Introduction

Günter Schmid

The term "Nanotechnology" is nowadays commonplace not only in all relevant scientific and technical areas, but also to a considerable extent in the public domain, based on reports in newspapers, on television and, justified or not, in a series of commercially available products with "nano" as part of their names. On the one hand, this development could be considered in a positive sense, indicating nanotechnology as an accepted new technology. On the other hand, it contains some risks that should not be neglected. This is due to the rather complex definition of nanotechnology and nanoscience as a sectional science, involving natural and materials sciences, engineering and medicine. Especially it is the lack of a generally accepted definition of nanotechnology and nanoscience that is responsible for many misunderstandings. The relevant scientific communities have agreed that the term "nano" must always be linked with the appearance of a novel property. If "nano" is restricted just to a length scale, one would preferably speak of "technology on the nanoscale", usually only based on scaling effects ranging from micrometer to nanometer dimensions, without being linked with the appearance of really novel physical or chemical properties. This imprecise view of nanotechnology is frequently misused for products that are linked with the term "nano", but do not really offer a "nano-effect".

The following chapters therefore deal with the principles and fundamentals of nanotechnology, explaining what nanoscience and nanotechnology really means and what it does not mean. Furthermore, this book contains philosophical and ethical aspects, since any new technology opens up questions concerning social consequences. Therefore, first of all, a scientifically unambiguous definition of nanotechnology and nanoscience is discussed in Chapter 2, followed by a series of examples elucidating this definition in various fields, reaching from size effects up to complex biosystems. Chapter 3 deals with the principles of how to generate effective nanosystems. Top-down techniques are completed by bottom-up procedures that are currently becoming increasingly important due to the use of ultimately small building blocks: atoms and molecules. Chapters 4 and 5 consider two kinds of fundamental objects of nanoscience: quantum dots, and wires, rods and tubes, respectively. Those species represent the world of size-determined properties of

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

manifold materials and so stand for one of the fundamental principles of nanotechnology, in agreement with the definition. Spherical or one-dimensional matter of appropriate size can no longer be described by classical physical laws, but by quantum mechanical rules, indicating the decisive change from the macroscopic or microscopic world to the nanoworld.

An extremely important field of nanoscience and also of nanotechnology is dealing with the intelligent combination of artificial nanoscopic building blocks with biomolecular systems, which can anyway be considered as the most powerful "nanotechnological" inventions that we know. Most building blocks of living cells represent perfect nanosystems, the interplay of which results in the microscopic and macroscopic world of cells. We have learned to learn from Nature and consequently try to develop technologically applicable devices reaching from novel sensor systems up to diagnostic and therapeutic innovations. Chapter 6 gives an insight into this fascinating part of the nanoworld.

Philosophical and ethical questions are discussed in Chapters 7 and 8. What kind of knowledge is produced and communicated by nanotechnology? What is its place in relation to other sciences? These and related problems are discussed in Chapter 7. Studying current and future developments in nanotechnology from the viewpoint of ethics is an essential requirement in order to elaborate rules and concerted actions on how to deal with them in society. Such reflections should accompany any novel technological development, especially nanotechnology, the power of which has already been compared with the beginning of a new genesis.

This is the first of a series of books dealing with the various fields of nanotechnology. In addition to the principles and fundamentals, treated in this volume, information technology, medicine, energy, tools and analytics as well as toxicity will be the subjects of subsequent other books. In all cases, developed fields of nanotechnology and future areas of nanotechnological applications will be described and discussed.

2
The Nature of Nanotechnology

Günter Schmid

2.1
Definition

Numerous definitions of "nanotechnology" exist in the literature. Most of them simply say that nanotechnology considers materials and architectures on the nanoscale. In some of the definitions it is stated that nanotechnology dealings mainly with structures in the region between 1 and 100 nm. In any case, the dimension plays the dominant role. For a more detailed description, however, this is much too simple. First, nanotechnology follows nanoscience, where fundamental effects have been discovered before. In a long course of development, a technology may result from scientific findings in some cases, but not in all cases by a long way. So, to understand nanotechnology, one has to define properly what nanoscience is.

Among these numerous attempts to define nanotechnology, the definition given by the Royal Society and the Royal Academy of Engineering is fairly close to the author's opinion on the matter [1]:

> "*Nanoscience is the study of phenomena and manipulation of materials at atomic, molecular and macromolecular scales, where properties differ significantly from those at a larger scale. Nanotechnologies are the design, characterization, production and application of structures, devices and systems by controlling shape and size at the nanometre scale.*"

A more recent definition, formulated by a team of scientists at the Europäische Akademie zur Erforschung wissenschaftlich-technischer Entwicklungen Bad Neuenahr-Ahrweiler GmbH, focuses still more the real intent of nanoscience and nanotechnology and will therefore be used in the following [2]:

> "*Nanotechnology comprises the emerging application of Nanoscience. Nanoscience deals with functional systems either based on the use of subunits with specific size-dependent properties or of individual or combined functionalized subunits.*"

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

This is the only existing definition without naming a particular lateral scale. It excludes any kind of simple scaling effect (see later). The decisive aspect is the appearance of novel properties. These can in principle be observed below 1 or above 1000 nm (1 μm). Therefore, the strict limitation to a distinct length scale does not appropriate seem. Scientifically, it would even be absurd to set a limit to size-dependent properties or novel properties of a construct of functionalized subunits. In spite of this deliberate leaving out of a particular lateral scale, the expressions nanoscience and nanotechnology are meaningful for practical use since most of the known "nano-effects" happen on the nanoscale. The limitation of the definition to the nanoscale, however, would degrade nanotechnology to the simple continuation of microtechnology. Microtechnology was and still is overwhelmingly successful by the continuous reduction of materials or tools, aiming not at the creation of novel abilities, but at other advantages. Some examples in the context of the above definition will help us to understand better what it is meant.

Typical *size-dependent* nano-effects that spontaneously occur when a critical dimension is reached are observed when metal particles are downsized. Depending on the kind of change of property, the critical size may vary for the same element.

A very typical and well known nano-effect is observed when gold is downsized. In the bulk state, the beautiful color of gold results from a very fundamental phenomenon, the relativistic effect, based on Einstein's Special Theory of Relativity. One of the basic messages of this theory is that the speed of light in vacuum is an absolute constant everywhere in the universe. It never can be surpassed. If an object were theoretically to be accelerated close to or even exactly to the speed of light, its mass would continuously increase with increasing speed, finally even *ad infinitum*.

Electrons in most atoms are moving around the atomic nucleus with speeds usually far below that of light. However, in very heavy atoms, the high mass of the nuclei accelerates electrons to such an extent that relativistic effects become obvious [3–5]. For instance, such effects are known for the elements lead, tungsten, mercury, platinum and gold. The interesting question is whether relativistic effects influence the physical and chemical properties of such a heavy element. Indeed they do! The acceleration primarily affects the s-electrons which are in the nuclear region, linked with an increase in their mass, reducing the average distance from the nucleus. Consequently, the s-orbitals and their energy are shrinking. As a secondary effect, d-electrons, being farer from the nucleus, become electronically better shielded. Their orbitals are therefore extended and increase energetically. For the p-electrons the effects approximately equilibrate. In bulk metals, the individual orbitals of atoms are extended to electronic bands. The valence band, resulting from the d-orbitals, is energetically increased, whereas the conduction band, formed from the s-orbitals, is lowered. The reduced energy difference between the valence band and conduction band finally allows the low-energy photons of blue light to lift electrons from the valence to the conduction bands. Consequently, gold absorbs blue light and shows the complementary color yellow. Relativistic effects are revealed in various ways: tungsten exhibits an unusually high melting point and mercury is the only metal that is liquid at normal temperatures. Figure 2.1 illustrates the relativistic effect of gold by shrinking the energy difference between the s- and d-orbitals.

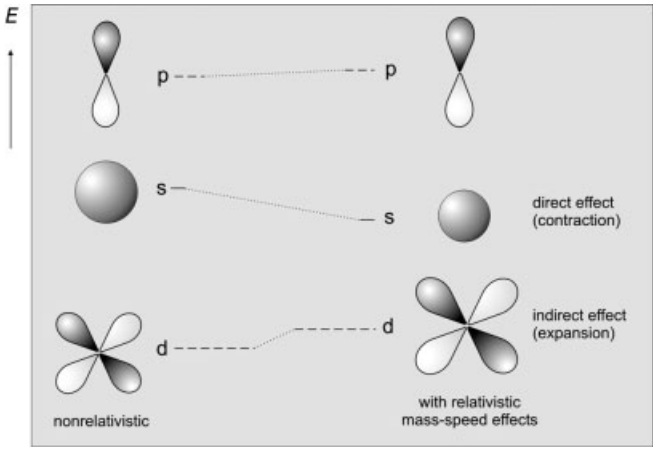

Figure 2.1 Influence of relativistic effects on the energy level of d-, s- and p-orbitals.

Since the relativistic effect is a property of each individual gold atom, it must also be present in nanosized particles, although their color is no longer golden. This metal changes its appearance at about 50 nm to become blue. Further reduction results in purple and finally, at about 15–20 nm, in bright red. This well-understood and long-known effect can be traced back to the existence of a so-called plasmon resonance. The phenomenon is quantitatively described by the Mie theory [6]. Qualitatively, the formation of a plasmon resonance can be explained by a collective electron oscillation with respect to the positive metal core of the particle, caused by the interaction of external electromagnetic radiation (visible light) with the confined electron gas of nanoparticles. The process is illustrated in Figure 2.2.

The energy taken up from light is responsible for the resulting color. This energy depends on, among others, the particle's size and shape and the surrounding medium. With decreasing size the color is shifted to shorter wavelengths. If the particles are not spherical but elongated, two plasmon bands may occur, one for the transverse and the other for the longitudinal resonance. Figure 2.3 shows the UV–visible spectra of spherical 18-nm gold nanoparticles (colloids) with an absorption maximum at 525 nm [7].

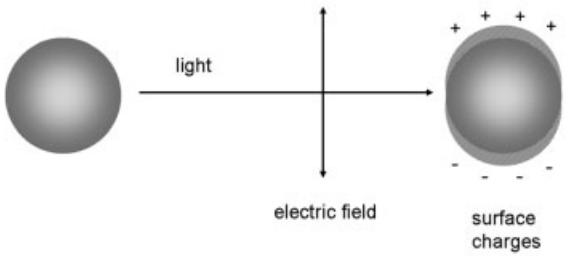

Figure 2.2 Formation of plasma resonance by the interaction of external electromagnetic radiation with the confined electron gas in a metallic nanoparticle.

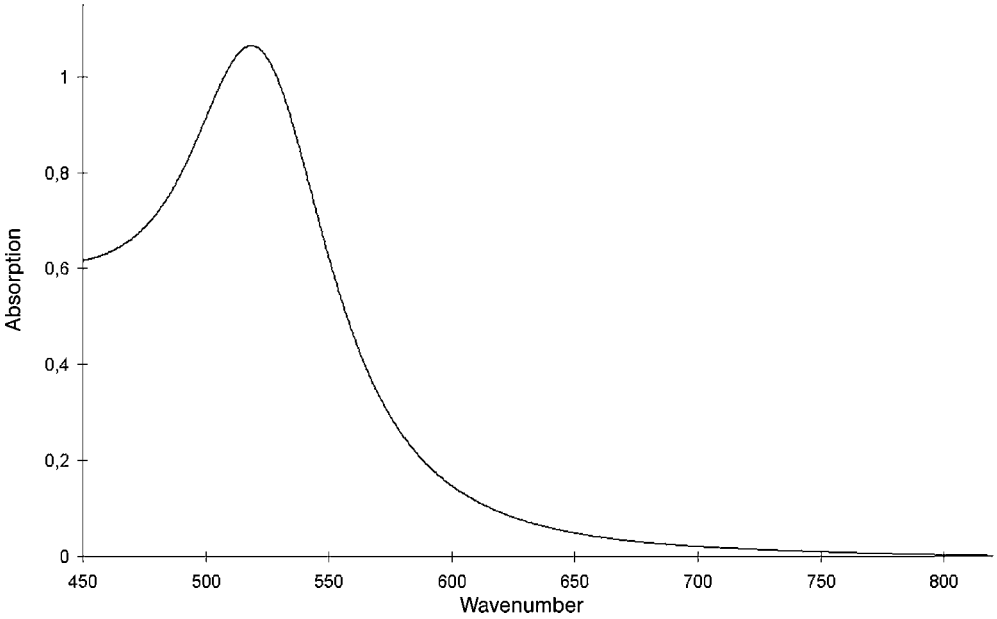

Figure 2.3 UV–visible spectrum of 18-nm gold particles.

Whereas the plasmon resonances of the three metals copper, silver and gold is in the visible region, for most other metals it is in the UV region and so cannot be observed with the naked eye.

The disappearance of the typical color in the case of gold when a critical size is reached and the appearance of blue or red colors simply means that the plasmon resonance superimposes the relativistic effect and so covers the typical color of bulk gold.

The second part of the above definition names the use of individual or combined functionalized subunits. As an *individual functionalized subunit* or building block, molecular switches may serve as an example. A molecular switch is a molecule that exists in two different states which can be adjusted by external stimuli. The two states must display different physical properties, each being stable with long lifetimes. If addressable by electrical or any other stimuli, such molecules could in principle serve as building blocks in future storage systems. For instance, catenanes consist of two interlocked rings equipped with electrochemically active parts (see Figure 2.4). Applied electric potentials cause Coulomb repulsion and make one of the rings move relative to the other, ending in another stable configuration. The sketch in Figure 2.4 elucidates the process [8].

Finally, an example of *combined functionalized subunits*, the last of the three conditions in the definition, can be given. Nature is a perfect nanoarchitect. Many parts of living cells can be considered as a combination of functionalized building blocks, although cells themselves have dimensions in the micro regime. The probably most exciting molecule in Nature is deoxyribonucleic acid (DNA) with its

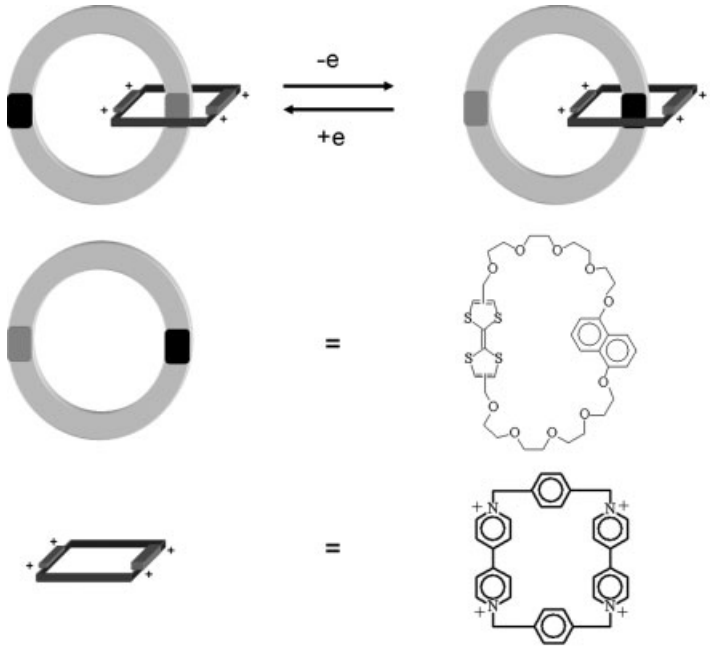

Figure 2.4 Sketch and molecular examples of a catenane-based switching device. The counteranions $[PF_6]^-$ have been omitted.

unique double helical structure. It consists of fairly simple subunits: four different heterocyclic bases, phosphate anions and pentose fragments. It is the shape complementarity of the bases that enables an almost infinite number of combinations to give base pairs, which finally encode the genome of any living system using hydrogen bonds to link complementary bases: thymine (T) combines only with adenine (A), cytosine (C) exclusively with guanine (G). The sugar fragments and the phosphates generate a backbone, holding the base pairs together. Figure 2.5 illustrates the decisive interaction between the four bases. The sequence of bases in one single strand determines the sequence in the other.

In practice, the number of different combinations in a human genome is infinite, considering the realistic length of a DNA double helix consisting of about 3.2 billion base pairs.

The above definition and the following elucidating examples clearly demonstrate that nanoscience and nanotechnology in a strictly scientific manner do not consider simple scaling effects. One speaks of scaling effects if a material is downsized from the macro/microscale even to the nanoscale and the properties, if at all, change continuously, but not spontaneously. In other words, characteristic properties are already present in the micro regime and only change gradually on reaching the nanoscale. A typical example will help to understand easily what a scaling effect is.

The well-known moth-eye effect is a well-developed natural system to avoid light reflection from the eyes of night-active insects [2]. The moth eye is built up from

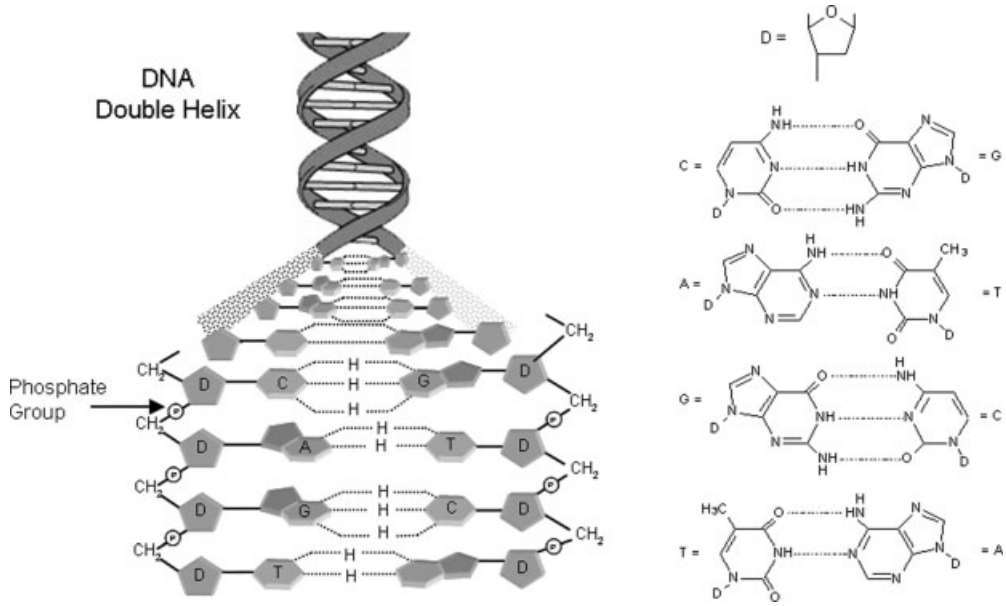

Figure 2.5 Illustration of the base pair interactions in DNA.

hemispheres 200–300 nm in diameter. Since they are smaller than the wavelength of visible light, a continuous increase in the refraction index follows, avoiding the strong reflection that occurs when light hits a flat and optically denser medium. The principle of the moth-eye effect can be used to structure surfaces artificially, for instance those of transparent materials, in order to avoid unintended reflection of light: windows, solar cells, spectacles, and so on. The techniques to nanostructure surfaces are manifold and will not be considered here. Antireflection does not start off from a distinct point. The only condition is that the structure units must be smaller than the wavelength of light. It works with 300-nm units and also with 50-nm building blocks, of course with varying results, but it works. Numerous such scaling effects have been developed into very important techniques. However, they are wrongly called "nanotechnology", since they are based only on scaling effects and not on real nano-effects as the definition demands.

2.2
From Nanoscience to Nanotechnology

Most of the currently known nano-effects are still deeply rooted in nanoscience, that is we cannot speak at all of a technology. In spite of the obvious contradiction, one usually speaks of nanotechnology even if a technology has not yet been realized. In the following, a careful differentiation will be put forward, not just between science and technology, but also with the usual intermediate step, called (nano)engineering. The development of a technique from a scientific finding never happens in a single

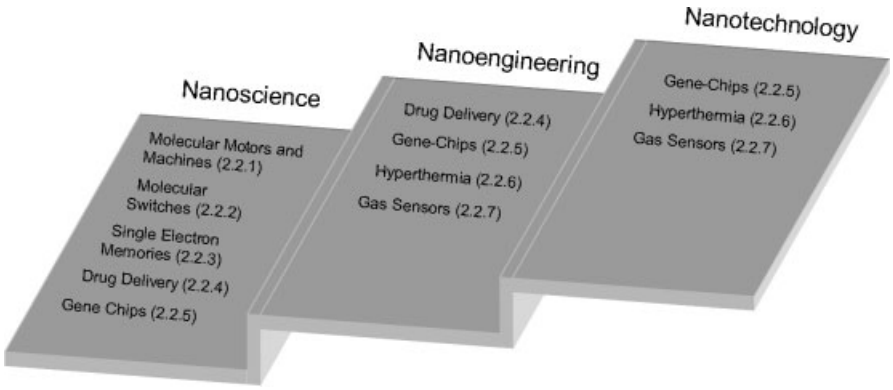

Figure 2.6 Examples of nanoscience, nanoengineering and nanotechnology.

step. Rather, a progressive procedure is necessary to develop a working device successfully. The "proof of principle" and provisional, but working, systems have to be generated before a final and commercially useful technique may result. Figure 2.6 illustrates in a rather simple manner what will be expressed.

Nanoscience, nanoengineering and nanotechnology are represented by three steps following each other. Each step contains several of very many possible examples, which will help to realize how nanoscience develops into nanotechnology. Some of the areas are still only to be found in "nanoscience", others have already developed into the "nanoengineering" step or even into "nanotechnology"; some are present in all three fields, indicating that there is still a further need for basic research to improve or to extend existing technologies. The examples presented for the three steps will be described below in order to elucidate the principles of development from basic research to nanotechnology.

2.2.1
Molecular Motors and Machines

Nature is a perfect nanotechnologist and we are well advised to learn from it. Distinct proteins and protein assemblies are known to perform special motions in response to biological stimuli [9–13]. Such systems are called molecular motors or molecular machines. Numerous attempts have been made during the last two decades to transfer the increasing knowledge of biological systems on a molecular level to devices consisting of completely artificial components or of hybrid systems where biomolecules and technical building blocks interact.

Myosins, kinesins and dyneins are frequently studied natural molecular motors [10–13]. Energetically fuelled by adenosine triphosphate (ATP), these proteins can move back and forth on actin filaments or microtubules transporting substrates. It is not the intension of this chapter to describe these natural molecular machines; rather, it is the discussion of man-made architectures in the sense of nanotechnology. Just one example illustrating Nature's principles will be briefly presented: the transport of actin filaments by myosins.

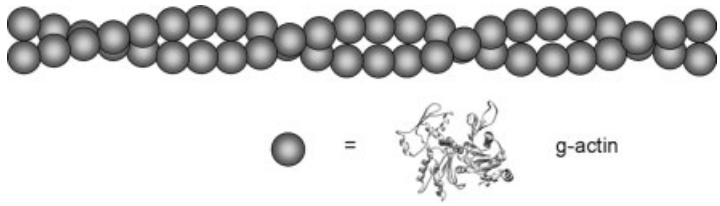

Figure 2.7 Sketch of an actin filament.

Actin filaments consist of double-stranded polymers, composed of globular actin monomers, as is indicated in Figure 2.7.

Eighteen different types of myosins exist, specialized for muscle contraction, signal transduction, vesicle transport, and so on. Myosins are composed of about 200-kDa "heavy chains" and 20-kDa "light chains", wound around the so-called neck domains. One myosin end is marked by the motor domain, as is indicated in Figure 2.8.

Figure 2.9 illustrates the formal transport of actin filaments on a myosin-modified surface. ATP is the energy supplier.

An impressive bio/artificial hybrid machine has been constructed using chaperonin systems. Chaperonins are proteins which can be isolated from *E. coli*, mitochondria and chloroplasts. A series of chaperonin crystal structures have been solved [14–18]. In Nature they make newly formed proteins, folding in their cylindrical cavities with the help of ATP as energy supplier [19]. A detailed description of the working mechanisms of different chaperonins has been published [20]. Instead of acting as host for natural proteins, chaperonins can also be used to capture and to release various nanoparticles with the help of ATP. In Figure 2.10 a primitive sketch of the uptake and the ATP-triggered release of 2–3-nm CdS nanoparticles is presented.

As mentioned above, kinesins are another class of natural molecular motors. They are capable of transporting cargo along intracellular microtubules [21]. In Nature they

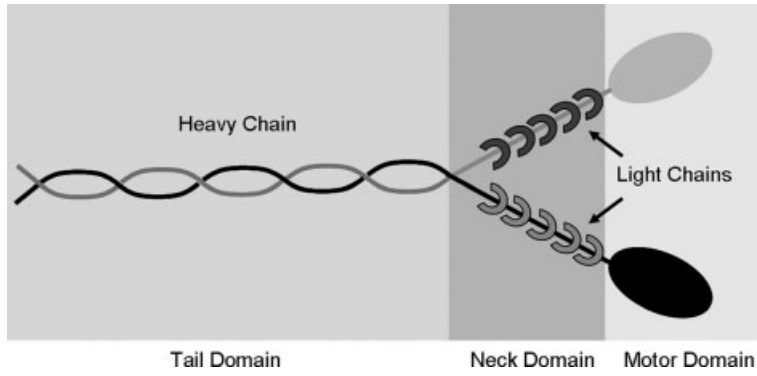

Figure 2.8 A double-headed myosin, consisting of heavy and light chains.

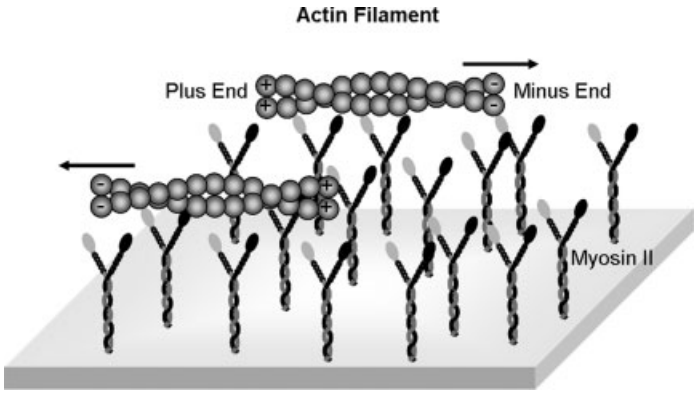

Figure 2.9 Myosin-coated surface transporting actin filaments from plus to minus. ATP serves as the energy supplier.

are part of the transport system for organelles, proteins and mRNAs. Conventional kinesin is composed of two 80-nm long 120-kDa chains, connected to two 64-kDa chains. The heavy chains are rod-like structures with two globular heads, a stalk and fan-like end [9, 22, 23]. One-headed kinesins are also known [24]. The mechanism of motion has been intensively studied using one-headed kinesins [25, 26], but will not be described here. Of course, it is also enabled by the energy of ATP hydrolysis. Microtubules are built up of 8-nm periodic building blocks of heterodimers of the subunits α- and β-tubulin, forming hollow tubes 24 nm in diameter.

Instead of a cargo of natural material such as vesicles or organelles, a recent example impressively demonstrates that artificial nanomaterial can also be transported by kinesin–microtubule systems; 7.6-nm core/shell CdSe/ZnS nanoparticles were functionalized with biotin–avidin. The as-modified quantum dot complexes were then bound to immobilized and fluorescently labeled microtubules. The movement of the loaded kinesin along the microtubules was observed by means of epifluorescence and total internal reflection fluorescence (TIRF) [27]. Figure 2.11 shows a sketch of the microtubule–kinesin–quantum dot hybrid system. The particle

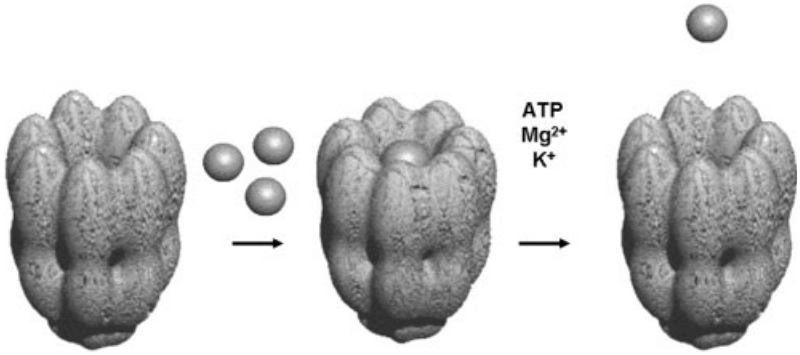

Figure 2.10 Capture and release of CdS nanoparticles by chaperonin.

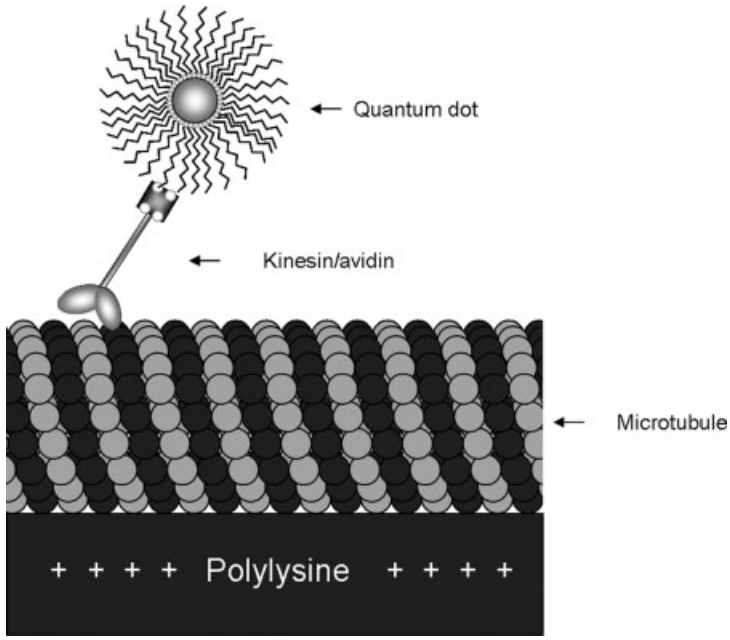

Figure 2.11 A kinesin–avidin–quantum dot hybrid system, moving on the surface of a microtubule.

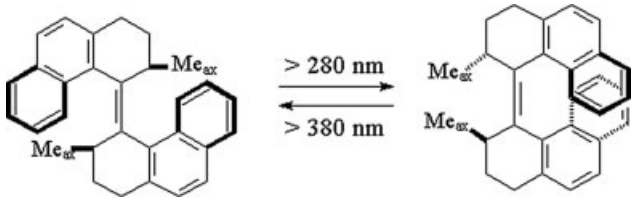
transport could be visualized over 1200 s, considerably longer than in any comparable experiment before.

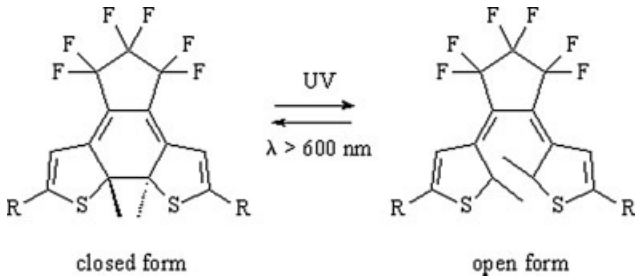
Numerous totally artificial molecular machines with non-biological components have also become known. For instance, the photoisomerization of substituted alkenes is another general method to create molecular motors, provided that the process is reversible and the two isomers are kinetically stable. In the example shown in Scheme 2.1, the four bulky substituents are responsible for an energy barrier at −55 °C between the *trans* and *cis* configurations [28].

Another light-driven system is the so-called "Irie" switch, a molecule with a light-sensitive C−C bond that can be opened or closed by two different frequencies (Scheme 2.2) [29].

Ring opening occurs under UV light and ring closure by light with a wavelength >600 nm. Switching processes induced by light are in practice much more easily



Scheme 2.1 A tetrasubstituted alkene acting as molecular motor by photoinduction.



Scheme 2.2 Light-induced closure and opening of a C–C bond ("Irie" switch).

managed than those using extensive chemistry. Nevertheless, this and comparable objects are still part of basic research.

Rotaxanes consist of two parts: a stiff bar-like part and a ring-shaped part, arranged around the bar. Due to electrostatic interactions, the ring prefers a distinct position. By chemical oxidation of the interacting position in the bar, repulsion results and the ring is shifted to another position. Reduction brings the ring back to the former position. Figure 2.12 shows a rotaxane molecule with the ring in two different positions [30]. Both configurations are stable without any voltage applied.

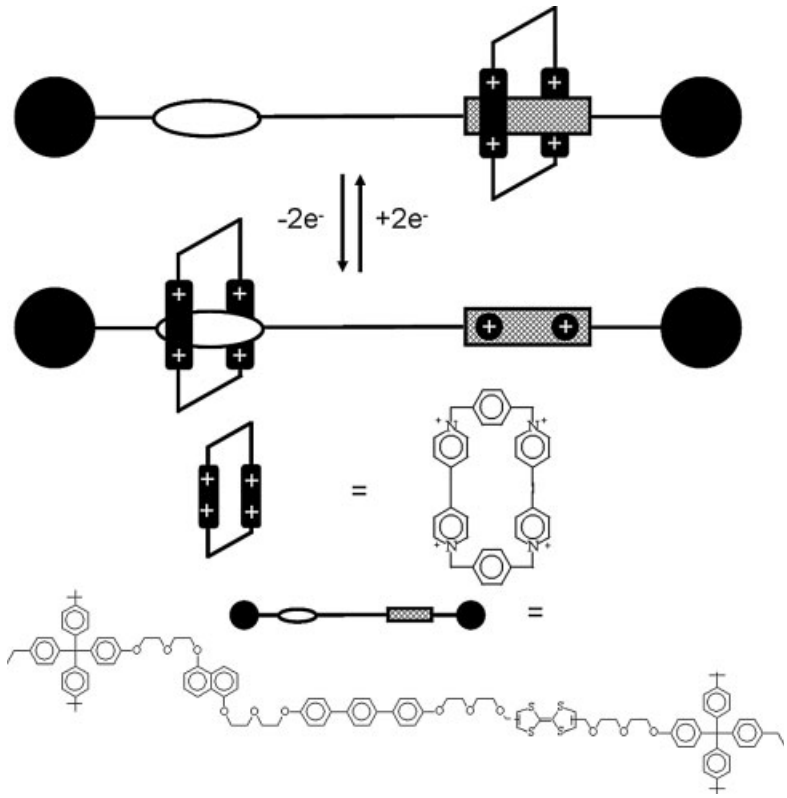


Figure 2.12 Illustration of a rotaxane system.

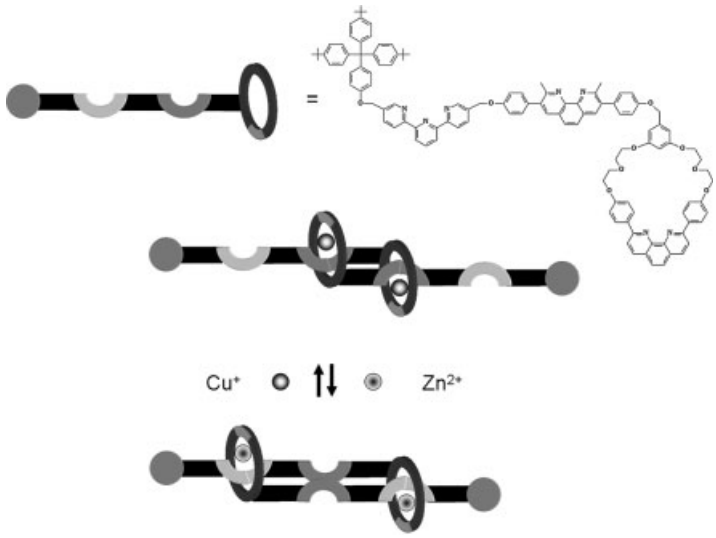

Figure 2.13 A redox-driven "molecular muscle" consisting of two combined rotaxane molecules.

Another elegant example of a rotaxane system is shown in Figure 2.13. A Cu^{+}-containing rotaxane dimer is contracted by the exchange of the Cu^{+} ions by Zn^{2+} ions and vice versa. Except as a molecular switch it can be considered as model of a molecular muscle [31].

A chemically driven rotaxane-like "molecular elevator" has been constructed and is illustrated in Figure 2.14. Protonation and deprotonation of the amine moieties of

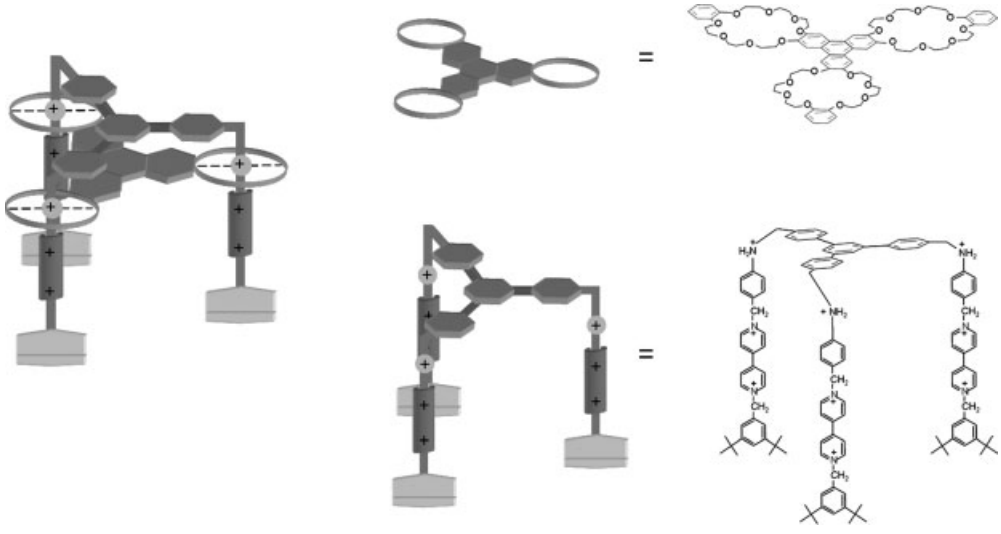

Figure 2.14 A rotaxane-based "molecular shuttle". The platform can be moved up and down by means of addition of acid or base.

part A makes the "platform" B move up and down depending on the NH/NH_2^+ situation in A [32, 33].

It is obvious that the above rotaxane examples are so far not really suited to work in devices, since complex chemistry is necessary to oxidize and to reduce the specific positions. However, the study of such or similar systems is of enormous importance in order to gather experience and to improve continuously the conditions to make such systems applicable.

2.2.2 Molecular Switches

The reasons for the worldwide and intensive search for novel generations of switches and transistors lie in the unavoidable fact that the limits of the present silicon technologies will eventually be reached. The famous Moore's law predicts that between 2010 and 2020 the two-year rhythm of doubling the capacity of computers will find a natural end due to a typical nano-effect [34]: below a not precisely known size barrier, silicon will lose its semiconductor properties and instead it will behave as an insulator. Other technologies which are based on very different nano-effects have to follow. For instance, magnetic data storage systems involving the so-called spintronics [35], magnetic recording systems using nanosized magnetic nanoparticles [36], magnetic domain walls in nanowires [37], and so on, are developing tremendously. All are still far from being of technological relevance in the near future and even the nanoengineering step has not really been reached so far. Hence they are still objects of intense basic research in nanoscience.

The term "molecular switch" is used for molecular systems which are stable in two different states. One state represents 1 and the other state 0. Different states may consist either of two different geometric conformations or of two different electronic states. Both states must be interconvertible by external stimuli. An example of molecular systems existing in two different geometric states has already been introduced in Section 2.1 with a catenane molecule that can in principle be switched by means of electrical pulses. Furthermore, all examples of artificial molecular motors described in Section 2.2.1 are at the same time molecular switches, since they exist in two different but convertible configurations. However, the use of systems, the switching of which is only based on more or less complex chemistry, looks not so much suited for application in future nanoelectronic devices; rather, it is the need to switch systems by light or electric pulses.

Molecular switches, based only on the change of the electronic spin situation in a molecule, are also promising candidates in this respect. Transition metal complexes with d^4–d^7 configurations can exist in either the high-spin (HS) or low-spin (LS) version. High-spin complexes are characterized by a maximum number of unpaired electrons, following Hund's rules. Low-spin complexes have zero or, in the case of an odd number of electrons, one unpaired electron. For instance, if an octahedral complex exists in the HS or the LS configuration depends on the energy gap between the t_{2g} and the e_g orbitals. The separation of the originally equivalent five d orbitals into three t_{2g} and two e_g orbitals (ligand field splitting) is due to the different influence of

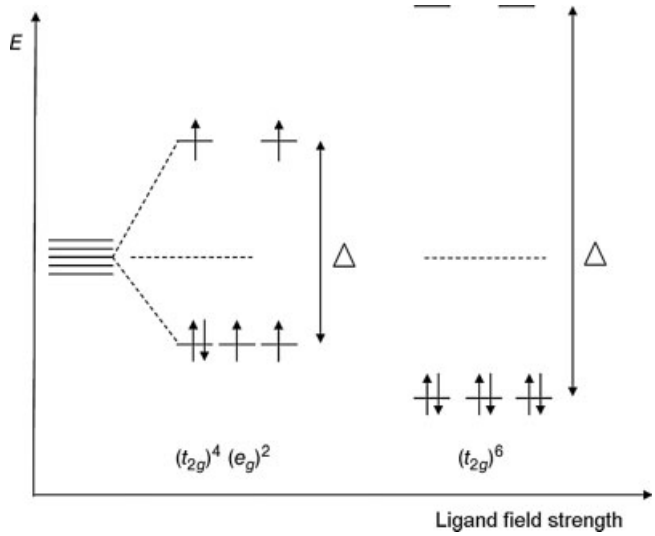

Figure 2.15 High- and low-spin configurations of a d^6 system.

the ligands coordinating the atom or ion along the x, y and z axes (e_g) or between the axes (t_{2g}). Small gaps Δ result in HS configurations and large Δ values in LS complexes. Figure 2.15 shows qualitatively the situation in both cases for a d^6 complex.

