreover, even polymers with extremely high degrees of crosslinking can undergo a rubbery deformation if the deformation is small. On the other hand, rubbery indentation implies temperatures above T_g, in clear contradiction to findings of a linear threshold curve all the way down to F_0. In the threshold curve no apparent transition through the glass transition exists.

In nanoindentation experiments, T_g is not easy to quantify. It can be expected, however, that T_g increases for the high indentation rates typical of these experiments and decreases for the high stresses. Even for the lowest stresses that can be applied in the experiments, significant shear stresses of ~100 MPa will have to be considered. Although at compressive stresses, T_g always increases in macroscopic experiments, it is expected that under shear or tensile stress the underlying alpha-transition is eased. We note that a theory on yielding by Robertson [62] predicts WLF (Williams–Landel–Ferry) kinetics below T_g under shear stress, but this theory was found to be useful only near T_g [63]. All in all, T_g is difficult to predict for such experiments.

As mentioned above, an important aspect of both models is the difference in the indentation dynamics because in the yield picture monomer friction is predominant, whereas in the rubbery picture the chain/network topology of the polymer is the limiting factor.

In the rubbery picture, polymer backbone dynamics above T_g generally follow the so-called 'time–temperature superposition' [1, 64] and their kinetics are well described by the WLF equation:

$$T = \frac{\log(\tau_{\mathrm{ref}}/\tau)T_\infty - c_1 T_{\mathrm{ref}}}{\log(\tau_{\mathrm{ref}}/\tau) - c_1}.$$

Here, τ, $T$and k_B are the indentation time, indentation temperature of the polymer, and the Boltzmann constant, respectively. The WLF parameters τ_{ref}, T_{inf}, T_{ref} and c_1 are the fit parameters characteristic for individual polymers. Note that usually these parameters are found to be independent of the actual quantity measured, be it shear modulus, viscosity or heat capacity. We therefore expect rubbery indentation to be essentially controlled by backbone kinetics following WLF.

In the yielding model, again the indentation kinetics is controlled by the dynamics of the backbone and is essentially of Arrhenius-type with a single activation energy E_{a} [65]:

$$\frac{1}{\tau} = \frac{1}{\tau_0}\exp\frac{E_a}{k_B T}.$$

Thus, to distinguish between 'rubbery indentation' and yielding, the indentation kinetics should be investigated.

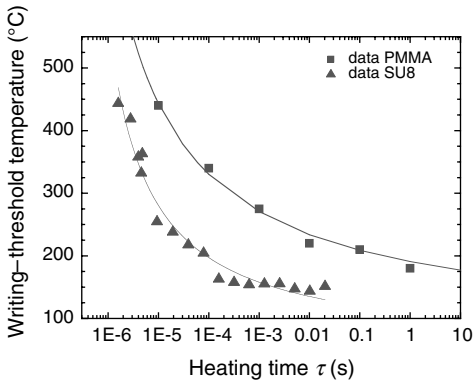

Figure 4.20 Writing-threshold heater temperature (i.e. the temperature required to write an indentation of 1 nm depth at a constant load force) as a function of heating time at a fixed load for a linear polymer PMMA (■) and a highly crosslinked epoxy SU8 (▲). The solid lines are fits using WLF kinetics (for which it was taken into account that the actual polymer temperature is significantly lower than the heater temperature).

First experiments [66] revealed that the indentation kinetics measured using PMMA and SU8 samples between 1 μs and 1 s cannot be fitted by a single activation energy (i.e. Arrhenius kinetics). An overall fit using WLF was satisfactory. An example of such an experiment is shown in Figure 4.20. Writing-threshold curves, defined as the minimum heater temperature needed to achieve an indentation depth of 1 nm at a given indentation time and at constant load force, were measured. Two prototype polymers are used: one is a thin film of PMMA; and the other a highly crosslinked thermoset, the epoxy SU8. A good fit with WLF can be obtained for PMMA. The temperatures needed are clearly above the T_g of about 120 °C, in agreement with our rubbery-indentation picture.

In a highly crosslinked system such as SU8, viscous flow can no longer account for the indentation. In this case, the load force was relatively high (200 nN), so that indentation times down to 1 μs were feasible with limited heater temperatures. Here also, a reasonable WLF fit was obtained despite the fact that, for long indentation times, the writing-threshold temperatures were considerably lower than the T_g of about 200 °C. Note, however, that for these data points the quality of the data does not allow the exclusion of a transition to Arrhenius-type behavior at long indentation times.

More detailed experiments using a crosslinked polystyrene sample were performed to investigate the topic further. These data are shown in Figure 4.21, in the form of an Arrhenius plot. Although the curve can be fitted linearly at long times, there is a clear deviation from the linear fit above a temperature of 180 °C that coincides with the T_g of the material measured using DSC. Above T_g, the data is well-fitted using WLF and a Vogel temperature T_∞ of $T_g - 50$ °C. Below T_g, however, the simple linear Arrhenius model is the best fit. Despite the many uncertainties, the

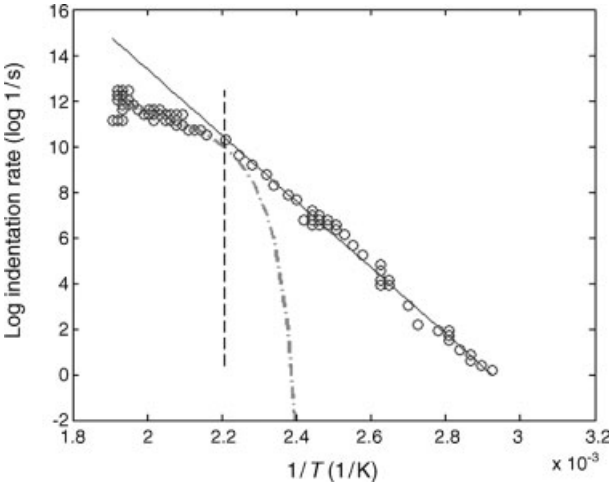

Figure 4.21 Arrhenius plot of thermomechanical indentation kinetics experiment. Below the glass transition temperature (T_g) of 180 °C (dashed line) an Arrhenius fit (solid line) is used. Above T_g, WLF yields a good fit (dash-dotted line). The sample used was a crosslinked polystyrene film; the indentation depth was 4 nm.

activation energy can be quantified and is found to be comparable with the activation energy of macroscopic polystyrene samples (1–2 eV).

It is concluded that WLF kinetics predominates at higher temperatures, and that a smooth transition to Arrhenius kinetics can be observed at lower temperatures/longer times. As expected, the transition occurs close to the T_g of the polymer.

These two physical pictures only manifest themselves in the different indentation dynamics. Only in the rubbery model above T_g does the chain-like nature of the polymers become apparent. On the other hand, it becomes clear that both physical pictures are useful to understand the experiments, and a distinction between them may appear artificial. The reason for this difference to the macroscopic polymer world is twofold: (i) because of the nanometer scale of the experiment and the crosslinked nature of the materials, macroscopic phenomena such as shear bands or crazes are absent; and (ii) the variations of shear stress and indentation rates are rather extreme. This forces a transition between the two conventionally fully separate regimes, which usually are switched only by the temperature and T_g.

In summary, a more unified picture of the indentation process emerges. For better clarity, we would like to propose a schematic, qualitative picture (see Figure 4.22). In this schematic, we capture the mechanics of the material using springs and dashpots. Springs k_s and k_p are connected in series and, correspondingly, in parallel to the dashpot. The elastic part of the medium is symbolized by k_s, whereas k_p is the elastic part linked to conformational changes of the polymer network. The dashpot, γ, is linked to the glass-to-rubber transition in the polymer. Below T_g, the dashpot is locked and can only be deformed by high stress; above T_g, it is open, representing the low-friction sliding of the polymer chains.

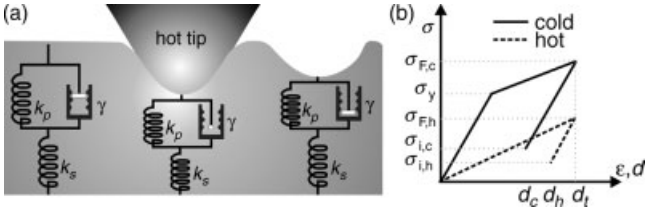

Figure 4.22 (a) Model representation of the polymer and the indentation process. From left to right: Undeformed polymer, polymer heated and deformed by the tip, and relaxed cold indentation; (b) Schematic of the stress–strain curves during an indentation experiment with hot and cold tips. See text for details.

Figure 4.22a describes (from left to right) the events during an indentation using a hot tip. If the hot tip is in contact with the polymer sample, the polymer is above T_g, which means that the dashpot is open and essentially free to move. Upon application of external stress, both springs will be deformed according to their strength, as shown by the dashed line in the stress–strain diagram in Figure 4.22b. Let us assume that the total deformation is d_t. Upon cooling, we lock the dashpot in the deformed state, and by releasing the external stress, $\sigma_{F,h}$, spring k_s relaxes to its uncompressed length. This state is show in the center of Figure 4.22a. We observe a partial loss of the indentation depth (to d_c for the cold case) as we retract the tip which results from elastic recovery in the material.

However, the $k_p - \gamma$ system is still deformed, and a residual stress given by the deformation of the polymer network spring k_p is locked in the deformation. In fact, this residual stress can be used to erase the indention (as will be shown in Section 4.6), and we also found stress-dependent relaxation in retention studies of the indentations. This deformation above T_g implies that the dynamics follows WLF kinetics because the backbone relaxation dynamics also follows this law. And indeed, we did observe this behavior for hot tips, as shown above.

If we deform the polymer below T_g, the situation is rather different, however. Under a cold tip, the dashpot is initially in the locked state. If we apply stress, the entire deformation at low stress values will first be absorbed only by the elastic spring k_s. The dashpot only opens once a critical stress, the yield stress σ_y, has been attained, as indicated by the solid line in Figure 4.22b. At the yield stress, the backbone motion is forced by the external stress and we have reached the writing threshold. As the dashpot opens, k_p is deformed accordingly, producing internal stress and, similarly to the hot case, we obtain elastic stress relaxation upon removal of the external force.

The state of the polymer after indentation is therefore remarkably similar in the two physical pictures discussed. Stress is stored in the deformed polymer network and is frozen in by the glassy state of the cold polymer. Only the amounts of elastic recovery (to d_c and d_h) and of the internally stored stress ($\sigma_{i,c}$ and $\sigma_{i,h}$) differ slightly. Experimentally, there is evidence of a higher remaining stress in cold indentations than in hot written ones because, at elevated temperature, the former relax faster (A. Knoll, unpublished results). The other significant manifestation of the two mechan-

isms is in the indentation dynamics, where we see a transient crossover from yielding to rubbery deformation with increasing temperature.

It is concluded that nanoindentation is a universal technique to study the deformation physics of polymers at the nanometer scale. By varying load, force, heat and temperature, important material properties – such as glass temperature, hardness, shift factors and yield-activation energies – can be extracted.

4.6 Application in Data Storage: The 'Millipede' Project

The capability of scanning probe techniques to modify and image a surface on the nanometer scale makes these techniques obvious candidates for data-storage applications. In fact, since the invention of the STM, many demonstrations of bit formation and imaging have been reported in the literature using almost every SPM technique and many different storage media and write mechanisms. Perhaps the most impressive of these demonstrations – at least from a density point of view – is the manipulation of individual atoms on a surface [67]. Although the storage densities that could be achieved with such techniques are very impressive, the construction of an actual storage system based on one of these ideas requires that numerous issues be addressed, including automated bit detection, system data rate, error correction, bit retention, power consumption, eraseability/cyclability, servo/tracking, reliability and cost. Many of these requirements are actually in competition with each other. For example, the highest storage densities demonstrated so far – that is, atomic scale – were achieved with very slow read-back speeds and had rather complex system requirements, such as ultra-high-vacuum conditions and low temperatures.

One scanning probe storage technology that achieves a balance between the many competing system requirements is the thermomechanical approach developed by IBM and referred to internally as the 'millipede' project [6, 7, 68]. In order to achieve a data rate comparable to those of conventional storage technologies, IBM has used microelectromechanical systems (MEMS) technology to fabricate large arrays of cantilevers that can be operated in parallel, with each cantilever writing and reading data in its own small storage field. The internal name of the project – 'millipede' – refers to the approximate 1000 cantilevers that were used in one of the first prototype systems.

4.6.1 Writing

The *write mechanism* used is the thermomechanical nanoindentation of polymers, as described in Section 4.5. The basic write process is illustrated in Figure 4.23. Data are written by pulsing the voltages applied to the cantilever to obtain suitable heat and force pulses while the tip is being scanned over the surface. Indentations placed at predefined positions along the data track can be used to encode data, with for

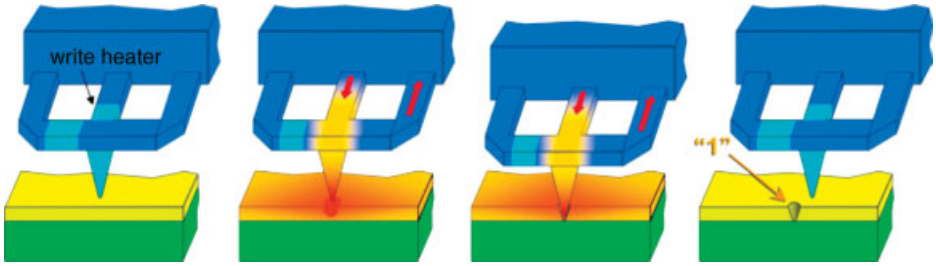

Figure 4.23 The principle of thermomechanical writing. The tip is heated by applying a current pulse to a resistive heater integrated in the silicon cantilever, directly behind the tip.

example, an indentation representing a logical '1' and the absence of an indentation a logical '0'. Storage densities greater than 1 Tb in^{-2} have been demonstrated using this scheme in combination with appropriate coding [69].

4.6.2 Reading

The data are read back by measuring the topography of the polymer surface using same tip that wrote the data. In the IBM approach, this is done using a read-back mechanism based on heat-transport sensing. For this purpose, a second heater has been integrated into the cantilever structure. This second heater is remote from the tip, and can be heated without causing much of an impact on the tip temperature. When operated in ambient air conditions, the thermal resistance of the read heater exhibits a strong dependence on the distance between heater and medium surface, as discussed in Section 4.4.1. This thermal resistance dependence results in turn in a heater temperature dependence and hence also an electrical resistance dependence on the distance between heater and medium surface. (The electrical resistance change with temperature is an intrinsic property of silicon, as discussed in Section 4.2.) This situation can be exploited to sense the topography by applying a constant voltage to the heater and monitoring the changes in the electrical resistance that result as the tip is being scanned over the surface. For example, when the tip moves into an indentation (a '1'), the distance between cantilever and surface is reduced and the heat-transfer rate increased. This leads to a resistance change of the $\sim$1 kΩ heater of $\Delta R/R \sim 10^{-4}$ per nanometer (Figure 4.24).

4.6.3 Erasing

Erasing [6] is achieved by exploiting the mechanical stress that is stored in an indentation. The thermomechanical writing process described above results in indentations that are a metastable, deformed state of the polymer with a significant amount of stored elastic energy. If a sufficiently hot tip is pressed against the surface

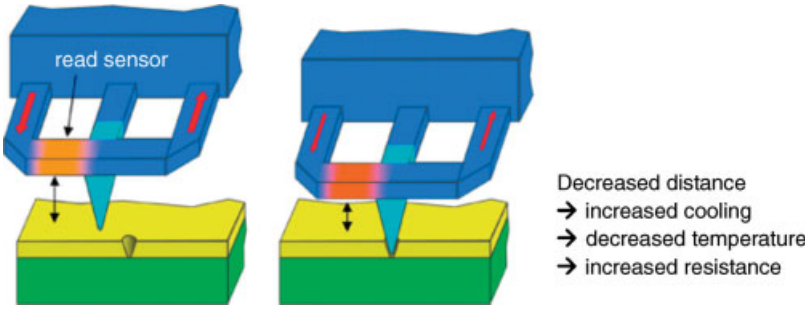

Figure 4.24 The principle of thermomechanical reading. Heat is generated by applying a current to a resistive heater integrated into the silicon cantilever. The heat transfer between heater and medium surface varies as a function of the distance between the cantilever and surface. Decreasing the distance between tip and medium leads to an increase in the cooling, which in turn decreases the temperature and increases the resistance, producing a detectable signal.

in the close vicinity of an indentation – that is, in the region of the rim around the indentation – then the increase in temperature in the indentation will result in a decrease in the viscosity of the polymer, which allows the elastic stress in the indentation to relax, effectively erasing the indentation. This process usually results in the creation of a new indentation, which can then be erased by repeating the procedure. Thus, a previously written data track can be erased by overwriting the data track with a series of closely spaced indentations. With this procedure, each new indentation erases the preceding one such that, at the end of the data track, all indentations will have been erased except for the last one. A demonstration of this principle is shown in Figure 4.25.

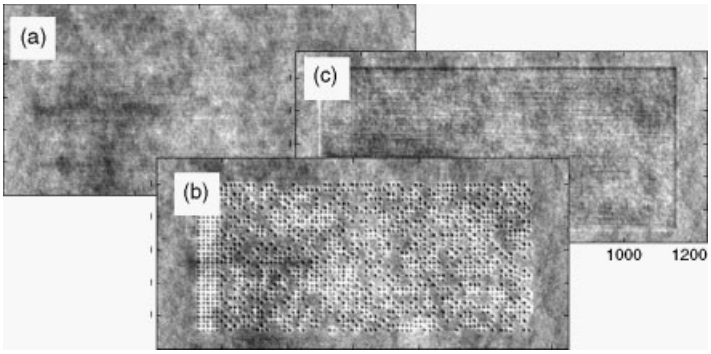

Figure 4.25 Atomic force microscopy topographical images illustrating the principle of thermomechanical writing and erasing. The images show (a) an empty area; (b) an area with indentations written at 1 Tb in^{-2}; and (c) an erased area. The grayscale covers 5 nm in all three images.

4.6.4
Medium Endurance

Medium endurance is a critical issue. The first challenge for polymer media is to be robust against repeated scanning with a sharp tip. In general, polymers tend to quickly roughen (and form ripples) when they are scanned repeatedly with a sharp tip, even at low load forces (see Section 4.6.5). Of the many solutions proposed to overcome medium wear, only a few can be readily applied to the nanoscale. On the nanometer scale, the homogeneity of the medium is crucial for nanoscale data-storage applications, and thus phase separation, filler particles or similar ideas cannot be used.

One elegant way to solve the issue of medium wear is to introduce a high degree of crosslinking into the polymer. This not only solves the roughening issue during sliding (reading) [56] but also facilitates erasing, because it provides the medium with a means of storing elastic energy and results in a type of 'shape memory'. To date, more than 10^4 write/erase cycles have been demonstrated using highly crosslinked polymer media (H. Podzidis *et al.*, unpublished results).

The dramatic improvement in wear endurance that occurs with increasing crosslinking is demonstrated in Figure 4.26, where the wear rate is plotted as a function of crosslink density for a set of polystyrene samples that were repeatedly scanned with a sharp tip. At a critical value of crosslinking, the mobility of the polymer is significantly reduced. This occurs when there is a sufficient number of crosslinks so that each region of cooperative polymer motion (typically ~1–3 nm in size) is affected.

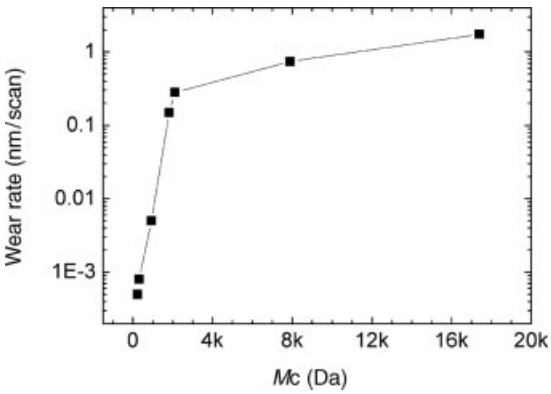

Figure 4.26 The peak amplitude of roughening induced by the wear of crosslinked polystyrene using a sharp tip scanning the surface, as in the reading operation. Here, the wear rate is defined as the cumulative amplitude of surface-topography changes normalized by the number of repeated scans of the same area. The wear rate is a strong function of crosslinkage. The crosslink density is given in units of molecular weight between crosslinks in the polymer chain. (Reprinted from Ref. [56]; © 2006, American Chemical Society.)

4.6.5
Bit Retention

Bit retention and the long-term stability of written data are also governed by the polymer mobility below the *Tg* value. This mobility is fundamentally provided by the activation energy of a backbone motion – that is, the so-called *alpha-relaxation*. Depending on the polymer, this can be as be as much as several electron volts, and can thus be sufficiently high for typical lifetime requirements. Lifetimes of 10 or more years at operating temperatures of up to $\sim$80 °C have been extrapolated from experimental data.

4.6.6
Tip Endurance

Tip endurance may limit the feasibility of several SPM-based data-storage schemes that involve mechanical contact between probe and surface. The endurance requirements of a tip will, of course vary, depending on the application and the system architecture. In general, however, a single tip will have to scan distances ranging from 10^4 to 10^8 m during the lifetime of the device, without losing its ability to read and write data. In thermomechanical data storage, the polymer medium is relatively soft compared to the hard silicon tips used for reading and writing. However, even for this combination, tip wear still is an important issue, and other – even harder – tip materials are also currently being investigated. Lubrication has proved to be key in improving the endurance of hard-disk drives, and may also prove to be useful for probe-based storage.

The density limits of thermomechanical data storage are predicted to be well above the 1 Tb in^{-2} mark. Ultimately, the density limits will be determined by the mobility of the polymer that corresponds to finite regions in which cooperative motions of polymer chains or chain segments occur. These regions range in size from 1 to 3 nm. As a small number of such regions must occur in each indented zone, a limit will appear somewhere at or below an indentation spacing of 10 nm.

4.6.7
Data Rate

The data rate is commonly one of the weaker aspects of SPM-related data-storage schemes. In the thermomechanical approach, two factors contribute to data-rate limitations:

- The cantilevered tip must be able to follow the topography mechanically; this translates into the requirement of a high mechanical resonant frequency.
- Temperature-based displacement sensor must be able to respond to these topography-induced height changes, ideally with a low power consumption.

The situation is further complicated by the requirement for low applied forces during the read operation in order to minimize tip and polymer wear. This low-force

requirement in turn entails the need for a small spring constant, which tends to reduce the resonance frequency. Finally, during the write operation, the cantilever must also be able to apply and withstand forces on the order of hundreds of nanoNewtons. Thus, in order to achieve a competitive thermomechanical storage technology, all of these competing requirements must be carefully balanced and the cantilever design highly optimized. However, even with optimization, a data rate per cantilever/tip well above 1 MHz appears speculative. Consequently, a high degree of *parallelization* of 10^2 to 10^4 tips operating in parallel is required to achieve a sufficient user data rate, and this is feasible only if the fabrication employs VLSI silicon technology. To date, the fabrication of prototype cantilever arrays with thousands of tips has been demonstrated, as illustrated in Figure 4.27. Moreover, parallel read/write operation at high densities using a small subset of cantilevers has been achieved [70]. Currently, three electrical connections to the array chip are required for each cantilever that is to be operated, and thus the number of cantilevers that can be operated in parallel is limited by the area available for bonding wires. The demonstration of higher degrees of parallelization will require the integration of some of the system electronics behind the cantilevers, and this is an area of current research. The other basic components required to make an actual prototype storage system based on this technology, including a MEMS scanner, a position-sensing and servo-control scheme, a bit-detection scheme and error-correction codes as well as a

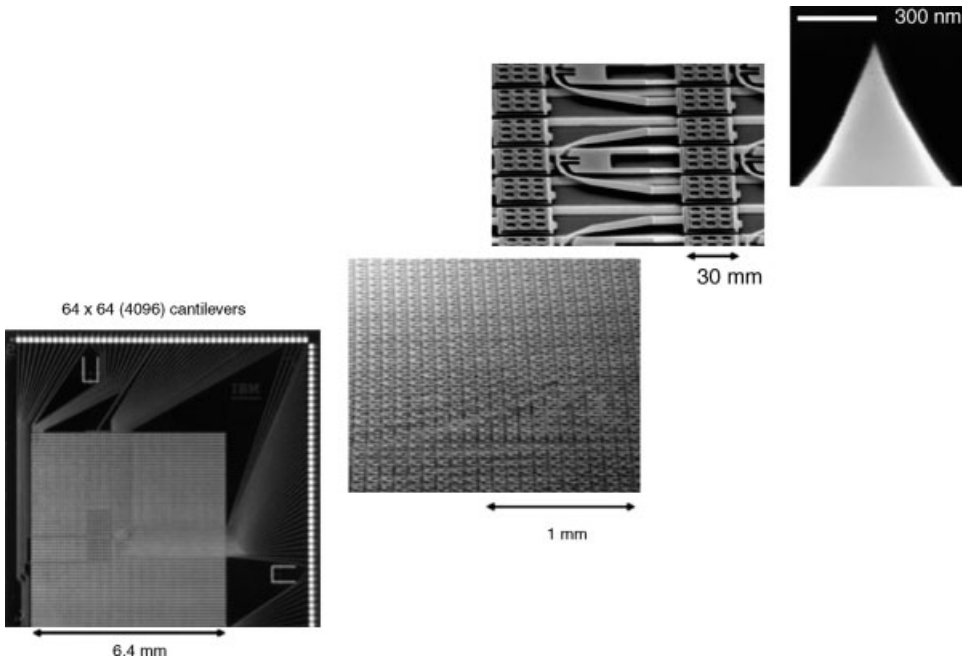

Figure 4.27 Microfabricated 64 × 64 cantilever/tip array for thermomechanical data storage.

system controller, have also been developed. All of this makes the route to highly parallel SPM-based storage appear feasible.

4.7 Nanotribology and Nanolithography Applications

Applications of heated probes going beyond thermal imaging and thermomechanical indentation can more generally be described as exposing surfaces to heated tips. In this section, examples are presented that lead to the modification and patterning of surfaces. First, experiments are described that involve scanning with a hot tip on polymer samples, with the aim of understanding nanoscale wear. Second, the *controlled* removal of material with the application to scanning-probe lithography (SPL) is developed and analyzed. Finally, dip-pen nanolithography using heated tips will be discussed.

4.7.1 Nanowear Testing

Nanowear testing using AFM is commonly performed to understand the nanoscale wear of various materials. Wear in general is a complex phenomenon, and often very different physical mechanisms come simultaneously into play, such as thermally activated bond rupture, adhesion, frictional shear stress, third-body lubrication, and so on [71]. Thus, in wear experiments, certain parameters are varied to elucidate the wear mechanisms. For example the repetition of wear cycles, the load force on the scanning tip, the scanning speed, or environmental conditions, such as humidity, are examined. Temperature is less suitable as a variable in such experiments, as mentioned above in the context of thermal imaging. However, temperature is a decisive parameter controlling wear, in particular of polymers. Let us, for example, consider the wear of polymer surfaces around T_g. The glass-transition region is often very sharp and covers only few degrees; for thin films T_g may vary by several degrees because of finite-size effects. A temperature variation of a sample around T_g therefore involves ramping the temperature in relatively small steps, with each step including settling for minutes, or even hours, to equilibrate the sample. In contrast, the *tip temperature* is easily varied and settles within microseconds. Therefore, heating the tip rather than the sample makes it possible to perform wide temperature variations in a single experiment [8, 14, 72].

As an example, let us consider experiments in which a variably heated tip is raster-scanned over polymer surfaces. While the tip temperature is continuously increased along the slow-scan axis, low loading forces are maintained between the tip and polymer surface. A real-space image of thermal degradation (a 'wear track') is generated, in which each fast scan line corresponds to a certain tip temperature. A wear experiment of a polymer film of polystyrene (PS), a standard linear polymer, is shown in Figure 4.28a. Here, three regimes can easily be identified:

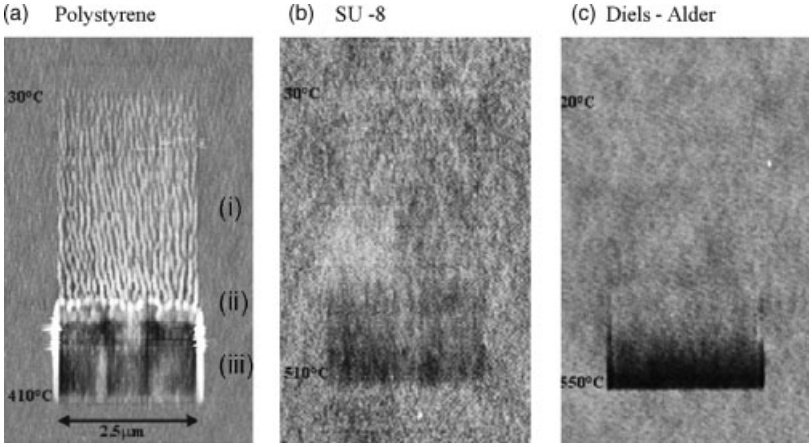

Figure 4.28 Wear tracks on different polymer samples obtained by raster-scanning a heated tip over a surface. The tip temperature is increased along the slow-scan direction (vertical). The wear track consists of 512 lines of 2.5 μm length scanned at 10 Hz. After the wear process, the images were obtained with an unheated tip in AFM imaging mode. (a) A polystyrene surface scanned four times; the grayscale covers an image corrugation of 17 nm. (Reprinted from Ref. [39]; (c) 2004, American Chemical Society.); (b) SU8 thermoset scanned 10 times; the grayscale covers a corrugation of 1.7 nm; (c) Diels–Alder polymer scanned 10 times; the grayscale covers a corrugation of 5 nm.

(i) At low temperatures, a *ripple pattern* is generated. The activated kinetics of ripple formation of PS has been studied using both variable sample temperatures [73] and heated tips [39]. Activation energies of the ripple process that exhibit a similarity with the yield process discussed above have been established.

(ii) A second regime is the glass-transition region – that is, at tip temperatures that lead to a heating of the polymer in the interaction region under the tip up to T_g. There rather drastic effects become apparent in a dramatic increase of the ripple amplitude.

(iii) In the third regime, above T_g, the material becomes so ductile that it is swept to the sides of the heated scan.

A very different trend is observed when the same experiment is performed with a thermoset material in which material transfer is more suppressed, for example in a highly crosslinked epoxy, such as a 100 nm-thick film of SU8 (see Figure 4.28b). Because of the high crosslink density of SU8, no ripple pattern can be formed. Overall, the surface remains unchanged by the wear test, and only a marginal depression is observed at the largest temperatures. If any debris is formed it is apparently so volatile that it cannot be traced on the surface with the probing tip after the wear procedure.

The third example (see Figure 4.28c) demonstrates yet another characteristic degradation mode, where a chemical reaction is induced by the heated tip. The

material is a highly crosslinked material in which the crosslinks are thermally reversible by virtue of a retro-Diels–Alder reaction [8]. The crosslinks are opened when a temperature of 130 °C is reached, and the material constituents are small molecular fragments that are rather volatile and may either diffuse onto the tip or evaporate. As observed in Figure 4.28c, no change in the surface is seen in areas scanned with heater temperatures of up to 320 °C. On further increasing the temperature, the depth of the wear track increases linearly up to 550 °C, although there is a clear lack of debris. In addressing the mechanism for track formation, compression is ruled out based on the observation that measured wear is cumulative. Repeating the experiment in a given area yields a proportional increase of the wear depth. Hence, it can be concluded that the material is lost by evaporation or diffusion onto the tip. The debris-less removal of material renders this method and the Diels–Alder polymer candidates for lithography applications. However, before we test this idea further let us briefly consider maskless lithography (ML2), in particular SPL.

4.7.2 Nanolithography Applications

In *microelectronics*, the time and expense required to produce a mask set is an issue in the prototyping of integrated circuitry [74]. For this reason, electron-beam lithography (EBL), which is an ML2 technique, is often used to prototype individual devices. The main drawback of ML2 efforts with respect to conventional lithography is the comparatively low exposure throughput. To remedy this, efforts are underway to develop EBL systems to operate a multitude of beams in parallel so as to reduce the overall exposure time [74]. However, further development and research is needed to control the crosstalk due to the high-voltage control signals and source brightness. The need for UHV conditions is also seen as an obstacle.

Currently, numerous SPL-based systems are under development – or have at least been proposed – and, in comparison to EBL tools, these will be more compact and simpler systems. The fabrication of large arrays of probes for massively parallel operation has been realized. One of the most powerful demonstrations of research-scale SPL used electrons extracted from a conducting tip to expose a resist [75]. Structures with resolutions of 30 nm have been transferred, and parallel operation has been demonstrated. The main challenges to this particular technique are the need for a conducting substrate, the high voltage necessary to extract electrons, the reliability of the electron-extraction process, and the lack of a simple overlay strategy.

Heated probes can also be used for SPL. For example, local heating has been used to induce the crosslink reaction of a conventional photoresist locally [76], after which the pattern is developed in the same way as in conventional lithography. Based on the example given in Figure 4.28c, an alternative SPL method can be applied that directly removes material from the exposed region. This approach offers specific advantages:

- It combines exposure and development in a single step, which not only makes the method simpler but also enables direct inspection of the exposure and direct repair

in a separate repair step. A prerequisite here is that the same probe can be used for imaging, which is possible because the exposure creates a surface topography that can easily be measured. Thereby, the difficult issue of reliability of SPL is directly tackled.

- It also facilitates the use of a simple overlay strategy based on exposure/development of alignment marks. These marks can be imaged and used to align the new layer to be exposed. Note that the same strategy could be used for stitching error correction or self-calibration of probe positioning.
- In contrast to conventional nanoindentation or nanoscratch-based methods [77], this variant helps to achieve high resolution because the material is not simply displaced but is actually removed from the exposure site [8]. This permits achievements similar to those with other SPL techniques.

A demonstration of a high-resolution exposure of such a material is given in Figure 4.29 [78]. The imaged area was inscribed using pixels spaced 3.0 nm apart in a line, with a spacing of 107 nm between the lines. Each pixel was written using a heat pulse of 20 μs duration and a loading force of 40 nN. The Diels–Alder polymers were shown to permit the production of repeatable lithographic features of 12–15 nm in size (full width at half maximum) by sequential inscription. This makes it possible to overlay line patterns and faithfully reproduce line-crossings, both features which are desirable in lithography.

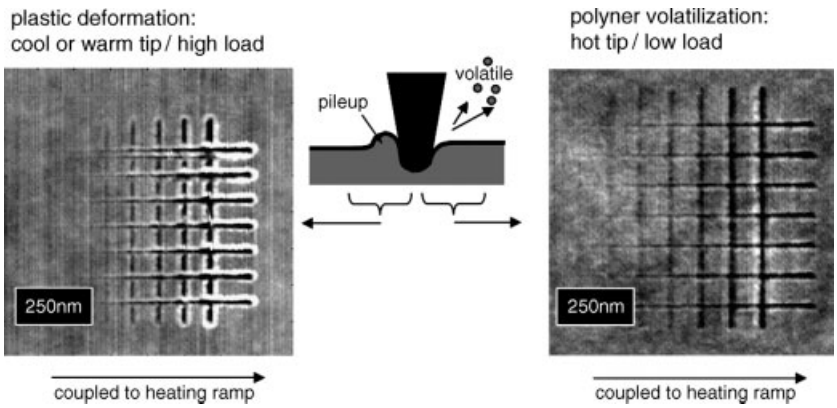

Figure 4.29 Comparison of lithography results using tips to (re)move material in a direct quasi-single exposure and development step. The material used is a reversibly crosslinked polymer described in Ref. [8]. Left panel: Conventional 'scratch'-type lithography using high forces (300 nN). The tip-heater temperature is varied from left to right, from room temperature to 440 °C. Independently of temperature, it is shown that the plastic deformation leads to a *displacement* of material to the sides of the individual lines written, making line-crossing impossible. Right panel: Similar experiment using a low load force (30 nN) and a heating ramp between 300 and 500 °C. In this case, material is *removed* and not just translated, and line-crossings are possible. A sketch of the difference between the two lithography processes is shown in the center panel.

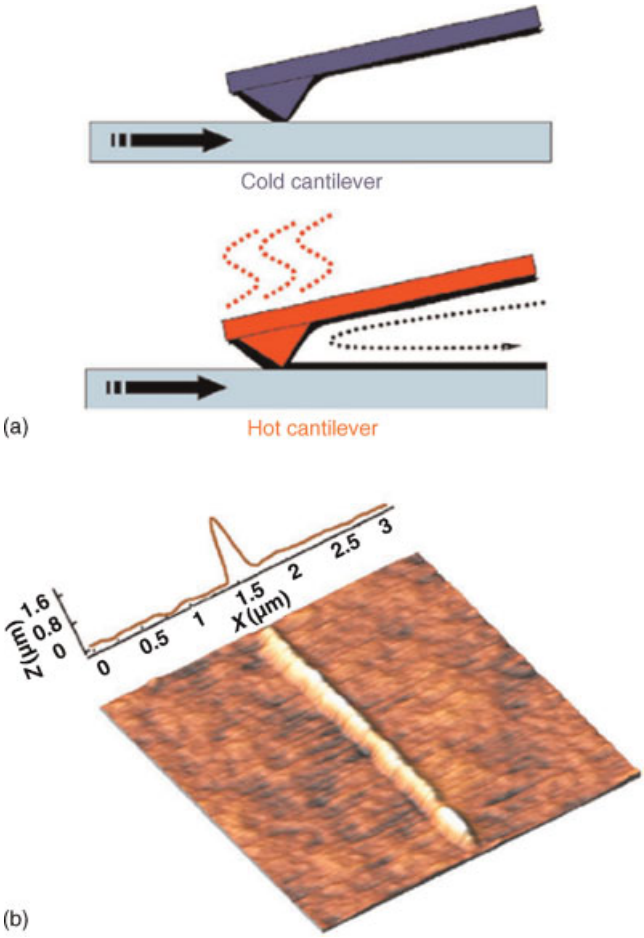

Figure 4.30 (a) Schematic of the operation of thermal dip-pen lithography (tDPN), which uses a heated AFM cantilever with a tip coated with a solid 'ink'. When the tip is hot enough to melt the ink, it flows onto the substrate. No deposition occurs when the tip is cold, thus enabling imaging without unintended deposition; (b) A topographic AFM image of a continuous nanostructure deposited from an indium-coated tip onto a borosilicate glass substrate. (Reprinted from Ref. [80]; (c) 2004, American Institute of Physics.)

The concept of removing material can be amplified by using materials that undergo an exothermic reaction when being volatized; in this regard, explosives have been used by King *et al.* [72]. The volatilization rate of a thin film of pentaerythritol tetranitrate exhibits a strong dependence on the tip temperature and exposure time. Although the study of King and coworkers emphasized the analytical application of heated probes, the nanostructuring context is evident.

For nanostructuring in a broader sense, it is interesting not only to *transfer* material along a surface (as in 'nanowear' experiments) or to *remove* material (as in the SPL examples above), but also to *deposit* materials. The deposition of material is particu-

larly appealing for biological applications. Although various methods exist to deposit material from liquid or gas phases using a scanned probe tip (such as local oxidation of semiconductor surfaces [79]), the direct deposition of liquid droplets or lines using dip-pen lithography (DPN) has recently attracted considerable attention. In this method, an AFM tip that has been covered with a liquid to be deposited is brought into contact with a surface at locations where the liquid is to be deposited. In numerous experiments performed over the past few years, a range of materials have been successfully deposited, notably those used for biopatterning applications. A major challenge of DPN is the controlled switching on and off of the deposition process. Since in many applications, arrays of probes must be run in parallel in order to achieve sufficient throughput, individual probes cannot easily be brought into and out of contact independently; otherwise, all probes would write the same pattern. One strategy to circumvent this problem relies on heated probes, where the temperature of the tip – the sidewalls of which are the 'ink' reservoir – can be used to turn the deposition on and off. This has been demonstrated by Sheehan *et al.* [80] (see Figure 4.30), where lines of ink (octadecylphosphonic acid) were written at linewidths down to 100 nm in a controlled manner.

Acknowledgments

The authors would like to thank C. Bolliger for carefully proof reading the manuscript of the chapter. They are also grateful to the 'Millipede' teams at the IBM Research Laboratories in Zurich and Almaden for their continued collaboration and helpful scientific discussions. Previously unpublished results were obtained in collaboration with J. Frommer, C. J. Hawker, J. Hedrick, M. Hinz and R. Pratt.

5
Materials Integration by Dip-Pen Nanolithography

Steven Lenhert, Harald Fuchs, and Chad A. Mirkin

5.1
Introduction

The concept of using a tip coated with an ink – that is, a pen – to write on a surface has been used throughout history and is widely used today for recording or communicating information by hand. Although the most ancient written texts appear to have been carved in surfaces using sharp tools such as a knife or chisel, there are several reasons why the pen has eventually become the hand-writing tool of choice. First, the constructive nature of the pen typically enables a higher contrast than carving, making it possible to distinguish the writing from the surface background without further processing steps. Second, pen writing is relatively independent of the contact force in comparison with carving. And finally, if desired, a variety of different inks can be readily integrated on the same surface.

The same conceptual advantages that make the pen a useful tool on the macroscale also translate to the nanoscale when the tip of an atomic force microscope is used as an ultra-sharp pen to transfer material to a surface with nanometer scale resolution, a method known as dip-pen nanolithography (DPN) [1]. By using this technique, high-resolution chemical patterns can be constructed on surfaces in a single deposition step. Because the ink-transfer is independent of the contact force between the atomic force microscope tip and the substrate in almost all known cases, it is possible to carry out DPN reproducibly and in parallel, without the requirement for feedback from individual tips. By coating different tips with different inks, it then becomes possible to integrate a wide variety of molecules on a surface. As with other scanning probe lithography (SPL) methods (e.g. mechanical modifications, oxidation, local thermal treatments), DPN offers ultra-high lateral resolution, well below 20 nm. As a direct write lithographic method, DPN enables arbitrary patterns to be drawn without the need for a mask, with capabilities comparable to those of electron-beam lithography (EBL). Additionally, it is a tool that is ideally situated to rapidly produce laboratory prototypes and structures that are incompatible with the harsh conditions associated with conventional microfabrication techniques (soft biological structures in particular).

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

Importantly, DPN makes it possible to integrate different materials on scales (both in size and complexity) that appear impossible to reach by any other direct-write fabrication method. Such a method is clearly desirable for the fabrication of biomolecular arrays, and opens entirely new possibilities in the study and development of nanotechnology. This chapter will introduce the fundamental concepts in DPN technology, with a focus on aspects which enable nanoscale materials integration. In order to gain an understanding of what to expect, theoretical models will be introduced, followed by experimental approaches to controlling ink transport of various ink–substrate combinations, tip-coating methods, driving forces and characterization methods. Examples of unique applications of materials integration by DPN will then be described that cannot be achieved by any other method. Excellent reviews have been produced by Mirkin and others that summarize the DPN literature, and the reader is referred to those works for a more complete description of the vast amount of work already published on DPN to date [2–4].

5.2 Ink Transport

DPN is made possible by the transport of a material (ink) from the tip of an atomic force microscope to a surface at point where the tip contacts the surface (Figure 5.1a). As in the case of a macroscopic pen, the ink must flow from the tip of the pen to the paper, and this transport process is typically driven by an interaction between the ink and the substrate. However, quantitative differences appear when this technique is carried out at the nanoscale tip of an atomic force microscope. Most striking is that DPN is able to produce patterns consisting of a single molecular layer. The most

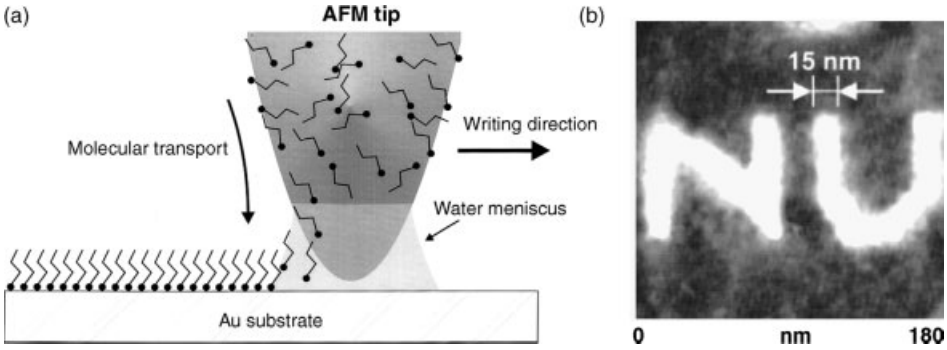

Figure 5.1 (a) Schematic illustration of the concept of dip-pen lithography DPN. (Reprinted from Ref. [1], with permission from the American Association for the Advancement of Science.); (b) Atomic force microscopy (AFM) friction image of patterns of the thiol mercaptohexadecanoic acid patterned on gold ⟨111⟩ with 15 nm line widths. (Reprinted from Ref. [5], with permission from the American Association for the Advancement of Science.)

thoroughly studied (and widely reproduced) ink–substrate combination for DPN is the patterning of alkanethiols on gold surfaces. Alkanethiols spontaneously self-assemble on gold surfaces under the appropriate conditions to form tightly packed self-assembled monolayers (SAMs). Typical thiol inks include octadecanethiol (ODT), which forms a methyl-terminated SAM, and mercaptohexadecanoic acid (MHA), which forms a carboxylic acid-terminated SAM. Figure 5.1b shows an example of a high-resolution DPN pattern of MHA on a single crystalline gold surface, with line widths of 15 nm. As the radius of curvature of the tip used to make that pattern was approximately 10 nm, it has been hypothesized that a sharper tip may enable the fabrication of even smaller features [5]. The ultimate resolution limit of DPN has yet to be determined. It has even been proposed that DPN can be used to generate features consisting of single molecules, and that the practical limit lies in detecting such small features by atomic force microscopy (AFM) [6].

In a typical experiment aimed at characterizing the transport rate of an alkanethiol such as MHA or ODT from the atomic force microscope tip to a gold surface, the coated tip is placed in contact with different areas of the surface for different amounts of time. These contact areas can then be imaged *in situ* by rapidly scanning the patterned area with the same tip in lateral force mode to obtain a friction contrast image such as that shown in Figure 5.2a. Upon plotting the area (or radius, r) of the spots as a function of contact time, it is possible to quantify ink transport rate. It is reproducibly observed that the surface area covered by a single dot is roughly proportional to the contact time, albeit with some exceptions – for example, in the case of very long contact times [7]. Based on this simple assumption, a single parameter can be used to describe the transport rate – namely a spreading constant C expressed in units of $\mu m^2\,s^{-1}$ (dashed line in Figure 5.2b). Once this transport rate has been determined, and is considered in a calibration, it then becomes possible to control dot dimensions and fabricate arbitrary patterns in a lithography process [8].

5.2.1
Theoretical Models for Ink Transport

The ability to obtain quantitative data on transport rates of inks, as well as the morphological information obtained by *in situ* AFM imaging, opens the possibility of testing theoretical models for the nanoscale ink transport in DPN. In addition to the perfectly round and sharp spots reproducibly achieved when patterning thiols on gold under optimal conditions, occasionally it can be observed that some spots appear more diffuse, are surrounded by a halo of lower lateral force microscopy (LFM) contrast or consist only of a ring. Furthermore, in some cases an 'anomalous diffusion' is observed where, instead of circles, fractal-like branches appear. Figure 5.3 shows schematics of four models that have been developed to explain and understand the different spreading phenomena observed in DPN experiments. The first three models (see Figure 5.3a–c) focus on the deposition of thiol SAMs on gold, where a strong chemical binding of the ink molecule to the substrate is expected and anomalous diffusion is not observed. The fourth model explains anomalous diffusion in terms of strong intermolecular interactions within the ink.

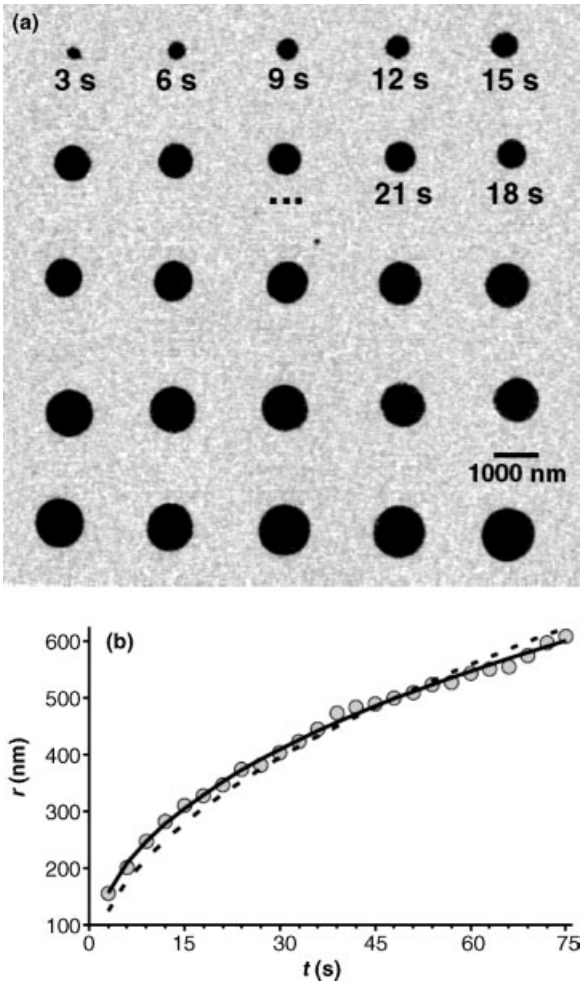

Figure 5.2 (a) Lateral force image of octadecanethiol dots deposited on a gold surface at different contact times; (b) A typical plot of the radius (r) of the spots versus contact time (t), including fits to two theoretical models. (Reprinted with permission from Ref. [9]; © 2002, American Physical Society.)

The first two models (Figure 5.3a and b) are based on diffusion theory, and are similar in that they both assume the tip to be an infinite point source, and use diffusion theory to describe the spreading of a thiol monolayer on a gold surface. The first model (Figure 5.3a) assumes a constant flux of molecules flowing from the tip, with a concentration of zero outside a spread island. That idea is consistent with the experimental observations that the area tends to increase linearly with contact time, and that the monolayer islands have sharp edges in the majority of AFM images. The second model (Figure 5.3b) assumes a constant concentration at the tip and an area of

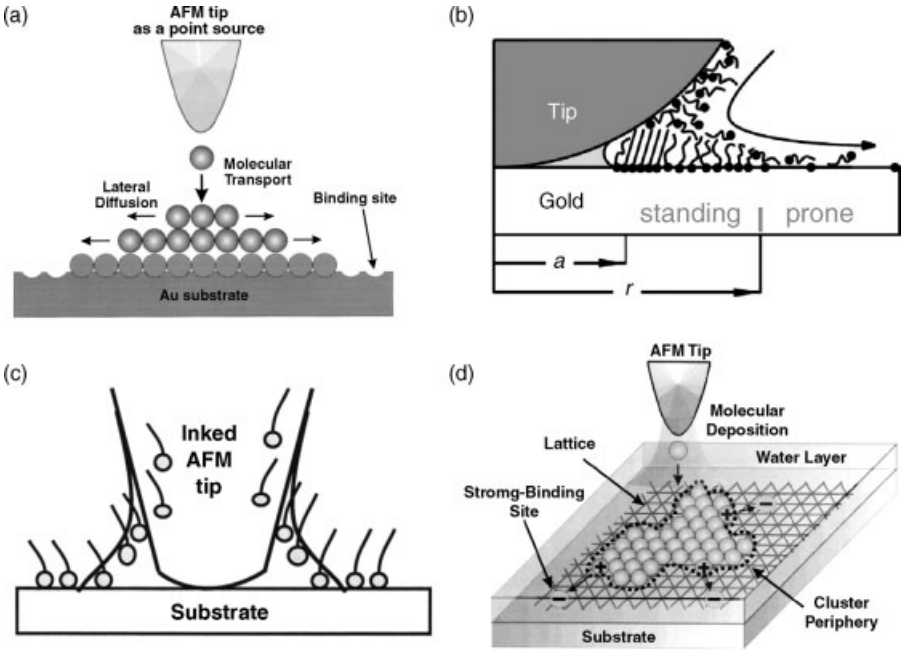

Figure 5.3 Drawings of different models of ink transport. (a) Diffusion model with constant flux from the tip. (Reproduced with permission from Ref. [14]; © 2001, American Institute of Physics.); (b) Diffusion model with a constant concentration at the tip. (Reprinted with permission from Ref. [9]; © 2002, American Physical Society.); (c) Meniscus interface transport model. (Reproduced with permission from Ref. [15]; © 2006, American Institute of Physics.); (d) Model for anomalous diffusion based on collective behavior. Reproduced with permission from Ref. [13]; © 2006, American Institute of Physics.)

a lower density of thiol molecules on the surface diffusing from the tightly packed monolayer. This second model allows for variation in the flux from the source, explains the occasional presence of halos and provides a slightly better fit to the experimental data (solid line in Figure 5.2b). The constant-concentration model also allows the derivation of an absolute diffusion coefficient using three physically relevant fit parameters (tip contact area, ratio of the concentration on the tip to that of a tightly packed monolayer and the diffusion coefficient).

In addition to the general idea of modeling the tip as a point source from which ink molecules diffuse, the effect that a microscopic condensed water meniscus forming at the tip–substrate contact point in the presence of humidity has been considered in order to further unravel the mechanisms by which the ink molecules make their way to the surface [10]. In particular, amphiphilic molecules such as MHA, which are only very slightly soluble in water, might be expected to show an affinity for the air–water interface. The meniscus interface transport model (Figure 5.3c) was therefore developed and can be used to explain the formation of hollow ring patterns. This model can also predict the transport behavior of a variety of amphiphilic molecules, including some that physisorb on the substrate.

Molecular dynamics simulations have suggested that SAM growth on the nanoscale involves a molecular basis that cannot be adequately described by analytical diffusion models [11]. For instance, it was shown that, even in the case of strong binding (e.g. alkanethiols on gold), the monolayer will grow as molecules from the tip displace molecules already bound to the surface, in a mechanism more akin to spreading than to diffusion. Computer simulations have also been able to recreate anomalous diffusion [12] *in silico* by considering the collective behavior of the molecules in a SAM (Figure 5.3d) [13]. There is evidence supporting aspects of each of these models, and there is no consensus as to which is the best. Further innovations from theoreticians, as well as carefully planned experiments designed to test the different models, are necessary to determine the true situation at the DPN tip.

5.2.2 Experimental Parameters Affecting Ink Transport

Several experimental parameters have been observed to influence the ink transport in DPN, including: driving forces (chemical interactions and external fields), ink composition, surface properties (chemistry and roughness), humidity, temperature and tip geometry. It is necessary to understand and control these parameters in order to optimize DPN processes for a particular application. This is especially important if different materials and nanostructures of the desired materials are to be integrated on the same substrate.

5.2.2.1 Driving Forces

In order for the ink to move from the tip to the substrate, a driving force is required, otherwise the ink will simply remain on the tip. Internal driving forces (i.e. in the absence of external fields) are typically based either on a chemical reaction of the ink with the substrate (chemisorption) resulting in a SAM, or on physical adhesion of the ink to the substrate (physisorption). Another approach is to apply an external field, for instance by heating the tip (thermal DPN) or applying a voltage (electrochemical DPN). It is worth noting that all DPN fabrication process require some sort of interaction between the ink and the substrate, even when the driving force is provided externally.

5.2.2.2 Covalent Reaction with the Substrate

The covalent reaction of the ink molecules with the substrate to form a SAM is the most straightforward and widely used driving force in DPN. The most reproduced and well-studied system is the formation of thiol SAMs, as described in Section 5.2.1. However, covalent self-assembly has also been used as a driving force for other ink molecules. As an example, considerable effort has been made to develop reproducible methods for DPN on semiconducting or insulating surfaces such as silicon and glass, as thiols are limited to self-assembly on metallic surfaces.

Functional silane molecules are widely used for the fabrication of SAMs on semiconductor surfaces, and are the therefore the first choice. However, a drawback of patterning silanes by DPN in air is that they polymerize in the presence of water,

and tend to be liquid in their monomeric state (thiol inks in contrast are typically solid at room temperature). Despite these challenges, it has been shown that through careful optimization of the experimental conditions – for example, selection of the molecule, control of humidity and functionalizing the AFM tip – it is possible to pattern SAMs of functional silanes [16–18]. Another approach is to choose a functional group for self-assembly that is not as sensitive to water; for example, silazanes have been shown to be suitable inks on semiconductor surfaces by covalent reaction with OH groups on the surface [19].

Perhaps the most generally applicable strategy for depositing and integrating arbitrary molecules on an arbitrary surface by DPN is to prefunctionalize the desired surface with a bulk SAM, which can then be covalently linked to the ink molecule of choice. This approach has been particularly useful for the patterning of biofunctional molecules (this will be discussed in more detail in Section 5.6). Briefly, it has been used successfully for direct DPN of synthetic macromolecules [20], peptides [21] and DNA [22].

5.2.2.3 Noncovalent Driving Forces

While chemisorption of the DPN ink results in highly stable patterns, covalent reactions tend to be highly specific – and therefore in some cases it is desirable to be able to deposit an ink noncovalently. Examples include patterning on inert substrates, the integration of different materials on the same substrate, and/or the fabrication of multilayer structures. Such noncovalent deposition is, for example, the method used for patterning with macroscopic pens.

Numerous examples of noncovalent patterning have been reported in the literature. For example, the first instance of controlled deposition of organic materials from an AFM tip was the deposition of thiols on mica [23]. Electrostatic interactions have been used as a driving force to pattern charged conducting polymers [24], as well as polyelectrolytes which could be used as templates for layer-by-layer assembly [25] on silicon substrates. Inorganic nanostructures were fabricated by depositing inorganic precursors dispersed in a copolymer surfactant or dissolved in an ethylene glycol solvent which wets the substrate [26, 27]. Luminescent polymer nanowires were patterned on glass using only adhesion as a driving force [6, 28]. Nanoparticles (Fe_3O_2 and gold) have been picked up by an AFM tip and deposited noncovalently in controlled fashion onto mica surfaces in air by DPN [29, 30]. Semiconductor precursors, which are expected to react with each other and precipitate CdS only in the water meniscus, were used as inks to fabricate semiconductor nanostructures on mica [31]. Another approach is to mix a functional molecule with a well-characterized ink, as has been demonstrated by the DPN patterning of binary ink mixtures [32]. Finally, surfactants can be added to the ink in order to tune the 'wettability' of the ink on the substrate, providing another parameter that can be used to control ink transport [33].

5.2.2.4 Tip Geometry and Substrate Roughness

In addition to chemical interactions between the ink and substrate, it is also apparent that the topography of the substrate and geometry of the tip play a role in ink

transport. The effect that these parameters have on the minimum feature size was systematically investigated in the case of alklythiol patterning on gold surfaces, where the smallest line widths (14 nm) could be achieved with the sharpest tips, and on the smoothest gold available [8]. In another study on the effect of tip-geometry, the AFM tips were deliberately made blunt using laser ablation [34]. It was then found that not only did the minimum feature size depend on the tip radius, but also the rate of ink transport – an idea consistent with several of the ink transport models described above.

5.2.2.5 **Humidity and Meniscus Formation**

A significant amount of evidence is available which suggests that the transport of ink molecules with polar groups (such as the thiol MHA) are heavily dependent on humidity, with higher humidity showing higher diffusion constants. Although there seems to be only a slight (if any) humidity dependence for the nonpolar molecule ODT [9, 10], the effect cannot be ignored in the patterning of just about all other molecules. *Humidity* is therefore an important parameter that must be controlled in order to optimize DPN conditions. Ideally, this is achieved by encasing the DPN apparatus in an environmental chamber, or locally by placing a water-containing capillary tube near the atomic force microscope tip. Although the possibility that the humidity might affect the ink properties or substrate reactivity has not been excluded, it is generally thought that the mechanism for humidity dependence depends on the presence of a meniscus that condenses at the tip of an AFM when it contacts a surface in the presence of humidity [35].

Theoretical studies of meniscus formation at an atomic force microscope tip based on Monte Carlo simulations have predicted that the meniscus should depend not only on humidity, but also on the tip geometry and surface chemistry [36]. Striking images confirming the presence of such meniscus formation (and indeed showing that the meniscus can grow larger than expected) have been made possible by using environmental scanning electron microscopy (ESEM), as shown in Figure 5.4 [37]. Interestingly, studies of the kinetics of meniscus formation between an atomic force microscope tip and gold surfaces showed similar trends as the early patterning rates of thiols on gold. It has therefore been hypothesized that growth of the water meniscus may in some cases be the rate-limiting step in DPN ink transport [15, 38].

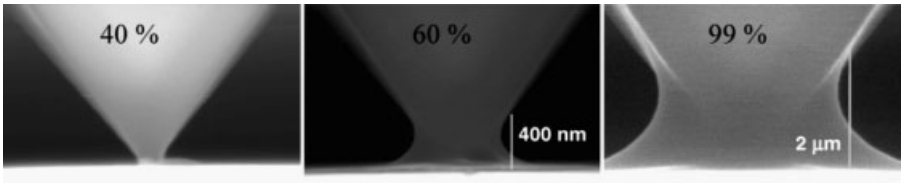

Figure 5.4 Environmental scanning electron microscopy (ESEM) series of meniscus formation on a cantilever tip at three different relative humidities (left, 40%; center, 60%; right, 99%). (Reproduced with permission from Ref. [37].)

It should be noted that, although the humidity clearly influences ink transport in DPN, it does not appear to be a prerequisite, as patterning has been achieved at 0% humidity and even in ultra-high vacuum [9, 10].

5.2.2.6 External Driving Forces

Another approach to controlling the transport of materials from an atomic force microscope tip to the surface is to apply an external driving force between the tip and the substrate. Although this poses an engineering challenge in fabricating externally addressable tips, the ability to switch a particular pen on and off greatly increases the versatility, especially when one considers parallel arrays of tips where each may be addressable for large scale integration. Two examples are the use of heatable cantilevers (thermal DPN) and the application of a voltage between the tip and sample (electrochemical DPN).

5.2.2.7 Thermal DPN

The idea of thermal DPN is similar to that of a soldering iron; that is, the material on the tip of the microscope should be heated above its melting temperature in order to facilitate transport to the surface. The concept is shown schematically in Figure 5.5. Although heating the ink can be a disadvantage for biological inks, which may be sensitive to high temperature and dehydration, it provides a useful means of patterning other materials. For example, octadecylphosphonic acid (OPA) was the first compound to be patterned on silicon by using thermal DPN [39]. It was observed that OPA only began to write when the tip was heated above a critical temperature.