The Δ values are dominantly determined by the nature of the ligand molecules coordinating the corresponding transition metal atom or ion. So-called weak ligands (H_2O, halides X^-) cause small ligand field splitting and strong ligands (CN^-, CO, olefins) cause large Δ values. However, situations exist where the energy difference between the HS and LS configurations is small enough to be influenced by stimuli from outside and, consequently, switching between both electronic configurations becomes possible, provided that the transition between the two states is abrupt. Numerous such spin transition complexes have been identified and are of increasing interest with respect to molecular switching systems. It is of special relevance that HS–LS transitions can be induced by different stimuli such as temperature, pressure or light.

An example of a temperature-switchable complex is given in Figure 2.16. The two configurations of the d^7 Co(II) complex can be followed by the magnetic susceptibilities. The HS version has a total spin of $S = 3/2$ and the LS form of $S = 1/2$ [38].

The energetically higher lying states of the HS configuration are reached by increasing the temperature from about 130 to 150 K and vice versa.

The tetranuclear d^6 iron complex shown in Figure 2.17 can be switched by temperature, pressure or light [39]. The four iron centers allow switching over three magnetically different configurations: 3HS/1LS, 2HS/2LS, 1HS/3LS. This special situation allows manifold storage and switching varieties. The chance to switch this complex by light makes it a remarkable candidate for future applications. The

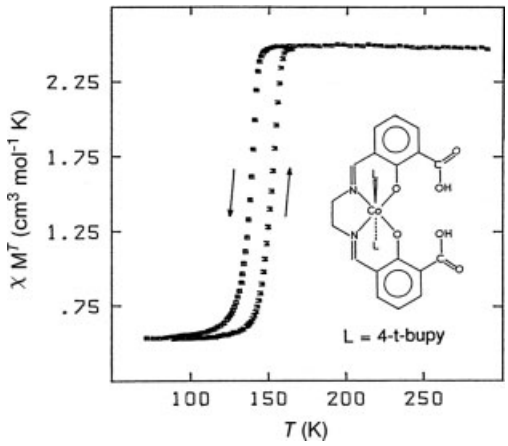

Figure 2.16 Temperature dependence of the magnetic susceptibility of an octahedral Co(II) complex. (© Elsevier, Amsterdam).

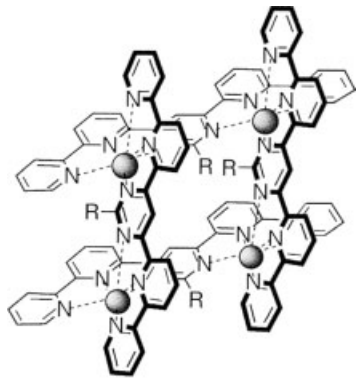
light-induced spin-state trapping (LIESST effect) however, could so far only be observed at 4.2 K with $\lambda = 514$ nm, but not the reverse effect.

Since HS and LS configurations are generally linked with a change of the bond length, pressure can be an alternative stimulus.

These few examples of existing molecular switches indicate a development in nanoscience opening up novel alternatives of storage systems on a level that can never be reached with traditional techniques. However, it is also obvious that giant efforts have to be made to reach the nanoengineering step or even the technology level. The route from the discovery of a novel fundamental effect to a product often fails due to unforeseen problems on the practical side. Nevertheless, the finding of fundamental effects in basic research is a presumption to install novel techniques, as history shows.



$[Fe_4L_4](ClO_4)_8$

Figure 2.17 Example of an LS ↔ HS switchable Fe(II) complex.

2.2.3 Single-Electron Memories

As already mentioned, the consequences of Moore's law demand alternatives, available on time. Single-electron memories might be a possible alternative to the present silicon technology if one succeeds in using the quantization of electric charge to handle digital information. Single-electron devices would be associated with enormous advantages compared with available techniques: extremely reduced power consumption, no or extremely reduced heat development, high density arrangements of building blocks and the principle possibility of generating three-dimensional memories. Single-electron memories would constitute the ultimate miniaturization of a memory device and it is worth intensively following up any chance to realize this goal. Single-electron memories, single-electron switches or single-electron transistors all require the transport of individual single electrons in a strictly controlled manner. This can only be realized by quantum mechanical tunneling. A device for single-electron tunneling (SET) must contain a unit that can be charged and discharged by single electrons. Charged and discharged units must be independently stable. To prevent uncontrolled transport of electrons, a charged unit must build up a so-called Coulomb blockade to prevent the transfer of a second, third, and so on, electron. Atoms would be ideal candidates to realize such conditions. The formation of an anion in chemistry is such an event, determined by the electron affinity of the neutral atom. However, atoms are still too small to be individually and routinely handled. Therefore, larger scaled, namely nanosized materials have to be found to overtake this "atomic capability". The ability of a unit to act as an atomic substitute depends decisively on the amount of energy to add an additional electron to an initially uncharged unit [40–44]. This charging energy scales roughly with $1/r$ (r = radius of the nanosized unit). What kind of material fulfils these conditions? – generally, all species that exhibit quantum size behavior. Nanotubes, nanowires and nanoparticles of conducting or semiconducting materials can have such extraordinary facilities. To observe quantum size behavior of a species, its dimensions in one, two or all three dimensions have to be reduced to such an extent that electrons are no longer freely mobile in all dimensions, but are confined to such an extent that they occupy more or less discrete energy levels. In Section 2.1, the phenomenon has already briefly been discussed in connection with the appearance of plasmon resonances. A detailed discussion of quantum size phenomena can be found in Chapter 4. A simplified demonstration of the consequences of electronic confinement of metals is depicted in Figure 2.18.

When reaching situation (c) in Figure 2.18, one speaks of quantum dots, since such particles no longer follow classical physical laws for bulk materials but obey quantum mechanical rules like atoms and molecules do, even at room temperature. Among many different ways to obtain information on whether the quantum dot situation has been reached or not, individual contacting of a particle by two electrodes and to study the current (I)–voltage (U) behavior gives the clearest answer. Figure 2.19 shows the principle of such an experimental arrangement.

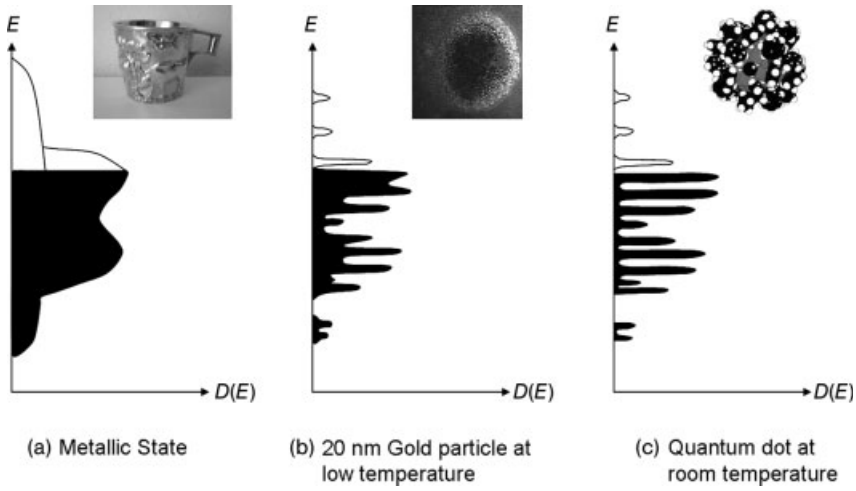


Figure 2.18 The electronic transition from the bulk state to a quantum dot.

SET from one electrode into the nanoparticle leads to an increase in charge by e^- (1.6×10^{-19} C) linked with an increase in the electrostatic energy E_C by $E_C = e^2/2C$, where C is the capacity of the nanoparticle. As can be seen from Figure 2.19, the metal nanoparticle does not directly touch the electrodes, but an insulating envelope (or a respective distance) separates it from the contacts to gain an appropriate capacity of the system. In order to avoid uncontrolled thermal tunneling of electrons, E_C must be much larger than the thermal energy $E_T = k_B T$ (k_B = Boltzmann's constant $= 1.38\times10^{-23}$ J K^{-1}): $e^2/2C \gg k_B T$. The observation of an SET process will only be possible either at very low temperatures or with very small C values. Since $C = \varepsilon\varepsilon_0 A/d$ (ε = dielectric constant, d = electrode distance from metal core, A = surface area of the particle), small C values can be realized by very small particles having a sufficiently thick insulating shell. The charge generated on the particles causes a voltage $U = e/C$, linked with a current $I = U/R_T$ (R_T = tunneling resistance).

The temperature dependence of SET has been convincingly demonstrated by the study of a 17-nm Pd nanoparticle, covered by a shell of $H_2NC_6H_4SO_3Na$ molecules. As can be seen from Figure 2.20, the I–U characteristic at 295 K is a straight line, following Ohm's law. At 4.2 K, however, a well-expressed Coulomb blockade is observed, indicating that between about −55 and +55 mV the current is interrupted due to the existence of an additional electron in the particle, blocking the transport of a second one [45].

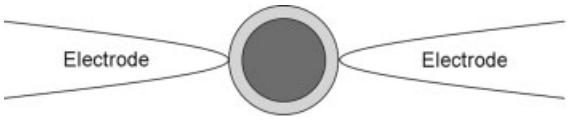

Figure 2.19 Experimental arrangement for the measurement of the *I*–*U* characteristic of a metal nanoparticle.

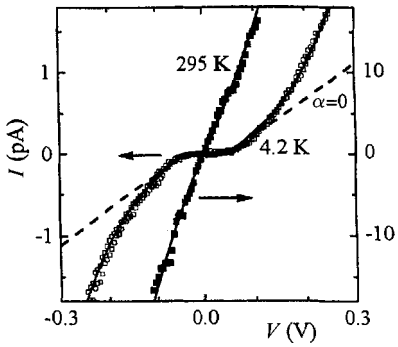

Figure 2.20 *I–U* characteristics of a 17-nm Pd particle at 295 K (Ohm's law behavior) and 4.2 K (Coulomb blockade). (© American Institute of Physics).

Instead of working at very low temperatures, in practice it is more attractive to decrease C sufficiently and to enable Coulomb blockade at room temperature. This aim has indeed been achieved by using the nanocluster $Au_{55}(PPh_3)_{12}Cl_6$ with its metal nucleus of only 1.4 nm and a 0.35-nm thick ligand shell [46, 47]. The *I–U* characteristic, shown in Figure 2.21, has been measured at room temperature. In spite of the high temperature, a Coulomb blockade between about −500 and +500 mV is registered [48].

The electric contacting of a single nanocluster has been performed using a tip of a scanning tunneling microscope (STM) and a conductive substrate on which the particles had been deposited from a very dilute solution.

A deeper insight into the electronic situation in these Au_{55} quantum dots was possible by studying the *I–U* behavior at 7 K [49]. Due to the low temperature, the

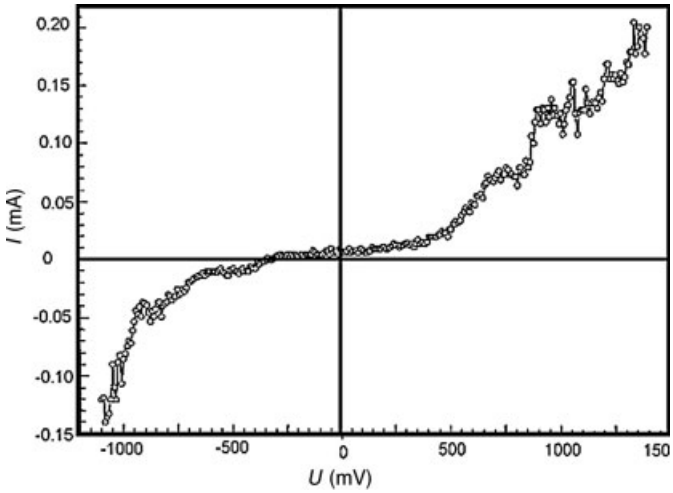

Figure 2.21 Room temperature Coulomb blockade of $Au_{55}(PPh_3)_{12}Cl_6$. (© Springer, Berlin).

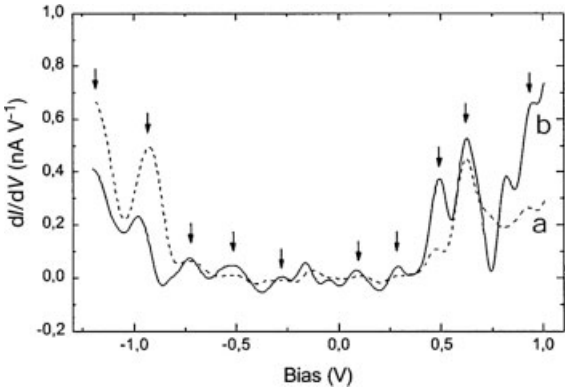

Figure 2.22 d*I*/d*V* diagram for $Au_{55}(PPh_3)_{12}Cl_6$ at 7 K indicating level splitting of 135 meV. (© American Chemical Society).

Coulomb blockade is enlarged; however, the most informative knowledge can be seen from a diagram using d*I*/d*V* values instead of *I* (Figure 2.22). Generally, the blockade then turns into a minimum on the *U* axis. Due to the low temperature, discrete energy levels in the minimum become visible in terms of conductivity oscillations with an average level spacing of 135 meV. The dashed line and the solid line result from two measurements on the same particle, but at different positions, namely above a phenyl ring of PPh_3 and at a position above bare gold atoms. They agree fairly well and so indicate that the result does not depend on the matter between the tip and Au_{55} nucleus.

This result demonstrates the existence of a perfect quantum dot, working at room temperature and representing exactly position (c) in the sketch in Figure 2.18. Figure 2.22 also makes it clear why such working units are sometimes called "artificial atoms".

The Coulomb blockade, based on the transfer of single electrons, represents a perfect single-electron switch and can in principle also be used as a single-electron transistor, as indicated in Figure 2.23.

These fundamental findings make Au_{55} and metal particles of similar size excellent candidates for use in future storage systems. Intensive research and development are still necessary to reach this ultimate goal. The very first steps from the science level to the engineering step are in progress, but nevertheless, quantum dot memories are still deeply involved in basic research.

2.2.4
Drug Delivery

The controlled release of a drug has a significant influence on the therapeutic efficiency. For numerous drugs there exists an area of concentration with the greatest success. Compared with traditional tablets or injections, drug delivery systems have a profile with continuous release, as indicated in Figure 2.24 [50].

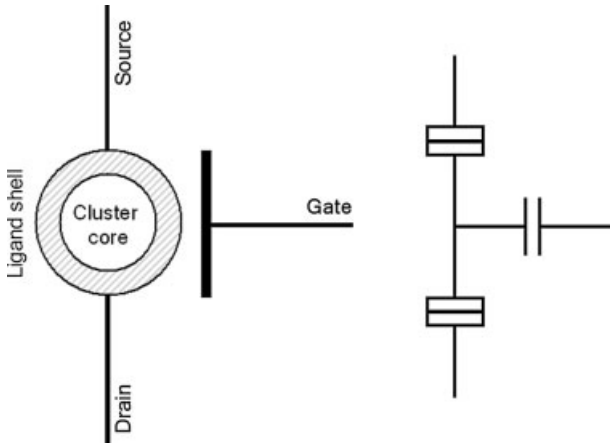

Figure 2.23 Circuit of a single-electron transistor.

Conventional methods are characterized by a rapid increase in release, followed by a fast decay (peak-and-trough cycle). Therefore, there is an urgent need for continuous drug release in the therapeutic area of concentration. The history of drug delivery based on implanted systems goes back to the 1960s [51]. Instruments at that time had considerable dimensions containing electrically driven pumps. In the course of the last two decades, numerous systems have been developed with novel principles [52–56]. Partially they also use novel principles such as release via the skin or the nasal mucous membrane. For longer times of therapy a drug delivery implant of reasonable size and high reliability would be the most effective system. Nanotechnology offers numerous chances to achieve that goal.

Entrapping and encapsulating drugs in nanostructured systems have been developed with remarkable success, releasing a drug uniformly over longer time periods. They are based on guest–host systems. Different kinds of chemical bonds between the guest (drug) and host system determine the speed of release. Hydrogen or van der Waals bonds and also electrostatic interactions can be used to combine the guest and

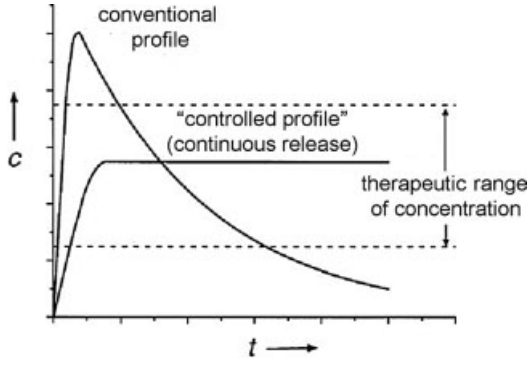

Figure 2.24 Concentration (c)–time (t) profile of a conventional and a controlled drug release.

host to such an extent that slow release is enabled. A host–guest system based on dendrimers as host molecules will be described briefly as an actual example of development. Dendrimers are highly branched molecules in the nanometer size regime. They consist of a core unit from where "branched branches" extend in different directions, forming a three-dimensional architecture bearing end groups of various functionality. Dendrimer structures unavoidably contain cavities inside the skeleton. These are able to take up guest molecules of appropriate size and to release them slowly depending on the surrounding conditions. With an increasing number of branches, the number and geometry of the cavities become variable and also increase [57]. Figure 2.25 shows a formal sketch of a dendrimer molecule taking up and releasing host particles.

Another interesting nano-based drug delivery system uses superparamagnetic iron oxide nanoparticles, usually embedded in a polymer matrix and attached to a drug system. External, high-gradient magnetic fields are applied to transport drug-loaded beads to the corresponding site in the body [58, 59]. Once the system has concentrated in the tumor, the drug is released using different techniques such as increase in temperature, change of pH value or enzymatic activity.

Another method uses superparamagnetic iron oxide nanoparticles, the surface of which is modified by DNA sequences. Those particles easily enter cells using receptor-mediated endocytosis mechanisms in combination with a magnetic field gradient [60]. Having entered the cell, the DNA is liberated and can enter the nucleus. This so-called non-viral transfection is of special interest for gene therapy.

A rapidly growing drug delivery development is based on the use of multifunctional nanoengineered capsules containing various kinds of active compounds. Attempts have been made to solve the general problem of treating only pathological cells and not healthy ones by using, for instance, functionalized polymer capsules having distinct release, permeability and adhesion properties. The inner volume can

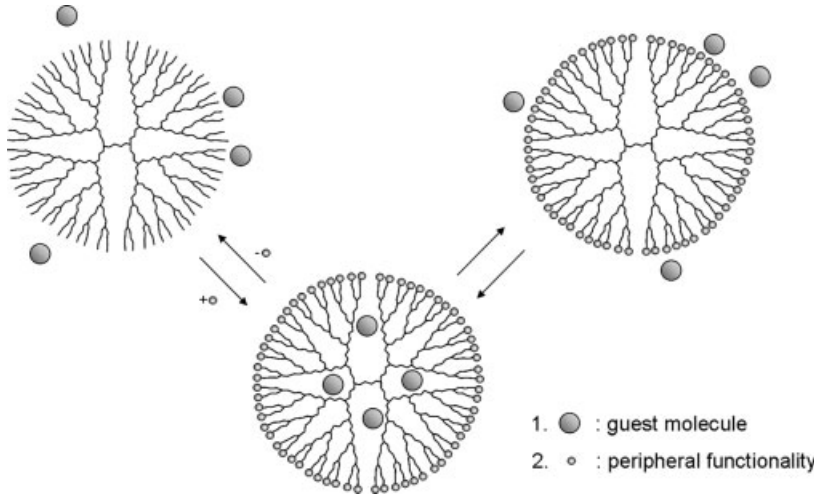

Figure 2.25 Inclusion of guest molecules in cavities of a dendrimer.

be filled with magnetic nanoparticles which allow aimed transport by outer magnetic fields, by modification of the capsule surface with specific receptors to target specifically diseased cells or by generating capsules acting as a nanoreactor producing products which are only toxic for diseased cells and cause selective apoptosis [61, 62].

Self-rupturing microcapsules consist of polyelectrolyte membranes, permeable to water, but not to the drug-containing degradable microgels, filling the holes of the capsules. The hydrolytic degradation of the microgels causes a swelling pressure, rupturing the outer membrane [63].

Polyelectrolyte capsules which degrade at physiological pH values open up novel prospects for drug delivery [64]. Intracellular targets such as nucleic acids or proteins can cause opening of the capsules. Using $CaCO_3$ particles as the carrying material for fluorescein isothiocyanate–dextran (FITC–dextran), assemblies of $CaCO_3$/FITC–dextran are formed by coprecipitation, followed by layer-by-layer polyelectrolyte membrane formation, for instance with poly-L-arginine as the polycation and dextran sulfate as the polyanion. Finally, the $CaCO_3$ particles are removed using buffered EDTA solution.

Finally, laser-induced opening of a polyelectrolyte membrane inside living cells can be mentioned [65].

A completely different drug delivery system has been developed using nanoporous alumina membranes for the controlled long-term release of drugs. Nanoporous alumina membranes with variable pore diameters between 10 and 200 nm are easy to prepare and are used to control the speed of release depending on the pore size [66]. Figure 2.26 shows a sketch of the implantable device and Figure 2.27 illustrates the influence of the speed of release of the same molecule depending on the pore diameter. Instead of a real drug, the system has been developed using crystal violet for the easy determination of concentrations by means of UV–visible spectroscopy. Of course, this system requires individual developments for each drug to optimize the pore size and solubility conditions, for instance with the help of surfactants.

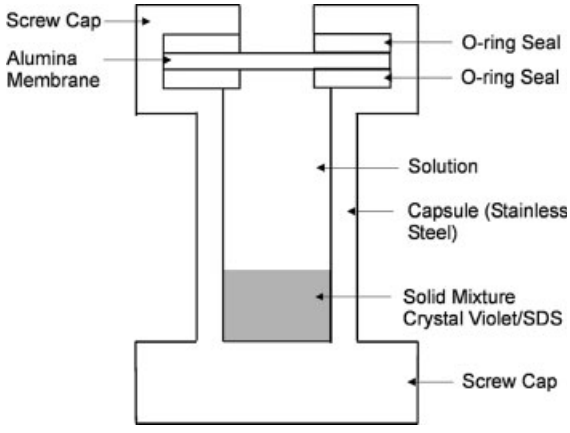

Figure 2.26 Sketch of a drug delivery system using nanoporous alumina membranes to control the speed of release.

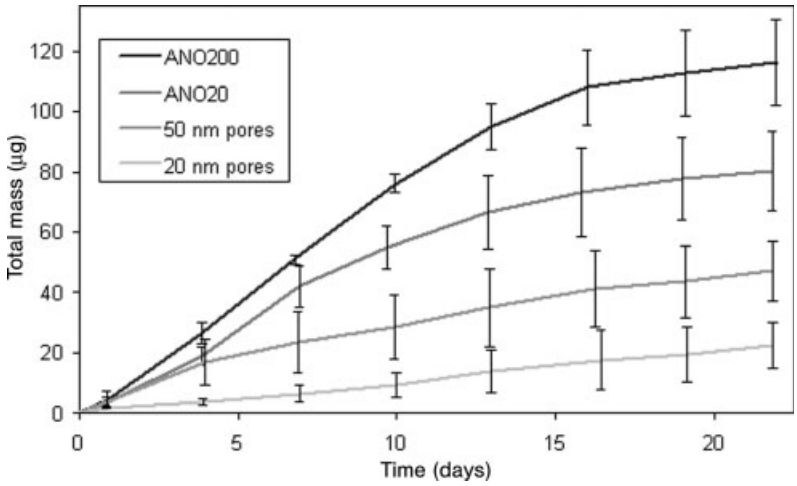

Figure 2.27 Dependence of the release of crystal violet on the pore size.

None of these nano-based techniques have yet reached the "technology standard". Rather, they are under development and have partially reached the "engineering state".

2.2.5 Gene Chips

Progress in the diagnostics of human diseases is of comparable importance to progress in therapy. Nanotechnology is, without doubt, the most promising field where improved developments can be expected. The scientific aim is to develop diagnostics on a molecular level, if possible with routine techniques. Gene chips, also called microarrays, represent the best way to fulfill such dreams. Gene chips are already commercially available, but are still also under investigation and development on the engineering level and also are still objects of intense scientific research. The early diagnosis of a cancer disease is crucial for successful therapy. So, this is a first example with a keyword existing in all three steps in Figure 2.6.

A gene chip consists of a collection of up to 400 000 single-stranded DNA segments (probes), fixed on a glass, silicon or plastic surface. Such DNA microarrays can be used to detect mRNAs which either interact with DNA fragments on the chip or not. Since there can be a huge number of reporters arriving, a microarray experiment can accomplish the equivalent number of genetic tests in parallel. Detection occurs by using organic fluorophore labels. So-called two-channel microarrays contain probes consisting of complementary DNA (cDNA), but also of oligonucleotides. This type of chip is then hybridized with cDNA from two different samples, labeled with two different fluorophores for comparison, for example from cancer cell lines and from a control. Mixing and hybridization on the microarray allow the visualization of the results. Gene chips working on that basis are commercially available and allow cheap and fast diagnosis on a level that was inconceivable one or two decades ago.

DNA microarrays are also used to analyze the sequence of particular genome sequences. Gene chips of this type have, in spite of their enormous contribution in diagnostics, inherent drawbacks due to the fluorophore labeling (in some cases even radioactive labeling is used). Recent advances in nanoscience open the door to increase the sensitivity of DNA detection to an unknown level. DNA–nanoparticle conjugates are powerful tools in this direction.

New developments of microarrays are based on the use of DNA, functionalized with quantum dots. Their excitation and emission properties make them powerful candidates for replacing fluorophore labeling techniques. Gold and silver nanoparticles, but also CdSe and ZnS quantum dots, have been successfully tested.

The surface plasmon resonance of gold nanoparticles and the resulting intense color allow the very sensitive and selective colorimetric detection of corresponding DNA sequences. Au nanoparticles in the size range from about 10 up to 100 nm, typically 10–20 nm, are linked with DNA probe strands by using 3′- or 5′-end mercapto-functionalized species. Due to the preferred formation of strong Au–S bonds, Au–DNA hybrid systems become easily available. Mirkin's group first reported the use of mercaptoalkyloligonucleotide-modified gold nanoparticles [67–71]. They used two samples, each complementary to one half of a target oligonucleotide, so that the formation of a polymeric network was induced by mixing the three species, as indicated in Figure 2.28. The purpose of this experiment was to perform a color change from red to blue, due to the aggregation of the nanoparticles.

Based on the colorimetric nanoparticle approach to DNA detection, microarrays using DNA–gold nanoparticle hybrid systems are being increasingly developed. A three-component system was first described by Mirkin and coworkers [69, 72, 73]. It consists of a glass chip, the surface of which is modified by capture DNA strands to recognize the DNA under investigation. The oligonucleotide-functionalized gold probe and the target DNA complete the system. Intense washing after the combination process results in a selectivity of 10 : 1 for single base-pair mutations. In a final special step, the gold nanoparticles are covered by a silver shell which is simply generated by the catalytic reduction of silver ions on the gold nanoparticles. The capture-strand–target–nanoparticle combination can then be visualized using a flatbed scanner. Due to the presence of silver shells on the gold particles, high

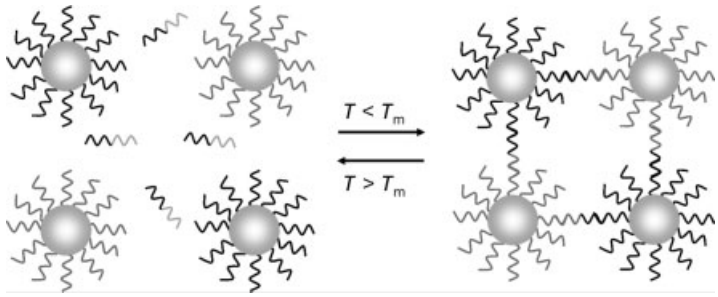

Figure 2.28 Aggregation of oligonucleotide-functionalized gold nanoparticles by means of complementary target DNA.

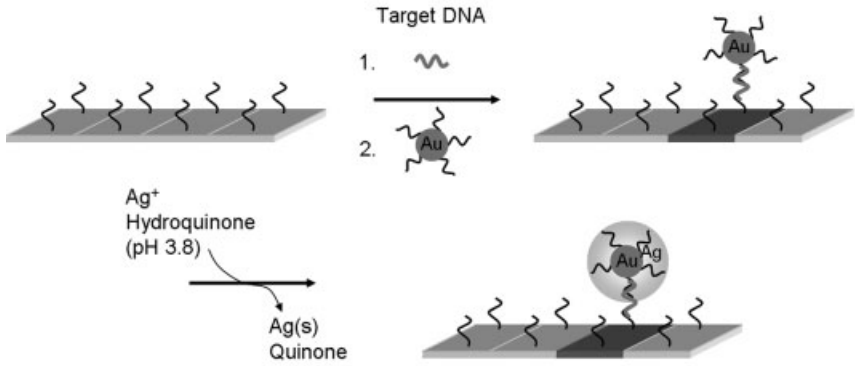

Figure 2.29 Principle of a scanometric DNA assay. A capture oligonucleotide on a surface binds one half of a target molecule and oligonucleotide gold nanoparticles bind the other half. A detectable signal results by the catalytic coverage of the gold nanoparticles by silver.

surface enhanced Raman scattering (SERS) is observed and can also be used for target DNA detection. Figure 2.29 elucidates the various steps.

The improvement of this technique, compared with conventional fluorophore-labeling techniques, is about 100-fold, namely as low as 50 fM. These remarkable nanotechnologically based developments will initiate great progress in diagnostics. As an example, first investigations of Alzheimer's disease (AD) can be mentioned [74].

Alivisatos and coworkers detected single base-pair mutations in DNA by the use of CdSe/ZnS quantum dots in chip-based assays [75]. The detection method was fluorescence microscopy and the detection limit was about 2 nM. This is not yet in the region of the detection limit described above, but it is likely that this technique can be improved considerably since it is known that even individual quantum dots can be detected under ideal conditions [76].

Gene chips based on the use of quantum dots belong to one of the most promising developments in nanotechnology. In an unusually short time, beginning with the very first experience with biomolecule–quantum dot interactions, a development started that has already led to commercially available devices. There are still simultaneous efforts to be made on all three levels. Further improvements of detection limits are still part of nanoscience. At the same time, improvements of routine detection processes are continuing in order to facilitate everyday clinical handling.

2.2.6 Hyperthermia

Hyperthermia, known for several decades, has more or less developed to a level of clinical applications based on nanotechnological attempts and can now be located in the field of "nanoengineering" and also "nanotechnology". It uses the fact that superparamagnetic nanoparticles can be warmed up by external alternate magnetic

fields. As has long been known, tumor cells respond sensitively with apoptosis on temperature increases of only a few degrees (40–44 °C) [77–81].

The superparamagnetic state of a material at room temperature is reached when the thermal energy kT (k = Boltzmann's constant) overcomes the magnetostatic energy of a domain or particle. If the particle or domain is small enough, a hysteresis no longer exists or, in other words, the magnetic unit no longer exhibits the ability to store the larger particle's magnetization orientation; rather, the magnetic moments rotate and so induce superparamagnetic behavior. Typical particle sizes for the transition from ferro- to superparamagnetism are in the range 10–20 nm for oxides. Metal particles have to be downsized to 1–3 nm. A great advantage of superparamagnetic particles is the fact that they can be dispersed in various liquids without any tendency to agglomerate, an important condition for applications in medicine.

Several types of superparamagnetic oxide nanoparticles have been investigated for application in hyperthermia. The most promising candidates are magnetite and maghemite since their biocompatibility has already been shown. The amount of magnetic material to reach the necessary temperature depends on the concentration of the particles in the cells. Direct injection allows larger quantities than intravascular administration or antibody targeting. On the other hand, direct injections into the tumor involve a certain danger of the formation of metastases. In any case, the amount of magnetic nanoparticles necessary for a sufficient temperature increase depends on the magnetic properties of the particles and on the external radio-frequency field. Under then optimum conditions only 0.1 mg per mL of tissue is necessary to induce cell death.

2.2.7 Gas Sensors

Gas sensors have been known and applied since the early 1960s [82, 83]. The fields of application range from industrial and automotive needs (NO_x, NH_3, SO_2, hydrocarbons, etc.) via domestic gas determinations (CO_2, humidity) up to the security sector, where traces of explosives have to be detected. In a working sensor system, the information resulting from the chemical or physical interaction between a gas molecule and the sensor has to be transformed into a measurable signal. Numerous possibilities such as electrochemical, calorimetric, acoustic, chemoresistant and other effects are well established. Chemoresistors typically use metal oxides. These change their electrical resistance when they oxidize or reduce gases to be detected [82–85]. Continuous improvements have been elaborated concerning sensitivity, selectivity, stability, response and recovery time [86]. In connection with nanotechnological developments sensors based on metal oxides and metal nanoparticles have been intensively studied and have reached the state of engineering and even technology (see Figure 2.6) [86].

Sensors based on nanosized *metal oxides* provide both receptor and transducer functions [87]. The receptor must ensure a specific interaction of the sensor's surface with the target analyte. The transducer's task is to transform the molecular information into a measurable change of the electrical resistance. For instance, the conductivity of n-type semiconducting metal oxides increases on contact with reducing

gases, whereas that of p-type oxides decreases. Oxidizing gases cause opposite effects. A frequently used wide-bandgap n-type semiconductor is SnO_2. A qualitative explanation (for details see [86]) of the working principle says that, in the presence of dry air, oxygen is ionosorbed on the oxide surface, depending on temperature as O_2^- (<420 K), as O^- (420–670 K) or as O^{2-} (>870 K). The electrons required for the reduction of O_2 come from the conduction band, so generating an electron-deficient region, the so-called space–charge layer Λ_{air} [88–91]. Λ_{air} depends on the Debye length L_D, a material- and temperature-dependent value. For SnO_2 at 523 K it is about 3 nm [92]. In real systems water is present to some extent, forming hydroxyl groups on the surface and affecting the sensor's properties. The influence of water has been discussed in detail [93].

Reducing gases interact with the ionosorbed oxygen species and are oxidized, for instance $CO \rightarrow CO_2$, which is desorbed. Even traces of reducing gases decrease the number of oxygen species to such an extent that, due to the release of surface-trapped electrons, the increase in conductance becomes measurable. In the case of oxidizing target gases, the process is inverse: additional electrons are removed from the semiconductor, resulting in an increase in Λ_{air}. Hence adsorption of oxidizing gases, for example NO_2 or O_3, causes a decrease in conductance.

The efficiency of a gas sensor depends not only on the material of which it is made, but decisively also on the size of the particles and their arrangement, since the relevant reactions occur on the particles' surface. In an ideal case all existing percolation paths are used, contributing to a maximum change in conductance. The response time depends on the equilibrium between the diffusion rate of the participating gases. Film thickness and porosity are therefore of special relevance for the quality of a sensor [94, 95].

A vital role in this connection is played by the size of the particles forming the macroscopic film. Since the analyte molecule–sensor interaction occurs on the particles surface, their surface:size ratio plays a dominant role. Since the relative proportion of the surface increases with decreasing particle size, smaller particles should be more efficient than larger particles. This can clearly be seen from Figure 2.30 [87].

SnO_2 particles with diameters below about 10 nm exponentially increase the sensor's response. In addition to the increase in surface area, particle radii in the range of the space–charge layer Λ_{air} decrease the Schottky barriers between depleted zones or even lead to an overlap, with the consequence that surface states dominate the electrical properties and so have a decisive influence on the sensor performance. Very small differences in the particle size can have crucial consequences for the sensor's ability. As has been shown for WO_3 nanoparticles, a reduction from 33 to 25 nm increases the sensitivity towards 10 ppm NO_2 at 573 K by a factor of 3–4 [96]. Several similar examples for other metal oxides are known [86].

Metal nanoparticles as building blocks for sensor systems have been under investigation since the late 1990s. Thin films of ligand-protected metal nanoparticles change their conductance when gas molecules are absorbed in the regions between the nanoparticles [97, 98]. Films of 2-nm gold nanoparticles, covered with octanethiol molecules, turned out to change the conductance reversibly if gas molecules such as toluene, 1-propanol or water became part of the interparticle sphere. This principle

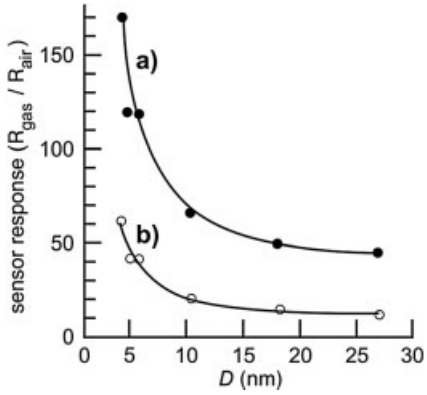

Figure 2.30 Dependence of the sensor response R on the particle diameter D (SnO_2), expressed as R_{gas}/R_{air}. (a) 800 ppm H_2 and (b) 800 ppm CO in air at 573 K. (© Springer, Berlin).

has since been improved by the introduction of specifically functionalized ligand molecules, increasing the sensitivity [99–102]. Self-assembled layers of gold nanoparticles and dendrimer molecules use the ability of dendrimers to host guest molecules in their cavities [101, 103].

Apart from gold, other noble metal nanoparticles have also been tested. Platinum nanoparticles, for instance, partially crosslinked by dithiol molecules, are active sensors towards toluene, H_2O, CO and NH_3 [104–107]. In the case of NH_3, traces down to 100 ppb could be detected. Figure 2.31 informs on the different sensitivities of such a chemoresistor towards different gases.

Whereas charge transport mechanisms between ligand-protected metal nanoparticles have been investigated in detail [86, 108–119], knowledge about the change in conductance due to the influence of various gases is still rather limited.

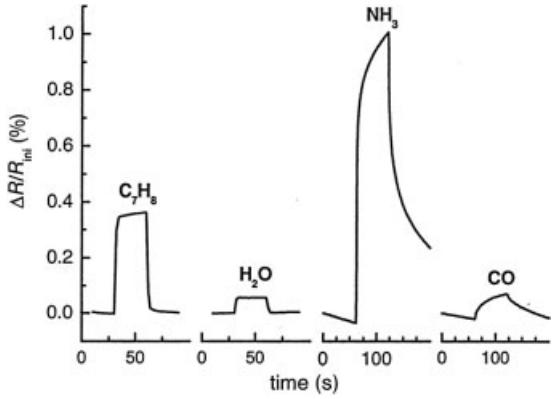

Figure 2.31 Response of a sensor system consisting of partially nonanedithiol-crosslinked Pt nanoparticles towards 400 ppm amounts of different gas molecules. ($\Delta R = R_{gas} - R_{ini}$; R_{ini} = resistance in dry air). (© Elsevier, Amsterdam).

2.3
Technologies on the Nanoscale

2.3.1
Introduction

This section deals with images of "nanotechnology" that do not fulfill the strict definition of nanoscience and nanotechnology, explained in Section 2.1. Why is this necessary? The term "nanotechnology" has now reached such a broad and thereby diffuse meaning that it seems helpful to discuss some examples of those already installed techniques that are falsely integrated into nanotechnology in a broader sense. Indeed, in some cases it is not trivial to decide if an effect and a thereby resulting technique follow the precise definition or not. From experience it can be seen that "wrong" nanotechnology means techniques that are settled on the nanoscale, but without the decisive size-dependent or functionality-determined nano-effect. What is usually meant by this common understanding is "technology(ies) on the nanoscale". The exclusion of those techniques from the scientifically exactly defined techniques is not discrimination. Rather, some of them became very important and others will follow. To conclude this introduction, one should try to differentiate clearly between nanotechnology and technologies on the nanoscale. The latter can also be considered as scaling effects without indicating nano-specific effects.

2.3.2
Structured Surfaces

It has long been known that structured surfaces change the physical and chemical properties of the corresponding material. Two property changes dominate the interest in structured surfaces: (i) change in wettability and (ii) change in optical properties. Both are of enormous importance both in nature and in technique. What kind of structure are we talking about? Let us consider first a natural "technique", that has been copied in many respects: the *wettability behavior*. Barthlott *et al.* have investigated since about 1990 the surface of lotus leaves for its special property of having a permanent clean surface [120–122]. Like all primary parts of plants, lotus leaves are covered by a layer of hydrophobic material. In case of lotus leaves, this layer consists of epicuticular wax crystals. Scanning Electron Microscopy (SEM) investigations additionally showed a structural design that is responsible for the super-hydrophobicity of lotus leaves. This special behavior has subsequently become known as the lotus effect. The SEM images showed that the surface of the leaves consists of a double structure of microsized cells decorated with nanosized waxy crystals.