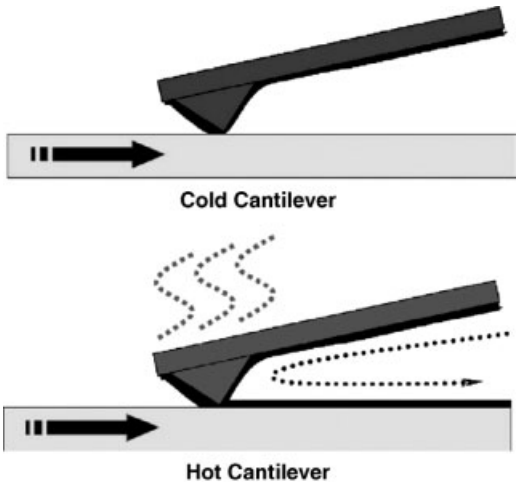

Figure 5.5 Schematic of the concept of thermal DPN. At low temperature, the ink does not transfer from the tip (top), while upon heating the tip the ink flow can be controlled (bottom). (Reproduced with permission from Ref. [39]; © 2004, American Institute of Physics.)

The method has since been applied to the deposition of conducting polymers [40]. Although it was initially suggested that thermal DPN is necessary for organic compounds with high melting points, it has since been shown that such compounds can also be patterned at room temperature (well below their melting temperatures) by humidity-controlled DPN. For instance, OPA as well as other compounds with melting points up to 230 °C have been patterned at room temperature under the appropriate humidity [41]. The mechanism of transport in thermal DPN of organic inks therefore remains unclear, although it appears to be possible to control the ink transport by controlling the tip temperature. Most striking is that indium metal nanostructures could be directly written by thermal DPN [42]. Furthermore, by filling a single carbon nanotube with molten copper and then dispensing it under observation with a transmission electron microscope, it has been suggested that using such a carbon nanotube-based spotwelder in thermal DPN might enable the ultra-high resolution of molten metals by thermal DPN [43]. Such direct, nanoscale writing of water-insoluble metals has not been shown to be possible below the melting point of the metal.

5.2.2.8 **Electrochemical DPN**

Another approach to controlling the transport of ink from the atomic force microscope tip is to use the water meniscus as a nanoscale electrochemical cell, where metal salts can be dissolved, reduced and precipitated to form metal nanostructures on the surface; this method, which is referred to as electrochemical DPN (E-DPN), is illustrated schematically in Figure 5.6 [44]. This method was further applied to the controllable transport of his-tagged proteins, which have an affinity to certain metal ions such as Ni^{2+}. By carrying out E-DPN on nickel-coated surfaces, the surface could be locally ionized, thereby allowing proteins on the microscope tip to transport the surface and bind. The same approach of combining local surface oxidation with material transport from the atomic force microscope tip was used to locally oxidize a pre-existing SAM and to simultaneously deposit organic inks to those same areas [45].

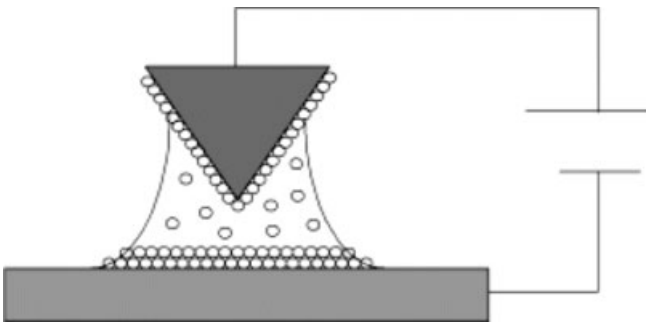

Figure 5.6 Schematic of electrochemical DPN (E-DPN). The water meniscus that condenses in air between the AFM tip and sample is used as a nanometer-sized electrochemical cell. (Reproduced with permission from Ref. [44].)

5.3
Parallel DPN

5.3.1
Passive Arrays

The constructive and chemically driven nature of DPN makes it uniquely amenable to being carried out in parallel, using arrays of tips, and without the need for accessing each tip electronically for force feedback. A rough alignment of the tip-array with the surface is sufficient, since if the tips are touching the surface then the ink will be transported at a constant rate which is determined primarily by the ink–substrate combination. The first demonstration that DPN could be readily carried out in parallel, employed micromachining processes to fabricate one-dimensional arrays with 32 silicon nitride tips or eight boron-doped silicon tips, the latter having sharper tips at the expense of pen densities [46]. The number of tips in a single linear array was then scaled up to the centimeter scale, using arrays of up to 250 tips, all of which wrote simultaneously [47]. Parallel DPN was then scaled up again to a two-dimensional arrays of tips that covered a square centimeter and consisted of 55 000 probes writing simultaneously; an example is shown in Figure 5.7 [48]. The parallel and constructive capabilities of DPN are what give it the potential to integrate materials on unprecedented scales.

5.3.2
Active Arrays

One factor which limits the complexity of patterns that can be generated by parallel DPN as described above, is that every tip necessarily writes the same

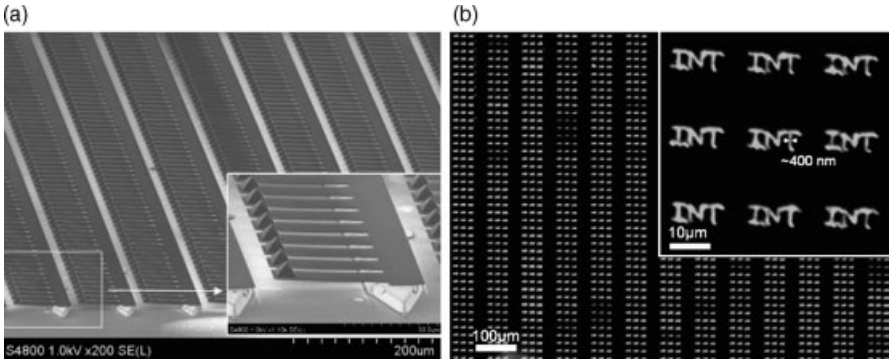

Figure 5.7 Massively parallel dip-pen nanolithography (DPN) with two-dimensional (2-D) tip arrays. (a) Scanning electron microscopy image of a small section of a 55 000 tip array covering an area of 1 cm^2. (Image courtesy of NanoInk.); (b) Fluorescence image of phospholipid patterns generated with the 2-D arrays at a throughput of 5 $cm^2\ min^{-1}$ [49].

pattern, provided that it is coated with ink. That is, it would be impossible to get each tip in an array to write a different pattern using passive tips. In addition to the possibility of controlling the driving force by external fields (e.g. by thermal DPN or E-DPN, as described earlier), another innovative step in the development of DPN probes for parallel materials integration was taken in which the cantilevers could be externally actuated. The first approach of this type used thermal bimorph cantilevers, where heating one side of the cantilever caused it to bend down so that the tip contacted the substrate and the ink could flow [50]. Again, by optimizing the tip fabrication the resolution of patterns generated by active pen arrays could be brought down below 100 nm [51]. Another approach would be to use electrostatically actuated cantilevers, where the cantilever bends towards the surface based on an applied electric field in order to avoid the possibility of unwanted heating of the tip or thermal crosstalk between neighboring cantilevers [51]. Actuated probes not only increase the available complexity of patterns that can be generated by a single ink, but also open the door to the integration of different materials from different tips in an array on an area smaller than the dimensions of the tip array itself. This can be done by writing with one tip, and then moving the array such that a neighboring tip writes on or near the same area that has already been patterned.

5.4 Tip Coating

5.4.1 Methods for Inking Multiple Tips with the Same Ink

An essential part of any DPN process is to bring the ink onto the atomic force microscope tips. This is typically achieved either by thermally evaporating the ink onto the tips, or by immersing the tips in the ink in a type of dip-coating process. Thermal evaporation is rather straightforward and typically results in a homogeneous ink coating, for instance of ODT. However, the majority of ink molecules – and especially the more polar ones – do not seem suited to evaporation, and tend to function better when the tip is coated from solution. For solution coating, the entire cantilever chip can be dipped by hand into an ink solution and, upon removing the tip and allowing the solvent to dry (e.g. under a stream of inert gas), a typically homogeneous coating results. However, the distribution of the ink on the tip when coated in this way will inevitably depend on exactly how the ink wets (or de-wets) the tip, and also on how the ink solutes concentrate on the tip as it is dried. Functionalization of the atomic force microscope tip before coating is therefore sometimes beneficial. For instance, in order to reproducibly pattern proteins it was found useful to precoat the tips with a SAM of a thiolated polyethylene glycol [11-mercapto-undecylpenta(ethylene glycol)disulfide(PEG)], which makes the tip hydrophilic but prevents the denaturing of adsorbed proteins [52].

5.4.2 Ink Wells

Inking the tips in the ways described above is well suited for single tips, or in the case that the requirement is to coat all tips with the same ink. However, in order to take advantage of the potential for DPN to integrate different materials on the same substrate in parallel, it is necessary to deliver different inks selectively to different tips in an array. For this purpose, microfluidic ink-delivery systems have been developed [53, 54]. An example of tips being dipped in wells that coat only every second tip in an array is shown in Figure 5.8a. An array where only every second tip is coated is useful for many experiments that require uncoated tips as negative controls, or in cases where there is a need to have the patterns spaced further apart than the spacing of the tips in the array. Today, ink wells are available commercially (from the company NanoInk) that allow the integration of up to 24 different inks on a one-dimensional array. Figure 5.8b shows an example of two different fluorescently labeled phospholipids integrated on a single cantilever array [49]. In similar fashion, a chip has also been developed that allows local vapor coating onto tip arrays [55].

Every second tip in the array is being dipped with one ink; (b) Multi-channel fluorescence and bright-field micrograph of phospholipids doped with different inks. Every second tip is coated with a red dye, every fourth tip with a green dye, and the remaining tips function as negative controls.

5.4.3
Fountain Pens

One particularly elegant approach to delivering ink to the atomic force microscope tip is through the integration of microfluidic channels directly onto the tip itself, in order to generate a nanofountain probe (NFP), such as that shown in Figure 5.9 [56]. As standard microfabrication techniques were used, it has been possible to generate parallel arrays of NFPs integrated on a single chip, with different ink reservoirs leading to different tips in the same array, thus enabling the parallel integration of different inks [57]. As in the case of macroscopic pens, NFPs can be expected to be particularly useful for the patterning of inks where the solvent must remain in the ink until after patterning, as tips coated by dipping in solution are subject to drying.

5.4.4
Nanopipettes

Although micropipettes and nanopipettes differ technically from DPN (in that they do not necessarily utilize an atomic force microscope tip), they are conceptually similar to DPN and NFPs in several ways, and are therefore worthy of brief mention at this point. Cantilevered micropipettes similar to those used for scanning near-field optical microscopy (SNOM) have been used for the local delivery of an etchant to a chrome film, with a resolution of 1 μm [58]; indeed, subsequent studies led to the

fabrication of spots of 280 nm diameter [59]. In similar manner, an electrochemical fountain pen was used to fabricate freestanding platinum nanowires with a diameter of 150 nm. By using a voltage-controlled feedback circuit derived from scanning ion conductance microscopy (SICM), submicron and multicomponent features consisting of biomolecules such as DNA and protein have also been fabricated [60, 61]. Although the practical resolution of micropipettes and nanopipettes is much lower than for DPN, and it is difficult to imagine them being used in parallel, they do have a significant advantage for the patterning of biomolecules in that they are able to function under water [62].

5.5 Characterization

In addition to tip inking and writing, a third indispensable part of the DPN process is the characterization and quality control of the resultant patterns. A convenient capability of DPN, which is also shared by most scanning probe-based lithography processes, is that the same tip can be used for both patterning and imaging, in the case of DPN by AFM. In particular, lateral force imaging is typically used for the characterization of chemical contrast in covalently bound inks such as thiols on gold (as described earlier and shown in Figure 5.2). There are two practical issues to be aware of when characterizing DPN patterns generated by the same tip that has been used for imaging:

- An inked tip will typically continue to write during imaging, and therefore high scan speeds must be used to minimize this effect.
- The vast majority of DPN is carried out in contact mode, using cantilevers with a too-low spring constant for use in intermittent contact or tapping mode imaging in air. This is especially the case for parallel DPN, where it is impractical to have a separate tapping feedback mechanism for each tip. As the contact mode typically provides inaccurate heights in air, it is often necessary to change the tip and realign it to find the patterned area in order to obtain quantitative height information.

Although these two issues represent disadvantages in a high-throughput lithography process, they can actually serve as significant advantages when characterizing the ink transport. For instance, in an early study using DPN, monolayer growth could be observed *in situ* by scanning the same area repeatedly at high resolution; this allowed observation of the monolayer growth dynamics as alkanethiols were transferred from the tip to a gold substrate [63]. It is also possible to carry out DPN in tapping mode by using a single tip for the simultaneous deposition and imaging of soft materials, as well as obtaining accurate height information [64]. When this method was applied to the deposition of poly-D,L-lysine hydrobromide onto mica surfaces, it was possible to observe the nucleation and growth dynamics of polymer crystals at a submicron scale that is inaccessible to other methods (Figure 5.10) [65].

In the DPN patterning of a new ink or substrate, it is essential to determine that the patterns generated are indeed composed of the intended ink. If a particular

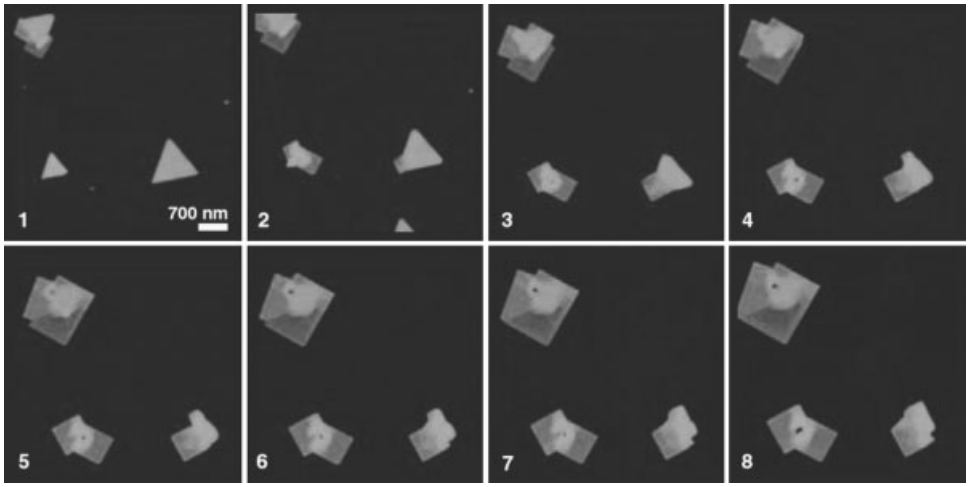

Figure 5.10 Topographical AFM image sequence (1 to 8) of epitaxial crystal nucleation and morphology changes from threefold to fourfold symmetry during growth of poly-D,L-lysine crystals on a mica surface as molecules are transferred from the microscope tip during each scan. (Reproduced from Ref. [65] with permission from the American Association for the Advancement of Science.)

topographical morphology is known, then this information can be obtained from AFM measurements. For instance, the AFM images of DPN-patterned collagen fibrils showed a helical repeat of 65 nm, which was consistent with scanning electron microscopy (SEM) observations of collagen fibrils. Another example is the formation of anisotropic structures formed during the DPN patterning of peptide amphiphiles [66]. Another way of distinguishing DPN patterns from artifacts that might result from mechanical contact of the tip, condensed water or residual solvent, would be to carry out the appropriate negative controls using either uncoated tips or tips dipped only in the solvent, in the absence of the desired ink molecules.

More often than not, it is necessary to confirm the chemical identity of the ink molecules on the surface by other analytical methods. For example, X-ray photoelectron spectroscopy (XPS) is often used to identify elements present in DPN patterns [17, 21, 25, 29, 31, 67–69]. Infrared spectroscopy [68] and mass spectrometry [67] are also powerful characterization tools that have the added advantage of providing structural information. Furthermore, AFM is a rather slow characterization method and, in the case of high-throughput, parallel DPN characterization can easily become the rate-limiting step in the fabrication process. In that case, optical characterization is ideal, and this can be achieved by using DPN-generated thiol monolayers as a resist against chemical etching so that the patterns become visible under optical microscopy [48]. Another approach would be to use a fluorescently labeled ink, which not only enables rapid characterization but also provides some chemical information about the patterns [6, 28, 49, 70–72]. Optical characterization using scanning near-field optical microscopy (SNOM) detection of single molecules deposited by DPN

suggests that the practical resolution limits of DPN may not be in the patterning, but rather in the ability to detect patterns with dimensions smaller than the AFM tip used to fabricate them [6]. Finally, it is often useful to characterize the AFM tips as well as the presence and distribution of the ink on the tips, which can typically be achieved using SEM or optical microscopy.

5.6 Applications Based on Materials Integration by DPN

Functional chemical patterns fabricated by DPN have been used for a wide variety of scientific applications, and it can be expected that industrial applications will follow. Even in the many published applications, including for example etch resists [73] or templates for selective deposition [74], when only a single ink molecule is patterned onto a single surface, DPN has several advantages over conventional direct-write lithographic techniques such as EBL. While the latter is able to provide competitive lateral resolution, it is severely limited in its throughput as well as its cost. Furthermore, in contrast to DPN, EBL involves removing material from the substrate, which requires an extra development step. One advantage of placing resists and template molecules directly onto the surface is that the remainder of the surface is left free of contaminants. That being said, the ability to generate multicomponent nanostructures opens entirely new possibilities that are inaccessible by any other method. Some of the more striking examples will be briefly described in the following sections, in order to provide an overview of the types of unique application made possible by DPN. Whilst the examples are categorized based on selective adsorption, combinatorial chemistry and biological arrays, these categories are by no means complete and a significant amount of overlap is apparent between them.

5.6.1 Selective Deposition

Although the selective deposition of materials onto patterned surfaces is not limited to DPN patterns, the rapid prototyping capabilities and ability for DPN to generate multicomponent nanostructures on a small scale adds a new dimension to the field. A few of the strategies that can be used to immobilize different particles from solution by selective adsorption or templating are shown in Figure 5.11. In addition to the adsorption strategies shown, covalent binding, nonpolar adhesion forces and entropic effects can also be used to direct binding towards desired areas of the substrate. The surface passivation of the background is often a crucial step in fabricating templates for selective adsorption. Most often, successful selective adsorption will involve combinations of more than one of these strategies.

As a first example of electrostatic templating on DPN patterns, positively charged colloidal particles were immobilized electrostatically onto negatively charged MHA patterns. By fabricating a variety of MHA dot array patterns with different dot sizes and spacings, it was possible to screen the pattern dimensions for those capable of

Figure 5.11 Schematic representation of different strategies for selective adsorption or templating. Left to right: charge-based recognition; macromolecular encoding (i.e. DNA); and specific binding of ligands. (Image courtesy of NanoInk.)

organizing the particles such that each dot had exactly one particle bound, in a combinatorial fashion [74]. Such an approach was later applied to the fabrication of arrays of individual bacterial cells [75]. In another approach, the positive and negatively charged polyelectrolytes poly(diallyldimethylammonium) chloride (PDDA) and poly(styrenesulfonate) (PSS) have been directly patterned on silicon surfaces by DPN. Upon the addition of a complementary polyelectrolyte, selective adsorption was observed which suggested a compatibility of the method with layer-by-layer assembly [25]. Furthermore, such electrostatic templates have been used in combination with *molecular combing* to organize *aligned DNA strands*, a biological molecule which also falls into the polyelectrolyte category and can readily be adsorbed electrostatically [76].

DNA-directed self-assembly on DPN patterns has been used to organize two different-sized nanoparticles into nanoarrays, with the spacing between different-sized particles in an array being as low as 500 nm [74]. This method of self-sorting was improved by using noncomplementary DNA as a *passivation layer*, enabling larger particles to be immobilized [87]. Protein nanoarrays selectively bound to MHA patterns [77], or patterned by direct write methods [52], have been used to subsequently immobilize other protein molecules by molecular recognition. Covalent linking of the biofunctional group biotin was carried out selectively on DPN patterns, enabling the binding of streptavidin protein by molecular recognition and subsequent binding of biotinylated materials [72]. Similarly, the covalent coupling of proteins to DPN templates was carried out using succinimide chemistry [78]. Finally, nonpolar carbon nanotubes were selectively adsorbed to DPN templates based on differences in surface energy between the patterned and passivated regions [79].

Although not often emphasized in the literature, *passivation* is a crucial step in selective adsorption, such that the materials to be integrated on the surface do not simply bind everywhere. In a DPN experiment, the background is typically blocked by a low-surface energy (methyl-terminated) compound such as ODT [74] or, in the case

of protein or cells, the adsorption of PEG-terminated passivation layers is preferred due to their nondenaturing character [52]. Nonspecific adsorption is in fact a major problem that limits the applicability of templating-based fabrication methods, although it can be overcome to some degree through chemical modification of the surface and optimization of the solution conditions (e.g. pH and ionic strength). Nonetheless, the fact that nonspecific adsorption cannot be completely eliminated is a qualitative advantage that constructive, parallel DPN has over serial methods based on sequential selective adsorption and patterning steps.

5.6.2 Combinatorial Chemistry

The idea of placing different chemical compounds on the same surface, for exposure to identical solution conditions, lends itself well to combinatorial chemistry. In addition to the possibility of ultra-high-density chemical arrays, the nanoscale resolution of DPN also enables studies of collective molecular interactions, as well as how the properties of nanoscale aggregates might differ from bulk behavior. For instance, the ability for nanopatterned SAMs to function as resists against the chemical etching of metallic films has been investigated combinatorially as a function of pattern dimension in order to minimize feature sizes [73]. Solid-state nanostructures with features as low as 15 nm have been fabricated by the direct deposition of etchant [67], while nanostructures of various metals such as gold, silver and palladium have been generated with 35 nm dot diameters and 53 nm line widths [80, 81].

As a first demonstration of the ability to screen the chemical behavior of different compounds on the same surface, four different thiol molecules were patterned within an area of 5 μm^2 on a single gold surface to form combinatorial libraries, as shown in Figure 5.12. The libraries were then used to study molecular

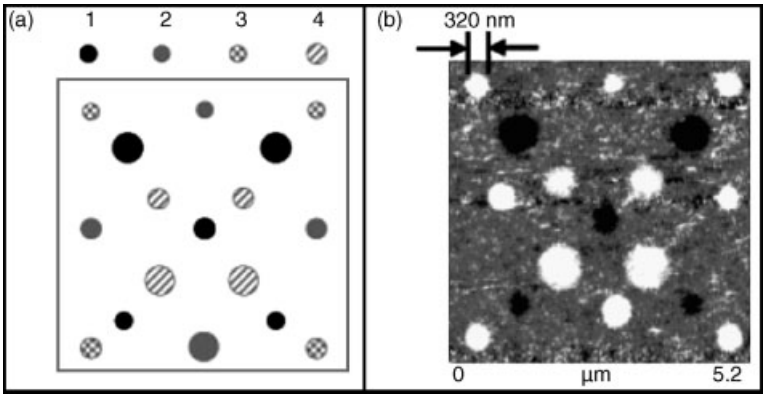

Figure 5.12 (a) Schematic representation of the combinatorial library design consisting of the four different molecular inks; (b) Lateral force microscopy image of the library described in panel (a). (Reproduced with permission from Ref. [82].)

displacement from the surface by repeatedly scanning the same area with an ink-coated tip and observing the order in which the spots disappeared as they were exchanged by new molecules from the tip [82]. In another creative approach to combinatorial chemistry, DPN was used to pattern molecules on cantilevers which could, in principle, be used as force sensors for determining interactions between molecular libraries [83].

Another unique application for DPN is in the study of microscale and nanoscale phase separation. For instance, phase separation and pattern formation in conjugated polymers spin-coated onto combinatorially nanostructured DPN templates was studied as a function of polymer concentration and MHA dot diameter [84]. The information resulting from those screenings of pattern dimensions enables one to control pattern formation in thin organic films, with potential applications in the fabrication of organic electronic and optical devices. Furthermore, by coating the tip with a mixture of two (or more) inks it becomes possible to observe if, and how, the molecules de-mix during the DPN writing process by using *in situ* AFM measurements [85]. The use of such separated phases for selective adsorption provided the ability to reduce line widths down to 10 nm.

5.6.3 Biological Arrays

The complex integration of biological molecules such as DNA, protein and phospholipids on hierarchical scales, ranging from molecular dimensions up to the size of entire organisms, provides the basis for the molecular machinery that makes life possible. The ability to understand, control and even mimic such interactions has long been a dream, not only for biologists but also for nanoscientists in a variety of disciplines. Robotic spotting methods have already proven valuable in the biotechnology industry for the fabrication of biological arrays, even with spot sizes on the order of hundreds of micrometers. Smaller spots not only have evolutionary advantages of higher spot density, sensitivity and lower requirements for sample volumes, but also open entirely new possibilities. For instance, the ability to integrate more than one biomolecule or biological entity (e.g. a virus) under the surface area covered by a single adherent cell in a spatially defined manner is especially exciting for unraveling the roles of intermolecular interactions in biological systems.

The patterning of DNA by DPN was first achieved by the selective deposition of oligonucleotides onto thiol-patterned surfaces [86]. Later, reproducible protocols for direct deposition from the AFM tip were developed [22, 87]. Figure 5.13 shows an example of a binary DNA array that was used to reversibly hybridize both fluorescently labeled oligonucleotides as well as gold nanoparticles of two different diameters [22]. This illustrates the ability for DNA arrays to organize nanomaterials in a highly specific manner. Furthermore, whilst fluorescence is an invaluable tool for characterizing biomolecular arrays, many biological materials are not easily obtainable in functional form with fluorescent labels. Therefore, label-free detection methods such as AFM topography show great promise [71]. The physical–chemical

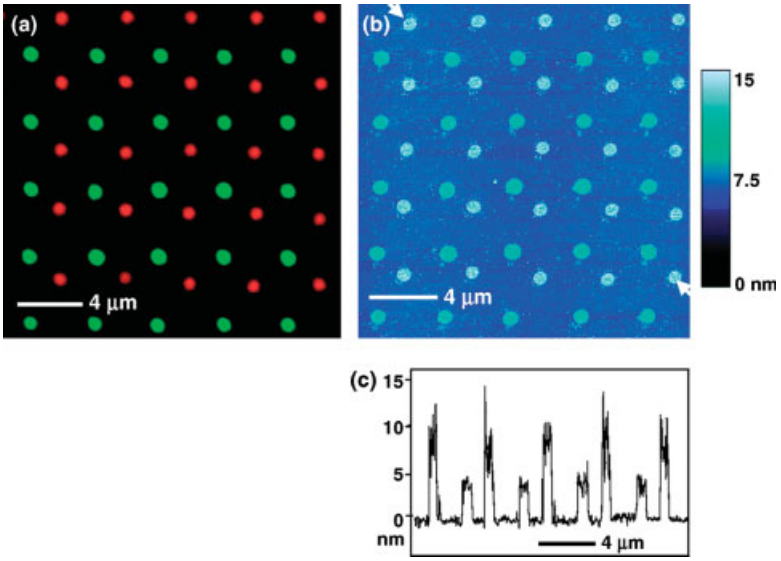

Figure 5.13 A binary DNA array fabricated by direct-write DPN. (a) Fluorescence image showing two different fluorescent probes selectively hybridized to the different spots; (b) AFM topography of the same area after dehybridization of the fluorescent probes and attachment of oligonucleotide-labeled nanoparticles of two different diameters (5 nm and 13 nm). (Reproduced from Ref. [22] with permission from the American Association for the Advancement of Science.)

similarity between different DNA strands of the same sequence renders them promising for parallel arraying, as DNA strands of different sequence can be patterned under the same environmental conditions.

A variety of different proteins have also been patterned by DPN, both by selective adsorption and by direct-write processes. In the majority of cases, selective adsorption using various coupling strategies appears to be most successful in fabricating functional protein nanoarrays to date, as selective adsorption can be carried out without dehydration of fragile proteins [70, 72, 77, 78, 88, 89]. For example, an antibody nanoarray-based detection assay for HIV in patients' plasma exceeded the limit of detection of conventional enzyme-linked immunosorbent assay (ELISA)-based immunoassays (5 pg ml^{-1} plasma) by more than 1000-fold [90]. Direct-write approaches hold the promise of larger-scale integration, and have also proven their ability to successfully generate functional protein nanoarrays. For example, collagen was the first protein to be directly deposited onto gold by first reducing disulfide bridges in the biopolymer, and then allowing the collagen fibrils to reassemble on the gold surfaces. Functional his-tagged proteins have been deposited directly onto nickel oxide surfaces via metal affinity [91]. Unmodified antibodies were directly patterned onto gold surfaces by nonspecific adsorption [52].

(Reproduced with permission from Ref. [49]; © Wiley-VCH Verlag GmbH & Co. KGaA.)

In addition to DNA and protein, phospholipids represent another ubiquitous biomolecule that can be patterned noncovalently by DPN on a variety of surfaces, with linewidths as small as 100 nm [49]. In contrast to the transport behavior of most other inks – where the dot and linewidth can be controlled by the tip-contact time and scan speed, as well as humidity – phospholipid inks tend to stack into multilayer structures where the thickness of the film can be controlled by those same parameters (Figure 5.14). Upon immersion into aqueous solution, the multilayers can be spread on the surface to form a single monolayer, a lipid bilayer membrane, or remain as stable multilayers, depending on the substrate. A unique property of phospholipids is that they amphiphilic and are lyotropic liquid crystals that tend to organize into different supramolecular structures, where their fluidity depends on the hydration. Their transport rate from ink wells onto the tips, as well as from the tip to the substrate, can therefore be precisely controlled.

If one views viruses as nanoparticles, the methods described earlier for templating can be applied directly to the immobilization of viruses. For example, arrays of virus particles have been generated using genetically modified cow pea mosaic virus that covalently couple to maleimides patterned by DPN [32, 92]. Another approach based on several steps of selective adsorption to the DPN pattern of MHA has resulted in arrays of influenza virus particles [70] and of single tobacco mosaic virus particles [93]. In this process, Zn^{2+} are first bound to the MHA nanopatterns, after which antibodies specific for the virus in question are selectively adsorbed; finally, the virus particles are adsorbed on top of those two layers. Remarkably, it was shown that this method could be used to position functional viruses capable of infecting cells cultured on the arrays, as illustrated in Figure 5.15. The use of DPN-based methods to organize biological molecules and particles on a subcellular level, and to interface them with living systems, opens numerous possibilities in the emerging field of nanobiology.

5.7 Conclusions

In conclusion, DPN provides the ability to simultaneously integrate and nanostructure a diverse range of materials on a variety of surfaces, at unprecedented levels of both spatial resolution and complexity. In principle, several thousand different materials could be integrated in thousands of different combinations with nanoscale resolution over square-centimeter (or larger) surface areas. Although much remains to be done before this dream is achieved, the barriers appear to be surmountable. Clearly, a basic understanding of the mechanisms behind the nanoscale transport of ink will be necessary in order to reproducibly carry out and extend the capabilities of DPN. In addition, innovative probe designs and inking strategies will be essential in order to expand the capability of DPN for large-scale materials integration.

6
Scanning Ion Conductance Microscopy of Cellular and Artificial Membranes

Matthias Böcker, Harald Fuchs, and Tilman E. Schäffer

6.1
Introduction

Eukaryotic cells are enclosed by a plasma membrane, which creates an internal environment that is separated from the outside. The membrane defines a physical border and is impermeable to macromolecules. Integral proteins in the membrane play an essential role for inter- and transcellular processes [1, 2]. In order to understand the properties of membranes and membrane proteins, it is important that cell biology, medicine and pharmacology gain insight into the complex barrier-crossing transport mechanisms. In particular, knowledge concerning the permeability of barriers for substances such as drugs is of great relevance.

Special electrochemical and microscopic methods are used to study the ion-permeability of barrier-forming cell structures. For example, transepithelial electrical resistance (TER)-spectroscopy provides information about the barrier properties of cell layers [3–5]. The development of artificial membranes was an important step in the characterization of membranes [6, 7]. One advantage of artificial membranes is the possibility of inserting selected proteins into the membrane, which in turn creates the possibility of performing single-channel measurements on these selected proteins [8].

For the microscopic characterization of local sample properties, scanning probe microscopes have been developed in various forms. Scanning probe microscopes are based on a small, locally confined probe that is sensitive to various types of physical quantity. To date, several instruments have been developed for the characterization of different sample properties, although only a few are suitable for application in an aqueous environment – an essential requirement when analyzing biological samples under native conditions. Perhaps the most prominent member of the group is the atomic force microscope [9], which allows the creation of high-resolution topographical images of biological samples in buffer solutions [10]. The atomic force microscope employs the mechanical interaction between a sharp tip and the sample surface under investigation on the nanometer scale. In addition to

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

topography, it is possible to measure mechanical sample properties such as elasticity [11]. Many analyses have already been conducted on cellular membranes [12, 13], artificial membranes such as solid supported membranes [14, 15] and membrane proteins [16–19].

Unfortunately, the investigation of soft and fragile samples often proves to be problematic due to mechanical interactions between the tip and the sample. In the case of cells, a force-induced deformation reduces the resolution of atomic force microscopy (AFM) imaging, and native conditions are therefore not always reproduced [20]. Additionally, the sample can be damaged irreversibly or be compressed, leading to errors, for example, in the measurement of sample height [21]. In particular, the investigation of free-standing, pore-suspending artificial membranes with AFM has proved difficult, with very few successful measurements on such membranes having been reported [22–25]. All such reports refer to the problem of interaction forces between the atomic force microscope tip and the suspended membrane, which often leads to rupture of the membrane, even at minimal imaging forces.

6.1.1 Scanning Ion Conductance Microscopy

Scanning ion conductance microscopy (SICM), as invented by Hansma *et al*. in 1989 [26, 27], is based on the measurement of an ion current through a small aperture, which is usually formed by a nanopipette. In order to provide a medium for ion conduction, the nanopipette is filled with an electrolyte. A silver/silver chloride (Ag/AgCl) electrode is placed inside the pipette (the pipette electrode), while the sample is placed in a dish that is filled typically with the same electrolyte. A second Ag/AgCl electrode is placed inside the electrolyte in the dish (the bath electrode). By applying a voltage between both electrodes and recording the ion current through the pipette (typically on the nanoampère scale), locally resolved images of sample topography can be generated when scanning the sample. The advantage of the SICM is that no mechanical forces are necessary for imaging a sample surface.

In SICM there is a heavy dependence of the ion current on the distance between the pipette tip and sample surface for generating the feedback signal for scanning. This distance dependence is based on a 'current squeezing effect', which allows the presence of the sample surface to be sensed at a distance where no mechanical interactions between tip and sample occur. In this way, soft and delicate samples such as living cells can be imaged in a 'noncontact' configuration [28, 29]. In addition, single ion channels on living cells can be recorded at specified positions with this technique [30]. Improved imaging techniques have been developed based on the principle of an ac measurement. For example, the tip–sample distance can be modulated, thereby modulating the measured ion current; the amplitude of the modulated current can then be used for feedback control [31–33]. The technique of SICM has proved useful in obtaining high-resolution images of fine surface structures such as microvilli [34, 35] or membrane proteins [36].

For many applications, however, it is important to measure the ion current independently of the sample topography, and for this purpose several different extensions to SICM have been developed. In one revision, the scanning ion conductance microscope was combined with an atomic force microscope [37, 38]. For this, a bent nanopipette [39, 40], coated with a reflective metal layer, was used as the atomic force microscope 'tip' and scanned over the sample surface. A laser beam was then focused onto the bent pipette and the reflected light projected onto a split photo-diode. The mechanical deflection of the pipette provided the feedback signal for topography imaging, while the ion current was recorded simultaneously. As an option, the bent pipette was driven in the tapping-mode [41, 42], which simplified the imaging of soft samples in liquid solutions.

Another modification involved the combination of SICM with scanning near-field optical microscopy (SNOM). This combined microscope allowed living cells to be investigated and topography images with additional optical information to be recorded [43–45]. Yet another extension of SICM was the combination with shear force microscopy [46, 47], a technique that is also used in conjunction with the scanning near-field optical microscope [48, 49]. In SICM with complementary shear force distance control, the pipette is transversally oscillated at a mechanical resonant frequency. The sample topography is then detected by shear forces between the pipette tip and sample surface, causing a reduction in the oscillation amplitude.

6.2 Methods

6.2.1 The Basic Set-Up

In a basic SICM set-up a nanopipette with a small tip opening diameter is positioned close to a sample surface (Figure 6.1a). The nanopipette is filled with an electrolyte and the sample is placed in an electrolyte-filled dish. Typically, the electrolytes in the nanopipette and in the dish are identical, so that no osmotic flow in or out of the pipette occurs. For the current measurement a voltage is applied between two silver/silver chloride (Ag/AgCl) electrodes. Ag/AgCl electrodes have electrochemical properties that make them well suited to applications in SICM. For example, they have a very small equilibrium constant at room temperature so that only a small amount of Ag^+-ions exists in the electrolyte. Additionally, they are easily fabricated, for example by the electrolytic deposition of silver chloride on a silver wire. One of the electrodes is placed inside the pipette (the pipette electrode), while the other electrode is place inside the electrolyte in the dish (the bath electrode). The ion current from the pipette electrode through the pipette, and through its small tip opening to the bath electrode, is measured with a high-impedance current amplifier. The applied voltage is in the range of some hundred millivolts, and the measured ion current is in the nano- and picoampère range. The closer the tip is to the sample surface, the more the

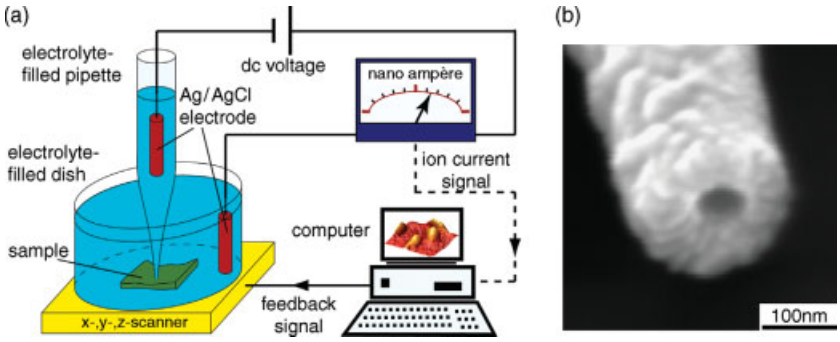

Figure 6.1 (a) Schematic of the scanning ion conductance microscope. A dc voltage between two Ag/AgCl electrodes induces an ion current through the pipette. The ion current signal is passed to a computer, which generates a feedback signal that controls the position of a *z*-scanner. Images are generated by scanning the sample in *x*,*y*-direction; (b) Scanning electron microscopy (SEM) image of the tip of a nanopipette. The inner opening diameter is 60 nm. For SEM imaging the pipette was sputter-coated with a 10 nm-thick aluminum layer.

ion current is restricted ('squeezed') by a narrow gap formed between the pipette tip and the sample surface [26, 50]. The measured ion current is therefore indicative of the tip–sample distance. The ion current signal is passed to a computer, where a feedback signal is generated and used to drive an *x*-, *y*-, *z*-scanner, consisting of piezoelectric actuators (abbreviated as piezos). Depending on the pipette geometry and on the imaging parameters used, topographical imaging without mechanical interaction between tip and sample is possible. Hence, noncontact images of sample topography can be recorded, which is especially valuable for the imaging of soft biological samples such as living cells and artificial membranes.

6.2.2 Nanopipettes

In order to deliver an ion current through a small opening, pipettes proved to be a practical solution. Pipette fabrication is a well-known technique, and pipettes have a wide range of applications in extracellular physiology, for example, in patch–clamp recording [51, 52]. Usually, pipettes are drawn (using a 'pipette puller') from glass capillaries with an initial diameter of 1–2 mm. The principle of a pipette puller is based on local heating of the capillary with a heated coil or a laser beam. While heating, a pulling force is applied to both ends of the capillary such that, when the melting point of the glass is reached, the pulling force leads to a separation of both ends of the capillary, thereby forming fine pipettes. The most commonly used glass is borosilicate; this softens at 825 °C and, as it is pulled, maintains its ratio of inner to outer diameter over the total drawn-out length [53]. A wide variety of opening diameters can be generated with borosilicate glass pipettes, down to some tens of nanometers (Figure 6.1b). Finer pipettes for higher-resolution imaging can be produced from quartz capillaries, with inner tip opening diameters of approximately 12 nm [36].

6.3
Description of Current–Distance Behavior

When placing the electrolyte-filled nanopipette with the pipette electrode into an electrolyte-filled dish with the bath electrode and applying a voltage U between the electrodes, an ion current is measured. When the tip of the pipette is far away from the sample surface the current is maximal (saturation current I_{sat}):

$$I_{sat} = \frac{U}{R_p}. \tag{6.1}$$

For calculating the pipette resistance R_p a simple analytical model can be used [46]. The geometry of the pipette is assumed to be conical (Figure 6.2a). The resistance can be approximated through sectioning the cone into successive disks of infinitesimal thicknesses, leading to

$$R_p = \frac{1}{\kappa} \cdot \frac{L_p}{\pi r_p r_i} \tag{6.2}$$

where κ is the specific conductivity of the electrolyte, L_p is the length of the drawn-out end of the pipette, r_p is the inner radius of the capillary, and r_i is the inner diameter of the tip opening. For typical borosilicate glass pipettes and electrolytes, R_p is in the range of 50–200 MΩ. The resistance of the electrolyte bath inside the dish is on the order of kilo-ohms, so that the total resistance of the circuit can be approximated by R_p. With this, the inner tip opening diameter can be estimated as

$$r_i \approx \frac{I_{sat}}{U} \cdot \frac{L_P}{\pi \kappa r_P}. \tag{6.3}$$

For standard 1 mm outer diameter borosilicate glass pipettes, for example, $r_p = 0.29$ mm. In many cases, a phosphate-buffered saline (PBS) solution with 137 mM NaCl ($\kappa \approx 1.3$ Ωm) is used as electrolyte. L_P is typically in the range of 5 mm, and $U = 200$ mV. For example, from a measured current $I_{sat} = 1$ nA, an inner tip opening radius of $r_i \approx 21$ nm is deduced.

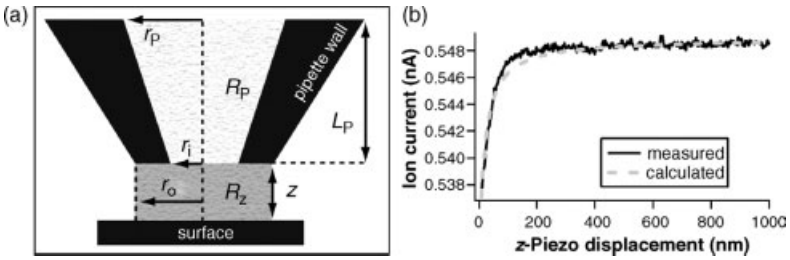

Figure 6.2 (a) Schematic of a simple model for the current–distance behavior of a cone-shaped pipette; (b) Measured and calculated ion current versus z-piezo displacement. Measurement were made with a borosilicate glass pipette over a mica surface, applying a voltage of $U = 200$ mV.

When the tip is at a distance to the sample surface that is comparable to the tip opening diameter, the measured ion current shows a heavy dependence on the tip–sample distance. This is because the current then has to 'squeeze' through the narrow gap between the pipette wall and the sample surface, which leads to an increase in the resistance. Nitz *et al.* [46] constructed an analytical model for the distance-dependent resistance R_z, obtaining

$$R_z(z) \approx \frac{3}{2\pi} \cdot \frac{\ln(r_o/r_i)}{\kappa z}, \tag{6.4}$$

where r_o is the outer tip diameter of the pipette and z is the tip–sample distance. This leads to a distance-dependent ion current of

$$I(z) \approx I_{sat}\left(1 + \frac{z_0}{z}\right)^{-1}, \tag{6.5}$$

with

$$z_0 = \frac{3}{2} \cdot \frac{r_p r_i \ln(r_o/r_i)}{L_p}. \tag{6.6}$$

The ratio of r_i to r_o usually stays constant while pulling the pipette from the borosilicate capillary [53]. In Figure 6.2b, a measurement of ion current versus z-piezo extension (the tip–sample distance with an unknown offset) is displayed (black trace). The range of the z-piezo extension is 1 µm. At a large tip–sample distance (right-hand side in Figure 6.2b), the ion current is independent of distance, yielding a saturation current of $I_{sat} = 0.549$ nA. By using Equation 6.3, r_i can be approximated as 12 nm. The calculated ion current $I(z)$ obtained from the analytical model (Equation 6.5) is also displayed (gray, dashed trace); a horizontal offset was applied here to optimize the match. The analytical model matches the measured data well. From the offsetting procedure, a tip–sample distance of 18 nm is found at the leftmost position in the graph (at a z-piezo displacement of 0 nm).

6.4 Imaging with SICM

6.4.1 Modulated Scan Technique

The dependence of the measured ion current on tip–sample distance can be utilized in a feedback loop to keep the tip–surface distance constant while scanning, thus allowing topographical images of a sample surface to be recorded. In practice, however, this imaging mode has proved vulnerable to current drift. One method of reducing the influence of current drift is to apply short voltage or current pulses [54, 55] instead of a constant voltage between the pipette and bath electrode.

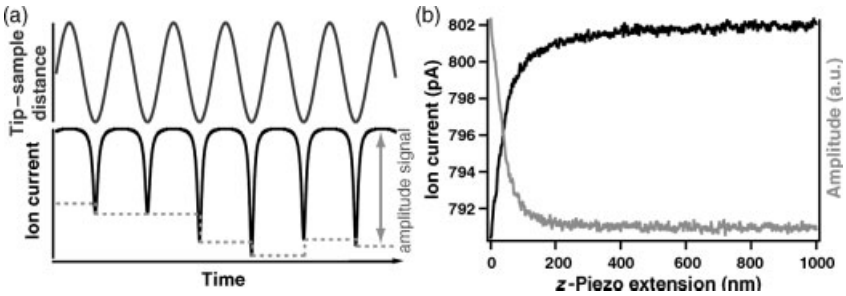

Figure 6.3 (a) Schematic diagram to illustrate the principle of the modulated scan technique. Upper trace: sinusoidal modulation of the tip–sample distance. Lower trace: the resulting ion current. The current decreases periodically at the points of closest approach between pipette tip and sample. The value of the maximal current drop provides the amplitude signal which is used for feedback; (b) Measured ion current (black trace) and ion current amplitude (gray trace) versus *z*-piezo extension while modulating the tip–sample distance with an amplitude of 120 nm at a frequency of 800 Hz.

Another method is based on modulating the tip–sample distance [31–33]. This distance is modulated sinusoidally with an amplitude of up to some hundred nanometers and with a frequency of a several hundred Hertz (Figure 6.3a, upper graph). For large tip–sample distances, this modulation does not have any influence on the ion current. For small tip–sample distances, the behavior of the ion current is displayed in Figure 6.3a (lower graph). At distances furthest from the surface, the ion current reaches the saturation current (plateaus in the graph). When approaching the sample surface during the modulation cycle, the influence of the squeezing effect becomes greater so that the current decreases. At the point of closest approach the current is smallest, but increases again when the tip retracts from the surface. An amplitude signal can be generated either by using a lock-in amplifier or a trigger-based method [47]. The amplitude of the current signal is used as input to a feedback loop, which regulates the mean tip–sample distance to keep the amplitude signal constant.

Measurement of the ion current (black, left axis) and of the amplitude signal (gray, right axis) versus *z*-piezo extension is shown in Figure 6.3b. The ion current shows the distance-dependent behavior (as discussed above), while the amplitude signal is constant for large tip–sample distances (right-hand side in Figure 6.3b) and increases for decreasing tip–sample distances. The amplitude signal is less sensitive to current drift than the ion current, and may also help minimizing the risk of lateral forces being applied to the sample.

6.4.2 Cellular Membranes

Use of the modulated scan technique allows the gentle imaging of delicate biological samples such as living cells, and also allows the recording of well-resolved images of fine surface structures such as microvilli [34] or membrane proteins [36]. Living,

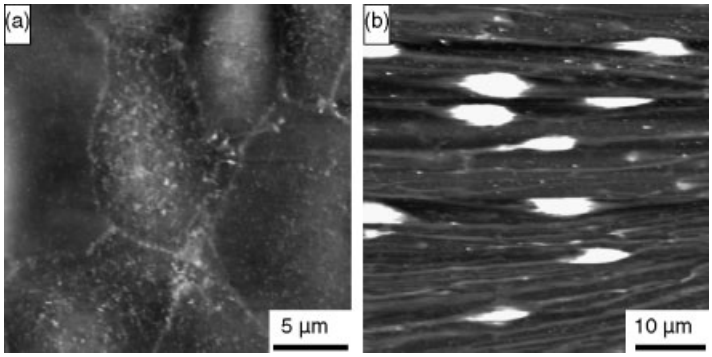

Figure 6.4 (a) Scanning ion conductance microscopy (SCIM) topographic image of living MDCK-II cells in phosphate-buffered saline (PBS) solution. The gray scale ranges from black to white over 1.8 µm; (b) SICM topographic image of living rat Schwann cells in PBS solution. The grayscale ranges from black to white over 5 µm.

confluent MDCK-II cells, for example, exhibit a large cell body and locally raised cell–cell contacts (Figure 6.4a); substructures on the cell membrane are also visible. Another example is the imaging of living Schwann cells (Figure 6.4b); these occur in the peripheral nervous system and are essential for generating the myelin sheath and maintaining the metabolism and integrity of the nerve. The SICM image shows the typical spindle-shaped body of the Schwann cell. On the basis of the excellent long-term stability provided by modulated scanning techniques it is possible to image specific surface areas, continuously, for several hours and thus to observe dynamic processes occurring on the cell membranes [35, 56]. As an example, Gorelik *et al.* were able to study the mechanism by which aldosterone activates sodium reabsorption via the epithelial sodium channel [57].

6.4.3
Artificial Membranes

The study of artificial membranes represents a new application area for SICM. The investigation of pore-suspending membranes with other scanning probe techniques such as AFM has proved difficult due to mechanical interactions that can cause damage to the membrane. In contrast, the noncontact imaging characteristic of SICM allows the mapping of such pore-suspending membranes without mechanical interaction between the pipette tip and the sample surface.

In a study of black lipid membranes (BLMs), highly ordered porous silicon proved to be a useful substrate for spanning the membrane over the pores, although for this purpose the substrate must first be functionalized. In the Müller–Rudin technique [6, 7], the membrane is applied in a solvent locally to the substrate; this causes it to spread over the surface, delivering a membrane monolayer (the spreading process is shown in Figure 6.5a). The scan was started directly after applying the membrane to the surface (scan direction: downwards). Initially, all of the pores were

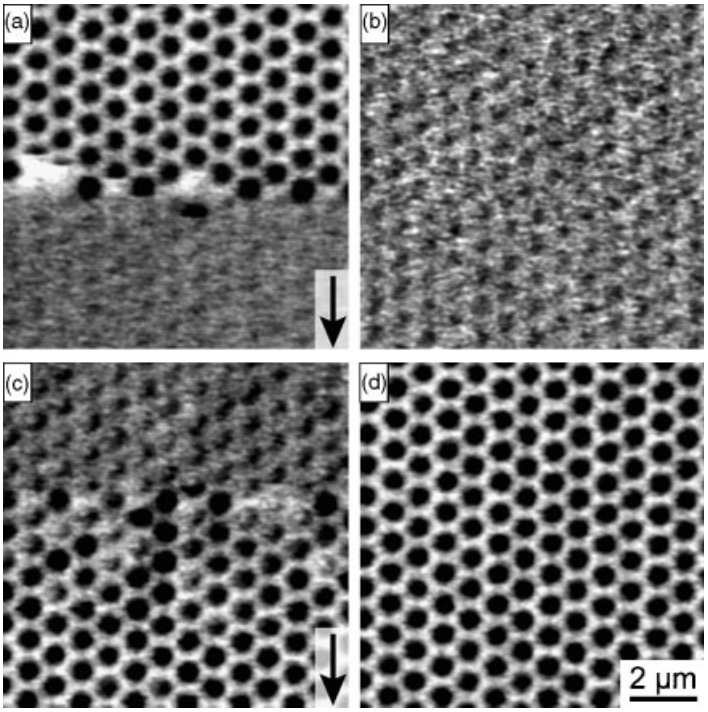

Figure 6.5 Scanning ion conductance microscopy topographic images of a highly ordered porous silicon substrate at different stages of coverage with a lipid membrane. (a) Topography imaged directly after applying the membrane solution to the silicon substrate (scan direction: downwards). In the lower section of the image, the membrane is already suspended over the pores; (b) After spreading over the surface the membrane is suspended over all pores and was stable for hours; (c) Applying a small amount of detergent (Tween 20) to the PBS solution destroyed the membrane (scan direction: downwards). In the upper section of the image, the membrane was still present, while in the lower section it was already destroyed; (d) Finally, the porous silicon substrate was totally free of membrane again. The scan rate was 5 s per line with a resolution of 256×256 data points. The grayscale ranges from black to white over 120 nm.

open (Figure 6.5a, upper half), but when reaching the vertical center of the image the first suspended pores became visible, with only suspended pores being observed in the lower section of the image. This effect was due to the solvent reaching the scan area while scanning, thus suspending the pores with membrane. The same area, after re-scanning, is shown in Figure 6.5b. Here, all the pores are suspended with membrane, although the porous structure of the substrate can still be recognized by the small depressions in the membrane surface. This state remained stable over several hours, after which time a droplet of a membrane-dissolving detergent was applied to the electrolyte (Figure 6.5c). Initially, the membrane remained unaffected (upper section), but after some minutes some pores began to re-open (middle section), and a few minutes later only open pores remained (lower section). A re-scan of the area showed only open pores (Figure 6.5d). Taken together, these measurements demonstrated the gentle imaging character of SICM.

6.4.4 SICM with Shear Force Distance Control

The fact that SICM can be used for imaging biological samples, with a resolution in the nanometer range, makes it an interesting candidate for combination with other scanning microscopy techniques. Of particular interest is the measurement of ion current independent of sample topography, and for this purpose the nanopipette can be used as a shear force sensor. Shear forces are well known from SNOM set-ups, where they serve to keep the optical fiber at a constant distance from the sample during scanning [48, 49]. In a shear force configuration, the probe is vertically oriented with respect to the sample surface, while a dither piezo excites a transverse mechanical vibration of the probe. The amplitude of the vibration depends heavily on the tip–sample distance: at small distances, the shear forces between the tip and sample reduce the vibration amplitude, which therefore can be used as a measure of tip–sample distance. To date, several methods have been established for detecting the vibration amplitude, including optical readout [48] and the use of a piezoelectric tuning fork sensor [58]. Although the latter method faced problems when adapted for use in liquids (due to electrical short circuits), several solutions were described, including a custom piezoelectric detection design [59], an electrically insulating layer [60] and a diving bell concept [61].

In a combined shear force and scanning ion conductance microscope, the nanopipette acts both as probe for the ion current and as probe for the shear force measurement. For the detection of vibration amplitude an optical readout was used [46], as this system functions equally well in liquid and in air [62]. An improved optical detection design was based on the use of a pair of periscopes (Figure 6.6) [47]. Here, a collimated laser beam from a laser diode passes down through one periscope tube. Inside the tube, the beam is reflected by a mirror and passes through a lens that provides the interface to the liquid and focuses the beam onto the thin end of the pipette. In the second periscope tube, a two-segment photo-diode detects the light scattered by the pipette, resulting in a vibration amplitude signal. With this periscope-based detection system the vibration amplitude can be detected close to the pipette tip, where the sensitivity is highest. Furthermore, the second tube can be positioned to detect either the transmitted or the reflected light from the pipette. The optical reflectivity of the pipette can be increased by coating with a thin metal layer. In order to induce pipette vibrations a dither piezo is used. By using the vibration amplitude as input to the feedback loop controlling the tip–sample distance, the sample topography can be imaged. The simultaneously recorded ion current then yields a complementary image of ion current at a constant tip–sample distance.

The combined scanning ion conductance and shear force microscope can be used for the investigation of local variations in ion conductance of biological specimens. This is of special interest for research in the field of the barrier-forming structures such as endothelial or epithelial cell layers. In multicellular organisms, these structures form the interface between different fluid compartments and play an important role in inter- and transcellular processes [1, 2]. Gaining insight into the complex barrier-crossing transport mechanisms is a common interest of cell biology,

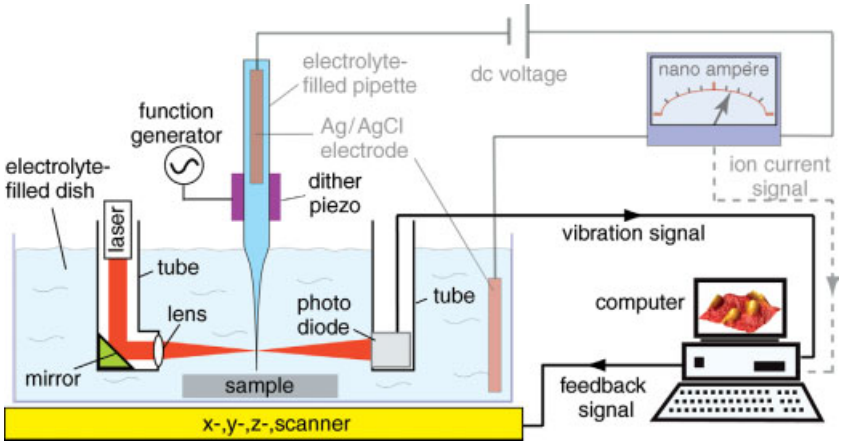

Figure 6.6 (a) Schematic of the combined ion current and shear force measurement set-up. The components for the ion current measurement are grayed out. The pipette is vibrated by a dither piezo parallel to the surface. A periscope design based on two tubes is used to measure the vibration amplitude optically. The first tube is used to focus a laser beam onto the pipette tip; the second tube contains a split photo-diode, which detects the modulated beam and thereby the vibration amplitude of the pipette. The vibration signal provides a complementary input to the computer.

medicine and pharmacology, as malfunctioning of these barriers may have pathological implications.

Special electrochemical and microscopic methods are required to study the ion-permeability of barrier-forming cell structures. For example, experimental techniques such as the measurement of TER may provide valuable information about the barrier properties of cell layers [63, 64]. In addition to such integrating measurements of the total cell layer impedance, the combined scanning ion conductance and shear force microscope can provide further insight into cellular transport mechanisms, as it allows the simultaneous recording of topographic data and local ion conductance with high lateral resolution. One such example is the investigation of the functionality of tight junctions between living MDCK-II cells (Figure 6.7). Here, the shear force image shows the topography of the cells, while the ion current image reveals lines of increased conductance at the position of the cell–cell contacts.

6.5 Outlook

The gentle character of SICM provides for a broad range of possible applications. Examples include the possible study of proteins in pore-suspending membranes, as well as combinations with other imaging techniques. By using the ion current signal of SICM to maintain a constant tip–sample distance, complementary signals such as

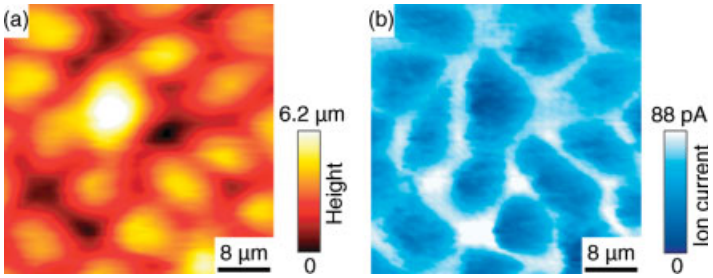

Figure 6.7 (a) Shear force topographic image of living MDCK-II cells; (b) Simultaneously recorded ion current image. The color shows the variation of the measured ion current while scanning.

local optical intensity can be recorded simultaneously. It has been shown that the end of a tapered nanopipette can serve as a near-field light source for SNOM [32, 43, 65], this being achieved by coupling a laser light into the nanopipette via an optical fiber. Coating the outside of the nanopipette with a reflective metal layer then helped to confine the laser light to the aperture (i.e. the tapered end of the nanopipette). Provided that the sample and substrate were transparent, the SNOM signal could then be collected through an objective and detected using a photomultiplier located beneath the SICM set-up. In this way, living cells have been successfully investigated using a combined SICM/SNOM set-up. An alternative use of the SICM probe as a confined light source for SNOM was suggested by Bruckbauer *et al.* [44, 45]. This method was based on the fluorescence that occurred when a calcium indicator (with which the nanopipette is filled) binds with calcium in the sample solution and is illuminated with laser light. The mixing zone where the fluorescent complex forms serves as a localized light source. Another viable combination was that of scanning confocal microscopy (SCM) [66], where the set-up comprised an inverted light microscope fully configured for SCM, on which the SICM set-up was placed. During lateral scanning the vertical position of the sample was controlled by SICM and, as a result, the optical confocal volume, which was located just beneath the end of the nanopipette, followed the topography of the sample. This allowed fluorescence images of a surface to be recorded simultaneously with topographic data.

Acknowledgments

The authors thank Boris Anczykowski, Yuri Korchev, Andrew Shevchuk, Roger Proksch, Eva Schmitt and Claudia Steinem for their stimulating discussions and support. The Schwann cells were a gift from Ilka Kleffner and Peter Young of the University Clinic Münster, while the MDCK-II cells were kindly provided by Joachim Wegener of the Institute of Biochemistry at the University of Münster. The authors are grateful to Asylum Research for support. In addition, the DFG is gratefully acknowledged for financial support (SCHA 1264/1 and STE 884/5). 7
Nanoanalysis by Atom Probe Tomography

Guido Schmitz

7.1
Introduction

The emergence of nanotechnology is closely related to progress in microscopy. Certainly, the existence of atoms as indivisible units of matter may be postulated, as did Greek philosophers several centuries BC (Demokritos 460-371). Also the important properties of small clusters of these elementary units may be deduced by a series of clever physical experiments and suitable reasoning. But it is almost impossible to master the technology of nanostructured devices and to establish their mass production without being able to monitor – to 'see' – the real structure of the fabricated devices. Thus, any important step in reducing the size scale of a technology will require the development of a suitable means of microscopy. Since the structural width of modern devices scales down to only a few nanometers, much interest persists in imaging techniques of atomic resolution. Furthermore, to go beyond mere imaging, chemical analysis of the structure with atom-by-atom accuracy and, perhaps, in three-dimensional (3-D) spatial resolution in desired.

With transmission electron microscopy (TEM), scanning probe microscopy (SPM) and field ion microscopy (FIM), three major branches of microscopy are currently able to achieve atomic resolution in everyday practical studies. Interestingly, the first demonstration of imaging individual atoms was achieved in 1951 [1], using FIM. Since that time, whilst both TEM and SPM have found widespread applications, FIM techniques have remained in a tiny niche, with very few laboratories being able to master and develop the related methods. This is all the more surprising as the fundamental process of FIM – the field evaporation of atoms – offers the exciting possibility to perform a chemical analysis simply by counting the individual atoms.