The physical background for this phenomenon can be seen in the behavior of water droplets on a micro/nanostructured surface. It is important to state that the effect is not dependent on a distinct size of the structure units. As it turned out, the lotus combination of micro- and nanosized units is advantageous, but it is not a condition. Also, the absolute size of the nanostructure units is not decisive to observe the effect, it can only improve or worsen the hydrophobic nature.

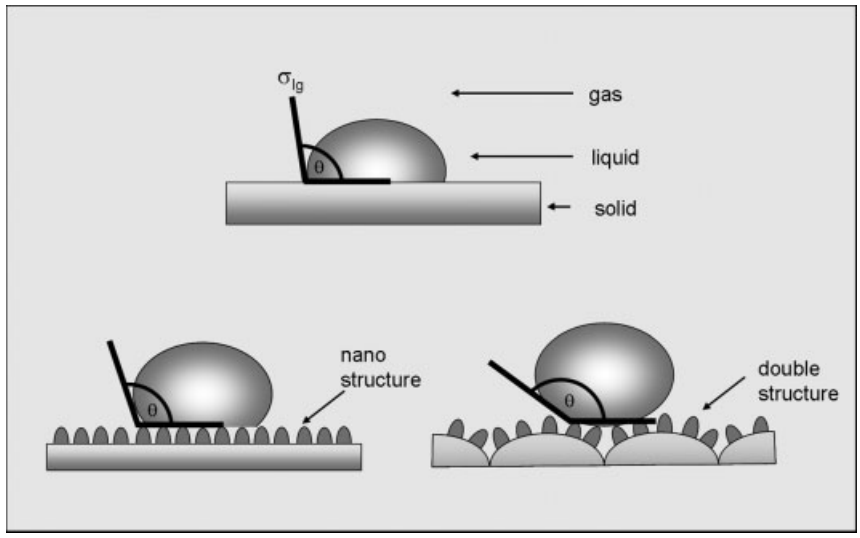

Figure 2.32 Sketch of the gas–liquid–solid three-phase system. (a) Water droplet on a smooth surface resulting in small contact angles θ, (b) on a nanostructured surface with increased θ value and (c) on a bimodal micro/nano structured surface with the largest contact angle.

The wettability generally describes the interaction of a liquid with a solid surface. It is described by the Young equation, $\sigma_{sg} - \sigma_{sl} = \sigma_{lg}\cos\theta$, where σ_{sg} = solid–gas interfacial tension, σ_{sl} = solid–liquid interfacial tension, σ_{lg} = liquid–gas interfacial tension and θ = solid–liquid contact angle [123]. The contact angle θ is the angle between the solid surface and the tangent applied at the surface of the droplet. Figure 2.32 illustrates the situation of a water droplet on a smooth surface, a nanostructured surface and a micro/nanostructured surface.

It is obvious that structured surfaces in any case cause larger contact angles than flat surfaces and so show an increased hydrophobicity. The reason is that the energy to distribute a water droplet on a structured surface extends the gain in energy by additional interactions of water molecules with the surface.

Soon after its recognition, the lotus effect led to the development of artificially micro/nanostructured surfaces. Lithographic techniques, self-assembly processes, controlled deposition, size reduction and replication by physical contact are applicable routes [124]. An elegant replication procedure will be briefly considered. It uses masks consisting of nanoporous alumina films. The advantage is their rather simple fabrication by anodization of aluminum surfaces, the easy adjustability of the pore diameters and the hardness and the temperature stability of alumina [125–129]. Using appropriate imprinting devices, various polymers and metals could be nanostructured [130]. The successful 1 : 1 polymer transfer from the mask to the surface is shown in Figure 2.33 by means of a poly(methyl methacrylate) (PMMA) surface.

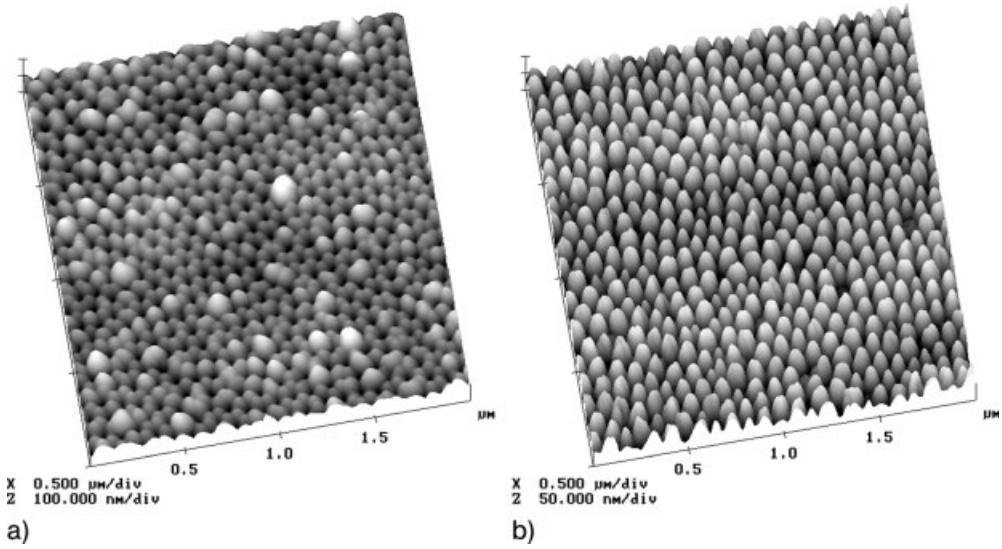

Figure 2.33 Proof of 1 : 1 pattern transfer. (a) AFM image of an alumina surface with 50-nm pores; (b) imprinted PMMA surface indicating some defects from the mask at the same positions.

Polycarbonate (PC) and polytetrafluoroethylene (PTFE) could also be nanostructured with different pore widths. Aluminum, iron, nickel, palladium, platinum, copper, silver and brass are examples of successfully nanostructured metals. Figure 2.34 shows an AFM image of a nanostructured silver surface using a mask with 50-nm pores.

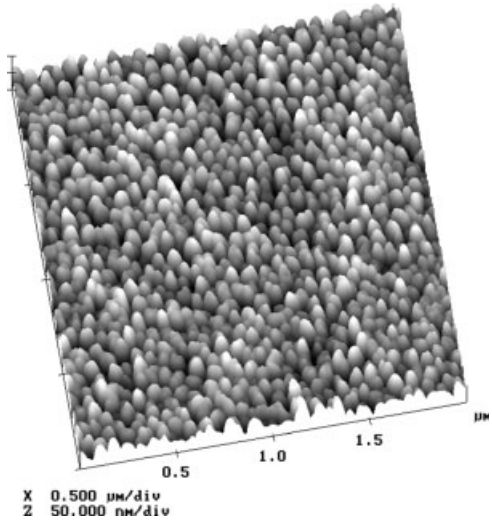

Figure 2.34 AFM image of an imprinted silver surface.

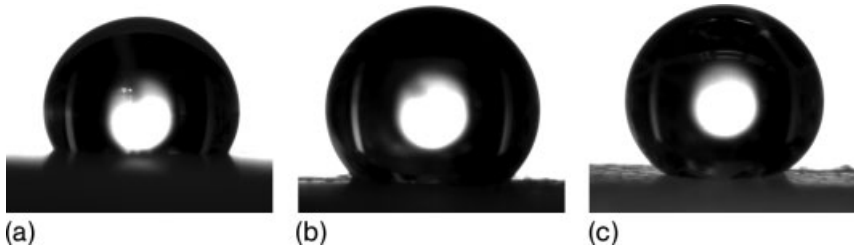

Figure 2.35 Light microscopic images of water droplets on (a) 50-nm, (b) 120-nm and (c) 170-nm structured PTFE surfaces.

By means of PTFE surfaces, imprinted with masks of 50, 120, 170 and 200 nm, it has been demonstrated that each of the surfaces makes the hydrophobicity increase, compared with an untreated surface. However, there is no spontaneous effect to be observed, rather it is a scaling phenomenon. In Figure 2.35, light microscopic images of water droplets on variously nanostructured PTFE surfaces are shown. There is an increasing contact angle to be registered if the pore width and thereby the pillars on the surfaces increase. This continuous development of the contact angles can also be followed from Figure 2.36.

In addition to the wettability properties, a second physical behavior changes with structure: the *light transmission* of transparent materials. In Figure 2.37, the increasing transmission of visible light through PMMA windows with decreasing structure size is demonstrated.

Improvements in the transparency of glasses, linked with a reduction in reflection, has important practical consequences in optical devices.

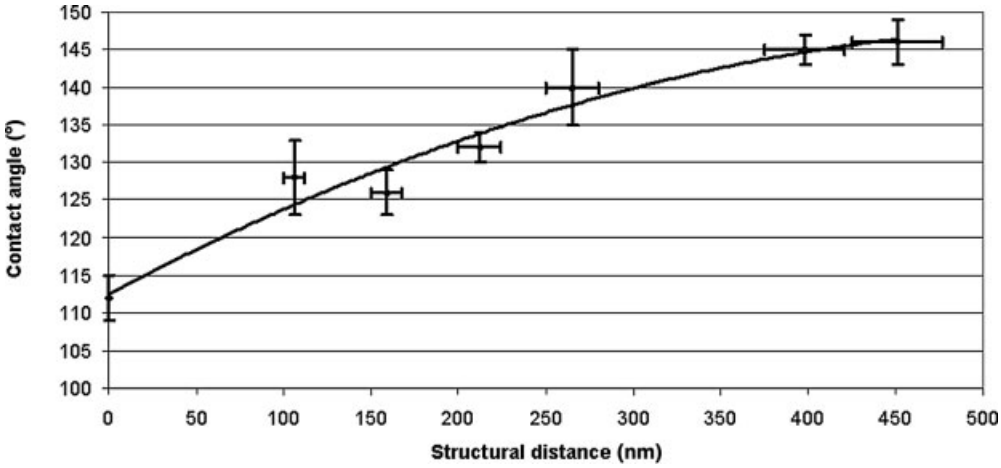

Figure 2.36 Dependence of contact angles of water droplets on PTFE surfaces on the structure size.

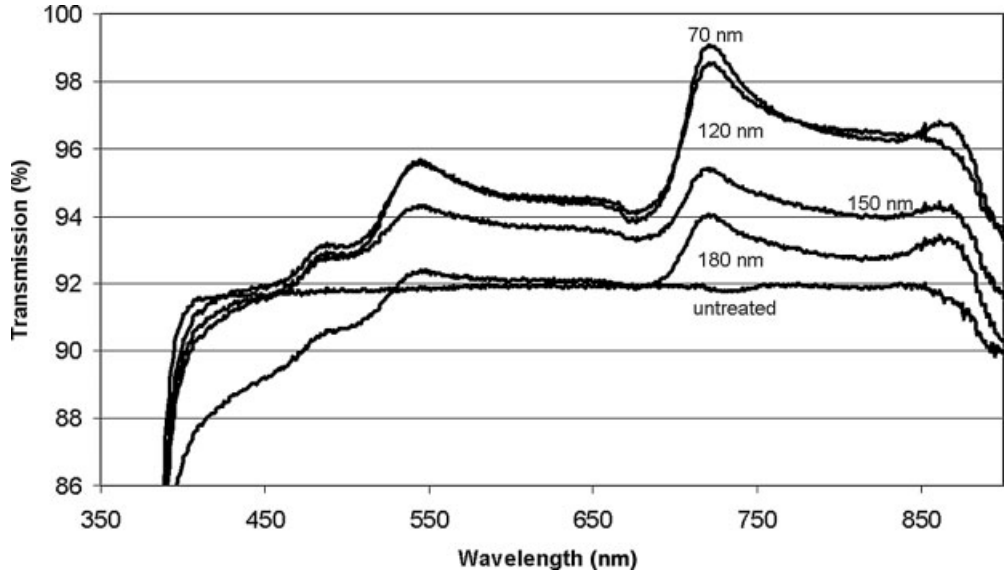

Figure 2.37 UV–visible transmission spectra of PMMA samples structured with 70-, 120-, 150- and 180-nm pillars and of a non-structured sample.

2.4 Final Remarks

Referring to Figure 2.6, only seven of a huge number of possible examples have been selected here to demonstrate the enormous diversity of nanoscience and nanotechnology. Nano-effects can occur everywhere, both in "simple" materials and in complex biological structures. This makes nanoscience and nanotechnology a unique field of research and development. The examples discussed illustrate the universality of this future-determining technology, which in many of the most attractive fields is still at the very beginning. However, it can be predicted that distinct fields that are still part of basic research will develop into techniques which will influence daily life dramatically. Others, usually those of easier and faster research and development, have already become routine techniques.

The selected examples also indicate that basic research is fundamental to developing nanotechnology further. Only by basic research will we discover nano-effects in the different fields named in the definition. However, also in basic science the research assignment should not just be to look for novel nano-effects: physics, chemistry, biology and materials science will also discover relevant effects when working in other fields.

3
Top-Down Versus Bottom-Up

Wolfgang J. Parak, Friedrich C. Simmel, and Alexander W. Holleitner

3.1
Introduction

Today, the term "nanotechnology" is a widely used keyword occurring in a variety of different contexts [1, 2]. Semantically, "nano" is an official SI prefix for physical units, which is equivalent to the factor 10^{-9}. This prefactor can be combined with units of physical quantities such as time (nanoseconds), mass (nanograms) or length (nanometers). Historically, nanotechnology has evolved from different scientific fields such as physics, chemistry, molecular biology, microelectronics and material sciences. Generally, nanotechnology aims to study and to manipulate real-world structures with sizes ranging between 1 nm, that is one millionth part of a millimeter, and up to 100 nm. The set of typical "nano"-objects includes colloidal crystals, molecules, DNA-based structures and integrated semiconductor circuits.

We can approach the scale between 1 and 100 nm from different sides, for instance by emphasizing biological and chemical aspects. On the one hand, we can conceptually subdivide complex biological organisms, such as a human body, into smaller and smaller subunits. In a simplified way, the entire body can be classified into organs, each organ is composed out of cells and each cell is a dynamically organized assembly of biological molecules. Arguably, complex molecules, such as lipids, proteins and DNA, are the smallest biologically relevant subunits. These molecules typically have dimensions of a few nanometers up to several tens of nanometers. On the other hand, the smallest integral part of a molecule is the physical bond between individual atoms. The latter have a size of a few tenths of nanometers. Molecules can be very small (such as hydrogen, H_2) and very big (such as polymeric macromolecules). If we leave aside the combination of molecular building blocks to new macromolecules (as in polymerization reactions or in supramolecular chemistry [3]), the typical size range of molecules that can be synthesized from atomic building blocks and their derivatives is again the region from a few nanometers up to several tens of nanometers. It can be concluded that if macroscopic objects such as biological organisms are investigated on a smaller and smaller length scale, one ultimately ends

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

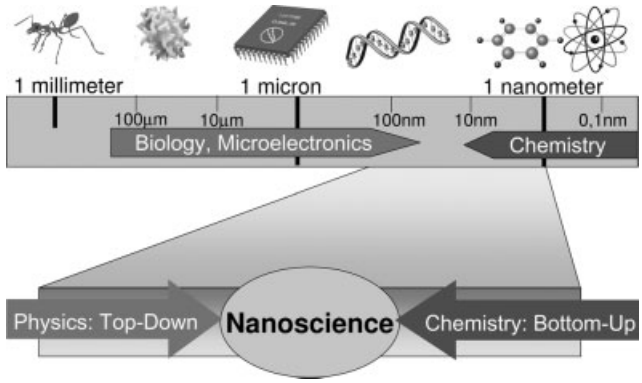

Figure 3.1 Some objects (ant, virus, circuits in computer chip, DNA, benzene, atom) are presented that are characteristic of different size scales ranging from milli- to nanometers. Adapted from a presentation by Professor Dr. J. P. Kotthaus.

up in the nanometer range as the smallest relevant scale for functional subunits. Then again, if materials are built up synthetically from their basic chemical building blocks, one will also first arrive at this length scale. In this sense, "nano" is the size scale where physics, chemistry and biology meet in a natural way (Figure 3.1).

The first scientist who pointed out that "there is plenty of room at the bottom" was Richard Feynman in 1959 [oral presentation given on 29 December 1959 at the Annual Meeting of the American Physical Society at the California Institute of Technology (Caltech)]. He envisioned scientific discoveries and new applications of miniature objects as soon as material systems could be assembled at the atomic scale. To this end, machines and imaging techniques would be necessary which can be controlled at the nanometer or subnanometer scale. Fifty years later, the scanning tunneling microscope and the atomic force microscope are ubiquitous in scientific laboratories, allowing to image structures with atomic resolution [4–12]. As a result, various disciplines within nanotechnology aim towards manufacturing materials for diverse products with new functionalities at the nanoscale.

As we have seen, we can approach the nanoscale from two sides: by making things smaller, that is, by downscaling, and by constructing things from small building blocks, that is, by upscaling. The first method is referred to as the "top-down" and the second as the "bottom-up" approach. The top-down approach follows the general trend of the microelectronic industry towards miniaturization of integrated semiconductor circuits. Modern lithographic techniques allow the patterning of nanoscale structures such as transistor circuits with a precision of only a few nanometers (see http://www.icknowledge.com and publications therein for more information). As we will see in this chapter, the industrial demand for ever smaller electronic circuits has provided several physical tools by which materials can be probed and manipulated at the nanometer scale. In contrast, the bottom-up approach is based on molecular recognition and chemical self-assembly of molecules [13]. In combination with chemical synthesis techniques, the bottom-up approach allows for the assembly

of macromolecular complexes with a size of several nanometers. To visualize the different strategies of these two approaches is the topic of this chapter. We first will give a few simple explanations and arguments. Then we will illustrate the differences of the two strategies in the context of a variety of examples. Finally, we will discuss the limits of both approaches.

3.1.1 Top-Down Strategies

How can we get to smaller and smaller sculptures and objects? The idea of top-down-strategies is to take processes known from the macroscopic world and to adopt them in such a way that they can be used for doing the same thing on a smaller scale. Since ancient times, humans have created artwork and tools by structuring materials. Let us take the artist as an example, who carves and sculpts figures out of blocks of wood or stone, respectively. For this purpose, the artist needs tools, usually a carving knife or chisel, with which he can locally ablate parts from the original piece of material and thus give it its desired shape (Figure 3.2). If we continue with the idea of a sculptor, it is evident that in order to sculpt smaller objects, smaller tools are needed, such as miniature rasps and knives. Chinese artisans have used such tools to carve little pieces of wood and other materials into sculptures in the submillimeter regime, which can only be seen with magnifying glasses [some of these highly impressive sculptures can be seen in the National Taiwan Museum (http://www.ntm.gov.tw)].

If we want to fabricate even smaller structures or objects and study their physical properties, classical mechanical tools such as rasps will no longer work. For that purpose, scanning probe microscopes are powerful instruments for probing and manipulating materials at the nanometer scale and can thus be seen as one of the key inventions for nanotechnology. On the one hand, they allow imaging and probing of the characteristics of nanoscale objects with the highest resolution. Examples include topology, material configuration and electrical, chemical and magnetic properties of the studied objects. On the other hand, scanning probe microscopes allow local manipulation and even shaping of the nanostructures. In a seminal work in 1982, Binnig and Rohrer invented the scanning tunneling microscope (STM) [4], for which they were awarded the Nobel Prize in 1986. In such a microscope, piezoelectric

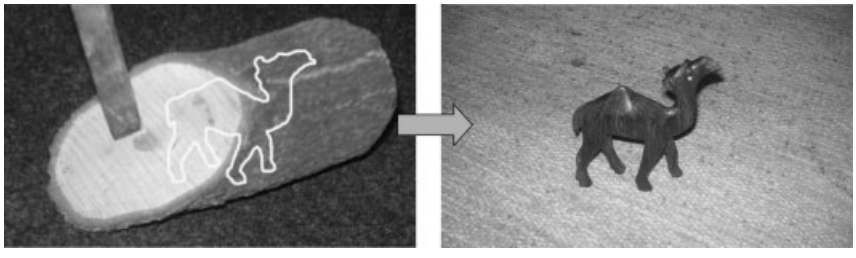

Figure 3.2 An artifact is made out of a piece of wood by carving. The wooden figure is created by locally ablating material from the initial block according to a building plan.

crystals move a scanning tip across the surface of a sample, while the electric current is recorded between the tip and the sample. If the tip is located very close to the surface of the sample, the electric current is composed of tunneling electrons. In the nanoscale quantum world, the wave character of electrons plays an important role. As soon as the distance between the tip and the surface is on the order of the electron wavelength, electrons can tunnel from the tip to the surface. The size of the tunneling current has an exponential dependence on the distance between the tip and surface. Therefore, the point of the tip which is closest to the surface predominantly contributes to the current. In principle, this point can be made up of only one atom, which allows for atomic resolution. The scanning tunneling microscope is sensitive to the electronic density at the surface of the sample, which allows for, for example, imaging of the electronic orbitals of atoms and molecules. The scanning tunneling microscope can operate not only under ultrahigh vacuum conditions, but also at atmospheric pressure and at various temperatures, which makes it a unique imaging and patterning tool for the nanosciences. For instance, scanning tunneling microscopes are utilized to pattern nanostructures by moving single atoms across surfaces, while the corresponding change of the quantum mechanical configuration can be recorded *in situ* [14].

The atomic force microscope (AFM) operates similarly to the scanning tunneling microscope [5]. Here, the force between the scanning tip and the sample surface is extracted by measuring the deflection of the tip towards the sample. Again, the atomic force microscope can be utilized as an instrument to image and to shape materials on the nanometer scale [15].

In experiments in which only a few nanostructures need to be patterned and probed, scanning probe microscopes can be exploited to structure and shape materials at the nanometer scale. To define an array of millions of nanoscale systems in parallel – such as in integrated electronic circuits – the top-down approach of microlithography is the technique of choice (Figure 3.3). Microlithography has been the technological backbone of the semiconductor industry for the last 45 years (see http://www.icknowledge.com and publications therein for more information). The minimum feature size of optically defined patterns depends on the wavelength of the utilized light and also factors that are due to, for example, the shape of the lenses and the quality of the photoresist. In 2003, the typical linewidth of semiconductor circuits fell below 100 nm, that is, the semiconductor industry can be literally seen as being part of the nanotechnologies. For this achievement, argon fluoride excimer lasers are applied with a laser wavelength of 193 nm in the deep ultraviolet region. For lithography in this optical range, tricks such as "optical proximity correction" and "phase shifting" were invented and successfully implemented. On the one hand, the miniaturization of semiconductor circuits is limited by economic costs for the semiconductor industry, since the implementation of new techniques for the realization of ever smaller feature sizes results in ever increasing costs. On the other hand, physical material properties, such as the high absorption level of refractive mirrors at short optical wavelengths, set a natural limit of a few tens of nanometers for the miniaturization process. Since the 1980s, the decline of optical lithography has been predicted as being only a few years away. However, each time optical

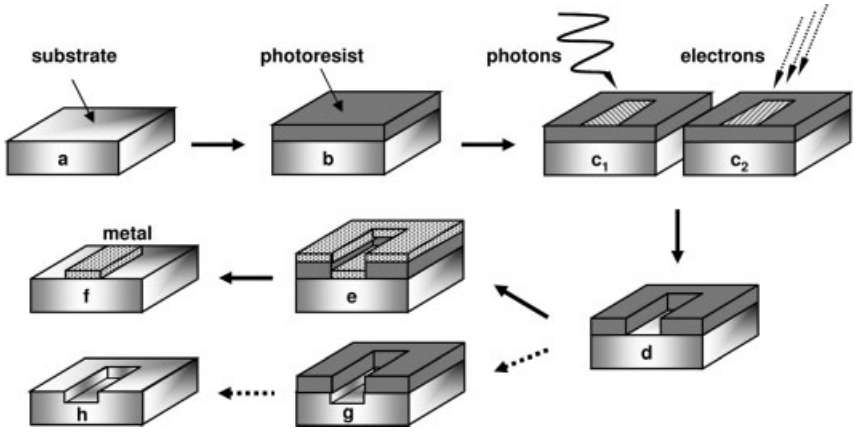

Figure 3.3 Top-down microlithography: in (a) and (b) a so-called photoresist – a liquid, photosensitive polymer – is spin-coated on to the polished surface of a substrate. (c) After hardening of the photoresist, for example, by heating, the substrate with the photoresist layer on top is locally exposed to photons or to electrons. Thereby, patterns can be defined in the photoresist. (d) After a photoresist specific developing process, the exposed (or the unexposed) parts of the original substrate are bared. By follow-up processes, such as metallization (e) or etching (g), the patterns in the photoresist can be translated to the substrate. To this end, the remaining parts of the photoresist are finally removed by a solvent, such as acetone [(f) and (h)]. Thereby, metallic conductor paths, logical circuits or memory cells can be defined.

lithography had reached traditional limits, new techniques extended the economically sustainable lifetime of top-down microlithography.

At present, there are several possible successor top-down nanotechnologies for industry, for example, extreme ultraviolet light lithography (EUV), electron beam lithography with multicolumn processing facilities [see also Figure 3.3(c_2)], the focused ion beam (FIB) technique and the ultraviolet nano-imprinting technique [16]. The implementation of each of these techniques requires enormous technical challenges to be overcome. One of the most promising techniques is that using EUV light with a wavelength of only 13 nm. For this technique, fabrication errors of the "optical" components need to be in the nanometer or subnanometer range. For comparison, state-of-the-art X-ray telescopes, such as the Zeiss XMM Newton telescope, exhibit a granularity of the mirror surfaces of 0.4 nm (see W. Egle, *Mission Impossible: XMM-Newton Proves the Opposite*, Innovation, Carl Zeiss, 2000, *8*, 12–14, ISSN 1431-8059; this file can be downloaded from http://www.zeiss.com). In addition to "state of the art" optical requirements, all metrological components of the EUV technique need to exhibit subnanometer resolution. As a result, the cost of a stepper machine for EUV exposure of photoresists is US$50 million per system, providing a linewidth of 35 nm (see http://www.icknowledge.com for more information).

For medium-sized businesses, the "ultraviolet nano-imprinting technique" seems to be the most promising method to fabricate nanoscale circuits [17]. Here, nanostructures are mechanically imprinted into a photoresist. The stamp with the

nanoscale patterns is made out of fused quartz, a material which is transparent to ultraviolet light. As soon as the stamp has been plunged into the photoresist, a short ultraviolet light pulse causes the photoresist to polymerize along the patterns on the stamp. In line with optical lithography, follow-up processes allow for the definition of nanoscale circuits in various geometries [Figure 3.3(e)–(h)]. The minimum feature size of the nano-imprinting technique is about 10 nm (see the webpage of the Chou group at Princeton University: http://www.princeton.edu/~chouweb/newproject/page3.html). At the same time, the technique is applicable to metals and plastic materials. The costs of an industrial nano-imprinting machine are less than US$1 million. However, the throughput of nano-imprinting machines is much lower than that for stepper machines.

What we have illustrated above is the top-down approach. We take tools and methods known in the macroscopic world and scale them down to structure materials on increasingly smaller length scales. As explained above, this downscaling process is not simply a reduction in size of the tools – we cannot make a nanoscale carving knife that directly resembles a macroscopic knife to take away material on the nanometer scale. In most cases, the relative importance of the forces and interactions involved changes with decreasing system size – and this also has to be considered when constructing the tools themselves.

3.1.2 Bottom-Up Strategies

The antipode of the top-down approach is the so-called bottom-up technique. Here a complex structure is assembled from small building blocks. These building blocks possess specific binding capabilities – often termed "molecular recognition properties" – which allow them to arrange automatically in the correct way. Self-assembly is an essential component of bottom-up approaches [18]. The ultimate examples of molecular recognition are biological receptor–ligand pairs: molecules that recognize and bind to each other with very high specificity. Prominent examples of such pairs are antibodies and their corresponding antigens and complementary strands of deoxyribonucleic acid (DNA) [19].

We can visualize the bottom-up assembly of materials with the example of LEGO building blocks, a common toy for children. Again we take the example of a small sculpture as also used to describe top-down approaches. LEGO building blocks can have different functions, as symbolized by their color (Figure 3.4). Furthermore, there are building blocks of different size and each building block has a defined number of binding sites, realized here as knobs. In this way the blocks can only be attached to each other in a defined way. This can be seen as "molecular" recognition. However, we should point out that the example of the LEGO blocks fails to describe self-assembly. There is still a helping hand needed to assemble the individual bricks to form the complete structure – the assembly process is not spontaneous (cf. the self-assembly models of Whitesides [20]). The example of LEGO blocks hold the basic concept of a bottom-up strategy: the construction of a new material by assembling basic small building blocks. If instead of LEGO blocks nanoscopic building blocks are

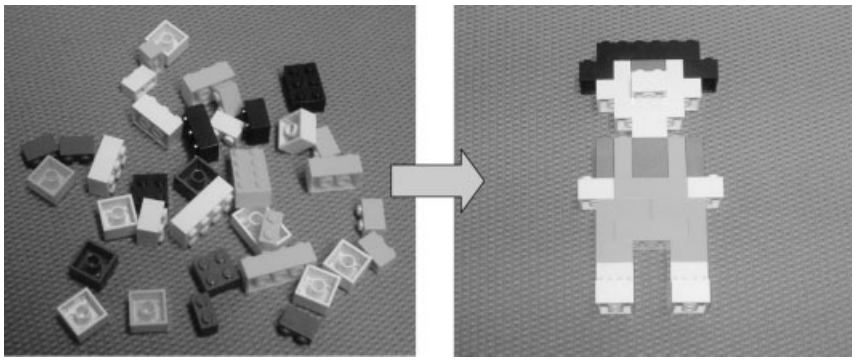

Figure 3.4 LEGO blocks can symbolize different functionalities (colors) and they can be assembled with their knobs in a defined way. Assembly of all building blocks (bricks) leads to the formation of the desired structure.

used, structures on the nanometer scale can be assembled in a very analogous way [21–24].

Generally, bottom-up assembly techniques seek to fabricate composite materials comprising nanoscale objects which are spatially ordered via molecular recognition. The prime examples of the technique are self-assembled monolayers (SAMs) of molecules [25]. A substrate is immersed in a dilute solution of a surface-active organic material that adsorbs on the surface and organizes via a self-assembly process. The result is a highly ordered and well-packed molecular monolayer. The method can be extended towards layer-by-layer (LBL) assembly, by which polymer light-emitting devices (LEDs) have already been fabricated [17]. The self-assembly technique also allows positioning of single molecules between two metal electrodes and subsequently into an experimental circuit. By this set-up, quantum mechanical transport characteristics of single molecules, such as photochromic switching behavior, can be studied in order to build electronic devices with new functionalities [26].

There are several combinations and variations of the SAM technique. It can be combined with nano-imprinting methods, the atomic force microscope or the focused ion beam technique, allowing the fabrication of geometric patterns of molecules with variable wetting properties, chemical functionality and/or topological characteristics [17]. Since most of the processes are performed in solution, electrical fields may be utilized to assemble charged compounds in a directed way, for example, for the creation of functionalized sensor electrodes. Electrodes modified with negatively charged gold nanoparticles and positively charged host molecules have proven highly sensitive for the detection of, for example, adrenaline (as the guest molecule) [27]. Another very promising field is the DNA-directed assembly of network materials [28]. Here, molecular recognition reactions between single DNA strands are translated into aggregate formation of nano-objects such as nanoparticles [21, 22]. Self-assembly can also be used to construct simple nanomechanical devices. For instance, the molecular recognition between DNA molecules has been exploited to build “nanotweezers” [29]. Further, networks of materials can be

synthesized on top of so-called block copolymer templates [30]. A typical application of this technique is the formation of networks of metallic nanowires, that is, metals are vapor deposited on to a preformed template matrix made out of copolymers. The polymer networks can be used as two- or even three-dimensional templates. Generally, there is a wide range of materials which can be engineered by bottom-up techniques. The research involved has led to numerous sensing, electronic and optoelectronic interfaces in addition to devices.

3.2
First Example: Nanotweezers

Among the fundamental tools for mechanical work are tweezers or fingers. The basic function of tweezers is to hold and release things. In principle, tweezers comprise two fingers, which can close to hold something and open to release it again. So far only a few functional nanofingers are available. Although a variety of tools exist which can hold nanometer-sized objects, the problem is to release them again. This problem is of fundamental rather than of technological nature. The interested reader is referred to the excellent articles by Nobel Prize winner Richard Smalley, who describes the problem of nonspecific adhesion as the problem of "sticky fingers" [31, 32]. The basic module of a nanofinger is a nanometer-sized hinge, that is, a structure which can repeatedly open and close. In this section, we will show examples of such nanofingers or hinges based on top-down microlithography and on bottom-up self-assembly of biological molecules.

3.2.1
Top-Down Nanotweezers

Lithographically defined tweezers have been realized as a so-called micro-electromechanical system (MEMS). Similar micron-sized mechanical resonators have already been applied in inkjet printers and in airbags of cars. MEMS resonators have also triggered major scientific interest, since the reduction in size of an electromechanical resonator down to the nanometer regime would allow researchers to study, for example, mechanical effects in the quantum realm [33–36] or the coupling of the eigenmode of such a nanoscale resonator to the electromagnetic field of a photon [37, 38]. Furthermore, the small mass of nanoelectromechanical devices makes them extremely sensitive adsorptive sensors, since the mass of adsorbed molecules can significantly change the eigenfrequency of a nanoscale mechanical device [39, 40].

For lifting and manipulation of objects on the nanoscale, it is necessary to use opposing forces to seize and hold a floating or a freely suspended nanostructure, such as a single protein in liquids or an individual nanowire within a three-dimensional electrical circuit. Kim and Lieber reported the first nanoscale tweezers in operation [42]. They attached two carbon nanotubes to metal electrodes on opposite sides of a micron-thick glass needle, in order to manipulate nanoscale clusters and nanowires with a size of about 500 nm. The tweezers were closed electrostatically using a voltage

difference between the nanotubes. Generally, nanotweezers can act as manipulators, sensors and injectors. For instance, they can investigate the interaction between nanomaterials and they can measure the electrical conductance of nanostructures by employing the two probes of the tweezer as electrodes. The tweezers combine a mechanical degree of control of a two probe sensing instrument with the spatial resolution of a scanning probe microscope. To date, scanning tunneling microscopy and atomic force microscopy have evolved to a level where individual atoms on surfaces can be arranged into the shape of nanoscale letters [43] and clusters of atoms can be pushed into tiny junctions to make quantum devices [44]. In order to move a nanoscale object with a single probe, there needs to be sufficient adhesion to the probe to ensure that the object can be picked up and then transported to its new destination. To deposit the object at the new location, the adhesion at the final site needs to be larger than the adhesion to the single probe. One way to overcome the problem is to use tweezers – nanoelectromechanical probes, which are attached to the tips of an atomic force microscope [45].

In most cases nanotweezers are closed and opened electrostatically using a voltage difference between the two nanoprobes. The electrical field and the potential difference between the probes may cause problems, especially when biological samples are investigated. Here, mechanical manipulation of the nanotweezers is favorable. Recently, piezo-driven tweezers have been developed with a size of about 1 μm that can grab, hold and transport bacteria in addition to micron-sized particles in liquids [46]. The experiment demonstrates that lithographically defined tweezers are a promising alternative to optical tweezers commonly applied for the manipulation of biological samples [47]. The latter utilize the effect that a focused laser beam provides an attractive force for dielectric objects.

One of the smallest tweezers devices – with a gap of only 25 nm – was fabricated by a technique which combines conventional silicon microlithography with electron beam deposition of carbon [48]. How carbon nanofingers can be fabricated by this technique is shown schematically in Figure 3.5 [41]. The fabrication process follows a classical top-down approach by microstructuring silicon with lithographic techniques [49]. To this end, silicon is partially covered by a protective polymer layer (see Figure 3.3 for top-down lithography). Then, the unprotected areas are etched away [Figure 3.5(a)–(c)]. The process uses a heterostructure with an intermediate silicon oxide layer, which can be selectively etched by hydrofluoric acid. As depicted in Figure 3.5(d), the technique enables freely suspended silicon fingers to be defined. Finally, a carbon nanofinger is defined on top of the freely suspended structure by focusing an electron beam on the silicon nanostructure in the presence of residual gases [Figure 3.5(e)] [41]. As a result, the electron beam-deposited carbon builds up to form the carbon nanofingers [Figure 3.5(f)]. The functioning of the resulting device [Figure 3.6(a) and (b)] is very intuitive. It looks like tweezers known in everyday life, only orders of magnitude smaller. By applying a voltage to the inner two, freely suspended silicon electrodes, the gap between the carbon nanofingers can be opened and closed. Most importantly, the carbon nanofingers are nonconductive. No voltage difference is applied between the nanofinger tips, making the device ideal for application with such fragile structures as organic objects.

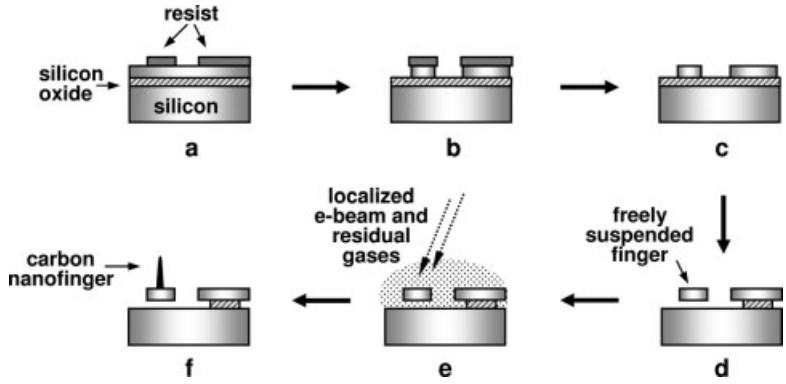

Figure 3.5 Fabrication of a freely suspended carbon nanofinger: (a) the photo- or e-beam resist is prepatterned by microlithographic steps on top of a multilayered silicon-on-insulator (SOI) wafer. The latter consists of a silicon top layer, an intermediate silicon oxide layer and a silicon substrate. (b), (c) In accordance with the pattern, the silicon top layer is removed either by wet-chemical or by reactive ion etching. (d) By the use of hydrofluoric acid, the silicon oxide layer is partially removed. Thereby, the smaller features of the prestructured silicon top layer become freely suspended. (e), (f) If an electron beam is focused on specific locations of the structure in the presence of residual gases, an electron beam-deposited carbon nanofinger can be formed [41].

As already mentioned, the release of objects picked up by the tweezers constitutes a severe conceptual problem. An object can only be released when it is deposited at a site to which its adhesion is higher than the adhesion to the nanofingers. This concept is based on hierarchical binding forces. Although this concept would allow for repeatedly picking up objects from one site A, transporting them to site B and releasing them there (in the case that $F_A < F_F < F_B$, where F_A, F_F and F_B represent the binding forces of the object to site A, to the nanofinger and to site B, respectively), it would fail in the reverse direction to transport objects from B to A (as F_B is larger than F_F, the holding force of the nanofinger would not be strong enough to detach the object from binding site B). Alternatively, the attachment of the object to the

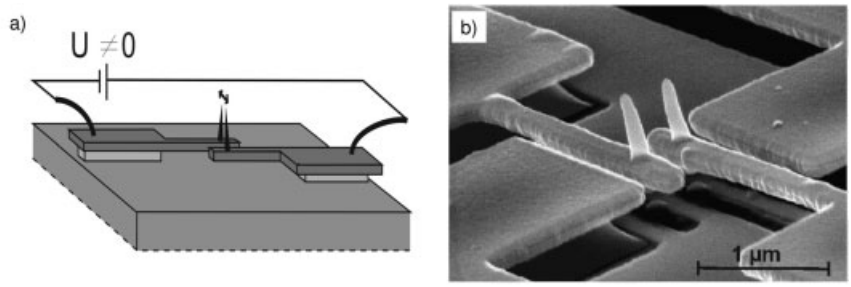

Figure 3.6 (a) By applying an electric voltage to the conductive silicon arms, the "fingers" move. (b) Electrically operated nanotweezers. The structure is made out of silicon with lithographic techniques. The tips on the silicon arms have subsequently been grown with electron beam deposition (EBD). The figure is based on the original work of Dr. Christine Meyer, Dr. Bert Lorenz and Professor Dr. K. Karrai and is reproduced with their permission [41].

nanofinger might be modulated by a biological molecule, for example, an antibody whose conformation can be modulated by light. In this way, the binding properties of the antibody could be remotely controlled by switching on or off the light and thus objects could be held and released. However, so far this concept has not been realized practically.

3.2.2 Bottom-Up Nanotweezers

In recent years, the unique biochemical and mechanical properties of DNA have been increasingly utilized for non-biological applications, for example, to realize tiny nanomechanical devices. Many of these devices exploit the different rigidity of single- and double-stranded DNA and can be switched back and forth between several structures by the addition or removal of DNA "fuel" strands. One of the prototype devices in this field are DNA nanotweezers [50]. Their operational principle is shown in Figure 3.7. In the open state, the DNA tweezers consist of three strands of DNA.