Instruments which use this approach are referred to as atom probes (APs), and have been used for about 40 years. Unfortunately, their detector and computing possibilities remained rather limited until the 1980s, with the technique being reserved to specialized laboratories. However, based on the recent substantial progress in instrumentation this situation has changed significantly and, indeed,

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

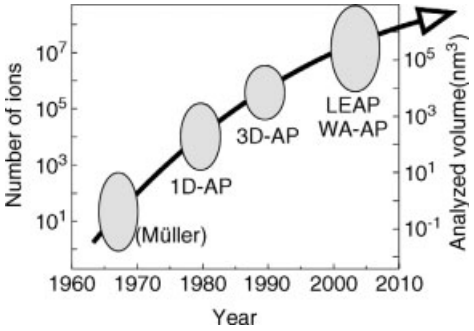

Figure 7.1 Evolution of the atom probe method in terms of analyzed number of atoms or total volume per measurement. For an explanation of the abbreviations, see Section 7.2.

is about to undergo further dramatic development. Depending on their standpoint, some research groups have claimed this to be a 'revolution' [2], while even those less euphoric scientists have admitted 'quite remarkable progress' over the past 20 years. By exploiting the achievements of fast electronics and modern computing, a real 3-D atomic reconstruction of the analyzed volume has become possible, with the maximum number of identified atoms being pushed beyond the hundred million benchmark (see Figure 7.1). Today, atom probe tomography (APT) is capable of providing the chemical analysis of a functional nanodevice as a complete unit, with atomic accuracy.

A second branch of innovation has emerged with the development of efficient pulsed laser sources. By assisting in the process of field evaporation by short laser pulses (of down to a few hundred femtoseconds duration), the practical analysis of nonconductive materials has become a realistic perspective. Recent successful measurements of former difficult classes of materials, such as semi-conductors and ceramics, are encouraging and have initiated intensive methodical research. The concept of laser assistance dates back almost 30 years when the technical limitations of the lasers available prevented their widespread use. As a consequence, the idea was buried among many other interests and, only very recently, has experienced a renaissance.

In the following sections we will examine atom probe tomography in greater detail which, with its increasingly widespread application, can no longer be neglected as an important branch of analytical microscopy. As the typical reader will most likely have only a basic knowledge of the subject, we will first describe the functional principles of the method, the basic algorithms of the 3-D reconstruction, and its accuracy. The instrumental technique and practical specimen preparation will then be considered. Applications of the method will be illustrated by some case studies which address actual problems of thin-film nanoscience. The final section is devoted to the most recent trends in atom probe tomography, including the use of pulsed laser sources to extend the method to complex materials, semiconductors, silicides and oxides as are found in microelectronic devices. It should be noted that the selected

examples were biased by the author's personal interests, and are not aimed to provide a complete overview of the extensive studies conducted in recent years. Those readers seeking additional information should consult recent reviews [2, 3] and textbooks and other reports on the atom probe method [4, 5] and FIM [6].

7.2 Historical Development

Atom probe tomography applies the principle of FIM, and represents the latest progress in this area. The method dates back to the pioneering studies of E. W. Müller, who invented the field ion microscope in 1951 [1] after years of experimentation with electron emission microscopy for which the resolution was limited by the finite thermal energy of the electrons. With FIM, Müller was able to demonstrate atomic resolution images of tungsten surfaces as long ago as 1957 [7]. Although capable of achieving image magnifications in the range of one million – and thereby of atomic resolution – a field ion microscope is a surprisingly simple instrument, when compared to the complex electron optics of electron microscopes. Usually, no imaging lens is needed here. Owing to its simple projective geometry, the instrument does not suffer from the problems of stability associated with electron microscopy.

In 1965, Müller and colleagues were the first to combine FIM with time-of-flight (ToF) mass spectrometry, thus creating the so-called one-dimensional atom probe (1D-AP), the first tool to be used for quantitative chemical analysis in the nanometer range [8]. Rapid progress in detector technology during the 1980s led to the creation of single-ion detectors with sufficient spatial resolution and high detection rates. Important milestones here were the introduction of microchannel plates, of CCD cameras, and of rapid charge-to-digital converters which allowed picosecond time measurements. With this equipment, the early atom probe of Müller experienced a remarkable improvement and, by combining chemical identification by ToF mass spectrometry with the spatial information of the atom position, the numerical 3-D reconstruction of the spatial arrangement of the atomic species became possible. The atom probe had truly advanced to become a modern tool of real 3-D analysis!

Meanwhile, a variety of instrumental concepts of three-dimensional atom probes (3D-APs) were designed and put into operation. The first effectively functioning instrument was the 'position-sensitive atom probe' (PoSAP), which was described in 1986 by Cerezo and Smith [9]. A second, improved, instrument which could handle data from multiple atoms in parallel, the tomographic atom probe (TAP), was presented later (in 1993) by Blavette and coworkers [10]. In fact, as this instrument became more popular and was used in many laboratories worldwide, it lent its name to the general term for the method, namely atom probe tomography (APT). Today, the technical development of APT is in a continual state of flux, with new instruments being introduced on a regular basis. The field of view, and in turn the size of the investigated volume, was significantly improved essentially by reducing the specimen–detector separation, which led to the wide- angle tomographic atom probe (WATAP). Likewise, the addition of a laser beam line led to the method of laser-assisted

field evaporation (LATAP) while, more recently, different energy focusing devices have been developed in order to improve the mass resolution [11, 12].

One remarkable achievement here has been that of the local electrode atom probe (LEAP) [13]. By placing a micrometer-sized electrode in front of an array of microtips, this instrument moderates the serious restrictions in specimen geometry, namely that a needle of high aspect ratio is needed. At the same time, the total number of atoms analyzed per measurement – and thus the size of the reconstructed volume – is increased by one to two orders of magnitude.

7.3 The Physical Principles of the Method

7.3.1 Field Ionization and Evaporation

All FIM techniques utilize the fact that electrical fields are concentrated at tips of sharp curvature. By supplying moderate voltages, enormous field strengths in the range of some $10\,V\,nm^{-1}$ are easily obtained at the apex of nanometer-sized tips, whereas fields of such magnitude could be never obtained with macroscopic geometries. Thus, a typical field ion microscope consists of an ultra-high-vacuum (UHV) chamber with a specimen stage which holds the sample tip, a high-voltage supply and a viewing screen with the capability of imaging the ion impacts (Figure 7.2). A positive potential is supplied to the metallic specimen, while the entrance face of the screen is kept at ground. In order to reduce thermal energies, a

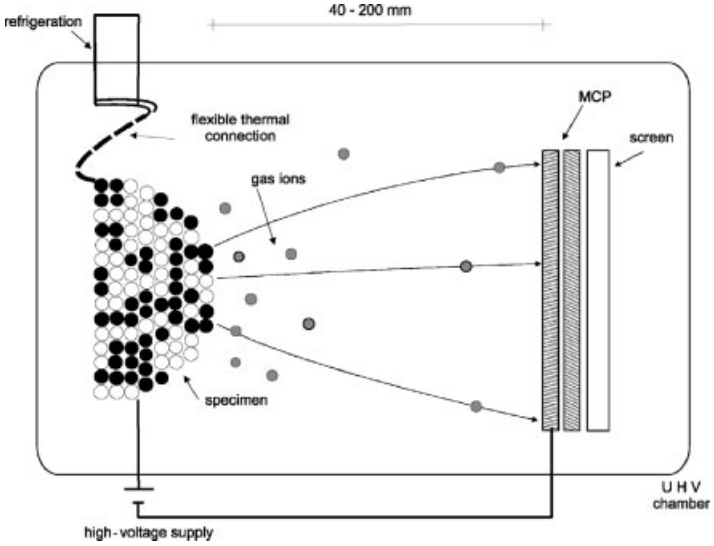

Figure 7.2 Schematic representation of a field ion microscope. MCP = multi-channel plate.

cryostat is required to cool the tip to 20–50 K. The field at the tip surface is controlled by the supplied voltage according to the relationship

$$F = \frac{V}{\beta \cdot R}, \tag{7.1}$$

in which V denotes the voltage supplied to the tip, and β denotes a dimensionless factor that varies with the exact geometry of the tip but is found in the range of 5 to 10. With increasing distance from the tip surface the field decays logarithmically, which means that the dominant drop of the field appears on the first millimeter from the tip surface.

In order to produce a field ion micrograph, an imaging gas (usually He, Ne, or a mixture of both) is introduced into the vacuum chamber. Close to the apex of the sample, the gas atoms are polarized and drawn towards the surface by the inhomogeneous field around the tip. Provided that there is sufficient field strength and a suitable distance between the gas atom and surface, a finite probability exists that an electron will tunnel from the gas atom into the band structure of the specimen. The potential well for electron transfer by tunneling is sensitively controlled by the local field strength. As a consequence, the ionization rate of the gas atoms is a function of: (i) the tip voltage; and (ii) the surface topography. After being ionized, the positively charged particle is accelerated towards the imaging screen where, by means of a multichannel plate and a phosphorus anode, the ion impact produces a visible light flash.

The trajectory of the ionized gas atom is determined by the shape of the electric field. As their thermal energy is negligible compared to the energy gain within the field, the ions are practically starting at rest. As a consequence, there is a one-to-one correspondence between the location of ionization at the tip surface and the impact position on the screen. Because of the discrete atomic structure of the sample, the local field at the surface varies in correlation to the surface corrugation. In particular, the edges of atomic terraces are protruding features and thus, are regions of elevated field strength and pronounced ionization rate. Therefore, the protruding edges of atomic terraces in crystalline structures are imaged as bright concentric rings that surround low-indexed pole directions of the crystal. This is illustrated in Figure 7.3, which shows a comparison of a field ion micrograph and the corresponding ball model of the imaged structure.

In order to achieve a clear field ion micrograph, the so-called 'best imaging field' must be established at the tip surface. To a good approximation, this field strength is only a function of the imaging gas (e.g. 35 V nm^{-1} and 44 V nm^{-1} for Ne and He, respectively). By increasing the field strength beyond this point, an alternative process of 'field evaporation' is observed. As soon as the field reaches a threshold which is characteristic of the sample material, atoms of the tip themselves are ionized, desorbed from the surface, and accelerated towards the screen thereby following very similar trajectories as the former gas atoms.

It is important to understand that the electrical field does not simply tear away the atoms, causing significant damage to the surface structure. Rather, the process remains controlled by a finite energy barrier, which must be overcome by thermal

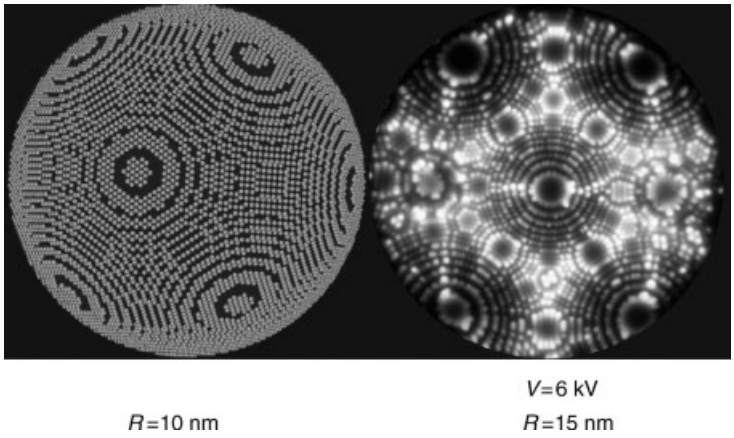

Figure 7.3 Ball model of a hemi-spherical apex (left) in comparison to an experimental field ion micrograph. Protruding atoms are represented by bright dots.The structure of the experimental FIM image at the right, comprising of concentric rings, is a natural consequence of the crystalline periodicity and the apex geometry. activation or by quantum mechanic tunneling at very low temperatures. In other words, there is a clear justification in using the term 'evaporation', as it resembles the situation of vaporization in thermal equilibrium. This can be explained by the most simple model suitable for understanding field evaporation.

In Figure 7.4, the one-dimensional potential curves of a surface atom in its neutral and its *n*-fold charged ionic state, are plotted against the distance to the sample surface. Transferring an atom into the *n*-fold charged state requires an ionization energy, I_n, while placing the free electrons back into the band structure of the metallic

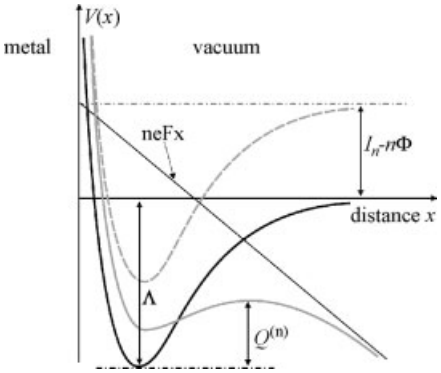

Figure 7.4 Potential curves of neutral atom (black) and ion (gray) close to the surface of the tip. The ionic curve is shown with (solid) and without (dashed) affecting field. For details of further variables, see the text.

sample delivers a payback of n times the work function, Φ. Thus, without the application of a field, the ionic potential experiences a constant shift of

$$\Delta V^{(n)} = I_n - n\Phi, \tag{7.2}$$

with respect to the potential of the neutral atom. If in addition the electrical field F is supplied, the ionic potential steadily decreases with increasing distance to the specimen surface, so that both potential curves necessarily intersect. It is also assumed in the so-called 'image hump model' that the ionic potential develops an intermediate maximum, which represents the important activation barrier. If short-ranged repulsive interactions are neglected, then the ionic potential can be approximated by

$$V(x) = -\frac{n^2 e^2}{16\pi\varepsilon_0 x} - neFx + \Delta V^{(n)}. \tag{7.3}$$

The first term on the right-hand side of the equation is caused by the image force of the metallic surface, while the second term is due to the influence of the field. Straightforward calculation yields the maximum at the hump as

$$V_{\max} = -\sqrt{\frac{n^3 e^3 F}{4\pi\varepsilon_0}} + \Delta V^{(n)}. \tag{7.4}$$

so that the activation barrier reads

$$Q^{(n)} = \Lambda + I_n - n\Phi - \sqrt{\frac{n^3 e^3 F}{4\pi\varepsilon_0}} =: Q_0^{(n)} - \alpha \cdot F^{1/2}. \tag{7.5}$$

In Equation 7.5, Λ denotes the sublimation energy of the sample material. If this activation barrier is overcome by thermal excitation, the temperature dependence of the evaporation rate is expected to follow an Arrhenius relationship:

$$\nu_{\text{evap}} = \nu_0 \exp\left(-\frac{Q_0^{(n)} - \alpha \cdot F^{1/2}}{k_B T}\right). \tag{7.6}$$

Although Equation 7.6 is derived under rather simplifying assumptions, it describes the evaporation behavior at least in a qualitative sense correctly. Some aspects – for example, the characteristic evaporation thresholds of different materials – are even in surprisingly good quantitative agreement with experimental observations. For metals, this evaporation threshold is found to lie in the range of 20–60 V nm^{-1}, a field strength which is easily achieved with specimens of approximately 30 nm curvature radius. Several modifications have been suggested to describe the evaporation, including the so-called 'charge exchange model' and also quantum mechanical concepts. These deliver partly different exponents of the field dependence in the numerator of the argument of the exponential in Equation 7.6. For the range of practical interest, the logarithm of evaporation rate varies almost linearly

with the applied field [14], so that Equation 7.5 is frequently replaced by the empirical relationship

$$Q^{(n)} \approx Q_0^{(n)} \left(1 - \frac{E}{E_0^{(n)}}\right), \tag{7.7}$$

in which $E_0^{(n)}$ denotes the field strength of vanishing barrier.

However, with all of these variations the obvious interpretation of Equation 7.6 is preserved: The desorption rate of the sample atoms is sensitively controlled by adjusting the field strength and, to a lesser extent, by the variation of temperature. In particular, the rate can be maintained at such a low level that the evaporation process can be studied in an atom-by-atom manner.

In order to perform a chemical analysis, a time- and position-sensitive detector system is placed opposite the sample, instead of a viewing screen (see Section 7.4.1). A positive dc voltage is then supplied to the tip, this being slightly too low to affect measurable field evaporation. Short high-voltage pulses of only a few nanoseconds duration are superposed to the base voltage to trigger the field evaporation. Measuring the time between the triggering pulse and the detection of a species allows identification of the evaporated particles by means of ToF spectroscopy. Typically, the pulse height is adjusted so that an event is detected after only about 1% of the pulses. Under these circumstances, the probability of evaporating multiple events comprising several atoms (which the detector system may not be able to split correctly into individual species) becomes negligibly small. In this way the sample atoms can be identified and counted, one-by-one.

For practical measurements, the choice of correct evaporation parameters, base and pulse voltages, pulse frequency and sample temperature, is an art which can only be mastered with profound experience. By continuously desorbing atoms, the samples become increasingly blunted. In order to maintain constant evaporation conditions, the tip voltage must be increased steadily during the measurement. In most cases, this is achieved under computer control, so that a constant evaporation rate in terms of the number of atoms per pulse is preserved. In order to avoid early specimen fracture, a rather low pulse amplitude and not too-low temperatures would be preferred. A low pulse amplitude would also improve the resolution of the mass spectra. However, on the other hand too-low pulses and high temperatures corroborate the accuracy of analysis, as alloy components with a low evaporation threshold may desorb in between the pulses and so become lost in the composition statistics. Suitable compromises are typically found at specimen temperatures between 30 and 50 K, and with a pulse fraction of $V_{\text{pulse}}/V_{\text{d.c.}} = 20\%$.

7.3.2
Ion Trajectories and Image Magnification

In order to understand the properties of field ion micrographs and the quality of the volume reconstruction, the ion trajectories must be discussed in more detail. An idealized specimen may be represented by the geometric model of a truncated cone closed by a hemispherical cap, as sketched in Figure 7.5 (the field lines and model

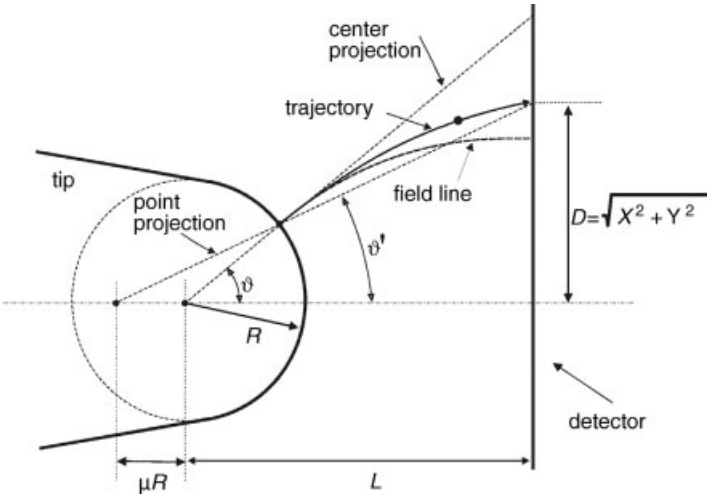

Figure 7.5 Electrical field and trajectory of an evaporated atom. The impact position and initial location at the tip surface are related by a point projection. The center of projection is shifted relative to the center of the spherical cap by μR. As an alternative, the ratio between polar angle ϑ and projection angle ϑ' may be used for evaluation.

trajectories are shown here for clarity). Owing to axial symmetry, the potential and the field can be considered in a two-dimensional space with r and z, the coordinates perpendicular and parallel to the rotational axis of symmetry, respectively. For convenience, the expression for the electrical potential Φ is split into the absolute tip voltage V and a spatial distribution function φ:

$$\Phi(r,z) = V \cdot \varphi(r,z) \tag{7.8}$$

while the equations of motion can be written in accordance to classical mechanics as:

$$\frac{d^2r}{dt^2} = -\frac{neV}{m}\frac{\partial\varphi}{\partial r}; \quad \frac{d^2z}{dt^2} = -\frac{neV}{m}\frac{\partial\varphi}{\partial z}, \tag{7.9}$$

where n and m denote the charge state and mass of the ion, respectively. Without any further calculation, it is seen that the acceleration in both coordinate directions depends on mass, charge state and voltage, in the same manner. Thus, when the ion is initially at rest, the shape of the trajectory becomes independent of all these variables. At given tip geometry, different species will follow the same path, and only the required flight time will vary and be characteristic for the given charge state and mass. This has the important consequence that the fundamental imaging relationship between the tip surface and the detector is universal for all species and that, besides minor modifications due to a slight difference in initial position, the imaging gas and specimen atoms will follow the same trajectory.

Since the ions start at rest, their motion follows initially the field lines, and they leave the spherical apex in radial direction. Later, after having gained considerable

kinetic energy, the trajectory becomes almost straight and deviates from the field lines only because of the forces of inertia. Let us define (as in Figure 7.5) the initial position of the ion by the polar angle ϑ, and the imaged position at the detector by the smaller angle ϑ'. In order to determine the original position at the tip's surface, only the function between both angles must be known. This function may vary from tip to tip, although from a practical point of view a simple proportionality holds, which is conveniently described by an imaging compression factor:

$$\kappa := \vartheta'/\vartheta. \tag{7.10}$$

This factor can be calibrated by means of field ion micrographs of single crystalline specimens, such as depicted in Figure 7.3. The angle between the different pole directions, and thus the polar angle ϑ, is known from crystallography, while the detection angle ϑ' is determined from the position of the pole in the FIM micrograph and the flight distance L between tip and screen. Typical data determined for an electropolished tungsten tip are shown in Figure 7.6. Clearly, the linear relationship of Equation 7.10 is well fulfilled; a compression factor of $\kappa = 0.54$ is determined for this exemplary specimen.

It is straightforward enough to quantify the magnification of the analytical microscope on the basis of the geometric model of Figure 7.5. The polar distance in the image $D = L \cdot \sin\vartheta' \approx L \cdot \vartheta'$ must be compared to the distance at the hemispherical cap $d \approx R \cdot \vartheta$, where R denotes the current radius of the apex. Thus, the magnification is given by

$$M := \frac{D}{d} = \frac{L \cdot \kappa}{R}. \tag{7.11}$$

Recalling that a typical tip radius amounts to about 30 nm, and that the distance between the detector and tip may reach 50 cm, a magnification of 10^7 is easily obtained.

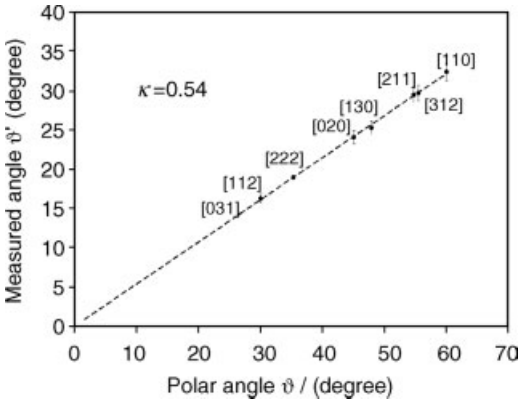

Figure 7.6 The relationship between measured angle ϑ' and polar angle ϑ, as determined for electropolished tungsten tips. The polar angle has been determined from crystallography. Tip axis aligned parallel to [011]. (Illustration courtesy of P. Stender, University of Münster.)

In Equation 7.11 an interesting detail is noteworthy. The magnification of the microscope depends on the tip radius of the specimen or, in other words, the specimen itself represents the essential lens of the microscope. Therefore, APT will only function in a reliable manner, if the specimens are prepared carefully and are notably reproducible in shape. Furthermore, the tip radius increases during the measurement, as the specimen field-evaporates continuously and, consequently, the magnification will decrease during the measurement. In order to reconstruct the spatial arrangement of the atoms after the measurement, the evolution of the radius must be recorded or estimated in a suitable manner.

The introduced geometric model of the tip neglects the roughness of the surface on the atomic scale. In reality, the edges of the atomic terraces and faceting of the spherical surface (low-indexed surface orientations become more pronounced in size due to anisotropy of the evaporation probability) will lead to slight modifications of the trajectories (this point is discussed further in Section 7.3.4).

7.3.3
Tomographic Reconstruction

During each measurement, several million events, the respective flight times and impact positions are recorded. From these raw data the original spatial arrangement of the atomic species is reconstructed by efficient, yet surprisingly simple, algorithms. In order to reduce the mathematical effort, we assume the specimen axis to be aligned perpendicular to the detector plane. The outlined scheme follows the studies of Bas *et al.* [15], and the general case of taking into account a relative rotation between tip and detector can be treated in an analogous manner (appropriate formulas are available in Refs [5, 16]).

The evaluation of data is conveniently subdivided into three steps:

- The specific mass m/n is calculated from the ToF.
- The lateral position at the tip surface is calculated from the impact position at the detector.
- The depth scale along the symmetry axis of the specimen is determined from the data sequence.

In the following section we use the geometric parameters as defined in Figure 7.5.

As the field lines are concentrated at the tip apex, the ions gain the major fraction of their kinetic energy during only the first millimeter of their trajectory. Later, the motion is almost straight and uniform, so that from conservation of energy the specific mass is calculated to sufficient approximation by:

$$\frac{m}{n} = \frac{2t_{\mathrm{ToF}}^2 e(V_{\mathrm{tip}} + V_{\mathrm{pulse}})}{L^2 + X^2 + Y^2}. \tag{7.12}$$

From the geometric detection angle

$$\tan\vartheta' = \sqrt{X^2 + Y^2}/L, \tag{7.13}$$

the Cartesian coordinates of the position at the tip's surface can be determined by

$$\begin{aligned} x &= \frac{X}{D} R \sin\vartheta = \frac{X}{D} R \sin(\vartheta'/\kappa) \\ y &= \frac{Y}{D} R \sin(\vartheta'/\kappa) \\ \tilde{z} &= R(1-\cos(\vartheta'/\kappa)). \end{aligned} \tag{7.14}$$

if the image compression factor κ has been calibrated before. In Equation 7.14 the axial coordinate $\tilde{z}$ has been marked by a tilde to express that this axial position is only preliminary, as it is still given relative to the position of the tip front z_0. As this reference point shifts during the measurement, we must correct the depth position in a final evaluation step. With each evaporated atom, the specimen is eroded by one atomic volume; thus, the number of detected atoms represents a natural depth scale. To establish this scale, the actual image magnification, which relates the sensitive area of the detector to the investigated area at the apex, must be taken into account. By expressing all of this in a differential equation, we obtain

$$dz_0 = \frac{\Omega}{\rho A_{\text{measured}}} dN = \frac{\Omega \cdot M^2}{\rho A_{\text{detector}}} dN, \tag{7.15}$$

where Ω and N denote the average volume per atom and the number of detected atoms, respectively. The factor ρ takes into account the limited detection probability of the detector ($\rho \approx 0.5$) and the magnification M is calculated by means of Equation 7.11. By applying Equation 7.15, the total shift of the tip front relative to its initial position at the start of the measurement is found by integration, and the final z-coordinate results from summing both contributions: $z = z_0 + \tilde{z}$.

In order to evaluate Equation 7.14 or 7.15, the instantaneous tip radius R must be known. If the evaporation properties of the investigated material are reasonably homogeneous, this radius is concluded from the total voltage (dc plus pulse voltage). The preset evaporation rate since is known to be obtained at the critical field strength E_{evap} of the investigated material, we can use by inversion of Equation 7.1.

$$R = \frac{U_{\text{tot}}}{\beta \cdot E_{\text{evap}}} \tag{7.16}$$

to determine the actual radius. However, this scheme is only feasible if the evaporation properties of the sample are reasonably constant. In heterogeneous specimens, for example the thin-film layer type, the radius must be concluded from geometric considerations (see e.g. Ref. [17]).

A typical reconstruction, calculated by the outlined formulas, is shown in Figure 7.7. In this case, the analyzed volume stems from a Cu/Co multilayer specimen. The position and chemical identity of each detected atom is marked by a color-coded dot. With modern wide-angle instruments, the lateral width of the reconstructed volumes reaches about 50 nm, but with blunted tips even 100 nm can be achieved. In view of the rather simple algorithms used, it comes as a surprise that even lattice planes of the

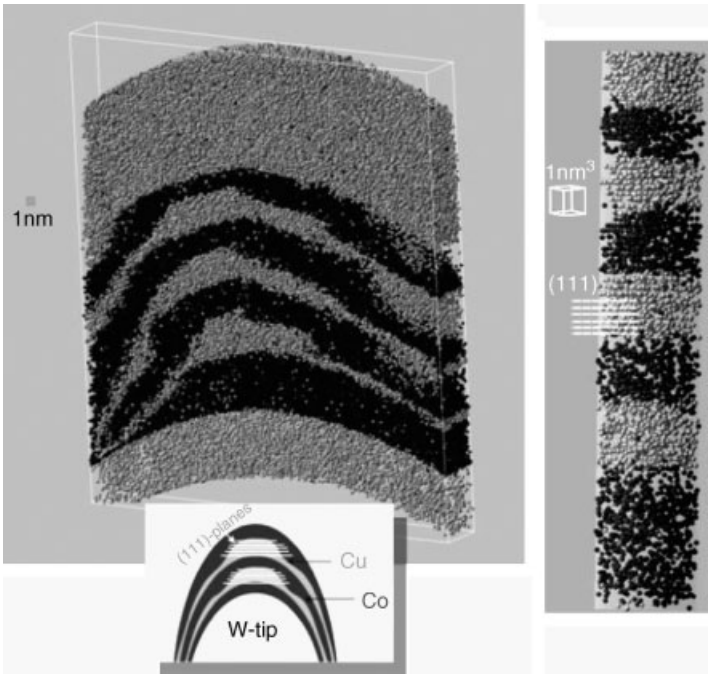

Figure 7.7 Atom probe tomography. Positions of individual atoms are represented by color-coded dots in a perspective representation. This is part of a larger data set of a Cu/Co multilayer after 60 min annealing at 450 °C. The detail on the right-hand side documents lattice plane resolution. (Measurements performed with the WATAP at University of Münster by V. Vovk [60].)

crystalline structure are resolved, as shown in the detail of Figure 7.7. This very welcome feature is explained by the physics of the evaporation process. As atoms at the edges of the atomic terraces have the highest evaporation probability, low-indexed lattice planes that are aligned parallel to the specimen surface have the tendency to desorb in a layer-by-layer mode. Resolved lattice planes demonstrate the outstanding spatial resolution of the method and allow the calibration of important parameters of the reconstruction algorithm. If the critical evaporation field strength, the field and image compression factors β, κ, and the detection probability are chosen correctly, indeed the correct lattice spacing expected for the material is reproduced.

After having reconstructed the spatial arrangement of the atoms, various averages, composition profiles, 2-D compositional maps and iso-concentration surfaces may be derived by sorting and counting the species in suitable subvolumes. Different algorithms were proposed, and are indeed in use, to detect precipitates and the shape of interfaces automatically [18]. The further analysis by Fourier methods [19, 20] or the calculation of pair correlation functions [21] similar to image analysis in the 2-D world of electron microscopy, has also been demonstrated.

7.3.4
Accuracy of the Tomographic Reconstruction

As discussed earlier (see Section 7.3.2), the sample itself represents the critical 'lens' in the projective geometry of the atom probe. Thus, it is not surprising, that a well-prepared shape of the specimen, usually produced by continuous field evaporation prior to the measurement, is the most critical issue in practical work. If the process of 'field development' is conducted too rapidly or insufficiently, then a variety of artifacts may be induced. Of particular danger here is the partial fracture of a specimen before or during measurement, as this usually produces surface topologies that are unsuitable for a reliable spatial reconstruction. In addition, the depth scale will be erroneously calibrated due to the intermediate loss of material. Yet, even if the experimentalist obeys all rules of good experimental practice, the positioning of the atoms cannot be perfect – at least as long as the evaluation scheme outlined in Section 7.3.3 is used. Apart from large angle corrections, this scheme is currently the 'state of the art'.

As illustrated in Figure 7.7 (an even clearer example is shown in Figure 7.20b), it is quite common to reproduce a set of lattice planes in volume reconstructions of pure metals. Usually, these planes are aligned almost parallel to the tip surface. In exceptional cases, several different lattice sets, inclined to each other, could be detected at the same time. By careful Fourier analysis of such examples, the accuracy of the atomic positions in the reconstruction was quantified [19, 20]. By deriving static Debye–Waller factors from the intensity of higher order Fourier components, the standard deviation of the individual atoms from their ideal lattice positions was determined at the example of a pure iron sample to $\sigma_{\perp} = 0.03$ nm in the direction perpendicular to the local tip surface, and to $\sigma_{\parallel} = 0.1 \ldots 0.15$ nm in lateral direction [20]. The strong anisotropy in resolution is a characteristic of the atom probe method. It should be noted here that this outstanding high accuracy has been observed under 'best-case' conditions – that is, the investigation of a pure, coarse-grained metal at rather low temperature. Frankly, a microscopic analysis of such a specimen is useless. In relevant cases, of heterogeneous samples measurements are significantly less accurate. In particular, it is impossible to exploit the impressive depth resolution, way better than 1 Å, in order to determine the shift of interstitial defects out of the host lattice planes. Owing to the principle of depth scaling, these defects will be assigned to either of the neighboring lattice planes. Even worse, the localization of these defects is determined by their relative evaporation threshold rather than their original physical position in between the host lattice.

It is instructive to consider the origin of these inaccuracies. The reconstruction scheme outlined in Section 7.3.3 is based on two important assumptions: (i) the tip apex may be represented by a perfect sphere; and (ii) atoms evaporate individually in a predictable layer-by-layer sequence. The former is the prerequisite for accurate lateral positioning, while the latter is critical for exact depth scaling. It is clear that already with pure metals neither assumption is perfectly met, as the atomic scale roughness and surface facets (which are unavoidable due to anisotropy of the evaporation threshold) are neglected. With alloys, the situation becomes even worse.

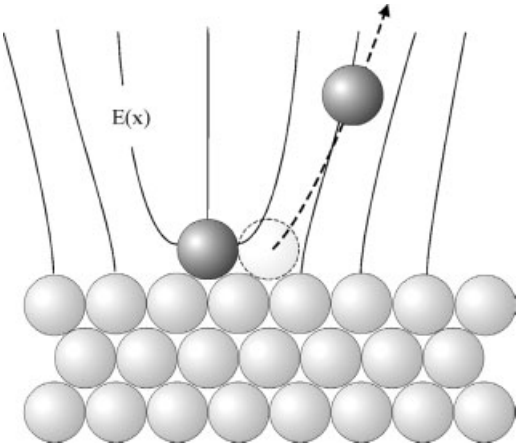

Figure 7.8 Schematic field distribution at a low indexed lattice plane just before being completely evaporated. The last but one atom is accelerated by a field which is significantly deformed by the last atom.

As the various components evaporate at quite different field levels, the sequence of evaporation can be severely disturbed in this case.

Furthermore, in heterogeneous microstructures, so-called 'local magnification effects' prevent the simple mapping of the projective geometry. For example, the embedded particles of a material of the higher evaporation threshold tend to protrude from the tip surface, which leads locally to an increased curvature of the surface and thus to an inhomogeneous magnification by the microscope. The undesired consequence is that the particles appear artificially broadened and that their atomic density is underestimated in the reconstructions. Worse still, due to overlapping of the trajectories artificial mixing of the materials from both sides of the particle interface is erroneously measured.

In order to understand why positioning in lateral direction is less accurate, we consider the situation sketched in Figure 7.8, when only very few atoms are left shortly before evaporating a further low-indexed lattice plane completely. In this case, the electrical field that controls the trajectory of the atom next in evaporation line will definitely deviate from the idealized field surrounding a spherical surface, due to local disturbance of the remaining protruding atoms. Thus, in order to calculate the trajectories exactly, the structure must be known in advance. We are faced with an implicit problem *when* the atoms should be localized exactly on the atomic scale. The solution of this problem remains a goal for the future. Meanwhile, in order to achieve a sound evaluation of atom probe data, the only promising strategy is to simulate the evaporation sequence of hypothetical specimen structures and to compare the simulated reconstructions with those of real experiments. Such a procedure is quite analogous to the normal practice in high-resolution electron microscopy, where experimental images are compared to those simulated from hypothetic structures until a good match is found.

For that task, Vurpillot and coworkers [22, 23] derived a simulation scheme that allowed an investigation of the spatial accuracy of tomography and the influence of

heterogeneous evaporation on theoretical grounds. As the simplest geometric model, which still reflects microscopic features on the atomic scale, these authors suggested constructing the apex from a simple cubic arrangement of Wigner–Seitz cells. In a first step, the electrical field surrounding the model tip is calculated by solving numerically Poisson's equation for the electrical potential by means of a finite element method. The electrical field strength at the locations of the surface atoms is determined, and the position of the highest field strength identified. In a second step, the atom at this specific position (meaning the corresponding Wigner–Seitz cell) is removed from the apex model and the field is recalculated for the new configuration. In a final step, the trajectory of the removed atom is calculated between the tip surface and detector in accordance with classical mechanics which considers the acceleration of the ion within the electrical field. In the case of alloys or heterogeneous systems, the different evaporation probabilities of the atomic species must be taken into account. Thus, before the position of highest field is selected in the first step, the electrical field is scaled artificially by a factor varying from atom to atom in order to reflect the respective evaporation probability.

By repeating this scheme recursively to predict the impact positions of several thousand atoms, a part of a measurement can be simulated quite realistically. The general features of the experimental data are well reproduced, although an artificially short flight distance between the tip and the detector, and rather small specimens of approximately 20 nm radius, had to be used to limit the computational effort. The statistical nature of thermal activation has also been neglected. In Figure 7.9, the

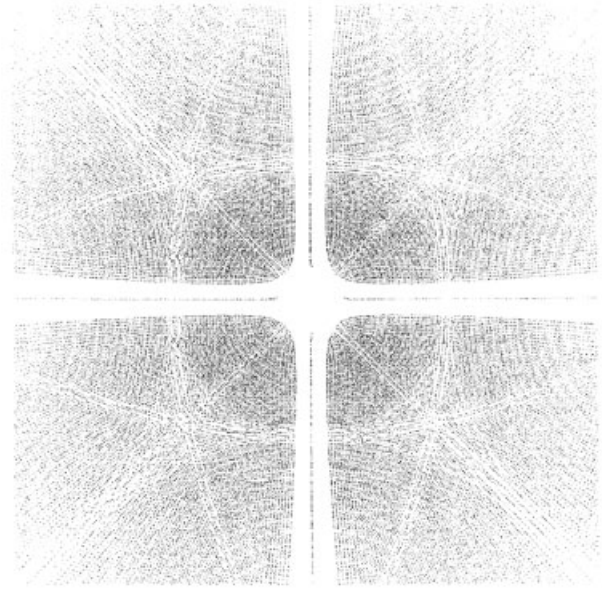

Figure 7.9 Simulated impact positions on the detector area, during evaporation of a few lattice planes of a simple cubic model alloy. The tip axis is aligned along [001]. (Reproduced with permission from Ref. [22].)

impact positions of several thousands of atoms on the detector are shown, as calculated from the simulated evaporation of a few lattice planes. In contrast to the behavior of an ideal microscope, the spatial density of the events is by no means homogeneous. Rather, lines of significant redistribution of the atoms are seen, which are related to low-indexed zones of the crystal structure. Clearly, this redistribution is related to the situation sketched in Figure 7.8. The last few atoms sticking on a flat, low-indexed surface are affected by severe field distortions and therefore, their trajectory is significantly disturbed in comparison to a simple point projection.

Deviations of the trajectories induced by the local surface topology on the atomic scale are the main limiting factor for the instrument's lateral resolution along the tip surface. Although various ideas have been proposed to correct for the pronounced deviations at zone lines in pure samples, a practicable improved reconstruction algorithm has not yet been presented. In the case of statistical alloys, the situation is particularly difficult, as the chemical neighborhood of the evaporated atom is not known. One may imagine iterative algorithms to refine the reconstruction. But even the atom probe detects only 60% of the atoms (see Section 7.4.1). Thus, the local chemistry is never known completely. The effect of disordered alloys becomes particularly clear if, in simulated measurements, the atom positions of a disordered alloy are compared to those of a pure tip of identical geometry. An example is shown in Figure 7.10. Owing to the different evaporation probabilities of the two species, the evaporation sequence is disturbed and the local fields are distorted in the case of an alloy in a different manner as compared to a pure specimen. Clearly, the reconstructed positions of the atoms do not agree. However, as can be seen from Figure 7.10, most positions agree within about one lattice constant. Only a minor fraction of atoms originating from zone line positions are shifted by much larger amounts, up to five lattice constants. In this way, the simulation indicates the lateral

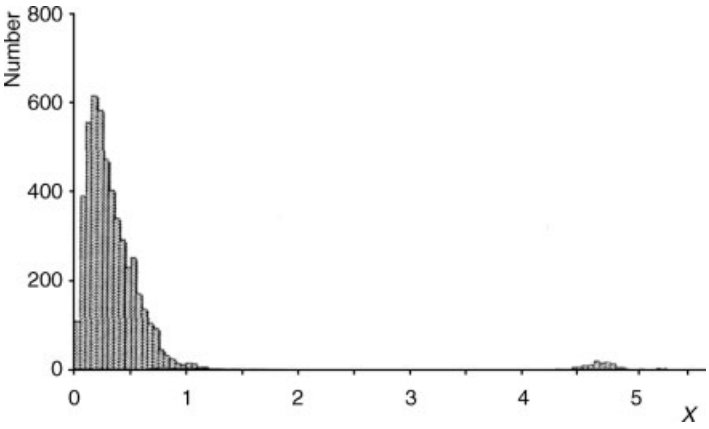

Figure 7.10 Statistics of reconstructed atom positions of an AB model alloy with respect to their ideal position in an homogeneous specimen (relative shift x in units of the lattice constant). (Reproduced with permission from Ref. [22].)

accuracy of the tomography to be slightly better than a lattice constant, as long as poles and zone lines are avoided for analysis.

7.4
Experimental Realization of Measurements

7.4.1
Position-Sensitive Ion Detector Systems

The rapid progress of APT in recent years has been made possible only by the remarkable evolution of spatially resolving detector systems with single-ion sensitivity. During the past two decades, several detector concepts have been proposed and put into operation. Those systems currently in use will be discussed at this point.

All available detector concepts are based on a stack of two to three multichannel plates (MCP). An MCP represents a secondary electron multiplier with many independent channels working in parallel. The device is composed of thousands of small glass tubes, each approximately 25 μm in diameter, and packed in parallel alignment to form a plate of about 1 mm thickness (see Figure 7.11). The front and reverse sides of the plate are coated with thin metallic films which serve as electrodes to supply a voltage in the 1 kV range. An ion which hits the inner wall of such a glass tube will produce a few secondary electrons that are accelerated by the supplied field. On their way towards the reverse side, they impact the glass wall several times and produce further secondary electrons. This cascade process finally produces a cloud of about 10^4 electrons per ion. If a consecutive stack of two or three MCPs is used instead of a single unit, the individual amplification factors will be multiplied so that a single ion hitting the front side with sufficient energy will produce finally a cloud of about

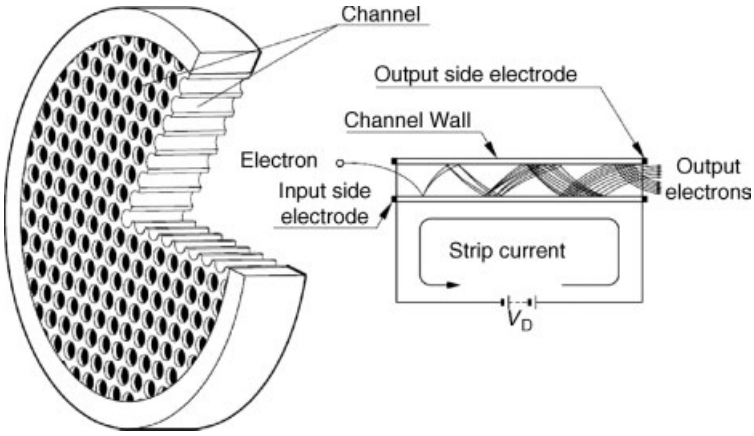

Figure 7.11 Functional principle of a multi-channel plate (MCP). The MCP is an arrangement of thousands of secondary electron multipliers working in parallel. Each of the electron multipliers is made from a tiny glass tube, 25 μm in diameter.

10^8 elementary charges, which is sufficient for further electronic evaluation. An MCP is a rather rapidly operating device; indeed, with optimized electronic circuitry the raise time of a single ion pulse is in the range of 100 ps. The spatial resolution of the MCP is determined by the dimension of the glass tubes. One important drawback here is that the detection efficiency of an MCP is way below 100%. Hence, only those charged particles which penetrate into one of the tiny tubes will induce the described avalanche process, while those hitting the massive front side are simply reflected. Due to mechanical requirements, channel plates cannot be produced with an open area fraction significantly larger than 60%. Attempts to improve the detection probability by placing additional electron mirrors in front of the channel plate have not been sufficiently successful so as to be used in modern-day instruments. Thus, based on principle, the presently available atom probes do count only half of the atoms of the analyzed volume.

For imaging purposes in FIM, it is sufficient to place a phosphorus screen behind the exit face of the MCP, so that each electron cloud produces a short light flash. Several attempts have been made to record these light flashes by means of a gated CCD camera in order to determine also quantitative positional information; examples include 'Optical PoSAP' [24] and 'Optical TAP' [25]. However, both systems suffered from a rather slow read-out of the camera, which severely limited the practical pulse frequency. Therefore, state-of-the-art instruments usually evaluate the charge clouds using methods mostly developed by nuclear physicists. For this, a multiple anode array is placed behind the MCP and connected to sensitive preamplifiers and fast converters in order to transform analogous charge information into digital data. Various concepts can be distinguished by their different layouts of the anode array and the complexity of the electronics. Historically, the first functioning system was the PoSAP, which was built around a 'wedge and strip anode' [26]. The name of this anode is self-explanatory, based on the sketch in Figure 7.12a. The geometry is designed in such a way that the relative fractions of the total charge measured on the three electrodes Q_X, $Q_Y$and Q_Z, vary with the position of the electron cloud. For the layout shown, the position may be calculated in a straightforward manner by

$$X \propto \frac{Q_X}{Q_X + Q_Y + Q_Z}; \quad Y \propto \frac{Q_Y}{Q_Y + Q_Z}. \tag{7.17}$$

Since only three independent anodes are used, the required electronics is reasonably simple. However, the layout has the important drawback that the total area of each electrode – and thus the respective capacities – are quite large and the drain of charges after the impact takes a considerable time. If a second ions hits the detector within this time gap, then both events cannot be separated; consequently, the operator is forced to use very low data rates.

Following a significant effort to improve the electronic instrumentation, a square array layout of many smaller electrodes was realized shortly afterwards, with the original TAP detector (see Figure 7.12b) [10]. By choosing the correct distance between the MCP and anode array, the electron cloud will always spread over at least three or four electrodes, so that its central position can be determined by charge

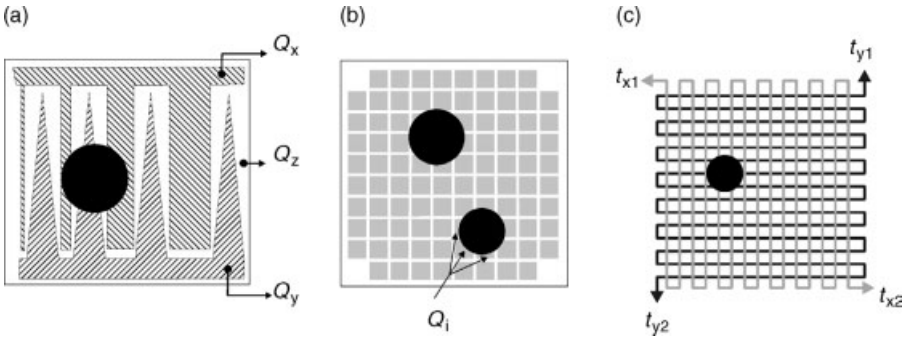

Figure 7.12 Anode layouts for the read-out of the positional information of a channel plate. (a) Wedge and strip detector; (b) TAP detector; (c) Delay line detector. Here, instead of the double-wire Lecher lines, only a single wire is shown to illustrate the principle. The extension of the electron cloud is symbolized by black circles.

weighting. Due to its parallel design the detector has some capability to separate multiple events, which allows much higher data rates than with the PoSAP detector.

The latest instruments (those constructed after 2003) mainly apply the delay line principle, which was first proposed in 1987 [27]. Here, instead of flat electrode areas, two independent double wire spirals are used that are wound along the *X* and *Y* axes of the detector, as shown schematically in Figure 7.12c. Each double wire represents a Lecher line, on which the pulse signal propagates with the velocity of light. As opposed to previous concepts, the spatial information is not determined from charge weighting but rather from time measurements, so that no expensive measurement of analogue signals is required. Each ending of the Lecher line is connected to a separate channel of a fast time-to-digital converter (TDC) with sub-nanosecond resolution. If the ion impacts at the center of the detector, the pulse signals will propagate symmetrically to both ends of the Lecher line, and will therefore reach the TDC at exactly the same time; in contrast, for an asymmetric impact position the two time signals will differ considerably. The sum and difference of the two time signals of such a Lecher line are presented in Figure 7.13; these were collected for many independent impacts on a circular detector of 120 mm diameter and a spire spacing of the anode of 1 mm. The sum of both time signals represents an instrumental constant, and corresponds approximately to the propagating time from one end of the line to the other. With 150 ns, this time interval is easily measurable. The time difference between both signals is proportional to the position according to

$$X = v_p\left(t_x^{(l)} - t_x^{(r)}\right), \tag{7.18}$$

where the calibration parameter v_p denotes the propagation velocity along the spiral axis, which amounts to about 0.4 mm ns^{-1}. An analogous equation holds for the *Y* direction. With modern computer electronics, a time resolution below 100 ps – and

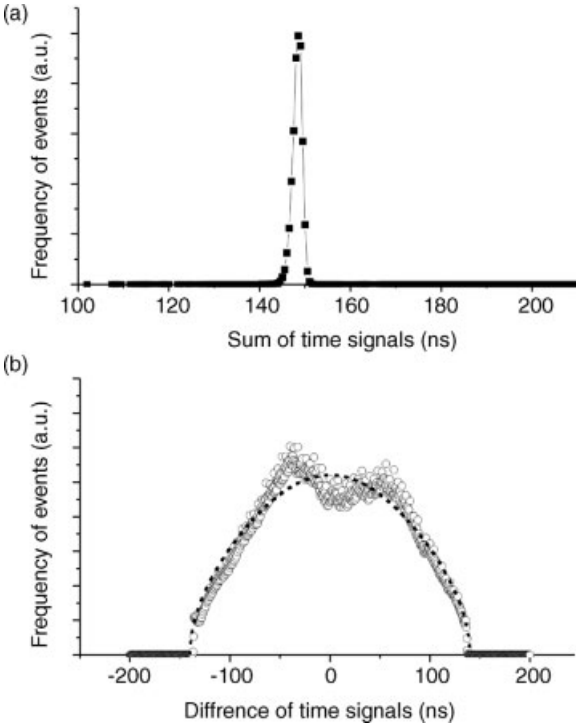

Figure 7.13 Evaluation of time signals of the delay line detector. (a) The sum of both signals is a constant which may be used to correlate time signals to individual events; (b) The difference is a direct measure of the position. The dashed line represents the spatial distribution expected for a circular detector in wide-angle configuration. Experimental data deviate due to anisotropic evaporation of the crystalline sample. (Illustration courtesy of P. Stender, University of Münster.)

thus a positional accuracy of better than 0.1 mm – is achievable. As a fast TDC is already required for ToF mass spectrometry, delay line detectors represent a very economic solution. Furthermore, the delay line principle allows very high data rates, so that evaporation pulses may be applied with frequencies of up to 300 000 Hz. In order to improve the multi-hit capability, a hexagon anode design [28] and quantitative evaluation of the pulse shape by use of fast oscilloscope electronics has been realized [29]. However, it is not yet clear whether this additional effort in instrumentation will provide an advantage in practical terms.

7.4.2
Instrumental Design of 3-D Atom Probes

In principle, a 3-D or tomographic atom probe consists of the same components as the FIM shown in Figure 7.2. Only the viewing screen must be replaced with one of the above-discussed position-sensitive detector systems, and the high-voltage supply

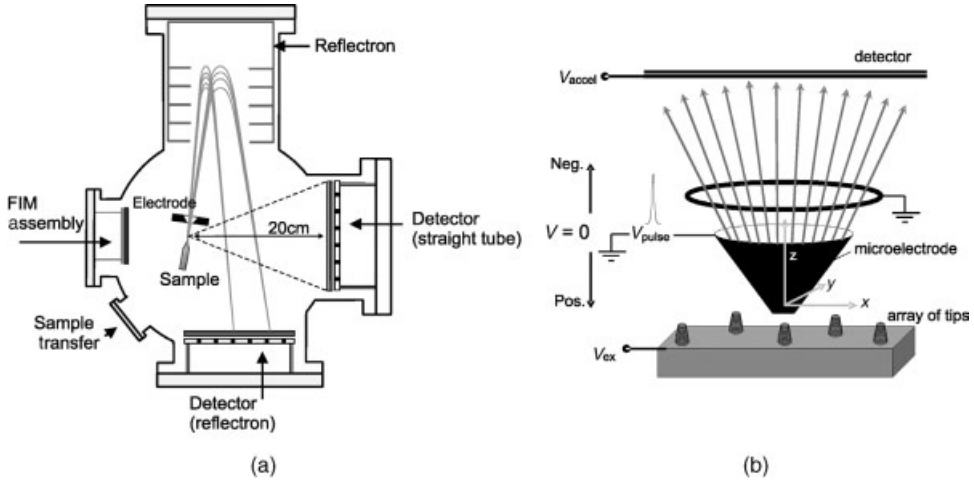

Figure 7.14 The design of the tomographic atom probe operated at the University of Münster [31]. The dedicated chamber layout allows switching between different geometries: (i) the straight flight tube yields a short flight path to optimize the open angle of the instrument; (ii) the reflectron arrangement yields an improved mass resolution; (b) The principle of a microelectrode atom probe. An extraction electrode with an open diameter of approximately 10 µm is placed close to a microtip to concentrate the electric field. (For an example, see Ref. [13].)

must be extended by the required voltage pulsing. By using the voltage pulse as start signal for an accurate time measurement, and the detector signal for stopping, the ToF of the ions can be measured in straightforward manner. However, the flight distance between the tip and detector must be adapted to obtain the desired mass resolution. During the past two decades, this flight distance has been steadily decreased in response to the improving time resolution of available measurement electronics. Recently, the flight path was reduced to 10–20 cm in so-called 'wide-angle instruments' [30, 31]. With detector diameters of up to 120 mm, this yields a geometrical aperture of $2\vartheta' \approx 44°$, which means an even larger effective opening in the range of $2\vartheta \approx 60°$ due to the curvature of the ion trajectories (as explained in Section 7.3.2). A schematic representation of a modern conventional 3-D atom probe is shown in Figure 7.14a. In contrast to the concepts discussed above, two modifications should be noted:

- Instead of a straight flight tube, a reflectron geometry is used with an ion mirror that leads to parabola-shaped ion trajectories. This geometry compensates for fluctuations in the kinetic energy of individual ions. A faster ion will penetrate deeper into the mirror field, and so will have a longer flight path. If the length and voltage of the reflectron are adjusted correctly, then ions of identical mass but with slightly varying initial velocity will hit the detector after identical flight times. In this way, the mass resolution is significantly improved. Originally, reflectrons were designed with a homogeneous mirror field. With such a device, a perfect time focusing is paid by trajectory deviations which can only be tolerated for small aperture angles. Therefore, a conventional reflectron is not compatible with the

wide-angle concept. Very recently dedicated reflectrons have been designed with curved electrode shapes, which eliminate this problem [12]. When using a reflectron, the typical mass resolution of a 3-D atom probe can be expected to be $\Delta m/m = 1/500...1/2000$, whereas without such a device the resolution is limited to $\Delta m/m \approx 1/100$ [all data full width at half maximum (FWHM), determined at an effective mass of $m = 30$].

- The evaporation trigger is supplied as a negative pulse to an extraction electrode in front of the tip, which allows shorter and better-defined pulse shapes. Recently, the use of an extraction electrode has created important progress towards miniaturization. If a large number of atoms were to be evaporated and measured in a reasonable duration of the experiment, the pulse frequencies would need to be as high as possible. However, this strategy finds a natural limit, as no practicable means are available to produce a 5 kV nanosecond pulse with frequencies exceeding 20 kHz. A very intelligent method to circumvent this technical problem is to use a micrometer-sized electrode, as suggested in 1994 by Nishikawa and Kimoto [32]. By placing a tiny extraction electrode of some 10 µm bore size close to the tip, the β-parameter of Equation 7.1 is reduced by a factor of 2 to 3, as exemplified by the experimental data in Figure 7.15. In consequence, much lower voltage pulses are required, which today can be produced with repetition rates far in excess of 100 kHz. After solving any related technical problems, the concept has been put into operation during the past few years. Meanwhile, these instruments are functioning well and available commercially [33]. Their efficiency of analysis is impressive [34]; a data rate higher than 10 000 atoms per second is obtainable and data sets with more than 10^8 atoms have been routinely achieved. Beside the high

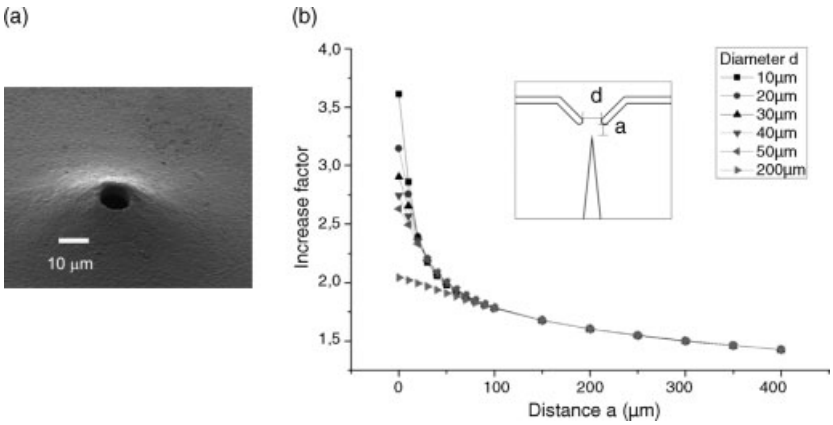

Figure 7.15 The increase of field by a microelectrode in front of the tip allows the voltage to be reduced by a factor of two to three at a constant tip radius: (a) SEM micrograph of an electro-plated Ni microelectrode (b) The relative increase of field at constant voltage for microelectrodes of 20 to 200 µm is plotted against the spacing between tip apex and electrode. (Illustration courtesy of Ralf Schlesiger, University of Münster [88].)

data rate, these instruments have an important advantage in specimen preparation. As indicated in Figure 7.14b, an array of microtips may be used rather than a single tip made from a supporting wire. As the requirement for a large aspect ratio is considerably relaxed by the microelectrode geometry, the tip array may be conveniently produced by sputtering through a suitable mask. Very recently, In As nanowires, grown naturally by using nanopatterned Au catalysts, were directly analyzed using a tomographic atom probe equipped with such a microelectrode [35].

7.4.3 Specimen Preparation

As APT requires a dedicated needle-shaped sample geometry, obtaining suitable specimens is a delicate matter. Although the art of preparation has undergone considerable progress, a large proportion of desired measurements fail due to this issue. Traditionally, the required needles were produced by the electropolishing of thin metallic wires under *in situ* observation by means of optical microscopy. At present, thin films and other complex nanostructure are the focus of interest, of which usually no conventional wire is available.

For studies on reactions in thin-film materials, layer systems have been deposited onto tungsten tips, which serve as a substrate. In order to achieve an optimum shape, the freshly prepared tungsten substrates are field-developed prior to deposition. As considerable stress is induced by the electrical field during the measurement, many investigations are prevented by insufficient mechanical stability of the interface between substrate and coating. Thus, this interface requires special care. Occasionally, an interlayer (often chromium) is used as an adhesion aid, while ion-beam cleaning of the substrates immediately before deposition has also been shown as advantageous [36]. In Figure 7.16a, a thin-film specimen produced in this way,

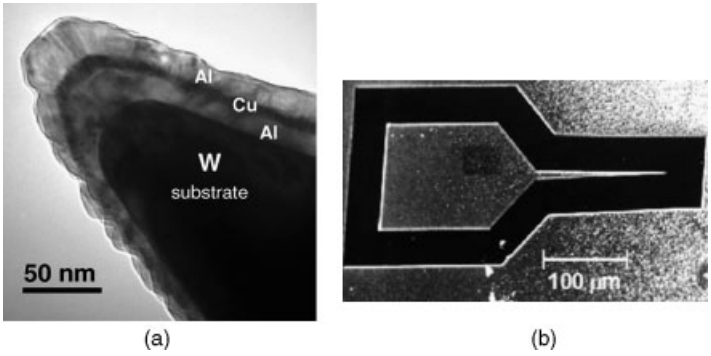

Figure 7.16 (a) Example of an Al/Cu/Al trilayer on a tungsten substrate tip, deposited using an ion beam sputtering technique. (Illustration courtesy of C. Ene, Göttingen.); (b) Scanning electron micrograph of a layer specimen prepared by electron-beam lithography. (Illustration courtesy of J. Schleiwies, Göttingen.)

namely an Al/Cu/Al trilayer deposited on tungsten, is presented. In this geometry, the main analysis direction is aligned normal to the interfaces, so that these specimens are especially suited for the investigation of reactive diffusion by local depth profiles of composition. However, when interpreting the analysis results it must be borne in mind that these films are deposited onto a curved surface. Usually, the curvature induces a rather small grain size, so that the microstructure is not directly comparable to that of thin films deposited onto conventional planar wafer substrates [37].

If this variation in microstructure cannot be tolerated – for example, because the properties of technical devices should be characterized – the tips may be cut by either lithography [38] or focused ion beam techniques. For the former a planar layer system is first coated with a suitable photo resist, and exposed to electron-beam lithography and developed chemically to obtain a suitable etching mask. A typical sample is shown in Figure 7.16b. The tip is attached to a 'handle' which is about 100 µm in length, with the wedge-shaped needle pointing to the right-side taper to a width below 100 nm at the apex. After etching by sputtering, the tips are removed from the substrate and glued to a supporting wire. In this geometry, the interesting interfaces are aligned parallel to the main analysis direction; thus, the method is well suited to investigations of interfacial roughness or pin holes in multilayers of small periodicity.

With the emergence of focused ion beam (FIB) facilities, equipped with a Ga beam of 5 to 30 keV, the preparation of difficult nanometric geometries has been revolutionized. Thus, it is no wonder that this technique is being used increasingly to prepare the required needles. Following an original proposition by Larson [39], thin films are deposited on top of flat-ended Si posts for that purpose. The width of the rectangular prism-shaped posts is chosen to be about $10 \times 10\,\mu m^2$ in cross-section – sufficiently large to mimic realistically the deposition conditions of a larger planar substrate, yet at the same time thin enough to limit the required beam time of the FIB. As an alternative, the cutting of a thin bar directly from a massive volume has also become usual practice as the intensity of available Ga beams has been further improved. Originating from transmission electron microscopy (TEM) studies [40], this 'lift-out' technique has been recently adapted to the needs of APT [34]. The essential preparation steps are shown in Figure 7.17. With any FIB method, the final step to produce a sharp tip is always an annular milling from the front face with a continuously decreasing size of the circular mask, as indicated in Figure 7.17c. It goes without saying that great care must be taken to avoid irradiation damage of the part which is to be analyzed. At 30 keV, the Ga ions of the cutting beam can be expected to penetrate at least 20 nm into the sample, and therefore suitable metallic coatings must be used to cover sensitive areas. Then, on completion of the procedure the energy of the beam should be reduced as much as is practicable.

The FIB has certainly revolutionized the preparation task, particularly if the tips are to be cut from chemically or mechanically difficult materials such as multilayers and semiconductors or ceramics. On the other hand, it cannot be overlooked that 'beam time' on these machines is still a rather limited resource. In this context, it should be noted that although many insulated measurements of FIB-prepared samples using

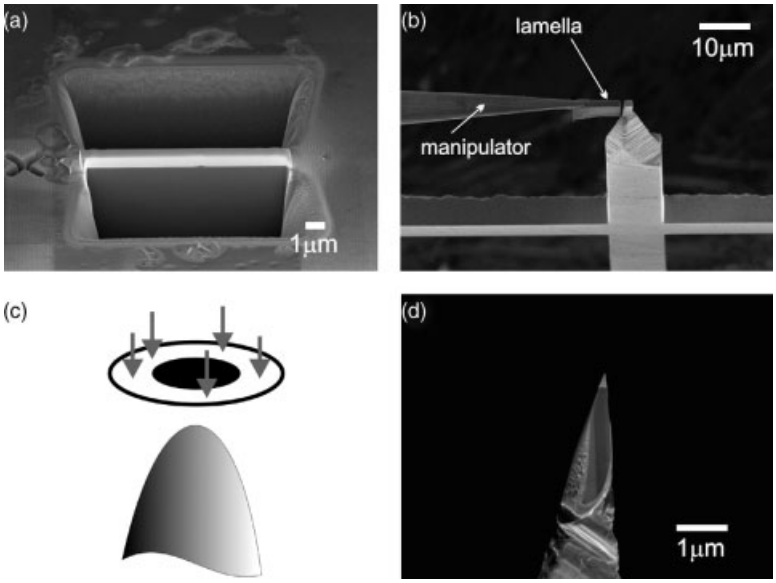

Figure 7.17 Stages of focused ion beam preparation using the lift-out procedure. (a) Cutting of lamella perpendicular to the substrate. The lamella edges are covered with deposited Pt; (b) Lamella moved to a supporting post (e.g. Cu). A part of the lamella had been fixed to the post and the remaining cut by the ion beam; (c) Annular milling from the front with continuously decreasing aperture size; (d) The final tip sample. (Illustration courtesy Ralf Schlesiger, University of Münster [86].)

APT are reported today, very few experimental series have been reported that characterize the different stages of a physical process. This may be seen as an indicator that the reliability and efficiency of the FIB procedures still require significant improvement.

7.5 Exemplary Studies Using Atom Probe Tomography

The application of APT to the physics of reactions is demonstrated here with some studies with nanosized, man-made geometries. As an analysis with an atom probe requires appreciable effort, the method should be used especially in those cases where its particular advantages can be best utilized. To summarize, the outstanding features of APT include:

- A spatial resolution of chemical analysis of a few Ångstroms. While theoretical performance data expect a similar resolution to be achieved with analytical TEM [electron energy loss spectroscopy (EELS) or energy-dispersive X-ray spectroscopy (EDS)], a comparison of composition profiles at interfaces reveals that APT has a significantly higher discriminating power.

- A standard-free chemical analysis with identical sensitivity of all elements across the periodic table. Whilst in TEM studies a variety of species cannot be measured due to physical limitation [e.g. low-mass elements in energy-dispersive X-ray (EDX) or peak overlap and low intensity in EELS], APT will always reveal a chemical contrast that even allows different isotopes to be separated.
- A real chemical mapping in three dimensions. While the 2-D image projection required in high-resolution TEM studies hinders the clear characterization of complex morphologies, APT is especially suited to investigate curved and buried interfaces in nanocrystalline matter.

The following examples have been selected to illustrate, in which way these advantages may be decisive in the success of experimental studies.

7.5.1 Nucleation of the First Product Phase

Owing to the technological trend towards miniaturization, the very early stages of reactive diffusion at thin-film interfaces have shifted into the focus of materials research. Frequently, it is argued that the thermodynamic driving force of forming a first reaction product is usually so high that the critical thickness of nucleation ranges down below the size of a lattice constant. Thus, nucleation should not be a rate-controlling step at all. However, initial evidence that this may not be true came from calorimetric studies of reactive diffusion in metallic thin films. Although only a single product forms, double-peaked heat releases were observed [41–43]. This experimental finding was interpreted as a two-stage mechanism [44]. In the first stage, nuclei form at the initial interface and grow quickly in lateral directions, while in the second stage heat release is attributed to parabolic thickness growth by volume diffusion. However, the process of nucleation remained quite unclear. Several mechanisms have been proposed to explain the apparent reduction of driving force in the presence of a sharp composition gradient [45–47]. In common, they predict that the composition gradient at the interface must first decrease by interdiffusion to a critical level before nucleation of the first intermetallic compound becomes possible. However, no clear experimental verification of this interpretation was provided.

A recent nanoanalytical study [48] was aimed at enlightening details of the early nucleation stages. For these experiments, bilayers of Co and Al, each 20–30 nm thick, were deposited on tungsten substrate tips, as described in Section 7.4.3. Two examples of 3-D reconstructions of the Co/Al interface are shown in Figure 7.18. Although the layers were deposited on curved surfaces, the initial interface appeared practically flat, as the radius of curvature was still significantly larger than the width of the analyzed volumes. This flat interface is preserved for short annealing so that the earliest reaction stages may be characterized by 1-D composition profiles determined normal to the interface, as shown in Figure 7.19. Due to the outstanding resolution, minor chemical modifications at the interface become noticeable. After a 5 min period of heat treatment at 300 °C, the zone of chemical transition at the interface

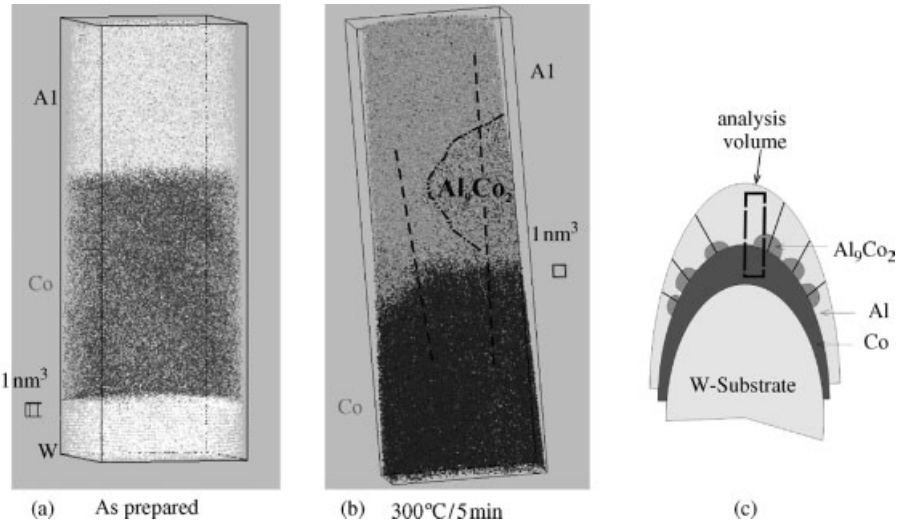

Figure 7.18 (a, b) Atomic reconstructions of the Al/Co interface in the as-prepared state (a) and after annealing at 300 °C for 5 min; (b) Positions of individual atoms are marked by gray coded dots; (c) Sketch of specimen geometry. (After [48]).

broadened to 3.5 nm, indicating a significant mixing of the components. However, the composition profile in this annealing state was well fitted by an error function. Thus, it follows that, up to this stage, only interdiffusion rather than formation of a new intermetallic product has taken place.

The first nucleation of a new phase is observed only in a small fraction of measurements at this annealing stage. In these cases, globular particles are detected at the interface towards the Al side (see Figure 7.18b). The fact that these particles

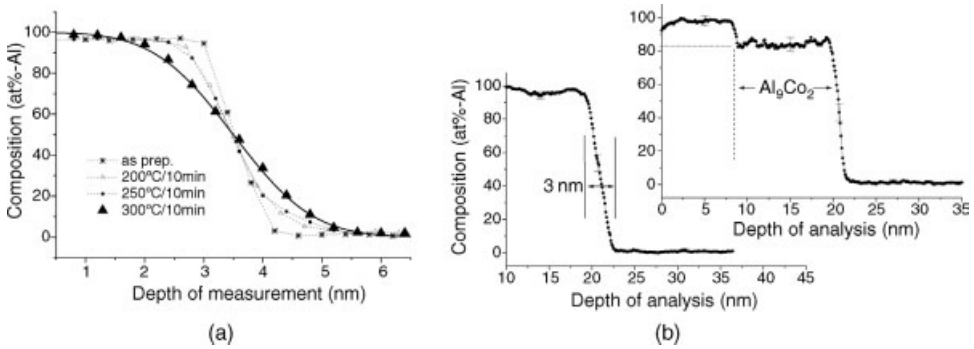

Figure 7.19 (a) Composition profiles determined perpendicular to the initial Al/Co interface after different annealing treatments; (b) Composition profiles determined along the left and right dashed lines in Figure 7.18b, demonstrating interdiffusion and phase formation, respectively. (After [48]).

appear only in part of the measurements after identical annealing conditions emphasizes the statistical nature of a nucleation process. Furthermore, it becomes clear from the volume reconstructions that nucleation takes place at heterogeneous sites at the interface, as sketched in Figure 7.18c. A composition profile across the newly formed phase identifies the product as Al_9Co_2 (see Figure 7.19b), while a profile determined across the remaining unreacted interface confirms again the interdiffusion on a depth of 3 to 4 nm as described previously.

The set of composition profiles in Figure 7.19, which could be obtained in this way only by APT, provide a clear demonstration that significant interdiffusion takes place before nucleation of the product. Furthermore, the experimental data quantify the critical diffusion depth before onset of nucleation to 3.5 nm (Al/Co at 300 °C).

If the theoretical nucleation thickness of the intermetallic product is estimated by the balance between the volume driving force and interfacial energy, a value of $d = 2\sigma/g_v = 0.2$ nm is expected. In view of this small value, it is very surprising, that the intermetallic Al_9Co_2 is only formed after the intermixed zone has already reached a thickness of 3.5 nm. However, based on the presented measurements, a theoretical study [49] was able to demonstrate that this behavior is clearly consistent with a polymorphic nucleation mechanism. Such a mechanism assumes that the nucleus of the new phase is produced by transforming the lattice structure, without modifying the local composition [45]. As any nucleus must have a minimum size in order to overcome the nucleation barrier, the ideal stoichiometric composition is only established in the center of the nucleus, whereas towards its boundaries the composition must deviate due to the existing concentration gradient. In other words, nucleation is only probable within a thin-layer fraction of the total diffusion zone, and the thickness of this layer shrinks with the chemical sharpness of the interface. In consequence, high concentration gradients will prevent nucleation.

In the cited theoretical study [49], the free energy ΔG required to form a nucleus under the constraint of a sharp concentration gradient was calculated. Numerical results are presented in Figure 7.20 for three different widths of the interdiffusion

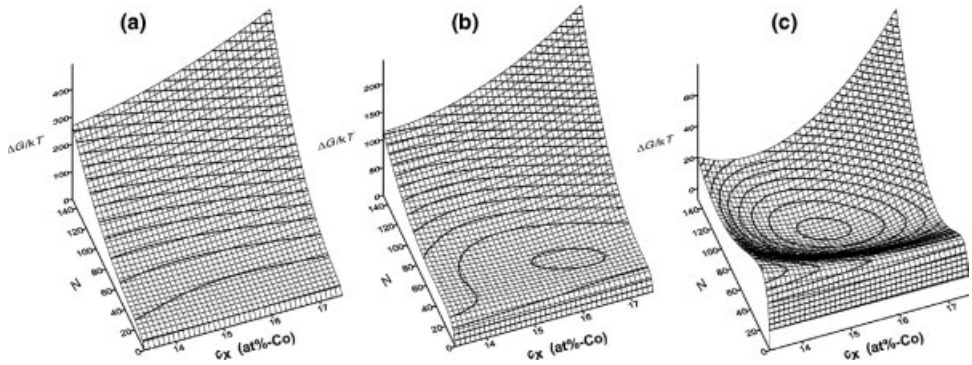

Figure 7.20 Surface $\Delta G(N, c_x)$ for the polymorphic transformation of a cubic volume into the Al_9Co_2 phase inside diffusion fields of width: (a) 3.0 nm; (b) 3.5 nm; and (c) 4.0 nm. Thermodynamic functions evaluated at a temperature of 573 K. (After [49]).

zone, namely 3.0, 3.5 and 4.0 nm. (In these plots, the size of the nucleus is expressed by the number N of atoms within the nucleus. The concentration c_x represents the composition at the center of nucleus.) For a diffusion width of 3.0 nm, the Gibbs free energy still increases monotonously with its size; thus, nucleation is forbidden. At 3.5 nm width, the situation has already slightly changed, with a weak local minimum appearing in the energy landscape. For 4.0 nm width, this minimum has become pronounced and its magnitude negative, which means that a product particle may now be formed under gain of energy. A nucleation barrier of 25 kT is determined from the energy landscape, which is a quite realistic value to obtain reasonable nucleation rates. Thus, the critical interdiffusion width is predicted to be slightly larger than 3.5 nm, in remarkably good agreement with the experimental observation by APT.

The same considerations were also performed for other suggested nucleation mechanisms. For example, calculation of the so-called 'transversal mode' [46] yielded a critical diffusion width smaller than 1.0 nm, in obvious contrast to the measurements. In conclusion, the atom probe analysis yielded convincing evidence for the interdiffusion process taking place before nucleation of the first product, although the depth of mixing ranged down to only a few nanometers. By using APT it has been possible to determine the critical diffusion depth with better than 1 nm accuracy, which allows a distinction to be made between different suggested nucleation modes.

Other studies on reactive metallic model systems made particular use of the calibration-free analysis of the atom probe. This chemical accuracy becomes especially important if metastable phases that spread over only two to three lattice constants are to be identified. Under these circumstances, a structural image is rarely achieved by high-resolution (HR) TEM, although the phases may be already clearly characterized by the local level of composition determined with APT, as for example demonstrated in studies on Ni/Al [50] and Ag/Al [51].

7.5.2
Thermal Stability of Giant Magnetoresistance Sensor Layers

In recent years, reading heads based on the giant magnetoresistance (GMR) effect have made possible a dramatic increase in magnetic recording density. As the periodicity of the required multilayers ranges down to a few nanometers, their spatially resolved analysis is a challenge, even with APT. Hence, several groups have used APT to characterize the as-produced state of GMR sensor layers [52–55]. Co/Cu and Cu/$Ni_{79}Fe_{21}$ are two of the most often-used metallic systems. The soft magnetic alloy $Ni_{79}Fe_{21}$ (Permalloy, Py) is especially suited for position sensors, as the effect of hysteresis is very low, while Cu/Co is mostly used for reading heads in data storage. For many potential applications, including for example angular sensors in motor vehicles, the thermal stability of the device is an important issue. It is well known that the Cu/Py system is much more sensitive to a thermal load than is Cu/Co. Whereas for the latter the GMR amplitude remains stable up to 400 °C, in the former case the GMR effect begins to degenerate at temperatures of only 150 °C [56]. As both metallic systems are immiscible in a thermodynamic sense, and furthermore all diffusivities

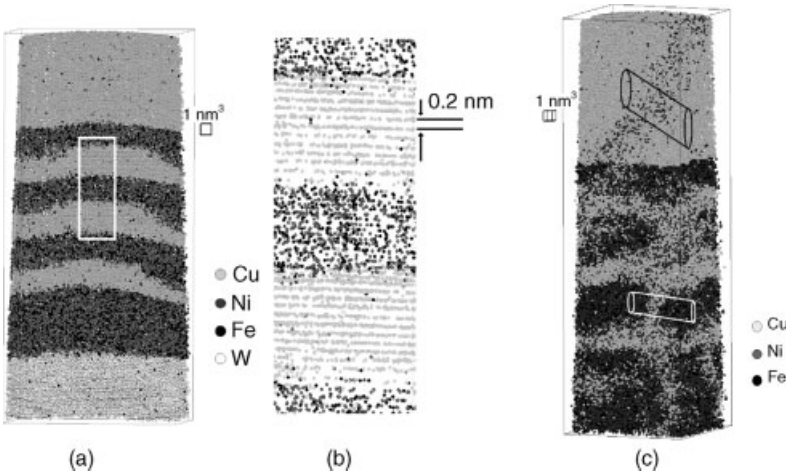

Figure 7.21 Atom probe tomography at a Cu/NiFe giant magnetoresistance structure. (a,b) In the as-prepared state; (c) After 30 min annealing at 400 °C. The detail (b) demonstrates lattice plane resolution and the outstanding chemical accuracy that allows the reproduction of sharp transitions in concentration from plane to plane. (After [58]).

are quite comparable, the low-temperature degradation of Cu/Py is surprising. In general, different mechanisms have been proposed as being responsible for GMR degradation: Van Loyen *et al*. [57] argued that at least two effects should contribute, namely grain boundary diffusion and inter- or demixing at the interface. In contrast, Hecker *et al*. [56] concluded that the alloying tendency of Ni and Cu above 250 °C controlled the decay of GMR in the Py systems.

In an extended APT study [58], $Cu_{2.5nm}/Py_{2.5nm}$ multilayers were deposited onto substrate tips and annealed in an UHV furnace. A typical volume reconstruction of an as-prepared state is shown in Figure 7.21a. The resolution is sufficient to distinguish individual (111) planes of Cu (Figure 7.21b), so that the dimensions of the reconstructed volume could be calibrated exactly. If the microstructures of the as-prepared state were compared to those after annealing up to 350 °C, then no remarkable difference was seen at first sight. Notably, the integrity of the multilayer was preserved. This was all the more striking as the magnetoresistivity vanished completely at the lower temperature of 150 °C. Only after annealing at even higher temperatures – at which the GMR effect also vanished in the more stable Cu/Co structure (400 °C) – was any clear indication of grain boundary transport observed (as shown in Figure 7.20c).

As an advantage of the 3-D experimental data, concentration profiles can be evaluated by defining analysis cylinders of smaller diameter and exactly aligning them perpendicular to the interfaces. In this way, artifacts due to local curvature or roughness of interfaces can be mostly excluded. An exemplary profile obtained after annealing at 350 °C is presented in Figure 7.22a, where the sharpness of the chemical

transition from almost 0% to 100 at% Cu on the length of two lattice plane distances, should be noted. Also of note, it is not possible to achieve such selectivity with analytical TEM.

Furthermore, the shape of the chemical transition can be characterized in detail and compared with expected model curves, as for example for interdiffusion (error-function) and interfacial thermodynamics (Cahn–Hilliard) shown in Figure 7.22b. Due to the outstanding sensitivity of APT, it is possible to note the smallest modifications of interfacial chemistry with temperature. The width of the chemical transition, defined exactly between 10% and 90% of the concentration amplitude, was used as a characteristic parameter. Clearly, although only on the order of 1 nm, the width is proven to increase significantly during low-temperature annealing (see Figure 7.22c). The formal description by an error function leads to the assumption that the width of the transition is controlled by kinetics of interdiffusion, as in the previously discussed study on Al/Co (see Section 7.5.1). However, the diffusion

coefficients derived in accordance with this interpretation reveal a way too-low activation energy in comparison to reported data (see Figure 7.22d). Furthermore, interdiffusion would be difficult to understand from the viewpoint of thermodynamics, as the layer system is expected to be stable up to a temperature of about 1070 K. In an analysis of these data [59], it could be shown that the temperature dependence of the interface width is rather based on interfacial thermodynamics within the frame of Cahn–Hilliard theory. The experimentally observed temperature dependence of the width of the interface agrees nicely with the related model curve, as presented in Figure 7.22c. In this way, it is possible to determine, via direct measurement with APT, the required – but experimentally almost unknown – gradient coefficients that are important in the Cahn–Hilliard theory.

By combining wide field-of-view FIM and atom probe analysis, it was also possible [58] to exclude definitely grain boundary transport as a significant reason for GMR degradation in Cu/Py multilayers. As shown in Figure 7.21c, segregation – as an indicator for grain boundary diffusion – can be demonstrated in the volume reconstructions, but clearly not at temperatures relevant to GMR breakdown. Many individual grain boundaries were investigated after annealing at up to 250 °C, but no segregation was found in any case.

For the design of GMR devices, the APT study has important consequences. Clearly, a short-ranged broadening of interfaces on the depth of 1–2 nm due to interfacial thermodynamics (which has been neglected in previous studies) has an important influence on magnetoresistivity. In view of the small multilayer periodicity of only 4 nm, this does not come as a surprise. It is, furthermore, in complete agreement with measurements of total electrical resistivity [56], which had shown that the base resistance of the multilayer, indicating complete alloying of the layers, increased significantly only at temperatures higher than 250 °C. Thus, only a weak interfacial alloying could take place at the relevant conditions below that temperature. In order to develop temperature-stable devices, it is insufficient to select only a thermodynamic stable system. In addition, the critical temperature of the respective miscibility gap should be at least threefold higher than the application temperature to suppress the described interfacial broadening. As confirmation, a similar study with APT on Cu/Co (a system distinguished by a much higher critical temperature of about 1600 K) revealed no significant broadening of the interfaces up to a temperature of 450 °C. As a consequence, the degradation of the GMR effect was considered due to grain boundary diffusion [60].

7.5.3
Influence of Grain Boundaries and Curved Interfaces

In nanocrystalline matter with grain sizes down to about 10 nm, the volume fraction attributed to the grain boundary (GB) can easily exceed 50%. With further decreasing grain size an additional necessary topological feature of the boundary arrangement – the so-called 'triple line' – may affect atomic transport. Along a triple line, three GBs merge to form a line-shaped junction defect, the structure of which is expected to differ considerably from that of ordinary GBs. Most likely, it is more disordered, so

that a rather high atomic mobility can be assumed. However, until now the measurement of triple line diffusion using analytical electron microscopy has been rare [61]. The difficulty of such measurement stems from the small effective cross-section of the defect, which requires chemical analysis of the highest possible resolution.

In atom probe experiments [62], both Au (15 nm thickness) and Cu layers (25 nm thickness) were deposited on top of tungsten tips. In order to slow down the intermixing of the soluble metals Cu and Au, a thin Co barrier (6 nm thickness) was inserted in between. Due to the strong substrate curvature, thin films deposited on the substrate tips tend to be very fine-grained, with grain sizes down to 5 nm [63]. Thus, these specimens are ideal candidates to observe the transport along topological singularities of the GB arrangement. A typical field ion micrograph of the upper Cu layer is shown in Figure 7.23a. Discontinuities in the structure of concentric rings mark grain boundaries (some of which are emphasized by dashed lines in the figure). Clearly, a polycrystalline structure with a grain size of about 15 nm has formed. Triple junctions are also seen, aligned approximately perpendicular to the surface so that they can be analyzed along the tip axis; in the figure a particularly clear junction is marked by a "T".

By selecting suitable areas for analysis, the local concentration field around the junction could be measured. The geometry of three GBs and an exemplary 2-D composition map is shown in Figure 7.23b. As the atom probe delivers 3-D data, 2-D composition maps can be evaluated in any arbitrary direction subsequent to the measurement, so that the penetration of solute into the triple line and the merging grain boundaries can be determined in a unique manner. The example 2-D map in the figure is aligned perpendicular to a triple line. Clearly, the line is locally enriched

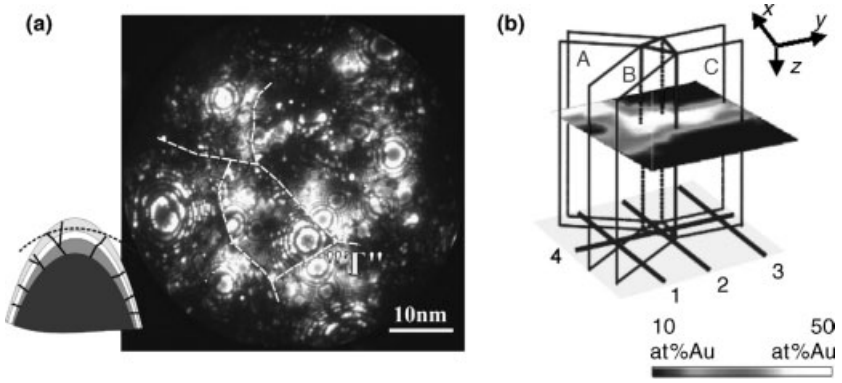

Figure 7.23 (a) Field ion micrograph of sputter-deposited Cu layer. The grain boundaries are marked by dashed lines, a triple junction by 'T'; (b) Two-dimensional composition map in gray-scale representation determined at a cross-section through a triple line and the related three boundaries (A, B, C). (After [62]).

in Au, and the three GBs are also distinguished by a measurable Au content, albeit of a somewhat lower level. The concentration fields around the triple line were evaluated by means of the approximate solution of transport equations proposed by Klinger *et al.* [64]. In the case of the triple line, the atomic transport may be understood by a three-level cascade process: (i) the material is transported along the triple line; (ii) leakage into the related three boundaries takes place; and (iii) atoms are drained from the grain boundaries into the bulk grain volume. Expressing this in a compact formula, the concentration field is described by:

$$c(x,y,z,t) = c_0 \cdot \exp\left(-\frac{\sqrt{3}\cdot\sqrt[4]{D_{GB}\cdot\delta\cdot s_{GB}}\cdot\sqrt[8]{4D_V/\pi t}}{\sqrt{D_{TL}\cdot q\cdot s_{TL}}}\cdot z\right)$$
$$\times \exp\left(-\frac{\sqrt[4]{4D_V/\pi t}}{\sqrt{D_{GB}\cdot\delta\cdot s_{GB}}}\cdot y\right) \qquad (7.19)$$
$$\times \exp\left(1-\mathrm{erf}\left[\frac{x}{2\sqrt{D_V t}}\right]\right)$$

(For a definition of the coordinates, see Figure 7.23b). If the volume diffusion coefficient D_V is known, the two other diffusion coefficients – or, more exactly, the respective transport products $p_{TL}:=D_{TL}\cdot q\cdot s_{TL}$ and $p_{GB}:=D_{GB}\cdot\delta\cdot s_{GB}$ – can be determined from logarithmic plots of composition versus penetration depth in the z- and y-directions. (δ, q, s_{TL} and s_{GB} define grain boundary width, effective cross-section of the triple line and the segregation factors of triple line and grain boundary, respectively.) Exemplary plots are presented in Figure 7.24, demonstrating the transport behavior in accordance with Equation 7.19. Indeed, by evaluating the slope of the straight lines in Figure 7.24, it was quantitatively found that D_{TL} is a factor 5600-fold larger than D_{GB} at a temperature of 295 °C, if potential segregation is neglected and $q=\delta^2$ is assumed.

7.6
Approaching Nonconductive Materials: Pulsed Laser Atom Probe Tomography

On completing this survey of the atom probe method, an additional and quite important methodical aspect must be addressed. The following point could have been presented earlier, in Section 7.3, and frankly – from a logical standpoint – such an order would be more valid. However, by postponing it to the end of the chapter, our aim is to highlight the fact that pulsed laser evaporation represents the most active recent field in methodical research in FIM. Indeed, this technique promises not only to expose APT to a much broader range of materials, but also raises some interesting controversy on the fundamental mechanisms of field evaporation by using ultra-short light pulses of about 100 fs duration.

7.6.1
The Limitations of High-Voltage Pulsing

The conventional atom probe technique based on high-voltage pulsing has always been restricted to the investigation of sufficiently conductive materials, usually metals. Very few measurements of ceramic materials have been reported, and in all successful cases the nonconducting phases had the geometry of tiny particles or thin films embedded in a metallic matrix [65–67]. Besides the unfavorable mechanical properties of ceramics or semi-conductors, this situation is first and foremost due to the limited possibility of transferring a short pulse to the specimen surface. As illustrated in Figure 7.25, the arrangement of sample and detector represents nothing else but a resistive–capacative (RC) oscillator which is naturally limited in its transfer frequency. A few lines of calculation are sufficient to estimate the required minimum conductivity of the tip material to achieve a sufficient band width of the transfer line. According to Poisson's law, the field in a vacuum is related to a density σ of charges at the surface of the metallic electrode:

$$\sigma = \varepsilon_0 \cdot F = \varepsilon_0 \frac{V}{\beta R}, \tag{7.20}$$

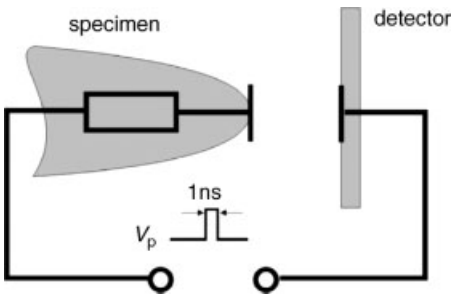

Figure 7.25 Electric equivalent circuit of the arrangement of sample and detector or vacuum chamber.

where we have made use of Equation 7.1 to formulate the second equation. Approximating the effective electrode surface by a semi-sphere, the electrical capacity of the arrangement reads

$$C = \frac{2\pi R^2 \sigma}{V} = \frac{2\pi R \varepsilon_0}{\beta}. \tag{7.21}$$

With regards to the specimen geometry ($R \approx 50\,\mathrm{nm}$), this capacity amounts to about 10^{-18} F. Likewise, the resistivity $R_{\mathrm{el.}}$ may be estimated by approximating the specimen shape with a truncated cone of length L and semi-shaft angle γ. So, one can formulate

$$R_{\mathrm{el.}} = \frac{\rho}{\pi} \int_0^L \frac{dl}{(\gamma \cdot l + R)^2} \approx \frac{\rho}{\pi} \cdot \frac{1}{\gamma \cdot R} \tag{7.22}$$

in which ρ denotes the specific resistivity of the material. In order to transfer pulses properly, the limiting frequency $\omega = 1/(R_{\mathrm{el.}}\, C)$ must reach 10^9 Hz, which requires the specific resistivity to be smaller than

$$\rho_c < \frac{\pi \gamma R}{\omega C} \approx 10^3\ \Omega\,\mathrm{cm}. \tag{7.23}$$

Clearly, the resistivity of metals is way below this limit, particularly at the low temperatures used for evaporation. However, already in the case of semi-conductors, sufficient conductivity is only achieved with very high doping. In the case of real insulators (such as oxides or nitrides) the condition of Equation 7.23 is failed by orders of magnitude in any case, leaving very little hope to perform successful measurements by electric pulsing.

Additional complications arise from the brittleness of the materials. If we multiply (for an estimate to order of magnitude) the charge density (Equation 7.20) by the field (Equation 7.1), then tensile stresses of up to GPa magnitude are predicted to be induced by the field. In the case of high-voltage pulsing, a significant fraction of this stress is supplied to the tip as a continuous sequence of mechanical shocks resembling a classical fatigue test. Considering that a stress of 1 GPa exceeds the fracture strength of many bulk materials, it is clear that specimens will fail frequently by fracture during the 'fatigue test' of the measurement, and that the risk of this failure increases with the brittleness of the tip material.

7.6.2
The Mechanism of Pulsed Laser Evaporation

With regards to Equation 7.6 (see Section 7.3), it is possible to imagine at least two alternative routes to trigger field evaporation. Either the numerator in the argument of the exponential could be reduced by a short increase of the electric field (as is done with conventional high-voltage pulsing), or the denominator may be increased by short rises in temperature. The latter can be achieved with the light flashes delivered

by pulsed laser sources, so it is not surprising that attempts to utilize this effect date back to the 1980s. The early studies with pulsed laser sources were motivated by studies of the photoionization of adsorbed species [68, 69], but shortly afterwards the potential to control field evaporation was also acknowledged and the pulsed laser atom probe (PLAP) introduced by Kellog and Tsong [70]. In these early experiments, nitrogen lasers of 1 ns pulse width (comparable to the length of high-voltage pulses) were normally used. The authors stated the following as the main advantages of the laser evaporation mode:

- As no fast charge transport is required, a low conductivity of the sample no longer represents a bottleneck to the atom probe analysis. The controlled field evaporation of intrinsic Si could be demonstrated.
- As the remaining field is supplied in dc mode, the PLAP does not suffer from the energy spread which is unavoidable under high-voltage pulsing. Thus, a much better mass resolution could be achieved, even with straight flight tubes, without using any time-focusing devices.
- The level of mechanical stress is reduced by the fraction that has been formerly induced by the high-voltage pulses. The remaining stress is produced by the constant base voltage, and thus loaded to the tip permanently. This is a much more favorable situation for the specimen life time than the above-mentioned 'fatigue test' condition.

The time resolution – and thus the accuracy of the energy measurement – was improved by Tsong and coworkers to the order of 10^{-5}. So, by careful measurement of the energy deficits of evaporating species, the mechanism of desorption could be identified [71]. For laser pulses of nanosecond duration, it could be shown that with metals the laser effect was merely thermal in nature, whereas in the case of semiconductors (which were distinguished by a significant band gap) the additional influence of direct photoionization was indicated. As the laser acted predominantly as a pulsed heat source, the question immediately arose as to whether heating of the specimen surface might diminish the spatial resolution of the atom probe analysis. However, already Tsong and coworkers had already shown that it was possible to trigger the evaporation reliably by temperature pulses below 200 K, at which surface diffusion remained frozen, at least for the refractory metals being studied.

Until 1990, the advantages of the pulsed laser mode were exploited not only in investigations of Si, SiC and SiO but also of Group III–V semiconductor materials. However, as these studies were mostly restricted to verify mass spectra and to prove the average composition of the materials, the total number of evaluated atoms was consequently very low. Except for some interesting studies on the oxidation of Si [72], very few attempts were made at a spatially resolved analysis. In this context, it is quite remarkable that reports on the different versions of 3-D atom probes which emerged at that time made no mention of any attachment of a laser beam line. Apparently, only the group at Oxford University attempted to use the PoSAP instrument with laser assistance to perform for example, a study on GaInAs quantum well structures [73]. However also in this case the fact that no volume reconstructions were presented

may be seen as an indication of the significant experimental problems that the group encountered. Compared to the vast amount of successful reports on conductive materials with high-voltage pulsing, the pulsed laser technique virtually disappeared during the 1990s. It might be speculated that this situation was essentially caused by the limited reliability of available laser systems and the involved alignment procedure.

Fortunately, this situation has changed remarkably since 2002, and many university research groups and commercial companies are now engaged in the development of atom probe instrumentation, both in terms of testing and offering instruments with the facility of laser-assisted evaporation. Today, commercial laser systems are much more stable, provide pulse frequencies, and have found vast improvements in the ease of operation. Moreover, continuous miniaturization in microelectronics has led to an enormous driving force to overcome any remaining barriers when developing new tools for high-resolution semiconductor analysis.

The first experiments with modern sub-picosecond laser pulses were reported by Gault *et al.* in 2005 [74]. These authors showed that the efficiency of laser pulsing depended on the orientation of light polarization with respect to the tip axis, and claimed this to be evidence of a direct, athermal influence of the optic wave. In other words, similar to high-voltage pulsing, the activation barrier in the numerator of Equation 7.6 should be temporarily decreased by the electrical field of the wave. This idea was very attractive, as in this way laser-triggered evaporation would become possible without heating the specimen. Moreover, since with a decreasing pulse width at constant pulse energy the electric field amplitude of the optical wave increased, this might indeed be the case. However, the average field strength of the laser beam in the experiments performed by Gault and coworkers was still in the range of only $0.1\,\mathrm{V\,nm^{-1}}$, which was much less than the effect of typical high-voltage pulses. Nonetheless, one might expect a field enhancement due to polarization of the metallic tip. In theoretical studies, enhancement factors of up to three orders of magnitude have been predicted [75–77], with the fields becoming quite capable of having a significant effect on the evaporation barrier in Equation 7.6. A further conceptual difficulty arises from the fact that optical fields oscillate with a frequency of 10^{15} Hz, while the spectrum of atomic vibration is limited at about 10^{13} Hz. So, how might an atom be excited way off resonance? The group of Gault argued that the rapidly oscillating field could be converted into a directed field for the duration of the pulse by a nonlinear response, in the same way that a diode might be used to demodulate high-frequency radio signals. Indeed, in recent theoretical calculations proof was furthered that this 'optical rectification' would indeed produce field pulses of an appropriate order of magnitude and polarity [78]. In addition, optical pump probe experiments demonstrated a rapid sub-picosecond response, which has been interpreted in the same direction [79].

On the other hand, meanwhile, it became clear that the interpretation of measurements in terms of a clear athermal triggering by Gault *et al.* [74] was too euphoric, and their evidence less clear [80]. The dependence of evaporation rate on the polarization of the wave could be naturally explained by scattering at the nanometer-sized, cylindrically shaped tip, as had been shown earlier [81]. The measurement of the

temperature rise produced by sub-picosecond pulses, although performed with a remarkable pump probe experiment that combined laser and voltage pulses [82], delivered an ambivalent result. Yet, the idea of achieving direct-field pulsing by using ultra-short laser pulses proved so attractive that considerable effort is currently being undertaken to clarify this aspect, notably by the group at the University of Rouen.

Today, several other teams are focusing on the practical consequences of laser pulsing to concrete analytical studies. With laser pulsing, several new parameters must be explored to define the optimum measurement conditions. An extended study [83] has investigated the influence of wavelength and energy density of the pulses, laser spot size, specimen geometry, and heat conductivity on the quality of mass spectra. Yet, interestingly, no significant influence of pulse width and wavelength on the quality of mass spectra was identified. The mass resolution achieved with laser pulsing is indeed significantly improved in comparison to high-voltage pulsing (up to $\Delta m/m = 1:1000$, without using a reflectron). However, significant thermal peak tails are observed in the mass spectra, with rather long laser pulses exceeding the important picosecond benchmark of electron phonon coupling, as well as with short pulses way below this threshold. Instead of the pulse width, the duration at which the ions are evaporated is essentially defined by the cooling period of the specimen after the pulse. Thus, samples of low heat conductance or of particularly long and thin geometry lead to poor mass resolution. With materials of low heat conductivity, such as stainless steels, a small heat spot achieved with an optimally focused laser beam has proved to be advantageous when achieving rapid cooling rates, and thereby good mass resolution. Remarkably, also in the case of a femtosecond laser, the tails of the mass peaks are correctly described by the principles of heat conduction, which proves that also with this type of laser a considerable temperature rise appears during the pulse.

In summary, it can be stated that today, a final conclusion of whether short pulses in the range of 100 fs provide any significant advantage in the analysis cannot be drawn. Although, in various reports, the impression is sometimes raised that femtosecond pulses are required for the reliable analysis of difficult materials (such as the measurement of oxides [84]), the opposite can be clearly demonstrated [85].

7.6.3
Application to Microelectronic Devices

Unaffected by the scientific controversy surrounding the mechanism of laser-assisted evaporation, the 3-D atom probe has advanced in recent years to a modern measurement tool, and is set to become an established component of those industrial laboratories involved with microelectronics. While the structural width of a transistor now ranges down to 35 nm, the measuring field of the atom probe has reached approximately 100 nm. This almost perfect matching of length scales has motivated the industrial application of the method. With the number of evaluated atoms exceeding 100 million, APT now permits the mapping of dopant distributions, in outstanding resolution, where the chemical sensitivity of analytical TEM is usually way too low (see e.g. [86]).

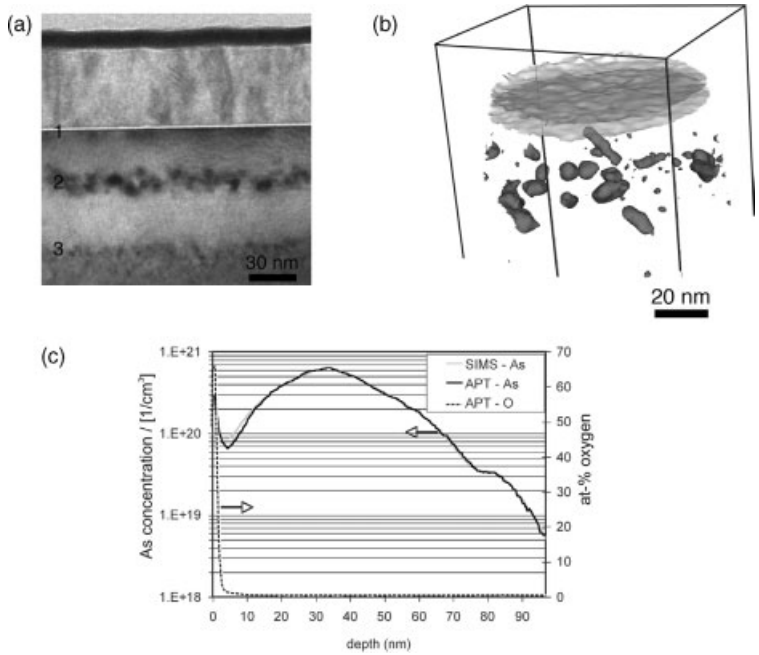

Figure 7.26 Analysis of As doping of Si by ion implantation. (a) Cross-section TEM image of the test structure showing an oxide layer (1), As-rich particles (2), and the end of damage range (3). The ion irradiation was apparent from the top; (b) Volume analysis by APT showing iso-concentration surfaces at 10 at.% oxygen (light gray) and 2 at.% As (dark gray); (c) Comparison of atom probe data with SIMS measurement. (Reproduced with permission from [87]).

These findings are illustrated by the results of the study shown in Figure 7.26. Here, a {001} Si wafer was implanted with 2×10^{15} As atoms per cm^2 with 30 keV kinetic energy. An oxide film of 2 nm thickness and 50 nm of undoped, polycrystalline Si were then deposited, to mimic the basic steps of microelectronics production. While forming the polycrystalline Si, the specimen had to be heated to 600 °C for about 30 min, so that the implanted As atoms could cluster. As shown in the TEM image (Figure 7.26a), a defect band was formed at approximately 30 nm beneath the substrate surface (this is localized in the figure by the thin light oxide layer). For atom probe analysis, tip-shaped samples were prepared by FIB milling. With pulsed laser assistance, the semiconductor sample could be properly evaporated, and from the volume reconstruction local composition maps calculated which allowed the compositional heterogeneities to be located by means of iso-concentration surfaces (Figure 7.26b). At a preset concentration level of 2 at.% As, these iso-surfaces mark As-rich clusters, which have formed by nucleation. The iso-surfaces at a level of 10 at.% oxygen were used to localize the interfaces to the oxygen layer. Quantitative composition profiles aligned perpendicular to the substrate surface could also be determined (as shown in Figure 7.26c) in

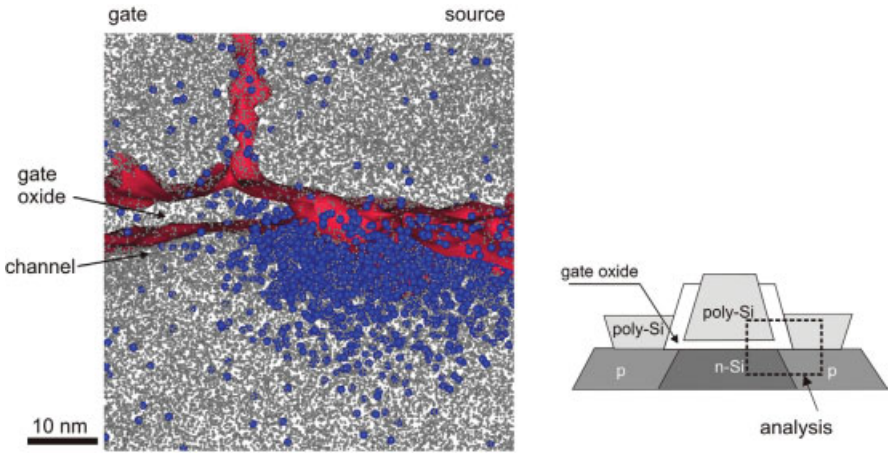

Figure 7.27 Three-dimensional reconstruction of a field effect transistor structure showing Si atoms (light gray dots) and boron dopant (blue). Iso-concentration surfaces at 3 at% oxygen localize the gate oxide film (red). (Illustration courtesy of D.J. Larson, Imago Scientific Instruments.) The schematic at the right clarifies the location of the analyzed region.

comparison to depth profiling by secondary ion mass spectrometry (SIMS), which represents the industrial standard. Clearly, the atom probe delivers quantitative data in agreement with SIMS, but more importantly the APT data proved to be more accurate. While the segregation of As to the substrate surface is indicated only faintly by SIMS, the corresponding composition peak appears very pronounced in the APT measurement, due to a significantly better spatial resolution of the latter technique. As the atom probe is equally sensitive to all chemical species, the oxygen content of the oxide is determined within the same measurement.

The final example refers to the preparation of tip samples of technical devices taken from industrial production. By using modern, dual-beam FIB, areas of interest can be selected for TAP measurement. In this way, the corner region of a field effect transistor – between the source contact and the channel beneath the gate contact – has been analyzed with regards to local dopant and oxygen distribution (see Figure 7.27). A few years ago, the achievement of such an analysis from a microchip was beyond thinking. Having mapped the spatial arrangement of the atoms, not only the depth profile beneath the source or drain contacts of the field effect transistor could be determined, but also the lateral distribution of the dopant. In this way, essential information can be obtained concerning dopant diffusion from the contact region into the channel under the gate oxide. As the structural width of transistors continues to decrease, the control of this sideward transport may in particular become a critical issue. It is likely that, in future, APT will become the most important tool for controlling this undesired process.

Cryoelectron Tomography: Visualizing the Molecular Architecture of Cells*

Dennis R. Thomas and Wolfgang Baumeister

8.1
Introduction

In order to reveal the networks of macromolecular interactions which underlie higher cellular functions on a systems level, new techniques are needed. As a starting point, it is crucial to have a validated and quantified list of all components, which can be provided by using mass spectrometry-based proteomics techniques [1]. The next challenge is to analyze the interaction patterns *in situ* with increasing degrees of complexity, ranging from that of supramolecular modules, to organelles or even whole cells. Some of these systems are tightly integrated complexes, robust enough to withstand the isolation and purification procedures that are used traditionally in biochemistry. These functional modules are amenable to detailed studies with the established tools of structural biology [2]. Other complexes interact transiently and weakly to form supramolecular networks that are designed to associate or dissociate in response to specific signals. Many such putative cellular complexes have been identified through affinity-based isolation methods. The components of these complexes can be identified using mass spectrometry to provide valuable information regarding the composition of such interacting complexes. In this manner interactions can be detected, whether they are direct or indirect [3]. However, this type of approach is prone to error and does not provide information about the order or molecular details of how the components interact. As the complexity of interacting systems increases, the component lists and affinity-based interaction data no longer suffice to describe the architecture of networks [4]. Ideally, the target would be a 'snapshot' of the system in action, acquired in a nondisruptive, noninvasive manner, avoiding perturbations to the system. Thus, we can hope to obtain a detailed three-dimensional (3-D) image of the system in action at molecular resolution.

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

Electron tomography is uniquely suited to studying large pleomorphic structures and visualizing macromolecules in their functional cellular context. The development and implementation of automated low-dose data-acquisition procedures, has made it possible to study biological samples embedded in vitreous ice. Electron cryotomography provides a 3-D picture of complex systems preserved in as near to a native state as can be achieved at molecular resolution [5]. Today, we have the tools to bridge the (resolution) gap that currently exists between cellular and high-resolution molecular structural techniques. The reconstructed tomograms of organelles or cells at molecular resolution represent snapshots of their proteomes. These 3-D snapshots can be interpreted using advanced pattern recognition techniques, revealing the molecular architecture present at the instant the sample was frozen. The fitting of tomographic maps of cells with high-resolution structures of their components should ultimately enable us to generate pseudo-atomic models of large – and otherwise elusive – assemblies and networks in the act of performing their cellular role [6].

8.2
Basic Principles and Challenges of Electron Tomography

An electron micrograph is a two-dimensional (2-D) projection of the sample present on the specimen support. Much like a medical X-ray, all structural features present in three dimensions are imaged, but are seen superimposed in the 2-D image. As a consequence, the images are difficult to interpret directly. In electron tomography, the specimen holder is tilted incrementally around an axis perpendicular to the electron beam, and images are taken at each position. These images are projections of the same object as viewed from different angles. Based on principles first described by Radon [7], these projections can be combined to produce a 3-D density map (Figure 8.1). Before such a density map is calculated – most commonly by using a 'weighted back-projection' algorithm – the projection images must be all be aligned to a common origin.

In order to successfully apply electron tomography to ice-embedded specimens, it is necessary to overcome two conflicting sets of limitations which have, for more than two decades, stood in the way of its widespread application to radiation-sensitive biological samples:

- In order to obtain the most detail with the least distortion in the reconstruction, it is necessary to sample as large an angular range as possible while tilting with increments as small as possible. This strategy calls for maximizing the number of projection images used for the reconstruction.
- Biological specimens embedded in vitreous ice, are extremely sensitive to radiation damage; therefore, it is very important to minimize exposure to the beam. To acquire a tilt series of perhaps more than a hundred images, the dose per image must be limited in order to prevent radiation damage from destroying the finer details of the structure or, worse yet, rendering reconstructions useless. The problem is, as one lowers the dose per image, the signal-to-noise ratio (SNR)

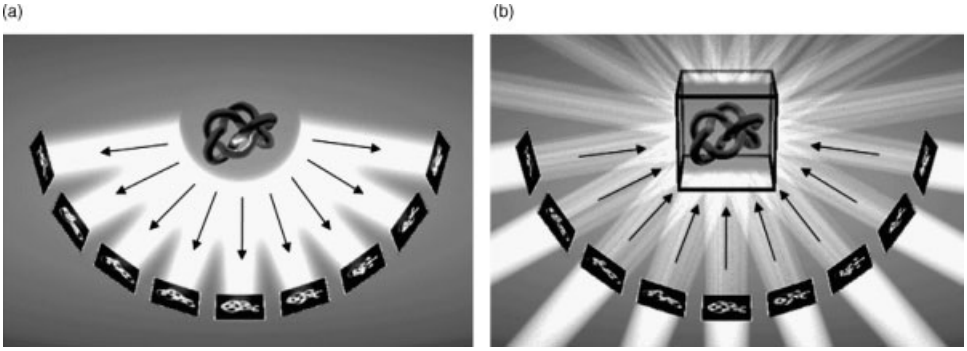

Figure 8.1 (a) Single axis tilt tomographic data acquisition. The unknown object is represented by a 'flexible knot' to emphasize the fact that electron tomography can reconstruct structures with unique topologies. A set of projection images is recorded as the object is tilted incrementally; (b) Following alignment of the projection images, the object is reconstructed generally by weighted back-projection. The 2-D projections are recombined to generate the 3-D density distribution of the object – the tomogram. The implementation of algorithms such as algebraic reconstruction techniques (ARTs) and simultaneous iterative reconstruction technique (SIRT) provide means for refining reconstructions [8, 9].

decreases. Thus, it is necessary to choose between having a better SNR but fewer projections, or more projections with a lower SNR.

Given the above considerations, we must consider how to 'spend' the allowable electron dose. Early theoretical considerations [10], corroborated by computer simulations [11], have suggested that, in principle, the electron dose needed to visualize structural features at a particular resolution limit is the same for 2-D and 3-D images containing equivalent information. In principle, if one were to average tomograms (3-D images), the dose could be distributed over as many projections as required to achieve the desired resolution, at the expense of lowering the SNR of the individual 2-D images. A consequence of combining the information from the projection images is an improvement in the SNR, similar to the improvement obtained by averaging statistically noisy images of repetitive structures. There is, nevertheless, a practical limitation, namely that the SNR of the 2-D images must be sufficient so as to permit the accurate alignment needed to establish a common framework of coordinates for all projection images.

If a constant exposure or dose per image were to be used throughout the tilt series then, as the tilt angles increased, images would be obtained with increasingly worse SNRs. This is because, as the tilt angle increases, the thickness of the specimen through which the electron beam passes also increases. One way to solve this problem would be to distribute the dose such that the dose or exposure time increased with the increasing tilt. The intended effect would be to keep the signal content of the images more or less constant. There are variations which can be used with this approach. One is to collect increasingly finer tilt increments at higher tilt angles without changing dose or, alternatively, to combine the previous two ideas and both increase the dose at higher tilt and collect finer increments. This latter approach

has the drawback of spending a great deal of the total allowed dose at high tilt angles which, due to increased specimen thickness and potential beam damage, may or may not contribute much to the information in the resulting tomogram.

Projection image alignment can be achieved using cross-correlation methods that may include area matching or feature tracking, or by the alignment of high-contrast fiducial markers, such as gold nanoparticles. The electron-dense gold particles have a relatively high SNR, even in very low-dose projections. However, gold – while not subject to radiation damage itself – is affected by the beam because the ice matrix in which it is embedded is subject to radiation-induced changes. If one compares the image of the untilted specimen at acquired at the start of the tilts series with an untilted image of the same area recorded after the tilt series has been completed, this can be observed as a movement of the gold relative to the specimen over the course of collecting a tilt series. Like radiation damage, this effect is dependent on the total dose and other factors such as specimen thickness. Thus, whether using cross-correlation only methods, or using fiducial marker-based alignment, the total electron dose which can be used is limited.

8.3 Automated Cryoelectron Tomography

Computer-controlled transmission electron microscopes first became commercially available during the late 1980s. This development, combined with the improving quality and availability of large-area charge-coupled device (CCD) cameras, made possible the development of sophisticated software that could be used to control the microscope and image-acquisition in a fully automated manner [12–15]. This software maintains the specimen centered in the field of view, by controlling the stage movement or beam shift, and determines image defocus automatically (Figure 8.2). An important development is the ability to track (center) and focus on areas some distance along the tilt axis away from the sample being imaged, thus minimizing the exposure of the area of interest. The fraction of the dose that is spent on overhead [search, centering, (auto) focusing] with automation has thus been reduced to as little as 3% of the total dose – something which is utterly impossible to achieve with manual operation [16].

These developments have greatly improved the status of electron tomography of cryopreserved specimens from that of a technique with potential to that of one beginning to produce exciting results. Starting with 'phantom cell' experiments – that is, liposomes encapsulating macromolecules [17, 18], and more recently with viruses, prokaryotic [19, 20] and eukaryotic cells [21] – we can now apply the potential of 3-D imaging to samples preserved in a close-to-life state. Vitrification by rapid freezing not only preserves the native molecular and cellular structures, but also allows 'snapshots' to be taken of dynamic events, thus freezing moments in time; an example would be trapping the short-lived open state of the acetylcholine receptor [22–24]. Vitrified samples do not suffer from the artifacts traditionally associated with chemical fixation and staining, nor with the dehydration of cellular structures. Tomograms of frozen-hydrated structures have a natural density distribution (albeit noisy), whereas staining and preservation reactions

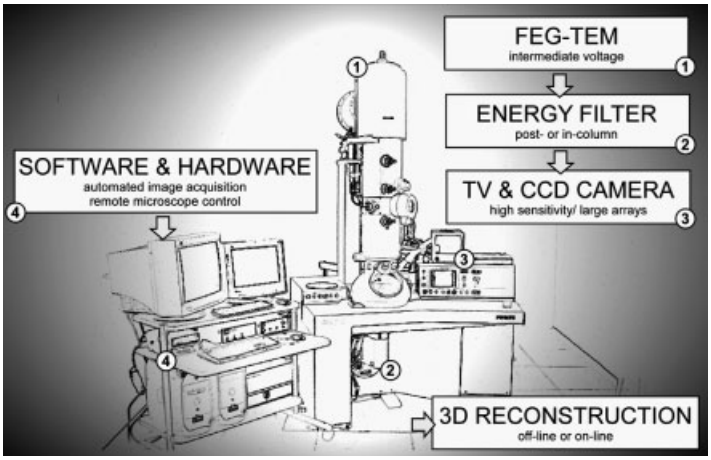

Figure 8.2 Cartoon showing where the advances in electron microscopy come into play. (1) The development of highly coherent intermediate-voltage electron sources [field emission guns (FEGs)] results in images with good signal-to-noise ratios extending to higher resolutions; (2) The application of energy filters to exclude inelastically scattered electrons from the image reduces noise in the image; (3) The acquisition of digital images on CCD cameras allows data acquisition to be automated; (4) The ability to control specimen movement, focusing, image tracking and image acquisition with computer software increases the efficiency of data collection and minimizes the electron dose spent on non-data-acquisition steps.

tend to produce artificial contrast from intricate mixtures of positive and negative staining. Unfortunately, the artifacts of staining and preservatives make the molecular interpretation of tomograms from such techniques very problematic [25].

8.4
Resolution, Signal-to-Noise Ratio and Visualization of Tomograms

Today, the development of automated procedures has made the recording of low-dose tilt series a routine procedure, with user-friendly software available for downstream processing [26, 27]. It is in fact now significantly less cumbersome and time-consuming to obtain a cryotomogram than to go through the conventional procedures of plastic embedding and sectioning biological samples. There is, however, one caveat – that sample thickness is a limitation. The thickness of whole prokaryotic cells, isolated organelles or thin (<1 μm) eukaryotic cells limits the resolution of cryotomograms to at best a range of 4–5 nm, although the prospects for improvement are good (see Refs. [26, 28]). The obstacle presented by sample thickness makes the development of reliable protocols for the sectioning of frozen-hydrated material a priority. While progress is clearly being made towards obtaining thin, artifact-free sections from samples preserved in vitreous ice, tomographic studies of thin cryosections are still not routine [29]. However, on-going improvements in instrumentation can be expected to make significant improvements in data quality. Better still, more efficient CCD detectors, in particular, would improve the resolution by

retaining the higher resolution signal that currently is lost to the modulation transfer function (MTF) of present-day CCDs. These improvements would allow tomography to enter the realm of molecular resolution (2–3 nm). In addition, with dual-axis tilting schemes, the effects of missing data (due to the restricted tilt range; usually $\pm 70^{\circ}$) could be reduced and resolution become more isotropic.

In electron tomography, as in the processing of single particles or 2-D crystals, an attainable resolution and the SNR are intricately linked. A signal may be present in a tomogram at high resolution, but detection of the information is limited by the limited degree of averaging which is inherent in the tomographic reconstruction process. As a consequence of averaging, the noise cancels (and thus is reduced in the averaging process) while the signal is summed. However, the signal can only be detected at frequencies where an acceptable SNR is achieved [30]. Electron microscopic single-particle analysis benefits greatly from the stratagem of combining a very large number of images (i.e. >10 000) of a structure viewed in random orientations, into a 3-D reconstruction, where averaging significantly improves the SNR [31]. The noise reduction resulting from averaging during reconstruction is quite limited in electron tomography (<150 images), given the uniqueness of cellular tomograms. Therefore, other means of noise reduction must be applied to the analysis of tomograms. For example, if the tilt series has been acquired in such a way that information does not extend past a certain resolution limit (say 5 nm), the tomogram may be Fourier-filtered with a cut-off at that resolution, thereby eliminating what can only be noise at frequencies higher than the cut-off frequency. Sophisticated 'de-noising' algorithms are also available; these are based on the same basic principle but employ 'diffusion' criteria based on local continuity of density [32]. Although the gain in SNR obtained from such methods is not very large, this does help in visualizing the underlying structure present in the tomograms. Nonetheless, new algorithms are required to achieve a greater noise reduction.

The interpretation of a tomogram at an ultrastructural level requires the identification of structural components – that is, membrane-bound organelles, cytoskeletal filaments or large macromolecular complexes. In the past, manual assignment has been commonly used as human pattern recognition is often superior to available segmentation algorithms; on the other hand, machine-based segmentation should, in principle, be more objective. Continuous structures are relatively easy to recognize and delineate, in spite of the low SNR present in cryotomograms. For example, visualizing the organization of the cytoskeleton in both *Spiroplasma melliferum* and *Dictyostelium discoideum*, was possible at the level of individual filaments, without the need for extensive post-processing (Figure 8.3) [21, 33].

Although averaging can obviously not be applied to tomograms of unique structures such as individual cells or organelles, such tomograms may nevertheless contain multiple copies of components such as ribosomes, chaperones or proteases. Small regions of the tomogram containing isolated complexes can be extracted from the tomogram *in silico*, and these so-called 'subtomograms' can be subjected to classification against a library of known structures (see Figure 8.4). The subtomograms can then be aligned to a common orientation and averaged within the appropriate class. The result should be an average with a better SNR and a higher

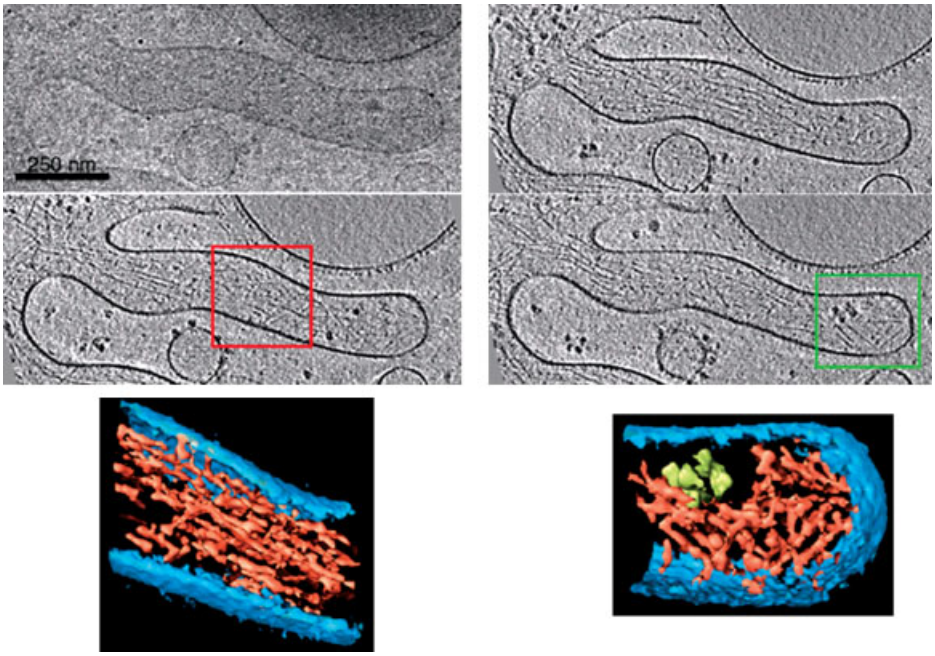

Figure 8.3 Actin filament organization in filopodia [34]. The upper left panel is a projection image from the tilt series. The next three images are sequential sections taken from the tomogram. Two segments of the filopod have been surface-rendered to reveal the organization of the actin filaments and interactions with the membrane. The red box indicates the region shown in the rendered image (lower left); the green box indicates the region rendered (lower right).

resolution. The original low-resolution tomographic image can be replaced by the average or by the higher-resolution template itself, if available. The result is a 'synthetic' tomogram with a much improved, local SNR. Such a procedure has been used in a tomographic study of enveloped *herpes simplex* virions [19] (Figure 8.5), and to also visualize nuclear pore complexes in intact nuclei [35, 36] (Figure 8.6).