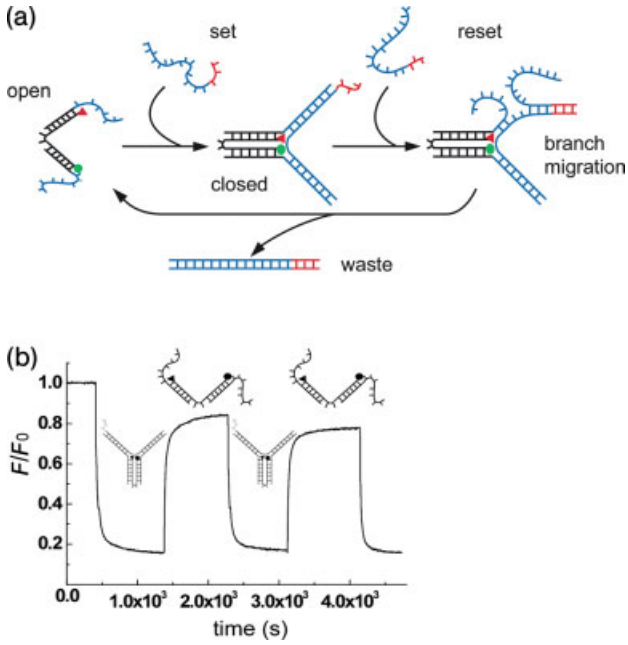

Figure 3.7 DNA nanotweezers. (a) Principle of operation. In the open state, three strands are hybridized together to form a molecular structure resembling tweezers. Due to hybridization with a "fuel" strand, the arms of the tweezers can be closed. Another DNA strand can be used to remove the fuel strand and restore the original open state via branch migration. (b) FRET experiment. The movement of the tweezers can be followed in fluorescence measurements. To this end, the arms of the tweezers are fluorescently labeled. One of the labels quenches the fluorescence of the other due to fluorescence resonance energy transfer. As this effect is strongly distance dependent, the motion of the arms is accompanied by a change in fluorescence intensity.

One central DNA strand is hybridized to two other strands in such a way that together they form two roughly 6-nm long, rigid double-stranded "arms" connected by a short, single-stranded flexible "hinge". In the open state, each of the arms still has single-stranded extensions available for hybridization. The addition of a long "fuel" strand which is complementary to these extensions can then be used to close the tweezer structure, that is, the two arms are forced together by the hybridization with the fuel strand. The device can be switched back to its original configuration with a biochemical "trick". In the closed state, a short single-stranded section of the device is deliberately left unhybridized. These nucleotides serve as an attachment point for an "anti-fuel" strand, which is exactly complementary to the fuel strand. A biochemical process known as "branch migration" unzips the structure, when fuel and anti-fuel try to bind with each other. After completion of this process, a waste "duplex" is ejected and the DNA tweezers have returned to their open configuration again. The device can be operated cyclically by the alternate addition of set and reset strands. The transition between the different states of the device can be characterized in fluorescence measurements, utilizing the distance dependent quenching of fluorophores due to fluorescence resonance energy transfer (FRET).

The same operation principle has since been used in many other DNA devices [51]. A simple variation of the DNA tweezers is the DNA actuator device [52]. Here, instead of two single-stranded extensions, the arms of the tweezers are connected by a single-stranded loop. Depending on the sequence of the fuel strands, the device can either be closed similarly to the tweezers or stretched into an elongated conformation. Whereas the intermediate configuration is a rather floppy structure (like the open tweezers), the closed and the stretched configurations are much more rigid. While these devices resemble macroscopic tweezers in shape, they cannot actually be used to "grab" nano-objects. However, such a function may be achieved by the incorporation of so-called "aptamers" into DNA devices [53]. These are special DNA or RNA sequences with a high binding affinity for other molecules, for example, proteins.

3.3 Second Example: Nanomotors

Another important mechanical element is the motor. A motor is a device that can generate periodic movements and carry a load with it. Similarly to the previous section, we will show two examples of nanomotors. The version using the top-down approach is again based on microlithography and follows the ideas of micromechanical engineering. The version using the bottom-up approach is based on functional organic molecules.

3.3.1 Top-Down Nanomotors

Nanomotors can also be created using refined lithographic techniques. As the strategies employed are somehow similar to those described in Section 3.2.1, we

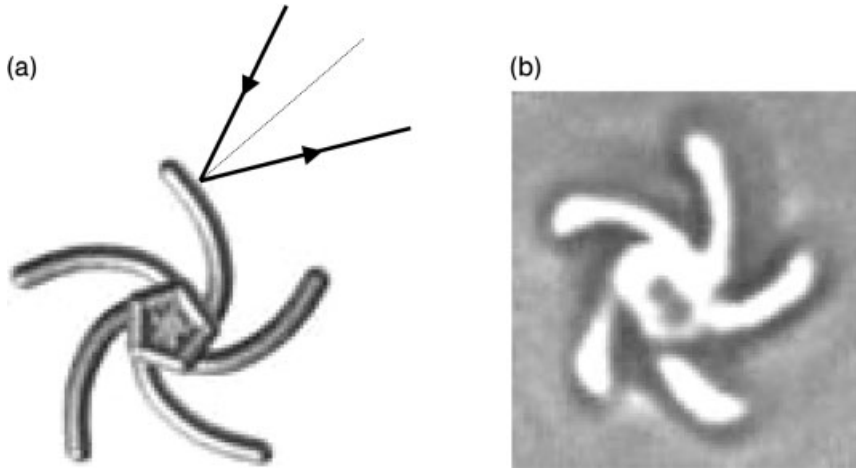

Figure 3.8 (a) A micrometer-sized rotor is driven by the momentum transferred due to reflection of an incident light beam. (b) Phase contrast image of the rotor in solution. Adopted from an paper by the group of Professor Dr. P. Ormos and is used with his permission. Details can be found in the original article [55, 56].

will only give two brief examples in this section. As with macroscopic motors, nanomotors also periodically convert input energy into mechanical work. The energy to drive the motor can originate from different sources, such as light, electric fields or chemical gradients.

A simple light-driven propeller has been demonstrated by Ormos's group. The propeller itself is created by selectively illuminating the parts of a light curing resin that resemble the shape of the propeller. The resin is cured at the illuminated regions due to photo-polymerization. Dissolution of the noncured parts of the resin finally results in a freestanding propeller (Figure 3.8) [54–57]. The propeller can be driven by incident light into rotation. When light is reflected at the arms of the propeller, momentum is transferred which causes the rotation. For a detailed description of the underlying physics we refer to the original article by Galajda and Ormos [55]. In order to achieve controlled rotation of the propeller, either a freestanding propeller is trapped in the focus of laser tweezers [55, 56] or a propeller bound to an axis on top of a substrate is driven by the light origination from an integrated waveguide [54]. So far the smallest propellers created in this way still have a size of a few micrometers.

An even smaller synthetic motor has been created by Zettl's group by scaling down MEMS technology to the nanometer scale [58]. The axis of this motor is formed by a carbon nanotube which is fixed between two anchor electrodes (Figure 3.9). A metal plate fixed to the carbon nanotube acts as a rotor. The outer shell of the nanotube beneath the rotor has been detached from the inner shells of the nanotube by shear forces so that a rotational bearing has been formed. The rotor is driven by an oscillating electric field between three additional electrodes. In practice, the rotor was

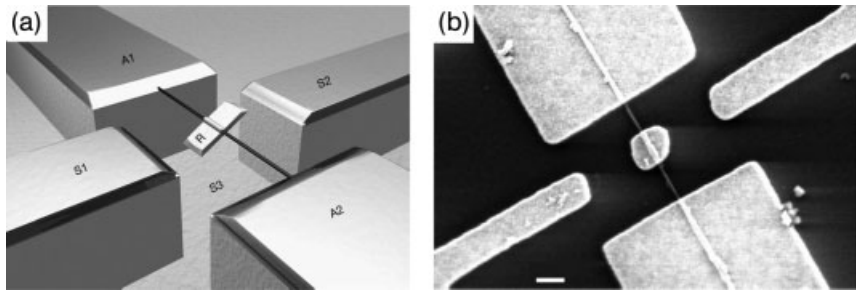

Figure 3.9 (a) Sketch of the nanomotor. A metal plate rotor (R) has been attached to a multi-walled carbon nanotube of which the outer shell beneath the metal plate can rotate freely around the inner shells and which is anchored on two electrodes (A1, A2). The motor is driven by electric fields applied from three stator electrodes, two on the SiO_2 surface (S1, S2) and one buried beneath the surface (S3). (b) Scanning electron microscope image of the nanomotor. Image reproduced with permission from the original article by Zettl's group [58].

realized by first depositing a multi-walled carbon nanotube on a silicon oxide substrate, followed by patterning the rotor and the electrodes using electron beam lithography and by etching down the silicon oxide below the rotor. More details can be found in the original breakthrough article by Zettl *et al.* [58].

3.3.2 Bottom-Up Nanomotors

Motors play an important role not only in our technical macroscopic life, but also on a molecular level in any biological organism. Molecular motors, for example, help bacteria to move and to transport cargo inside cells, and they are also the basis for contracting and expanding our muscles [59]. Since the field of nanotechnology emerged, scientists have thought about how to harness molecular motors for the construction of artificial machines. For example, the molecular motor kinesin has been used to transport colloidal quantum dots along the tracks of microtubules [60]. Such a concept might eventually lead to a scenario where building blocks could be transported along rails to their designated positions. Another example is the membrane-bound protein ATP synthase [61]. This rotary motor is driven by a proton gradient and is used in cells for the synthesis of ATP [61]. In the reverse direction the motor uses the energy of ATP hydrolysis to create a proton gradient. The rotation of the motor could be used to propel an actin filament that had been attached to the upper subunit of the motor with ATP as fuel [62]. Such a concept might eventually be used as a nanopropeller for moving small vesicles. While these concepts are based on using naturally existing molecular motors, synthetic molecular motors have also been chemically synthesized [63]. In this section we will briefly describe the concept and realization of such a motor that has been demonstrated by Gaub's group [64].

Molecules can often assume different structural arrangements called "conformations". Azobenzene, for example, can be reversibly switched upon illumi-

nation at two different excitation wavelengths between an extended *trans* and a shorter *cis* conformation [65]. In order to obtain longer effective length changes upon switching between the two different conformations, many azobenzene molecules can be linearly connected to one long polyazobenzene molecule. Single force spectroscopy techniques allow for attaching single molecules between the tip of an atomic force microscopy (AFM) cantilever and a substrate that is placed on top of a piezo-actuator [66]. In a periodic cycle, a single polyazobenzene molecule fixed between the tip and piezo of an AFM can now be elongated and shortened by illumination, which can be used to lift a load (as realized by the pulling force of the piezo-actuator) (Figure 3.10). In this way, in each cycle light energy is converted into mechanical energy [64]. Although the estimated efficiency of the motor is relatively low (total mechanical energy output/total optical energy input $\approx 10^{-4}$), it nevertheless demonstrates nicely how a light-driven artificial nanomotor can look.

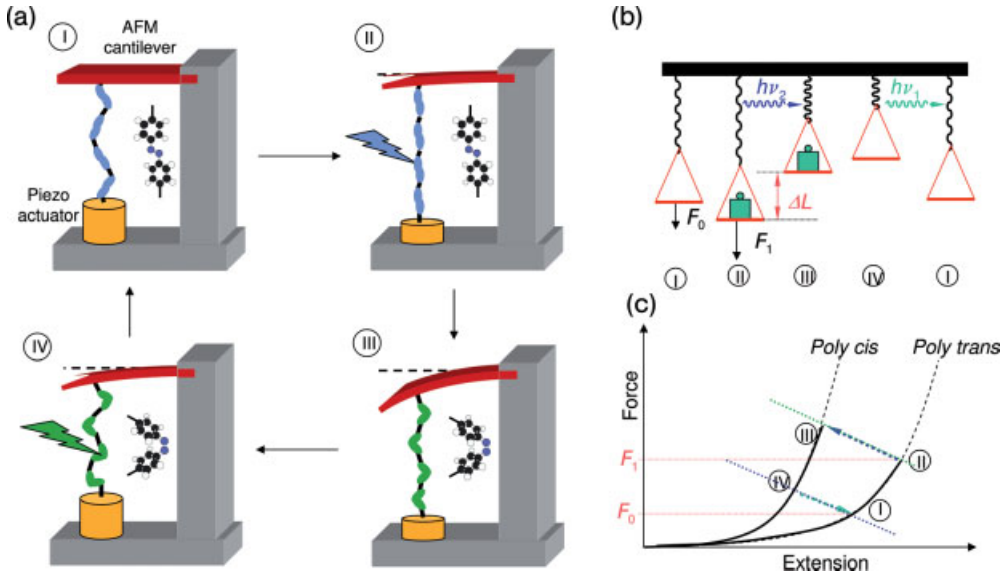

Figure 3.10 (a) A single polyazobenzene molecule is fixed between the tip of an AFM cantilever and a glass substrate mounted on top of a piezo-actuator. In a periodic cycle first the polyazobenzene is stretched by applying a load by retracting the piezo-actuator (I ⇒ II). Then, upon a light flash $h\nu_2$ the polyazobenzene is brought from the stretched *trans* to the shortened *cis* configuration (II ⇒ III). The load is now released by moving the piezo-cantilever upwards and thus the polyazobenzene can elongate (III ⇒ IV). With another light flash $h\nu_1$ the polyazobenzene is driven back to the extended *trans* configuration (IV ⇒ I). (b) Visualization of the load that is applied to the polyazobenzene by moving the piezo-actuator. (c) The cyclic process can be described in a force–extension diagram, where *F* is the force applied to the polyazobenzene by stretching it between the AFM cantilever and the glass substrate on top of the piezo and the extension describes the effective length of the polyazobenzene. Adapted from a presentation by Professor Dr. H. Gaub; details can be found in the original publication by Gaub's group [64].

3.4 Third Example: Patterning

One basic requirement for many technologies and applications is the ability to form controlled patterns on a surface. This can be exemplified with the components and techniques needed to fabricate an electronic circuit [67]. In order to make circuits, one essentially has to master three different steps. First, active elements such as transistors must be realized which are able to process information [68]. Second, the active elements have to be arranged into a functional geometry [28]. Third, the active elements have to be connected by wires [69]. Arranging elements on a surface is basically the same as forming a pattern. Another example is controlled cell attachment. If a surface is patterned partly with molecules that promote cell adhesion and partly with molecules that repel cells, cells only will grow on the desired parts of the surface. This is very important, for example, for bioelectronic interfaces, where cells have to be guided in such a way that they adhere on top of the active electronic elements, but not to other parts of the surface [70].

In this section we will briefly describe two examples for making small surface patterns. Soft lithography is a top-down approach, whereby surfaces can be structured with lithographically generated stamps. Following a self-assembly strategy, two-dimensional lattices of biological molecules, in particular DNA, can be formed in a bottom-up approach.

3.4.1 Soft Lithography

Soft lithography is an increasingly popular application of traditional lithographic techniques for the ordered deposition of "soft" materials such as small molecules, biomacromolecules or even live cells on surfaces. A variety of different techniques can be summarized under the term "soft lithography", for example, microcontact printing, replica molding and micromolding in capillaries [71, 72]. Most of these techniques utilize the soft, rubber-like material polydimethylsiloxane (PDMS). A schematic depiction of a typical soft lithographic process is shown in Figure 3.11. Usually the desired structure is first patterned into a "hard" material using conventional lithography. In Figure 3.11(a)–(c) a pattern defined on a mask is transferred into a negative resist on a silicon substrate. The structured resist film can be used as a template to transfer the patter into PDMS. To this end [Figure 3.11(d)–(f)], polymer precursors are poured over the template, followed by a curing step. After complete polymerization of the PDMS, the resulting "soft" structure can be peeled off from the substrate. There are many different applications for the structured PDMS material. In microcontact stamping, for example, the PDMS is used as a stamp with which molecules can be transferred on to a substrate in a pattern. Examples are shown in Figure 3.11(g) and (h), where fluorescently labeled proteins and also live cells have been patterned into an array of squares. PDMS-based structures are not only utilized for patterning, but have also been extensively used for the definition of microfluidic systems [73].

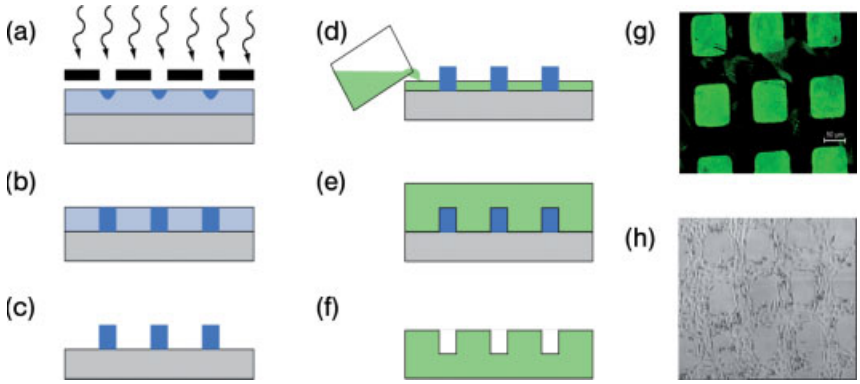

Figure 3.11 Soft lithography and microcontact printing of molecules. (a)–(c) Using conventional photolithography, a pattern is defined in a negative photoresist (blue) on a silicon wafer (gray). After exposure and development of the resist, a relief pattern remains on the surface. (d)–(f) This pattern can be used as a "master template" to create flexible microstamps from PDMS. Polymer precursors are poured over the master and cured. The resulting stamp can be peeled off the master and then used for soft lithographic processes such as stamping. (g) A square pattern of fluorescently labeled proteins stamped on a glass surface. (h) Live cells only reside outside of the square pattern which has been stamped with hydrophobic molecules which do not promote cell adhesion.

3.4.2
Two-Dimensional DNA Lattices

Whereas soft lithography can be mainly regarded as a top-down method to arrange molecules into a particular pattern, a different approach relies on molecular recognition events and self-assembly. As mentioned before, interactions between complementary strands of DNA can be utilized for the "programmable" assembly of molecular structures. Starting with the synthesis of a DNA molecule with the topology of a cube by Chen and Seeman in 1991 [74], DNA has been used to construct molecules with the structure of a truncated octahedron [75], DNA catenanes [76], tetrahedra and octahedra [77, 78] and other geometric objects. DNA has also been used to construct two-dimensional molecular lattices from DNA branched junctions [19, 79–81]. One of the central building blocks of such lattices is the so-called "double-crossover" (DX) construction. In a DX molecule, two double-stranded DNA molecules exchange strands twice, creating an entity which can be regarded as the molecular analogue of a LEGO building block [Figure 3.12(a)]. The rigid DX molecule has dimensions on the order of 4×15 nm. Depending on the sequence of single-stranded "sticky ends" at the corners of the DX molecules, they can arrange into large two-dimensional lattices [Figure 3.12(b) and (c)]. In fact, the assembly of such DX "tiles" closely resembles a computational process – regarding DNA self-assembly as the execution of a molecular "program" can actually be exploited to realize more complex molecular structures than with any other self-assembly technique [82]. When these networks fold back to themselves, they can also form DNA "nanotubes" [83–85]. Recently, such networks have even been utilized to arrange nanoparticles and proteins in two dimensions

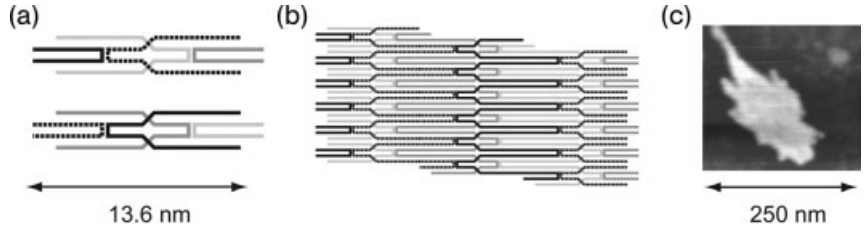

Figure 3.12 DX assembly. (a) The basic building blocks – DX molecules – are composed of two DNA double strands which exchange strands twice, creating a structure held together by two DNA crossovers. (b) Depending on the "sticky ends" at the corners of the DX tiles, a variety of two-dimensional lattices may be formed in a self-assembly process. (c) A small patch of a 2D DX lattice imaged with an atomic force microscope under air. Functionalization of these lattices allows for the arrangement of nanoparticles or proteins into sequence-programmed patterns.

[28, 86–89] and the impressively powerful "DNA origami" scheme [82] will soon allow the arrangement of these nanoparticles into arbitrary geometries and patterns.

3.5
Fourth Example: Quantum Dots[1)]

In Chapter 4, the physical principles of quantum dots are described. Quantum dots are arguably the ultimate examples of nanometer structures. In this section, we will show that we can manufacture quantum dots both with top-down (Section 3.5.2) and with bottom-up techniques (Section 3.5.4). Depending of the manufacturing process used, the properties of the quantum dots vary and we will explain this in particular with respect to their optical properties. Also the possible applications vary among the different types of quantum dots.

3.5.1
Different Methods for Making Quantum Dots

Here we will give a brief overview of the most popular methods used to fabricate quantum dots in practice. Lithographically defined quantum dots are the classical example of the application of a top-down method, whereby the quantum dot is created by locally etching away parts of the raw material. Colloidal quantum dots, on the other hand, are an example of a bottom-up approach, in which they are assembled from small building blocks (in this case surfactant-stabilized atoms).

The ultimate technique for the fabrication of quantum dots should be able to produce significant amounts of sample, with such high control of quantum dot size, shape and monodispersity that single-particle properties are not averaged out by sample inhomogeneity. So far, ensembles of quantum dots produced by the best

1) This paragraph has been adopted from a previous edition and the authors acknowledge their former coauthors Dr. Liberato Manna, Dr. Daniele Gerion and Prof. Dr. Paul Alivisatos 90.

available techniques still show a behavior deriving from a distribution of sizes, but this field is evolving very rapidly. In this section we give a short survey of the most popular fabrication approaches. Different techniques lead to different typologies of quantum dots. The confinement can be obtained in several different ways and in addition the quantum dot itself can have a peculiar geometry, it can be embedded into a matrix or grown on a substrate or it can be a "free" nanoparticle. Each of these cases is strictly related to the preparative approach chosen.

3.5.2
Lithographically Defined Quantum Dots

Lithographically defined quantum dots are formed by isolating a small region of a two-dimensional electron system (see Chapter 4) via tunneling barriers from its environment. Such two-dimensional electron systems (2DES) or 2D electron gases (2DEGs) can be found in metal–oxide–semiconductor field effect transistors (MOSFETs) or in the so-called semiconductor heterostructures [91, 92]. Heterostructures are composed of several thin layers of different semiconductor materials grown on top of each other, using molecular beam epitaxy (MBE). The layer sequence can be chosen in such a way that all free charge carriers are confined to a thin slice of the crystal, forming essentially a two-dimensional electron system. A superstructure derived from the periodic repetition of this sequence of layers is also called a "multiple quantum well". One of the most widely investigated systems is, for instance, the aluminum gallium arsenide/gallium arsenide (AlGaAs/GaAs) quantum well. AlGaAs has the same lattice constant as GaAs but a wider bandgap, whose exact value depends on the aluminum content of the layer. Therefore, electrons in the GaAs layer are confined to this layer and form a two-dimensional electron gas.

Quantum dot systems can be generated in a lateral or in a vertical arrangement, as shown in Figure 3.13. In the lateral geometry, the 2DEG is locally electrostatically depleted by applying negative voltages to electrodes deposited on top of the crystal. We can understand this effect with the following argument. Let us assume that we apply a negative voltage to the metal electrodes above the two-dimensional electron gas. Due to electrostatic repulsions, electrons will be repelled by the electric field of the electrodes and the region of the 2DEG below the electrodes will be depleted of electrons. A charge-depleted region behaves like an insulator. Therefore, by applying an electric field with metal electrodes of an appropriate shape, it is possible to create an island of charges insulated from the rest of the 2DEG. If small enough, the island within the 2DEG behaves as a quantum dot. In the vertical geometry, a small pillar of the 2DEG is isolated by etching away the heterostructure around it. In such an arrangement charge carriers are again confined in all three dimensions.

Most of the electron transport measurements on quantum dots that have been performed to date have used the two types of quantum dots as samples that we have just described. The lateral arrangement offers a relatively high degree of freedom for the design of the structure, as this is determined by the choice of the electrode geometry. In addition, it is possible to fabricate and study "artificial molecules" [93–99] composed of several quantum dots linked together. With the

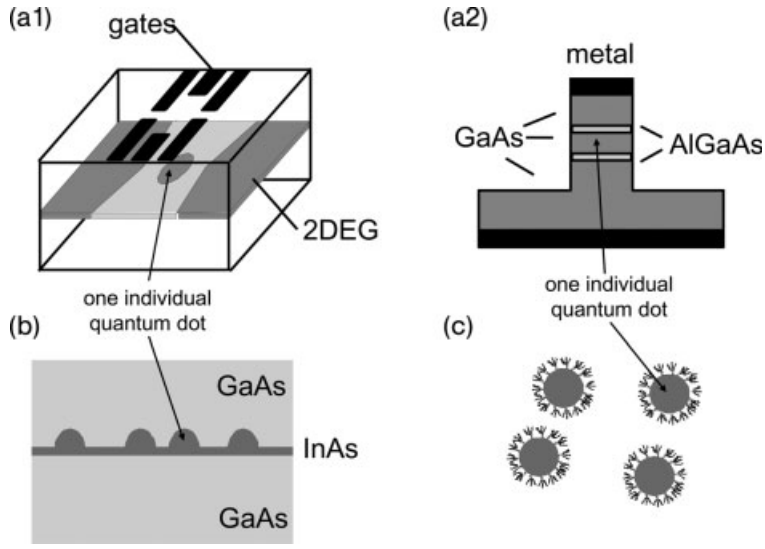

Figure 3.13 Three different types of quantum dots. (a1) A lithographically defined quantum dot in a lateral arrangement can be formed by electrostatic depletion of a two-dimensional electron gas (2DEG, shown in dark gray) via gate electrodes. The 2DEG is formed typically 20–100 nm below the surface of a semiconductor heterostructure (usually GaAs/AlGaAs). Application of negative voltages to metal gates on top of the heterostructure depletes the 2DEG below the gates (shown in light gray) and cuts out a small electron island from the 2DEG. Electrons can still tunnel on to and from the island. Electrical contact to the 2DEG is realized through ohmic contacts (not shown). (a2) A vertical quantum dot can be formed in a double barrier heterostructure. A narrow pillar is etched out of a GaAs/AlGaAs/GaAs/AlGaAs/GaAs heterostructure. The AlGaAs layers (light gray) form tunnel barriers that isolate the central GaAs region from the contact region. This central GaAs region behaves now as a quantum dot (shown in dark gray). Electrical contact is made via metal contacts (depicted in black) on top of the pillar and below the heterostructure. (b) Self-assembled quantum dots: molecular beam epitaxy (MBE) growth of InAs (dark gray) on GaAs (light gray) first leads to the formation of an extended layer of InAs (the wetting layer) and then to the formation of small InAs islands. Single electrons or electron–hole pairs (excitons) can be confined in these InAs quantum dots, either electrically or optically. (c) Colloidal quantum dots: these colloidal particles, having a diameter of only a few nanometers, are formed using wet chemistry and can be produced for most of the type II–VI, III–V, IV–VI and some type IV semiconductors. The surface of colloidal quantum dots is coated with a layer of surfactant molecules that prevents aggregation of the particles.

vertical arrangement, structures with very few electrons can be realized [100]. Recently, several research efforts have been focused on the investigation of many-body phenomena in these quantum dot systems. Relevant examples are, for instance, the study of the Kondo effect [101–104] and the design and control of coherent quantum states with the ultimate goal of quantum information processing [105, 106].

A remarkable advantage of lithographically defined quantum dots is that their electrical connection to the "macro-world" is straightforward. The manufacturing processes are similar to those used in chip fabrication and in principle such structures could be embedded within conventional electronic circuits. However, as the geometry

of these quantum dots is determined lithographically, it is restricted by the usual size and resolution limits of lithographic techniques. Even by using electron beam lithography for the creation of the quantum dots, it is not possible to tailor their size with nanometer precision. Lithographically fabricated quantum dots are typically larger than 10 nm and so relatively low lateral confining energies can be achieved.

3.5.3 Epitaxially Self-Assembled Quantum Dots

A breakthrough in the field of epitaxially grown nanostructures was the discovery of epitaxial growth regimes that favored the formation of nanometer-sized islands of semiconductor materials on suitable substrates (Figure 3.13). These islands, exhibiting quantum dot behavior, are obtained naturally by epitaxially growing a thin layer of a low bandgap material over a higher bandgap material, using MBE or MOCVD techniques [107–110]. The respective crystal faces in contact must have a significant lattice mismatch (1–8%), as in the case of InAs on GaAs [111, 112] and Ge on Si [113]. During the growth, a strained film, called the "wetting layer", initially forms. The maximum thickness of this layer is related to the difference in the lattice constants between the two materials. Past this critical thickness, a 2D → 3D transition in the growth regime is observed, with the spontaneous formation of an array of nanometer-sized islands (Stranski–Krastanov regime), leading to partial release of the strain. If the growth is not interrupted at this step, misfit dislocations form because the energy of formation of these defects becomes smaller than the elastic energy accumulated in the strained film. The formation of dislocations in highly strained epilayers (when the lattice mismatch is of the order of 10% or more) before the formation of islands limits the range of possible substrate–island materials. The shape of the islands can be controlled by the growth conditions. Usually, the islands have a truncated pyramidal shape, but it is also possible to form, for example, ring-shaped quantum dots [114]. The final step consists in the growth, on the top of the islands, of several layers of the substrate material, so that the dots are completely buried and interfaces are passivated. The relative alignment of the bandgaps creates a confining potential for charge carriers that accumulate inside the quantum dots. In addition, strain fields in the proximity of the island–substrate interface, due to the lattice mismatch between the two materials, create potentials that modify the bandgap of the quantum dots at the bottom of the island. Holes are more likely to be localized in this region, as they are heavier than the electrons.

Self-assembled quantum dots can have a diameter as small as a few nanometers and so very pronounced quantum size effects can be observed in these systems. Self-assembled quantum dots have predominantly been characterized using optical or capacitance spectroscopy in a regime where they contain only a small number of charge carriers. Measurements on ensembles still suffer from inhomogeneous broadening of the spectroscopic features. However, in recent years it has been possible to look at only a few or even single self-assembled quantum dots at a time by reducing the number of quantum dots by mesa-etching [115] or by using confocal microscopy techniques [116]. Photoluminescence from single self-assembled quantum dots is a highly efficient process, characterized by several narrow emission lines,

related to different exciton states in the dots, and is reminiscent of the emission from atoms. As mentioned already for lithographically defined quantum dots, many parallels can be drawn between atoms and quantum dots [115, 117–119]. For these reasons, quantum dots have gained the nickname "artificial atoms". Current research efforts are devoted to quantum dot ordering and positioning and also to the reduction of the quantum dot size distribution. In contrast to the case of lithographically defined quantum dots, it is challenging to make electrical contact to self-assembled quantum dots and therefore most of the possible applications can be found in optics. One of the major goals of research on self-assembled quantum dots is the fabrication of non-classical light sources from single dots. Another is to use them as light-addressable storage devices.

3.5.4 Colloidal Quantum Dots

Colloidal quantum dots are remarkably different from the quantum dot systems mentioned above as they are chemically synthesized using wet chemistry and are free-standing nanoparticles or nanocrystals grown in solution (Figure 3.13) [120]. In this case, colloidal quantum dots are just a subgroup of a broader class of materials that can be synthesized at the nanoscale using wet chemical methods. In the fabrication of colloidal nanocrystals, the reaction chamber is a reactor containing a liquid mixture of compounds that control the nucleation and the growth. In a general synthesis of quantum dots in solution, each of the atomic species that will form the nanocrystal building blocks is introduced in the reactor as a precursor. A precursor is a molecule or a complex containing one or more atomic species required for growing the nanocrystal. Once the precursors have been introduced into the reaction flask they decompose, forming new reactive species (the monomers) that will cause the nucleation and the growth of the nanocrystals. The energy required to decompose the precursors is provided by the liquid in the reactor, either by thermal collisions or by a chemical reaction between the liquid medium and the precursors or by a combination of the two mechanisms [121].

The key parameter in the controlled growth of colloidal nanocrystals is the presence of one or more molecular species in the reactor, broadly termed here "surfactants". A surfactant is a molecule that is dynamically adsorbed on the surface of the growing quantum dot under the reaction conditions. It must be mobile enough to provide access for the addition of monomer units, but stable enough to prevent the aggregation of nanocrystals. The choice of surfactants varies from case to case: a molecule that binds too strongly to the surface of the quantum dot is not suitable, as it would not allow the nanocrystal to grow. On the other hand, a weakly coordinating molecule would yield large particles or aggregates [122]. Some examples of suitable surfactants include alkanethiols, phosphines, phosphine oxides, phosphates, phosphonates, amides, amines, carboxylic acids and nitrogen-containing aromatics. If the growth of nanocrystals is carried out at high temperatures (e.g., at 200–400 °C) then the surfactant molecules must be stable under such conditions in order to be a suitable candidate for controlling the growth.

At low temperatures, or more generally when the growth is stopped, the surfactants are more strongly bound to the surface of the nanocrystals and provide their solubility in a wide range of solvents. This coating allows for great synthetic flexibility in that it can be exchanged with another coating of organic molecules having different functional groups or polarity. In addition, the surfactants can be temporarily removed and an epitaxial layer of another material with different electronic, optical or magnetic properties can be grown on the initial nanocrystal [123, 124].

By controlling the mixture of surfactant molecules that are present during the generation and the time of growth of the quantum dots, excellent control of their size and shape is possible [121, 125–127] (Figure 3.14). As described in Chapter 4, the wavelength of emission of quantum dots depends on their size. This can be nicely seen by observing the fluorescence light of solutions of colloidal quantum dots with different size [128, 129] (Figures 3.14 and 3.15).

In contrast to organic fluorophores, colloidal quantum dots have a continuous absorption spectrum for energies higher than their bandgap, a symmetric emission

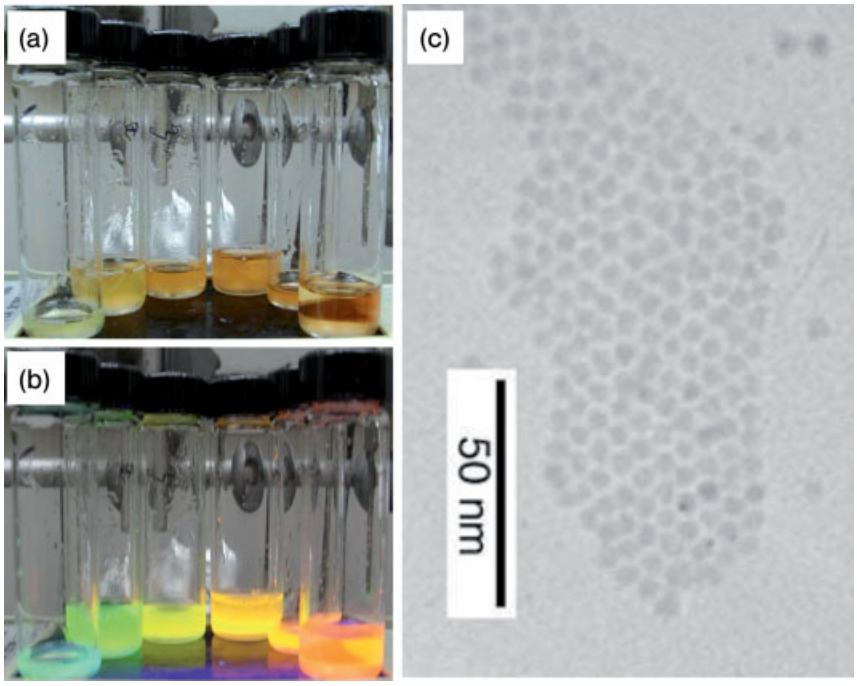

Figure 3.14 Colloidal CdSe quantum dots of different size dissolved in chloroform. The size of the quantum dots increases from the left to the right vial. (a) Photograph of the solutions. (b) Photograph of the solutions upon UV illumination from below. The different colors of fluorescence can be seen. (c) Each quantum dot corresponds to a spherical CdSe nanoparticle that is dispersed in the solvent. When a drop of this solution is put on a grid, the solvent evaporates and the quantum dots can be imaged with transmission electron microscopy (TEM). The authors are grateful to Stefan Kudera for recording the TEM image.

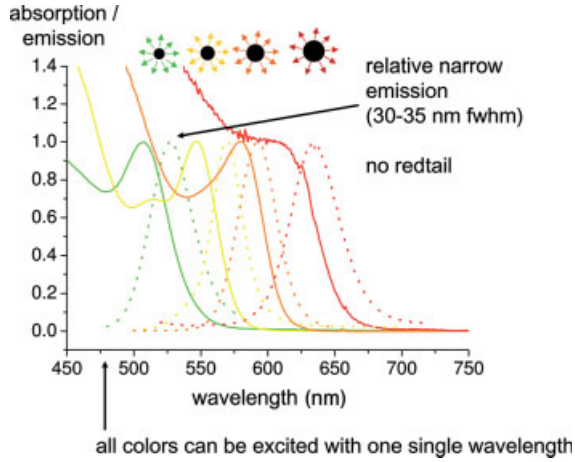

Figure 3.15 Absorption (solid lines) and emission spectra (dotted lines) of colloidal CdSe quantum dots of different sizes. The absorption peaks of green/yellow/orange/red fluorescent nanocrystals of 2.3/4.0/3.8/4.6 nm diameter are at 507/547/580/605 nm and the fluorescence peaks are at 528/57/592/637 nm.

spectrum without a red tail and, most importantly, reduced photobleaching [130, 131] (Figure 3.15).

Since colloidal nanocrystals are dispersed in solution, they are not bound to any solid support as is the case for the other two quantum dots systems described above. Therefore, they can be produced in large quantities in a reaction flask and later they can be transferred to any desired substrate or object. It is possible, for example, to coat their surface with biological molecules such as proteins or oligonucleotides. Many biological molecules perform tasks of molecular recognition with extremely high efficiency. This means that ligand molecules bind with very high specificity to certain receptor molecules, similarly to a key-and-lock system. If a colloidal quantum dot is tagged with ligand molecules, it specifically binds to all the positions where a receptor molecule is present. In this way it has been possible, for example, to make small groupings of colloidal quantum dots mediated by molecular recognition [22, 23, 132] and to label specific compartments of cell with different types of quantum dots [133–135].

Although colloidal quantum dots are rather difficult to connect electrically, a few electron transport experiments have been reported. In these experiments, nanocrystals were used as the active material in devices that behave as single electron transistors [68, 136].

3.6
Perspectives and Limits of Top-Down and Bottom-Up Approaches

In 1965, Gordon Moore, co-founder of Intel Corporation, predicted that the number of transistors on a computer chip would double about every 18 months [137]. The

exponential law, also known as Moore's first law, has described the development of integrated circuits surprisingly well for decades. As the market for information technology continues to grow, the demand for computer hardware instigates more and more sophisticated top-down techniques to build more densely packed transistor circuits. Moore's second law states that the implementation of a next generation of integrated circuits at minimum cost will be exponentially more expensive. Until all the constraints finally limit the growth of the semiconductor top-down industry, scientists and engineers assume that nanotechnology will give answers to most of the technological challenges. For instance, as soon as the feature size of the semiconductor transistors reaches the level at which quantum phenomena are important, different concepts for the assembly need to be considered. One possibility is the bottom-up approach, which is based on molecular recognition and chemical self-assembly of molecules [13]. In combination with chemical synthesis techniques, the bottom-up approach allows the assembly of macromolecular complexes with new functionalities. Assuming Moore's laws apply [137], the final limit for optical top-down lithography is likely to be reached in less than a decade.

There are limitations also for the bottom-up assembly of complex nanostructures. We can illustrate this by the example of assembling nanoparticles with DNA to groupings of particles. Although building blocks exist in which each nanoparticle is modified with an exactly defined number of binding sites, still no controlled assemblies of more than around five particles exist. There are two fundamental technological problems: nonspecific adsorption and "floppyness" of biological molecules. Nonspecific adsorption causes particles to stick together, although they are not supposed to be connected. Many biological molecules that can be used as "glue" for the assembly of particle groupings, such as proteins and DNA, tend to adsorb nonspecifically on the surface of nanoparticles. Although covalent attachment of these molecules dominates over nonspecific adsorption and thus connection of the particles via their designated binding sites, there is a non-negligible amount of nonspecific interaction between the particles. For a larger particle grouping, just a single nonspecific connection can destroy the build-up of the whole grouping. One major task in this direction is to improve the surface chemistry of particles in order to obtain inert surfaces to which biological molecules do not adsorb nonspecifically. Biological molecules are intrinsically "soft" compared with inorganic materials. This implies that the connection between particles that are connected via biological molecules will always retain a certain degree of flexibility. In particular, the attachment of the "glue", that is, the biological molecule, to the particle surface is not rigid. Therefore, it will be almost impossible to form large, nonperiodic three-dimensional stiff structures with static geometry of particle groupings connected via biological molecules. Further, particle assemblies involving biological molecules as glue will be always limited in stability. Biological molecules are bound to their natural environment and cannot withstand many artificial conditions, such a high temperatures.