8.5
Merging High Resolution with Low: The Molecular Interpretation of Cryotomograms

In tomographic reconstructions of vitrified samples, the macromolecular content of an organelle or cell is present in its native state, thereby making interpretation at the molecular level less problematic. Although the resolution of an individual tomogram may be limited, the advantage is that everything can be seen in its native context. A vast amount of information is available, as tomograms are 3-D images of the entire proteome, and should ultimately enable the spatial relationships of macromolecules to be mapped in an unperturbed cellular environment. However, the retrieval of this information is faced with major problems. First, although everything can be seen, the identification of what is seen may be difficult in the crowded macromolecular

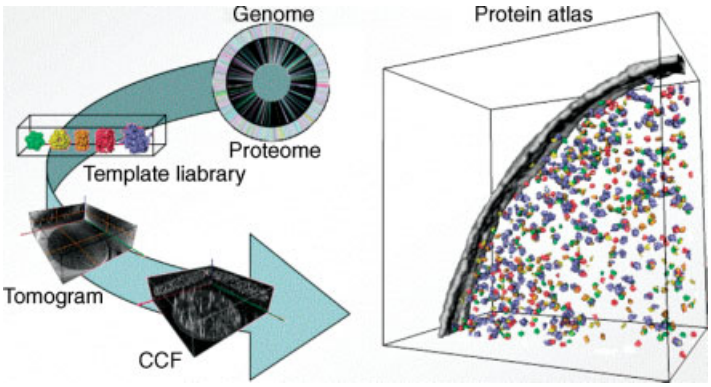

Figure 8.4 Using template matching to generate a protein atlas of a cell. Proteomics, nuclear magnetic resonance, X-ray crystallography and electron microscopy have produced a wealth of structural templates which can be used as a library for analyzing tomograms. In this example, templates from the library have been chosen as probes for the tomogram. Each template, in a number of different orientations, is cross-correlated against the tomogram. The positions of complexes appear as peaks in the 3-D cross correlation function (CCF). A box or subvolume is extracted centered on each of these peaks, resulting in a dataset of 3-D images or subvolumes. These subvolumes are then aligned in three dimensions against the library of complexes. Each volume is assigned to the class to which it correlates best, and each of the classes is averaged, increasing the signal-to-noise ratio and improving resolution. Finally, the class average or original template for the class can be substituted for the original complex in the tomogram, in the determined orientation. This produces a 3-D map of the cell with the contents identified. It is now possible to consider how the various complexes might be related in the cellular context.

environment where complexes literally touch each other [36]. Therefore, the interpretation of low-SNR cryo-tomograms is difficult and can be tedious. Furthermore, because it is not possible to tilt a full 180°, the tomographic reconstructions are distorted by missing data, and this results in a nonisotropic resolution. There are essentially only two options for identifying macromolecules in tomograms, namely *specific labeling* or *pattern recognition methods*, where complexes are matched against a library of known structures. Of course, the two approaches are not mutually exclusive.

8.5.1 Specific Labeling

Proteins exposed on the surface of cells or organelles can be labeled with antibodies or, specific ligands bound to gold nanoparticles. These labels provide indicators for the presence of a specific molecule within a broad molecular landscape. Intracellular labeling is more problematic and requires innovative approaches. These approaches could be based on noninvasive genetic manipulations generating covalent fusions with a protein such as metallothionein, which has the potential to bind heavy metals such as gold [38, 39]. Ideally, the aim would be to introduce a label in a time-resolved experiment (thereby identifying a particular event), and subsequently to remove the background, as is achieved with the ReAsH compound in fluorescence microscopy [40]. However, the achievement of labeling that can be statistically quantified is a

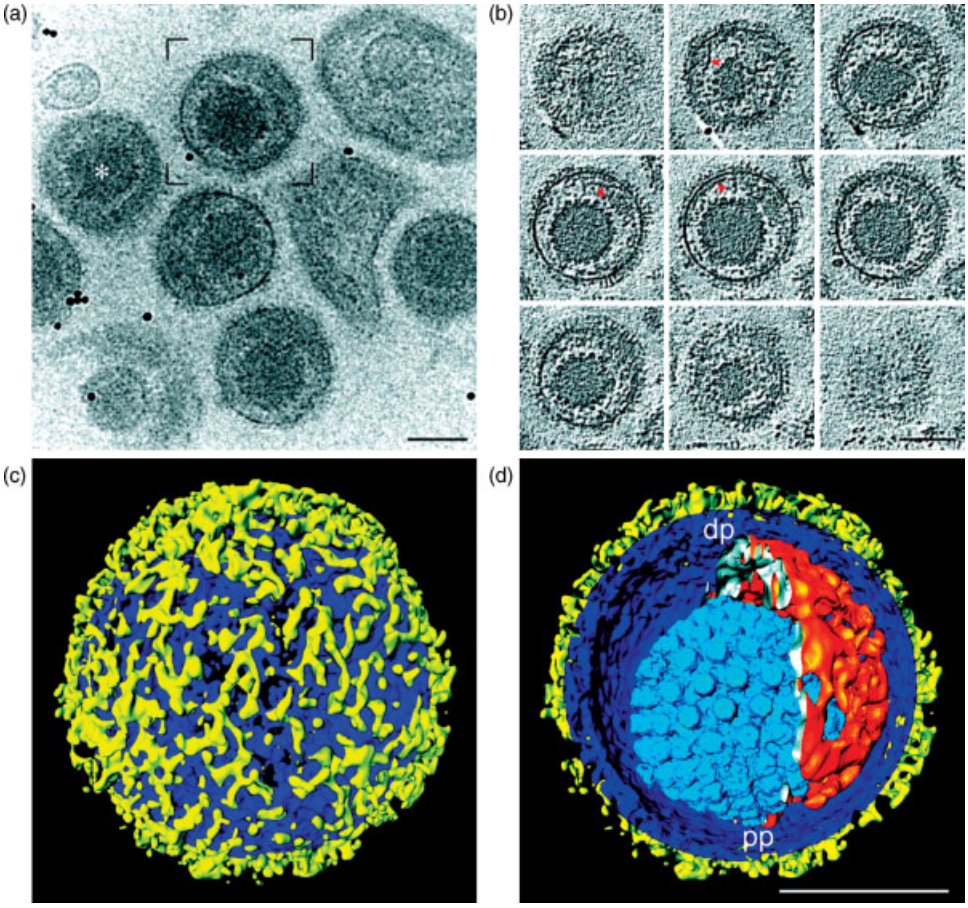

Figure 8.5 (a, b) Tomographic reconstruction of HSV-1 virions in vitreous ice (based on Ref. [19]). (a) The untilted projection from a tilt series. The black dots are 10 nm gold particles used as fiducial markers; (b) Gallery of sections from the tomogram taken from the virion framed in panel (a). Each section is an average of seven planes from the tomogram, and represents a slab which is 5.2 nm thick. The sections are separated by 15.5 nm. Red arrowheads mark filaments in the tegument. All scale bars are 100 nm. (c, d) The surface-rendered tomogram from the same virion after denoising; (c) Outer surface showing the distribution of glycoprotein spikes (yellow) protruding from the membrane (blue); (d) Cutaway view of the virion interior, showing the capsid (light blue) and the tegument 'cap' (orange) inside the envelope (blue and yellow). pp = proximal pole; dp = distal pole.

daunting task. It is also difficult to imagine that labeling can be developed such that it becomes a high-throughput technology capable of mapping entire proteomes. In order to identify every molecule of interest, the entire procedure of labeling, as well as data acquisition and reconstruction of the tilt series, must be repeated. Moreover, the unique nature of cellular tomograms makes the direct correlation of the different maps impossible, which in turn poses a major problem when deriving such maps from the molecular interaction patterns.

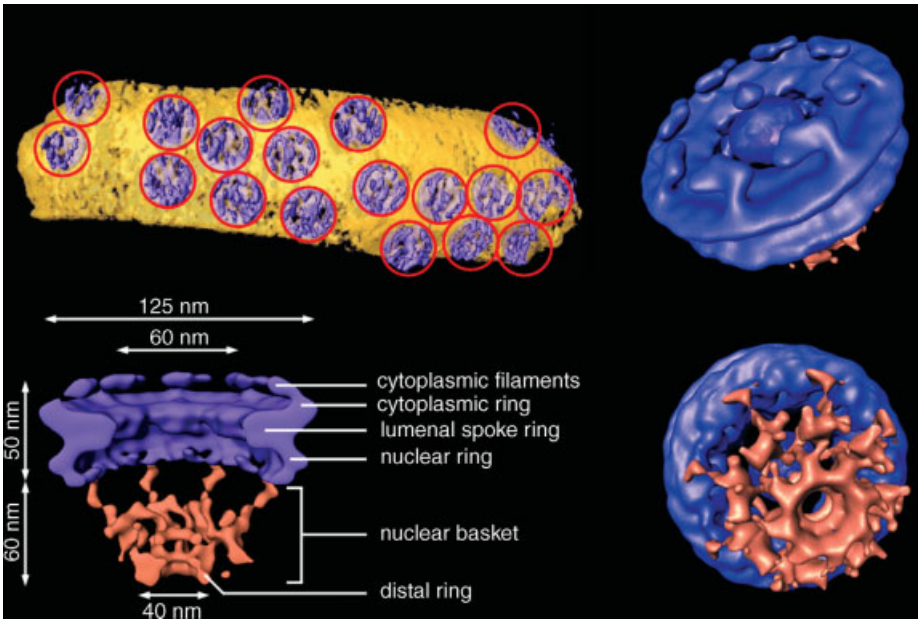

Figure 8.6 The structure of the nuclear pore complex (NPC) obtained from averaging subvolumes [35]. A surface-rendered representation of a segment of nuclear envelope (NPCs in blue, membranes in yellow). The dimensions of the rendered nuclear volume are 1680 nm × 984 nm × 558 nm. The upper right diagram shows the cytoplasmic face of the NPC, and the lower right the inward (nuclear) face. The distal ring of the basket is connected to the nuclear ring by the nuclear filaments. The lower left diagram shows a cutaway view of the NPC. The dimensions of the main features are indicated. The nuclear basket is shown in brown.

An alternative strategy is to combine fluorescent light microscopy and cryotomography. Specific fluorescent labels can be engineered into proteins of interest, or alternatively fluorescent labels can be applied and taken up by the cells. Progress has been made in the development of the cryogenic light microscope [41, 42], which can visualize fluorescence in vitrified specimens. This allows a fluorescence image of the frozen hydrated specimen to be recorded on the grid, and for any targets of interest for tomography to be identified. The specimen is then transferred directly to the electron microscope, where tomographic tilt series can be recorded of the target areas. Software-based methods can be used to align the fluorescence image with a low magnification image from the electron microscope, thus locating the desired areas in the electron microscope overview image.

8.5.2 Pattern Recognition

The identification of a single 26S proteasome in the cytoplasm of a *Dictyostelium* cell suggested that a template-matching approach could be used for mapping cellular proteomes [21]. Given that one can see 'everything' in a tomogram, it makes sense to

probe the tomogram with a library of templates derived from known structures, using intelligent pattern recognition algorithms. The intent is to locate known structures and determine the molecular context in which complexes are organized in organelles or cells, with less emphasis on the discovery of novel molecular features and more on determining whether there is some correlation in the spatial arrangement of complexes, relative to one another. To achieve this, a 'template-matching' strategy is being pursued [43, 44]. Given the array of high- to medium-resolution relevant structures that are available to be included in a template library, the systematic analysis of tomograms by scanning for the presence of these known templates is feasible. The procedure is computationally intensive, as not only must the positions matching a given template be determined, but also their spatial orientations. The tomogram must be probed with every template, and the best match determined for each complex in the tomogram. Ideally, such a multi-template search would result in a 3-D map with each low-resolution complex that was identified replaced by the higher-resolution template that it matched, in the orientation determined (Figure 8.4). Simulations and experiments with 'phantom cells' have shown that such an approach is feasible [44], and that the search results can be validated. At present, only large complexes such as the ribosome have been identified with an acceptable accuracy (> 95%) at the routinely attained resolution of 4–5 nm. Yet, an improvement in resolution to 2–3 nm would allow the accurate identification of smaller complexes [45].

8.6
Creating Template Libraries

Once the challenges of obtaining a sufficiently good resolution have been met, the next target will be to expand the libraries of available templates. Many approaches can contribute to achieve this goal. Structural genomics efforts will increase the pace at which high-resolution structures of domains, subunits or larger entities become available, and eventually will provide a comprehensive structural dictionary. Hybrid methods, combining information from different sources and of variable quality, will also play an important role [2, 4]. Electron microscopic single-particle analysis will undoubtedly continue to provide many medium-resolution structures of complexes. Clearly, the prospects for accelerating throughput by means of automated data collection and analysis show great promise [15].

Nonetheless, sample preparation continues to be the major bottleneck that slows progress in the field. Today, improvements are required in the methods used to isolate and purify proteins. This is especially true for labile macromolecular assemblies (which are probably more abundant in cells than stable complexes), with novel strategies being required. Whilst traditional biochemical methods tend to optimize for yield and/or purity, they are frequently time-consuming, and labile or transient complexes are generally lost during a traditional course of isolation. Given the modest requirements of single-particle analysis – where only very small quantities of material are needed and impurities can be removed computationally – there is no reason to

purify labile complexes to exhaustion. It has been shown recently, by using lipid monolayer techniques and taking advantage of His tags, that it is possible specifically to pick up only the desired His-tagged protein from a crude extract and directly freeze and image the specimen in vitreous ice [46]. There is, therefore, plenty of scope for innovative approaches aimed either at minimizing the purification steps, or even avoiding purification altogether by taking advantage of optimized *in vitro* translation systems.

8.7 Outlook

With cryoelectron tomography providing 3-D images at molecular resolution, and with image analysis tools at our disposal for interpreting the tomograms, we are now poised to integrate structural data into pseudo-atomic maps of organelles or cells. Whilst these maps will provide unprecedented insights into the molecular architecture that underlies cellular behavior, they will also pose new challenges. It will not be a trivial task to extract generic features from the maps, nor to derive general rules regarding the principles that govern supramolecular organization, given the stochastic nature of cellular systems as well as their dynamics. Most importantly, systems analysis will need to start taking this into account, and there will also be a need to develop statistical methods similar to those used when analyzing macroscopic social systems. Alternatively, sophisticated molecular dynamics software could be expanded to model large-scale systems.

9
Time-Resolved Two-Photon Photoemission on Surfaces and Nanoparticles

Martin Aeschlimann and Helmut Zacharias

9.1
Introduction

Occupied and unoccupied states of solid-state materials are traditionally investigated using photoemission and inverse photoemission spectroscopies. Due to the limited and short path length of electrons in the 20 to 100 eV range, an excellent surface specificity is achieved with these methods, enabling differentiation to be made between signals from the bulk of a material and from layers in the vicinity of the surface. The advent of ultra-short laser pulses among those laboratories investigating surface sciences has extended the field of research, as this technique provides the possibilities both to investigate occupied states with photon energies sufficiently high to surpass the work function of the material, and to study unoccupied states by using resonantly enhanced two-photon photoemission (2PPE). In this process, electrons are promoted by a first laser photon to an unoccupied state; this may be a volume, surface, an adsorbate state or an image potential state (IS) [1] of the material. Before the electron can re-equilibrate, a second photon from the same (or a different) laser beam is absorbed by the excited state. This promotes the electron of the excited state above the vacuum level, leading to an emission of photoelectrons which thus have been interacting with two laser fields. In this way, the spectral resolution for the intermediate unoccupied states is greatly improved compared to inverse photoemission [2].

The two-pulse scheme of photoemission bears another extremely important advantage, in that it allows the delay of one pulse against the other. This so-called time-resolved two-photon photoemission (TR-2PPE) allows investigation of the dynamics of the intermediate electronically excited state on a femtosecond time scale. Moreover, energy and momentum transfer processes in the excited state can also be studied, while scattering phenomena can also be addressed. These time-resolved photoemission experiments have been conducted for about 25 years. Initially, the thermalization dynamics of band edge carriers in semiconductors and electron–phonon (e–ph) dynamics in metals were studied using lasers of typically a

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

few tens of picoseconds pulse duration [3–6]. More recently, however, by using lasers with femtosecond time resolution, the lifetimes of image potential states on silver surfaces [7] and questions regarding electron–electron (e–e) scattering dynamics in bulk metals have been addressed [8–10].

During the past two decades, photoemission techniques have been coupled with electron imaging by means of photoemission electron microscopy (PEEM), and this has allowed material-specific microscopic images of nanostructures on surfaces to be obtained with sub-100 nm resolution [11]. Important information concerning various new and unexpected phenomena, including the nonlinear behavior of surface reaction dynamics [12] and of layered magnetic materials, has been obtained using this method. These imaging methods, when combined with time resolution in the femtosecond regime [11, 13], will become increasingly important in emerging areas such as molecular electronics, self-assembled and self-organized functional layers, organic solar energy converters and photocatalytic reaction centers.

In this chapter we will provide examples of the imaging methods, together with their recent application in the preparation of metallic nanostructures. Such nanostructures will become increasingly important as fields of molecular switching and electronics, plasmonics and functional molecular assemblies evolve. Moreover, as the dimensions of structures shrink to the submicrometer level, novel properties and functions will undoubtedly emerge. The spectral tuning of the emission of entities and controlled charge transport in organized nanostructured environments [14–16] represent just two aspects of functional modification in molecular electronics. It is further envisioned that the optical phase control of charge transport [17] may become very important in such systems. It follows that a precise knowledge of the basic electronic properties of these nanostructured systems is, therefore, of major importance.

9.2 Theoretical Background

The electron dynamics in metallic nanostructures are governed by a few elementary processes which will now briefly be described. Besides the fundamental charge screening, which takes place on an attosecond time scale, the decoherence of excited electrons and electron–electron scattering processes are primary processes leading to a rapid redistribution of electron energy and momentum. Thereby, a hot electron gas is created. On nanostructures a coherent excitation of the whole electronic system – the creation of particle plasmons – is of fundamental nature and a specific element to be considered in these systems. The decay processes of particle plasmons are presently under intense investigation. The hot electrons created by various processes then couple to the phonon system, eventually dissipating the energy to heat. A concise theoretical description of the basic processes involved, which is beyond the scope of this chapter, can be found in recent reports [18–20].

9.2.1
Electron–Electron Interaction

The simplest description of electronic interaction in metals can be derived from the Drude theory of metals [21]. Although based on currently outdated assumptions, this theory provides a good estimate of the magnitude of electron scattering for various classes of metals. The electron mean free path, divided by their velocity at the Fermi energy, yields the collision free time which denotes the lifetime of an electron at a certain energy. At room temperature, this lifetime ranges from a few femtoseconds in transition metals to a few tens of femtoseconds in noble metals.

A more quantitative description of the electron–electron scattering rate is obtained from the Fermi liquid theory [22, 23] for a free electron gas (FEG FLT). In brief, phase space arguments are invoked to describe the interaction of an electron with kinetic energy above the Fermi level with unexcited electrons. Due to the same mass of the interacting electrons, and the fact that all states below the Fermi level are occupied, the inelastic scattering of a hot electron with the cold Fermi gas yields two electrons, both with kinetic energies now above the Fermi level. For a single excited electron this inelastic process yields a new kinetic energy and momentum, thus limiting the mean free path of an electron at a given energy. It is clear that electrons far above the Fermi level have a larger phase space available for scattering than those close to the Fermi level. Therefore, the scattering rate strongly decreases as the energy of the hot electron relaxes towards the Fermi level.

These inelastic processes continue, and finally a hot electron gas is rapidly created. When an intense laser pulse creates the primary excitation, the excitation density is high and therefore also the density of the hot electron gas. Scattering events with adsorbed molecules then become probable, and processes such as desorption induced by electronic transitions (DIET) and desorption induced by multiple electronic transitions (DIMET) or electronic friction induced adsorbate excitation my become observable.

Within the relaxation time approximation, and invoking Boltzmann transport theory with the Fermi–Dirac distribution for the occupation, the Fermi liquid theory yields in three dimensions for the scattering rate [24]

$$\tau^{-1} = \tau_0^{-1}(E-E_F)^2 + b(k_B T)^2 \tag{9.1}$$

At excitation energies above 200 meV, the thermal contribution can usually be neglected at all practical temperatures. The prefactor τ_0 depends only on the electron density in the metal under consideration:

$$\tau_0 = \frac{64}{\sqrt{3}\pi^{5/2}} \sqrt{\frac{m_e}{ne^2}} \quad E_F^2 \tag{9.2}$$

The inelastic lifetime of an electron above the Fermi level, given by the inverse scattering rate, is therefore inversely proportional to the square of the energy difference to the Fermi level and, taking the dependence of E_F on the electron density into account, proportional to $n^{5/6}$. At excitation energies of about 3 eV this amounts to a few femtoseconds, whereas close to the Fermi level, $E < 0.2$ eV, it may approach the picosecond range, depending on the metal under consideration [25, 26].

Usually, the FEG FLT serves as a benchmark for comparison of the observed hot-electron inelastic lifetimes τ with the theory, and therefore electron relaxation dynamics has first been investigated for noble metals, where a reasonable agreement with the FEG FLT was expected [10, 27–30]. For all other metals, the key role in the low-energy electron relaxation dynamics is played by the electronic structure of the system close to the Fermi level. For example, in transition metals the high density of *d* bands in the proximity of the Fermi level leads to a very fast electron relaxation. In this context, the exact energy position and shape of the *d* bands must be considered in detail in order to achieve a complete understanding of the relaxation processes. During the past decade, several TR-2PPE experiments have been performed for the transition metals Ta [31], Ru [32], Mo and Rh [33], for ferromagnetic 3*d* metals Fe, Co and Ni [34], and for high-T_C superconductors [35] and 4*f*- rare earth metal Yb [36].

Theoretical calculations of excited electron lifetimes have been performed in the past within the *GW* approximation (GWA) for electron self-energy for bulk noble [37, 38] and 4*d* transition metals [39–42], as well as for the 5*d* transition metal Ta [31]. In contrast to noble metals, which show qualitatively similar band structure and density of states (DOS) [43], the electronic structure of 4*d* metals varies strongly on moving from the start of the 4*d* series to the end [43]. Calculations performed by Zhukov *et al.* [41] and Bacelar *et al.* [42] have shown that the evaluated lifetimes also vary widely along the 4*d* series, following trends in electronic structure. The extension, $GW + T$, of the *GW* approximation by inclusion of multiple electron-hole scattering within a *T*-matrix approximation [44–48] results in a decrease of the *GW* lifetime value that brings theory and experiment to better agreement [47, 48].

9.2.2 Plasmonic Processes

In noble metal nanoparticles collective electronic oscillations – so-called particle plasmons or localized surface plasmons (LSPs) – can be excited by electromagnetic waves. Therefore, they are detectable as pronounced resonances in the scattering and absorption cross-section, for the noble metals Ag and Au commonly located in the visible or ultraviolet (UV) region of the spectrum [49]. The resonance frequency of the plasma oscillation is determined by the dielectric properties of the metal and the surrounding medium, as well as by the particle size and shape [49–51]. The collective oscillation can be interpreted as a displacement of the electrons in the particle against the positively charged background of the atomic nuclei. Resonant excitation of this collective charge oscillation causes a large enhancement of the local field inside and near the particle [52] which dominates the linear and nonlinear responses of the particles to the light field. The field enhancement caused by the electron oscillation (see Figure 9.1) is thought to be responsible for the enhancement of nonlinear optical effects such as surface-enhanced Raman scattering (SERS) [53], surface second harmonic generation [54, 55] and multiphoton photoemission [56]. In recent years, the promising research field of plasmonics and ultrafast nano-optics has emerged, exploiting the high potential of plasmons to concentrate and channel light into subwavelength structures of nanoscopic circuits [57].

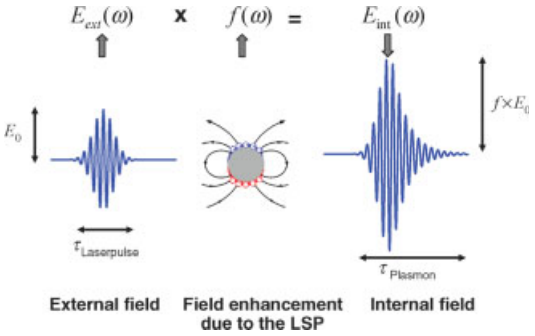

Figure 9.1 In metallic nanostructures collective electronic oscillations – local surface plasmons – can be excited by light; this results in a strong enhancement of the local field both inside and near the surface structure.

Although, the spectral positions of the resonances of particle plasmon excitations as a function of particle size, shape and dielectric properties are well understood [49–52], the ultrafast dynamics of these collective electronic excitations have remained a highly interesting topic to be studied in more detail. In order to understand the dynamics, it is essential to investigate those mechanisms relevant to the loss of phase coherence between the electrons contributing to the collective excitation – that is, the dephasing of the plasmonic state.

9.2.3 Two-Temperature Model

When a strong femtosecond laser pulse produces a large primary population of hot electrons, the electron–electron scattering leads to the formation of a hot electron gas. The formation and decay of this not-equilibrated hot electron distribution was first observed by Bokor and coworkers in thin gold films. The equilibration process of this electron gas can, in general, be described fairly well by the Fermi liquid theory, together with the Boltzmann transport equation in the relaxation time formulation [8, 9]. However, deviations from this description were noted at an early stage of these investigations. An important (and, at first sight, counterintuitive) finding was that the relaxation to a heated thermal distribution occurred faster if a more intense laser excitation was applied, and thus the density of hot electrons was higher.

The hot electron dynamics is usually modeled using a two-temperature model [58], where the electronic and phonon systems assume different temperatures; this is justified due to the wide differences in the heat capacities.

$$C_{e\ell}\frac{\partial T_{e\ell}}{\partial t} = \frac{\partial}{\partial z}\left(\kappa\frac{\partial T_{e\ell}}{\partial z}\right) - g_{\infty}(T_{e\ell} - T_{ph}) + S(z,t) \tag{9.3}$$

$$C_{ph}\frac{\partial T_{ph}}{\partial t} = g_{\infty}(T_{e\ell} - T_{ph}) \tag{9.4}$$

$S(z,t)$ represents the exciting optical intensity as it penetrates into the bulk of the material. The lateral dimensions are usually large, and thus uniform compared to the large gradients in z direction. $C_{el} = \gamma\, T_{el}$ represents the electronic heat capacity, and C_{ph} that of the phonon system. The coupling between the electronic system and the phonons is described by g_{∞}. With this system of equations, a good estimate of the magnitude and time dependence of electronic and phonon temperatures is usually achieved. This can easily be extended by frictional coupling to an adsorbate [59, 60], which thereby acquires internal energy and also serves as a cooling heat bath for the excited surface layers. Similarly, diffusive and ballistic electron transport from the surface layers represents an important sink for the deposited laser energy (see for example, Ref. [32]).

9.2.4 Electron–Phonon Coupling

The hot electron gas created by electron– electron collisions then couples to the phonons of the substrate, which eventually leads to a dissipation of the energy into a second heat bath. A theoretical description of this process has only in recent years become possible. Usually, the structure of a solid and the motion of its atomic constituents is very successfully described by the Debye model using quasi-particles, the phonons. For the electronic system, on the other hand, Bloch waves describe the motion and energetics of the quasi-particles. In both descriptions they are considered independent of each other, and this constitutes the usual Born–Oppenheimer approximation, which is well known from molecular physics. In this picture an electron–phonon interaction cannot take place, and therefore one must go beyond the Born–Oppenheimer approximation and formulate a description of these nonadiabatic processes.

As a formal derivation of the approach is beyond the scope of this chapter, the reader is advised to consult the appropriate literature, which is based on the Fröhlich description [61] of the electron–phonon (e–ph) interaction [62]. Physical insight into the problem is gained with the introduction of the so-called Eliashberg function, $\alpha^2 F(\omega)$, the product of the phonon density of states $F(\omega)$ and the electron–phonon interaction strength α^2 [63]. For the emission of a phonon it is given by

$$\alpha^2 F_{i,k_i}(\omega) = \int \mathrm{d}^2 q \sum_{f,\nu} \left| g^{i,f}_{q,\nu} \right|^2 \delta(E_{i,k_i} - E_{f,k_f} \pm \omega_{q,\nu}) \delta(\omega - \omega_{q,\nu}) \tag{9.5}$$

where $g^{i,f}_{q,\nu}$ denotes the electronic part of the interaction [62]. For the evaluation of $g^{i,f}_{q,\nu}$ one has to enter the screening potential. In order to illustrate this Eliashberg function, its dependence on phonon frequency is shown in Figure 9.2 for Be [64]. It transpires that the simple Thomas–Fermi screening yields results which are well compatible with experimental data. The electron–phonon coupling parameter $\lambda(E_i, k_i)$ is then obtained from

$$\lambda(E_i, k_i) = 2 \int_0^{\omega_{\max}} \frac{\alpha^2 F_{i,k_i}(\omega)}{\omega} \mathrm{d}\omega \tag{9.6}$$

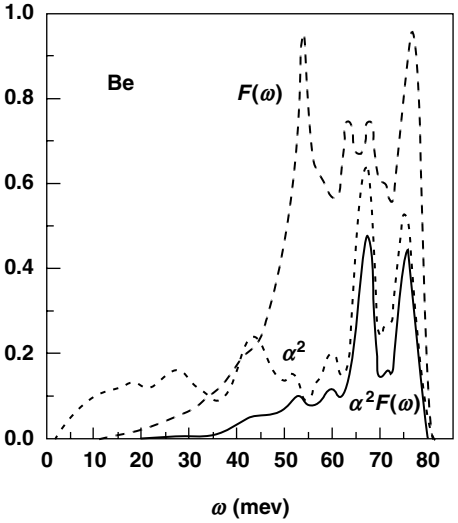

Figure 9.2 Phonon density of states $F(\omega)$ and Eliashberg function $\alpha^2F(\omega)$ for Be(0001). (From Ref. [64].)

Any phonon-induced interaction should be proportional to the occupation number $n_B(\omega)$ of phonons. The spectral broadening due to e–ph coupling is then

$$\Gamma(E_i, k_i) = 2\pi \int \alpha^2 F_{i,k_i}(\omega)[(2n_B(\omega) + 1) + f(E_{k_i} + \omega) - f(E_{k_i} - \omega)]\mathrm{d}\omega \qquad (9.7)$$

For increasing temperature this occupation number follows

$$n_B(\omega) \rightarrow k_B T/\omega, \qquad (9.8)$$

and thus shows at high temperatures a linear dependence on T [65]. The spectral broadening of a state due to e–ph coupling can then be written as

$$\Gamma(E_i, k_i) = 2\pi\lambda(E_i, k_i)k_B T. \qquad (9.9)$$

In order to calculate this width, it is necessary to know the phonon density of states $F(\omega)$ and the e–ph coupling strength $|g^{i,f}_{q,n}|^2$, given by [18]

$$g^{i,f}_{q,\nu} = \frac{1}{\sqrt{2M\omega_{q\nu}}} \langle \psi_{k_i} | \hat{\varepsilon}_{q\nu} \cdot \nabla_R V_{sc} | \psi_{k_f} \rangle \qquad (9.10)$$

where $\bigtriangledown_R V_{sc}$ is the gradient of the screened potential, $\hat{\varepsilon}_{q\nu}$ the polarization of the phonons, and M the atomic mass. ψ_{k_i,k_f} denotes the electronic wave functions of the initial and final states.

Experimentally, this e–ph coupling manifests itself via the spectral width Γ of states. An ideal situation to study this coupling arises therefore from surface states located in projected bulk bandgaps, as on the {111} surfaces of noble metals or of quantum-well states [66]. In this case, e–e scattering and electron–defect scattering may also contribute to the total linewidth Γ, and hence it is necessary to

seek alternative ways to separate these contributions. The e–ph coupling is also important when describing the cooling of a hot, nonequilibrium electron gas created by an intense laser pulse, as described above. Here, a connection between the microscopic constant λ and the phenomenologically used value g_∞ is given by [67]

$$g_\infty = \frac{3\hbar\gamma}{\pi k_B}\lambda\langle\omega^2\rangle, \tag{9.11}$$

where $\langle\omega^2\rangle$ denotes the second moment of the phonon spectrum.

9.3 Experimental

The investigation of electronic dynamics on nanostructures requires first an *in situ* preparation of the nanostructured system. For this purpose, a surface science ultra-high-vacuum machine with standard techniques for cleaning and preparation, like low-energy electron diffraction (LEED) and Auger electron spectroscopy, must also be equipped with instruments for either surface structuring or controlled growth techniques. Further, an *in situ* control and manipulation of the sample is suggested, which can be achieved by using scanning electron microscopy (SEM), scanning tunneling microscopy (STM) [68] or atomic force microscopy (AFM) [69] or by photoelectron emission spectroscopy [70] and microscopy [11]. Each of these techniques has in the past been described extensively, and the reader is referred to respective review articles.

In order to study the ultrafast electron dynamics, an appropriate laser source must be added, as well as a means of detecting the laser-generated photoelectrons. This can be achieved by a conventional dispersive electron spectrometer, equipped with two-dimensional (2-D) signal detection, or by a time-of-flight (ToF) detector, which makes use of the multiplexing advantage, especially when a multi-anode assembly is added. Figure 9.3 shows, in schematic form, a typical experimental set-up. The standard laser system consists of a Ti : sapphire laser oscillator operating in the spectral vicinity of 800 nm and with pulse durations of typically 12–25 fs. As the work functions of typical metals range from about 4 to 6 eV, frequency doubling and tripling in optically nonlinear crystals, such as β-BaB_2O_4 (BBO) and $LiBO_3$ (LBO), is often employed. For an optimal time resolution the frequency doubling crystal should be thin, with about 100–200 μm thickness depending on the spectral width that is to be converted. Efficiencies to produce 400 nm radiation in the range of 15–20% can be achieved. The third harmonic of the 800 nm fundamental radiation is produced by sum frequency mixing the fundamental with its second harmonic in a second BBO crystal. The frequency-converted pulses should be recompressed to compensate for the material dispersion in both the doubling and mixing crystals as well as the chamber windows, or any other optics in the beam path from the laser to the sample (see Figure 9.3). Besides simply reducing the number of photons required to reach the vacuum level of a system, the use of two colors – one from the fundamental and one from a

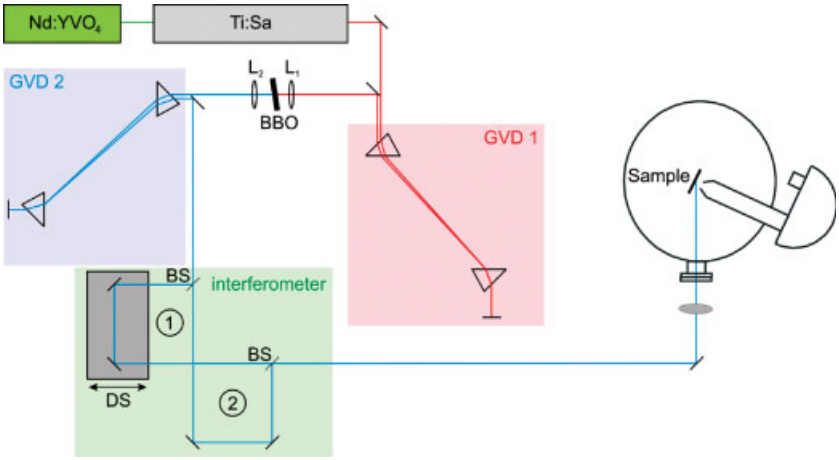

Figure 9.3 Schematic set-up for space and time-resolved two-photon photoemission experiments. The sketched dispersive hemispherical electron energy analyzer can be replaced by a time-of-flight detector or an imaging PEEM. Pulse compressors (GVD 1 and 2) (pre-)compensate a pulse stretching in optical elements in the path of both the fundamental and an harmonic beam.

frequency-doubled or -tripled beam – leads to a significant increase in the analytical power of the experiment.

Amplified Ti : sapphire radiation is required when an optical parametric oscillator is to be pumped in order to obtain radiation that is tunable across the visible spectrum. This allows one specifically to tune to and excite unoccupied resonance states of the sample. The dispersion of a state can also be followed. Amplified Ti : sapphire radiation with pulse energies in the 1 mJ regime and durations of 20–35 fs can also be used to produce extreme ultraviolet (XUV) radiation by high harmonic generation, with tunable photon energies up to about 100 eV and beyond [71–74]. Besides accessing more strongly bound states, or even shallow core levels, this radiation also allows the momentum space of a state to be addressed in the whole Brillouin zone. In addition, high-lying plasmonic states of all metals can, in principle, be reached directly. By shortening the pump pulse duration in the sub- 10 fs regime, using nonlinear optical techniques, it may be possible to produce not only high harmonics in the water window spectral range ($\lambda \sim 4.4$ to 2.3 nm) [71, 72]. By employing carrier envelope phase-stabilized pulses and correctly selecting the XUV spectral range, pulse trains of approximately 100 as [75–78] or even single pulses with durations as short as 80 as [79] can be produced. Such an approach will undoubtedly open a future window for investigating the electron dynamics of screening and dephasing processes.

For time-resolved experiments, care must be taken to properly delay and recombine both pulses on the sample. For this, either a Mach–Zehnder or a Michelson interferometer set-up may be employed. A temporal delay of both pulses is achieved

with different path lengths for the two interferometer arms; this difference must be controlled at better than 150 nm when a time step resolution of 1 fs is to be achieved, as the pulse will travel twice through the delayed arm. When the two pulses are collinearly overlapped, interferometric correlation signals with a periodicity of the optical wavelength are obtained. Due to a cycle duration of about 1.3 fs for 400 nm light, a much smaller step size (20 nm) and higher stability and reproducibility is required. Then, instead of using a conventional motorized translation stage, a piezoelectrically driven stage and an interferometer that is actively controlled with a frequency-stabilized HeNe laser beam are employed [80]. It is also important to control the polarization (s, p or circular) of both beams applied to the sample. The performance of both phase-resolved and phase-averaged 2PPE has been tested on a polycrystalline tantalum film (see Figure 9.4; photon energy 3.1 eV) [81]. In this way, the oscillation fringes due to the interference between pump- and probe- pulse are clearly resolved; that is, the accurate reproduction and periodicity of these measurements over the entire temporal delay proves the position stability of the set-up employed.

Due to increasing interest in the specific hot-electron dynamics of spatially heterogeneous systems such as metallic nanostructures, an extension to a space- and time-resolved 2PPE set-up, using time-resolved photoemission electron microscopy (TR-PEEM) for 2-D-electron detection has been established [13]. This method is capable of high spatial resolution in the 20 nm regime, which enables the focus to be set on the details of an individual nanoparticle. A typical TR-PEEM experiment is shown schematically in Figure 9.3 which is, except for the detector, identical to that of a TR-2PPE set-up. The TR-PEEM method has been well reviewed [11]. For a full pump-probe scan, the delay between the two pulses is varied in small steps (typically $\Delta t = 1$ fs), and for each step a PEEM image is taken

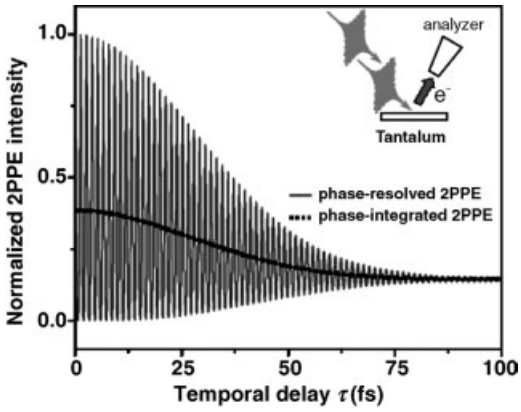

Figure 9.4 Time- and phase-resolved 2PPE from polycrystalline tantalum measured at an electron kinetic energy of 6 eV. The gray line is the 2PPE interferogram; the black dotted line shows the data for a conventional phase-averaged 2PPE measurement. (From Ref. [81].)

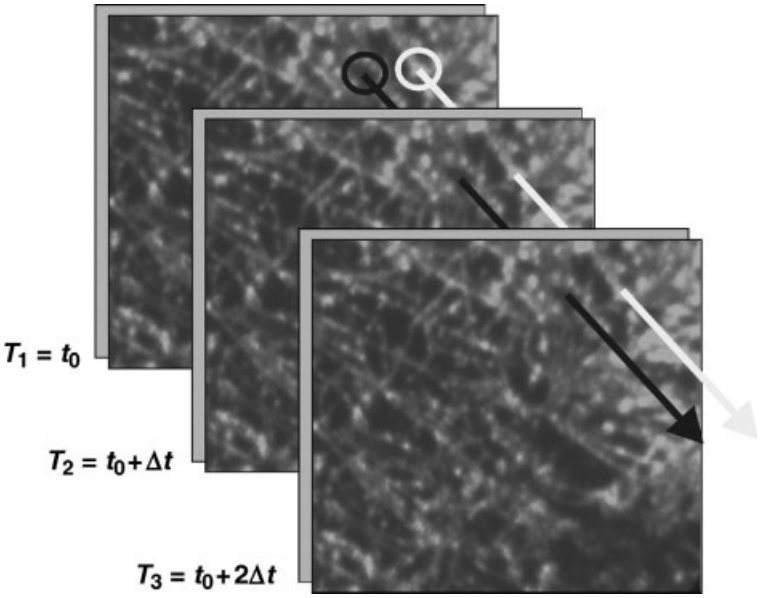

Figure 9.5 Schematics of measuring time-resolved 2PPE pump–probe images obtained with a PEEM.

(see Figure 9.5). This results in a series of images that contains a correlation trace for each pixel (Figure 9.6); these can then be plotted in a lifetime map deduced from a pixel-wise analysis of the cross-correlation traces of a TR-PEEM scan, as shown in Figure 9.7. The lifetime map contains information on the dynamic behavior of the electron system at the sample surface (decay time T_1 of the intermediate state) with the spatial resolution of the PEEM.

Nanostructured samples are, in general, prepared using either electron beam lithography (EBL) for larger structures (<40 nm), or cluster deposition for nanostructures as small as <1 nm. EBL, as a lift-off process, allows the controlled and

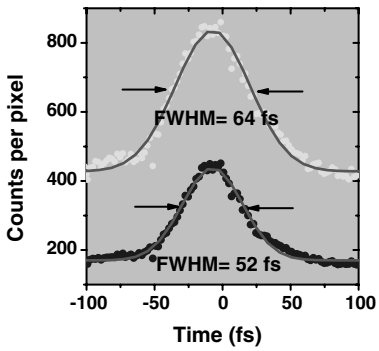

Figure 9.6 Typical autocorrelation traces of individual pixels of the PEEM images of Figure 9.5.

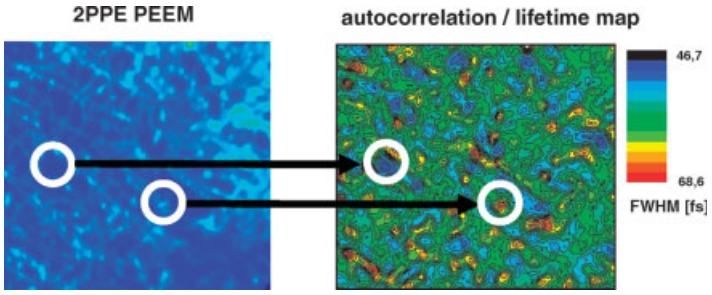

Figure 9.7 2-D autocorrelation map (right) obtained from time-resolved PEEM images taken according to Figure 9.5.

flexible design of metallic nanoparticles with regards to their shape and size. The optical properties – and especially the position and width of the LSP-resonance – depend critically on the shape and size of the particles, and this allows the characteristic LSP resonance frequencies to be tuned to the wavelength regime accessible by the available femtosecond laser system, e.g., the fundamental and second harmonic of a Ti : sapphire laser. Figure 9.8 shows SEM images of different silver nanostructures deposited on indium tin oxide (ITO) -covered glass substrates [82]. The dimensions of the elliptically shaped silver nanoparticles in Figure 9.8a are 140 nm (long axis), 60 nm (short axis) and 50 nm (height). These constitute versatile samples for investigating variations in the LSP decay in respect of resonant or off-resonant excitation. The silver nanodot array (Figure 9.8b; diameter 200 nm, height 50 nm) and the silver nanowire array (Figure 9.8c; length 1.6 µm, width 60 nm, height 50 nm) can be used to illustrate the potential of the time-resolved PEEM technique to map retardation effects associated with a plasmon excitation at nanometer resolution. Studies of the plasmon-induced coupling between neighboring nanoparticles are possible with nanodot pairs of varying center-to-center spacing. Figure 9.8d shows an example of 50 nm dimers (height 40 nm) at an interparticle spacing of 130 nm (grating constant 740 nm).

For small cluster deposition onto surfaces, an UHV gas-aggregation cluster source is required including a quadrupole mass selector [83]. This allows the flexible *in situ* preparation of monodisperse cluster distributions over a broad size range. An alternative possibility would be to produce a defined density of atomic defects in a graphite surface, known as the Hövel-method [84]. This involves using a focused ion beam (FIB) technique that allows for the etching of well-defined nanopits into highly ordered pyrolytic graphite (HOPG) substrates and a subsequent oxidation procedure. The pits have a statistical variation in their depth between one and three monolayers (MLs). Further details on the FIB technique and oxidation procedure are available in Ref. [85]. The evaporation of about four MLs of silver at room temperature results in the condensation of near-monodisperse silver clusters in the native and artificially created defects in the HOPG surface.

9.4 Relaxation of Excited Carriers

During the past two decades, the study of image potential states has evolved as a paradigm for the investigation of electron dynamics at surfaces. This field has recently extensively been reviewed [86], and therefore only selected aspects will be discussed here. The main decay channel of these states isolated in a directional bandgap is the overlap of their wave function with bulk electronic wave functions. This overlap increases as the energy of the states approach the band edges. Then also the phonon contribution to the decay rate increases. For well-isolated image states, such as the $n = 1$ state on Cu(100), this contribution to the linewidth is expectedly very low, with a coupling parameter of $\lambda \sim 0.01$ and a contribution to the spectral width of $\Gamma < 1$ meV [87, 88], while for Cu(111) λ increases to 0.06 [89].

On the other hand, interband and intraband electron scattering also constitute important scattering mechanisms for image potential states. Steps and adatoms on the surface play an important role in these scattering phenomena. For example, on stepped surfaces scattering within the $n = 1$ image state results in a broadening of the level and thus in a shortening of the lifetime [90]. On vicinal Cu surfaces with (111) terraces, Roth *et al.* [91] found that for electrons with a downwards momentum the steps show a greater decay rate than in the opposite direction, and this results in lifetime differences within $n = 1$ of up to 4fs. Copper and cobalt adatoms induce intraband and interband scattering between the image states [92, 93]. An inelastic interband scattering of $n = 2$ electrons with bulk electrons populates the bottom of the $n = 1$ band. When probing levels within the $n = 1$ band above the bottom of the $n = 2$ level, a resonant (quasi-)elastic interband scattering occurs from $n = 2$ to $n = 1$, with strongly increasing probability as the energy increases further. On the other hand, the adatoms do not have any significant influence on the intraband scattering rate. It can be envisioned that a lateral confinement of nanostructures might also lead to an increased coupling between image states and bulk bands due to a shift of the band edges.

An especially illustrative example for a hole decay has been provided by Berndt and coworkers, who studied the occupied surface states of noble metals by using

Table 9.1 Experimental and theoretical hole lifetimes of occupied surface states on noble metals. (From Ref. [94].)

				Experiment		Theory	
Metal	**Δ (meV)**	**β**	**τ (fs)**	**Γ_{STM} (meV)**	**Γ_{PES} (meV)**	**Γ_{old} (meV)**	**Γ_{new} (meV)**
Ag	8	0.89	120	6	20[a]	5.3	7.2
Au	23	0.82	35	18	60[b]	8.6	18.9
Cu	30	0.80	27	24	21[c]	10.2	21.7

STM [94]. The width Δ of the onset of dI/dV spectra can be transformed into lifetimes τ via

$$\tau = \beta h/(4\Delta), \tag{9.12}$$

where h denotes Planck's constant and β is a scale factor close to unity. Using this method, it can be ensured that the surface area studied is indeed clean, and therefore defect scattering can be excluded. The results obtained, together with a comparison of values derived from photoelectron spectroscopy [70, 95, 96], and a comparison with theoretical calculations, is shown in Table 9.1. The agreement between these measurements and the latest theoretical calculations is excellent. The results show that the holes created in the surface state are filled by electron–electron scattering from the 2-D electron gas of the still-occupied surface state band, rather than from the underlying 3-D bulk electron gas.

The global relaxation dynamics of a hot, nonequilibrium electron gas can be assessed by measuring the energy distribution function as a function of delay time after creating the hot distribution. This may be exemplified for hot electrons in Ru as studied by Wolf and coworkers [32]. The group investigated the relaxation dynamics at different pump pulse fluences. The relaxation dynamic is then modelled using a modified two-temperature model, where the electron distribution was parametrized by splitting it into a thermalized component at low temperature, while a second component was also thermalized, albeit at a higher temperature and with a lower population. This procedure describes the nonthermal electron energy distribution quite well. Both electron distributions couple to the phonon heat bath (for details, see Ref. [32]). Besides the expected localization of energy at the surface by electron–phonon coupling (as discussed above), it has also been found that ballistic transport out of the surface region has a significant influence on the temperatures and their time dependencies in the surface region. This leads in turn to notably lower temperatures (as shown impressively in Figure 9.9), with corresponding consequences for electronic coupling to adsorbates and laser-induced desorption dynamics. Such transport effects have also been observed for copper surfaces [97].

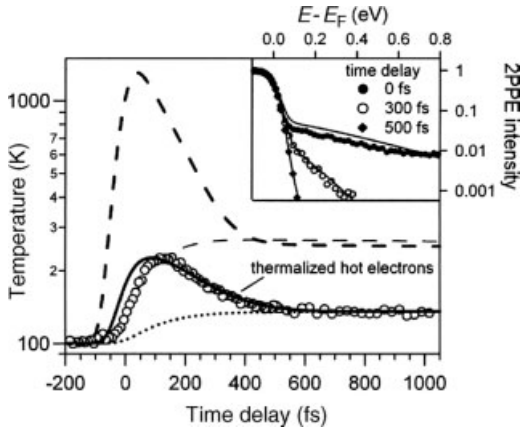

Figure 9.9 Time evolution of the electron and phonon temperatures according to the two-temperature model (thick and thin dashed lines). The extended heat bath model yields significantly lower values (shown by the thick and dotted lines) for the electrons and phonons, respectively. The open dots are experimental results. The inset shows measured electron kinetic energy distributions at different delay times. Data and calculations are for a Ru surface with a pump fluence of about 500 μJ cm^{-2}. (From Ref. [32].)

As mentioned above, on a microscopic level the electron–phonon coupling phenomena are best studied via isolated states in the band gap of materials. By using high-resolution photoelectron spectroscopy, the occupied surface states of noble metals have been studied [96, 98]. Figure 9.10 shows the experimental linewidth of the surface states, together with theoretical calculations [99], whereby an excellent agreement is obtained. This figure also shows the theoretically determined contribution of e–e scattering (Γ_{ee}) to the total width of the states. At low binding energies of the hole, the contribution of the Rayleigh phonon mode is dominant, while the overall spectral width becomes small. A similarly good agreement between theory and experiment was obtained previously for the very isolated surface state at Γ on the Be (0001) surface [100]. Here, the main contribution comes again from intraband scattering.

When defects are present on the surface, an additional broadening occurs. Such an effect has recently been reported for the Au (111) [101, 102] and Al(111) occupied surface states [102]. By monitoring the deviation of broadening from the expected linear temperature dependence, an activation energy for the creation of surface defects can be derived

$$\Gamma_{ed} = C \exp\{-[E_a/k_B T]\}. \tag{9.13}$$

On aluminum, the experimentally determined value for the activation energy of about $E_a = 170$ meV compares well with theoretical expectations for the creation of defects by kinks on a step edge, while the creation of adatoms requires about 300–600 meV. The corresponding value for Au(111) amounts to $E_a = 81$ meV, which suggests that kinks at step edges might well be responsible for the observed broadening.

In image states such a defect scattering can be isolated from the e–ph scattering, because these states are located in front of the surface and therefore are detached

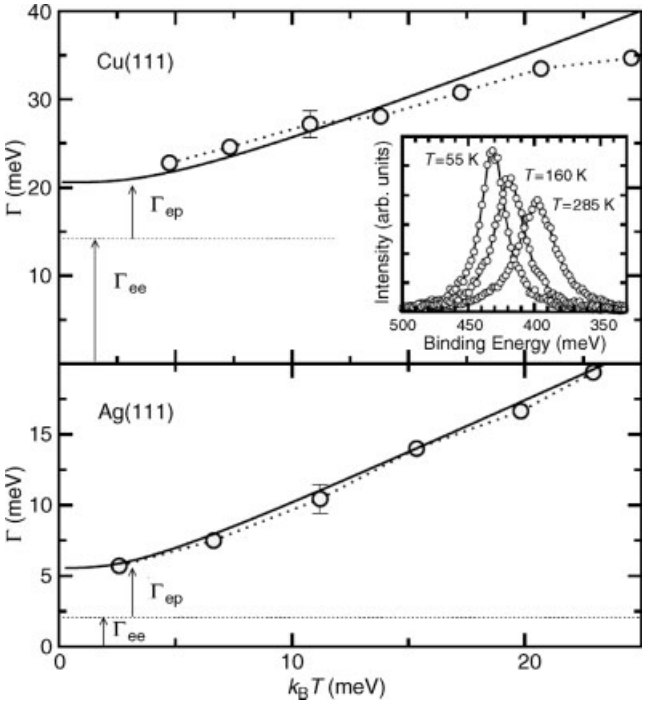

Figure 9.10 Temperature dependence of the experimental and theoretical line width of the occupied surface state on Cu(111) and Ag(111). Γ_{ee} denotes the e–e scattering contribution to the line width, independent of temperature. The inset shows experimental photoemission spectra at the Γ point at selected temperatures. (From Ref. [99].)

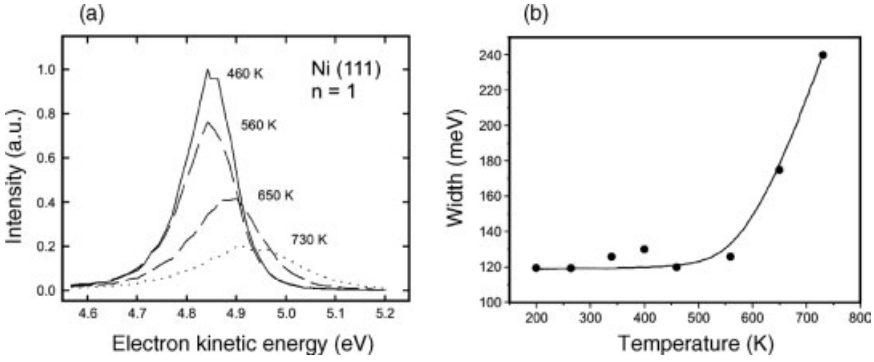

Figure 9.11 (a) Spectra and (b) line width of the ($n = 1$) image state on Ni(111) as a function of temperature. The state is resonantly excited from the occupied surface state at $E_b = 0.2$ eV.

from the motion of the atomic surface constituents. A similar strong temperature dependence of the width of an isolated state has been observed for the ($n = 1$) image potential state on Ni(111) (H. Zacharias and R. Paucksch, unpublished results). In this experiment, one photon at $\lambda = 263$ nm ($h\nu = 4.7$ eV) resonantly excites the image state from the occupied surface state at $E_b = 0.2$ eV [103], while a second photon of the same energy liberates the excited electron. Figure 9.11 shows the resonant spectra of $n = 1$ and the observed widths as a function of temperature. Above 450 K, an exponential growth of the spectral width is observed. Based on this temperature dependence, an activation energy of about $E_a = 130$ meV was derived, this again being in agreement with the creation of kinks at step edges.

9.5
Volume Excitation in Metallic Nanostructures Investigated by TR-PEEM

The potential of TR-PEEM as a versatile tool for mapping the electron dynamics of metallic nanoparticles was introduced by Schmidt *et al.* [13]. Figure 9.12a shows the investigated lifetime map of a patterned silver film (hexagon-shaped patches) on a silicon substrate. The mapped color variations correspond to a change in the full-width half-maximum (FWHM) of the correlation trace for each pixel, which becomes more evident from a statistical analysis (histogram) of the investigated regions, as shown in Figure 9.12b.

Figure 9.13a shows a PEEM image of a Ag nanoparticle array (as shown in Figure 9.8b) at resonance excitations. The 400 nm laser light used for the TR-2PPE experiment couples almost resonantly to the in-plane mode of the particle. The 2PPE image shows distinct interparticle brightness variations which are dominated by defect-induced indirect transitions rather than by differences in the collective electron response [104]. Although the properties of the particles' plasmon resonances are not affected by this, they must of course be included in the analysis of the time-resolved data. The lifetime map, as shown in Figure 9.13b, visualizes the lateral

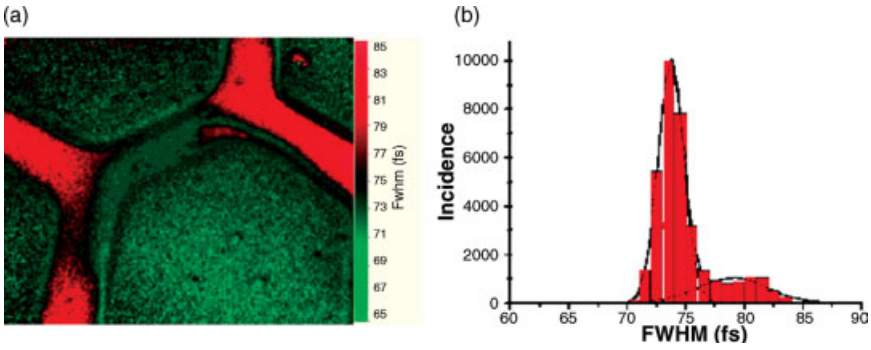

Figure 9.12 (a) Lifetime map of a hexagonal silver nanoparticle; (b) Lifetime map distribution showing a most probably value of 73.5 fs with a distribution width of ± 1.5 fs.

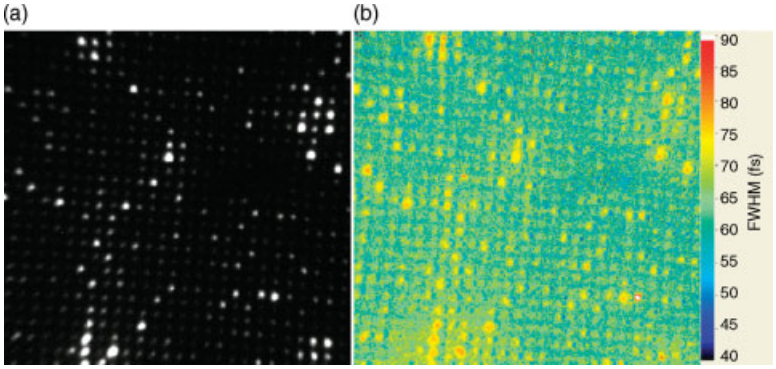

Figure 9.13 (a) PEEM image and (b) corresponding lifetime map of the nanostructure from Figure 9.8b. The FWHM of the autocorrelation curves ranges from 60 to 90 fs.

variations in the electron dynamics in color coding. Here, the red tones correspond to high FWHM values, indicating long decay times, while blue tones are associated with a faster decay. There is certain correlation between brightness in the 2PPE image and the FWHM values of the lifetime map: those particles which appear bright in the 2PPE image tend to exhibit longer average decay times in the lifetime image. This effect must obviously be related to the defect induced transitions. Whilst on the one hand the involved intermediate single-electron states give rise to a higher overall transition probability and a higher photoemission yield, on the other hand they show longer decay times.

The dynamic processes associated with a plasmon excitation in a single particle can be studied in further detail when the phase-resolved set-up is employed. The image

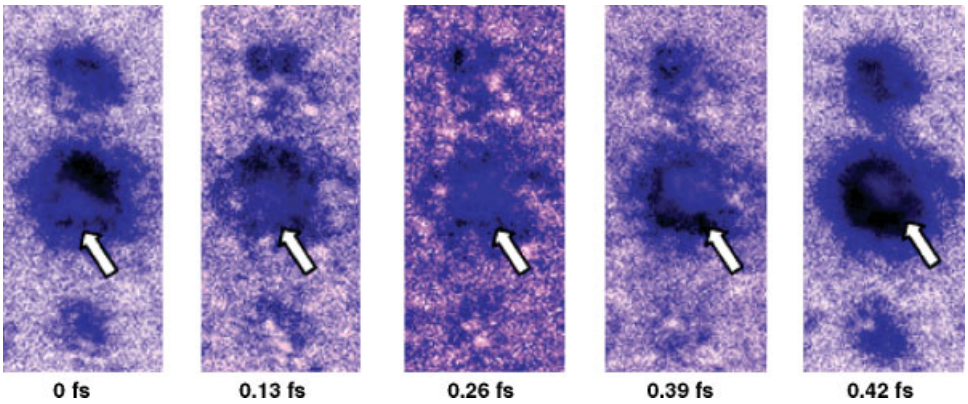

Figure 9.14 Spatiotemporal femtosecond dynamics of a silver nanoparticle with a diameter of 200 nm. A modulation of the lateral photoemission distribution as a function of phase delay between two identical exciting femtosecond laser pulses for 2PPE is observed. This is assigned to a phase propagation of a plasmon through the nanoparticle.

sequence in Figure 9.14 shows the plasmon dynamics in a single particle, where the time interval between the two images is 0.13 fs. A clear variation in the contrast within the area of the nanoparticle in the sub-femtosecond time scale is detectable. The result can be explained in the following way: The electric field amplitude is determined by the phase delay $\Delta\varphi(\tau)$ between the pump and the probe laser pulse, as adjusted by the Mach–Zehnder interferometer, as well as the polarization field of the particle plasmon which is oscillating at its resonance frequency. Due to oblique incidence from the right, the laser light would be expected to couple first to the LSP-mode at the right edge of the particle. Here, the external (laser) field and internal (plasmon) field attain a fixed phase relation. As the propagation velocity of the external and internal fields vary, a position-dependent phase lag between the two field components is acquired as the plasmon excitation travels through the particle. The particle internal structure visible in a single PEEM image of Figure 9.14 is a residual of the varying interference between the external light field and the particle internal LSP-field, directly connected to the plasmon phase. The parallel data acquisition by the PEEM allows any systematic errors to be excluded.

These results are in good agreement with the findings by Kubo *et al.* [105, 106], who also combined ultrafast laser spectroscopy and electron microscopy in order to image the quantum interference of localized surface plasmon polariton (SPP) waves with sub-wavelength spatial resolution and sub-femtosecond temporal precision. The sample used was based on a 400 nm-thick silver film perforated by an array of 100 nm-wide slits with a period of 780 nm. This approach resulted in a silver grating, which had the properties of an optical band-pass transmission filter. The polycrystalline grating creates nanoscale roughness, in which localized plasmon modes can be excited. So, by scanning the time delay between identical, phase-correlated pump and probe pulses in 174 optical cycle steps, and recording the resulting change in the polarization interference pattern, a movie of the SPP propagation wave packet at the Ag–vacuum interface can be created, as shown in Figure 9.15. As the driving pulse wanes, the coherent polarization excited at each dot shifts to its own resonant frequency. For instance, as shown in Figure 9.16, the phase of dots A, B and D (dot C) is retarded (advanced), causing the intensity maxima to rise later (sooner) with respect to the phase of the driving field. The circled hotspots in Figure 9.15 indicate the change in the intensity maxima (constructive interference) in five cycle intervals due to the phase slip of the surface plasmon modes with respect to the driving field.

The SPP wave packet propagation length – and hence coherent control studies – can be improved by using single-crystal nanostructures, as demonstrated by L.I. Chelaru *et al.* [107]. Figure 9.17 shows an example of the appearance of SPP waves in Ag single-crystal particles that were formed by self-assembly [108]. In Figure 9.17a, a SPP wave is started at the marked edge of the triangular island, and travels across the island during the time of observation. The striped pattern on the otherwise dark islands is a representation of the SPP wave by means of a beat pattern formed between the propagating plasmon wave and the laser pulse used to probe the structure [109]. Modulation of the local near-field in the surrounding of the island is caused by diffraction of the laser pulse. In Figure 9.17b, the two independent SPP waves are created at the edges of a hexagonal Ag island. The SPP waves superpose,

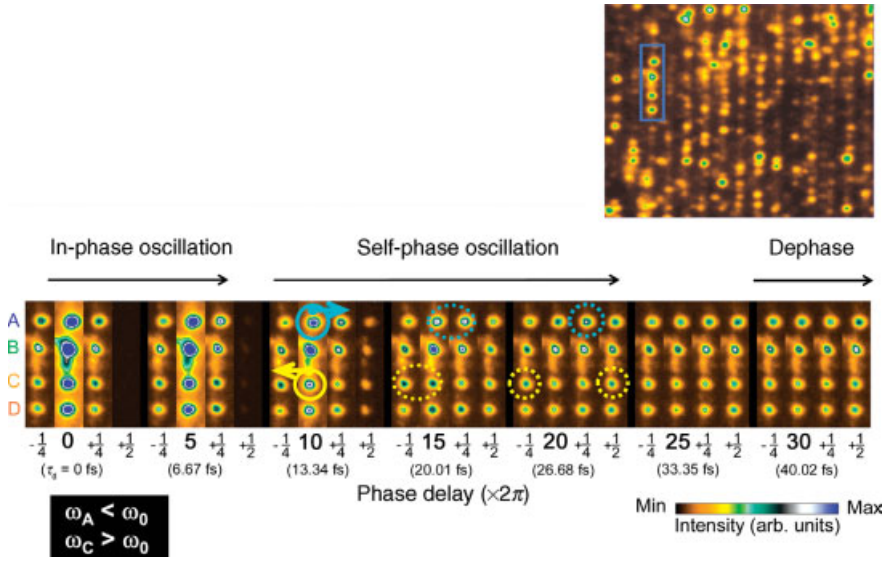

Figure 9.15 Interferometric TR-PEEM image of four localized surface plasmons on a Ag grating. The delay time between pump and probe pulses is advanced from −0.33 fs to + 40.69 fs in π/2 steps (0.33 fs) of the carrier wavelength of 400 nm. During excitation (up to 5½ × 2π) all dots oscillate in phase; later the phase in dots A, B and D is retarded, but in dot C it is advanced compared to the exciting laser field. (Reproduced from Ref. [105].)

modulate the overall local electric field, and are reflected at the end of the structure. This is different in panel Figure 9.17c, where the angle between the two overlapping SPPs is smaller and the modulation of the electric field strength is much more pronounced. The field strength at the edge of the particle is strongly modulated and

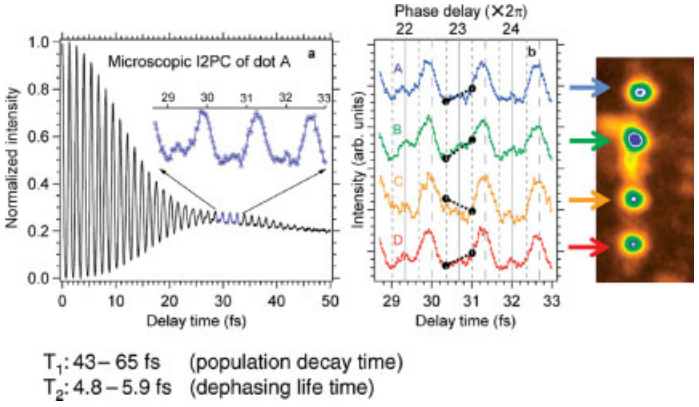

Figure 9.16 Phase slip between the LSP and the advancing light field of dots A to D in Figure 9.15. (From Ref. [105].)

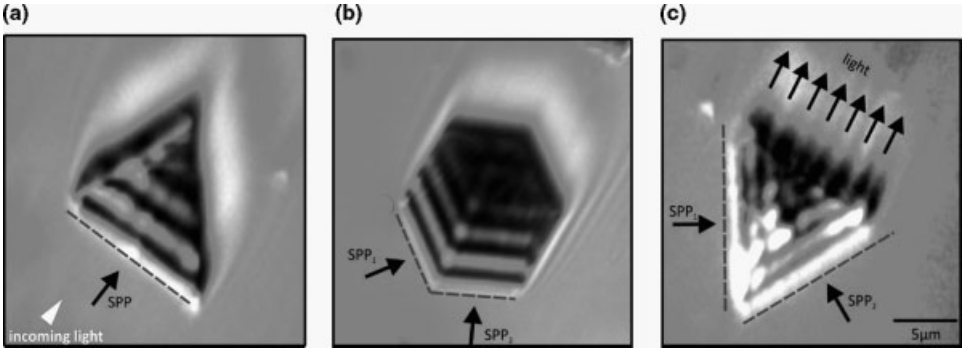

Figure 9.17 SPP waves on silber islands observed by PEEM illuminated under $\theta = 75^{\circ}$. (a) Triangular shape; (b) Hexagonal islands with SPP interferences; (c) Interference between two SPP waves where the island acts as beam splitter for the SSP wave. The scale bar represents 5 µm. (From Ref. [108].)

the SPP is converted back into light only at those positions where the field strength is particularly high. Ultimately, the island in panel Figure 9.17c acts as a beam-splitter. For particles such as those shown in Figure 9.17, propagation of the plasmon with ~60% of the speed of light is observed as a systematic shift of the beat pattern as a function of the delay time between pump pulse and probe pulse [106].

9.6 Long-Lived Resonances in Adsorbate/Substrate Systems

Adsorbate atoms may not only serve as general scattering centers on well-prepared surfaces but also shorten the lifetime of well-defined surface states. When the electrons do scatter resonantly into unoccupied states of adsorbates, or when such states are directly optically excited, the lifetimes may be significantly prolonged compared to those expected from a simple Drude or Fermi liquid picture for electrons at the same excitation energy. A prominent example is the adsorption of alkali atoms on noble metal surfaces. In the low coverage limit an adsorbate-induced antibonding (A) state around 2.5–3 eV above Fermi is found on noble metals. The experimentally observed relatively long lifetimes of excited adsorbate states of up to 50 fs at low temperatures for Cu(111) [110, 111] and Ag(111) [112, 113] have initiated a number of theoretical investigations of this effect.

Although the decay of such states could, in principle, be viewed as a one-electron resonant charge transfer, which would yield very short lifetimes in the sub-femtosecond regime, the directional band gap at these surfaces hinders a fast decay, because the overlap of the state with bulk wave functions is small. With one-electron wave packet propagation calculations this reasoning could be supported [114–117]. Figure 9.18 shows the differences of the wave packet propagation for the Cs 6s state adsorbed on a jellium and a Cu(111) surface. Initially, the wave packet propagates in

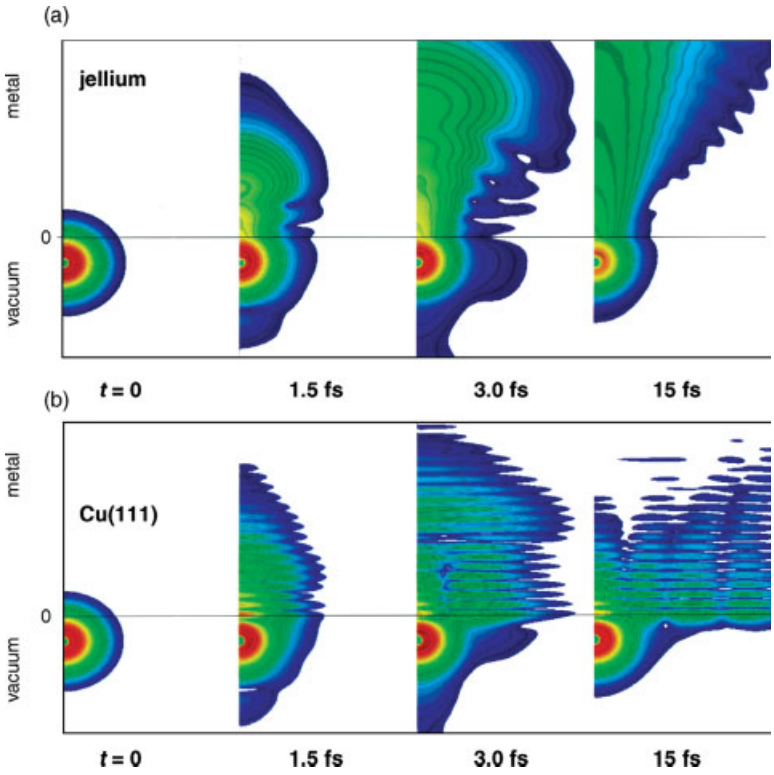

Figure 9.18 Dynamics of the Cs (6s) wave packet excited in front of (a) a jellium and (b) a Cu(111) surface. The Cs atom is placed at z = 10 a.u. from the image plane. A propagation along the surface normal into the bulk initially observed for both substrates continues only for the jellium surface. For Cu(111), propagation stops after only 3 fs, followed by a propagation in a high-$\vec{k}_{||}$ direction along the surface. A high intensity of the 6s wave packet remains in the vicinity of the surface. (After Ref. [114].)

both cases into the bulk. On jellium (Figure 9.18a), this propagation continues with minimal lateral spreading of the wave packet, but on Cu(111) (Figure 9.18b) the movement of the wave packet into the bulk has come to a halt after only 3 fs, followed by a propagation in high-$\vec{k}_{||}$ directions parallel to the surface, with the highest intensity remaining in the vicinity of the surface. Such behavior causes a relatively long resonance lifetime. Whilst these long-lived states were unexpected in the adsorbate/substrate systems, an understanding of the origin of long-lived states has opened some extremely interesting new possibilities towards the control of reactions at surfaces. Then, other processes may also come into play, including inelastic e–e scattering with bulk electrons, where the adsorbate atom begins to move on the new electronically excited potential energy surface. The excited electron then couples to the nuclear motion, and processes as in DIET or DIMET become important [118]. This type of motion has been observed directly and spectroscopically using TR-2PPE [119].

By taking into account the bandwidth of the ultrashort laser pulse and the nuclear motion of the adsorbate after excitation, an excellent agreement between experimental and theoretical lifetimes of the excited state for all alkalis studied has been achieved [114–117]. In differing from many other antibonding states of adsorbate/substrate systems, for the alkalis on noble metal surfaces this state can be populated by a direct dipole-allowed transition from the occupied surface state, also located in the same directional bandgap. This provides the opportunity to initiate the excitation with temporally and spectrally shaped pulses in order to control the desorption process [120]. For excitation laser pulses shorter than the lifetime of the excited A state, a complete population transfer to the A state can be achieved when dissipation is neglected. Including dissipation, the populations transfer falls to about 40% for a Gaussian pulse of 20 fs duration and a peak intensity of 0.5 TW cm^{-2}, while for an optimal pulse shape a transfer of 95% can still be achieved. In the case of longer and less intense pulses, the optimally controlled pulses are even more successful. Using again 20 fs-long Gaussian pulses, but now at only 10^{10} W cm^{-2} (which represents an experimentally feasible intensity at metal surfaces), only 3% population transfer is to be expected (in theory). For controlled pulses of 60 fs duration – that is, much longer than the lifetime of the A state – a transfer of 75% may still be achieved. In the control cases pulses are used which show the highest intensities at the extreme end of the pulse, although it will be difficult to produce such pulses experimentally. Nevertheless, even when taking the nuclear motion of the Cs atom on the excited potential into account, the use of shaped pulses might lead to an increased yield also for dissipative surface reactions.

With organic adsorbates, modified and new properties of nanostructures are obtained, the aim being to create functional materials in a controlled manner [121]. The organic constituents of such adsorbate layers provide a wide variability in the desired properties, which may range from sensor and molecular recognition to molecular electronics, photo-switches and molecular magnets. In most of these envisioned applications a nanostructured assembly of the functional materials is necessary. Many of the systems' properties rely on an heterogeneous electron transfer between the adsorbate and substrate and, in the case of sensor or recognition devices, between the active layer and the incoming molecules. The dynamic properties of these organic adsorbate films are therefore of fundamental interest for such functional materials.

Basic investigations of the action of alkane layers on the electronic properties of the underlying metals, as well as the electron localization in organic overlayers, have been carried out by Harris and coworkers [122, 123]. In the context of this chapter, the photo-induced electron transfer dynamics from (self-) organized and specifically bound organic molecules are of particular interest, because here the dynamics can be probed directly in the time domain. These processes also relate to light-harvesting applications, either for reactions or for the direct production of an electrical current.

Willig and coworkers investigated the influence of various anchor groups between a perylene-derived chromophore and the (110) surface of rutile TiO_2 on electron transfer [124]. These anchor groups were seen to serve two purposes: (i) to separate the electronic states of the chromophore and the solid surface; and (ii) to enable a

control of the electronic coupling strength between both systems. The anchor groups also stabilize the complex and provide the option of definite binding angles and sites. The electron transfer is initiated by a direct femtosecond laser excitation of the singlet state of the chromophore. In the case of one conjugate anchor group – acrylic acid, which may be viewed as a molecular wire – the electron transfer time is found to be about fourfold faster ($\tau \sim 13.5$ fs) than for an insulating group of the same length, propionic acid, which acts as a tunneling barrier. For an even wider barrier which consists of a three-ring structure, where the central ring is aliphatic and rigid, the transfer times are prolonged to tenfold that of the first type [124].

When the electron transfer time is short – which can be achieved by directly binding the organic molecule to the substrate – the electron migration inside the substrate can be monitored using TR-2PPE. The experimentally observed times for the electron to escape from the surface layers (or, more specifically, from the detection depth of 2PPE) agrees well with rates obtained from density functional theory (DFT) calculations for alizarin adsorbates [125]. For the system investigated, it turned out that in rutile the energy does not relax on a 200 fs time scale, which is tentatively assigned to the population of new interface states created as the bonds with the organic adsorbates are formed. Such electron escape to the bulk states of a substrate is important in terms of the total energy transfer from an organic adsorbate to unoccupied states of a solid. When this process is rapid, charge conduction across the interface is favored; however, when it is slow an accumulation of charge in excited states of the organic adsorbate, with the possibility of a radiative deactivation, may occur.

A somewhat unexpected feature of organic adsorbates derives from the existence of very long-lived triplet states with lifetimes in the microsecond range. As yet, such states have not been identified for small inorganic adsorbates or for bare surfaces. Here, the dynamics in unoccupied states of ordered C_{60} on metal surfaces will be discussed as a specific example of an organic adsorbate. Due to the large work function of C_{60} of 6.8 eV above the highest occupied molecular orbital (HOMO), and depending on the work function of the metal, the lowest unoccupied molecular orbital (LUMO) state of the first C_{60} ML may be either below or above the metal Fermi level. Therefore, the character of the C_{60} film may be either metallic or semiconducting [126]. For thicker layers above about 5 ML the properties of C_{60} crystals are generally assumed, in which the interaction energies of the individual C_{60} constituents are comparatively weak. Hence, the properties of the film resemble those of the C_{60} clusters. Such layer dependency already provides the possibility of tuning the properties of a functional film, whilst in addition a substitution at a C–C bond by functional groups enables further variability [127, 128].

The symmetry properties of C_{60} allow optical transitions from the HOMO to the LUMO + 1, and from the HOMO-1 to the LUMO states – which are actually comparatively broad bands rather than sharply defined single states. With the third harmonic of a Nd-laser at photon energies of about $h\nu = 3.5$ eV ($\lambda \sim 355$ nm), a direct excitation via both transitions is possible. The population both in these states and in the energetically lower lying excitonic states, which are populated via internal energy transfer, can be probed with the fifth harmonic of a Nd-laser at 210 nm ($h\nu \sim 5.88$ eV).

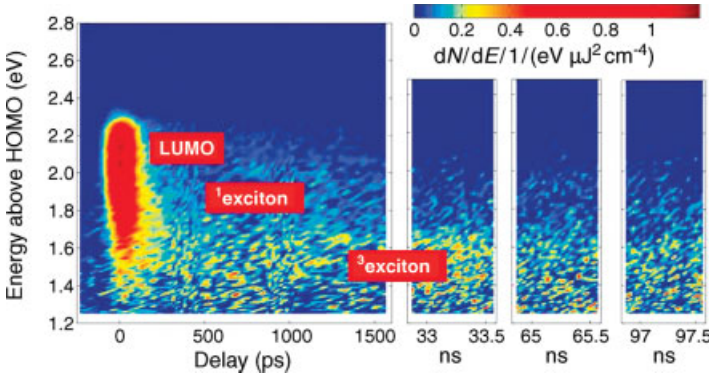

Figure 9.19 2-D lifetime plot for the LUMO, ^{1}exciton, and ^{3}exciton states on C_{60} up to a delay time of 100 ns. On this time scale the intensity of the ^{3}exciton decreases only marginally.

This second photon has insufficient energy to directly emit photoelectrons from the HOMO state. Figure 9.19 shows, in a 2-D plot, the kinetic energy distribution of emitted photoelectrons as a function of time delay between a pump and a probe laser pulse. In this case, the LUMO state has been directly populated in a dipole-forbidden transition, and it is evident that, besides the LUMO, lower-lying states are populated. Even for delay times exceeding 100 ns after pumping a signal intensity is observed for these energetically lower states. This long-lived state is assigned as a signature of the triplet exciton. In energetic terms, the singlet exciton is identified somewhat higher and below the directly excited LUMO.

An analysis of the intensity dependence at certain kinetic energies revealed for the LUMO a lifetime of about 84 ps – shorter than a previously reported value of 134 ps [129]. For the singlet exciton a lifetime of about 1050 ps was found, and was in good agreement with earlier reports [129]. In order to measure the lifetime of triplet excitons a second pump laser was used such that the probe laser could be electronically delayed with respect to the pumping laser. For these states, lifetimes between 22 μs for free and up to 200 μs for bound excitons were observed, depending also on the thickness of the C_{60} film (A. Rosenfeldt, B. Göhler and H. Zacharias, unpublished results). This was significantly longer than had been observed for a photo-polymerized C_{60} film [130], and in good agreement with lifetimes of these states in solution [131]. When the density of triplet excitons becomes high, the comparatively fast (spin-allowed) process of triplet–triplet annihilation can be observed (Figure 9.20).

It should be noted that these longlived states may be chemically active. Following the adsorption of NO molecules onto a thick, ordered C_{60} film, UV laser excitation of the system led to a desorption of the NO, with delay times of up to 200–400 μs after pumping. An analysis which yielded a chemically active state with a decay time of about 160 μs [132] was recently confirmed by directly measuring the velocity of the late-arriving molecules. Their velocity was found to be much greater than the corresponding arrival time at the detecting laser, which meant that these molecules

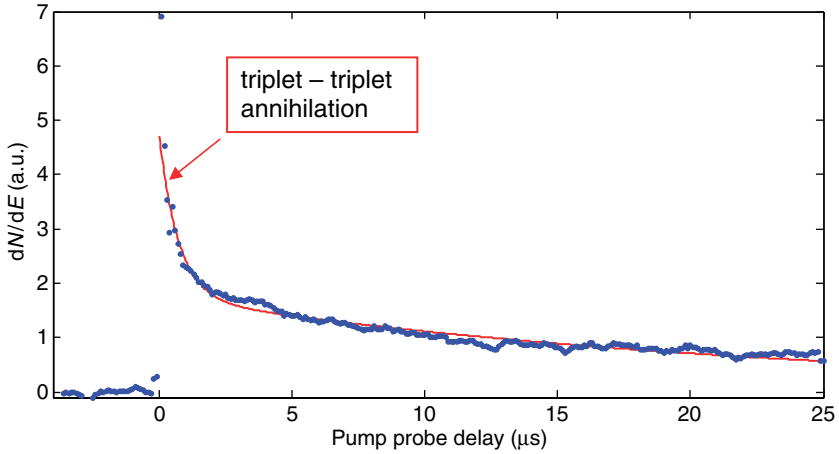

Figure 9.20 Lifetime of a C_{60} triplet excitonic state with $\tau = 22\,\mu s$ in a 14 ML film. Also indicated is an exciton–exciton annihilation occurring on a time scale of 720 ns.

were not desorbed promptly but rather at a later time (T. Hoger *et al.* unpublished results). Hence, these excitonic states in organic thin films may serve as efficient energy reservoirs for photochemical activity and reactions [133].

9.7 Outlook: Spatial and Temporal Control of Nano-Optical Fields

The optical response of nanostructures creates a variety of fascinating properties, including sub-wavelength variation of the field, local field enhancement and local fields with vector components perpendicular to those of the incident field. Moreover, the combination of ultrafast laser spectroscopy (i.e. illumination with broadband coherent light sources) and near-field optics continue to open new realms for nonlinear optics on the nanoscale. As an example, the spectral phase of the incident light will influence the peak intensity of the local field distribution [134], thus providing a means to manipulate the nonlinear response of a nanostructure. More recently, it has been shown theoretically that the interaction of polarization-shaped laser pulses with a nanostructure allows the simultaneous control of spatial and temporal evolution of the optical near-field distribution [135].

A first step towards the experimental demonstration of simultaneous spatial and temporal field control used adaptive control, combining multi-parameter pulse shaping with a learning algorithm, and demonstrated the generation of user-specified optical near-field distributions in an optimal and flexible fashion. Shaping of the polarization of the laser pulse provides a particularly efficient and versatile nano-optical manipulation method [136]. Additionally, pump-probe sequences can be generated, in which excitations occur not only at different times but also at different

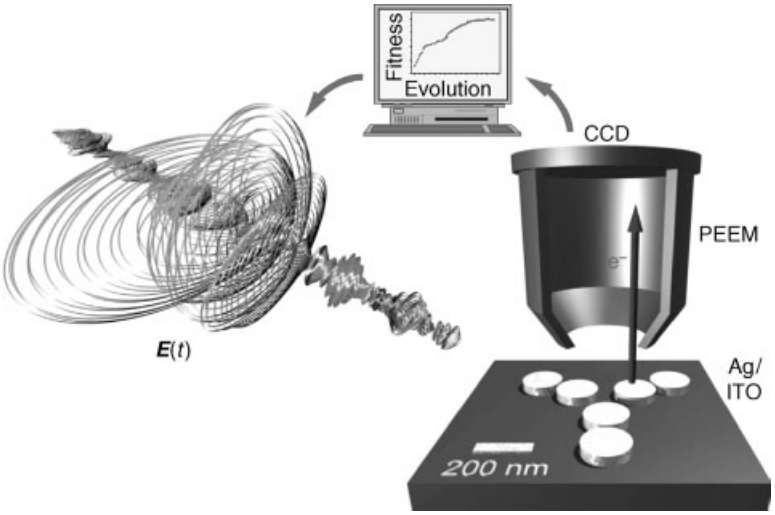

Figure 9.21 Experimental set-up for applying polarization-shaped femtosecond pulses to a nanostructure. A PEEM was used to measure the 2PPE signal.

positions that are separated by less than the diffraction limit. This in turn opens a route towards space–time-resolved spectroscopy with potential for the direct observation of nanoscopic energy or electron transport [135]. In a first experiment [137], femtosecond polarization shaping, adaptive optimization and two-photon PEEM were combined (see Figure 9.21). The pulse shaper contains a two-layer, 128-element liquid crystal display (LCD) spatial light modulator in the Fourier plane of a zero-dispersion compressor in folded 4f configuration [136]. Each LCD layer modulates the spectral phase of one of the two transverse polarization components, leading to a spectral variation of polarization state and phase. Hence, in the time domain the intensity, instantaneous oscillation frequency and polarization state (elliptical eccentricity and orientation) can be controlled to vary within a single laser pulse. Pulse-shape optimization occurs for both LCD layers independently. The data in Figure 9.22 show that adaptive polarization pulse shaping allows the optimization of a particular emission pattern. In Figure 9.22b and c, the ratio A/B between the emission yields integrated over the two rectangles A and B was optimized using an evolutionary algorithm. The experimental results showed that the local interference of the optical near-fields generated by the two orthogonal incident polarization components could be utilized to manipulate the local field distribution.

Currently, in these experiments two-photon PEEM is used to qualitatively monitor the local field distribution, with the interpretation of the acquired images being based on the assumption that the highest local field intensity will produce the highest photoemission yield in a 2PPE process. However, this yield is influenced by additional parameters such as the intermediate state lifetime in the metal, or the field component perpendicular to the surface. A detailed modeling of the emission process, together with a comparison with the experimentally observed emission

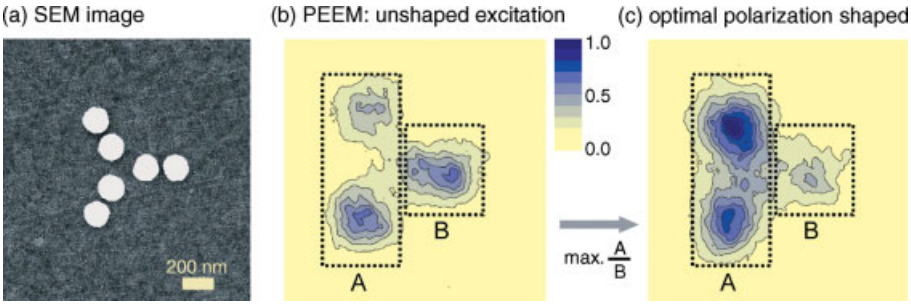

Figure 9.22 Control of nanoscopic photoelectron emission. (a) Scanning electron microscopy image of a single nanostructure; (b) An unshaped laser pulse is used as a reference; (c) Maximization of the integrated emission ratio A/B by optimal polarization shaping leads to emission patterns that exhibit a high contrast between region A versus region B. Hence, the photoelectron emission can be controlled experimentally on a nanoscopic length scale.

pattern, should provide an improved understanding of two-photon photoemission from nanostructured objects.

Acknowledgments

The authors enjoyed fruitful and stimulating discussions and support with and by many colleagues, notably E.V. Chulkov and P.M. Echenique (San Sebastian), J. P. Gauyacq (Paris), F.-J. Meyer zu Heringdorf (Duisburg), W. Pfeiffer (Bielefeld) and M. Bauer (Kiel). They also wish to thank their coworkers and graduate students. Financial support from the Deutsche Forschungsgemeinschaft via the priority programs SPP 1093 'Dynamics of electron transfer processes at interfaces', through projects Za 110/21 and AE 19/3, and SPP 1153 'Cluster in contact with surfaces' through project AE 19/12, is gratefully acknowledged.

Nanoplasmonics

Gerald Steiner

10.1
Introduction

The basic foundation of nanoplasmonic involves interactions between light and metal particles. Such particles, which are often referred to as *clusters*, have been the subject of a large number of investigations. Gustav Mie's theory about the study of optical properties of small gold particles, published in 1908, was the starting point for the new field of plasmonics. During the past half-century the nature of interactions between photons and electrons in metal clusters has been the focus of many research fields, including not only physics but also chemistry, materials science, medicine, biology and the environmental sciences. Clearly, metal cluster photonics is important in many fields, even in nanotechnology. Although the term 'cluster' is often used for a number of unspecified particles, there is no precise definition of a cluster. Hence, in this chapter clusters are defined as particles composed of a certain number of atoms that form a spherical or elliptical particle with the dimension in the range between 5 and 100 nm, corresponding to $500 \ldots 10^7$ atoms. The range from single atoms to bulk material is illustrated in Figure 10.1. It should be noted, that some publications use the term cluster just for very small clusters consisting of less than 100 atoms. The defined cluster region covers a rather wide range in relation to their optical properties. Metal clusters are subjected to variations not only in size but also in shape (some frequently identified forms are shown in Figure 10.2), but they are rarely spherical. In particular, clusters adsorbed onto a surface are ellipsoid in shape. Nanorods are tiny rod-shaped particles, less than 100 nm in diameter, but often with a length in excess of a few micrometers. The advantage of nanorods lies in their high aspect ratio (the ratio of length to diameter), as this permits them to show certain properties not seen with spherical or elliptical clusters. The optical properties of metal clusters depend heavily on the shape, the environment of the cluster, and the type of metal. Nonetheless, the two general features of all clusters are their ability to interact with light and to produce a localized electromagnetic field, the details of which are discussed in the following sections [1–3].

10.2 Single Clusters

In general, the description of the interaction between light and metal clusters is obtained by the solution of Maxwell's equation and imposing the boundary conditions. A simple approach to understand the optical response of metal clusters is to consider the free electrons. The positive charges are assumed to be immobile; then, if the cluster is illuminated by light the electric vector of the light wave will displace the free electrons. Under consideration of the boundary condition the cluster exhibits polarization; this effect is illustrated in Figure 10.3.

The internal field E_i of a spherical cluster is given by

$$E_i = E_0 \frac{3\varepsilon_1}{(\varepsilon r_{Cl} + \varepsilon i_{Cl}) + 2\varepsilon_1} \tag{10.1}$$

where E_0 is the electric field of the incident light. The dielectric function of the cluster material is given by the real part εr_{Cl} and the imaginary part $\varepsilon i_{Cl.}$ The surrounding

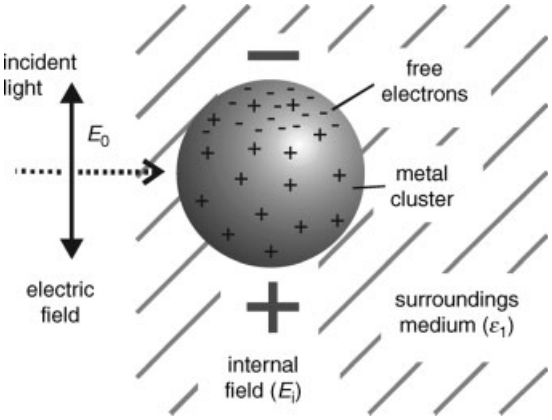

Figure 10.3 Polarization of a metal cluster caused by the electric vector of the incident light wave.

medium is characterized by the dielectric function ε_1. An important parameter is the static polarizability α of the cluster

$$\alpha = 4\pi\varepsilon_0 d^3 \frac{(\varepsilon r_{Cl} + \varepsilon i_{Cl}) - \varepsilon_1}{(\varepsilon r_{Cl} + \varepsilon i_{Cl}) + 2\varepsilon_1} \tag{10.2}$$

with the cluster diameter d. Unfortunately, this solution describes only static conditions. If the cluster is placed in an electromagnetic field, the free electrons will move inside the metal cluster with frequency of the external field. The excitation of the free electrons leads to an internal field. In this case, the dielectric constants must be replaced by their frequency-dependent values. As the magnetic fields do not occur, the complex dielectric function (ε_{Cl}) must be replaced with the frequency-dependent values:

$$\bar{\varepsilon}_{Cl} = \bar{\varepsilon}_{Cl}(\omega) \tag{10.3}$$

where ω is the angular frequency of the incident light wave.

The internal electric field shows a resonance when

$$|\varepsilon r_{Cl}(\omega) + 2\varepsilon_1|^2 + |\varepsilon i_{Cl}(\omega)|^2 = \min \tag{10.4}$$

This means that, in a spherical cluster, the resonance frequency is found by the relationship

$$\varepsilon r_{Cl}(\omega) = -2\varepsilon_1 \tag{10.5}$$

The real part of the dielectric function can be also expressed by the relationship

$$\varepsilon r_{Cl} \approx 1 - \frac{\omega_P^2}{\omega^2} \tag{10.6}$$

where is ω_P the Drude plasma frequency. Consequently, the resonance frequency ω_R of a spherical cluster is given by

$$\omega_R = \frac{\omega_P}{\sqrt{2\varepsilon_1 + 1}} \tag{10.7}$$

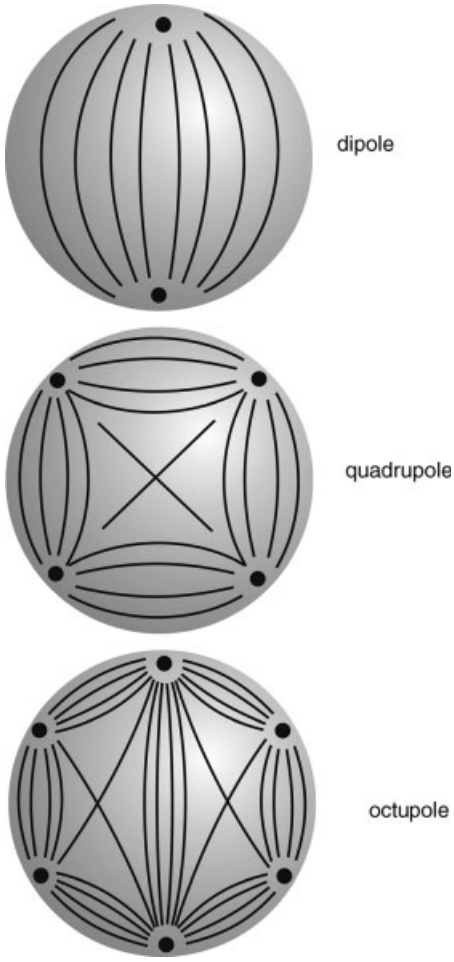

Figure 10.4 Excitation of multipoles within a metal cluster.

A metallic cluster exhibits not only a distinct dipole but also a quadrupole and higher multipole, as depicted in Figure 10.4. The excitation of these dipoles is dependent on the size, the shape and the type of metal, as well as on the wavelength of the incident light. The internal field at the resonance frequency, where the free electrons exhibit a strong collective oscillation, is known as the *surface plasmon*. This term is normally used to describe the excitations at a metal surface, whereas the plasmons in a metal cluster are localized and are thus referred to *localized surface plasmons*. One consequence of the internal field is that there is a strong electromagnetic field in the proximity of the cluster, as shown in Figure 10.5. It should be noted that the term 'localized surface plasmons' also describes the resulting external field of the cluster. As mentioned above, the spectral position of the localized surface

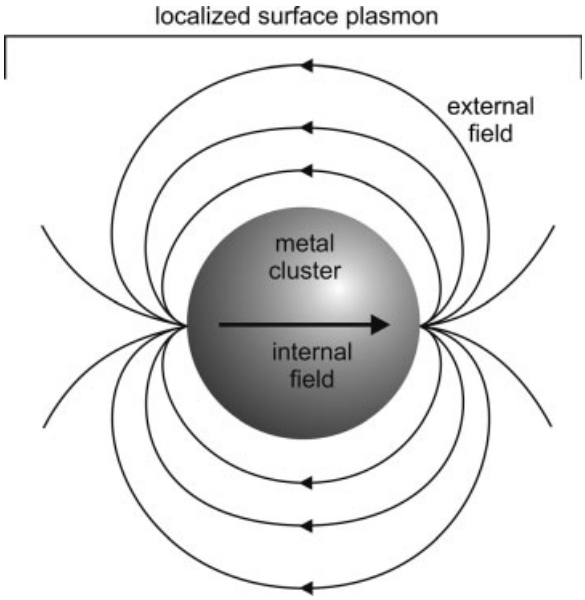

Figure 10.5 The excitation of an internal field causes a strong electromagnetic field around the cluster.

plasmons is dependent on the size, shape and metal type of the cluster, and the dielectric function of the surrounding medium. As an example, Figure 10.6 illustrates the effect of cluster size on the spectral position of the resonance for a gold cluster placed on a glass slide. For larger clusters, higher-order multipoles become important, and this results in a more pronounced shift of the localized surface plasmon resonance (SPR) as the particle size increases. In addition, the position and shape of the resonance are also dependent on dielectric function of the surrounding medium [3–6].

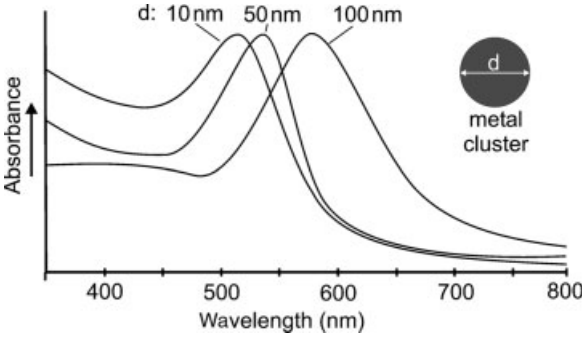

Figure 10.6 Calculated absorbance spectra of a single spherical gold cluster with different sizes.

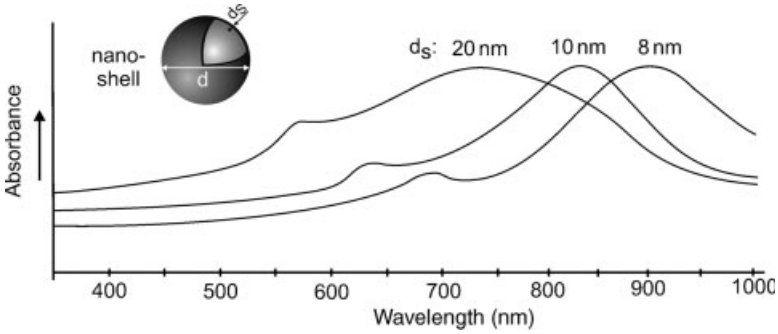

Figure 10.7 Absorbance spectra of nanoshells consisting of a glass core and gold shell.

10.3 Nanoshells

A nanoshell contains different materials in the core and shell. Often, the core material is metallic while the shell forms a thin dielectric layer, and in this case the localized SPR is affected by the shell. When the dielectric constant or the thickness of the shell is changed, however, the resonance conditions are also changed. For example, when the shell material is metallic and the core is a dielectric material, the change in SPR can be dramatic, with the spectral position of the resonance being shifted to longer wavelengths than those in the corresponding solid metal cluster. The same effect occurs when the metal shell thickness is decreased. The calculated absorbance spectra for nanoshells consisting of a glass core and a thin gold shell are shown in Figure 10.7. These nanoshells serve as the main component of many applications in biosensing and semiconducting [2, 7].

10.4 Layer of Clusters

When clusters become closer to each other, the electromagnetic field causes an electromagnetic coupling between the individual units [8]. One simple way to describe this coupling is with a system of two interacting dipolar oscillators, when two principal situations are possible: (i) the orientation of the cluster dipole is in the *same direction*; or (ii) the orientation is in the *opposite direction*. These two configurations are illustrated in Figure 10.8. In the case of perpendicular orientation (Figure 10.8a), the internal dipole vectors have a different polarization, whereas for parallel orientation (Figure 10.8b) the internal dipole vectors exhibit the same polarization. If both dipoles are excited together with the same polarization, then the resulting field is enhanced. In the case of perpendicular orientation when both clusters are excited together, but with different polarization, the resulting field will be weaker – a fact which has a major influence on the spectral position of the SPR. Although the interaction between clusters is also determined by the cluster size and

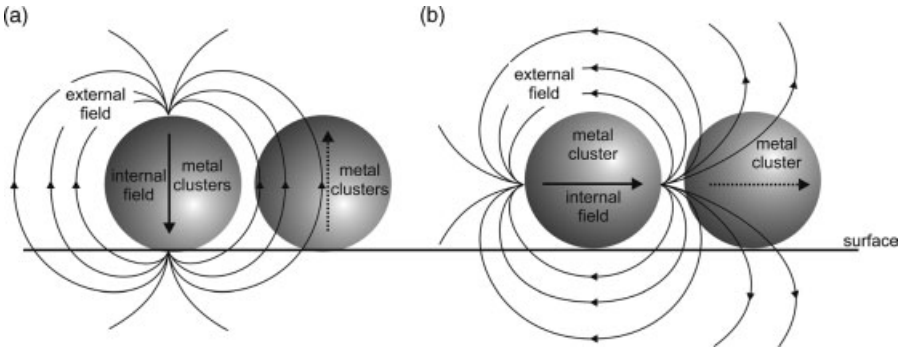

Figure 10.8 Electromagnetic coupling between two clusters.
(a) Different polarization; (b) Similar polarization.

distance, as well as by the optical properties of the medium between the clusters, the most critical parameter is polarization of the localized surface plasmons. To illustrate this fact, Figure 10.9 shows the absorbance spectra of two identical gold clusters with the same and different polarizations of the localized surface plasmons. When the

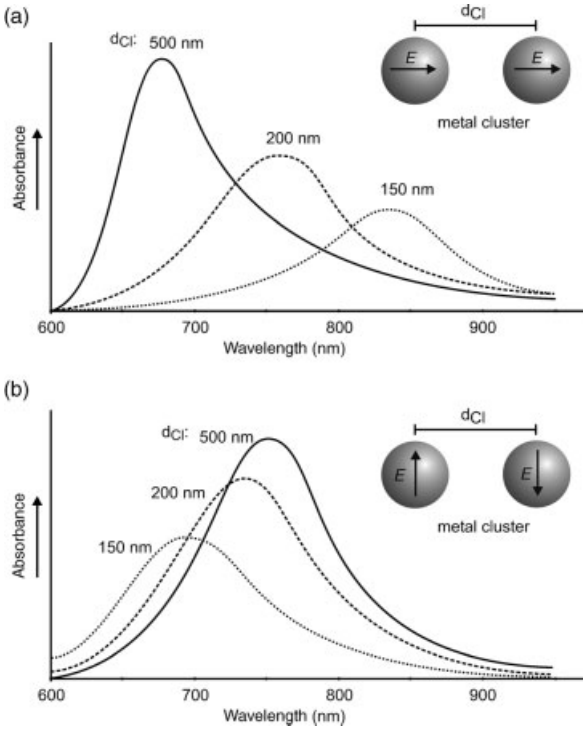

Figure 10.9 Calculated absorbance spectra for two gold clusters at a certain distance. (a) With the same polarization; (b) With different polarization.

internal field of the clusters exhibits the same polarization, the position of the SPR shifts towards longer wavelengths as the inter-cluster distance is increased. In the case of a different polarization a weak blue-shift occurs when the inter-cluster distance is increased. This different optical response – which is also evident for more than two clusters – has major consequences on the sensitivity when a cluster film is used to enhance a weak optical signal. As the red-shift is much stronger than the blue-shift, the cluster that exhibits localized surface plasmons with the same polarization provides a higher sensitivity. A similar behavior can be observed when a cluster film is excited by light with a different polarization of the wave. The substantial difference in electromagnetic fields around clusters caused by an excitation with parallel and perpendicular polarized light is illustrated in Figure 10.10. The direction of the electric vector (E) of the exciting field is the critical parameter. The induced dipoles in the clusters have the same direction as the exciting field. In the case of a perpendicular orientation, E is oriented perpendicular to the surface. The induced dipoles in the clusters must then point in the same direction, and the fields around the clusters develop accordingly. Due to the parallel direction of the dipoles, almost no electric coupling can occur between clusters. However, the

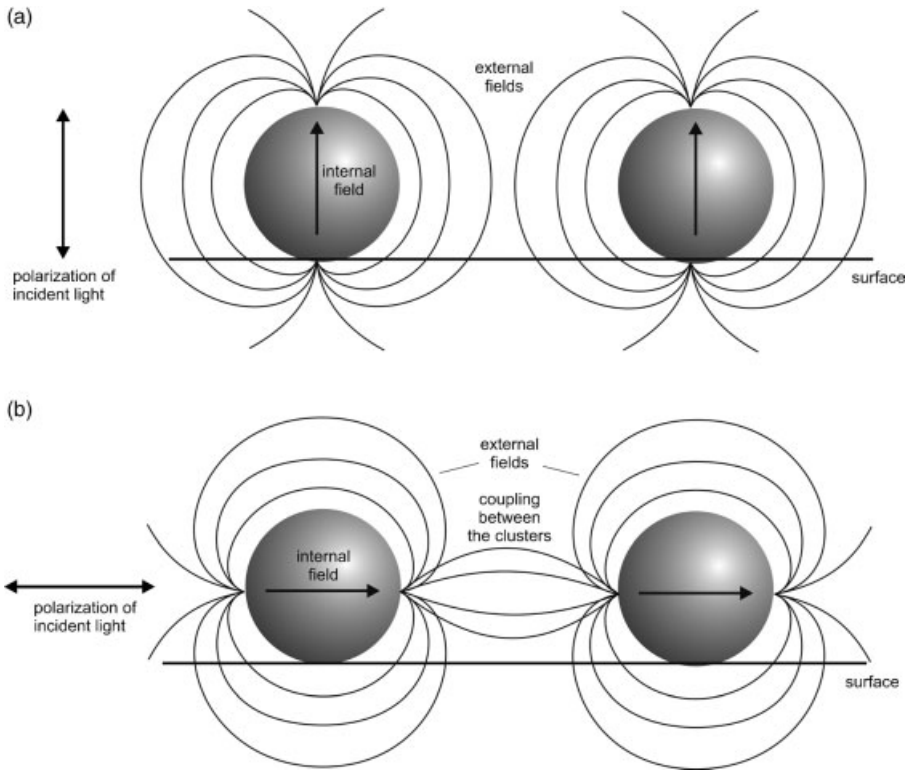

Figure 10.10 Excitation of localized surface plasmons in case of (a) perpendicular orientation and (b) parallel polarization of the incident light wave.

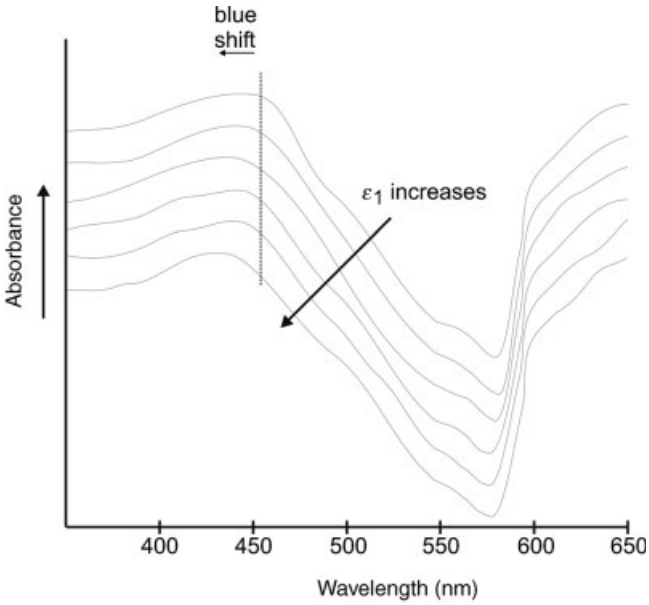

Figure 10.11 Absorbance spectra of a cluster layer for different refractive indices of the surrounding medium (ε_1), measured with unpolarized light.

situation changes dramatically when the orientation of E is parallel to the surface. Now, because of the induced dipoles, the field of the clusters will stretch both towards the substrates and towards the surrounding medium. The direction of the internal dipoles permits a powerful coupling between neighboring clusters, and only in this case will the position of the SPR shift when the refractive index of medium between the clusters changes. The absorbance spectra of cluster layers with different refractive indices of the surrounding medium are shown in Figure 10.11. Since coupling between the clusters occurs only at a parallel polarization of the electric field vector, a spectral shift of the SPR is observed only for parallel polarized light. Upon increasing the refractive index of the medium, however, the field coupling between metal clusters becomes stronger and the SPR shifts towards shorter wavelengths.

Although the optical analysis of cluster arrangements plays an important role, it is impossible to describe the optical properties by extending Equations (10.1) to 10.7 to an arrangement of thousands of clusters. In such a case, an effective medium theory must be applied. Such theories describe the connection and interaction *between* clusters, as well as with their surrounding medium, and provide the 'effective' optical behavior of a cluster arrangement (Figure 10.12).

Several different effective medium theories have been devised, each of which is more or less accurate depending on the cluster material, the size form and the distance between clusters. However, they all assume that the macroscopic material is homogeneous, and generally fail to predict the properties of a composite material.

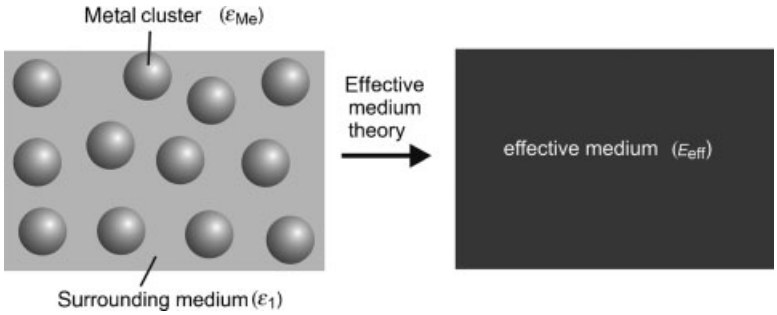

Figure 10.12 The transition from a macroscopically inhomogeneous medium to a homogeneous, optically effective medium.

Details of the three most frequently used effective medium models are summarized in Table 10.1 [9, 10].

The first application of an effective medium theory was made by Maxwell-Garnett to explain the color of a discontinuous metal film. The model was based on clusters which were assumed to be spheres in a host medium; this resulted in an effective dielectric function of the composite material. The *Maxwell-Garnett model* is valid at low volume fractions as it is assumed that the metal clusters are spatially separated. In contrast, the *Bruggeman model* does not distinguish between embedded metal clusters and matrix; rather, the two materials appear in a completely symmetric manner, and consequently the Bruggeman model can easily be extended to more than two components. Free structures of the embedded metal clusters and the matrix and a static treatment of the geometry are also possible using the Bergmann model. The spectral density $g(n,f)$ function (see Table 10.1) carries all of the geometric information and depends only on topology. As a result, the Bergmann model can be used to distinguish between geometric quantities and dielectric properties [11–13].

10.5 Surface-Enhanced Spectroscopy

10.5.1 Surface-Enhanced Raman Scattering

The effect of surface-enhanced Raman scattering (SERS) on small metal clusters has been recognized for more than 30 years. The Raman scattering of a molecule located in close proximity to the surface of a gold or silver cluster is 'enhanced' up to one million-fold. Such an enhancement effect is based on two principal mechanisms:

- The strong electric field of the localized surface plasmons interacts with the electron orbitals of the molecule, which leads to an enhancement of the Raman cross-section by up to four orders of magnitude.

Table 10.1 Most common effective medium model.

Model	Formula	Properties
Maxwell-Garnett	$\frac{\varepsilon_{\text{eff}}-\varepsilon_E}{\varepsilon_{\text{eff}}+2\varepsilon_E}=f_{\text{Me}}\frac{\varepsilon_{\text{Me}}-\varepsilon_E}{\varepsilon_{\text{Me}}+2\varepsilon_E}$ (f_{Me}: volume fraction of the metal clusters)	Suitable for uniform and spherical clusters with a relatively low volume fraction; computations are very efficient; describes poorly composite materials with high volume fraction of the metal clusters.
Bruggeman	$f_{\text{Me}}\frac{\varepsilon_{\text{Me}}-\varepsilon_{\text{eff}}}{\varepsilon_{\text{Me}}+2\varepsilon_{\text{eff}}}+(1-f_{\text{Me}})\frac{\varepsilon_E-\varepsilon_{\text{eff}}}{\varepsilon_E+2\varepsilon_{\text{eff}}}=0$	Self-consistent; provides a quite good correlation between theory and experiment also for higher volume fractions; the result can be a dielectric function of a higher polynomial.
Bergmann	$\varepsilon_{\text{eff}}=\varepsilon_E\left(1-f_{\text{Me}}\int_0^1\left(\frac{g(n,f_{\text{Me}})(\varepsilon_E-\varepsilon_{\text{Me}})}{\varepsilon_E-n(\varepsilon_E-\varepsilon_{\text{Me}})}\right)\mathrm{d}n\right)$ the zeroth and first moment of $g(n,f)$ are $\int_0^1 g(n,f_{\text{Me}})\mathrm{d}n=1\int_0^1 ng(n,f_{\text{Me}})\mathrm{d}n=\frac{1-f_{\text{Me}}}{3}$	Best approximation of composite materials; percolations of the cluster are considered; computations are more complex.

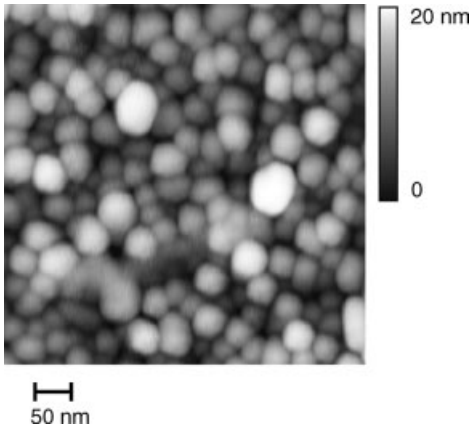

Figure 10.13 Atomic force microscopy image of a silver cluster layer, prepared by evaporation onto a smooth silicon wafer.

- The second effect is related to charge transfer processes; such a chemical interaction may cause an additional enhancement by typically two orders of magnitude.

SERS has been observed for many molecules when adsorbed to gold or silver clusters, or even to nanoscopic rough metal surfaces [14]. The intensity of the Raman scattering is increased as the wavelength is increased. For example, the strongest enhancement for gold clusters may be obtained with a laser excitation wavelength beyond 1000 nm. The SERS spectra obtained are almost completely depolarized. Figure 10.13 shows an atomic force microscopy image of a silver cluster layer used as a substrate for SERS. An example of the SERS effect is represented in Figure 10.14,

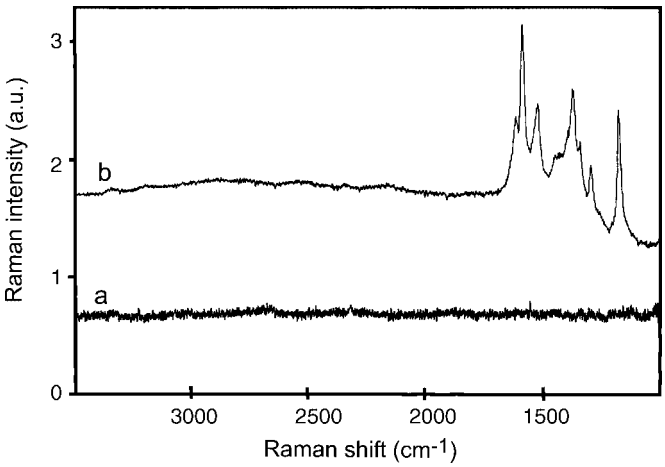

Figure 10.14 Raman spectrum (a) and surface-enhanced Raman spectrum (b) of a very thin film basic fucsine. The Raman spectrum is enhanced 25-fold.

which shows the SER and Raman spectra of a very thin-film basic fucsine on the SERS substrate and a pure silicon wafer.

Clearly, the cluster layer yields an enhancement which is manifested on the most prominent Raman bands. In contrast to the conventional Raman spectrum (Figure 10.14, spectrum a), where no bands can be observed, prominent Raman modes – such as the ring vibration at 1614 cm^{-1}, a deformation vibration of the NH_2 groups at 1586 cm^{-1}, and the valence vibration of the C–NH_2 groups at 1340 cm^{-1}, appear in the SERS spectrum.

Unfortunately, in recent years the SERS effect has not been used as a routine method in Raman spectroscopy. Although the strong enhancement provides many advantages, such as high sensitivity and the opportunity to characterize thin layers of molecules, SERS does not permit quantitative measurements to be made, despite these very often being required in a routine analysis. The reason for this is that the cluster layers themselves are poorly reproducible. Nonetheless, recent developments have been devoted to overcoming this limitation by using sol–gel clusters embedded in porous glass, or by using photonic crystals with a uniform metal-covered nanostructure.

10.5.2
Surface-Enhanced Fluorescence

Surface-enhanced fluorescence (SEF) is comparable to the SERS effect. The enhancement of the fluorescence signal is also caused by strong interactions between the localized surface plasmons of a metal cluster and the electrons of molecule next to the cluster surface [15]. However, at least two important factors must be considered here:

- First, it is well known that a direct contact between a molecule and a metal leads to a quenching of the fluorescence – this is also known as the 'first layer effect'. Therefore, the optimum enhancement of fluorescence does not derive from molecules that are adsorbed to the metal cluster surface; rather, maximum fluorescence is obtained at a certain distance of few nanometers between the molecule and the cluster surface.
- The second factor includes the size and form of the metal clusters. When the clusters become large, the damping of the fluorescence will be increases, whereas small clusters may not be stable and exhibit only a weak electric field.

The enhancement factors for SEF are comparable to those for SERS. The spectra in Figure 10.14, which were measured at 544 nm excitation, also exhibit a fluorescence which is seen as a very broad signal across the whole spectral range. Although the fluorescence of the first (or more) layer of adsorbed molecules is quenched, the enhancement factor is approximately 50. Experiments with silver clusters covered with a dielectric film of SiO_2 a few nanometers thick, produced a much greater fluorescence than did pure silver clusters. As with SERS, SEF has not become a routine method, due not only to the poor reproducibility of the metal cluster but also to the 'first layer effect'.

10.5.3
Surface-Enhanced Infrared Absorption Spectroscopy

Surface-enhanced infrared absorption (SEIRA) spectroscopy also originates from the enhanced electromagnetic field around a metal cluster. The enhancement of infrared absorption is generally on the order of one to two magnitudes [16, 17]. As such enhancement is remarkable for adsorbed molecules on a metal cluster surface, an increase in absorption coefficients and a selection rule for the absorption bands provide additional enhancement and information regarding the orientation of the adsorbed molecule [18, 19]. Figure 10.15 shows a Fourier-transformed infrared (FTIR) spectrum and a SEIRA spectrum of basic fucsine. Both spectra were measured using an attenuated total reflection (ATR) method, with the same measurement parameters. Enhancement of the absorption bands in spectrum b in Figure 10.15 can be clearly seen. Yet, in comparison to the SERS spectrum in Figure 10.14, the strongest band (at 1586 cm^{-1}) exhibited only a threefold enhancement.

Due to the surface selection rule, some absorption bands do not appear, or appear only weakly [21]. Shifts of the absorption bands may seem due to the influence of chemisorption of the complex. Although the optimum thickness for SEIRA-active metal cluster films shows some variation from study to study, it is consistently in the range of 5 to 12 nm. The preparation of the SEIRA active surface is straightforward, usually by the evaporation of an ATR crystal surface with gold or silver. A fresh gold surface shows a strong affinity towards many organic substances. In particular, sulfur complexes are chemisorbed immediately and very strongly onto gold cluster surfaces, and this may lead to an unwanted SEIRA spectrum.

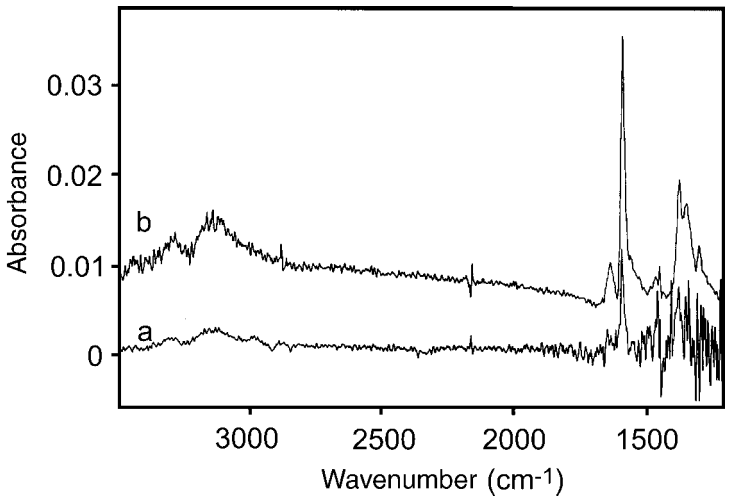

Figure 10.15 FTIR spectrum (a) and SEIRA spectrum (b) of a very thin layer of basic fucsine.

10.6 Biosensing

Metal clusters of gold or silver are stable, inexpensive and simple to prepare, easy to modify, and have optical properties that make them attractive for biosensing and biochips. Today, metal clusters with a functionalized surface are used to detect biomolecules, with an extremely high sensitivity [22, 23]. As mentioned above, the SPR of a metal cluster is also affected by other metal clusters that are in its immediate vicinity. When two or more clusters are brought into proximity, the electric fields will couple, and this will result in a shift of the resonance wavelength. This effect can be easily used in biosensing as an intrinsic enhancement of the detection signal. An example of this is the study of the dynamics of DNA hybridization at the single-molecule level [24]. The principal mechanism of detection is illustrated schematically in Figure 10.16. Here, surface-functionalized metal clusters are used as an anchor for single-stranded DNA (ssDNA). The ssDNA molecules have a biotin molecule attached at one end, and this allows them to bind to the streptavidin-coated 'anchor cluster'. When the surface-bound ssDNA are introduced into a solution with biotin-functionalized clusters, a spectral shift of the SPR occurs, such that gold clusters with a diameter of approximately 40 nm turn from green to orange, while the color of silver metal clusters changes from blue to yellow-green. The limit of detection is in the zeptomolar range. The binding of proteins, interactions between antibodies and antigens and receptor–ligand interactions, can also be detected in this way. The coupling of localized surface plasmons between individual clusters also represents

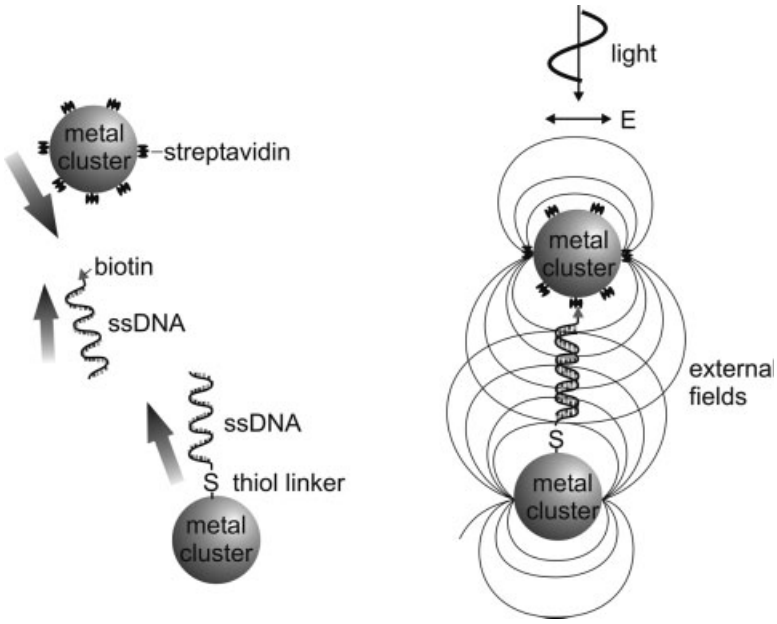

Figure 10.16 High-sensitivity detection of a biomolecular interaction using metal clusters.