Although both top-down and bottom-up strategies have clear limitations, we are still far away from having reached them. In fact, the intrinsics may finally be overcome by combining both approaches. Still, Feynman's statement is true: "there is plenty of room at the bottom!"

Fundamental Principles of Quantum Dots[1)]

Wolfgang J. Parak, Liberato Manna, and Thomas Nann

4.1
Introduction and Outline

4.1.1
Nanoscale Science and Technology

In the last decade new directions of modern research, broadly defined as "nanoscale science and technology" have emerged [2, 3]. These new trends involve the ability to fabricate, characterize and manipulate artificial structures, whose features are controlled at the lower nanometer scale. They embrace areas of research as diverse as engineering, physics, chemistry, materials science and molecular biology. Research in this direction has been triggered by the recent availability of revolutionary instruments and approaches that allow the investigation of material properties with a resolution close to the atomic level. Strongly connected to such technological advances are pioneering studies that have revealed new physical properties of matter at a level which is intermediate between the atomic and molecular level and bulk.

Materials science and technology is a rapidly evolving field and is currently making the most significant contributions to research in nanoscale science. It is driven by the desire to fabricate materials with novel or improved properties. Such properties can be, for instance, strength, electrical and thermal conductivity, optical response, elasticity and wear resistance. Research is also evolving towards materials that are designed to perform more complex and efficient tasks. Examples include materials with a higher rate of decomposition of pollutants, a selective and sensitive response towards a given biomolecule, an improved conversion of light into current and more efficient energy storage. For such and more complex tasks to be realized, novel materials have to be based on several components whose spatial organization is engineered at the molecular level. This class of materials can be defined as

1) This chapter has been partly adapted from a previous version which included contributions also from Dr. Daniele Gerion, Dr. Friedrich Simmel and Professor Dr. Paul Alivisatos [1].

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

"nano-composites". They are made of assembled nanosized objects or molecules. Their macroscopic behavior arises from the combination of the novel properties of the individual building blocks and their mutual interaction.

In electronics, the design and assembly of functional materials and devices based on nanoscale building blocks can be seen as the natural, inevitable evolution of the trend towards miniaturization. The microelectronics industry, for instance, is fabricating integrated circuits and storage media whose basic units are approaching the size of few tens of nanometers. For computers, "smaller" goes along with higher computational power at lower cost and with greater portability. However, this race towards higher performance is driving current silicon-based electronics to the limits of its capability [4–7]. The design of each new generation of smaller and faster devices involves more sophisticated and expensive processing steps and requires the solution of new sets of problems, such as heat dissipation and device failure. If the trend towards further miniaturization persists, silicon technology will soon reach limits at which these problems become insurmountable. In addition, scientists have found that device characteristics in very small components are strongly altered by quantum mechanical effects. In many cases, these effects will undermine the classical principles on which most of today's electronic components are based. For these reasons, alternative materials and approaches are currently being explored for novel electronic components, in which the laws of quantum mechanics regulate their functioning in a predictable way. Perhaps in the near future a new generation of computers will rely on fundamental processing units that are made of only a few atoms.

Fortunately, the advent of new methods for the controlled production of nanoscale materials has provided new tools that can be adapted for this purpose. New terms such as nanotubes, nanowires and quantum dots are now common jargon in scientific publications. These objects are among the smallest, man-made units that display physical and chemical properties which make them promising candidates as fundamental building blocks of novel transistors. The advantages envisaged here are higher device versatility, faster switching speed, lower power dissipation and the possibility of packing many more transistors on a single chip. Prototypes of these new single nanotransistors are nowadays fabricated and studied in research laboratories and are still far from commercialization. How millions of such components could be arranged and interconnected in complex architectures and at low cost still remains a formidable task to solve.

With a completely different objective, the pharmaceutical and biomedical industries try to synthesize large supramolecular assemblies and artificial devices that mimic the complex mechanisms of nature or that can potentially be used for more efficient diagnoses and better cures for diseases. Examples in this direction are nanocapsules such as liposomes, embodying drugs that can be selectively released in living organs or bioconjugate assemblies of biomolecules and magnetic (or fluorescent) nanoparticles that might provide faster and more selective analysis of biotissues in addition to less invasive cures for several types of diseases. These prototype systems might one day evolve into more complex nanomachines, with highly sophisticated functional features, able to carry out complicated tasks at the cellular level into a living body.

Nanoscience and nanotechnology will definitely have a strong impact on many aspects of future society. The scientific community envisages that nanotechnology will strongly permeate key areas such as information technology and telecommunications, medicine, energy production and storage and transportation. This chapter, however, is not meant as a survey of the present state and future developments of nanoscale science and technology and the list of examples mentioned above is far from complete. Here, we simply want to stress the point that any development in nanoscience must necessarily follow the understanding of the physical laws that govern matter at the nanoscale and how the interplay of the various physical properties of a nanoscopic system translates into a novel behavior or into a new physical property. In this sense, this chapter will serve as an overview of basic physical rules governing nanoscale materials, with particular emphasis on quantum dots, including their various physical realizations and their possible applications. Quantum dots are the ultimate example of a solid in which all dimensions shrink down to a few nanometers. Moreover, semiconductor quantum dots are probably the most studied nanoscale systems.

The outline of this chapter is as follows. In Section 4.2 we will try to explain with a few examples why the behavior of nanoscale materials can be very different from that of their bulk and from their atomic counterparts and how quantum mechanics can help us in rationalizing this. Following this discussion, we will give a definition of "quantum dot". In Section 4.3, we follow a bottom-up approach and give a simplified picture of a solid as being a very large molecule, where the energy levels of each individual atomic component have merged to form bands. The electronic structure of a quantum dot, being intermediate between the two extreme cases of single atoms and the bulk, will then be an easier concept to grasp. In Section 4.4, we will use the model of a free electron gas and the concept of quantum confinement to explain what happens to a solid when its dimensions shrink one by one. This will lead us to a more accurate definition of quantum wells, quantum wires and quantum dots. In Section 4.5, we will examine in more detail the electronic structure of quantum dots, although we will try to keep the level of the discussion relatively simple.

4.2
Nanoscale Materials and Quantum Mechanics

4.2.1
Nanoscale Materials are Intermediates Between Atomic and Bulk Matter

Nanoscale materials frequently show a behavior which is intermediate between that of a macroscopic solid and that of an atomic or molecular system. Consider, for instance, the case of an inorganic crystal composed of very few atoms. Its properties will be different from those of a single atom, but we cannot imagine that they will be the same as those of a bulk solid. The number of atoms on its surface, for instance, is a significant fraction of the total number of atoms and therefore will have a large influence on the overall properties of the crystal. We can easily imagine that this

crystal might have higher chemical reactivity than the corresponding bulk solid and that it will probably melt at lower temperatures. Consider now the example of a carbon nanotube, which can be thought of as a sheet of graphite wrapped in such a way that the carbon atoms on one edge of the sheet are covalently bound to the atoms on the opposite edge of the sheet. Unlike its individual components, a carbon nanotube is chemically extremely stable because the valences of all its carbon atoms are saturated. Moreover, we guess that carbon nanotubes can be good conductors because electrons can move freely along these tiny, wire-like structures. Once again, we see that such nanoscopic objects can have properties which do not belong to the realm of their larger (bulk) or smaller (atoms) counterparts. However, there are many additional properties specific to such systems which cannot be understood by such a simple reasoning. These properties are related to the sometimes counterintuitive behavior that charge carriers (electrons and holes) can exhibit when they are forced to dwell in such structures. These properties can only be explained by the laws of quantum mechanics.

4.2.2 Quantum Mechanics

A fundamental aspect of quantum mechanics is the particle–wave duality, introduced by de Broglie, according to which any particle can be associated with a matter wave whose wavelength is inversely proportional to the particle's linear momentum. Whenever the size of a physical system becomes comparable to the wavelength of the particles that interact with such a system, the behavior of the particles is best described by the rules of quantum mechanics [8]. All the information we need about the particle is obtained by solving its Schrödinger equation. The solutions of this equation represent the possible physical states in which the system can be found. Fortunately, quantum mechanics is not required to describe the movement of objects in the macroscopic world. The wavelength associated with a macroscopic object is in fact much smaller than the object's size and therefore the trajectory of such an object can be derived with the principles of classical mechanics. Things change, for instance, in the case of electrons orbiting around a nucleus, since their associated wavelength is of the same order of magnitude as the electron–nucleus distance.

We can use the concept of particle–wave duality to give a simple explanation of the behavior of carriers in a semiconductor nanocrystal. In a bulk inorganic semiconductor, conduction band electrons (and valence band holes) are free to move throughout the crystal and their motion can be described satisfactorily by a linear combination of plane waves whose wavelength is generally of the order of nanometers. This means that, whenever the size of a semiconductor solid becomes comparable to these wavelengths, a free carrier confined in this structure will behave as a particle in a potential box [9]. The solutions of the Schrödinger equation are standing waves confined in the potential well and the energies associated with two distinct wavefunctions are, in general, different and discontinuous. This means that the particle energies cannot take on any arbitrary value and the system exhibits a

discrete energy level spectrum. Transitions between any two levels are seen, for instance, as discrete peaks in the optical spectra. The system is then also referred to as "quantum confined". If all the dimensions of a semiconductor crystal shrink down to a few nanometers, the resulting system is called a "quantum dot" and will be the subject of our discussion throughout this chapter. The main point here is that in order to rationalize (or predict) the physical properties of nanoscale materials, such as their electrical and thermal conductivity or their absorption and emission spectra, we need first to determine their energy level structure.

For quantum confined systems such as quantum dots, the calculation of the energy structure is traditionally carried out using two alternative approaches. One approach was just outlined above. We take a bulk solid and we study the evolution of its band structure as its dimensions shrink down to few nanometers. This method will be described in more detail later (Section 4.4). Alternatively, we can start from the individual electronic states of single isolated atoms as shown in Section 4.3, and then study how the energy levels evolve as atoms come closer and start to interact with each other.

4.3
From Atoms to Molecules and Quantum Dots

The chemical approach towards quantum dots resembles the "bottom-up" strategy by which molecules are formed by chemical reactions between individual atoms or smaller molecules. Molecules are stable assemblies of an exactly defined finite number of atoms, whereas solids are stable assemblies of atoms or molecules with quasi-infinite dimensions. If the assembly of units within a solid does not follow translational symmetry, the solid is called amorphous. If, on the other hand, the units are repeated regularly, the solid is called crystalline. Since quantum dots have finite dimensions and are regular assemblies of atoms, such nano-objects are regarded as large molecules from a chemist's point of view, whereas physicists see them usually as small crystals.

The electronic properties of quantum dots can now be described and calculated by linear combinations of atomic orbitals (LCAO method or Hückel theory) and other approximations [10]. Here, the starting point is an atom, whereas the physical approach in Section 4.4 starts with an infinite wavefunction. It will be shown that the results of both approaches are basically the same.

The fundamental idea of quantum theory was developed at the beginning of the last century and affirms that particles have wave-like properties and vice versa. In about 1923, de Broglie suggested his famous momentum–wavelength relationship (4.3)[2)] by combining Einstein's relativistic energy (4.1) with the energy of a photon (4.2):

2) (1) = (2) $\Rightarrow mc^2 = h\nu$ (h = Plank's constant, c = speed of light).
Momentum of a photon $p = mc \Rightarrow pc = h\nu$.
Wavelength of a photon $\lambda = c/\nu \Rightarrow p = h/\lambda$
$\Rightarrow \lambda = h/p$.

$$E = mc^2 \tag{4.1}$$

$$E = h\nu \tag{4.2}$$

$$\lambda = h/p \tag{4.3}$$

The left-hand term (wavelength) in Equation 4.3 represents the wave nature of a particle, whereas the right-hand term (momentum) represents the particle-nature of a wave. Equation 4.3 can be written as[3)]

$$\lambda = h/p = h/\sqrt{2m(E-V)} \tag{4.4}$$

where m is the mass of the particle and E and V are its total and potential energy, respectively. Combining Equation 4.4 with the classical three-dimensional wave equation:

$$\nabla^2\psi(x,y,z) = -(2\pi/\lambda)^2\,\psi(x,y,z) \tag{4.5}$$

where Ψ is the wavefunction results in

$$\nabla^2\psi = -[2\pi\sqrt{2m(E-V)}/h]^2\,\psi = -8\pi^2 m/h^2(E-V)\psi \tag{4.6}$$

Some trivial rearrangements and insertion of $\hbar = h/2\pi$ result in Schrödinger's equation:

$$\nabla^2\psi + \frac{2m}{\hbar^2}(E-V)\psi = 0 \tag{4.7}$$

or

$$\hat{H}\cdot\psi = E\cdot\psi \tag{4.8}$$

using the Hamiltonian operator $\hat{H} = H\left(x,\ldots,\frac{\hbar}{i}\frac{\partial}{\partial x},\ldots\right)$; ψ is called eigenfunction of the operator and E is the eigenvalue, which represents the energy.

The first step to calculate electronic properties of matter is to apply Schrödinger's equation to the hydrogen atom. Therefore, we look at the wavefunction of the electron in the potential field of the nucleus, which is basically the coulomb attraction between electron and nucleus:

$$V = -\frac{e^2}{4\pi\varepsilon_0 r} \tag{4.9}$$

Furthermore, the wavefunction has to be separated into equations in terms of spherical coordinates:

$$\psi(r,\vartheta,\varphi) = R(r)\cdot\Theta(\vartheta)\cdot\Phi(\varphi) \tag{4.10}$$

The solution of Schrödinger's equation with the separated variables leads to three quantum numbers associated with the three functions and the hydrogen atom's

3) $E = p^2/2m + V$ (total energy E = kinetic energy $p^2/2m$ + potential energy V)
$\Rightarrow p^2 = 2m(E-V) \Rightarrow (3)\lambda = h[2m(E-V)]^{-1/2}$

energy levels. Furthermore, each one-electron wavefunction can exist in two forms called "spin states".[4] The function ψ^2 ($\psi\psi^*$, respectively) gives the probability density of finding an electron at a given point. The different eigenfunctions ψ for different sets of quantum numbers are called "atomic orbitals" (AOs) with corresponding energies (eigenvalues) E [10, 11].

Schrödinger's equation for multi-electron atoms and molecules becomes increasingly complicated, since all of the interactions between different electrons and nuclei contribute to the potential energy. In the Born–Oppenheimer approximation, the terms that describe movement of the nuclei are decoupled from those that describe the movement of the electrons, which move much faster compared with the nuclei. Thus the Hamiltonian for a molecule with N atoms and K electrons reads

$$\hat{H} = \left(-\frac{\hbar^2}{2m} \sum_{i=1,K} \nabla^2 - \sum_{j=1,N} \sum_{i=1,K} Z_j / r_{ij} \right) + \sum_{i=1,K-1} \sum_{l=i+1,K} 1/r_{il} + \sum_{j=1,N-1} \sum_{m=j+1,N} Z_j Z_m / r_{jm} \tag{4.11}$$

where Z_i are charges of the nuclei and r_{ij} distances between two charges. Schrödinger equations for molecules cannot be solved analytically. Therefore, approximation methods have to be used. These methods can be categorized as either "*ab initio*" or "semiempirical". *Ab initio* methods use only natural constants to solve Schrödinger's equation. The most prominent *ab initio* method is the Hartree–Fock method. Semiempirical methods use measured values (usually spectroscopic data) for the same purpose.

The numerical solution of the Hartree–Fock equation is only valid for atoms and linear molecules. Therefore, another approximation is needed: orbitals are written as the product of so-called basis functions (usually exponential functions) and the wavefunctions of hydrogen. These functions are called basis sets and vary for different approaches. *Ab initio* methods have high computing requirements, so that they are restricted to the calculation of some dozens of atoms.

In order to calculate electronic states of larger molecules, one has to introduce further simplifications. Semiempirical methods make use of experimental or fitted data to replace variables or functions in the Hartree–Fock matrices. The general procedure for calculating solutions for Schrödinger's equation remains the same as described above, but due to the simplifications, semiempirical methods allow for the calculation of molecules with several hundred atoms, including nanocrystals.

Figure 4.1 displays schematically the "transition" from atomic orbitals (s, p or sp^3) over molecular orbitals (σ, σ^*) to quantum dots and semiconductor energy bands. Since electrons populate the orbitals with lowest energy first, there is a highest occupied (molecular) or "binding" orbital (the "valence band" in semiconductors) and a lowest unoccupied (molecular) or "antibinding" orbital (the "conduction band"). The energy gap between the highest occupied (molecular) orbital (HOMO)

4) Readers who are interested in the details of this solution can find it in every common physical phemistry textbook [10, 11].

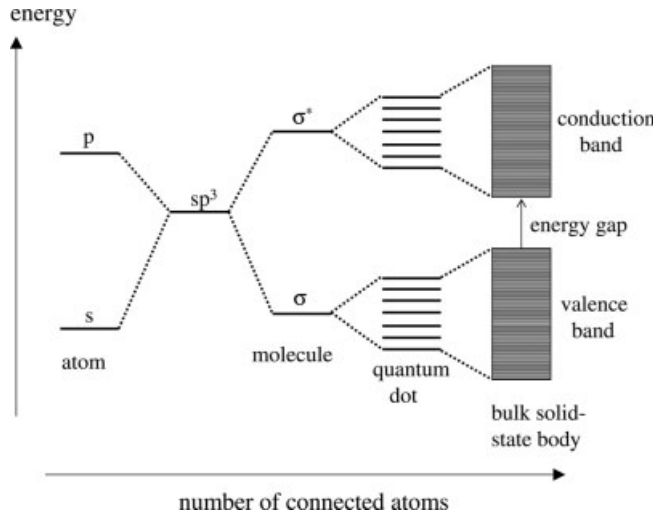

Figure 4.1 Electronic energy levels depending on the number of bound atoms. By binding more and more atoms together, the discrete energy levels of the atomic orbitals merge into energy bands (here shown for a semiconducting material) [12]. Therefore, semiconducting nanocrystals (quantum dots) can be regarded as a hybrid between small molecules and bulk material.

and lowest unoccupied (molecular) orbital (LUMO) is characteristic for luminophores, quantum dots and semiconductors. The energy gap decreases with increasing number of atoms in the transition region between molecules and bulk solids, as indicated in Figure 4.1. The exact calculation of this (most interesting) transition region follows the mathematical scheme described above. Alternatively, one can view the problem similar to a "particle-in-a-box" approach, which is outlined in Section 4.4.

First calculations of the energy of the first excited state in semiconductor quantum dots were carried out in the early 1980s by Brus [13, 14]. Brus did not solve Schrödinger's equation for the quantum dot, but for the exciton within a semiconductor nanocrystal by means of a variational method [effective-mass approximation (EMA)]. This approach thus resembles the particle-in-a-box method (see Section 4.4). The first semiempirical calculation was published in 1989 by Lippens and Lannoo [15]. They used the tight-binding approach to model CdS and ZnS quantum dots. As depicted in Figure 4.1 and calculated firstly by Brus, they found an increasing energy gap between HOMO and LUMO with decreasing nanocrystal size. Moreover, their results fit much better with experimental data than those obtained with the effective mass approximation (EMA).

Further refinements include the linear combination of atomic orbitals (LCAO) [16], the semiempirical pseudopotential calculation [17] and the *kp* method [18]. All of these methods provide estimates for the size-dependent bandgap of quantum dots. Even though the agreement of the calculations with the experimental data differs slightly, the general result is clear: the bandgap of the quantum dots increases with decreasing size of the nanocrystals. These results were as expected and thus not very

useful for the experimental scientist so far. However, they paved the way for more sophisticated calculations including the inclusion of defects in nanocrystals and the presence of surface ligands. Very few examples of such calculations have been published so far. One example is the calculation of the size-dependent behavior of the quantum dot–ligand bond [19].

4.4
Shrinking Bulk Material to a Quantum Dot

In this section, we will go back to the concept of quantum confinement of carriers in a solid from a physicist's point of view and will use it to derive a more detailed description of the electronic band structure in a low-dimensional solid. This description will catch the general physics of a solid when its dimensions shrink one by one down to few nanometers. We will start first with an elementary model of the behavior of electrons in a bulk solid. This model will then be adapted to the case of confined carriers.

4.4.1
Three-Dimensional Systems (Bulk Material)

We now consider the case of a three-dimensional solid with size d_x, d_y, d_z containing N free electrons. "Free" means that those electrons are delocalized and thus not bound to individual atoms. Furthermore, we will make the assumption that the interactions between the electrons, and also between the electrons and the crystal potential, can be neglected as a first approximation. Such a model system is called "free electron gas" [20, 21]. Astonishingly, this oversimplified model still captures many of the physical aspects of real systems. From more complicated theories, it has been learnt that many of the expressions and conclusions from the free electron model remain valid as a first approximation even when one takes electron–crystal and electron–electron interactions into account. In many cases it is sufficient to replace the free electron mass m by an "effective" mass m^* which implicitly contains the corrections for the interactions. To keep the story simple, we proceed with the free electron picture. In the free electron model, each electron in the solid moves with a velocity $\vec{v} = (v_x, v_y, v_z)$. The energy of an individual electron is then just its kinetic energy.[5)]

$$E = \frac{1}{2} m \vec{v}^2 = \frac{1}{2} m (v_x^2 + v_y^2 + v_z^2) \tag{4.12}$$

According to Pauli's exclusion principle, each electron must be in a unique quantum state. Since electrons can have two spin orientations ($m_s = +{}^1/_2$ and

5) The total energy E is the sum of the kinetic energy $p^2/2m$ and the potential energy V. For free particles (free electron gas) there is no potential energy and therefore their total energy is equal to their kinetic energy.

$m_s = -1/2$), only two electrons with opposite spins can have the same velocity $\vec{v}$. This case is analogous to the Bohr model of atoms, in which each orbital can be occupied by two electrons at maximum. In solid-state physics, the wavevector $\vec{k} = (k_x, k_y, k_z)$ of a particle is more frequently used instead of its velocity to describe the particle's state. Its absolute value $k = |\vec{k}|$ is the wavenumber. The wavevector $\vec{k}$ is directly proportional to the linear momentum $\vec{p}$ and thus also to the velocity $\vec{v}$ of the electron:

$$\vec{p} = m\vec{v} = \frac{h}{2\pi}\vec{k} \tag{4.13}$$

The scaling constant is Planck's constant h and the wavenumber is related to the wavelength λ associated with the electron through the de Broglie relation [20, 21] (Figure 4.2):

$$\pm k = |\vec{k}| = \pm\frac{2\pi}{\lambda} \tag{4.14}$$

The calculation of the energy states for a bulk crystal is based on the assumption of periodic boundary conditions (Figure 4.2). Periodic boundary conditions are a mathematical trick to "simulate" an infinite ($d \to \infty$) solid. This assumption

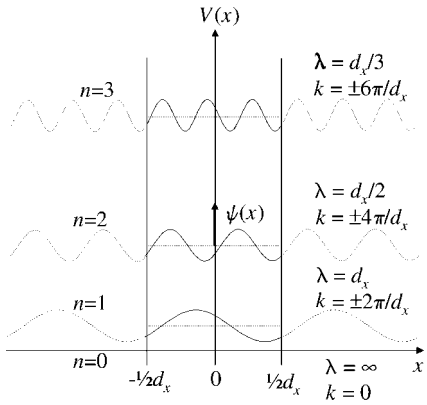

Figure 4.2 Periodic boundary conditions (only drawn for the x-dimension) for a free electron gas in a solid with thickness d. The idea of periodic boundary conditions is to "simulate" mathematically an infinite solid. Infinite extension is similar to an object without any borders. This means that a particle close to the "border" must not be affected by the border, but "behaves" exactly as in the bulk. This can be realized by using a wavefunction $\psi(x)$ that is periodic within the thickness d of the solid. Any electron that leaves the solid from its right boundary would re-enter under exactly the same conditions on its left side. For the electron the borders are quasi-nonexistent. The probability density $|\psi(x)|^2$ is the probability that an electron is at the position x in the solid. Different states for the electrons ($n = 0, 1, 2, \ldots$) have different wavefunctions. λ is the de Broglie wavelength of the electrons and k is their corresponding wavenumber. A "real" bulk solid can be approximated by an infinite solid ($d \to \infty$) and its electronic states in k-space are quasi-continuously distributed: $\Delta k = 2\pi/d_x \to 0$.

implies that the conditions at opposite borders of the solid are identical. In this way, an electron that is close to the border does not really "feel" the border. In other words, the electrons at the borders "behave" exactly as if they were in the bulk. This condition can be realized mathematically by imposing the following condition on the electron wavefunctions: $\psi(x, y, z) = \psi(x + d_x, y, z)$, $\psi(x, y, z) = \psi(x, y + d_y, z)$ and $\psi(x, y, z) = \psi(x, y, z + d_z)$. In other words, the wavefunctions must be periodic with a period equal to the whole extension of the solid number [21, 22]. The solution of the stationary Schrödinger equation under such boundary conditions can be factorized into the product of three independent functions $\psi(x, y, z) = \psi(x)\psi(y)\psi(z) = A\exp(ik_x x)\exp(ik_y y)\exp(ik_z z)$. Each function describes a free electron moving along one Cartesian coordinate. In the argument of the functions $k_{x,y,z}$ is equal to $\pm n\Delta k = \pm n2\pi/d_{x,y,z}$ and n is an integer [20–22]. These solutions are waves that propagate along the negative and positive directions for $k_{x,y,z} > 0$ and $k_{x,y,z} < 0$, respectively. An important consequence of the periodic boundary conditions is that all the possible electronic states in the $\vec{k}$ space are equally distributed. There is an easy way of visualizing this distribution in the ideal case of a one-dimensional free electron gas: there are two electrons ($m_s = \pm^1/_2$) in the state $k_x = 0$ ($v_x = 0$), two electrons in the state $k_x = +\Delta k$ ($v_x = +\Delta v$), two electrons in the state $k_x = -\Delta k$ ($v_x = -\Delta v$), two electrons in the state $k_x = +2\Delta k$ ($v_x = +2\Delta v$) and so on.

For a three-dimensional bulk material we can follow an analogous scheme. Two electrons ($m_s = \pm^1/_2$) can occupy each of the states $(k_x, k_y, k_z) = (\pm n_x\Delta k, \pm n_y\Delta k, \pm n_z\Delta k)$, again with $n_{x,y,z}$ being an integer. A sketch of this distribution is shown in Figure 4.3. We can easily visualize the occupied states in $\vec{k}$-space because all these states are included in a sphere whose radius is the wavenumber associated with the highest energy electrons. At the ground state, at 0 K, the radius of the sphere is the Fermi wavenumber k_F (Fermi velocity v_F). The Fermi energy $E_F \propto k_F^2$ is the energy of the last occupied electronic state. All electronic states with an energy $E \leq E_F$ are occupied, whereas all electronic states with higher energy $E > E_F$ are empty. In a solid, the allowed wavenumbers are separated by $\Delta k = \pm n2\pi/d_{x,y,z}$. In a bulk material $d_{x,y,z}$ is large and so Δk is very small. Then the sphere of states is filled quasi-continuously [21].

We need now to introduce the useful concept of the density of states $D_{3d}(k)$, which is the number of states per unit interval of wavenumbers. From this definition $D_{3d}(k)\Delta k$ is the number of electrons in the solid with a wavenumber between k and $k + \Delta k$. If we know the density of states in a solid we can calculate, for instance, the total number of electrons having wavenumbers less than a given k_{max}, which we will call $N(k_{max})$. Obviously, $N(k_{max})$ is equal to $\int_0^{k_{max}} D_{3d}(k)\mathrm{d}k$. In the ground state of the solid all electrons have wavenumbers $k \leq k_F$, where k_F is the Fermi wavenumber. Since in a bulk solid the states are homogeneously distributed in $\vec{k}$-space, we know that the number of states between k and $k + \Delta k$ is proportional to $k^2\Delta k$ (Figure 4.3). This can be visualized in the following way. The volume in three-dimensional $\vec{k}$-space scales with k^3. If we only want to count the number of states with a wavenumber between k and $k + \Delta k$, we need to determine the volume of a spherical shell with radius k and thickness Δk. This volume is proportional to product of the surface of the sphere (which scales as k^2)

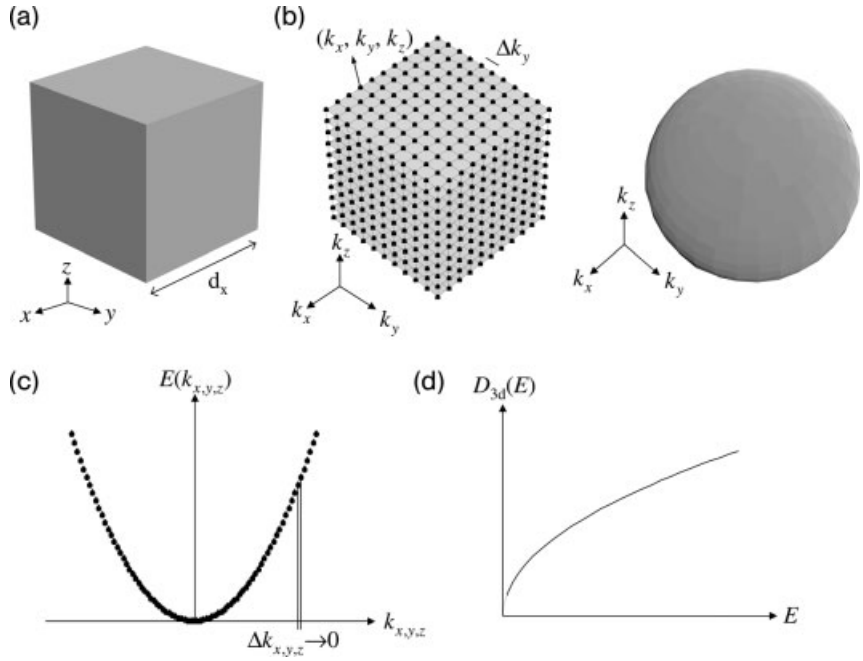

Figure 4.3 Electrons in a three-dimensional bulk solid [21]. (a) Such solid can be modeled as an infinite crystal along all three dimensions *x*, *y*, *z*. (b) The assumption of periodic boundary conditions yields standing waves as solutions for the Schrödinger equation for free electrons. The associated wavenumbers (k_x, k_y, k_z) are periodically distributed in the reciprocal *k*-space number [22]. Each of the dots shown in the figure represents a possible electronic state (k_x, k_y, k_z). Each state in *k*-space can be only occupied by two electrons. In a large solid the spacing $\Delta k_{x,y,z}$ between individual electron states is very small and therefore the *k*-space is quasi-continuously filled with states. A sphere with radius k_F includes all states with $k = (k_x^2 + k_y^2 + k_z^2)^{1/2} < k_F$. In the ground state, at 0 K, all states with $k < k_F$ are occupied with two electrons and the other states are empty. Since the *k*-space is homogeneously filled with states, the number of states within a certain volume scales with k^3. (c) Dispersion relation for free electrons in a three-dimensional solid. The energy of free electrons scales with the square of the wavenumber and its dependence on *k* is described by a parabola. For a bulk solid the allowed states are quasi-continuously distributed and the distance between two adjacent states (here shown as points) in *k*-space is very small. (d) Density of states D_{3d} for free electrons in a three-dimensional system. The allowed energies are quasi-continuous and their density scales with the square root of the energy $E^{1/2}$.

with the thickness of the shell (which is Δk). $D_{3d}(k)\Delta k$ is thus proportional to $k^2\Delta k$ and, in the limit when Δk approaches zero, we can write

$$D_{3d}(k) = \frac{dN(k)}{dk} \propto k^2 \tag{4.15}$$

Instead of knowing the density of states in a given interval of wavenumbers, it is more useful to know the number of electrons that have energies between E and $E + \Delta E$. From Equations 4.12 and 4.13 we know that $E(k)$ is proportional to k^2 and thus $k \propto \sqrt{E}$. Consequently, $dk/dE \propto 1/\sqrt{E}$. By using Equation 4.15, we obtain for

the density of states for a three-dimensional electron gas [22]

$$D_{3d}(E) = \frac{dN(E)}{dE} = \frac{dN(k)}{dk}\frac{dk}{dE} \propto E \times 1/\sqrt{E} \propto \sqrt{E} \tag{4.16}$$

This can be seen schematically in Figure 4.3. With Equation 4.16 we conclude our simple description of a bulk material. The possible states in which an electron can be found are quasi-continuous. The density of states scales with the square root of the energy. More details about the free electron gas model and more refined descriptions of electrons in solids can be found in any solid-state physics textbook [20].

4.4.2
Two-Dimensional Systems

We now consider a solid that is fully extended along the *x*-and *y*-directions, but whose thickness along the *z*-direction (d_z) is only a few nanometers (Figure 4.5). Free electrons can still move freely in the *x*–*y* plane. However, movement in the *z*-direction is now restricted. Such a system is called a two-dimensional electron gas (2DEG) [23]. As mentioned in Section 4.2, when one or more dimensions of a solid become smaller than the de Broglie wavelength associated with the free charge carriers, an additional contribution of energy is required to confine the component of the motion of the carriers along this dimension. In addition, the movement of electrons along such a direction becomes quantized. This situation is shown in Figure 4.4. No electron can leave the solid and electrons that move in the *z*-direction are trapped in a "box". Mathematically this is described by infinitely high potential wells at the border $z = \pm^1/2d_z$.

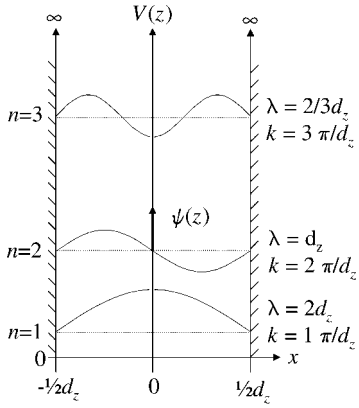

Figure 4.4 Particle in a box model for a free electron moving along in the *z*-axis. The movement of electrons in the *z*-direction is limited to a "box" with thickness *d*. Since electrons cannot "leave" the solid (the box), their potential energy *V*(*x*) is zero within the solid, but is infinite at its borders. The probability density $|\psi(z)|^2$ is the probability that an electron is located at position *x* in the solid. Different states for the electrons ($n = 1, 2, \ldots$) differ in their wavefunction.

The solutions for the particle in a box situation can be obtained by solving the one-dimensional Schrödinger equation for an electron in a potential $V(z)$, which is zero within the box but infinite at the borders. As can be seen in Figure 4.4, the solutions are stationarywaves with energies[6] $E_{nz} = \nabla^2 k_z^2/2m = h^2 k_z^2/8\pi^2 m = h^2 n_z^2/8md_z^2$, $n_z = 1, 2, \ldots$ [10, 22]. This is similar to states $k_z = n_z \Delta k_z$ with $\Delta k_z = \pi/d_z$. Again, each of these states can be occupied at the maximum by two electrons.

Let us compare the states in the k-space for three- and two-dimensional materials (Figures 4.3 and 4.5). For a two-dimensional solid that is extended in the x–y plane there are only discrete values allowed for k_z. The thinner the solid in the z-directions, the larger is the spacing Δk_z between those allowed states. On the other hand, the distribution of states in the $k_x - k_y$ plane remains quasi-continuous. Therefore, one can describe the possible states in the k-space as planes parallel to the k_x- and k_y-axes, with a separation Δk_z between the planes in the k_z-direction. We can number the individual planes with n_z. Since within one plane the number of states is quasi-continuous, the number of states is proportional to the area of the plane. This means that the number of states is proportional to $k^2 = k_x^2 + k_y^2$. The number of states in a ring with radius k and thickness Δk is therefore proportional to $k\Delta k$. Integration over all rings yields the total area of the plane in k-space. Here,

6) The particle-in-a-box approach (Figure 4.4) looks similar to the case of the periodic boundary conditions (Figure 4.2). There are indeed important differences between the two cases. Periodic boundary conditions "emulate" an infinite solid. A quantum mechanical treatment of this problem yields propagating waves that are periodic within the solid. Such waves can be seen as superposition of plane waves. For an idealized one-dimensional solid, with boundaries fixed at $x = \pm d/2$, a combination of plane waves can be for instance $\psi(x) = A\exp(ikx) + B\exp(-ikx)$ with $k = n \times 2\pi/d$. Written in another way, the solutions are of the type $\exp(ikx)$, with $k = \pm n \times 2\pi/d$. The solutions for $k = +n \times 2\pi/d$ and $k = -n \times 2\pi/d$ are linearly independent. The waves $\exp(+in \times 2\pi x/d)$ propagate to the right, the waves $\exp(-in \times 2\pi x/d)$ to the left side of the solid. Neither wave feels the boundaries. Since $\exp(ikx) = \cos(kx) + i\sin(kx)$ and $\exp(-ikx) = \cos(kx) - i\sin(kx)$, we also can write $\psi(x) = C\sin(kx) + D\cos(kx)$ with $k = n \times 2\pi/d$ as solutions. The only constraint here is that the wavefunction must be periodic throughout the solid. The state with wavenumber $k = 0$ is a solution, since $C\sin(0) + D\cos(0) = D \neq 0$. Therefore, the state with the lowest kinetic energy is $E \propto k^2 = 0$ for $k = 0$. The individual states in k-space are very close to each other because $\Delta k = 2\pi/d$ tends to 0 when d increases. On the other hand, the particle in a box model describes the case in which the motion of the electrons is confined along one or more directions. Outside the box the probability of finding an electron is zero. For a one-dimensional problem the solutions are standing waves of the type $\psi(x) = A\sin(kx)$ with $k = n\pi/d$. There is only one solution of this type. The function $\psi(x) = B\sin(-kx)$ can be written as $\psi(x) = -B\sin(kx)$ and therefore is still of the type $\psi(x) = A\sin(kx)$. Because of the boundary conditions $\psi(x = \pm d/2) = 0$ there is no solution of the type $\psi(x) = B\cos(kx)$. Since the standing wave is confined into the box, there is only the solution $k = +n\pi/d > 0$. For a small box the energy states are far apart from each other in k-space and the distribution of states and energies is discrete. An important difference with respect to the extended solid is the occurrence of a finite zero-point energy . There is no solution for $k = 0$, since $\psi(0) = A\sin(0) = 0$. Therefore, the energy of the lowest possible state ($n = 1$) is equal to $E = h^2/8md^2$, that is $k = \pi/d$. This energy is called zero-point energy and is a purely quantum mechanical effect. It can be understood as the energy that is required to "confine" the electron inside the box. For a large box the zero-point energy tends to zero. However, for small boxes this energy becomes significant as it scales with the square of the reciprocal of the box size d^2.