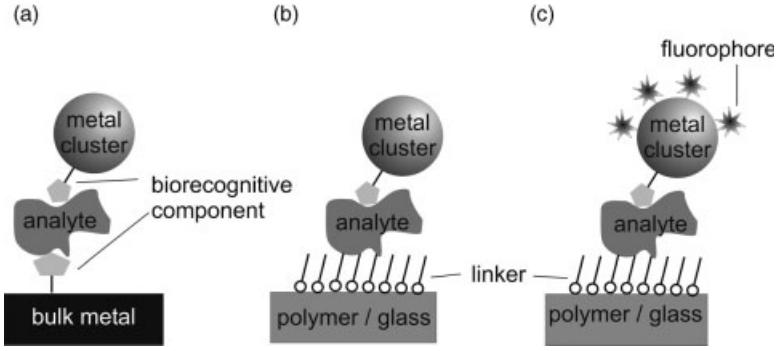

Figure 10.17 Different strategies for metal cluster-enhanced biosensing.

an alternative to the Förster resonance energy transfer (FRET) for monitoring nanometer-scale distances. The plasmon coupling allows measurements to be made over longer time periods and larger distances compared to FRET [20].

Other strategies for biosensing are represented in Figure 10.17. Metal clusters at a defined distance from the surface of a bulk metal (Figure 10.17a) interact with the free electrons of the metal. At a certain distance between the metal cluster and surface, a feedback mechanism enhances the absorption of light, which is then reflected onto the metal surface. The intensity of the absorption is directly proportional to the number of clusters interacting with the metal surface. Metal clusters can be also coupled to a polymer surface (Figure 10.17b); here, the linker molecules not only keep the clusters at a defined distance from the surface but also maintain their spatial distance to other clusters. An optically detectable signal occurs when a certain number of clusters are coupled due to biochemical recognition. Finally, Figure 10.17c shows a similar arrangement where the metal clusters are labeled with fluorophores, and where the fluorescence signal is directly proportional to the bound clusters. The advantage here is an extremely high sensitivity (in the lower femtomolar range) with, under optimal conditions, even single clusters being visible as a color change. The response of the SPR systems is proportional to the product of the adsorbed molecules and the refractive index of the surrounding medium [25]. In addition, metal cluster-based detection provides real-time information on the course of binding over a broad range of binding affinities. Recently, several groups have shown that stable metal cluster layers can be prepared on optical substrates, which makes SPR sensors potentially applicable for continuous-flow detection, as well as for *in vivo* applications in cells and biological fluids [26–29].

More recently, the trend has been towards using nanotechnology to develop sensing surfaces embedded in metal clusters, with such devices improving the sensitivity of a common SPR prism coupler system by a factor of 10. Another novel approach – the use of hydrogels is shown in Figure 10.18. These represent a novel class of polymer that can swell and shrink, depending on their chemical and/or physical environment. As such swelling and shrinkage can be controlled by various molecules, hydrogels may also serve as a host medium for metal clusters. The swelling of a hydrogel containing embedded metal clusters will also cause an increase

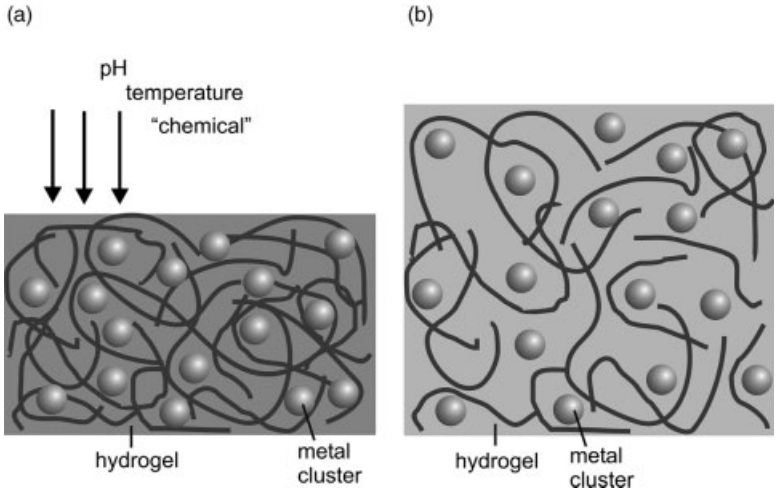

Figure 10.18 Metal clusters embedded in a swelling hydrogel allow sensitive, multiple and reproducible detection of chemical and biochemical parameters.

in the inter-cluster distance, with a spectral shift in color occurring that can easily be measured. An added attraction is that this type of sensor is not only reversible but is also stable over a large number of measurement cycles [30].

Impedance Analysis of Cell Junctions

Joachim Wegener

11.1
A Short Introduction to Cell Junctions of Animal Cells

Within the human body there are more than 200 different, highly specialized cell types, each of which has its own individual functions and the corresponding molecular equipment. However, in order to achieve a specific physiological functionality, it often requires the concerted action of a population of cells, whether of the same kind or of a mixed but well-defined population. Within these organized assemblies of cells – known as *tissues* – the cells must interact with each other mechanically by direct cell-to-cell contacts, chemically by secreting chemicals on the one side and responding to these signals on the other, or electrically by means of cell junctions that transmit electrical signals. In an *in vivo* environment the cells also have to interact with their surrounding *extracellular* material for orientation, migration and signaling. This extracellular material – which is known as the extracellular matrix (ECM) – is most often a complex mixture of proteins and carbohydrates embedded in a more or less aqueous environment, depending on the precise location inside the body. The interactions of cells with other cells of the same or a different type, and the interactions of the cells with the ECM, are summarized by the term cell junctions, including both, cell–cell junctions and cell–matrix junctions [1]. The different cell junctions, as found in epithelial cells, are shown schematically in Figure 11.1. Epithelial cells serve as a good example here as they express most of the important cell junctions very prominently, and in a highly organized fashion. It should be noted that other cell types may lack the more specific junctions, such as tight junctions or gap junctions.

From a functional viewpoint, cell junctions can be grouped in three categories which:

- Provide mechanical contacts and stability of the tissue
- Chemically seal extracellular pathways between cells
- Allow direct molecular or ionic exchange between adjacent cells [2].

Nanotechnology. Volume 6: Nanoprobes. Edited by Harald Fuchs

ISBN: 978-3-527-31733-2

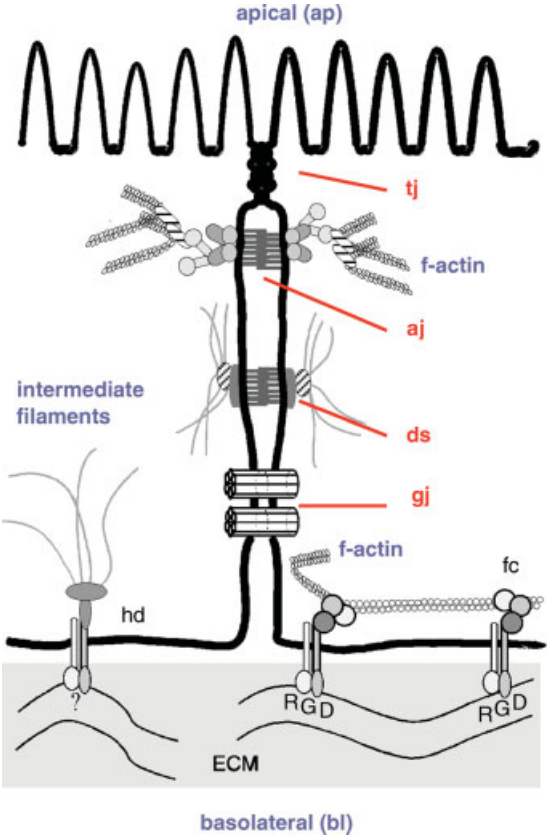

Figure 11.1 Cell–cell and cell–matrix junctions in epithelial cells. The following cell–cell junctions are found in the intercellular cleft between two adjacent epithelial cells: tight junctions (tj), adherens junctions (aj), desmosomes (ds) and gap junctions (gj). The cells are anchored to the extracellular matrix (ECM) by focal contacts (fc) or hemidesmosomes (hd). Cells that provide mechanical stability to cells and tissue are connected to the intracellular filament system of the cytoskeleton, such as the intermediate filaments or the actin cytoskeleton.

However, only specific interactions of the receptor–ligand type mediated by molecular recognition will be addressed in this chapter. Unspecific (electrostatic, electrodynamic, entropic) interactions between two adjacent cells, or between a cell and the surrounding ECM, will not be considered.

11.1.1 Cell Junctions for Mechanical Stability of the Tissue

The mechanical stability of a tissue is provided by cell–cell as well as cell–matrix junctions, which also show a remarkable similarity with respect to their molecular architecture. For both types of junction transmembrane receptors make contact via

their extracellular domains to a corresponding protein on the surface of an adjacent cell, or to a binding site within the ECM. On the intracellular site these receptor proteins are connected to the cytoskeleton mediated by highly specialized adaptor proteins. It is this connection of the receptor proteins to the cytoskeleton (an intracellular network of protein filaments) which provides the molecular basis for the mechanical stability of the individual junction that distributes any punctual mechanical load into the entire tissue. With regard to the individual proteins or protein families involved in junction formation, the mechanical junctions can be subdivided as follows.

11.1.1.1 **Adherens Junctions**

Adherens junctions (aj; see Figure 11.1) are cell–cell junctions that are formed by transmembrane proteins of the *cadherin* family [3]. The name cadherin is derived from the fact that these proteins only bind to their cadherin counterparts on the surface of adjacent cells in the presence of Ca^{2+} (calcium + adhesion). As cadherins on one cell interact with the same cadherins on the opposing cell, the interaction is termed *homophilic*. On the intracellular site, the cadherins are linked to the actin cytoskeleton (also called the *microfilament system*) by a distinct set of linker proteins such as α-, β- or γ-catenin, actinin or paxilin. As shown in Figure 11.1, the adherens junctions with their underlying microfilaments form a very localized structure located close to the upper (apical) pole of the cells, and circumscribe the cell bodies like a belt with bundles of filaments running along on the intracellular site.

11.1.1.2 **Desmosomes**

Desmosomes (ds in Figure 11.1) have a very similar molecular architecture compared to adherens junctions. The transmembrane proteins are also of the cadherin type, although the adaptor proteins on the intracellular side are different and are connected to the *intermediate filament* instead of the microfilament system [4, 5]. As the intermediate filaments are very different from the microfilaments with respect to their dynamic and mechanical properties, both junctions serve the individual needs of the cells that will not be addressed in detail in this chapter (the reader is referred elsewhere for further details [2, 6]). Both types of junction are synergistically responsible for the mechanical properties of cell–cell adhesion. The desmosomes are located further down the intercellular cleft, just beneath the adherens junctions. However, they do not form a belt-like structure around the cells but rather more punctuate, bullet-like contact sites. The connection between cadherins and intermediate filaments is provided by the adaptor proteins *desmoglein* and *desmocolin*. Although both the adherens junctions and desmosomes tie the intercellular cleft together mechanically, they do not operate as barriers for diffusion along the intercellular cleft, other than confining the cleft width.

11.1.1.3 **Focal Contacts**

Focal contacts (fc in Figure 11.1) are the most prominent sites of cell–matrix adhesion [7]. They are clusters of individual molecular connections between the cell interior and the ECM. In general, cell–matrix junctions that eventually develop

into mature focal contacts are composed of a transmembrane protein that makes contact with the extracellular binding partner. The major family of transmembrane proteins involved in cell–matrix adhesion is the *integrin* family [8]. Integrins are α,β-heterodimeric proteins that extend out of the membrane by approximately 20 nm, and are capable of binding specifically to the ECM proteins. Integrins present in focal contacts are connected to the actin cytoskeleton via linker proteins such as vinculin, paxilin and talin. By means of this molecular construction, an intracellular macromolecular network is connected mechanically to an extracellular macromolecular network, such that the cells and the extracellular environment form a unit that is remarkably resistant to mechanical challenges [8, 9]. Moreover, the binding affinity of integrins in focal adhesion sites can be regulated by the cells either to form or to loosen, and in this way they play a major role in transmembrane signaling in both directions, inside-out and outside-in [2].

11.1.1.4 **Hemi-Desmosomes**

The hemi-desmosomes (hd in Figure 11.1), as the second class of cell–matrix junctions, differ from the focal contacts in essentially the same way as do desmosomes from adherens junctions. The transmembrane component is provided by a special type of integrin ($\alpha_6\beta_4$) that is exclusively localized in the hemi-desmosomes. Moreover, hemi-desmosomes are connected to the *intermediate filament* system rather than to the microfilaments. As mentioned above, the different properties of these intracellular cytoskeletal networks provide individual functionalities to the two different classes of cell–matrix adhesion sites.

11.1.1.5 **Less-Prominent Types of Mechanical Junctions**

In addition to the above-mentioned cell junctions there are other, less-prominent molecular assemblies that provide mechanical stability. These include mainly the Ca^{2+}-independent cell adhesion molecules (CAM) as important mediators of cell–cell adhesion, or transmembrane proteoglycans for cell–matrix adhesion. Further details regarding these assemblies are provided elsewhere [2].

11.1.2
Cell Junctions Sealing Extracellular Pathways: Tight Junctions

There is only one type of junction responsible for sealing the extracellular pathway between adjacent cells, and these are known as *tight junctions* (tj in Figure 11.1). To the author's present knowledge, tight junctions are expressed only in epithelial and endothelial cell layers which form the interfacial layers along all inner and outer surfaces of the human body, such as the skin, the gut lining, the bladder or blood vessels. By virtue of their location, it is the predominant physiological task of these tissues to serve as an interface between the two separated compartments, and to control the flux of metabolites or xenobiotics from one compartment to another [10]. Flux control and the exclusion of selected substances is, however, only effective as long as any uncontrolled paracellular diffusion through the intercellular cleft between adjacent cells is limited. Tight junctions provide this seal or *occlusion* of the intercellular

cleft and are, thus, also referred to as *occluding junctions* or *zonula occludens*. The tight junctions are located at the apical pole of two apposing epithelial cells (cf. Figure 11.1). Similar to adherens junctions, they are also very focused structures that span no more than 200 nm along the intercellular cleft. Nonetheless, they can be extremely efficient in maintaining chemical or electrochemical gradients in highly specialized tissues such as those which form the blood–brain or the blood–CSF barriers. In other epithelia or endothelia, the barrier function is significantly lower according to the physiological task at the particular location inside the body [11].

Structurally, the tight junctions are not yet fully understood. Many transmembrane or peripheral proteins have been localized almost exclusively to functional tight junctions, including *Occludin*, members of the *Claudin* or *Jam* family, as well as the peripheral proteins ZO-1, ZO-2 and ZO-3, to mention a few. Although a large number of proteins have been identified as constituents of functional tight junctions, various experimental indications exist which suggest that lipids must be involved in junction formation and thus provide some of the junctions' unique properties [12]. (For additional information the reader is referred to [13–17].) Yet, no matter how they are molecularly composed, the formation of tight junctions requires close cell-to-cell-apposition. Tight junctions will only form when a mechanically stable cell–cell adhesion site has been established through adherens junctions and desmosomes before.

11.1.3 Communicating Junctions: Gap Junctions and Synapses

Both, *chemical synapses* and *gap junctions* (gj in Figure 11.1) are cell junctions that are involved in intercellular communication, despite their entirely different structure and molecular architecture. Moreover, it is well known that synapses are only formed at the contact sites between two neurons or a neuron and a muscle cell, whereas gap junctions are expressed by most cell types within the human body, although to very different degrees.

11.1.3.1 Chemical Synapses

In chemical synapses [18] the opposing membranes of two cells approach each other very closely, leaving a water-filled cleft of only 20 nm between them (the synaptic cleft). When a membrane depolarization wave passing along the presynaptic membrane reaches the synapse, transmitter molecules are released from the sender cell, diffuse through the synaptic cleft, and open ligand-gated ion channels in the plasma membrane of the receiver cell (postsynaptic membrane). This incident triggers a depolarization wave in the receiver cell, such that the electrical signal is transmitted. Depending on the length of the axon, the distance between two communicating nerve cells can be up to 1 m [19].

11.1.3.2 Gap Junctions

In contrast to the chemical synapses, gap junctions are simply water-filled channels which locate between two adjacent cells and allow the sharing of molecules with a molar

mass of less than 1000 g mol^{-1} (this is termed metabolic coupling) [20, 21]. From a structural viewpoint gap junctions are composed of two hemi-channels, one provided by each of the opposing cells. Each hemi-channel is known as a *connexon*, which in turn is composed of six *connexins* (each of which is a single span transmembrane protein) arranged in a hexagonal pattern. The central opening in this protein cluster ($d = 1.5$ nm) provides an aqueous channel between the two connected cells. These channels are not static but can be precisely regulated in their permeability by both cells, the sender and the receiver. As membrane depolarization waves can also be transmitted from one cell to the neighboring cells via gap junctions (e.g. in heart muscle cells), they are also referred to as *electrical synapses*. Notably, the transfer of electrical signals occurs significantly faster via gap junctions than via chemical synapses.

11.2 Established Physical Techniques to Study Cell Junctions

In this section we will provide a rather brief overview of the techniques which have been applied in the past to study cell–cell or cell–matrix junctions from a structural or functional viewpoint. It should be noted, however, that within the chapter we cannot provide a complete survey of all available techniques, nor details of the selected methods. However, further information is available via the references provided in the appropriate passages of the text.

11.2.1 Cell–Matrix Junctions

When studying cell–matrix junctions *in vitro*, the ECM proteins are commonly predeposited on a technical surface such as a Petri dish or a microscope slide, with the cells adhering to this protein-decorated surface. Thus, analyzing *cell–matrix junctions* also means studying *cell–surface junctions* or *cell–substrate junctions* [22]. Today, these three terms are generally used synonymously, depending on the background of the study under discussion.

From the structural viewpoint our current knowledge of cell–matrix or cell–surface junctions is largely based on light microscopy or transmission electron microscopy (TEM) of chemically stabilized (fixed) samples, in combination with the powerful tools of modern molecular biology and immunology. Often, the target molecule suspected of being involved in cell–matrix adhesion is specifically tagged by an antibody – which itself is labeled with a fluorochrome or an electron-dense marker – and then imaged microscopically under various experimental conditions. Studies like this, together with the biochemical analysis of interaction partners, have identified the molecular architecture of cell–matrix junctions as known today and described above.

11.2.1.1 Scanning Probe Techniques

Until now, scanning probe techniques have not contributed a lot to the structural analysis of cell–matrix adhesion sites, as the latter are protected from one side by the

cell body and from the other side by the growth substrate. Nanoprobes simply cannot gain access to these structures in living cells. Most recently, scanning electron microscopy (SEM) has been used in combination with controlled erosion of the sample by a focused ion beam (FIB). Thereby, the organic material of the cell bodies was locally removed in order to obtain a side view of the cell by SEM. These images provided a detailed view on the profile of the cell–substrate interface [23]. Recently, Wrobel *et al.* studied the cell–surface interface using TEM after preparing of thin sections of the sample [24].

11.2.1.2 **Nonscanning Microscopic Techniques**

Several nonscanning light microscopy techniques have been developed that utilize certain optical effects to provide images from this internal interface between the cell body and the growth substrate. Reflection interference contrast microscopy (RICM) – also referred to as interference reflection microscopy (IRM) – has contributed the most to the existing literature about cell–substrate interactions [25, 26]. This technique allows imaging of the 'footprints' of cells on a substrate rather than only the projections of the cell body. RICM in its basic form is applied to living cells grown on ordinary coverslips, and does not require any staining or fixation. The sample is illuminated from below with an inverted microscope, using monochromatic light. In a first approximation the image is generated from the light reflected either from the glass/medium interface or the lower plasma membrane. Interference of the reflected light then provides an image of the cell–substrate contact area in which the brightness of the pixels code for the optical path difference between the two interfaces. Thus, RICM images map the distance between the lower cell membrane and the glass surface, while time-lapse RICM studies provide a microscopic view of the dynamics of cell–surface junctions with video rate time resolution.

11.2.1.3 **Fluorescence Interference Contrast Microscopy**

A major improvement with respect to absolute cell–substrate distance measurements was introduced by Braun, Lambacher and Fromherz in 1997 [27–29]. For this technique, which is referred to as fluorescence interference contrast microscopy (FLIC), the cells are grown on silicon substrates that have well-defined steps made from silicon oxide on their surface. The step height ranges between 20 and 200 nm and is, thus, only a fraction of the wavelength of visible light. For the measurement, the adherent cells are stained with a fluorescent dye that integrates into the plasma membranes. As the silicon/silicon oxide interface acts as a mirror, the intensity of the fluorescence light emitted by the dye in the lower membrane is dependent on the distance between the membrane and the silicon surface. The steps on the surface serve as well-defined spacers and make the intensity–distance relationship unique. FLIC microscopy provides the cell–substrate separation distance with an accuracy better than 1 nm.

11.2.1.4 **Total Internal Reflection (Aqueous) Fluorescence Microscopy**

Total internal reflection fluorescence microscopy (TIRF) and total internal reflection aqueous fluorescence microscopy (TIRAF) are variants of the same microscopic

principle, and are based on fluorophore excitation by an evanescent electric field. Here, the cells are grown on a transparent substrate that is illuminated from below with a laser beam at an angle θ relative to the surface normal that is bigger than – or equal to – the critical angle of total reflection, θ_{crit}. Under these conditions diffraction phenomena at the interface generate an evanescent wave at the surface. The penetration depth of the associated electric field is rather short, and the field decays within 100 nm of the surface, or slightly beyond. Thus, fluorescence is only excited in those molecules that are close enough to the surface. In TIRF, membrane proteins or other membrane constituents are fluorescently labeled and can be imaged with improved resolution, as fluorescence light from further inside the sample is not excited. For TIRAF measurements a water-soluble fluorescent dye is added to the extracellular fluid. If a cell adheres to the surface it displaces the aqueous phase and thereby the fluorophore from the interface. Thus, cell-covered areas appear dark in TIRAF images. Both techniques have contributed significantly to our understanding about cell–matrix adhesion *in vitro* [30, 31].

11.2.1.5 **Quartz Crystal Microbalance**

Another emerging tool to study cell–matrix junctions *in vitro* is based on using thickness shear-mode piezo resonators as growth substrates for adherent cells. The interactions of cells with the protein-decorated crystal surface is monitored by reading the resonance frequency and the energy dissipation of the shear oscillation [32]. In principle, this approach has evolved from the so-called quartz crystal microbalance (QCM) technique that is a widely accepted technique for following adsorption reactions at the solid–liquid interface. However, in combination with cells it is not the mass of the cells that determines the signal but rather their anchorage to the oscillating quartz surface, together with the viscoelasticity of the cell bodies. Time-resolved measurements of the resonance frequency can be used to follow the attachment and spreading of cells to the quartz surface that may be precoated with a matrix component of interest [33]. Even though the growth substrate of the cells oscillates mechanically, the technique is considered as being noninvasive as the maximum shear displacement in the center of the resonator is in the order of 1 nm, with a frequency in the MHz regime.

11.2.1.6 **Other Techniques**

Besides the various techniques mentioned above, several other experimental methods can be used to provide information on cell–matrix adhesion *in vitro*; some details of these are listed very briefly here. Many assays study the forces necessary to remove a cell from a protein-coated surface after it has been allowed to attach and anchor for a predefined time. These approaches can be applied either in an integral manner to a population of cells, or on the single-cell level. The former method is, for instance, realized by exposing the cells to centrifugal forces and counting those that are capable of remaining attached to the matrix proteins on the surface [34]. On the single-cell level, a variant of classical scanning force microscopy – then referred to as cell adhesion force microscopy – is used to measure the forces required to remove a cell from a particular ECM-coated substrate, either by pulling or pushing [35]. Moreover

much has been learned from extracellular recordings of neuronal action potentials by means of field effect transistors (FET) regarding the electrochemical properties of the thin cleft between cell and surface as the sealing properties of the junctional area determine the sensitivity of the measurement [36].

11.2.2 Cell–Cell Junctions

The molecular architecture of cell–cell junctions, as shown in Figure 11.1, has been unraveled significantly by using both TEM and SEM after freeze-fracture preparation or other contrasting protocols, as well as with fluorescence microscopy after immunolabeling of the molecular target. When used in conjunction with the molecular biology technique to knock out or knock in a gene of interest, to silence the expression of a given gene or to identify interactions partners, these techniques have provided a comprehensive understanding of the molecular composition of cell–cell junctions. Whilst understanding the molecular arrangements of a given cell junction under stationary conditions is one thing, to follow and identify the changes that occur during regulation or development is another. Thus, a detailed understanding of cell–cell junctions, their interplay and regulation remains an area of intense research worldwide, notably because of their extraordinary biomedical and pharmaceutical relevance. Among the four different types of cell–cell junction (tight junctions, adherens junctions, desmosomes, gap junctions), tight and gap junctions have received most attention with respect to their functional properties, and hence only these will be addressed here. Both of these junctions provide control over the flux of chemicals (metabolites, xenobiotics), either through the interspaces between two adjacent cells or between adjacent cytoplasms.

11.2.2.1 Tight Junctions

Tight junctions, as expressed by endothelial and epithelial cells, form the structural basis for the barrier function of epithelial and endothelial cell layers. A straightforward and popular approach to probe the efficiency of this barrier function – and thus the tightness of the junctions – is a simple *permeation/diffusion assay* [37]. Here, the cells are grown on highly porous filter membranes that support the cell layer mechanically without acting as a significant diffusion barrier themselves. The cell-covered membrane is then placed between two fluid compartments such that any flux of solutes from one compartment to the other must pass the interfacial cell layer. In a typical experiment, a tracer compound is added to one compartment (donor), while samples are taken from the other compartment (acceptor) after well-defined time intervals. From the concentration increase of the tracer in the acceptor compartment, it is possible to calculate the permeation rate P_E that reports on the barrier properties of the cell layer under study. As long as the probe cannot migrate across the cell membranes and is dependent on extracellular diffusion, the experimentally measured flux is predominantly determined by the functional properties of the tight junctions. By using probes of different molecular mass or shape, the size-exclusion properties of the junctions can be inferred from such measurements [38].

The probes can either be radio- or fluorescence-labeled, otherwise their concentration must be determined using chromatography. The readout of this widely established assay is, however, easily compromised by defects in the cell layer (even single cell defects) that may serve as short-cuts for the substrate flux leading to a serious underestimation of the barrier function. Moreover, such a permeation assay is not an *in situ* method but rather requires time for the probe to accumulate in the acceptor compartment [39].

Another method of probing the functional properties of tight junctions relies on measuring the *electrical resistance* of the cell layer, when it is placed on a porous filter membrane between two fluid compartments, as described above. Either compartment is equipped with a pair of Ag/AgCl electrodes, that are used for current injection and voltage reading in either compartment. The resistance value, which is then referred to as the transepithelial or transendothelial electrical resistance (TER), strictly reports on the ionic permeability of the entire cell layer. However, as the extracellular ionic current pathway around the cell bodies through the cell–cell junctions is significantly less resistive in most cases than the ionic current pathways across the dielectric plasma membranes, TER reports on the tightness of the junctions as a first approximation. Unfortunately, the TER approach suffers from the same shortcomings as do readings of the P_E rate (see above), namely that it is very prone to artifacts arising from defects within the cell monolayer. On the other hand, TER readings can provide a snapshot of the barrier function of the junctions, and the readings can be performed in a time-resolved manner. Accordingly, changes in junctional tightness can be monitored more or less in real time with a time resolution that can be reduced to the order of minutes [40].

TER measurements with lateral resolution have been performed by using microelectrodes for local potential measurements while a uniform and homogeneous current density was established across the entire cell layer [41, 42]. By scanning the electrode across the cell layer, it was possible to establish resistance maps that could identify local shortcuts in the barrier function of the cell layers [43]. Moreover, it was possible to quantify the resistance of the *paracellular* current pathway across the tight junctions in contrast to the *transcellular* current pathway across the membranes [42]. In particular, this discrimination between paracellular and transcellular resistance is not possible with the integral TER approach, and may leave data interpretation with some ambiguity as the transcellular current pathway has a high but finite resistance after all. Several modifications of the basal conductance scanning technique have been described and, in scanning ion conductance microscopy (SICM), the lateral resolution has been improved to the submicrometer regime such that the junctional tightness along the periphery of a single cell can now be recorded and analyzed. Korchev and coworkers have even studied the conductance of a single ion channel on a living cell by using SICM [44].

11.2.2.2 **Gap Junctions**

As for the other junctions, the general structure and composition of gap junctions has been revealed to a large extent by using electron and fluorescence microscopy after labeling individual molecules suspected of being involved. From a functional

perspective, junctional performance is routinely monitored by electrical measurements. Either of the two cells that are connected via gap junctions will be impaled by a microelectrode such that current can be injected to flow from one cell the other. When gap junction performance is discussed, the measured resistance is usually expressed as *conductance*. Amazingly, the conductance of a single gap junction channel depends on the individual member of the connexin protein family that forms the transmembrane channels, even though they are highly conserved [45].

Another approach involves the use of micropipettes to inject nonmembrane-permeable fluorescent dyes into the cytoplasm of a cell; the spread of the dye into adjacent cells connected via gap junction channels is then followed. Using this technique allows complete control over the size, surface charge and morphology of the probe, so that the junctional permeability can be extensively analyzed [46]. Along the same lines, but at a much lower experimental cost, it is possible to visualize gap junction conductance using the so-called scrape loading assay. Here, the cell layer is bathed in a buffer that contains the fluorescent gap junction probe. In order to introduce the dye into the cytoplasm of the cells, a needle is moved (scraped) through the cell layer. Those cells lying in the path of the needle are ripped by the moving pipette tip such that their membrane is ruptured. This allows the extracellular dye to enter the cytoplasm through the ruptured membrane, and then diffuse via gap junctions into neighboring cells. The diffusion performance of the dye reports on junctional coupling [47].

11.3 Impedance Spectroscopy

Impedance spectroscopy (IS), which is also referred to as electrical or electrochemical impedance spectroscopy (EIS), represents a versatile approach for probing and characterizing the dielectric and conducting properties of bulk materials, composite samples or interfacial layers. The technique is based on measuring the impedance – that is, the opposition to current flow – of a system while it is excited with low-amplitude alternating current or voltage. The impedance spectrum is obtained by scanning the sample impedance over a broad range of excitation frequencies, typically covering several decades. In continuous-wave IS, the impedance is measured sequentially at each individual frequency. In contrast, with pulse techniques the system is exposed to a superposition of multiple sine waves with different frequencies, at the same time. The impedance spectrum of the system is then extracted from the transient response by means of Fourier transform algorithms. Both data acquisition modes have their unique advantages. Whereas continuous-wave recordings are easier to conduct and have better signal-to-noise ratios, pulsing techniques are much faster, provide a better time resolution and are, thus, more suitable to study dynamic systems that change within seconds.

As long ago as the 1920s, research groups first began to investigate the impedance of tissues and biological fluids, and it was known even then that different tissues exhibit distinct dielectric properties, and that the impedance undergoes changes

during pathological conditions or upon changing the cellular environment [48, 49]. Thus, the value of impedance measurements for the analysis of biological samples such as organs, tissues, cell aggregates or even single cells was obvious from an early stage. One of the most important advantages of IS compared to other techniques is its noninvasiveness, as the technique relies entirely on low-amplitude currents and voltages that ensure damage-free examination with a minimum disturbance of the cells or tissues. This noninvasive nature of the method, combined with its high information content, has made it a valuable tool for biomedical research *in vitro*. More recently, *in vivo* applications in clinical settings have also been developed, including electrical impedance tomography (EIT), which is being used increasingly as a noninvasive monitoring tool for heart and/or lung function during surgery [50]. In the following sections, however, attention will be focused on the use of impedance spectroscopy to study cell junctions of animal cells *in vitro*. A broad survey of the use of EIS for biological samples such as tissues and organs is provided elsewhere [50].

11.3.1 Fundamental Relationships in Impedance Analysis

The electrical impedance, Z, is a complex quantity that describes the ability of the system under study to resist the flow of alternating current. In a typical IS experiment a sinusoidal voltage $U(t)$ with angular frequency $\omega = 2\pi f$ is applied to the system and the resulting steady-state current $I(t)$ associated with the voltage is measured. According to Ohm's Law, the impedance is given by the ratio of these two quantities:

$$Z = \frac{U(t)}{I(t)} \tag{11.1}$$

The impedance measurement is typically conducted within a linear voltage–current regime of the sample (i.e. the measured current amplitude is proportional to the amplitude of the applied voltage), so that the resulting current will also be a sine wave with the same frequency ω as the applied voltage signal, but it may be phase-shifted relative to the voltage by the phase angle φ. By introducing a complex notation, Equation 11.1 translates into

$$Z = \frac{U_0}{I_0}\exp(i \cdot \varphi) = |Z|\exp(i \cdot \varphi) \tag{11.2}$$

with U_0 and I_0 representing the amplitudes of voltage and current, respectively, and with $i = \sqrt{-1}$. Thus, at each frequency of interest the impedance is described by two quantities: the magnitude $|Z|$, which is the ratio of the amplitudes of U_0 and I_0, and the phase angle φ between voltage and current.

Instead of presenting the complex impedance Z in polar coordinates, $|Z|$ and φ, it can also be expressed in Cartesian coordinates, with a real (R) and an imaginary (X) component:

$$Z = R + i \cdot X \tag{11.3}$$

$$\begin{aligned} &\text{with} \quad R = \mathrm{Re}(Z) = |Z| \cdot \cos(\varphi) \\ &\text{and} \quad X = \mathrm{Im}(Z) = |Z| \cdot \sin(\varphi) \end{aligned} \tag{11.4}$$

The real part is called the *resistance R*, and corresponds to the impedance contribution arising from current that is in-phase with the applied voltage. The imaginary part is termed the *reactance X*, and describes the impedance contribution from current which is 90° out-of-phase with the voltage. With respect to biological samples, the resistive portion R of the impedance mirrors either the concentration of ions available for current flow within the sample, or their limited ability to migrate under the influence of the applied electric field. The latter is commonly caused by a geometric confinement of the ionic current pathways by means of insulating cell membranes or cell junctions that occlude or narrow down the aqueous spaces available for current flow. The reactance X arises from the presence of storage elements for electrical charges like, for instance, capacitors or coils in electrical circuits. In biological tissues, the dielectric (or insulating) cell membrane acts as a capacitor, separating two conducting fluids (extracellular and intracellular) by its hydrophobic core, whereas an inductive behavior of biological systems is only described in very rare cases. Thus, as a rule of thumb for animal cells and tissues, it can be said that the measured resistance arises from extracellular or intracellular fluids and their geometric dimensions, whereas the capacitive reactance originates from the cell membranes.

In some cases it is more convenient to use the inverse quantities of Z, R and X, which are referred to as *admittance* $Y = 1/Z$, *conductance* $G = \mathrm{Re}(Y)$ and *susceptance* $B = \mathrm{Im}(Y)$, respectively. In the linear voltage–current regime, the two representations are interchangeable and contain the same information. Accordingly, IS is occasionally entitled admittance spectroscopy.

In IS the impedance is measured over a range of frequencies covering several decades between mHz and GHz, depending on the type of sample and the problem being studied. The frequency regime typically studied to analyze cell junctions ranges from 1 Hz to 1 MHz.

11.3.2
Data Representation and Analysis

When the complex impedance of a system of interest (real and imaginary part) is recorded as a function of frequency, the complete presentation of the data requires a specialized method of data plotting. Most frequently, a so-called Bode diagram is used; here, the impedance magnitude $|Z|$ and the phase shift between current and voltage φ are plotted as a function of frequency on a logarithmic or semi-logarithmic scale, respectively. Figure 11.2a shows such a Bode diagram for an arbitrary electrical network shown in the inset of Figure 11.2b as an example. Alternatively, the imaginary component of the impedance X is plotted versus the real component R in a so-called impedance locus or Wessel diagram (Figure 11.2b). The latter presentation does not provide any further information on the frequency. Normally, an arrow is added to include the direction in which the sampling frequency

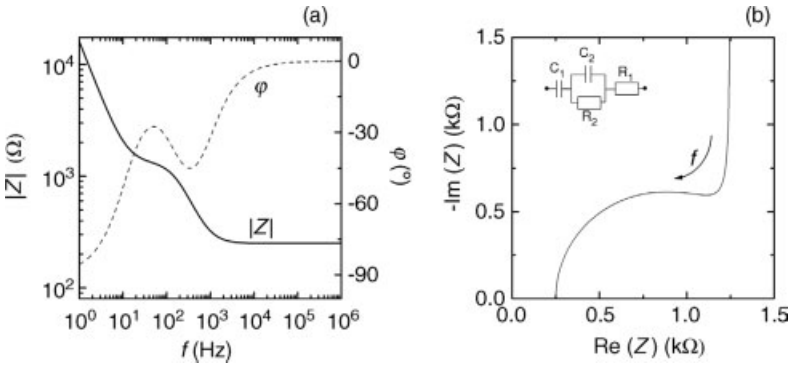

Figure 11.2 Different representations of impedance spectra. (a) Bode diagrams provide impedance magnitude $|Z|$ and phase shift φ between voltage and current as a function of frequency; (b) Impedance loci or Wessel diagrams display the imaginary part of Z as a function of the real part of Z. The arrow indicates the direction of increasing frequency (f). The insert shows the electrical circuit that was used to calculate the impedance data.

increases. The advantage of using impedance loci for data presentation is that the shape of the curve provides information on the electrical structure (perhaps even substructures of the sample), and also whether the behavior of the system deviates from that of ideal electrical networks. For example, a resistive current pathway in parallel to a capacitive one gives rise to a semicircle within an impedance locus that is centered on the x-axis. From the center and the radius of the semicircle one can directly extract the resistance and capacitance of this particular structure (cf. Figure 11.2b).

Although the shape of the curve in impedance loci may be useful for direct analysis, the most common method of analyzing experimental impedance spectra is by means of equivalent circuit modeling. Here, the system under study is described by an electrical network (as shown in the insert of Figure 11.2b) that mirrors the (predicted) electrical structure of the system. The system's equivalent circuit is composed of series or parallel connections of impedance elements (resistors, capacitors), as known from electronic circuitry, plus additional impedance elements that have been empirically derived for ionic systems, for example Warburg impedance or constant phase elements (CPEs). These elements have no correspondence in electronic systems. As described above, the impedance spectrum contains much information about the electrical properties of the system, and with experience it is possible to make a 'qualified guess' of a proper model based on the features in the diagrams. For a given equivalent circuit, the frequency-dependent impedance (transfer function) is then derived from the individual components and their interconnection using Ohm's law and Kirchoff's laws. The best estimates for the parameters – that is, the unknown values of the resistors and capacitors within the equivalent circuit – are then iteratively computed by ordinary least-squares algorithms, such as the Levenberg–Marquardt approach. If the impedance and phase spectra of the chosen model fit the

Table 11.1 Individual impedance contributions of ideal and empirical equivalent circuit elements.

Component of equivalent circuit	Parameter	Impedance Z	Phase shift φ
Resistor	R	R	0
Capacitor	C	$1/(i\cdot\omega\cdot C)$	$-\pi/2$
Coil	L	$i\cdot\omega\cdot L$	$+\pi/2$
Constant phase element (CPE)	A, $n(0 \leq \alpha \leq 1)$	$1/(i\cdot\omega)^{n}\cdot A$	$-n\cdot\pi/2$
Warburg impedance σ	σ	$\sigma\cdot(1-i)\cdot\omega^{-0.5}$	$-\pi/4$

data well, the parameter values are used to describe the electrical properties of the system and its changes throughout an experiment.

In order to find an equivalent circuit model that accurately predicts the impedance of biomaterials, it is often necessary to include nonideal circuit elements – that is, elements for which the parameters are themselves frequency-dependent. Such empirical elements account for ionic phenomena such as adsorption and diffusion that cannot be realized with standard electronic impedance elements. A list of all common circuit elements used to describe biomaterials in terms of their impedance and their phase shift is provided in Table 11.1. The CPE, which represents a nonideal capacitor and is one of these empirical impedance elements, was originally introduced to describe the interface impedance of noble metal electrodes immersed in electrolyte solutions. Although the physical basis of CPE behavior is not fully understood in detail, it is thought to be associated with surface roughness and specific ion adsorption to interfaces. Another empirical element is the Warburg impedance σ, which accounts for the impedance contribution arising from the diffusion limitation of many electrochemical reactions. The parameters that determine the individual impedances of these elements are listed in Table 11.1.

At this point it is important to place a word of caution concerning the equivalent circuit modeling approach. Different equivalent circuit models (which deviate with respect to either the components or the network structure) may produce equally good fits to the experimental data, yet ascribe the sample a very different physical structure. In such a case, independent experiments (microscopy and other spectroscopic approaches) are required to obtain further insight into the electrical structure of the sample and to identify the most appropriate model. It may also be tempting to increase the number of elements in a model to obtain a better agreement between experiment and model. However, the model may then become redundant because the components can no longer be quantified independently. Thus, an overly complex model can easily provide artificially good fits to the impedance data but, at the same time, highly inaccurate values for the individual parameters. Thus, it is sensible to use the equivalent circuit with the minimum number of elements that still describes all details of the impedance spectrum (the nonredundant model) [51].

Another approach towards analyzing impedance data (although less often applied) is based on deriving the current distribution in the system by means of differential

equations and boundary values. Solving the differential equations provides the impedance transfer function with the respective model parameters. Fitting of the transfer function to the recorded data then allows extraction of the best estimates for the model parameters. It should be noted that both approaches are essentially only different formalisms.

11.4 Impedance Analysis of Cell Junctions

11.4.1 General Remarks about Experimental Issues

11.4.1.1 Two-Probe versus Four-Probe Measurement

In order to analyze the impedance characteristics of a given electrochemical system, it must be interfaced with electrodes that are required for current injection and voltage sensing at appropriate frequencies. These electrodes are placed at opposite ends of the sample in order to provide the electrical structure of the entire system as a readout. In many cases the measurement can be made with four electrodes, two for current injection and two for voltage sensing. Here, the voltage sensing electrodes are usually placed very close to the sample surface so that only the voltage drop across the sample is measured without contributions from the bathing fluid or other parts of the measurement chamber. The current-injecting electrodes are often placed at the very end of the experimental chamber to avoid any disturbance of the sample when electrochemical reactions occur at the electrode surfaces. When low-amplitude signals are used and no significant faradaic currents (electrochemical reactions at the electrode surface) occur, it is often more convenient to work with two electrodes only. Under these conditions, either electrode is used for both current injection and voltage sensing. The major advantage of such a two-probe measurement is the reduction of electrodes, including the necessary cables and connectors, that must be integrated into the experimental set-up. Moreover, some approaches simply do not allow the use of four electrodes at the required location, as will be detailed below. The disadvantage of two-probe measurements is, however, that the electrical properties of the bathing fluid, the chamber and the electrodes themselves will be included in the experimental data. Thus, it is necessary to find ways to reduce their impact, to perform a meaningful and justified subtraction, or to include them into the model that is used for data analysis.

11.4.1.2 Introducing Electrodes for Impedance Readings into an Animal Cell Culture

In order to apply electrochemical impedance techniques to study cell junctions of animal cells, the initial experimental challenge is to introduce the necessary electrodes without causing major disturbances to normal cell division or differentiation. The measurement requires a homogeneous electric field to be applied across the cell layer or to the individual cells. In recent years, three systems have been established that fulfill these conditions in principle. The most popular set-up makes use of highly

permeable membranes that are manufactured either from polymers such as polycarbonate, or from aluminum oxide, and mechanically support the cell layer at the interface between two fluid compartments. When the electrodes are introduced into these fluid compartments below and above the cell layer, an impedance analysis of the cells on the filter can be carried out. It is important that the electrodes provide a homogeneous electric field across the entire cell layer. As the filter membranes on which the cells are grown often range from several millimeters to centimeters in diameter, it is insufficient to introduce point-like Pt or Ag/AgCl electrodes in either compartment. For meaningful impedance readings, it is necessary to use 2-D electrodes for current injection in order to ensure a homogeneous current penetration through the system. In the past, both, four-probe and two-probe electrode configurations have been used to study cells attached to permeable membranes [40, 52].

A slightly different approach that is, however, only suitable for intact tissues or tissue fragments, uses grids made from Pt or Ag/AgCl to serve simultaneously as the bottom electrode and as a mechanical support for the biological sample. Small pieces of tissue are fixed mechanically to these grids after having been excised from an animal or organ [53]. The electrodes in the upper compartment above the cell layer are easier to realize as they can simply be dipped into the bulk electrolyte above the cell layer. As the pore size of these grids is significantly larger than the size of the individual animal cells (5–20 µm in diameter), these systems cannot be used for cultured cells as these are normally seeded into the culture vessels as single-cell suspensions that will form a continuous cell layer with time.

The third and most recent approach uses thin-film electrodes made from inert noble metals such as gold or inert metal oxides such as indium-tin oxide (ITO). The cells are grown directly on the surface of the electrodes after a layer of adhesive proteins has been preadsorbed; such preadsorption is either performed intentionally before the cells are introduced, or occurs spontaneously from the culture medium. This technique, known as electric cell–substrate impedance sensing (ECIS), was pioneered by Giaever and Keese during the 1980s [54, 55], and today is on the verge of becoming a routine laboratory technology. The measurement principle is illustrated in Figure 11.3 where, as indicated in the insert, the distance between the electrode surface and the cell body is only on the order of 20–200 nm. As the electrical potential within this thin cleft is position-dependent, it is impossible to design a four-probe measurement for these systems. Thus, impedance readings of cells or cell layers that have been grown directly on the surface of thin-film electrodes will always contain contributions from the measuring electrodes and the bathing fluid that must be taken into account. Hence, the experimental set-up and electrode layout must be designed such that these contributions do not mask the impedance of the sample.

The coplanar electrode design shown in Figure 11.3 is composed of two electrodes of very different surface area (factor 1000). The smaller electrode is referred to as the *working electrode*, whereas the larger electrode is called the *counter electrode*. The area ratio between the counter- and working electrodes is typically 500 to 1000. The rationale behind this electrode layout is to make one electrode the bottleneck for the current, so that the total impedance of the system is dominated by the small electrode

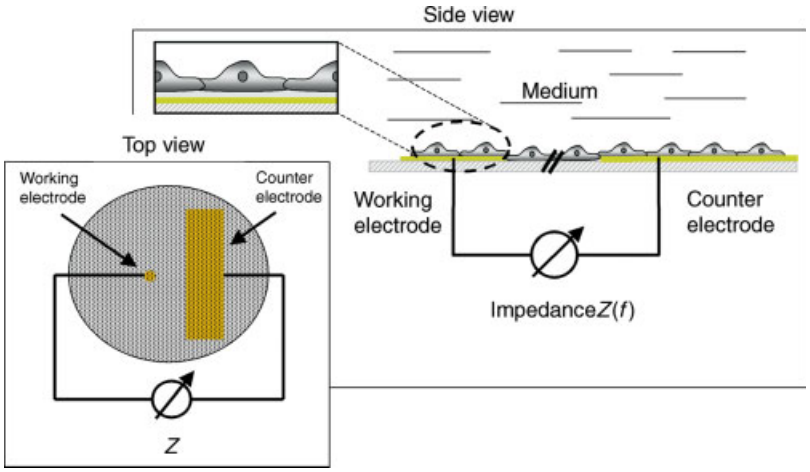

Figure 11.3 Schematic illustrating the principle of impedance analysis of adherent animal cells by means of thin-film electrodes. The cells are grown directly on the surface of the electrodes. The working electrode is made approximately 1000-fold smaller in surface area than the coplanar counter electrode, so that the cell-covered working electrode dominates the readout.

with its small population of cells. Contributions from the counter electrode can be neglected because of its larger area, even though it is also entirely cell-covered. The use of thin-film electrodes, on which the cells are grown, results in several technical advantages:

- Instead of using a dipping electrode that reaches into the bulk electrolyte from above, the second electrode is also a thin-film electrode deposited on the growth surface at sufficient distance from the first electrode (cf. Figure 11.3). A coplanar electrode arrangement avoids the need to open the chamber during the measurement, and also helps to maintain physiological, nonharmful conditions. At first sight, one would suspect that sneak currents might flow underneath the cell bodies in parallel to the surface, from one electrode to the other, without passing the cell layer. However, as the cells are rather close to the surface with only a nanometer-sized, electrolyte-filled cleft between lower cell membrane and electrode surface, this suspected 'sneak pathway' provides a much higher resistance than the current pathway across the cell layer, and is not relevant.
- The area of cell layer under examination largely determines the sensitivity of the measurement. The smaller the electrode (and cell layer), the more sensitive is the readout for the cellular parameters. Whereas, the filter set-up is difficult to miniaturize down to the single cell level, this is technically not problematic for thin-film electrodes. Circular electrodes with diameters of 20 µm (roughly the diameter of an animal cell) can be produced using standard photolithography techniques.

- As the electrodes can be manufactured using standard photolithography procedures, they can be customized for individual assays or experimental needs. Moreover, several electrodes can be arranged to a multiwell format on a common substrate so that several experiments can be performed in parallel. Nowadays, 96-well devices are commercially available.
- Noble metal electrodes in contact with an ionic solution behave, electrically, almost like an ideal capacitor. Small deviations, such as a phase angle smaller than the expected 90°, have been often observed and reported but are not of major importance. When the cells attach and spread on an almost perfectly capacitive electrode, the impedance contribution arising from the thin cleft between the cell membrane and the electrode surface is dependent on the frequency. This frequency dependency of the impedance arising at the site of cell–matrix junctions allows discrimination to be made between this particular impedance and the contribution arising from cell–cell junctions. The latter (most notably the tight junctions) are entirely resistive with respect to their electrical properties and, thus, are frequency-independent. This difference is decisive when assigning cell–cell and cell–matrix junctions their individual impedances. In contrast, when the cells are attached to a porous filter membrane which behaves electrically like a small resistor, the impedance contributions from cell–matrix and cell–cell junctions are both frequency-independent and can no longer be separated. Thus, the use of capacitive thin-film electrodes provides a significant analytical advantage over measurements on porous membranes. With the latter, the impedance contributions of cell–matrix and cell–cell junctions cannot be specified individually but only in combination.

The impedance experiments reported in the following sections were all conducted by using circular thin-film electrodes with diameters between 250 μm and 6 mm. All electrodes were prepared from 100 nm-thick gold or indium-tin oxide films, with the cells being grown directly on the electrode surfaces after an adhesive protein film had been established. The electrodes were held inside a cell culture incubator with a humidified atmosphere, 37 °C and 5% (v/v) CO_2 (the use of CO_2 was necessary to establish a stationary pH inside the bulk electrolyte).

11.4.1.3 **Experimental Set-Up**

A block diagram of the experimental ECIS set-up, as used for experiments described in the following sections, is shown in Figure 11.4. Here, five working electrodes are arranged side-by-side with one common counter electrode, such that five individual measurements can be performed. The electrode array is placed inside an ordinary cell culture incubator. Outside the incubator, a computer-controlled relay switch allows each of the individual working electrodes to be addressed. The impedance analyzer records the data, while the external function generator is an optional device that can be used to manipulate the cells on the electrode surface by invasive electric fields (electroporation, wounding). The impedance data are acquired in continuous-wave mode using noninvasive sinusoidal voltages of 10 mV_{rms} amplitude. The frequency range for analysis depends on the cell type under study, the surface area of the electrode, and the required time

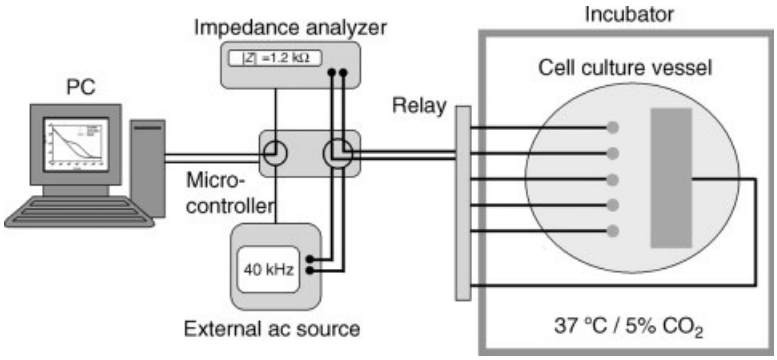

Figure 11.4 Experimental set-up to perform impedance analysis of animal cells grown on the surface of thin-film electrodes such as gold or indium-tin oxide. One or more working electrodes and a common counter electrode are deposited on the bottom of a cell culture dish. The electrode-containing dish is placed inside an ordinary cell-culture incubator to provide physiological conditions. A computer-controlled relay is used to address individual electrodes, the impedance analyzer records the frequency-dependent impedance of the system, and an external ac source may be used for invasive manipulations of the cells on the electrode.

resolution. Full spectral information is typically provided when the impedance is scanned from 1 Hz to 1 MHz.

11.4.2
Time-Resolved Impedance Measurements at Designated Frequencies

The information content of impedance measurements over a range of frequencies during the establishment of a cell monolayer starting from a suspension of single cells is best demonstrated by a 3-D presentation. To account for the complex nature of the impedance Z, the choice can be made to study the impedance magnitude $|Z|$ and the phase angle φ or resistance and reactance or any other representation of the real and imaginary components, as listed above. In the literature about impedance measurements on cultured animal cells by means of thin-film electrodes, one presentation has evolved that provides certain practical advantages [56]. Here, the complex impedance is decomposed in resistance $R = \mathrm{Re}(Z)$ and reactance $X = \mathrm{Im}(Z)$, followed by transformation of the reactance into an equivalent capacitance according to $X = (2\pi \cdot f \cdot C)^{-1}$. In other words, the measured impedance is interpreted as if it had been recorded for a system that behaves like a resistor and a capacitor in series, with the resistance and capacitance of the elements being frequency-dependent. In order to avoid confusion between the parameters of the entire sample and of individual parts of the sample, the total impedance, resistance and capacitance of the entire sample are from now on represented by Z, R and C without subscripts, whereas subordinate components are labeled with appropriate indices.

The time course of the total resistance R and total capacitance C as a function of frequency, when a suspension of epithelial MDCK cells is seeded on the electrodes at

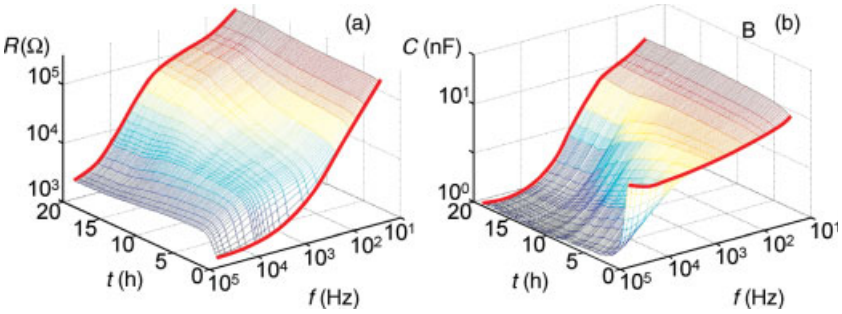

Figure 11.5 Total resistance *R* (a) and capacitance *C* (b) of a gold-film electrode ($d = 250\,\mu m$) when a suspension of MDCK cells is seeded on the electrodes at time zero. The seeding density was sufficiently high that no cell division was needed to establish a confluent cell layer. The red lines highlight the resistance and capacitance spectra for a cell-free and a fully cell-covered electrode at the beginning or end of the experiment, respectively.

time zero, is shown in Figure 11.5a and b [57]. The density of the cells was adjusted such that all adhesion sites on the surface were occupied by the settling cells, without any further cell division. At time zero, the resistance and capacitance spectra corresponded to those of an empty electrode (area $= 5 \times 10^{-4}\,cm^2$), whereas the spectra at the very end of the observation time (20 h) corresponded to the spectra of fully established cell layers with all cell junctions being expressed. (Note that the resistance and capacitance are plotted on a logarithmic scale.) When examining the resistance plot, it is easy to recognize that the time course of *R* is strongly dependent on the monitoring frequency. Whereas, the resistance increases immediately after cell seeding at high frequencies, it follows a biphasic pattern at intermediate frequencies and a retarded increase at the low-frequency end. The data for the total capacitance shows a less involved (but somewhat similar) pattern, with the largest and immediate changes at the high-frequency end and only very minor changes at the low-frequency end. An overlay of the resistance and capacitance spectra of a cell-free (filled symbols) and a cell-covered electrode (open symbols) as extracted from the 3-D profiles, is shown in Figure 11.6a and b, respectively.

The question is how such frequency-dependent resistance and capacitance characteristics arise. The answer to this point is shown in Figure 11.7, where the contributions to the total resistance/capacitance of a cell-free electrode can be described by an equivalent circuit of just two elements (Figure 11.7a): (i) the impedance of the electrode/electrolyte interface (hereafter referred to as the electrode impedance (Z_{el}); and (ii) the constriction resistance (R_{constr}) in series. As discussed above, the impedance of the electrode Z_{el} cannot be modeled accurately by an ideal capacitor, and is therefore represented by the complex impedance Z_{el}. The constriction resistance arises from constricting the electric field from the extended bulk phase down to the size of the electrode. This scales with $1/r$, where r is the radius of the electrode. Although the resistance of the bulk electrolyte is an inherent part of

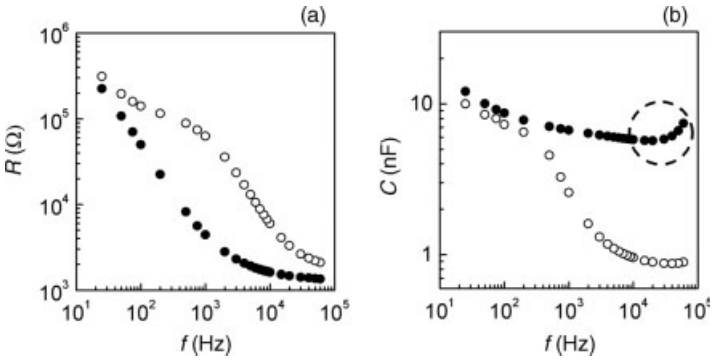

Figure 11.6 Direct overlay of the frequency-dependent resistance (a) and capacitance (b) spectra as recorded for a circular gold-film electrode with a diameter of 250 µm before (filled symbols) and after (open symbols) a monolayer of MDCK cells is established on the electrode surface. The presented spectra have been sliced out of the 3-D presentation shown in Figure 11.5 at times $t = 0$ h and $t = 20$ h. The circle in panel (b) indicates a parasitic increase of the measured capacitance which is due to cables and wiring.

R_{constr}, for the electrode sizes studied here the current constriction dominates this parameter. When referring to the spectra shown in Figure 11.6, the electrode impedance Z_{el} determines the total resistance of a cell-free electrode (filled symbols) at low frequencies, whereas R_{constr} dominates at high frequencies. The total capaci-

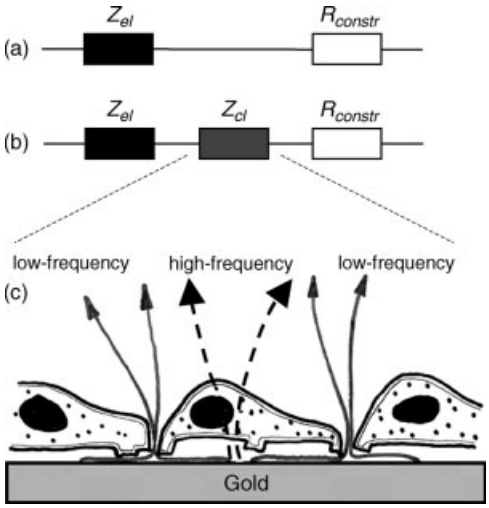

Figure 11.7 Equivalent circuit presentation of a cell-free (a) and a cell-covered (b) gold-film electrode. The cell-free electrode is completely described by a series combination of resistor R_{constr}, representing both, the constriction resistance due to the finite size of the electrode and the resistance of the bulk electrolyte, as well as the impedance of the electrode/electrolyte interface, Z_{el}. The impedance contributions of the cell layer, Z_{cl}, arise from the transcellular current pathway through the cells (broken arrows) and the paracellular current pathway around the cell bodies (solid arrows), as sketched in panel (c).

tance of the cell-free electrode arises solely from Z_{el}. It should be noted that the finite slope of the capacitance spectrum indicates that the electrode is not a perfect capacitor.

For a cell-covered electrode the impedance contribution associated with the presence of cell bodies on the electrode surface Z_{cell} must be added in series to the equivalent circuit of the cell-free electrode discussed above (see Figure 11.7b). The impact of Z_{cell} on the total resistance and capacitance is made very clear by comparing the corresponding spectra for a cell-free and a cell-covered electrode, as provided in Figure 11.6. In order to help understand the origin and contributions to Z_{cell}, Figure 11.7c illustrates the frequency-dependent current flow across the cell layer that can be explained in a two-case approach:

- At high frequencies ($f > 10$ kHz), the current can flow as a displacement current across the membranes, straight through the cell bodies (dashed line) as the plasma membranes behave electrically like capacitors. This is evident from the step-like drop in the spectrum of total capacitance towards higher frequencies (Figure 11.6b). Thus, at these high frequencies C holds information on the capacitance of the plasma membranes C_m, and can be used to monitor its changes during experimental challenges. However, there is another important aspect to this. As the drop in total capacitance at high frequencies is caused by the presence of the plasma membranes on the electrodes, the readings of total capacitance at these high frequencies can be used to determine the electrode coverage. As will be shown below, this relationship between changes in high-frequency capacitance and electrode surface coverage is extremely useful when monitoring cell attachment and spreading to the electrode surface, and in turn the formation of cell–matrix junctions [57].
- When the frequency of the ac signal is lowered well below 10 kHz, the plasma membranes become blocked due to their capacitive nature and the current must flow around the cell bodies in order to escape into the bulk electrolyte (straight lines). On bypassing the cell body, the current must pass through the narrow cleft between the lower cell membrane and the electrode surface, and further on through the cell–cell junctions. Thus, the signal holds information on the electrical properties of cell–matrix and cell–cell junctions, and so can be used to monitor these particular structures.