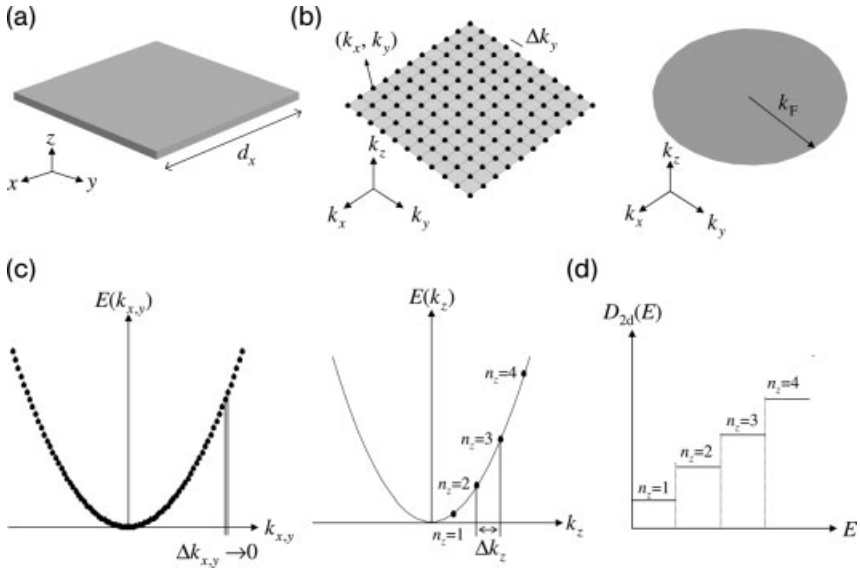

Figure 4.5 Electrons in a two-dimensional system. (a) A two-dimensional solid is (almost) infinitely extended in two dimensions (here x, y), but is very thin along the third dimension (here denoted z), which is comparable to the de Broglie wavelength of a free electron ($d_z \to \lambda$). (b) Electrons can still move freely along the x- and y-directions. The wavefunctions along such directions can be found again by assuming periodic boundary conditions. k_x and k_y states are quasi-continuously distributed in k-space. The movement of electrons in the z direction is restricted and electrons are confined to a "box". Only certain quantized states are allowed along this direction. For a discrete k_z state, the distribution of states in three-dimensional k-space can be described as a series of planes parallel to the k_x- and k_y-axes. For each discrete k_z state, there is a separate plane parallel to the k_x- and k_y-axes. Here only one of those planes is shown. The k_x and k_y states within one plane are quasi-continuous, since $\Delta k_{x,y} = 2\pi/d_{x,y} \to 0$. The distance between two planes for two separate k_z states is large, since $\Delta k_z = \pi/d_z \gg 0$. For each k_z value the k_x and k_y states are homogeneously distributed on the $k_x - k_y$ plane [22]. The number of states within this plane is therefore proportional to the area of a disk around $k_x = k_y = 0$. This means that the number of states for a certain wavenumber scales with k^2. In the ground state all states with $k \leq k_F$ are occupied with two electrons, while the remaining states are empty. (c) Free electrons have a parabolic dispersion relation [$E(k) \; (k^2]$. The energy levels $E(k_x)$ and $E(k_y)$ for the electron motion along the x- and y-directions are quasi-continuous (they are shown here as circles). The wavefunction $\psi(z)$ at the border of a small "box" must be zero, leading to standing waves inside the box. This constraint causes discrete energy levels $E(k_z)$ for the motion along the z-direction. Electrons can only occupy such discrete states (n_{z1}, n_{z2}, ..., shown here as circles). The position of the energy levels now changes with the thickness of the solid in the z-direction or in other words with the size of the "box". (d) Density of states for a two-dimensional electron gas. If electrons are confined in one direction (z) but can move freely in the other two directions (x, y), the density of states for a given k_z state ($n_z = 1, 2, \ldots$) does not depend on the energy E.

in contrast to the case of a three-dimensional solid, the density of states scales linearly with k:

$$D_{2d}(k) = \frac{dN(k)}{dk} \propto k \tag{4.17}$$

In the ground state, all states with $k \leq k_F$ are occupied with two electrons. We now want to know how many states exist for electrons that have energies between E and $E + \Delta E$. From Equations 4.12 and 4.13 we know the relation between k and E: $E(k) (k^2$ and thus $k \propto \sqrt{E}$ and $dk/dE \propto 1/\sqrt{E}$. By using Equation 4.17 we obtain the density of states for a two-dimensional electron gas; see also Figure 4.5 [22].

$$D_{2d}(E) = \frac{dN(E)}{dE} = \frac{dN(k)}{dk}\frac{dk}{dE} \propto \sqrt{E} \times 1/\sqrt{E} \propto 1 \tag{4.18}$$

The density of electronic states in a two-dimensional solid is therefore remarkably different from the three-dimensional case. The spacing between the allowed energy levels in the bands increases, because fewer levels are now present. As soon as one dimension is reduced to nanometer size, dramatic changes due to quantum confinement occur, as for example the non-negligible zero-point energy. In two-dimensional materials the energy spectrum is still quasi-continuous, but the density of states is now a step function [22, 24].

The quantum mechanical behavior of electrons in a two-dimensional solid is the origin of many important physical effects. With recent progress in nanoscience and -technology, the fabrication of two-dimensional structures has become routine. Two-dimensional systems are usually formed at interfaces between different materials or in layered systems in which some of the layers may be only a few nanometers thick. Structures such as this can be grown, for example, by successive deposition of the individual layers with molecular beam epitaxy. In such geometry, charge carriers (electrons and holes) can move freely parallel to the semiconductor layer, but their movement perpendicular to the interface is restricted. The study of these nanostructures led to the discovery of remarkable two-dimensional quantized effects, such as the integer and the fractional quantum Hall effect [25–28].

4.4.3
One-Dimensional Systems (Quantum Wires)

Let us now consider the case in which the solid also shrinks along a second (y) dimension. Now electrons can only move freely in the x-direction and their motion along the y- and z-axes is restricted by the borders of the solid (Figure 4.6). Such a system is called "quantum wire" and – when electrons are the charge carriers – a one-dimensional electron system (1DES). The charge carriers and excitations now can move only in one dimension and occupy quantized states in the other two dimensions.

The states of a one-dimensional solid can now be obtained by methods that are analogous to those described for the three- and two-dimensional materials. In the x-direction electrons can move freely and again we can apply the concept of periodic boundary conditions. This gives a quasi-continuous distribution of states parallel to the k_x-axis and for the corresponding energy levels. Electrons are confined along the remaining directions and their states can be derived from the Schrödinger equation for a "particle in a box" potential. Again, this yields discrete k_y and k_z states. We can now visualize all possible states as lines parallel to the k_x-axis. The lines are separated by discrete intervals along k_y and k_z, but within one line the distribution of k_x states is

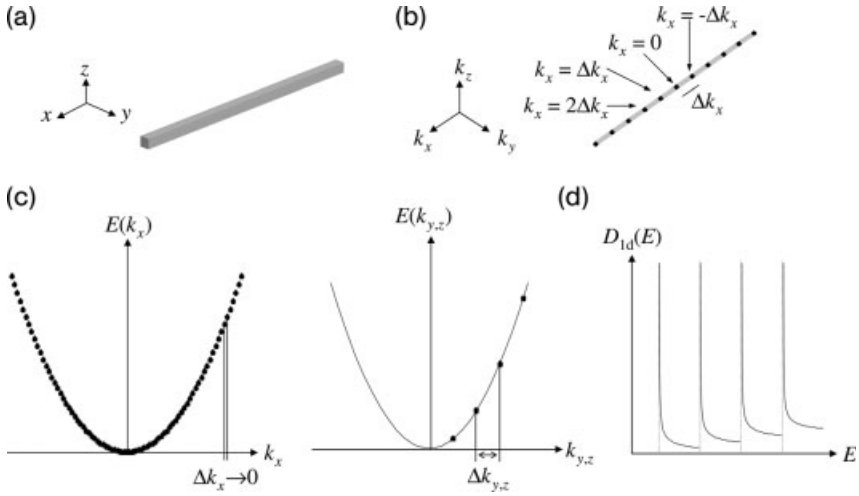

Figure 4.6 (a) One-dimensional solid. (b) The allowed (k_x, k_y, k_z) states can be visualized as lines parallel to the k_x-axes in the three-dimensional k-space. In this figure only one line is shows as an example. Within each line, the distribution of states is quasi-continuous, since $\Delta k_x \to 0$. The arrangement of the individual lines is discrete, since only certain discrete k_y and k_z states are allowed. (c) This can also be seen in the dispersion relations. Along the k_x-axes the energy band $E(k_x, k_y, k_z)$ is quasi-continuous, but along the k_y- and k_z-axes only certain energies exist. (d) The density of states within one line along the k_x-axes is proportional to $E^{-1/2}$. Each of the hyperbolas shown in the D_{1d} diagram corresponds to an individual (k_y, k_z) state.

quasi-continuous (Figure 4.6). We can count the number of states along one line by measuring the length of the line. The number of states is therefore proportional to $k = k_x$. Hence the number of states with wavenumbers in the interval between k and $k + \Delta k$ is proportional to Δk:

$$D_{1d}(k) = \frac{dN(k)}{dk} \propto 1 \tag{4.19}$$

In the ground state, all states with $k \leq k_F$ are occupied with two electrons. From Equations 4.12 and 4.13, we know the relation between k and E for free electrons: $E(k) \propto k^2$, and thus $k \propto \sqrt{E}$ and $dk/dE \propto 1/\sqrt{E}$. By using Equation 4.19, we obtain the density of states for a one-dimensional electron gas:

$$D_{1d}(E) = \frac{dN(E)}{dE} = \frac{dN(k)}{dk}\frac{dk}{dE} \propto 1 \times 1/\sqrt{E} \propto 1/\sqrt{E} \tag{4.20}$$

The density of states is depicted in Figure 4.6. In one-dimensional systems the density of states has an $E^{-1/2}$ dependence and thus exhibits singularities near the band edges [22]. Each of the hyperbolas contains a continuous distribution of k_x states, but only one discrete k_y and k_z state.

The quantization of states in two dimensions has important consequences for the transport of charges. Electrons can only flow freely along the x-axes but are limited to discrete states in the y- and z-directions. Therefore, they are only transported in

discrete "conductivity channels". This may be of considerable importance for the microelectronics industry. If the size of electronic circuits is reduced more and more, at one point the diameter of wires will become comparable to the de Broglie wavelength of the electrons. The wire will then exhibit the behavior of a quantum wire. Quantum aspects of 1D transport were first observed in so-called quantum point contacts which were lithographically defined in semiconductor heterostructures [29, 30]. More recent examples for such 1D wires include short organic semiconducting molecules [31–36], inorganic semiconductor and metallic nanowires [37–42] and break junctions [43–45]. A particular role is played by carbon nanotubes [32, 46–52]. Carbon nanotubes have been extensively studied both as model systems for one-dimensional confinement and for potential applications, such as electron emitters [53].

4.4.4
Zero-Dimensional Systems (Quantum Dots)

When charge carriers and excitations are confined in all three dimensions, the system is called "quantum dot". The division is somewhat arbitrary since, for instance, clusters made of very few atoms are not necessarily considered as quantum dots. Although clusters are smaller than the de Broglie wavelength, their properties depend critically on their exact number of atoms. Larger clusters have a well-defined lattice and their properties no longer depend critically on their exact number of atoms. We shall then refer to such systems with the term "quantum dots" [54–64] (Figure 4.7).

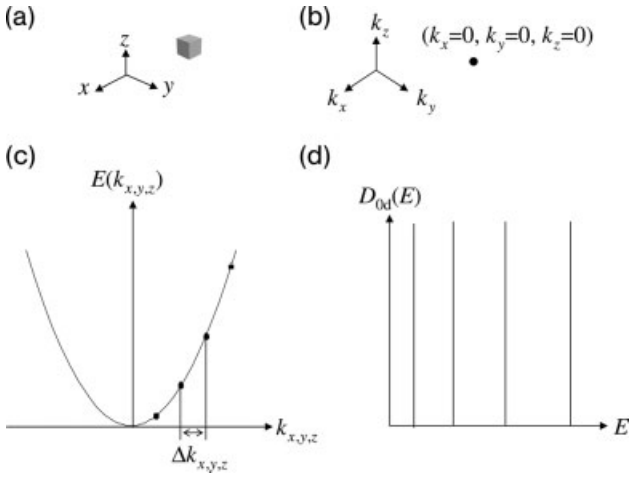

Figure 4.7 A zero-dimensional solid. (a) The solid is shrunk in all three dimensions to a thickness that is comparable to the de Broglie wavelength of its charge carriers. (b) Because of such confinement, all states (k_x, k_y,k_z) are discrete points in the three-dimensional *k*-space. (c) Only discrete energy levels are allowed. (d) The one-dimensional density of states $D_{0d}(E)$ contains delta peaks, that correspond to the individual states. Electrons can occupy only states with these discrete energies.

In a quantum dot, the movement of electrons is confined in all three dimensions and there are only discrete (k_x, k_y, k_z) states in the k-space. Each individual state in k-space can be represented by a point. The final consequence is that only discrete energy levels are allowed, which can be seen as delta peaks in the distribution $D_{0d}(E)$. As we can see, the energy bands converge to atom-like energy states, with the oscillator strength compressed into few transitions. This change is most dramatic at the edges of the bands and influences semiconductors more than metals. In semiconductors, the electronic properties are in fact strongly related to the transitions between the edges of the valence band and the conduction band. In addition to the discreteness of the energy levels, we want to stress again the occurrence of a finite zero-point energy. In a dot, even in the ground state electrons have energies higher than bulk electrons at the conduction band edge. These points will be discussed in more detail in the next section.

4.5
Energy Levels of a (Semiconductor) Quantum Dot

In this section, we will describe in more detail a zero-dimensional solid. Since many quantum effects are more pronounced in semiconductors than metals, we will focus on the case of a semiconducting material. In Section 4.4 we described how the properties of a free electron gas change when the dimensions of the solid are reduced. The model of the free electron gas does not include the "nature" of the solid. However, from a macroscopic point of view we distinguish between metals, semiconductors and insulators [20]. The model of a free electron gas describes relatively well the case of electrons in the conduction band of metals. On the other hand, electrons in an insulating material are only poorly described by the free electron model. In order to extend the model of free electrons for semiconducting materials, the concept of a new charge carrier, the hole, was introduced [21]. If one electron from the valence band is excited to the conduction band, the "empty" electronic state in the valence band is called a hole. Some basic properties of semiconducting materials can be described by the model of free electrons and free holes. The energy bands for electrons and holes are separated by a bandgap [20, 21]. The dispersion relations for the energy of electrons and holes in a semiconductor are parabolic to a first approximation. This approximation holds true only for electrons (holes) occupying the levels that lie at the bottom (top) of the conduction (valence) band. Each parabola represents a quasi-continuous set of electron (hole) states along a given direction in k-space. The lowest unoccupied energy band and the highest occupied energy band are separated by an energy gap E_g(bulk), as shown in Figure 4.8. The bandgap for a bulk semiconductor can range from a fraction of an electronvolt up to a few electronvolts.

We could expect that the energy dispersion relations would still be parabolic in a quantum dot. However, since only discrete energy levels can exist in a dot, each of the original parabolic bands of the bulk case is now fragmented into an ensemble of points. The energy levels of a quantum dot can be estimated with the particle-in-a-box

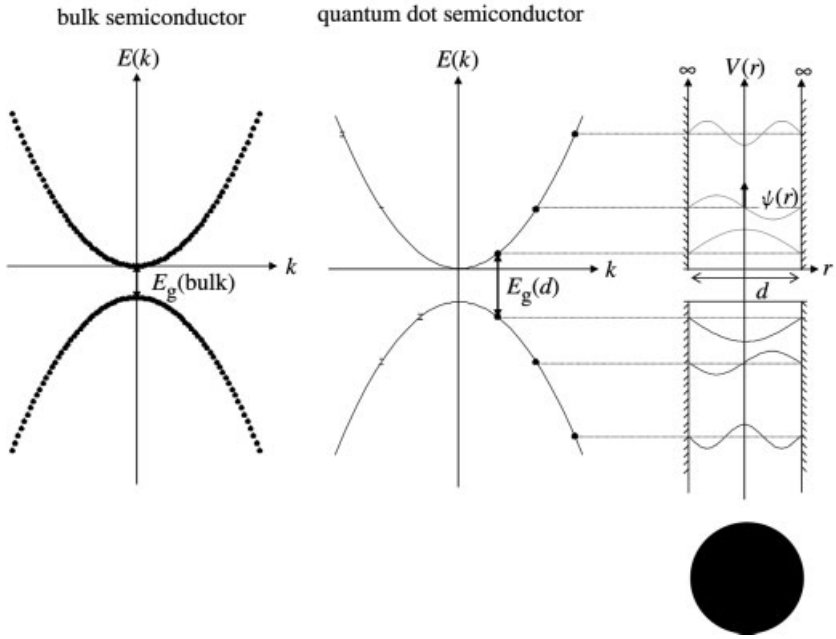

Figure 4.8 Free charge carriers in a solid have a parabolic dispersion relation [$E(k) \propto k^2$]. In a semiconductor the energy bands for free electrons and holes are separated by an energy gap E_g. In a bulk semiconductor, the states are quasi-continuous and each point in the energy bands represents an individual state. In a quantum dot the charges are confined to a small volume. This situation can be described as a charge carrier confined in an infinite potential well of width d. Here, the width d of the potential well corresponds to the diameter of the quantum dot. The only allowed states are those whose wavefunctions vanish at the borders of the well 8. This leads to discrete energy levels [8, 11]. The energy gap between the lowest possible energy level for electrons and holes $E_g(d)$ is larger than that of a bulk material E_g(bulk).

model. As described in the previous section (Figure 4.4), the lowest energy for an electron in a one-dimensional potential well is

$$E_{\text{well,1d}} = (1/8)h^2/md^2 \tag{4.21}$$

where d is the width of the well. In a quantum dot, the charge carriers are confined in all three dimensions and this system can be described as an infinite three-dimensional potential well. The potential energy is zero everywhere inside the well but is infinite on its walls. We can also call this well a "box". The simplest shapes for a three-dimensional box can be, for instance, a sphere or a cube. If the shape is cubic, the Schrödinger equation can be solved independently for each of the three translational degrees of freedom and the overall zero-point energy is simply the sum of the individual zero point energies for each degree of freedom [10, 65]:

$$E_{\text{well,3d(cube)}} = 3E_{\text{well,1d}} = (3/8)h^2/md^2 \tag{4.22}$$

If the box is a sphere of diameter d, the Schrödinger equation can be solved by introducing spherical coordinates and by separating the equation in a radial part and in a part that contains the angular momentum [66, 67]. The lowest energy level (with angular momentum = 0) is then

$$E_{\text{well,3d(sphere)}} = (1/2)h^2/md^2 \tag{4.23}$$

The effect of quantum confinement is again remarkable. More confined charge carriers lead to a larger separation between the individual energy levels, and also to a greater zero-point energy. If carriers are confined into a sphere of diameter d, the zero-point energy is higher than that for charges that are confined to a cube whose edge length is equal to d [$E_{\text{well,3d(sphere)}} > E_{\text{well,3d(cube)}}$]. This is because such a sphere simply has a smaller volume [$(\pi/6)d^3$] than the cube (d^3).

An electron–hole pair can be generated in the quantum dot, for instance by a photoinduced process or by charge injection. The minimum energy E_g required for creating an electron–hole pair in a quantum dot is made up of several contributions. One contribution is the bulk band gap energy, E_g(bulk). Another important contribution is the confinement energy for the carriers, which we call $E_{\text{well}} = E_{\text{well}}(e^-) + E_{\text{well}}(h^+)$. For large particles (bulk: $d \to \infty$), E_{well} tends to zero. We can estimate the overall confinement energy for an electron–hole pair in a spherical quantum dot. It is the zero point energy of the potential well or in other words the energy of the state of a potential box with the lowest energy. This can be written as

$$E_{\text{well}} = h^2/2m^*d^2 \tag{4.24}$$

where m^* is the reduced mass of the exciton and is given by [68]

$$1/m^* = 1/m_e + 1/m_h \tag{4.25}$$

were m_e and m_h are the effective masses for electrons and holes, respectively. In order to calculate the energy required to create an electron–hole pair, another term (E_{Coul}) has to be considered. The Coulomb interaction E_{Coul} takes into account the mutual attraction between the electron and the hole, multiplied by a coefficient that describes the screening by the crystal. In contrast to E_{well}, the physical content of this term can be understood within the framework of classical electrodynamics. However, an estimate of such a term is only possible if the wavefunctions for the electron and the hole are known. The strength of the screening coefficient depends on the dielectric constant ε of the semiconductor. An estimate of the coulomb term yields

$$E_{\text{Coul}} = -1.8e^2/2\pi\varepsilon\varepsilon_0 d \tag{4.26}$$

This term can be fairly significant because the average distance between an electron and a hole in a quantum dot can be small [13, 14, 55, 69, 70]. We can now estimate the size-dependent energy gap of a spherical semiconductor quantum dot, which is given by the following expression [13, 14, 55, 68–70]:

$$E_g(\text{dot}) = E_g(\text{bulk}) + E_{\text{well}} + E_{\text{Coul}} \tag{4.27}$$

Then, by inserting Equations 4.24 and 4.26 into Equation 4.27, we obtain

$$E_g(d) = E_g(\text{bulk}) + h^2/2m^*d^2 - 1.8e^2/2\pi\varepsilon\varepsilon_0 d \tag{4.28}$$

Here we have emphasized the size dependence in each term. Equation 4.28 is only a first approximation. Many effects, such as crystal anisotropy and spin–orbit coupling, have to be considered in a more sophisticated calculation. The basic approximation for the bandgap of a quantum dot comprises two size-dependent terms: the confinement energy, which scales as $1/d^2$, and the Coulomb attraction, which scales as $1/d$. The confinement energy is always a positive term and thus the energy of the lowest possible state is always raised with respect to the bulk situation. On the other hand, the Coulomb interaction is always attractive for an electron–hole pair system and therefore lowers the energy. Because of the $1/d^2$ dependence, the quantum confinement effect becomes the predominant term for very small quantum dot sizes (Figure 4.9).

The size-dependent energy gap can be a useful tool for designing materials with well-controlled optical properties. A much more detailed analysis on this topic can be found in, for example, a paper by Efros and Rosen [61].

In this chapter, we have shown how the dependence of the energy gap of semiconductors on the size of the material can be explained by either shrinking down the material from bulk to nanometer dimensions or by assembling the material atom by atom. Both views, one in a top-down and the other in a bottom-up approach, ultimately lead to the same physics. In Chapter 3, a more general description of these two types of approaches is given.

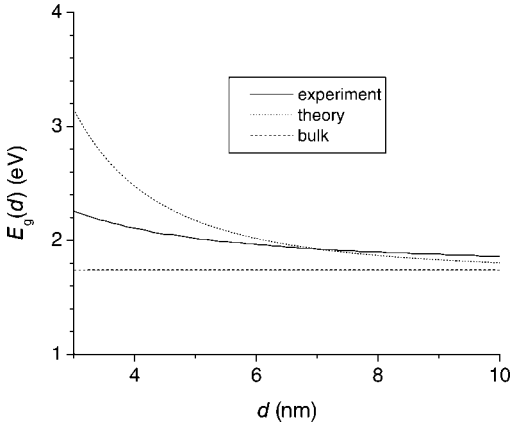

Figure 4.9 Size dependence of the energy gap $E_g(d)$ for colloidal CdSe quantum dots with diameter d. The bulk value for the energy gap is $E_g(\text{bulk}) = 1.74$ eV [68]. The theoretical curve was obtained using Equation 4.28 with the following parameters: effective mass of electrons/holes $m_e = 0.13m_0$, $m_h = 0.4m_0$, m_0 = mass of free electrons ($m = 9.1095 \times 10^{-31}$ kg) $\Rightarrow m^* = 0.098m$ [68]; dielectric constant $\varepsilon_{CdSe} = 5.8$ [71], permittivity constant $\varepsilon_0 = 8.854 \times 10^{-12}\,C^2\,N^{-1}\,m^{-2}$, Planck's constant $h = 6.63 \times 10^{-34}$ J s, $1\,eV = 1.602 \times 10^{-19}$ J. The experimental values were obtained by recording the absorption spectra of CdSe quantum dots of different sizes and determining the size of the quantum dots by transmission electron microscopy (TEM) [72].

Fundamentals and Functionality of Inorganic Wires, Rods and Tubes

Jörg J. Schneider, Alexander Popp, and Jörg Engstler

5.1
Introduction

Nanostructured one-dimensional inorganic tubes, wires and rods are known for a variety of single elements and combinations thereof. The number of studies towards their synthesis and properties is now vast. For nanowires – anisotropic nanocrystals with large aspect ratio (length to diameter) – around 5000 papers have been published during the last 2 years. An excellent comprehensive monograph and timely reviews presenting the current state of the art up to 2005 exist [1].

In this chapter, physical properties of 1D inorganic structures will be discussed first, followed by a section devoted to general techniques for the synthesis of inorganic wires, rods and tubes. The chapter then highlights some of the material developments made over the last few years in the very active area of nanostructured inorganic rods, wires and tubes with respect to their specific materials functionality. [The field of carbon nanotubes (CNTs) is probably still the fastest growing of all 1D materials. CNTs will only be touched upon in this chapter as far as sensing and nano–micro integration in functional devices are concerned. For further reading on this topic, the reader is referred to numerous excellent monographs in the field.] Due to the breadth of the field, the selection of materials and applications is somewhat subjective and reflects what the authors personally feel are "hot" topics. Where could the materials discussed impact on future technological developments? Fields of sensing and micro/nanoelectronics integration will be selectively addressed here. It is the intention of this chapter to introduce the reader to these fields and the currently ongoing rapid developments in these promising future fields of functional 1D nanomaterials.

A drastic change in materials properties is often connected with the nanoscale range (1–100 nm). In addition to an understanding of fundamental size-related electronic effects [quantum size effects (QSE)], which are connected with this "miniaturization" of matter (for an intriguing description of how quantum phenomena arise in 0D and 1D nanostructured matter, see Chapter 4), interest in nanostructured materials often arises from the fact that the small size connected with nanoscaled matter creates new chemistry. For example, the extremely high number of interfaces connected with

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

small-scale matter, be it in 0D (particles), 1D (wires, rods, tubes) or 2D (films) dimensions create high chemical reactivity. Interfaces control important material properties such as catalytic activity or analytical sensing behavior in addition to electronic properties of nanomaterials, which are highly dependent on such interfacial contacts of individual nano-building blocks and also on the individual QSE of the nano-building blocks. Besides such effects connected with the nanoscale regime, morphological properties of assembled nanomaterials such as habit (size, shape) and surface structure are also important for new and desired materials properties arising from the sequential build-up of larger structures from nano-building blocks.

The morphology of mesostructures can be tailored by synthetic techniques, for example, self-assembly, which arranges individual small building blocks such as molecules or even nanoparticles into larger mesostructured objects by employing secondary interactions such as hydrogen bonding, van der Waals, capillary or hydrophobic forces. Therefore, the shaping of materials, be it on the molecular or the nanoscale, presents a major task to the experimentalist since it is the key to organizing matter on the mesoscopic scale (Greek *mesos*, in between); the dimension between the pure nanostructured regime in which QSE reign nearly every type of material property and the macroscopic world in which solid-state physics is the key to describing and understanding material properties.

A very successful and intriguing example of controlled 1D assembly from the chemist's workbench can be found in the technique of supramolecular assembly of compact or porous 1D structures. Such structures can be built up sequentially starting first from defined molecular precursors, followed by self-assembly of 0D (nano)particle aggregates via controlled condensation. In this approach, the individual building blocks arrange in hierarchical order (from the molecular to the nanoscale and finally to the mesoscale) by supramolecular organization (Figure 5.1) [2].

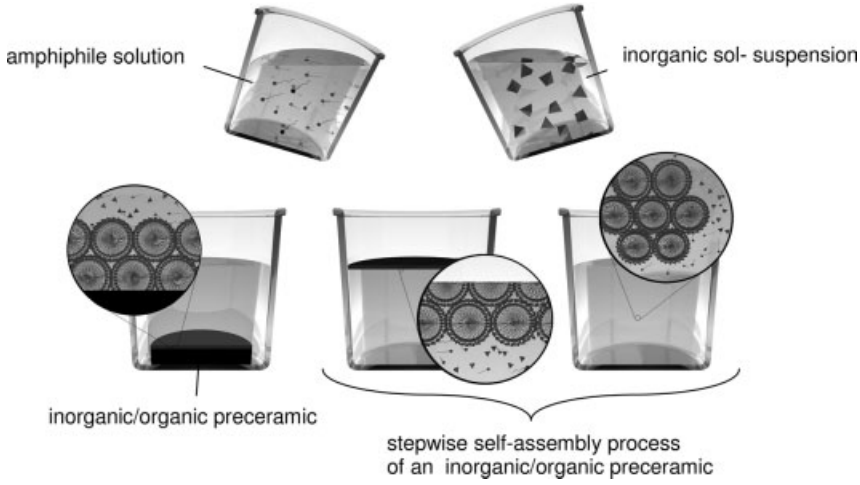

Figure 5.1 Schematic of the process of self assembly of inorganic sol particles on a polymeric micellar amphiphile assembly leading to an organic/inorganic composite. The composite structure is formed via self assembly. Adapted from Ref. [2f].

A polymeric macromolecule (called a template) steers, in addition to temperature, solvent and concentration of all reactants, the complex arrangement of individual building blocks into the final macro-sized structure.

5.2
Physical Properties of 1D Structures

Starting from a three-dimensional solid, the confinement of electrons into a one-dimensional structure leads to the quantization of electronic states in two directions (lets us say x and y). In the z-direction electrons can move freely and give rise to a quasi-continuous distribution of energy states along this dimension. Along x and y they are confined and only one discrete state is possible. Once the diameter of the 1D system is comparable to the de Broglie wavelength of the electrons, the 1D structure will become a quantum wire. Probably the most important application-related aspect of this dimensionality reduction in 1D materials is the restricted flow of charge carriers in only a single direction, the "conductivity channel" (see Section 5.4.3.1). An intriguing example can be found in single crystalline silicon nanowires smaller than

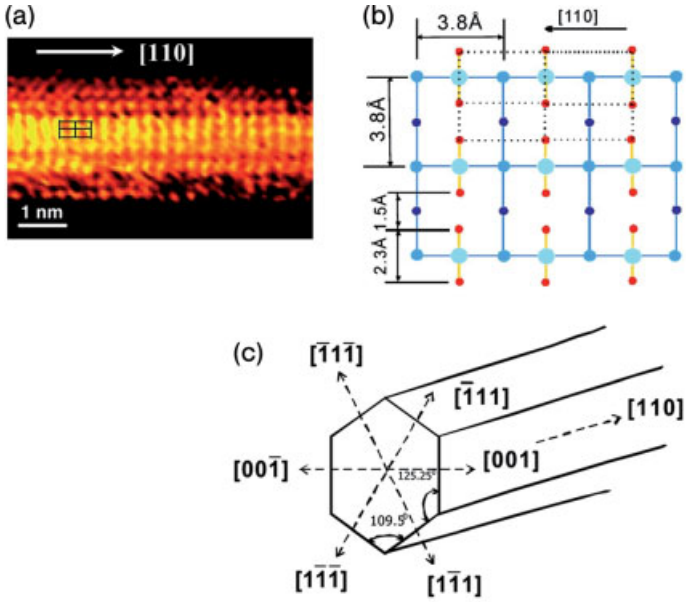

Figure 5.2 Scanning tunneling microscopic (STM) image and schematic view of an Si nanowire with an Si (0 0 1) facet. (a) Constant-current STM image of an Si nanowire on a HOPG substrate. The wire's axis is along the [110] direction. (c) Schematic view of an Si nanowire bounded by four (11)-type facets and two (0 0 1)-type facets. The wire's axis is along the [110] direction. Reprinted with permission from Ref. [3].

5 nm in diameter (5 nm is the exciton size for Si). Via scanning tunneling microscopy (STM), the electronic states and the bandgaps of such Si wires have been probed for wires with different diameters <10 nm. Gaps ranging from 1.1 eV (7 nm Si wire diameter) up to 3.5 eV (1.3 nm Si wire diameter) have been determined, demonstrating the extreme quantum confinement effect in such structures (Figure 5.2) [3].

A variety of direction-dependent electronic effects, for example, polarizability of light, are also different for anisotropic 1D materials compared with 0D materials [4].

Although electron conductivity in 1D wires and rods is favored along the preferred direction, phonon transport is greatly impeded, in thin 1D nanostructures, due to boundary scattering in the confined directions. Electrons may suffer elastic scattering events during their journey along the wire. This has important implications on the heat conductivity of 1D nanowire structures and for application of such structures in wiring or circuiting next-generation semiconductor devices. On the other hand, poor heat transport in confined nanowires may be used for development of thermoelectric materials. The thermoelectric effect (Seebeck effect), which is responsible for this property, describes the enhancement of the thermal electronic conductivity through a material as phonon transport in the structure worsens (due to the 1D confinement effect). Theory has predicted a significant increase over bulk values of this thermoelectric effect depending on the diameter, composition and charge carrier concentration of the 1D material of choice [5]. Nevertheless, research in that technologically important area is still in its infancy. An example is discussed in Section 5.3.1. For a detailed discussion of mesoscopic transport phenomena, for example, boundary scattering in 1D confined structures, the reader is referred to Ref. [6].

5.3
Synthetic Methods for 1D Structures

Synthetic methods for obtaining 1D nanostructures are numerous and have been reviewed by various authors recently [7]. They can be divided into top-down and bottom-up techniques; in the former a desired nanostructure is formed by sophisticated physical techniques, for example, electron beam structuring or laser structuring of a bulk material. Such techniques, however, are always restricted to the wavelength of the structuring beam, thus nanomaterials with dimensions well below 10 nm are still beyond the scope of these methods.

Bottom-up techniques, however, show a rich diversity towards desirable chemical and materials compositions and also structure (amorphous, crystalline), morphology (0D, 1D and 2D) and size. Several bottom-up synthetic techniques leading to the formation of 1D structures which seem to have a more general impact can be identified: the template method, self-assembly techniques, vapor to liquid–solid synthesis of 1D nanostructures and electrochemical techniques. These techniques show an enormous breadth since a variety of elemental compositions for different structures and morphologies and also sizes are accessible. Often combinations of individual techniques are employed, broadening further the scope for the experimentalist.

5.3.1
The Template Approach

This is probably the most versatile method for the synthesis of 1D structures. A host structure with a pore morphology – the template – is filled with a compact, more or less dense material or as film. The former produces compact wires or rods and the latter results in the formation of tubes.

Filling of the pores is possible either via solution (simply by capillary filling), by electrochemical deposition techniques or via the gas phase.

Oxidation of valve metals such as aluminum, titanium, tantalum and hafnium leads to porous metal oxide films on metal surfaces [8]. For aluminum this is a useful and outstanding technique to prepare both surface-attached and free-standing porous 2D alumina films (after detachment from the metal surface) with varying pore diameters. The pore size of these films is strongly dependent on the experimental conditions and can be varied between 10 and several hundred nm [9]. Especially in the case of aluminum, these films can be fairly thick (up to several tens of μm) or thin (down to several hundred nm), but still self-supporting, free-standing and handable. The diameter of the pores (D_p) and the cells (D_c) of a porous alumina membrane are dependent on the anodization potential applied in the electrolytic process [9]. Additional experimental parameters governing the pore size are temperature and current density. The latter is influenced by the concentration and type of electrolyte used in the electrolysis process. Nearly perfectly ordered pores are accessible by prestructuring the metallic surface [9a] (Figure 5.3).

Consequently, porous alumina membranes have been widely used to prepare various types of mesoscale materials within their pores. Their enormous synthetic impact in the area of mesostructured 1D materials comes from the ability to combine well-established wet chemical synthesis techniques (e.g., sol–gel chemistry) with the straightforward synthesis and subsequent filling of porous alumina templates.

Preparation of active sol precursors, filling and aging within the mesopores of alumina, followed by final calcination steps, have led to a huge variety of different mesostructured 1D materials, for example, in the ceramics field [1e,11]. The pores can even be used to arrange silica in a columnar or circular arrangement with a defined internal mesostructure. Further entrapment of a variety of 1D nanostructures into the mesopores of alumina such as metallic rods (Pt, Au, Pd), semiconductor rods and carbon nanostructures have been reported recently [1e,11].

Using a combination of sol–gel processing on the surface of (1 0 0)-oriented silicon templates, a porous structure with an ordered arrangement of pores is formed. These studies show that a topographic structure (here Si) can be used to engineer pores on this solid surface, allowing a high degree of freedom. The filling of such pores with cobalt has been demonstrated [12].

Another template technique giving porous, free-standing membranes, but of polymeric materials, uses heavy ion track etching of polymer foils [13] to fill the statistically formed ion tracks within the polymer with nanoscale materials in order to form rod-like structures [14, 15] (Figure 5.4). This led to bunches of randomly

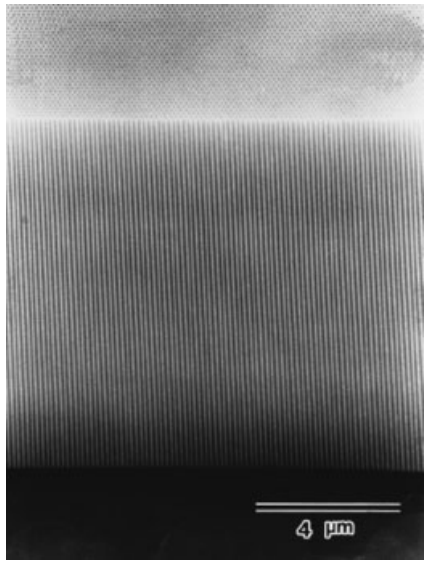

Figure 5.3 Cross-sectional view of a channel array of a porous alumina membrane which can be used for arranging 1D nanomaterials. The scanning microscopic (SEM) observation was carried out without removal of Al and barrier layer of the oxide film. Reprinted with permission from Ref. [9i].

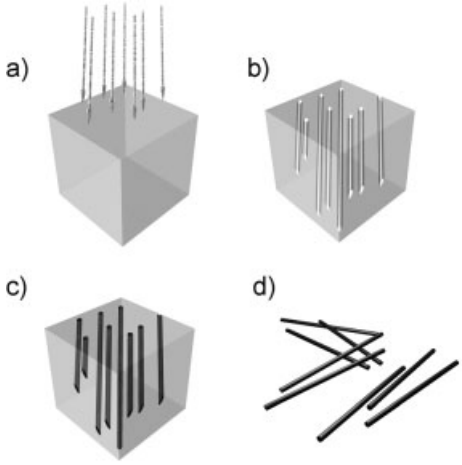

Figure 5.4 Ion track etching process of a polymer film. Heavy ions hit the polymer foil, and generate tracks in the membrane (a). The tracks are stochastically arranged (b); solid rods are synthesized in the tracks, for example, via electrochemical deposition (c); free rods after complete polymer membrane dissolution (d).

oriented composite 1D structures. Careful dissolution of the template gives free-standing aligned metallic rods with well-defined crystal lattices (Figures 5.5 and 5.6).

Using the template approach in connection with electrodeposition allows the pores of such templates to be filled with single- or multicomponent metallic rods. After deposition of a metal electrode on the back side of such a porous template, one or even more metals can be densely deposited inside the pores on purpose. This has been used, for example, for deposition of Au/Pt segments. The deposition of gradient materials via electrodeposition is also possible. This technique can also be has used for the deposition of magnetic structures. Their magnetic behavior depends on the aspect (length-to-diameter) ratio of the individual rods. The easy axis of magnetization is parallel to the nanorod or nanowire axis if the electrodeposited structure is longer than its width [16]. Otherwise, it is perpendicular to the deposited structure. This difference depending on particle shape (morphology, platelet vs. rod structure) can be used to align bimetallic nanorods side-by-side (Figure 5.7) [17a] or one after the other when the magnetic field is applied parallel to the substrate and to the 1D magnetic materials easy axis [17b].

Hybrid Co/Au nanorod structures are accessible by using organometallic chemistry. The appropriate choice of the molecular Co and Au precursors and the

stabilizing ligand allows control of the growth process and of the overall morphology of the rod (tip or whole body growth) [18]. Combining this technique with the template method should lead to 2D-arranged hybrid metallic rods.

Devising methods for aligning 1D materials with a uniform growth front is of general importance for optimizing device performance, for example, in thermoelectric materials such as bismuth telluride. For example, overgrowth of rods when the template pores are already filled has to be avoided in order not to cover the pores of the template with an active material, which may lead to short-circuiting. This has been achieved by applying a pulsed potential deposition technique and has yielded a uniform growth front of Bi_2Te_3 nanowire arrays in porous alumina [19]. Using nanorods as sacrificial templates to generate polymeric or ceramic nanorod structures is another method that uses porous alumina as the initial template and shows the high versatility of this porous template structure. Electrodeposition of, for example, nickel rods into porous alumina, followed by dissolution of the oxide template and coating of the metallic wires with either organic polymers or inorganic polyelectrolyte ceramics, finally gives the corresponding polymeric or ceramic (after subsequent calcinations) 1D structures. The complete method uses a hybrid technique of first templating followed by a layer-by-layer deposition technique [20].

Although the nano-templating approach using porous alumina (Figure 5.8) works well for template diameters down to about 20 nm, reports on 1D nanomaterials with smaller diameters prepared with this so-called "hard template technique" [1e] are still scarce so far [21].

5.3.2 Electrochemical Techniques

5.3.2.1 Electrospinning

This technique can be used to create nano- to microscale fibers of mainly polymeric materials [22]. Recent advances in the technique of electrospinning have brought this

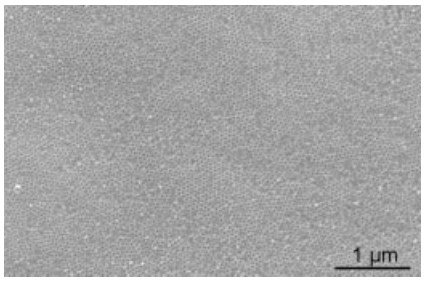

Figure 5.8 Scanning electron microscopic (SEM) view of a porous alumina template membrane with pores in the range 15–17 nm (J.J. Schneider, J. Engstler, M. Naumann, TU Darmstadt).

already well-established method again in the focus of the experimentalists as a valuable method for synthesizing large quantities of, for example, ceramic nanofibers of various compositions with dense or hollow morphology [22–24].

In the technique, a precursor solution is held in the hollow tip of a needle-like capillary by its own surface tension. This capillary is subjected to an electric field and induces an electric field on the surface of the liquid precursor. On reaching a critical value, the repulsive electric field overcomes the surface tension and a charged jet of the solution is ejected from the capillary. Once the jet has started, its trajectory can be controlled by the electric field. These charged fibers are then deposited on a grounded collector. The process depends on a number of parameters such as solution properties (viscosity, conductivity and surface tension) and also process parameters such as hydrostatic pressure and electric potential at the capillary tip, distance between the tip and the collecting metal plate and general parameters such as temperature and humidity [23]. This technique gives access to isolated fibers [24–26], fiber agglomerates (mats) and dense or hollow fibers of different composition (e.g., single phase or composite) [27]. However, experimental electrospinning conditions are critical for the morphology of the resulting material; nevertheless, the morphology of the material can be tuned from 0D particles up to 1D filaments (hollow or dense morphology) (Figure 5.9).