11.4.2.1 *De novo* Formation of Cell–Matrix and Cell–Cell Junctions

From theoretical considerations (as detailed above) and a set of validation experiments, we have learned that capacitance readings at high frequencies (ca. 10 kHz for the electrodes used here) are best for monitoring the *de novo* formation of cell–matrix contacts during attachment and spreading of initially suspended cells, whereas the resistance at frequencies below 1 kHz (usually 400 Hz for the electrodes used here) is best suited for reporting on the formation of cell junctions, in particular barrier forming tight junctions. A typical readout of the resistance R at 400 Hz and the capacitance C at 40 kHz during the establishment of a mature cell layer is summarized in Figure 11.8a and b for a duplicate experiment. Here, a suspension of epithelial

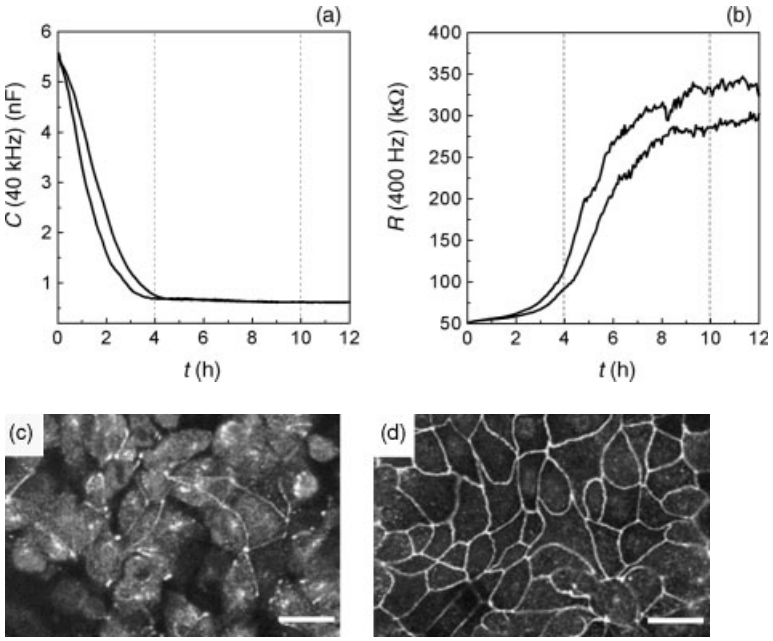

Figure 11.8 Time course of the total capacitance *C* at a monitoring frequency of 40 kHz (a) and the total resistance *R* at 400 Hz (b) during attachment, spreading and differentiation of initially suspended MDCK cells. The number of cells seeded on the electrodes was sufficiently high to form a confluent monolayer without cell division. The vertical dashed lines indicate the times at which immunolabeling of duplicate cultures was performed that are shown in panels (c) and (d). The fluorescence micrographs show the MDCK cell monolayer at the indicated times of 4 h (c) or 10 h (d) after seeding on the growth substrate. The cells were stained for the tight junction-associated protein ZO-1. Scale bar = 25 µm.

MDCK cells has been seeded on the electrode at time zero. The initial cell density (500 000 cm^{-2}) was sufficiently high so that a complete monolayer of cells could form without any further cell division. (MDCK cells are a well-known epithelial cell line that is used extensively worldwide to study tight junctions.) The capacitance drop presented in Figure 11.8 a reports to the attachment and spreading of cells on the electrode surface, which began immediately after the cell suspension had been introduced into the electrode-containing chamber. The cells had been suspended in a serum-containing medium, which led to the spontaneous and immediate adsorption of adhesive proteins from the serum onto the electrode surface. The time course of the total capacitance indicated that the *de novo* formation of cell–matrix junctions was complete, and that the surface was entirely covered with spread cells within 4 h. At approximately the time when cell adhesion was complete, the resistance at 400 Hz began to increase considerably for the next 6 h (Figure 11.8b), indicating the formation of barrier forming tight junctions between adjacent cells. Thus, from a cell biology viewpoint, the formation of tight junctions requires fully established cell–matrix contacts. The minor increase in resistance observed during the initial 4 h of the experiment was

caused by the constriction of current flow underneath the cells during attachment and spreading, and was therefore due to the formation of cell–matrix junctions. However, as the drop in capacitance C at 40 kHz correlates linearly with the fractional surface coverage of the electrode, C is to be the more useful parameter to monitor.

In order to back up these impedance data by microscopic studies, two aliquots of the same cell suspension were seeded on ordinary microscope slides and immunostained for the tight junction-associated proteins ZO-1. The fluorescence micrographs in Figure 11.8c and d provide typical snapshots of the distribution of ZO-1 in MDCK cells at 4 h and 10 h after cell inoculation, respectively. Whereas, after 4 h only very few cell–cell contact sites showed a positive staining for ZO-1, the protein was completely allocated to the cell borders after 10 h, consistent with the time course of R at a monitoring frequency of 400 Hz. Taken together, the results of these experiments show that it is possible to monitor the formation of cell–matrix and cell–cell contacts in one and the same cell population by utilizing noninvasive impedance measurements in real time, and that the impedance readings are in line with microscopic studies.

Additional experimental support for the claim that spreading of cells and formation of cell–cell junctions can be monitored individually simply by examining different ac frequencies is provided by an experiment in which, again, MDCK cells were seeded on electrodes that had been precoated with an adhesive protein (fibronectin). In this experiment, one population of cells was suspended in a buffer that contained 1 mM Ca^{2+} as the only divalent cation, while a second population was suspended in buffer containing 1 mM Mg^{2+} as the only divalent cation. The rationale of this approach was that the formation of cell–matrix junctions is dependent on the presence of either Ca^{2+} or Mg^{2+} (or Mn^{2+}), whereas tight junction formation is known to depend on the presence of Ca^{2+}, which cannot be substituted by a different cation. Figure 11.9a shows the time course of the capacitance C at 40 kHz for

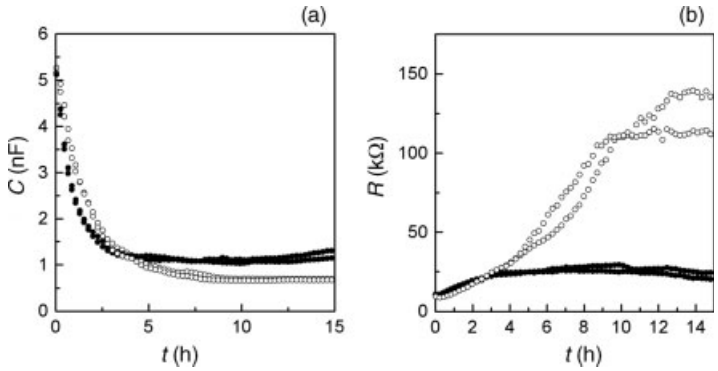

Figure 11.9 Time course of the total capacitance C at a monitoring frequency of 40 kHz (a) and the total resistance R at 400 Hz (b) during attachment, spreading and differentiation of initially suspended MDCK cells in different salt solutions. Cells were suspended in a buffer containing either 1 mM Mg^{2+} (filled symbols) or 1 mM Ca^{2+} (open symbols) as the only divalent cation.

duplicates of both conditions, while Figure 11.9b shows the resistance R at 400 Hz. In the presence of Mg^{2+}, the cells attached and spread slightly faster than in the presence of Ca^{2+}, whereas only in the presence of Ca^{2+} the resistance at 400 Hz increased significantly, indicating that tight junctions were formed only under the latter conditions. Although, from a cell biology viewpoint these experiments did not provide any new insight, they did demonstrate the capability of impedance analysis for monitoring cell junctions noninvasively and in real time. Recently, it was shown that this technology is well suited to unravel the different spreading rates of MDCK cells on various different protein coatings on the electrode surface, with unprecedented time resolution [57].

11.4.2.2 Modulation of Established Cell Junctions

In the experiments described above impedance measurements were used to follow the *de novo* formation of cell junctions when suspended cells were seeded onto the measuring electrodes. Another – perhaps more often conducted – experiment addresses the modulation of already established cell junctions within a confluent monolayer of cells upon exposure to a given stimulus. These stimuli can be biological (bacteria, viruses, cancer cells), physical (electric fields, mechanic shear) or chemical (toxins, drugs) in nature.

As an example of such an experiment, Figure 11.10 traces the time courses of resistance R at 100 Hz and capacitance C at 100 kHz when a confluent layer of epithelial MDCK cells is exposed to a 5 µM solution of Cytochalasin D (CD). CD is a fungal toxin that interferes with the actin cytoskeleton of animal cells. Actin filaments

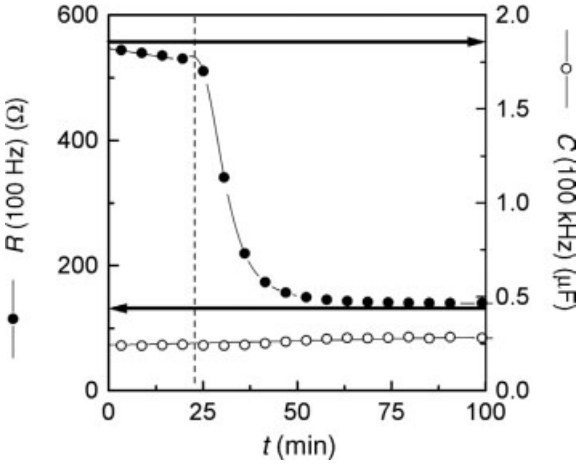

Figure 11.10 Time course of the total resistance R at a monitoring frequency of 100 Hz and total capacitance C at a frequency of 100 kHz before and during a confluent monolayer of MDCK cells was exposed to 5 µM Cytochalasin D (CD). The vertical dashed line indicates the time of CD addition to the cell population; horizontal arrows indicate the corresponding resistance or capacitance value of a cell-free electrode. The arrowheads point to the *y*-axis to which the arrow refers. Note: this experiment was performed with a working electrode with a surface area of 0.33 cm^2.

(f-actin) are polymers made from globular actin monomers (g-actin), and are highly dynamic structures that grow continuously at one end (polymerization) while shrinking at the other end (de-polymerization), depending on the requirements of the cells in a given physiological situation. Although CD interferes rigorously with actin polymerization, depolymerization is left unaffected so that the actin filaments become disassembled with time. With respect to the impedance readout, exposure to CD leads to a striking drop in the resistance at 100 Hz, whereas the capacitance changes only marginally. In Figure 11.10, the horizontal arrows indicate the values of R and C for the cell-free electrode, with the arrowheads pointing at the axis to which they refer. When translated into a molecular perspective, these time courses reveal that the cell–cell junctions must have completely disassembled during the exposure to CD, whereas the cells remain attached to the surface. Even though cell–matrix junctions might be compromised by the fungal toxin, they can still withstand the inner tension of the cell body and prevent cells from rolling up and losing their matrix anchorage.

The same experiment has been followed using fluorescence microscopy in order to correlate both readouts, comparing a layer of MDCK cells before and 50 min after exposure to 5 μM CD (see Figure 11.11a and b, respectively). For both images, the cells were stained with fluorescently labeled phalloidin. (Phalloidin binds to filamentous but not globular actin, and is therefore the classical stain for studying the actin cytoskeleton when using fluorescence microscopy.) After exposure to CD, the actin filaments visible inside the cell bodies of the control had entirely disappeared, as had the belt of actin filaments that ran around the periphery of the MDCK cells. Only actin aggregates were left in the CD-treated cells which, however, were still anchored to their growth substrate. Fluorescence micrographs of MDCK cells exposed to either 5 μM CD for 50 min or control conditions are shown in Figure 11.11c and d, respectively, although now the tight junction-associated protein ZO-1 is labeled with fluorescent antibodies. Under control conditions the junctional staining completely circumscribed the periphery of the individual cells. In contrast, after CD exposure the junctional staining was punctuated and discontinuous, indicating a loss of junctional tightness. To summarize, these microscopic studies on molecules that contribute to the cellular junctions are perfectly in line with the impedance readings on the time course of junctional disintegration, and their interpretation.

At this point it should be noted that monitoring the capacitance at high frequency only reports on electrode coverage. As long as the *de novo* formation of cell-matrix junctions is considered, coverage of the electrode is indicative of the formation of cell–matrix junctions. However, in an established cell monolayer, cell–matrix junctions may be moderately altered, without causing complete removal of the cell layer from the electrode surface. Under these conditions capacitance readings are insensitive, but improvements can be achieved if the impedance data are recorded over an extended frequency range (instead of only one or two designated frequencies), and when the impedance spectrum of a completely cell-covered electrode is modeled in detail. If the experiment is conducted in this way, even minor changes in the cell–matrix adhesion sites can be identified and followed with time. The model used to analyze the impedance spectra of established cell monolayers is described in the following section.

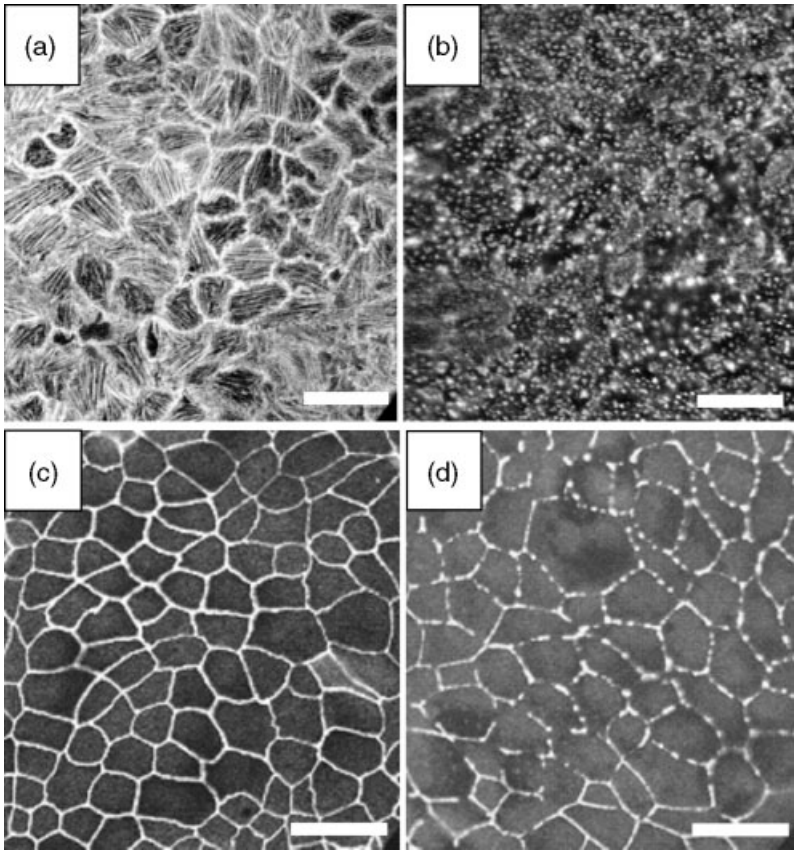

Figure 11.11 Micrographs of confluent MDCK cell layers with fluorescently labeled actin cytoskeleton (a, b) or with an immunofluorescence tag addressing the tight junction-associated protein ZO-1 (c, d). Panels (a) and (c) show control populations; cell layers in panels (b) and (d) were exposed to 5 μ*M* Cytochalasin D for 50 min. Scale bars = 25 μm.

11.4.3
Modeling the Complex Impedance of Cell-Covered Electrodes

In order to interpret the impedance spectra of cell-covered film-electrodes, a physical model has been developed that accounts for the impedance contributions associated with the presence of cells on the electrode surface, as described qualitatively above [58, 59]. In this model (Figure 11.12), the cells are treated as disk-shaped objects with a radius r_c, and are considered to hover at an average distance h above the electrode surface. Hence, two current pathways can be considered:

- At low ac frequencies the current will mainly flow from the electrode through the thin fluid-filled cleft between the cell and the electrode, and leave the cell sheet

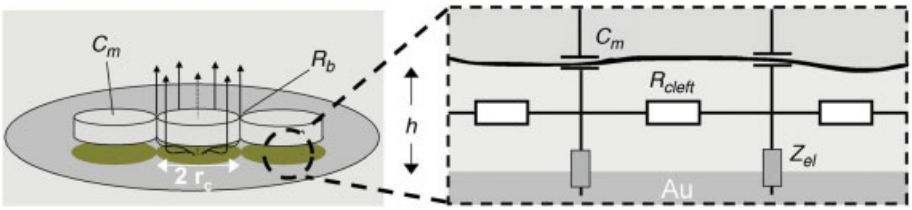

Figure 11.12 Sketch illustrating the physical model used to analyze and predict the complex impedance of cell-covered gold-film electrodes. The resistance R_b represents the resistance of the current pathway between two adjacent cells through the cell–cell junctions; the resistance R_{cleft} represents the resistance of the aqueous cleft underneath the cells at the site of cell–matrix junctions. The capacitance of the plasma membranes is accounted for by C_m. In the model, the cell bodies are treated as cylindrical disks with radius r_c that are separated from the electrode surface by distance h.

through the cell–cell junctions between adjacent cells (straight arrows). The model parameter R_{cleft} accounts for the impedance arising at the site of cell–matrix junctions, whereas R_b represents the resistive properties of the cell–cell junctions.

- At high frequency, the cell membrane, which is modeled as a capacitor C_m, allows a displacement current to pass through the cells (broken arrow). The resistive component of the plasma membrane impedance due to the presence of ion channels is neglected in the calculation as it is significantly higher than the paracellular resistance in most cases.

At intermediate frequencies the current makes use of both pathways and splits up in frequency and position-dependent ratios. Thus, the cell–electrode junction behaves like a 2-D core-coat conductor, with the inner electrolyte core and plasma membrane as well as the electrode surface as outer dielectric coats. Solving the 2-D cable equation with proper boundary conditions provides the following transfer function for the impedance of a cell-covered electrode Z_{cell}:

$$\frac{1}{Z_{cell}} = \frac{1}{Z_{el}}\left(\frac{Z_{el}}{Z_{el}+Z_m} + \frac{\frac{Z_m}{Z_{el}+Z_m}}{\frac{\gamma r_c}{2}\cdot\frac{I_0(\gamma r_c)}{I_1(\gamma r_c)} + R_b\left(\frac{1}{Z_{el}}+\frac{1}{Z_m}\right)}\right) \tag{11.5}$$

$$\text{with} \quad \gamma r_c = r_c \cdot \sqrt{\frac{\rho}{h}\left(\frac{1}{Z_{el}}+\frac{1}{Z_m}\right)} = \alpha \cdot \sqrt{\left(\frac{1}{Z_{el}}+\frac{1}{Z_m}\right)} \tag{11.6}$$

$$\text{and} \quad \alpha^2 = R_{\text{cleft}}$$

Here, I_0 and I_1 are modified Bessel functions of the first type of order 0 and 1, R_b is the resistance of cell–cell junctions, ρ is the specific electrolyte resistance inside the cell–electrode junction, and Z_m accounts for the impedance of the transcellular high-frequency pathway across both, the upper and lower membranes $Z_m = 2/(\omega \cdot C_m)$. Finally, the impedance of a cell-free electrode Z_{el} is most accurately modeled by a CPE

behavior, thus $Z_{el} = {}^{1}/_{A(i\omega)^n}$ with the parameter n ($0 \leq n \leq 1$) as an indicator for the deviation from ideal capacitive behavior, with $n = 1$ [60].

Fitting the above-described model to experimental impedance spectra provides three parameters to describe the changes that occur within the cell layer: R_{cleft} describes alterations at the site of cell–matrix adhesion; R_b describes changes within cell–cell junctions; and C_m reports on changes of the membrane capacitance.

The nonredundant model outlined above has been extended to represent the cellular structure with respect to geometry and electrical structure. More accurately for instance, the above model for disk-like cells has been adapted for elliptical cells, however, the long and small axes of the cellular ellipsoid must be determined independently from microscopic images [61]. Another approach accounts individually for the capacitance of the apical, basal and lateral membrane [62]. However, this latter model introduces two more parameters into the transfer function that cannot be determined independently, thus making it redundant. As can be seen from the microscopic images presented in Figures 11.8 and 11.11, the circular approximation is well justified for MDCK cells.

11.4.4
Spectroscopic Characterization of Cell–Cell and Cell–Matrix Junctions

If a cell layer is studied by continuously recording impedance spectra over a sufficiently extended frequency range during an experimental challenge, the analysis of these spectra with the above-described model will provide the time course of the model parameters R_b, R_{cleft} and C_m, which allows the cell response to be characterized in more detail. For demonstration, the data of MDCK cells challenged with 5 μM CD are reconsidered. The cell response to the CD challenge was monitored by repeatedly recording the impedance spectra, from 1 Hz to 1 MHz. In Figure 11.10, only the time courses of resistance at 100 Hz and capacitance at 100 kHz, respectively, are presented. An analysis of the complete full-width impedance spectra provides the time courses of R_b, R_{cleft} and C_m, but such modeling is only meaningful if the cell layer is still confluent, without significant defects. When the MDCK cells were exposed to 5 μM CD the membrane capacitance did not alter significantly during the time of the study. The changes in R_b and R_{cleft} are shown in Figure 11.13. As already deduced from the resistance readings at 100 Hz, the epithelial barrier function disappeared completely on exposure to CD. R_b fell from almost 100 $\Omega \cdot cm^2$ to values not significantly different from 0. Although the capacitance readings at 100 kHz correctly indicated that the cells had not detached from the electrode surface, there is nevertheless a drastic change in cell–matrix adhesion. The values for the R_{cleft} fall, from 250 to 25 $\Omega \cdot cm^2$. Thus, whilst the matrix anchorage is still sufficiently strong to keep the cells attached to the surface, there has been a considerable reorientation of the cell–matrix adhesion sites due to the activity of CD. According to the definition of R_{cleft}, which is

$$R_{cleft} = r_c^2 \frac{\rho}{h} \tag{11.7}$$

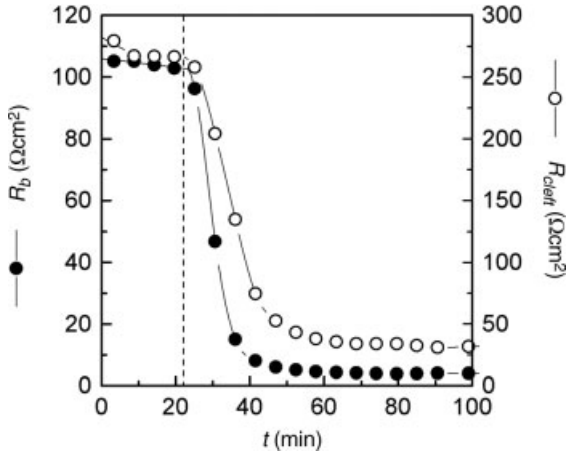

Figure 11.13 Time course of the model parameters R_b and R_{cleft} before and during a confluent monolayer of MDCK cells being exposed to 5 µ*M* Cytochalasin D. The model parameters were extracted from complete impedance spectra recorded over six frequency decades from 1 to 10^6 Hz. The membrane capacitance C_m (data not included) did not change during the course of the experiment.

the observed changes may be due to changes in r_c, ρ or h. As the cell radius cannot be changed very much in a continuous monolayer, the changes must arise from either changes in the specific electrolyte resistance ρ in the cell–electrode junction, or from an increase in the average distance between the lower cell membrane and electrode surface h, or both. This ambiguity cannot be resolved unless one of these two quantities is measured independently. If it is assumed that all changes in R_{cleft} are due to an increase in the average cell–substrate separation distance h (which has been determined as 25 nm under control conditions, using FLIC microscopy), then the observed changes in R_{cleft} translate into a change of h from 25 to 250 nm. However, this seems unlikely, and indicates that both, h and ρ may have changed. This example illustrates that, despite not being an imaging technique, impedance analysis is still sufficiently sensitive to report changes on the nanoscale, even at hidden interfaces such as the cell–electrode junction that are not accessible by scanning probe techniques.

Taken together, the impedance analysis of cell-covered film electrodes provides functional information concerning cell–cell and cell–matrix junctions in a time-resolved and noninvasive, but integral and nonimaging, manner. An approximate calculation using the above-described model, plus realistic estimates for the resolution of each model parameter, reveals that impedance analysis is more sensitive than light microscopy and capable of identifying differences on the nanometer scale. Moreover, the data can be recorded without opening the incubator door and with multiple samples in parallel, both of which are important considerations for screening processes.

Top-Down Fabrication of Nanostructures

Ming Liu, Zhuoyu Ji, and Liwei Shang

1.1
Introduction

The "top-down" approach to nanofabrication involves the creation of "nanostructures" from a large parent entity. This type of fabrication is based on a number of tools and methodologies which consist of three major steps:

1) The deposition of thin films/coatings on a substrate.
2) Obtaining the desired shapes via photolithography.
3) Pattern transfer using either a lift-off process or selective etching of the films

Compared with general chemical fabrication and processing methods, top-down fabrication techniques for the creation of nanostructures are derived mainly from the techniques applied for the fabrication of microstructures in the semiconductor industry. In particular, the fundamentals and basic approaches are mostly based on micro-fabrications. In this chapter, methods of top-down nanofabrication will be discussed, with attention being focused primarily on methods of lithography, especially optical, electron-beam, X-ray and focused ion beam lithography. A brief introduction will also be provided on how to create nanostructures using various methods of thin film deposition and etching materials. Finally, the methods for pattern transfer through etching and lift-off techniques will be discussed.

In the past, top-down fabrication techniques have represented an effective approach for nanostructures and, when complemented with bottom-up approaches during the past few decades, have led to amazing progress having been made with a variety of nanostructures. The traditional top-down technology used to create nanostructures and nanopatterns is discussed in the following sections.

1.2
Lithography

Lithography, which is also often referred to as "photoengraving," was invented in 1798 in Germany by Alois Senefelder. It is the process of defining useful shapes on

Nanotechnology, Volume 8: Nanostructured Surfaces. Edited by Lifeng Chi

ISBN: 978-3-527-31739-4

the surface of a semiconductor wafer [1–5]. Typically, it consists of a patterned exposure into some form of photosensitive material that has already been deposited onto the wafer. Many techniques of lithography have been developed during the past fifty years, by using a variety of lens systems and exposure radiation sources that have included photons, X-rays, electrons, ions, and neutral atoms. In spite of the different exposure radiation sources used in the various lithographic methods, and the instrumental details, all of these techniques share the same general approaches and are based on similar fundamentals. *Photolithography* is the most widely used technique in microelectronic fabrication, particularly for the mass production of integrated circuits (ICs) [2], and has been the driving force behind the miniaturization of such circuits since they were first produced at Fairchild and at Texas Instruments during the early 1960s [6].

1.2.1 Photolithography

Photolithography (also called "optical lithography") is simply lithography using a radiation source with wavelength(s) in the visible spectrum. It has served as the dominant patterning technology in the semiconductor industry since the IC was invented almost sixty years ago. From the onset, optical lithography has always managed to keep pace with Moore's law [7, 8], including its recent acceleration. In order to keep pace with the shrinking feature size, a steady stream of improvements in the field of resolution, image placement, and pattern transfer have been introduced time after time, and these have enabled optical lithography to hold off the challenges of the competing lithography technologies.

The key historical events in photolithography have been as follow:

- 1826: Joseph Nicephore Niepce, in Chalon, France, takes the first photograph using bitumen of Judea on a pewter plate, developed using oil of lavender and mineral spirits.
- 1843: William Henry Fox Talbot, in England, develops dichromated gelatin, patented in Britain in 1852.
- 1935: Louis Minsk of Eastman Kodak develops the first synthetic photopolymer, poly(vinyl cinnamate), the basis of the first negative photoresists.
- 1940: Otto Suess of Kalle Division of Hoechst AG, develops the first diazoquinone-based positive photoresist.
- 1954: Louis Plambeck, Jr, of Du Pont, develops the Dycryl polymeric letterpress plate.

Optical lithography is a process used in microfabrication to selectively remove parts of a thin film (or the bulk of a substrate). It involves the use of an optical technique to produce images at smaller scales, which employs light to transfer a geometric pattern from a photomask to a light-sensitive chemical (photoresist, or simply "resist") on the substrate. The steps involved in the photolithographic process include: wafer cleaning; barrier layer formation; photoresist application; soft baking; mask alignment; exposure and development; and hard-baking.

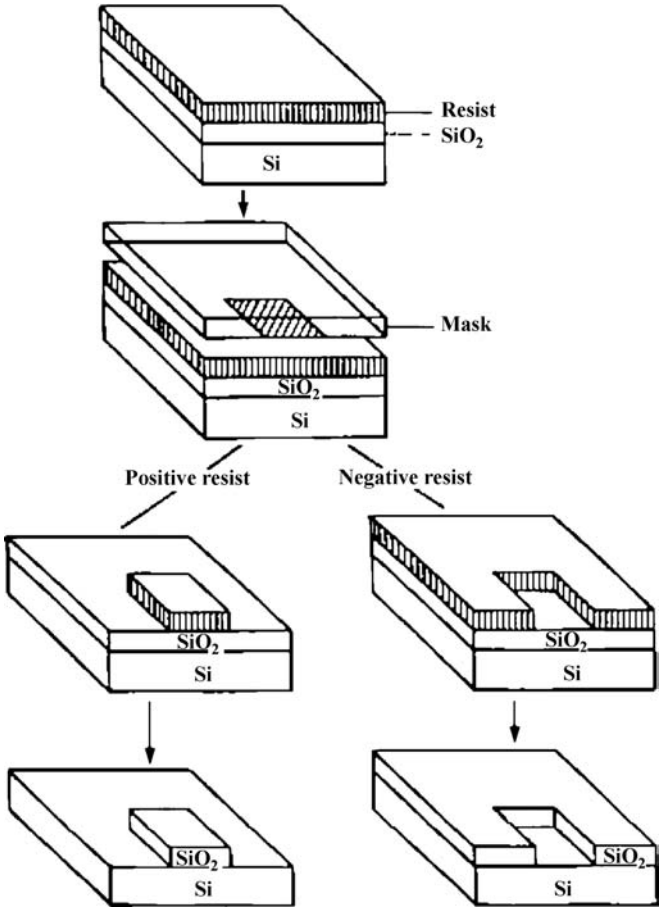

Figure 1.1 Schematic representation of the photolithographic process sequences, in which images in the mask are transferred to the underlying substrate surface.

The basic scheme of photolithography (as shown in Figure 1.1) involves three steps [9]: (i) a thin film of resist material is cast over the substrate; (ii) the substrate is then exposed to a pattern of intense light through a mask, during which time the resist material is selectively struck by the light; (iii) the exposed substrate is then immersed into the development solvent.

Depending on the chemical nature of the resist material, the photoresist is defined as either a positive or a negative type. For positive resists, the resist is exposed to ultraviolet (UV) light wherever the underlying material is to be removed. In these resists, exposure to the UV light alters the chemical structure of the resist, which causes it to become more soluble in the developing solvent than in the unexposed areas. The resist exposed under the UV light is then washed away by the developer solution. Overall, the process can be described as "whatever shows, goes away." In contrast, in the case of a negative resist, the exposed areas may be rendered less

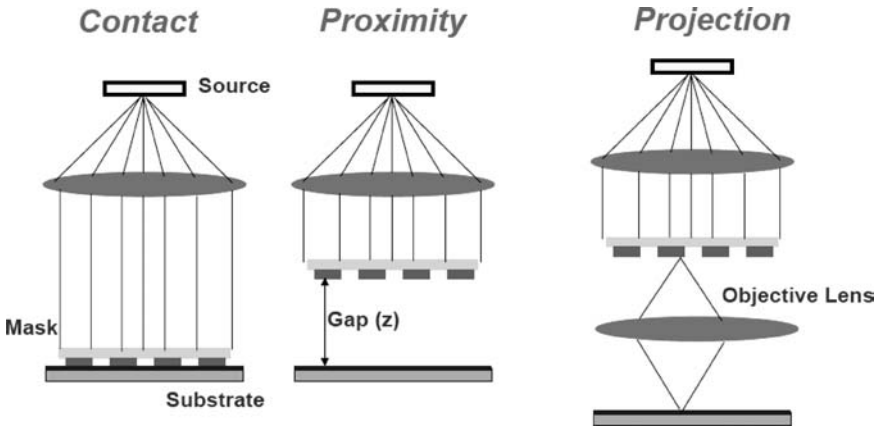

Figure 1.2 Schematic diagram of working modes of photolithography.

soluble in a certain developing solvent; this leads to the production of a negative tone image of the shadow mask, a process described as "whatever shows, stays behind."

In addition to conventional photoresist polymers, Langmuir–Blodgett films and self-assembled monolayers (SAMs) have also been used as resists in photolithography [10, 11]. In such applications, photochemical oxidation, crosslinking, or the generation of reactive groups are used to transfer patterns from the mask to the mono-layer [12, 13].

A *master mask* is necessary in the process of photolithography, and in general this is scribed using an optical method and produced by chemical etching. In this case, the light passes through the mask to define the actual structure in the material; according to the position of the mask with respect to the sample, three types of exposure lithography can be defined, namely contact, proximity, and projection lithography (see Figure 1.2).

Up until to the early 1970s, most lithography was carried out as either a contact or a close-proximity printing process, in which blue and near-UV light was passed through a photomask directly onto a photoresist-coated semiconductor substrate [14]. This apparently simple shadow imaging process has been described in many research reports and handbooks [15, 16].

1.2.1.1 **Contact Printing**

In contact-mode photolithography, the resist-coated silicon wafer is brought into intimate physical contact with the glass photomask. For this, the wafer is held on a vacuum chuck and the whole assembly rises until the wafer and mask make contact with each other. The photoresist is exposed to UV light while the wafer is in contact position with the mask, and this allows a mask pattern to be transferred into a photoresist with almost 100% accuracy, as well as providing the highest resolution (e.g., 1 μm features in 0.5 μm of positive resist). Unfortunately, however, the maximum resolution is seldom achieved owing to the presence of dust on the

substrates and the nonuniform thicknesses of both the photoresist and the substrate. The main problem with contact printing is that debris, trapped between the resist and the mask, can damage the mask and cause defects in the pattern.

1.2.1.2 **Proximity Printing**

The proximity exposure method is similar to contact printing, and involves introducing a gap about 10–25 μm wide between the mask and the wafer during the exposure stage. This gap minimizes (but may not eliminate) the mask damage. Although a resolution of about 2–4 μm is possible with proximity printing, increasing the gap will reduce the resolution by expanding the penumbral region caused by diffraction. The main difficulties associated with proximity printing include the control of a small and very constant space between the mask and wafer, which can be achieved only by using extremely flat wafers and masks.

1.2.1.3 **Projection Printing**

Generally speaking, projection techniques have a lower resolution capability than that provided by shadow printing. However, unlike shadow printing, in projection printing the lens elements are used to focus the mask image onto a wafer substrate, which is separated from the mask by several centimeters so that damage to the mask is entirely avoided. An image of the patterns on the mask is projected onto the resist-coated wafer, which is located several centimeters away. In order to achieve a high resolution, only a small portion of the mask is imaged, and the small image field is scanned or stepped over the surface of the wafer. Projection printers that step the mask image over the wafer surface are termed "step-and-repeat" systems, and are capable of approximately 1 μm resolution.

The first widespread use of projection printing for semiconductor manufacturing was fostered by a very well-accepted family of tools from Perkin-Elmer, the so-called "Micralign" projection aligners developed during the early 1970s. For the first time, these tools allowed a higher performance pattern definition by scanning and imaging only a fractional area of the wafer at any instant. Moreover, the optical resolution and pattern overlay performances were also significantly enhanced. The technique of projection printing was further developed when a new class of projection exposure tools – typically referred to as "steppers" – was introduced during the late 1970s [17]. For the first time, the pattern definition imaging on the semiconductor wafers was performed one chip at a time, in a step-and-repeat fashion. This had profound implications not only on the requirements for the photomask but also on the precision mechanical movements needed to accurately overlay a new pattern on underlying patterns already on the wafer substrate.

1.2.1.4 **Resolution Enhancement Techniques (RETs)**

Various RET approaches have undergone intense investigation during the past few years, and many reports have been made worldwide at leading lithography conferences. Moreover, most of these techniques have been introduced into high-volume wafer manufacture. The RETs interact in many ways, and Smith has discussed in some detail the impact of interacting factors when designing and refining the lithography

Table 1.1 The main categories of resolution enhancement technique in current use and undergoing investigation.

Resolution enhancement technique	Type	Advantage(s)	Disadvantage(s)
Phase-shift masks	Wavefront engineering	Improves DoF and exposure latitude	High mask cost, inspection and repair difficult
Modified illumination	Wavefront engineering	Improves DoF for dense line/space feature	Less improvement for holes or isolated lines affected by lens aberrations
Optical proximity correction (OPC)	Mask engineering	Improved CD control for various patterns	Additional design data processing masks more complex and expensive
Wafer control – antireflective layers	Resist engineering	Improved CD control reduces notching	Increased cost and process complexity may complicate etch
Pupil filtering	Wavefront engineering	Improved CD control and exposure latitude	Pattern-specific capability must be designed in by lens manufacturer
Multilayer and surface imaging resists	Resist engineering	Improved CD control, resolution, including antireflective functionality	Increased process complexity and cost

CD = critical dimension.

process [18]. The main categories of RETs currently being investigated and used are listed in Table 1.1; two of these techniques – phase-shifting mask (PSM) lithography and optical proximity correction (OPC) – are discussed in the following sections.

Phase-Shifting Mask Lithography Phase-shifting masks for optical lithography were developed by Levenson and coworkers at IBM during the early 1980s [19], although the independent development of phase shifting was also underway at the same time by Shibuya [20] and Smith [21, 22]. Phase-shifting masks are photomasks that take advantage of the interference generated by phase differences to improve the image resolution in photolithography, and exist in either alternating or attenuated forms.

Alternating Phase-Shifting Masks. In the case of an alternating PSM, a thin layer of transparent material of correct thickness is added onto the mask; this induces an abrupt change of the phase of the light used for exposure, and causes optical attenuation at desired locations. These phase masks (which are also known as "phase shifters") have produced features of −100 nm [23, 24] in photoresist. The correct thickness of the shifter is usually demonstrated by the physical thickness that provides an optical path length exactly one-half wavelength longer than the optical path length in the same thickness of air.

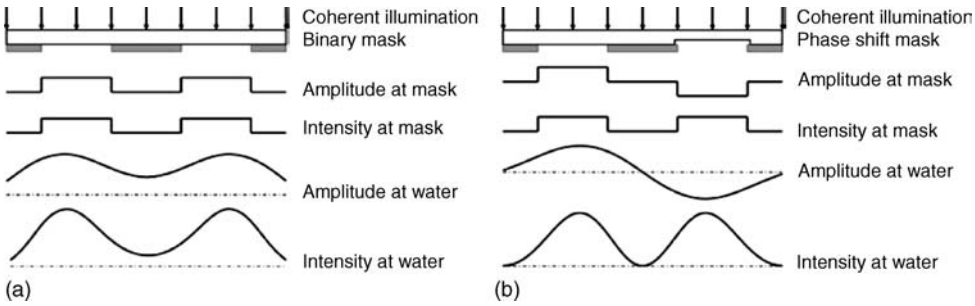

Figure 1.3 Alternating-phase shift masks. (a) Superposition of aerial image amplitudes for coherent illumination of a binary mask; (b) Superposition of aerial image amplitudes for coherent illumination of an alternating-phase shift mask.

The required phase shifter thickness is given by:

$$t = \frac{\lambda}{2(n-1)}$$

where n is the index of refraction of the shifter material. For typical conditions with $n = 1.5$, the phase shifter thickness is the same as the exposure wavelength.

The general concept of phase-shifting lithography is illustrated schematically in Figure 1.3. Phase masks may be used in both projection and contact mode photolithographic techniques, with the achievable photolithographic resolution being approximately $-\lambda/4n$, where λ is the wavelength of the exposure light and n is the refractive index of the photoresist. In fact, feature lines as narrow as 50 nm have been generated in this way [25, 26], with the resolution achieved corresponding approximately to $\lambda/5$. One improved approach to conformal near-field photolithography is to use masks constructed from "soft" organic elastomeric polymers.

Attenuated Phase-Shift Masks. Attenuated PSM lithography improves the pattern fidelity by "darkening" the edges of shapes through the destructive interference of light, using a mildly translucent photomask. Now commonly called "embedded attenuated phase masks," mask substrates are used that allow a small amount of light (~7–10%) to penetrate the normally opaque mask regions. Terazawa and coworkers have developed a significantly different implementation of the PSM concept, which is often referred to as the embedded attenuated phase-shifting mask (EAPSM) [27]. The attenuated PSM functions with the same basic interference principles as the alternating PSM, but the details are totally different: some sketches of the attenuated PSM enhancement mechanism are shown in Figure 1.4.

Due to their simpler construction and operation – particularly in combination with optimized illumination for memory patterns – attenuated PSMs are already widely used. Although alternating PSMs are more difficult to manufacture, and this has slowed their adoption, their use is becoming more widespread. For example, the alternating PSM technique is currently being used by Intel to print gates for their 65 nm and subsequent node transistors [28, 29].

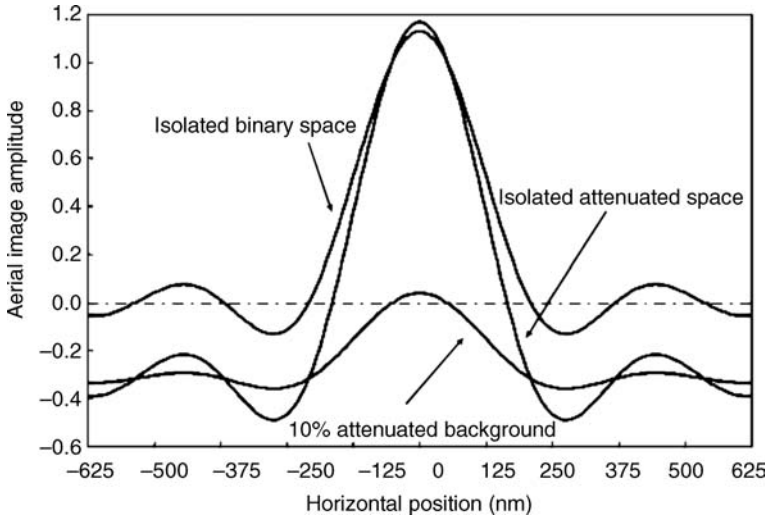

Figure 1.4 Attenuated-phase shift masks: Superposition of aerial image amplitudes for coherent illumination.

1.2.1.5 **Optical Proximity Correction (OPC)**

Optical proximity correction, as a photolithography enhancement technique, is frequently used to compensate for image errors caused by diffraction or process effects. The need for OPC applies mainly to the creation of semiconductor devices, the main reason for which is the limitation of light to resolve ever-finer details of patterns on the photomasks used to etch semiconductor passivation layers, and the difficulty in creating the building blocks of the transistors and other elements that constitute ICs. These projected images appeared as irregularities such as rounded corners, and with trace widths that were narrower than designed. If the diffraction effects could not be compensated, then the electrical properties of the fabricated unit would be significantly altered due to these distortions. OPC anticipates the irregularities of shape and size, and applies a corrective compensation to the photo mask images, which then produce a light beam that more closely approximates the intended shapes.

The two most common applications for OPC are line width differences between features in regions of different density (e.g., center versus edge of an array, or nested versus isolated lines), and line end shortening (e.g., gate overlap on a field oxide). In the case of the line width differences, scattering bars (subresolution lines placed adjacent to resolvable lines) or simple line width adjustments are applied to the design. For line end shortening, "dog-ear" (serif or hammerhead) features are attached to the line end in the design. OPC has a cost impact on photomask fabrication, as the addition of OPC features means more spots for defects to manifest themselves. Additionally, when using OPC the data size of the photomask layout will rise exponentially.

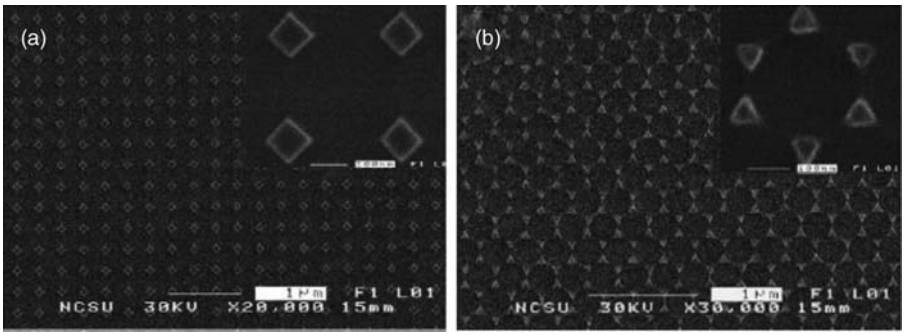

Figure 1.5 (a) Diamond shape pattern with the size of 80 nm × 80 nm and periods of 300 nm; (b) triangular shape pattern with the size is ∼73 nm and periods of 159 nm.

The OPC process is started by characterizing the patterning operation and all its inaccuracies from various sources, such as the mask build, wafer exposure, etch, and so on. In the now commonplace "model-based OPC," this mathematical description of the process is used in iterative optimization routines to predistort the mask shapes to compensate for known, systematic, and modeled patterning inaccuracies.

The OPC technique improves the "effective resolution" of a patterning process by overlapping the conditions with which different feature types can be imaged accurately. Nested features typically image on-size and with the best image quality at a different exposure dose than do isolated features. However, both feature types can be imaged adequately in a single exposure by biasing the mask patterns appropriately. However, OPC does not alter the fundamental resolution limits of a lithography system.

The in-plane anisotropic nanostructures fabricated by using deep UV lithography are shown in Figure 1.5. In this case, Figure 1.5a shows an 80 nm × 80 nm (113 nm axis length) diamond-shaped pattern with a 300 nm period, while Figure 1.5b shows the triangle-shaped pattern [30].

1.2.2
Electron Beam Lithography

Electron-beam lithography (EBL; also termed E-beam lithography) involves scanning a beam of electrons in a patterned fashion across a surface covered with a resist [31]. The first EBL system was developed during the late 1960s, and was based on the principle of scanning electron microscopy (SEM). Because of its excellent high resolution and flexibility, EBL represents a specialized technique for creating the extremely fine patterns required by the modern electronics industry for use in ICs [32–35].

Typically, a EBL system consists of the following parts: (i) an electron gun or electron source that supplies the electrons; (ii) an electron column that "shapes" and focuses the electron beam; (iii) a mechanical stage that positions the wafer under the electron beam; (iv) a wafer handling system that automatically feeds wafers to the system and unloads them after processing; and (v) a computer system that controls the equipment.

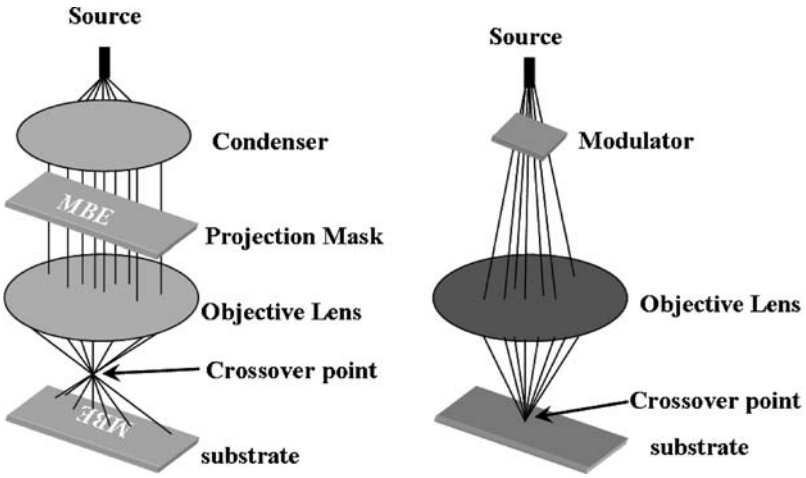

Figure 1.6 Schematic diagram of direct write and project printing.

In general, two distinct schemes are used in EBL:

- *Projection printing*, in which a relatively large-sized electron beam pattern is projected in parallel through the mask onto a resist-coated substrate by using a high-precision lens system.
- *Direct writing*, in which a small spot of the electron beam is written directly onto a resist-coated substrate, thus eliminating the expensive and time-consuming production of masks.

The principles of direct write and project printing are illustrated schematically in Figure 1.6.

EBL displays certain *advantages* over conventional photolithography techniques:

- It is capable of very high resolution, almost to the atomic level. Typically, EBL has a three orders of magnitude better resolution, although this is limited by the forward scattering of electrons in the resist layer, and back scattering from the underlying substrate.
- It is a flexible technique that can function with a wide variety of materials and an almost infinite number of patterns.

Unfortunately, however, EBL has certain *disadvantages*. Notably, it is slow in operation, being one or more orders of magnitude slower than optical lithography. Perhaps more importantly, however, it is expensive and complicated, with EBL systems costing many millions of dollars to purchase and requiring frequent servicing to maintain performance. Yet, despite these drawbacks, EBL currently represents the most powerful tool for the fabrication of features as small as 3–5 nm [36, 37].

Today, EBL is used principally in support of the IC industry, where it has three niche markets:

- In mask-making, typically the chrome-on-glass masks used by optical lithography tools. EBL is the preferred technique for masks because of its flexibility in providing a rapid turn-around of a finished part described only by a computer CAD file. The ability to meet stringent line width control and pattern placement specifications, on the order of 50 nm each, is a remarkable achievement.
- In direct writing for the advanced prototyping of ICs [38] and the manufacture of small-volume specialty products, such as gallium arsenide ICs and optical waveguides.
- For research into the scaling limits of ICs [39] and studies of quantum effects and other novel physics phenomena, at very small dimensions.

Since it is impossible to deflect an electron beam to cover a large area, in a typical EBL system mechanical stages are required to move the substrate through the deflection field of the electron beam column. Stages can be operated in a stepping mode in which the stage is stopped, an area of the pattern written, and the stage then moved to a new location where an adjacent pattern area is exposed. Alternatively, stages can be operated in a continuous mode where the pattern is written on the substrate while the stage is moving. Figure 1.7 shows SEM images of dots with a 15 nm diameter and a 35 nm pitch (64 mC cm^{-2}) fabricated in a 30 nm calixarene resist layer on a Si substrate at 50 keV acceleration voltage [40].

1.2.3 X-Ray Lithography

X-rays with wavelengths in the range of 0.04 to 0.5 nm represent another alternative radiation source with the potential for high-resolution pattern replication into

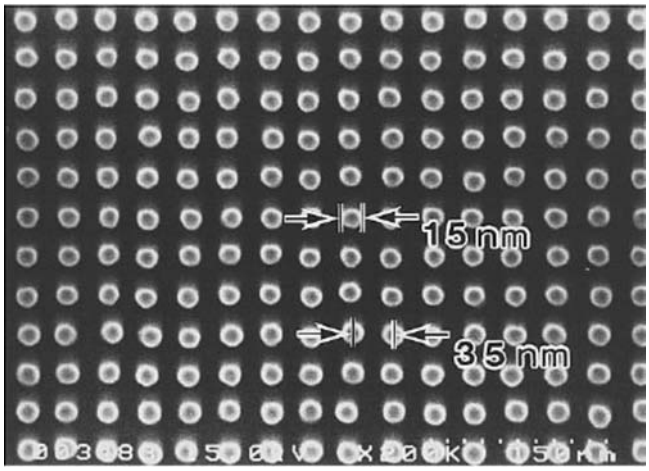

Figure 1.7 Scanning electron microscopy image of 15 nm dots at a pitch of 35 nm written in 30 nm-thick calixarene resist [40].

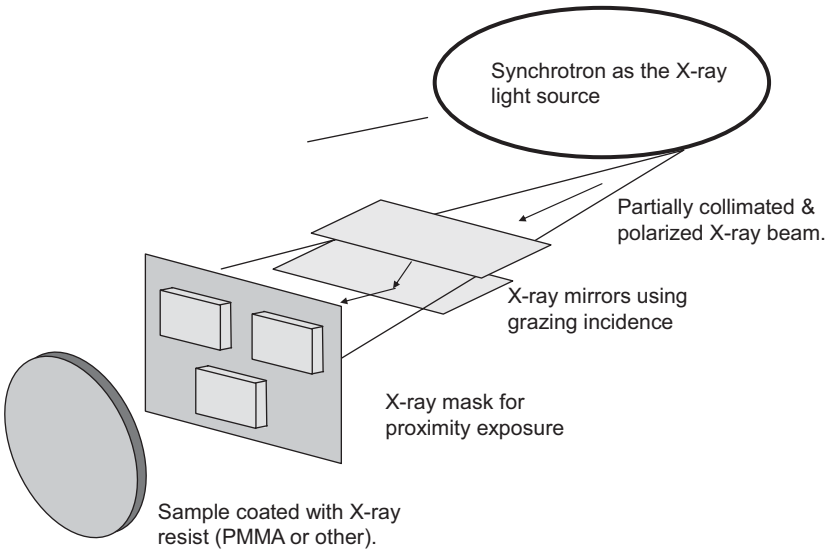

Figure 1.8 Schematic of X-ray lithography.

polymeric resist materials [41]. X-ray lithography was first shown to produce high-resolution patterns, using X-ray proximity printing, by Spears and Smith [42]. Although X-ray lithography uses the same procedure as optical lithography and EBL, an X-ray source is applied rather than using UV light or an electron beam. It would seem that X-ray lithography represents a next-generation lithography developed for the semiconductor industry, as its novel technology can be used in the same capacities as optical lithography, but with better results.

The principle of X-ray lithography is shown schematically in Figure 1.8. Basically, X-ray lithography is a shadow printing process in which patterns coated on a mask are transferred into a third dimension in a resist material, normally poly (methyl methacrylate) (PMMA). The essential ingredients in X-ray lithography include:

- A shadow mask, prepared on a thin membrane of X-ray transmitting material consisting of patterns made from an X-ray absorbing material.
- An X-ray sensitive material, which serves as the X-ray resist of high resolution and is suitable for the subsequent fabrication.
- An X-ray source of sufficient brightness in the suitable region to expose the resist through the mask.

The X-ray radiation sources represent important factors in this type of lithography, and may be generated in several ways, including: (i) by electron bombardment; (ii) by electron impact; (iii) via synchrotron sources; and (iv) as laser-generated plasmas as X-ray sources, among which synchrotron radiation sources are by far the brightest sources of soft X-rays [43–47].

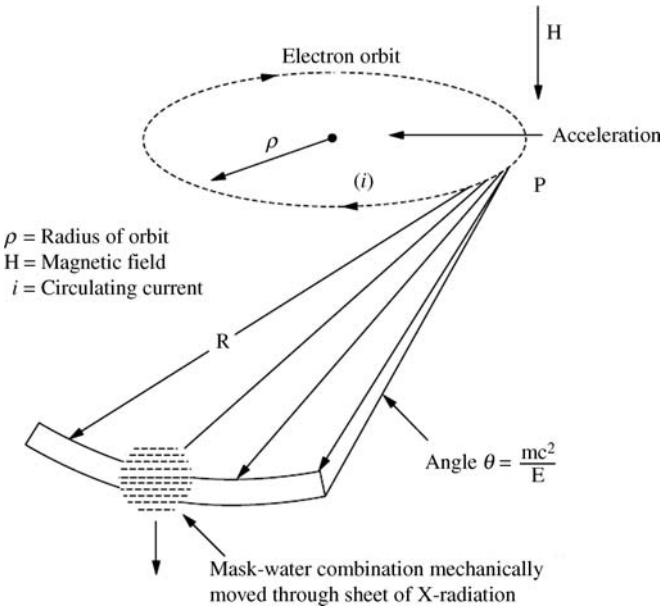

Figure 1.9 Schematic diagram of an X-ray exposure station with a synchrotron radiation source.

Synchrotron radiation is emitted by high-energy relativistic electrons in a synchrotron or storage ring, and then accelerated normal to the direction of their motion by a magnetic field. This leads to the production of a range of electrons over the entire electromagnetic spectrum, from radiowaves to infrared (IR) light, visible light, UV light, X-rays, and gamma rays. Synchrotron or storage rings, which produce a broad spectrum of radiation stemming from the energy loss of electrons in motion at relativistic energies, have been developed primarily for experiments in high-energy physics. A schematic of an X-ray exposure station with a synchrotron radiation source is shown in Figure 1.9, where the X-ray radiation opening angle, θ, is tangential to the path of the electron describing a line on an intersecting substrate.

X-ray proximity lithography is known to provide a one-to-one replication of the features patterned on the mask, and the resolution limit of the X-ray lithography is ~25 nm [48]. The first components to be created using X-ray lithography were surface acoustic wave devices [49], and this was soon followed by bipolar [50] and metal oxide semiconductor (MOS) transistors [51]. The first sub-100 nm Si transistors were produced using X-ray lithography [52], and a velocity overshoot was observed as well as transconductances greater than $1\,S\,mm^{-1}$ [53]. A wide variety of sub-100 nm quantum-effect devices have been fabricated using X-ray lithography [54], including those in which the Coulomb-blockade effect was first observed [55]; this has led to what is often referred to as the "single-electron transistor".

The SEM images of 35 nm-wide Au lines and 20 nm-wide W dots fabricated by electroplating and reactive ion etching, in combination with X-ray lithography, are shown in Figure 1.10 [56].

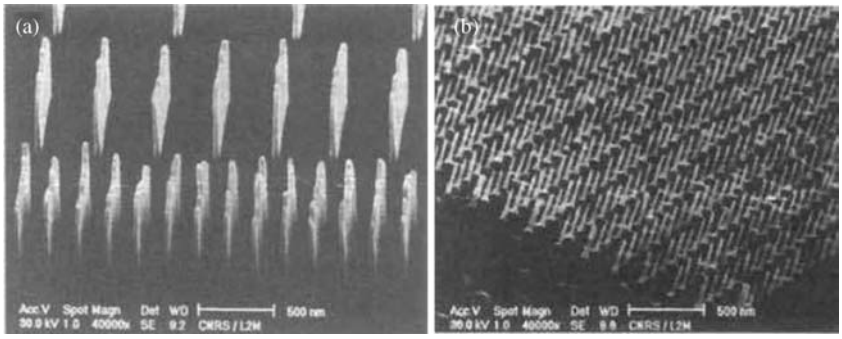

Figure 1.10 (a) 35 nm-wide Au lines grown by electroplating using a template fabricated by X-ray lithography. The mean thickness is about 450 nm, which corresponds to an aspect ratio close to 13; (b) 20 nm-wide W dots obtained after reactive ion etching of a 1250 nm-thick W layer [16].

1.2.4
Focused Ion Beam (FIB) Lithography

During the past few decades, a wide variety of nanofabrication techniques using photons, electrons, and ions have been investigated, and today focused ion-beam (FIB) technology represents one of the most promising techniques for nanofabrication, due to its great flexibility and simplicity.

Since the introduction of FIB technology to the semiconductor industry during the early 1980s, various applications have been developed for both the removal (direct ion milling, FIB chemical etching) and deposition (ion implantation, FIB chemical deposition) of a number of conductor and isolator materials, with sub-micron precision [57]. The FIB technique has also been rapidly developed into a very attractive tool for lithography, etching, deposition, and doping [58]. Because of the matching of ion and atom masses, the energy transfer efficiency of the ion beam to resist is significantly greater than with electron beams. Coupled with the fact that a focusing ion system typically operates at elevated potentials (up to 150 kV), the effective sensitivity charge per unit area of ion beams is two to three orders of magnitude higher than for electron beams, ion-beam lithography has long been recognized as offering an improved resolution [59, 60], and has also shown promise for high-resolution microfabrication [61]. When compared to EBL, FIB lithography has the advantages of a high resist exposure sensitivity, negligible ion scattering in the resist, and low back-scattering from the substrate [62].

Among the different FIB processes, direct-write milling and the dry development of FIB-implanted resists have been widely investigated for both the microfabrication and nanofabrication of advanced IC devices [63, 64].

1.2.4.1 **Direct-Write Milling**

The direct-write milling of the substrate by FIB represents the simplest process for pattern fabrication. In this method, the resists are eliminated and the dose of ions can be varied as a function of position on the wafer. The technique also utilizes heavy-ion

species such as Ga^+ and Au^+. Direct FIB milling has also been applied for lithography mask repair and circuit microsurgery, with resolution down to 100 nm [65]. Moreover, any opaque defects, such as any excess metal on the chromium-based masks, can simply be milled off, while clear defects can be repaired by milling a light-scattering structure (prism) into the area to be rendered opaque. FIB milling has also been applied to bilayer-structure lithography, in which a thin film of gold is usually deposited on top of the conventional resist [64].

1.2.4.2 Dry Development FIB Lithography

Dry development FIB lithography will also yield high aspect ratio structures, with nanometer resolution [63, 66, 67]. Likewise, FIB lithography may be combined with dry development processes by using the well-known top surface imaging (TSI) technique [68], which eliminates the need for wet processing and thus avoids any pattern deformation due to swelling. The limited penetration range of ions is a perfect match for the TSI processes, in which the surface of the resist is selectively manipulated by exposure to silicon-containing chemicals, so as to withstand oxygen dry development in unexposed areas [68, 69]. Other TSI processes utilize the dry development of ion-beam-irradiated resists for negative image formation in exposed areas [60, 70]. In these studies, PMMA resist regions implanted with different ion species (such as Ga^+ and Si^+) have demonstrated significant reductions in the etching rates during the oxygen reactive ion etching (RIE) process. The ion-beam-inhibited etching phenomenon can be explained on the basis of the formation of stable oxide layers during the etching process (i.e., Ga_2O_3 and SiO_2) [64]. Another explanation for etch resistance occurring in the implanted resist regions is the concept of a *physical hardening* of the resist [67]. According to this interpretation, the incident ions may break chemical bonds within the photoresist resin by sputtering the hydrogen and oxygen atoms away, which in turn results in the formation of a stable, carbon-rich "graphitized" structure.

1.3 Two-Dimensional Nanostructures: Thin-Film Deposition

Generally, the term "thin film" is applied to layers which have thicknesses on the order of microns or less, but which may be as thin as a few atomic layers. The deposition of thin films has been the subject of intensive study for almost a century, and a wide range of appropriate methods have been developed and improved. Today, electronic semiconductor devices and optical coatings are the main applications to benefit from thin-film construction. Although many excellent textbooks and monographs have been published on this topic [71–73], in this section a brief introduction of the fundamentals will be provided, and the typical experimental approaches of various well-established techniques of film deposition summarized.

Depending on the depositing process, film growth methods can be generally divided into two broad categories, namely *physical deposition* and *chemical deposition*. The former processes (often just called thin-film processes) are atomistic deposition

processes in which material is vaporized from a solid or liquid source in the form of atoms or molecules, and include evaporation, molecular beam epitaxy (MBE), sputtering, pulsed laser deposition, and cathodic arc deposition. In contrast, the latter processes are based on chemical reactions that include chemical vapor deposition (CVD), plasma-enhanced chemical deposition (PECVD) and atomic layer deposition (ALD). Recently, a considerable number of novel processes that utilize a combination of different methods have been developed. This combination allows a more defined control and tailoring of the microstructure and properties of thin films. Typical processes include ion beam-assisted deposition (IBAD) and plasma-enhanced CVD (PECVD).

1.3.1
Fundamentals of Film Growth

The growth of thin films, as with all phase transformations, involves the processes of nucleation and growth on the substrate or growth surfaces. The nucleation process plays a very important role in determining the crystallinity and microstructure of the resultant films. Lattice mismatch has a marked effect on film morphology, as strain resulting from lattice mismatch contributes to the interface energy, which is a key parameter in determining the growth mode. In general, nucleation in film formation is a heterogeneous process, although the surface free energies for the substrate and film materials also influence the mode of growth. Depending on the resulting film morphology, the growth modes have been placed into three categories [74]:

- Frank–van der Merwe (FM) or layer-by-layer growth
- Volmer–Weber (VW) or 3-D island growth
- Stranski–Krastanow (SK) or 3-D island-on-wetting-layer growth.

These three basic modes of initial nucleation in film growth are illustrated in Figure 1.11.

In the FM growth mode, the interatomic interactions between the substrate and film materials are stronger and more attractive than those between the different atomic species within the film material; this results in the first complete monolayer being formed before deposition of the second layer occurs. The most important examples of layer growth mode are the epitaxial growth of single crystal films.