5.3.2.2 **Electrophoretic Deposition**

This technique is widely used in the deposition of both mesoporous and dense thin films from colloidal suspensions. The electrophoretic technique can be ideally combined with the sol–gel synthetic approach since in the latter charged species are the active components (colloids or charged stabilized sols). These can be moved in an external electric field [28–30]. In general, reduction or oxidation of the particles occurs at the electrodes, the initial deposition surface for the preceramic material. Combining sol–gel and electrophoretic synthesis techniques basically uses the (field) oriented motion of the charged sol colloids (electrophoretic motion), (Figure 5.10) [31]. To produce, for example, a 1D ceramic material, a structure-directing template is necessary. Porous alumina is an ideal host for this purpose and a number of 1D ceramics obtained by this technique have been reported (see Chapter 4).

As the deposition of the particles is from suspension, an additional post-deposition compaction or annealing step has to be performed in order to obtain, for example, a

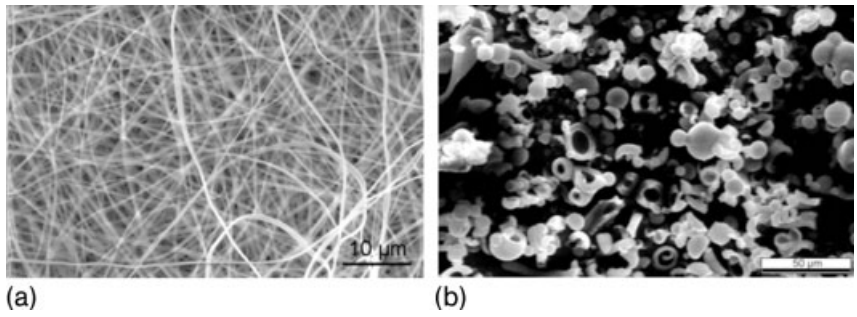

Figure 5.9 (a) Electrospun polymer fibers derived from Eudragit L100-55 (methacrylic acid–ethyl acrylate (1 : 1) copolymer. (b) Hollow spheres obtained via elctrospinning of aluminum *sec*-butylate in light petroleum (J.J. Schneider, J. Engstler, TU Darmstadt).

dense mesostructured ceramic. Since the as-prepared structure is already built from nanosized particles, this step can often be performed under smoother conditions as typically used in conventional ceramic processing [32].

5.3.3
Vapor–Liquid–Solid (VLS) and Related Synthesis Techniques

For the synthesis of 1D structures from the gas phase, vapor–liquid–solid (VLS) and vapor–solid (VS) processes are the typical growth mechanisms which are accepted to explain the 1D growth of mesoscopic structures [33]. In this growth process, a catalyst particle first melts, becomes saturated with a gaseous precursor and, when oversaturated, either an elemental wire or a compound wire depending on the precursor extrudes from this catalyst droplet to form a single-crystal nanowire. This is essentially the method proposed for whisker growth from the vapor [33]. Nanowires

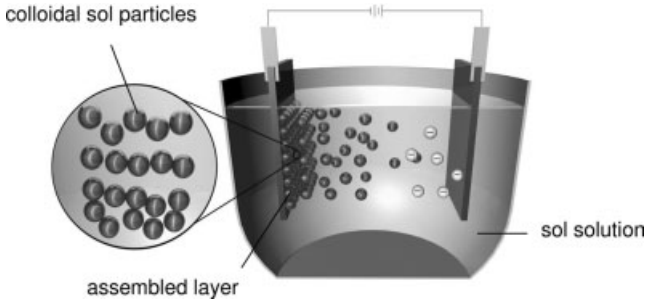

Figure 5.10 Schematic drawing of an experimental setup used for synthesis of mesostructured films by electrophoretic deposition. Particles are deposited from a colloid suspension to form a film on the surface of the electrodes. If the deposition is done in a porous template nanostructured rods are accessible. The compaction of the as prepared rods or films into a ceramic material follows in a post process.

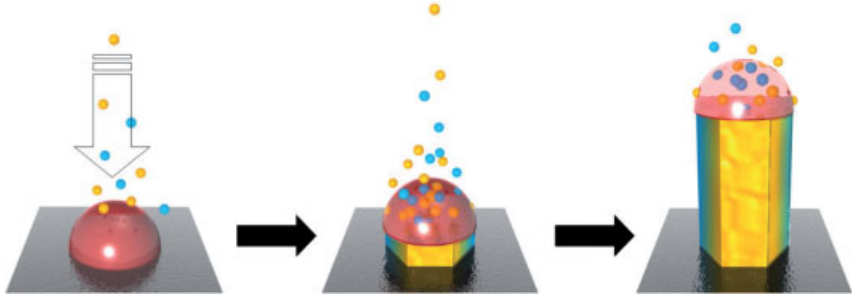

Figure 5.11 Growth mechanism for a pseudo-1D crystalline morphology. $V_{apor}L_{iquid}S_{olid}$ mechanism proposed by Wagner and Ellis for growth under CVD conditions.

grow as long as active catalyst is supplied and the growth temperature is maintained (Figure 5.11).

Recent model studies on the influence of various metal catalysts on the growth, structure morphology and size of inorganic nanowires have shown that different catalyst metals with different crystal morphologies are able to generate different wire morphologies based on the VLS formation process [34, 35]. For the growth of Si nanowires with Au nanocluster catalysts, it was found that the lowest energy surface, which is a {1 1 1} plane for Si, controls nucleation and growth (Figure 5.12) [34]. The results point towards the importance of an additional effect of oxygen in the gold-catalyzed growth kinetics of Si wires. The presence of oxygen can suppress Au catalyst

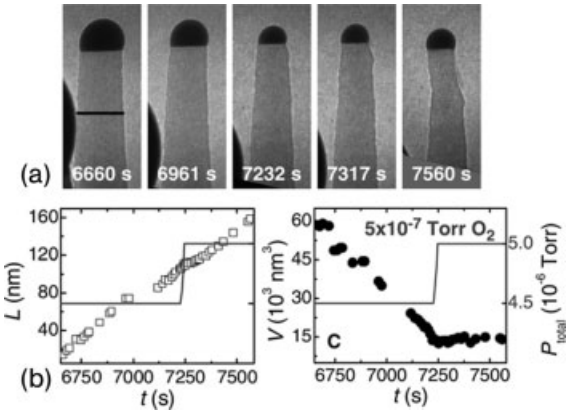

Figure 5.12 Effect of increasing oxygen pressure on Si nanowire growth kinetics. (a) Series of images extracted from a video sequence showing the effect of introducing oxygen to an Si wire that was previously growing in disilane (Si_2H_6). The growth was carried out in 4.5×10^{-6} torr disilane at 610 °C for 111 min; 5×10^{-7} torr oxygen was introduced while maintaining the disilane pressure constant. Scale bar is 50 nm. (b) Length *L* of the Si wire as a function of time *t*. (c) Volume *V* of the droplet as a function of time *t*. Reprinted with permission from Ref. [36].

migration and influences the wire diameter and the overall wire morphology [36]. The presence of oxygen, be it in the form of gas-phase oxygen or surface-bound oxygen, could be an important experimental parameter to modulate nanowire morphology further in a more general way during VLS growth [36].

For ZnO nanowires, it has been shown recently that control of the partial O_2 pressure under growth conditions is crucial for reproducible large-scale wire formation (Figure 5.13). It is very likely that the gas-phase conditions play a major role in the VLS growth of this and speculatively also other 1D materials made by this technique. Studies towards understanding the influence of reactive gas-phase species are central to deducing how individual morphologies of 1D materials depend on catalyst composition, shape and crystallinity in addition to the overall reaction conditions [37].

The current understanding of growth control of nanowires via the VLS technique is that (a) interplay given by the phase diagram of temperature–pressure and (b) the composition ofthe precursor elements and the catalyst particle under consideration are crucial. Careful control of these conditions can give rise to a variety of wire morphologies which are accessible at will once the conditions are thoroughly adjusted.

As shown, indicative for the VLS mechanism are catalyst tips at the faceted ends of the nanowires. Silicides are interesting semiconductors, with promising thermoelectric properties. Even though silicide wires (MSi_2, M = Fe, Co, Cr) were grown in the presence of nickel or iron [38], no catalyst metal particles are detected on the faceted nanowire ends as usually observed for the VLS growth mode. Obviously, in the chemical vapor transport technique (CVT) which is used for the synthesis of silicide wires a different gas-phase mechanism than in the most widely found catalyst-driven VLS growth may operate.

A promising technique related to the VLS Au seeded nanowire growth method has been reported. It allows oriented low-temperature gas-phase growth of pure Si nanowires [39]. Plasma growth at temperatures as low as 300 °C enables an additional degree of synthetic control over nanowire orientation (Figure 5.14). The crucial step in the formation process seems to be Si incorporation at the vapor–liquid interface.

Additional techniques also related to the traditional VLS-type growth mechanism are catalyst-driven growth from the solution/liquid phase into the solid state (SLS) and also from a supercritical liquid (fluid) solution (SLFS) into the solid state. The SLFS technique is synthetically complementary to the long-established technique of seed-mediated growth from solution, which yields one-dimensional colloidal metallic nanostructures [40]. In the former, a molecular precursor and in the latter a nanoparticle is decomposed under controlled conditions in solution or under supercritical conditions and then serves as a source for the metal catalyst particles from which the crystalline 1D structure grows (Figure 5.15) [41]. For this growth process from solution, low-melting metals as catalyst particles are essential (e.g., In, Bi, Sn). For metals with higher melting points (e.g., Au, Ge), supercritical solvent conditions have been successfully employed [41–43]. This synthetic technique allowed for the first time access to colloidal Au quantum wires which show a spectroscopic QSE.

5.4
Contacting the Outer World: Nanowires and Nanotubes as Building Blocks in Nano/Micro/Macro-Integration

The key for applying 1D structures in future nanotechnological applications will be first assembly of nanostructures and then integration of such assembled nanostructures into existing micro-building blocks and their subsequent packaging into larger structures to allow for micro and macro manipulation of these integrated

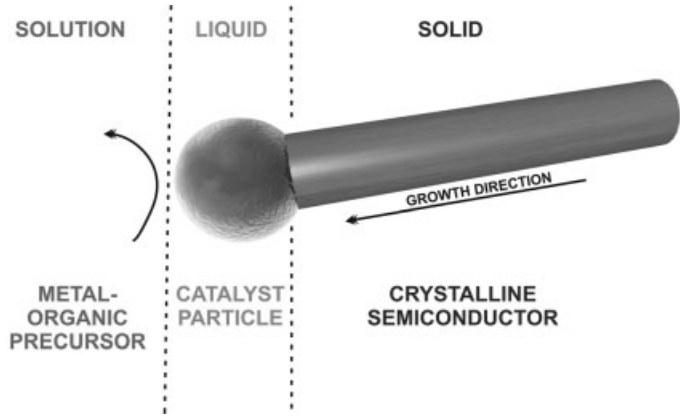

Figure 5.15 $S_{olution}L_{iquid}S_{olid}$ mechanism for nanowire growth from solution. Adapted from Ref. [41].

assemblies. This is especially challenging since a priori pertinent and incompatible length scales, nano vs. micro vs. macro, have to be bridged. Here the so called pitch problem is an important issue. It is related to the controlled formation of any nanowire structure into an array of individual wires packed into a defined order with definite distances between the individual objects.

For this purpose, techniques such as field-assisted assembly, fluid flow alignment and Langmuir–Blodgett techniques for placement and assembly of nanowires have been successfully studied and progress in these areas has been impressive in recent years. Precise positioning which allows the use of a huge number of 1D structures is no longer fiction [44–46]. Furthermore, the ability to develop even more powerful methods which have the potential to bridge that gap is still a major goal, especially for large-scale integration into electronic and sensing devices.

In 2003 it was still pointed out that "precise positioning of single-walled CNTs is beyond the capability of current growth and assembly technology and presents a major hurdle for CNT based electronic applications" [47]. In the following section selected examples of assembly and integration of 1D structures from different material classes will be highlighted to show current progress in that field.

5.4.1
Nanowire and Nanotube Sensors

Sensors based on a one-dimensional morphology (wire, tube) offer selective recognition for biological and chemical species of interest [48, 49]. This is based on their unique electronic and optical properties, which have been studied in detail either for isolated objects or in an unordered fashion for bundles of them. However, the control and use of well-arranged, aligned 1D structures have also made enormous progress within the last few years and have an impact on the applicability of such structures in sensor devices. The basis for this is the field effect transistor (FET) geometry, which

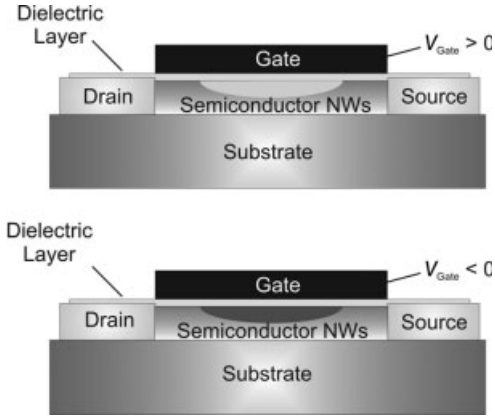

Figure 5.16 Schematics of field effect transistor (FET) geometry with nanowires as active channel material and different channel sensitivity. With a depletion of charge carriers conductance increases (upper FET schematic) When charge carriers are accumulated the conductance increases. For a p-type nanowire FET device, generation of positive charges on the nanowire's surface leads to a decrease in conductance. This can be induced, for example, by binding a protein to the wire's surface, which has a net positive charge in aqueous solution.

has been extensively explored as a device bridging the micro- and the nanoworld. In a FET device the contact between the source and drain electrode consists of a semiconductor. Its conductivity can be modulated by a third electrode, the gate coupled to the semiconductor by a dielectric layer through which charge is injected into the semiconductor. Since the binding of charged or polar molecules to the 1D semiconductor structure alters the channel electrode characteristics, this may lead to an accumulation or depletion of charge carriers and thus an increase or decrease in device conductance (Figure 5.16).

The idea was already put forth in the 1980s, but only for planar devices, which however, show only limited applicability for this sensor principle [50–52]. In a planar 2D film, only the near-surface region is altered by this effect, whereas in a single-crystalline rod surface, binding of an analyte has a strong impact on the depletion or accumulation of charge carriers in the overall structure of the nanoscale 1D object. The size of this effect depends, of course, on the size of the wire (which needs to be in the region of 2–5 nm) and its hybridization with a biomolecule (e.g., DNA). This can create a high charge density on the nanowire surface, which produces an electrostatic gating effect. This so-called field effect reduces the charge carrier concentration and results in an increase in resistance ($V_{gate} > 0$) (Figure 5.16).

With respect to CNT structures, recently the separation of metallic and semiconducting single-walled CNTs, albeit still in low quantities, has been achieved. Dielectrophoresis is the key to the nanoscale manipulation and separation of CNTs. An AC field induces polarization in a nanoscale object and this results in a force which can be used to manipulate and assemble nano-objects [53].

Dielectrophoresis in physiologically relevant saline solution has been performed and it has been shown that this technique is useful in manipulating nanowires across

electrode gaps in saline solutions. Individual carbon nanowires can be switched between bridging and unbridging events in microelectrode gaps. This may be important for, for example, contacting biomolecules, DNA recognition or protein binding, all of which typically operate in highly conducting aqueous saline solutions [54]. Also intriguing is the arrangement of semiconducting or metallic CNTs using electrophoresis techniques into highly integrated structures [55]. Altogether these findings these findings may pave the way to integrated sensor devices since they allow to use the whole individual tube length of the CNT as active element.

When dispersing commercial single-walled CNTs into an appropriate solvent with the aid of a dispensing polymer, printable and conductive inks have been obtained which allow the fabrication of robust, flexible, transparent (85%) and conductive (100 kΩ) single-walled CNT–polymer composite films on plastic substrates via inkjet printing. Their use as sensors for alcohol vapors under static and dynamic flow conditions has been reported [56]. Obviously no discrimination between metallic and semiconducting CNT can be made here. However, the approach's beauty lies in its simplicity of handling, storage and fabrication of mechanically stable, flexible and sensitive CNT sensor devices.

The precise alignment of single Si wires (diameter 20–30 nm) has been achieved by a combination of electrostatic positioning and conventional lithography (Figure 5.17) [57]. With this technique, the individual Si nanowire resistance and their contact resistance has been determined. It can be envisaged that this technique is capable of arranging 1D structures up to a high precision and opens up new avenues into sensing of single particles with individually arranged ensembles of nanowires.

Directed assembly of Si nanowires between two electrodes has been achieved by electrical field assembly out of a nanowire suspension. The aligned nanowires remained bound to the electrodes by van der Waals forces. So far arrays of 18 planar electrode pairs with micrometer spacings have been studied for nanowire alignment [58].

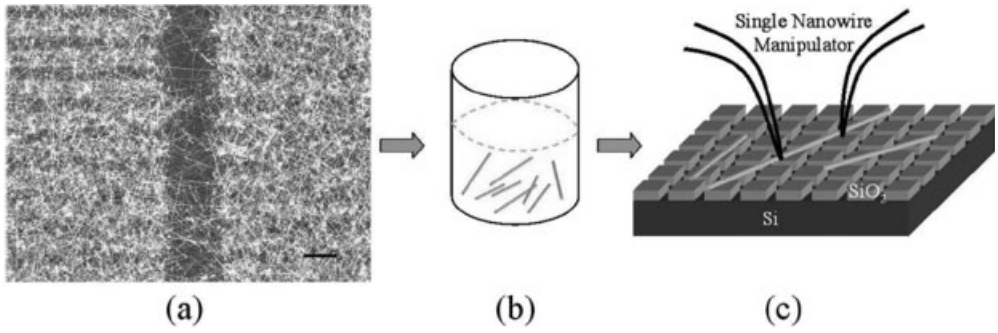

Figure 5.17 (a) SEM image of Si nanowires grown from patterned Au catalyst on a silicon wafer (VLS growth). Nanowires were removed into a suspension of deionized water. (b) A drop of the nanowire solution was dispersed on a template substrate and evaporated under vacuum. (c) Schematic of manipulator tips picking up a nanowire from a template substrate. The patterned structure of the template minimizes the adhesion forces of the wire.

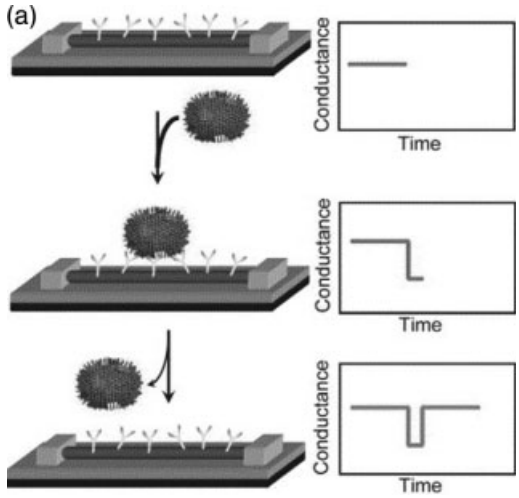

Figure 5.18 Schematic of a single virus binding and unbinding event at the surface of an Si nanowire device modified with antibody receptors and the corresponding time-dependent change in conductance. Reprinted with permission from Ref. [62].

The sensing mechanism in nanowires is due to a change in charge density on the wire's surface and probably deep into the "bulk" of the nanowire structure. This has been proposed to lead to ultrasensitive biosensors [59] and indeed was realized a few years later [60]. The upper sensing limitation of viruses as disease carriers and potential warfare agents with single-wire devices has been the subject of recent studies [61]. The working principle relies on the modification of a single wire, modified with antibody receptors (Figure 5.18) [62]. The corresponding time-dependent change in conductance is monitored. A real binding event monitored with an influenza A virus has been unraveled by measuring the change in the time-dependent conductance (Figure 5.19) [62].

With the use of the recently developed electrostatic positioning technique [57] for individual nanowires (see Figure 5.17), an integrated device configuration seems conceivable. Other successful approaches for assembling arrays of wires for multi-detection of analytes have been described [63]. Intriguing with respect to multiplexing methods for the detection of analytes is a transfer technique for arranging arrays of doped silicon wires on flexible plastic substrates. First, on to a prepatterned p-type doped Si substrate, highly aligned Si nanowires were prepared via anisotropic etching. Transfer on to plastic substrates was made possible by a polydimethylsiloxane (PDMS) stamping technique. Via selective chemical functionalization techniques of the Si nanowires using silanes, a sensor library with different end-group functionalization of the wires could be formed (Figure 5.20) [64]. This array finally worked as a highly sensitive integrated electronic nose for different vapors (Figure 5.21) [64].

The arrangement and contacting of up to 1 million cm^{-2} CNTs into individually contacted nanotube devices was achieved by dielectrophoretic deposition of metallic

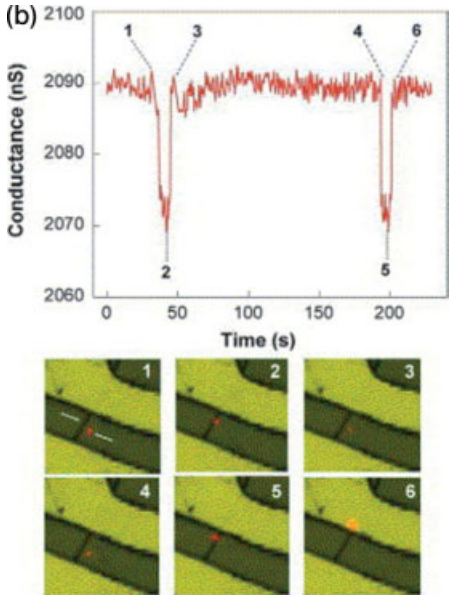

Figure 5.19 Simultaneous conductance and optical data recorded for an Si nanowire device after introduction of a influenza A virus solution. The images correspond to the two binding/unbinding events highlighted by time points 1–3 and 4–6 in the conductance data, with the virus appearing as a red dot in the images. Reprinted with permission from Ref. [62].

and semiconducting CNTs. The technique uses a field change occurring during nanotube deposition between individual electrodes of a preformed microstructured device (Figure 5.22) [55, 65]. Although not fully understood yet, redistribution of the electric field around the CNT in the gap seems to be important for the organization, rather than short-circuiting of the gap electrodes by the entrapped object [65].

In this approach, the overall dimensions of an individually contacted CNT device are only limited by the dimensions of the contacting electrodes rather than the

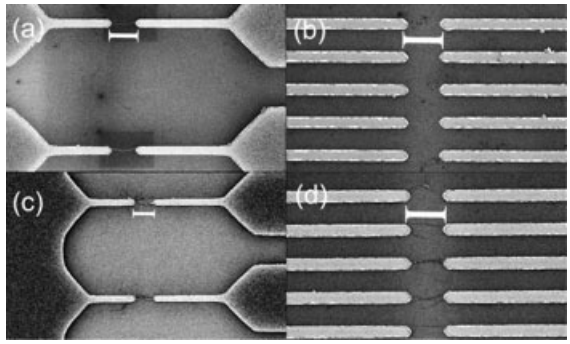

Figure 5.22 SEM images after nanotube deposition on chips with a designed electrode configuration. Effect of oxide thickness and counter electrode area of the chip on the directed assembly of nanotube devices, in terms of number of bridging nanotubes per electrode pair. Single nanotubes were assembled for 800-nm thick oxide layer and 10-μm^2 counter electrode area (a). No nanotubes were assembled for 800-nm oxide and 1-μm^2 electrode area (b). Only a few nanotubes were assembled for 50-nm oxide and 10-μm^2 electrode area (c). One or two nanotubes were assembled for 50-nm oxide and 1-μm^2 electrode area (d). Scale bars equal 1 μm in all images. Reprinted with permission from Ref. [55].

dimensions of the CNT itself. However, this seems to be the case for other approaches also [66]. So far the electrical device characteristics of over 100 CNTs have thus been measured individually. Only up to 10% of the electrodes were bridged by multiple CNTs [55].

Taking further into account the established routes for functionalizing CNTs [67], this approach seems viable for applying CNTs in a comparable way to that described above for Si wire arrays, for example, as sensor devices for the multiple detection of analytes. The field of immobilization of biomolecules is a sector of intense research activity [68]. Due to the electronic properties of individual CNTs (e.g., as semiconducting or metallic tubes), their sensing towards biomolecules could be very selective. Therefore, combining nanotubes with biosystems may provide access to nanosized biosensors. The first step for biomolecular interaction is the attachment of the biomolecule to the tube. This could be achieved either via a covalent bonding interaction or via a wrapping mechanism which uses non-covalent interactions, for example, on the basis of van der Waals interactions. The former needs functionalization of the CNTs followed by covalent bonding of the target biomolecule and is already well established. The latter rely on physisorption mechanisms and work typically for proteins.

For the development of covalent CNT functionalization techniques, a tool box of methods which have shown success in fullerene functionalization have been advantageously employed so far [67]. For example, for the case of functionalization of CNTs with bromomalonates containing thiol groups, attachment to gold surfaces is possible, allowing the synthesis of electrode arrays for sensor applications [69].

Chemical functionalization of CNTs has also paved the way to DNA–CNT adducts and subsequently to studies of their properties as biosensors. However, it seems that DNA attachment occurs mainly towards the end of the nanotubes [70]. This site-specific interaction points towards a sequence-specific poly(nucleic acid)–DNA base pairing rather than an unspecific interaction. This might be helpful for differentiation between two DNA sequences [68]. Pyrene functionalization of DNA itself can lead to a very specific DNA–CNT adduct. Its stability is mediated via hydrophobic interactions of the graphite-type sidewalls of the nanotubes and the pyrene anchors of the DNA [71].

DNA–CNT adducts are highly water soluble and therefore DNA functionalization of nanotubes avoids the use of surfactants, which are often used to solubilize CNTs alone. As with native DNA, the adducts with CNTs are still charged species. Specific DNA sequence detection with electrochemical CNT–DNA biosensors has been reported [72]. So far still a theoretical promise, the specific size-selective major groove binding mechanism of B-DNA towards single-walled CNTs could lead to a composite structure with unique sensor properties for ultrafast DNA sequencing or electronic switching based on the combination of the individual electronic properties of the single components CNT and DNA joined together in this composite structure (Figure 5.23). [73].

In this respect, it is intriguing to see the results that a strong binding capability of the major groove of DNA towards 0D nanoparticles has already been proven for gold nanoclusters, both theoretically and experimentally [74].

Figure 5.23 Theoretically proposed DNA–CNT composite structure. The single-wall CNTs are intercalated within the major groove of DNA. Adapted from Ref. [73].

5.4.2
Piezoelectrics Based on Nanowire Arrays

Converting mechanical energy into electric energy or signals is the area of piezoelectronics and relies on specific structures and morphologies of materials. Recently, nanomaterials have come into the focus of this application-driven area. ZnO is a material which probably exhibits the most diverse morphological configurations of any nanomaterial so far studied in detail. In addition to particles and wires there are nanobelts, nanosprings, nanorings, nanobows and nanohelices known and

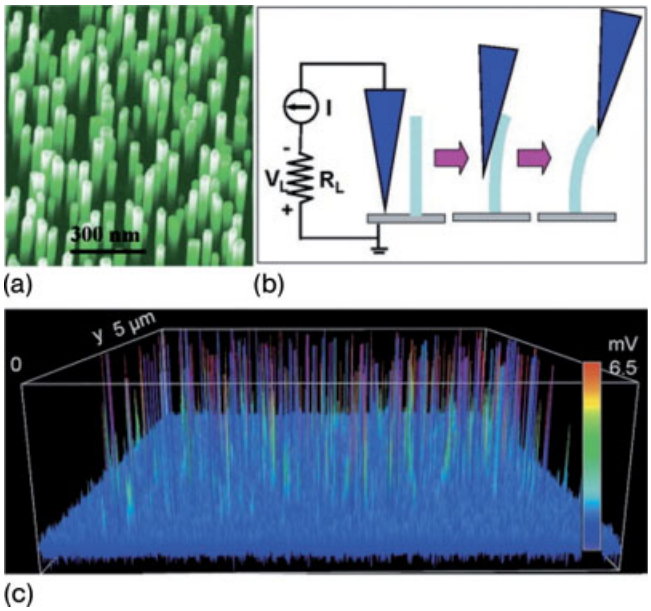

Figure 5.24 Scanning electron microscopy (SEM) images of aligned ZnO nanowires grown on an α-Al_2O_3 substrate (a). Experimental setup for generating electricity through the deformation of a semiconducting and piezoelectric nanowire using a conductive AFM tip. The root of the nanowire is grounded and an external load of $R_{load} = 500$ MW is applied, which is much larger than the inner resistance R_{inner} of the nanowire (b). The AFM tip is scanned across the nanowire array in contact mode. Output voltage image obtained when the AFM tip scans across the nanowire array (c). Reprinted with permission from Ref. [78].

characterized for ZnO [75]. Apart from use as a catalyst and sensor material which can be considered as more traditional areas for 1D nanoscale ZnO [76], the semiconducting and piezoelectric properties of ZnO nanowire arrays have recently been probed as piezoelectrics with unique properties. Such a ZnO-based nanogenerator converts mechanical energy into electric power and vice versa using massively aligned ZnO nanowires (Figure 5.24) [77, 78]. An electric field is created by deformation of a ZnO nanowire within the array by the piezoelectric effect. Across the top of the nanowire the potential distribution varies from negative at the strained side of the surface (V_s^-) to positive at the stretched surface (V_s^+). This potential difference is measured in millivolts and is due to the piezoelectric effect. On an atomic scale, the displacement of Zn^{2+} ions in the wurtzite lattice with respect to the O^{2-} counterions is responsible for that. The charges cannot move or combine without releasing strain via mechanical movement. As long as the potential difference is maintained (via constant deformation), the system is stable. When external free charges (e.g., via a metal tip) are induced, the wire is discharged. As an effect, the current which then flows is the result of the ΔV (V_s^+/V_s^-)-driven flow of electrons from the semiconducting ZnO wire to the metal tip. This flow of electrons neutralizes the ionic charges in the volume of the ZnO wire and reduces the potentials V_s^+ and V_s^- [78, 77].

The potential technological impact of such a nano-piezoelectronic effect might be in converting various type of energies (mechanical, vibration, hydraulic) into electrical energy. Thus extremely large deformations are possible, which are interesting for flexible electronics as a power source and realizing a much larger power/volume density output. The effect has already been shown to work for field effect transistor devices [79], piezoelectric gated diodes [80] and piezoelectric resonators [81], all on a ZnO material basis.

5.4.3 With Nanowires and Nanotubes to Macroelectronics

Using top-down techniques for scaling conventional microelectronic devices has by now reached the size regime of about 50 nm with a gate length of about 30 nm for a FET. This demonstrates impressively how far the conventional top-down technique using lithography, deposition techniques and etching methods have developed. Nevertheless, scaling down characteristic feature sizes and the channel gate length even further seems limited using these techniques.

On the other hand, despite tremendous success in recent years, incorporating nanosized materials into typical FET device architectures is still in its infancy. Exciting new developments have been reported over the last few years which might have the potential to bridge the nano–micro–macro gap for certain device architectures. Due to their aspect ratio, 1D materials can be produced in micrometer-long structures, but displaying nanometer size diameters. Hence they are *a priori* ideally suited to be incorporated in current microdevice technology.

Due to the possibility that a variety of semiconductor nanowires, including the workhorse element Si, show great promise to be processable from solution, a couple of areas of high technological input might appear on the horizon for such materials (e.g., flat panel displays or flexible solar cells). Especially when these nanomaterials are available as single-crystalline matter in 1D morphology, they show electronic performances even exceeding those of high-quality macro (bulk)-sized single crystals or thin films. Combining their high electronic performance with the possibility of arranging 1D inorganic nanowires over larger dimensions offers the ability finally to bridge the gap from nano- over micro- to macroelectronics and thus puts these materials one step closer to the realm of application.

5.4.3.1 Inorganic Nanowire and Nanotube Transistors

In general, inorganic semiconductors have the intrinsic advantage over organic-based semiconductors that the electronic mobility μ (electron–hole) usually drastically exceeds those of organic materials. The mobility μ is the proportionality constant between an applied electric field and the corresponding average charge carrier drift velocity. It is therefore a direct measure of the switching speed of an electronic device. The carrier mobility thus depends critically on the crystallinity of the material. In inorganic semiconductor wires of high crystallinity, a high order of atomic or molecular building blocks over long distances is maintained due to strong ionic or covalent bonds, whereas in organic semiconductors the mobility μ seems fundamentally

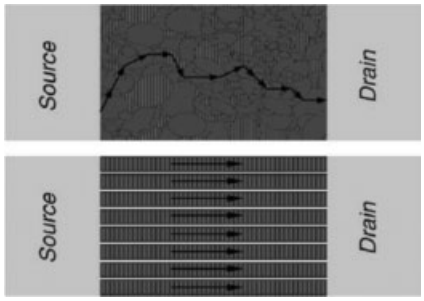

Figure 5.25 In polycrystalline silicon thin field effect transistors (TFTs), electrical carriers have to travel across multiple grain boundaries, resulting in low carrier mobility. Nanowire TFTs have conducting channels consisting of multiple single-crystal nanowires in parallel. Therein charges travel from source to drain within single crystals, ensuring high carrier mobility. Reprinted with permission from Ref. [82].

limited due to weak van der Waals bonds between electronically active molecular building blocks. This situation is a general one for an inorganic crystalline semiconductor compared with crystalline organic ones.

It is important for the exploitation of inorganic semiconductor nanowires to integrate them in massive arrangements in semiconductor devices, for example, thin-film transistors (TFTs), in which they might offer an increased electronic performance and future device integration. The former is due to the fact that drastically higher charge carrier mobilities μ can be obtained when using multiple single-crystal nanowires in FET devices instead of polycrystalline thin films (Figure 5.25) [82].

In a poly-Si TFT channel material, the electrical carriers have to travel across multiple grain boundaries (curved pathway), whereas in a massive parallel-arranged single-crystal nanowire array, charge carriers travel from source to drain within a single-crystalline structure, which ensures a high carrier mobility μ. The same effect has been observed, for example, for compound semiconductors such as ZnO. First sintering of isolated ZnO 0D nanoparticles has to be employed to obtain coarse grain polycrystalline thin films (Figure 5.26) [83]. When comparing the electronic performance of polycrystalline ZnO thin films with that of single-crystalline ZnO nanowires deposited between the source and drain of a FET device, the performance of ZnO nanowires is intriguing (Table 5.1).

Calculations have shown that for a channel length (geometric source to drain distance) of 20 μm in a FET device, the number of grain boundary contacts is diminished by a factor of 6 compared with a polycrystalline ZnO semiconductor electrode against one composed of a 1D wire morphology. In addition, the reduced hoping frequency for the charge carriers across the grain boundaries in the 1D ZnO structures compared with the polycrystalline ZnO thin-film morphology adds towards their increased mobility (Figure 5.27) [85]. One may imagine how this can

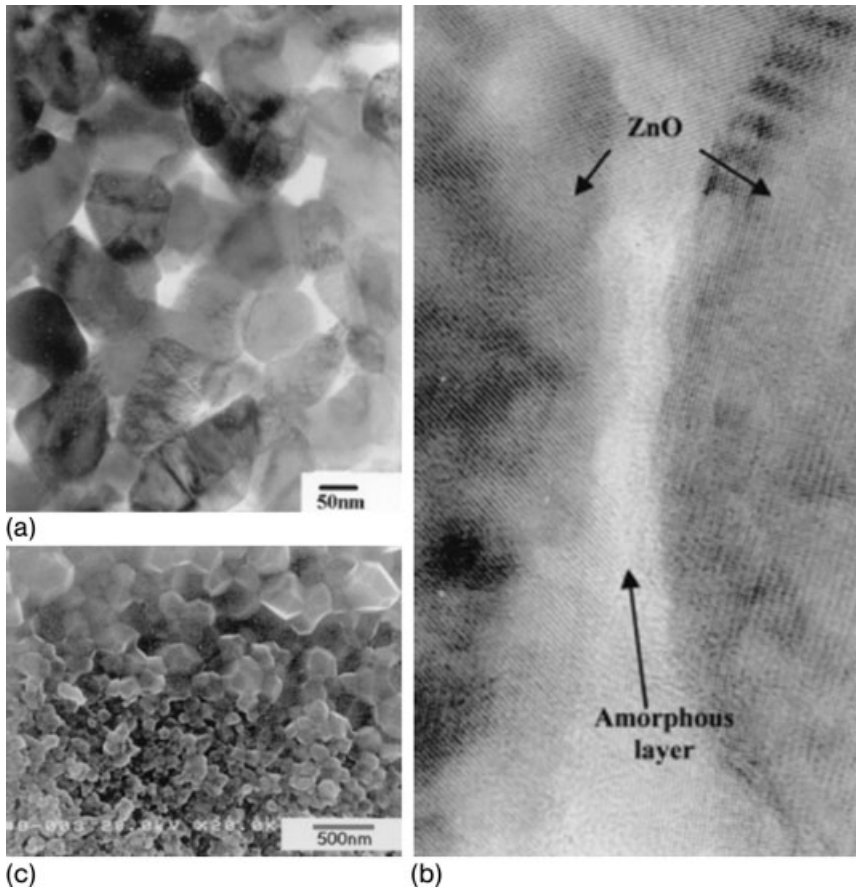

Figure 5.26 Transmission electron microscope (TEM) image of a nanocrystalline ZnO film. Processing temperature 550 °C (a); TEM of the grain boundary of two ZnO nano particles (b), Processing temperature 600 °C, sintered ZnO nanostructures can be observed (c). be further improved if it were possible to arrange such wires in a massive parallel fashion.

Dramatically higher carrier mobilities for well-aligned single-walled CNTs compared with randomly oriented networks of CNTs [86] have been measured [87]. The CNT alignment was achieved along the $[21\bar{0}]$ plane of a right-handed α-quartz substrate. The process is attractive since Y-cut α-quartz is a commercial substrate. The tube orientation is so far not fully understood, but is directed along step edges and/or micro/nanofacets on the surface of the quartz (Figure 5.28). Device mobilities of up to 125 $cm^2 V s^{-1}$ have been measured, which correspond to individual tube

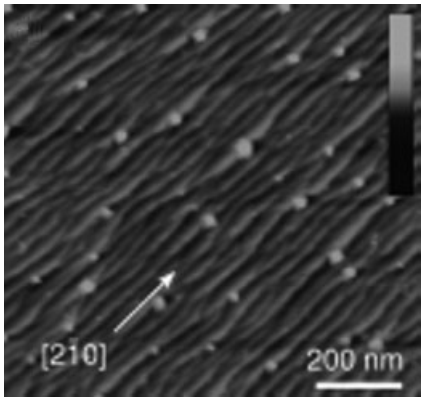

Figure 5.28 AFM image of terraced quartz surface structures after thermal annealing. The steps are 0.7–1 nm in height with spacing 30–35 nm. The dots seen are ferritin-derived Fe catalyst particles. Scale bar, 5 nm height. Reprinted with permission from Ref. [87].

mobilities within the array comparable to those already measured in pristine single tubes. These results clearly indicate that alignment of 1D nanostructures is crucial for the most effective device integration of CNTs [87].

The channel conductivity for nanowire and nanotube transistor devices has been treated theoretically and a universal analytical description has been developed. It has been found that the transconductance of the channel differs from classical device theory because of the specific nanowire charge distribution. Mainly different electrostatics for the 1D channel structure are responsible for the different device characteristics [88].

Due to the microscale length dimensions in which many semiconductor nanowire materials are obtainable, large-area substrates such as standard FET device structures can already be applied in device fabrication using 1D nanomaterials. An intriguing example is the arrangement of crystalline, several tens of micrometer long Si nanowires, which have been arranged between the source and drain of a FET device from a solution-derived process (Figure 5.29) [84]. Therein growth and integration of the particular nanowire material are separated from the device fabrication. Wire synthesis is done via a CVD approach, which of course is not compatible with the device fabrication process. However, the wires can be solution processed and in a second follow-up step deposited in a highly aligned fashion. The two-step route is applicable to sensitive FET substrates such as plastics and points towards a general route for future integration of nanowires into micro–macro integrated device architectures. Always a single-crystalline Si wire connects the source and drain; the distance between such individual wires is 500–1000 nm. This assures that

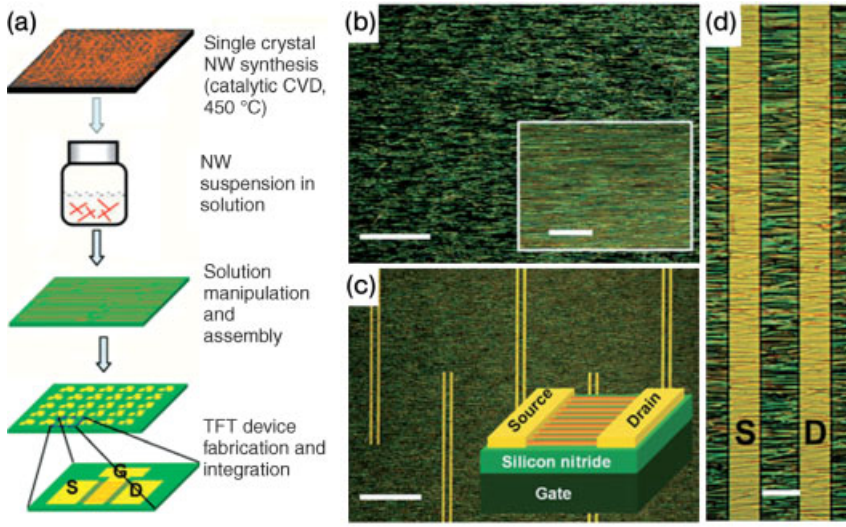

Figure 5.29 Scheme of parallel aligned crystalline Si nanowires between source and drain structure of a FET (b–d). Distance between individual wires is 500–1000 nm and can be adjusted via the solution deposition process (a). Reprinted with permission from Ref. [89c].

the wires have no contact. Extraordinary high charge carrier mobilities have been realized [82, 89].

The idea of separating the two individual processes, (i) material synthesis and (ii) materials processing, into device architectures has been used to arrange semiconductor nanowires on flexible polymer-based substrates. Seminal to the development of this field of printed inorganic devices was probably the report of the first printed all-inorganic thin-film field effect transistor based on 0D CdSe nanoparticles [90].

Synthesis of semiconductor rods or wires was performed, for example, via a CVD process on a silicon wafer. First the wafer-based source material was structured via a lithographic etching procedure. This technique works for a variety of 1D materials such as single-walled CNTs, GaN, GaAs and Si wires [84a]. An independent dry transfer process of the previously synthesized nanowires using an elastomeric stamp-based printing technique involves transfer of the 1D structures to a flexible substrate, for example, polyimide. It was thus possible to fabricate transistor devices with the highest electronic performance and also very high mechanical flexibility (Figure 5.30).

A general applicable condensed-phase approach for the alignment of nanowires uses the Langmuir–Blodgett technique [91]. It allows a massive parallel arrangement on planar substrates. The technique can be used in a layer-by-layer process allowing crossed nanowire structures with defined pitch to be formed (Figures 5.31 and 5.32). Moreover, this approach may allow the use of nanowires of different composition within the layering process. This gives rise to organized nanowire heterostructures.

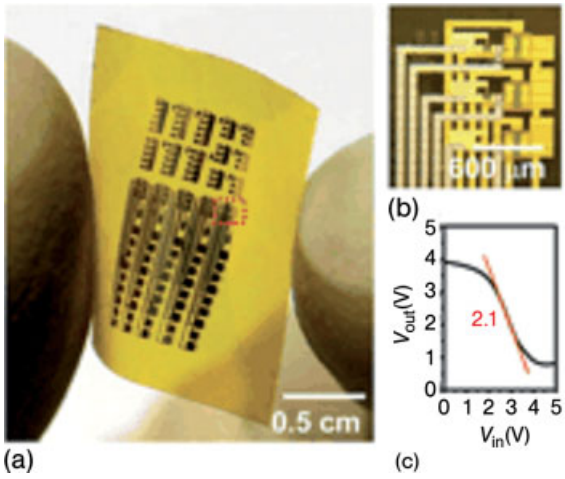

Figure 5.30 (a) Image of a printed array of 3D silicon n-channel metal oxide semiconductor inverters on a polyimide substrate. The inverters consist of MOSFETs (channel lengths of 4 μm, load-to-driver width ratio of 6.7 and a driver width of 200 μm) on two different levels. (b) View of the region indicated by the red box in (a). (c) Transfer characteristics of a typical inverter. Reprinted with permission from Ref. [89b].

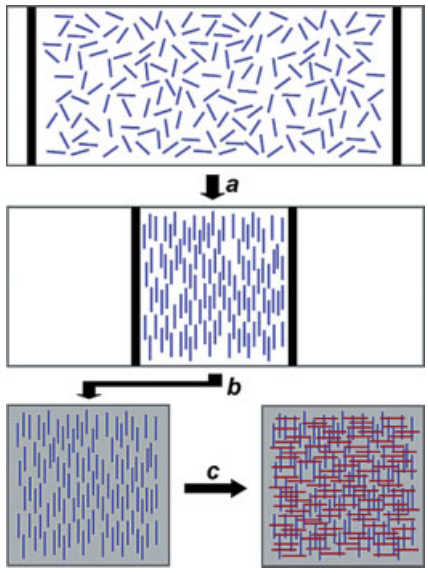

Figure 5.31 Nanowires (blue lines) in a monolayer of surfactant at the air–water interface are (a) compressed on a Langmuir–Blodgett trough to a specified pitch. (b) The aligned nanowires are transferred to the surface of a substrate to make a uniform parallel array. (c) Crossed NW structures are formed by uniform transfer of a second layer of aligned parallel nanowires (red lines) perpendicular to the first layer (blue lines). Reprinted with permission from Ref. [91].

Due to the hierarchical scaling of the structures from the nanometer up to the micrometer regime, reliable electrical contacting is possible.

Molecular precursors for the synthesis of polycrystalline silicon wires represent a promising alternative route to the widely employed synthetic CVD technique to inorganic semiconductor materials. Known since the early days of organosilicon chemistry, hydrogenated silicon compounds are known as chain (Si_nH_{2n+2}) or ring molecules (Si_nH_{2n}). For $n \geq 3$, these molecules are liquids and decompose around

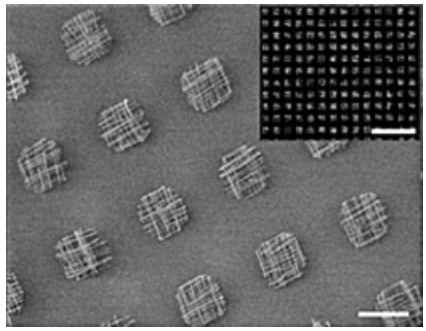

Figure 5.32 SEM image of patterned crossed nanowire arrays; scale bar 10 μm. Inset: Large area dark-field optical micrograph of the patterned crossed nanowire arrays; scale bar 100 μm. Reprinted with permission from Ref. [91].

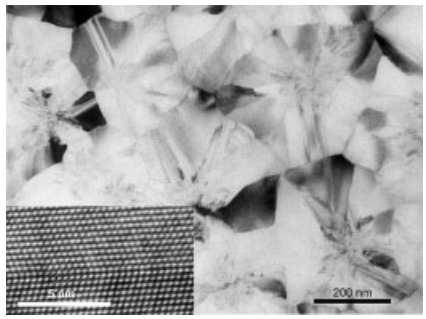

Figure 5.33 The polycrystalline Si thin film was formed by spin-coating and baking of the liquid single source Si_5H_{10} precursor followed by laser crystallization. The TEM inset picture highlights the atomic image of the silicon crystal. Grain size in the film is about 300 nm, which is comparable to that of conventional CVD-formed poly-Si film. Reprinted with permission from Ref. [92].

300 °C to give Si. Using cyclopentasilane Si_5H_{10}, thin films of this precursor have been solution processed and converted to polycrystalline Si (Figure 5.33) [92].

This route is compatible with inkjet printing and has been used to set up a complete TFT device architecture via printing. Charge carrier mobilities of 6.5 $cm^2 V^{-1} s^{-1}$ have been reported [92]. Other FET device architectures have also been studied using nanowires as active materials. FETs with surrounding gates have been synthesized and their electrical performance studied for Si [93]. Similar structures have been fabricated for InAs as active semiconductor. InAs performs with a high electron mobility and tends to form ideal ohmic contacts to many metals (Figure 5.34) [94]. Such structures are expected to show enhanced transconductance along the wire [95].

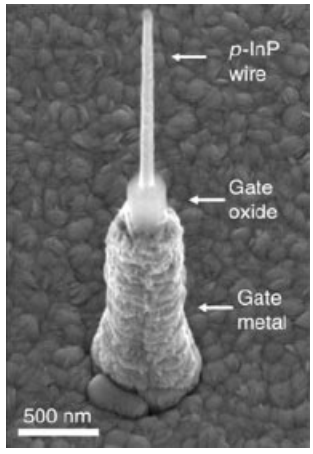

Figure 5.34 SEM micrograph of a vertical device with surrounding gate structure consisting of a p-type InP wire covered with gate oxide and gate metal. Reprinted with permission from Ref. [94].

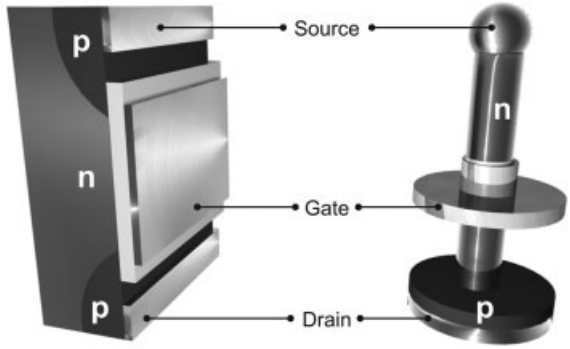

Figure 5.35 Schematics of a conventional p-channel MOSFET and a silicon nanowire surround gate FET. Adapted from Ref. [96].

A complete flow process for the fabrication of a silicon nanowire array with vertical surround gate FETs has been devised (Figure 5.35) [96]. Such an architecture was proposed earlier for CNTs but inorganic nanowires have the advantage that they can be grown as mechanically stiff vertical objects, whereas this is more complicated with single-walled CNTs [97].

Surround gate-type FETs have also been reported for Ge nanowire arrays. First, the nanowire array with the surround gate shell structure is synthesized via a multistep CVD process, followed by patterning of the nanosized core shell $Ge/Al_2O_3/Al$ from solution on to an Si substrate. Finally, the structure is electrically contacted. This leads to a macroscopic device with a multiple number of surround gate nanowires arranged in a quasi-parallel fashion (Figure 5.36) [98].

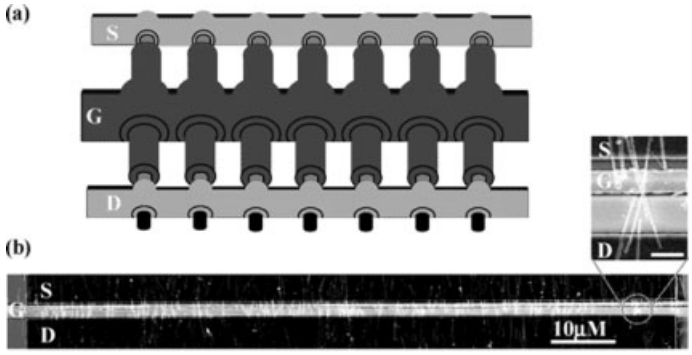

Figure 5.36 Transistor comprised of multiple surround-gate nanowires in parallel. (a) An idealized schematic presentation of a device. (b) SEM image of a device with ~35 surround gate nanowires in parallel. Crossing wires (each with its own gate shell) are seen in the zoomed-in image (scale bar = 1 μm). Reprinted with permission from Ref. [98].

5.4.3.2 Branched Nanowire Structures

Growth of 1D nanowires into certain defined directions leads to branched nanowire structures. In these, a higher degree of complexity is reached than in isolated wires. For example, the number of connection points and interconnecting possibilities to other nanostructures are enhanced compared with classical 1D structures. Their potential as interconnects for nanoelectronics, for example, circuiting, is obvious and certainly drives research into that area to some extent. One prerequisite for forming branched nanowire structures is the wide ability of semiconductors to undergo polymorphism, its characteristic feature to exist in more than one stable crystal structure.

Due to their nanosized dimensions, efficient strain release due to lattice mismatch of element combinations is much more efficient in nanowire architectures than in bulk film heterostructures of semiconductors. Therefore, lattice mismatches of $>3\%$ are not detrimental for a sharp interface growth process of wires [99]. In recent years, the scope of materials within the area of branched nanowire structures has broadened significantly. Condensed-phase (solution) and gas-phase synthetic techniques, the latter based on both physical vapor and chemical vapor deposition, have been used successfully to generate branched structures for many elemental combinations [100]. Compositions such as CdSe, PdSe, CdS, MnS and CdTe have been made available through solution-based techniques [101]. A successful technique to initiate branching of individual nanorods is to add nanoparticles as new growth sites. This has been demonstrated for GaP, InP, Ga As, AlN and GaN [102]. Successful studies even towards the hierarchical growth of interconnected nanobranched structures have been undertaken and reviewed recently [103]. Again, ZnO is a material which has shown an enormous breadth of structures with branched characteristics [104]. The growth of ZnO tetrapods is well understood and may serve as a model system to illustrate some general points of the growth of branched nanostructures. Although several models have been discussed and differ in some detail, it is accepted that growth of the cylindrical arms of a tetrapod proceeds via nucleation of a core structure. As determined by detailed high-resolution transmission electron microscopy studies, a zinc blende structure represents the core structure from which wurtzite arms grow. The former thus serve as seed templates for wurtzite arm growth. Growth of the $[00\bar{1}]$ wurtzite facets is outwards from the four [111] crystal faces of the zinc blende seeds. The same growth mode has been discussed for CdSe and CdTe tetrapod architectures [105]. Although the synthesis and growth of ZnO tetrapods is well studied, the electronic properties of this architecture have only recently been addressed.

Making electrical contacts to the edges of the tetrapod nanocrystal is, of course, difficult. A diode configuration has been realized with rectification characteristics (W forms an ohmic contact, Pt forms a Schottky contact to the tetrapod) (Figure 5.37) [106].

Branching out of nanowires has been achieved by using Au particles as catalyst seeds, resulting in the formation of Group III and V compound semiconductor rods (Figure 5.38).

Au catalyst particles are prepared via a gas-phase aerosol process and are size selected using a differential mobility analyzer [107]. The wire growth process is

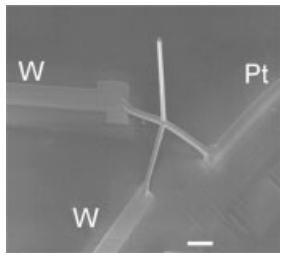

Figure 5.37 SEM image of a ZnO tetrapod with two W contacts and one Pt contact made to each arm of the structure. Scale bar = 1 μm. Reprinted with permission from Ref. [106].

repeated on the initially formed nanowire trunks to yield finally the branch structure in a follow-up process step. In this second process step, individual synthesis conditions, for example, the molecular wire precursor, can be varied, giving rise to branched nanowire heterostructures. The individual nanowire diameter of the branches is determined by the Au catalyst particle size; however, additional deposition of material on the side facets of the wires leads to thickening of the wires, and a tapered structure is therefore often observed [108].

The hierarchical growth of already branched nanowire structures to higher organized ensembles can also be realized in a solution-based growth process [105]. The precursor (e.g., an elemental chalcogenide) and a capping agent [e.g., an alkyl

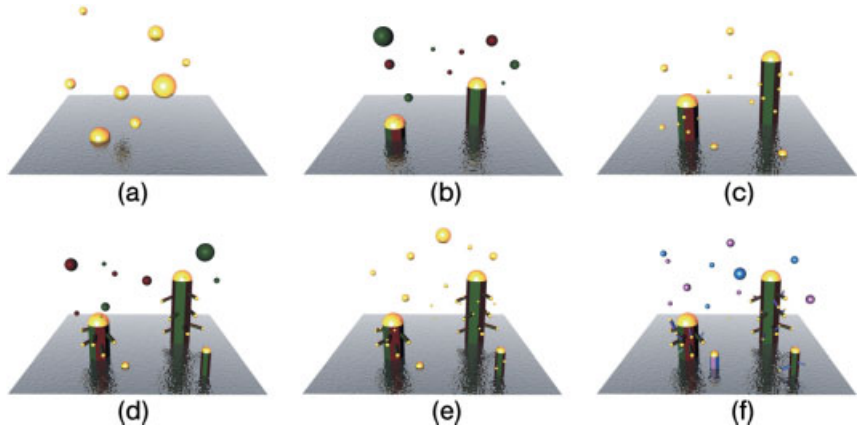

Figure 5.38 Branched nanowire and hetero nanowire formation process. Au particles are deposited on a substrate (a); precursor molecules (arrows) are introduced at elevated temperatures and combine beneath seed particles to form compound nanowire trunks (b); a second set of Au particles is deposited onto these trunks (c); branched nanowires grow in the same way as for (b) in (d); a third set of Au particles is introduced (e), followed by a new set of precursor molecules, which results in the growth of branched hetero nanowires (f). Adapted from Ref. [108].

(aryl)phosphine] first initiates the nanorod growth, followed by branching due to the facetted growth mechanism into a nanotetrapod structure. An end selective extension and further branching of such nanotetrapods are then possible by adding a new precursor to the same mixture. However, removal of the nano-objects from the initial synthesis mixture of the grown nanostructures, redispersion and regrowth, for example, with a different precursor, are also possible and allow further hierarchical growth at the ends of the original tetrapod structures. This growth gives rise to the formation of branched heterostructures. Thus, interfaces with different compositions can be designed in these structures, allowing control over charge carriers (electrons or holes) due to tailoring of the interface.

A detailed catalyst-driven (via Au aerosol particles) growth study of branched heterostructures by combining Group III–V materials, GaAs, GaP, InP and AlAs, has led to the conclusion that the growth mechanisms of such heterostructures depend on the relationship of the interface energies between the growing materials and the catalyst particle. It turned out that the growth of straight heterostructures in a particular direction seems favored over growth in another direction.

Finally, comparing gas-phase techniques and solution-based routes to branched nanowire structures, both methods show great potential towards the synthesis of higher organized morphologies based on 1D wires. It is remarkable that in both synthetic approaches the growth can be initiated on already formed branched structures just by adding fresh catalyst particles. However, the solution-based methods surely are favored due to the relative ease of formation of such structures and their further assembly potential towards higher organized multibranched wire structures. One further step towards this end has been demonstrated by tipping the ends of individual CdSe rods or tetrapods on both sides with Au nanoparticles, in solution (Figure 5.39) [109].

Although already a truly composite structure on its own (e.g., the excitonic spectra of the CdSe nanorod structure and the plasmonic Au spectra are not a superposition of the individual features of the individual semiconductor material and the metal nanoparticle), functionalization of the nanoparticle ends with alkanedithiols has led to assembled lines of individual composite nanowires (Figure 5.39) [109].

Figure 5.39 Schematics of dumbbell-like structures of a CdSe nanorod with Au gold tips at both ends. Single CdSe dumbbell doubly tipped with Au nanoparticles (a); typical unordered arrangement of Au tipped CdSe nanorods, where the Au tip size can be varied by increasing the $AuCl_3$ concentration during tip growth (b); self-assembled chain of nano CdSe dumbbells (real size 29 × 4 nm) formed by adding hexanedithiol bifunctional linker molecules which connect Au tipped ends of CdSe dumbbells. Adapted from Ref. [110].

5.5 Outlook

Studies towards functionality in inorganic 1D materials are an interesting and interdisciplinary field, bringing together fundamental science and opening up opportunities towards possible applications of these materials in various areas. Directed, organized growth of such 1D objects is surely a key in most of the envisioned areas of application of nanoscience.

In recent years, it has become clear that in addition to a bottom-up synthetic approach to 1D nanomaterials, a top-down approach which allows structuring, assembly and integration of 1D nanomaterials on the next higher length scale is necessary to organize and use 1D materials as building blocks in functional devices. The question no longer seems to be which of the two techniques, bottom-up or top-down, is the more powerful approach to new functional devices, but rather how we can make use in the most efficient way of both technologies to bridge the dimension gap: nano–micro–macro. In areas where current microtechnologies and materials are best compatible with bottom-up techniques for the synthesis and handling of 1D nanomaterials, they already work hand in hand and the unique properties of, for example, 1D materials have to be exploited successfully. This has already been demonstrated in current electronic and optoelectronic devices such as field effect transistors, light-emitting diodes, gas sensors and nanoresonators [110]. A key to this development of the field is certainly strong interdisciplinary research efforts between chemists, physicists and engineers.

Biomolecule–Nanoparticle Hybrid Systems

Maya Zayats and Itamar Willner

6.1
Introduction

Metal and semiconductor nanoparticles (NPs) or quantum dots (QDs) exhibit unique electronic, optical and catalytic properties. The comparable dimensions of NPs or QDs and biomolecules such as enzymes, antigens/antibodies and DNA suggest that by the integration of the biomolecules with NPs (or QDs) combined hybrid systems with the unique recognition and catalytic properties of biomolecules and with the electronic, optical and catalytic features of NPs might yield new materials with predesigned properties and functions. For example, metallic NPs, such as Au or Ag NPs, exhibit size-controlled plasmon excitons. These plasmon absorbance bands are sensitive to the dielectric properties of the stabilizing capping layers of the NPs [1, 2] or to the degree of aggregation of the NPs that leads to interparticle-coupled plasmon excitons [3, 4]. Thus, spectral changes occurring in metal NP assemblies as a result of biomolecule-induced recognition events that occur on NP surfaces and alter the surface dielectric properties of the NP or stimulate aggregation might be used for optical biosensing. Similarly, semiconductor QDs reveal size-controlled absorption and fluorescence features [5–7]. The high fluorescence quantum yields of QDs and the stability of QDs against photobleaching can be used to develop new fluorescent labels for optical biosensors [8, 9]. Alternatively, metallic NPs exhibit catalytic functions reflected by their ability to catalyze the reduction and growth of the NP seeds by the same metal or a different metal to form core–shell NPs. These properties may be applied to form NP-functionalized proteins or nucleic acids that provide hybrid systems that act as electroactive labels for amplified biosensing [10, 11] or as templates for growing nanostructures [12]. Furthermore, the coupling of biomolecules to metallic or semiconductor NPs might allow the use of the electron-conducting properties of metal NPs or the photoelectrochemical functions of semiconductor NPs to develop new electrical or photoelectrochemical biosensors. Indeed, tremendous scientific advances have been achieved in the last few years by conjugating biomolecules and NPs to functional hybrid systems. Numerous new

biosensors and bioanalytical paradigms were developed, and substantial progress in the use of these hybrid systems as building units of nanodevices was achieved. Several comprehensive review articles addressed different aspects and future perspectives of biomolecule–NP hybrid systems [13–18]. This chapter is aimed at summarizing the different venues where the unique optical and electronic properties of biomolecule–NP hybrid systems have been applied and to discuss future opportunities in the area. Naturally, this review is not aimed at providing full bibliographic coverage of the different topics, but it will highlight the different scientific directions that use biomolecule–NP hybrid systems, and address some specific examples.

6.2
Metal Nanoparticles for Electrical Contacting of Redox Proteins

The electrical contacting of redox proteins with electrodes is a key issue in bioelectronics. Numerous redox enzymes exchange electrons with other biological components such as other redox proteins, cofactors or molecular substrates. The exchange of electrons between the redox centers of proteins and electrodes could activate the bioelectrocatalytic functions of these proteins and thus provide a route to design different amperometric biosensors. Most of the redox proteins lack, however, direct electron transfer communication with electrodes, and hence, the bioelectrocatalytic activation of the redox enzymes is prohibited. The lack of electrical contact between the redox centers and the electrode surfaces is attributed to the spatial separation of the redox sites from the electrode by means of the protein shell [19]. Different methods to electrically communicate redox enzymes with electrodes were developed, including the application of diffusional electron mediators [20], tethering redox relays to the proteins [21–23] and the immobilization of redox proteins in electroactive polymers [24–26]. A recently developed procedure for the electrical contacting of redox proteins with electrodes involved the extraction of the native redox cofactor from the protein and the reconstitution of the resulting apo-enzyme on a surface modified with a monolayer consisting of a relay tethered to the respective cofactor units [27–30]. The reconstitution process aligned the protein on the electrode surface in an optimal orientation, while the relay units electrically contacted the cofactor sites with the conductive support, by shortening the electron transfer distances [31]. All of these methods permitted the bioelectrocatalytic activation of the respective enzymes and the development of amperometric biosensors and biofuel cells, [32, 33].

The availability of metal nanoparticles exhibiting conductivity allowed the generation of nanoparticle–enzyme hybrid systems for controlled electron transfer [34, 35]. Recently, highly efficient electrical contacting of the redox enzyme glucose oxidase (GOx) through a single Au nanoparticle (Au NP) was demonstrated [36]. The GOx–Au NP conjugate was constructed by the reconstitution of an apo-flavoenzyme, apo-glucose oxidase (apo-GOx) on a 1.4-nm Au_{55} nanoparticle functionalized with N^6-(2-aminoethyl) flavin adenine dinucleotide (FAD cofactor, amino derivative, **1**). The resulting enzyme–NP conjugate was assembled on a

thiolated monolayer by using different dithiols (**2**–**4**) as linkers [Figure 6.1(A), route a]. Alternatively, the FAD-functionalized Au nanoparticle was assembled on a thiolated monolayer associated with an electrode, and apo-GOx was subsequently reconstituted on the functional nanoparticles [Figure 6.1(A), route b]. The enzyme electrodes prepared by these two routes revealed similar protein surface coverage of about 1×10^{-12} mol cm^{-2}. The Au NP was found to act as a nanoelectrode that acted as relay units transporting the electrons from the FAD cofactor embedded in the protein to the electrode with no additional mediators, thus activating the bioelectrocatalytic functions of the enzyme. Figure 6.1(B) shows the cyclic voltammograms generated by the enzyme-modified electrode, in the presence of different concentrations of glucose. The electrocatalytic currents increase as the concentrations of glucose are elevated, and the appropriate calibration curve was extracted [Figure 6.1(B), inset]. The resulting nanoparticle-reconstituted enzyme electrodes revealed unprecedented efficient electrical communication with the electrode (electron transfer turnover rate about 5000 s^{-1}). This effective electrical contacting, far higher than the turnover rate of the enzyme with its native electron acceptor, oxygen (about 700 s^{-1}), made the enzyme electrode insensitive to oxygen or to ascorbic acid or uric acid, which are common interferents in glucose biosensing. The rate-limiting step in the electron transfer communication between the enzyme redox center and the electrode was found to be the charge transport across the dithiol molecular linker that bridges the particle to the electrode. The conjugated benzenedithiol (**4**) was found to be the most efficient electron-transporting unit among the linkers (**2**–**4**).

A similar concept was applied to electrically contact pyrroloquinoline quinone (PQQ)-dependent glucose dehydrogenase [37]. Apo-glucose dehydrogenase (apo-GDH) was reconstituted on PQQ-cofactor units (**5**) covalently linked to the amino-functionalized Au NPs [Figure 6.2(A)]. The electrocatalytic anodic currents developed by the enzyme-modified electrode, in the presence of variable concentrations of glucose, are depicted in Figure 6.2(B). The resulting electrocatalytic currents imply that the system is electrically contacted and that the Au NPs mediate the electron transfer from the PQQ-cofactor center embedded in the protein to the electrode. Using the saturation current value generated by the system [Figure 6.2(B), inset] and knowing the surface coverage of the reconstituted enzyme, 1.4×10^{-10} mol cm^{-2}, the electron transfer turnover rate between the biocatalyst and the electrode was estimated to be 1180 s^{-1}, a value that implies effective electrical communication between the enzyme and the electrode, which leads to the efficient bioelectrocatalytic oxidation of glucose.

6.3
Metal Nanoparticles as Electrochemical and Catalytic Labels

The possibility to functionalize metallic nanoparticles with different biomolecules allows the use of the biomolecule–-NP conjugates as labels for the amplified detection of biorecognition events. The NPs may be modified by their direct functionalization with the biomolecules, for example, the binding of thiolated nucleic acids to Au or Ag

NPs [3, 38, 39], the covalent tethering of the biomolecules to chemically functionalized NPs [40, 41] or the supramolecular binding of biomolecules to functionalized NPs, for example, the association of avidin-tagged nucleic acids with biotinylated NPs [42]. The biomolecule-modified NPs may be employed as electrochemical tracers for the amplified detection of biorecognition events [43, 44]. The chemical dissolution of the NP labels associated with the biorecognition events followed by electrochemical preconcentration of the released ions on the electrode and the subsequent stripping off of the collected metal provide a general means for the use of the particles as amplifying units for the biorecognition events [45]. Alternatively, the direct electrochemical stripping off of the NPs bound to the biorecognition complex was employed to transduce the biorecognition events [46–48]. These methods for stripping of the electrochemically pre-concentrated metals or the direct electrochemical dissolution of the metals led to 3–4 orders of magnitude improved detection limits, compared with normal pulse voltammetric techniques used to monitor DNA hybridization.

The method for the detection of DNA by the capturing the gold [49, 50] or silver [51] nanoparticles on the hybridized target, followed by the anodic stripping off of the metal tracer is depicted in Figure 6.3. Picomolar and sub-nanomolar levels of the DNA target have thus been detected. For example, the electrochemical method was employed for the Au NP-based quantitative detection of the 406-base human cytomegalovirus DNA sequence (HCMV DNA) [50]. The HCMV DNA was immobilized on a microwell surface and hybridized with the complementary oligonucleotide-modified Au nanoparticles as labels. The resulting surface-immobilized Au nanoparticle double-stranded assembly was treated with HBr–Br_2, resulting in the oxidative dissolution of the gold particles. The solubilized Au^{3+} ions were then electrochemically reduced and accumulated on the electrode and subsequently analyzed by anodic stripping voltammetry. The same approach was applied for analyzing an antigen [52] using Au nanoparticle labels and stripping voltammetry measurement. Further sensitivity enhancement can be obtained by catalytic enlargement of the gold tracer in connection with nanoparticle-promoted precipitation of gold [49] or silver [53–55]. Combining such enlargement of the metal particle tags, with the effective "built-in" amplification of electrochemical stripping analysis, paved the way to sub-picomolar detection limits. The silver-enhanced Au NP stripping method was used for the detection of DNA sequences related to the BRCA1 breast cancer gene [53]. The method showed substantial signal amplification as a result of

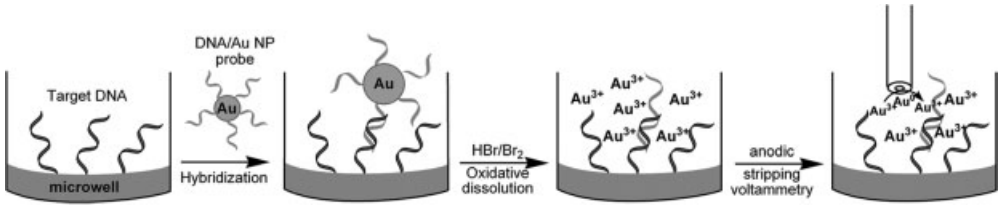

Figure 6.3 Electrochemical detection of a DNA by its labeling with a complementary nucleic acid-functionalized Au NP and the subsequent dissolution of the NPs and the electrochemical stripping of the Au^{3+} ions.

the catalytic deposition of silver on the gold tags; the silver signal was 125 times greater than that of the gold tag. A detection limit of 32 pM was achieved.

A further modification of the metal NP-induced amplified detection of DNA involved combination of magnetic particles and biomolecule-functionalized metallic NPs as two inorganic units that operate successfully in biosensing events. The formation of a biorecognition complex on the magnetic particles followed by labeling of the complex with the metallic NPs allowed the magnetic separation of the metal-labeled recognition complexes and their subsequent electrochemical detection by stripping voltammetry [49, 53]. Whereas the magnetic separation of the labeled recognition complexes enhanced the specificity of the analytical procedures, the stripping off of the metallic labels contributed to specific analysis [56, 57]. Furthermore, the use of the metallic NP labels accumulated on the magnetic NPs as catalytic seeds for the electroless enlargement of the particles by metals provided a further amplification path for the electrochemical stripping of the labels [57].

Figure 6.4 depicts the amplified detection of DNA by the application of nucleic acid-functionalized magnetic beads and Au NPs as catalytic seeds for the deposition of silver [57]. A biotin-labeled nucleic acid (**6**) was immobilized on the avidin-functionalized magnetic particles and hybridized with the complementary biotinylated nucleic acid (**7**). The hybridized assembly was then reacted with the Au-nanoparticle-avidin conjugate (**8**). Treatment of the magnetic particles–DNA–Au nanoparticle conjugate with silver ions (Ag^+) in the presence of hydroquinone results in the electroless catalytic deposition of silver on the Au nanoparticles, acting as catalytic labels. The latter process provided the amplification path since the catalytic accumulation of silver on the Au nanoparticle originates from a single DNA recognition event. The magnetic separation of the particles by an external magnet concentrated the hybridized assembly from the analyzed sample. The current originated by the voltammetric stripping off of the accumulated silver then provided the electronic

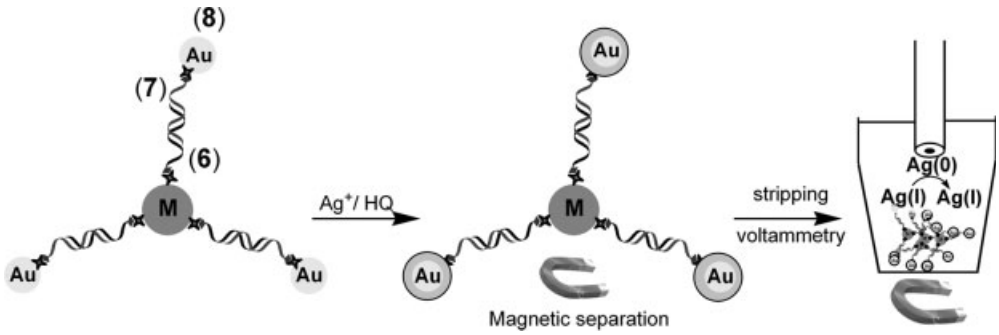

Figure 6.4 Electrochemical analysis of a DNA (**7**) by its hybridization with the complementary nucleic acid (**6**)-functionalized magnetic particle and the hybridization with the complementary nucleic acid (**8**)-modified Au NPs, followed by the deposition of Ag^0 on the particles. The analysis is performed by the magnetic separation of the particles aggregates, followed by the electrochemical stripping of the metallic NPs.

signal that transduced the analysis of the target DNA. Also, Au nanoparticle-based detection of DNA hybridization based on the magnetically induced direct electrochemical detection of the 1.4-nm Au_{67} NP tag linked to the target DNA was reported [58]. The Au_{67} NP tag was directly detected after the hybridization process, without the need for acid dissolution.

An additional method to enhance the sensitivity of electrochemical DNA detection involved the use of polymeric microparticles (carriers) loaded with numerous Au nanoparticle tags [59]. The Au NP-loaded microparticles were prepared by binding of biotinylated Au NPs to streptavidin-modified polystyrene spheres. The hybridization of target DNA immobilized on magnetic beads with the nucleic acid functionalized with Au nanoparticle-carrier polystyrene spheres, followed by the catalytic enlargement of gold labels, magnetic separation and then detection of the hybridization event by stripping voltammetry (Figure 6.5) allowed the determination of DNA targets at a sensitivity corresponding to 300 amol. A further method for the amplified detection of biorecognition complexes included the use of Au NPs as carriers of electroactive tags [60]. That is, the redox-active units capping the Au NPs linked to the biorecognition complexes allowed the amperometric transduction of the biosensing process. A detection limit of 10 amol for analyzing DNA with the functionalized NPs was reported.

The metal NP labels might be linked along double-stranded DNA, rather than be tethered by hybridization to the analyzed DNA, for the amplified electrical analysis of DNA. The generation of the metal nanoclusters along the DNA and their use for the amplified electrical analysis of DNA are depicted in Figure 6.6 and they follow the concepts used for the fabrication of metallic nanowires (see Section 6.10) [61]. The method involves the immobilization of a short DNA primer on the electrode that

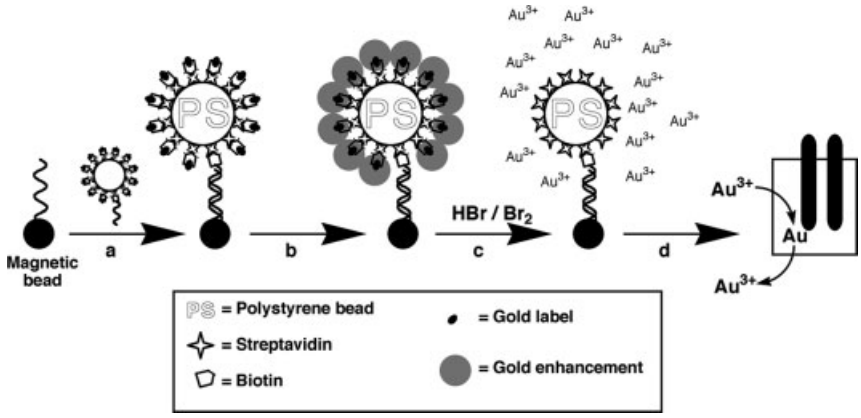

Figure 6.5 Amplified electrochemical detection of DNA by using nucleic acid–Au NP-functionalized microparticles as labels, and electroless catalytic deposition of gold on the NPs as a means of amplification: (a) hybridization of the nucleic acid–Au NP-functionalized microparticles with the target DNA, which is associated with a magnetic bead; (b) enhanced catalytic deposition of gold on the NPs; (c) dissolution of the gold clusters; (d) detection of the Au^{3+} ions by stripping voltammetry. Figure 6.6 Outline of the steps involved in the amplified electrochemical detection of DNA by the deposition of catalytic silver clusters on the DNA strand: (A) hybridization of the complementary target DNA with the short DNA primer, which is covalently linked to the electrode surface through a cystamine monolayer; (B) loading of the Ag^+ ions on to the immobilized DNA; (C) reduction of Ag^+ ions by hydroquinone to form silver aggregates on the DNA backbone; (D) dissolution of the silver aggregates in acidic solution and transfer of the solution to the detection cell for stripping potentiometric measurement (PSA = potentiometric stripping analysis).

hybridizes with the target DNA (step A). The negative charges associated with the phosphate units of the long target DNA collect Ag^+ ions from the solution to form phosphate–Ag^+ complexes (step B). The bound Ag^+ ions are then reduced by hydroquinone, resulting in the formation of metallic silver aggregates along the

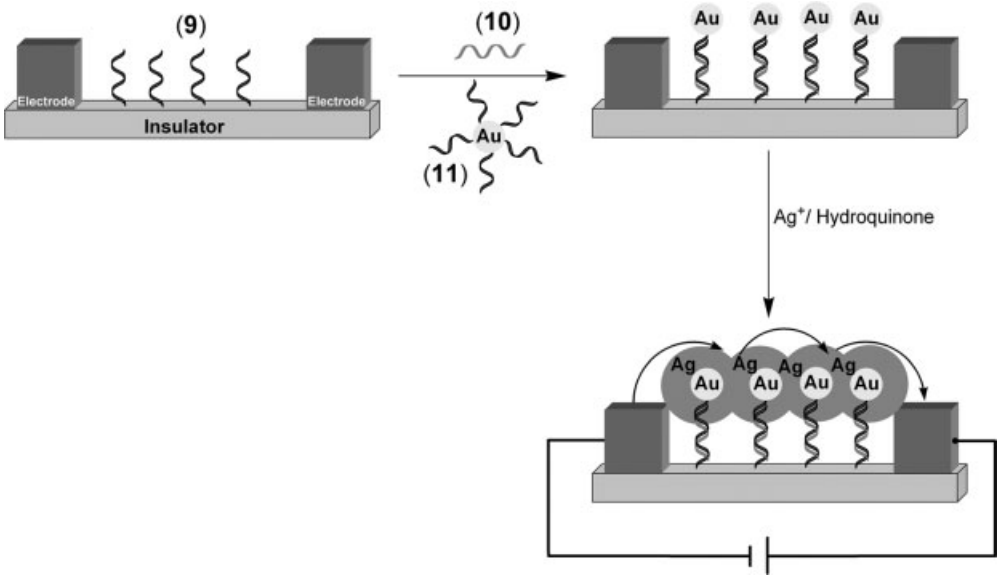

Figure 6.7 The use of a DNA–Au NP conjugate and subsequent silver deposition to connect two microelectrodes, as a means of sensing a DNA analyte.

DNA (step C). The subsequent dissolution and electrochemical stripping of the dissolved silver clusters (step D) then provide the route to detect the hybridized DNA.

The catalytic features of metal nanoparticles permit the subsequent electroless deposition of metals on the nanoparticle clusters associated along the DNA and the formation of enlarged, electrically interconnected, nanostructered wires. The formation of conductive domains as a result of biorecognition events then provides an alternative path for the electrical transduction of biorecognition events. This was exemplified by the design of a DNA detection scheme by using microelectrodes fabricated on a silicon chip [62] (Figure 6.7). The method relied on the generation of a DNA–Au NP sandwich assay within the gap separating two microelectrodes. A probe nucleic acid (**9**) was immobilized in the gap separating the microelectrodes. The target DNA (**10**) was then hybridized with the probe interface and, subsequently, the nucleic acid (**11**)-functionalized Au nanoparticles were hybridized with the free 3′-end of the target DNA, followed by silver enhancement of the Au NP labels. Catalytic deposition of silver on the gold nanoparticles resulted in electrically interconnected particles, exhibiting low resistance between the electrodes. The low resistances between the microelectrodes were controlled by the concentration of the target DNA, and the detection limit for the analysis was estimated to be about 5×10^{-13} M. A difference of 10^6 in the gap resistance was observed upon analyzing by this method the target DNA and its mutant. A related conductivity immunoassay of proteins was developed, based on Au NPs and silver enhancement [63].

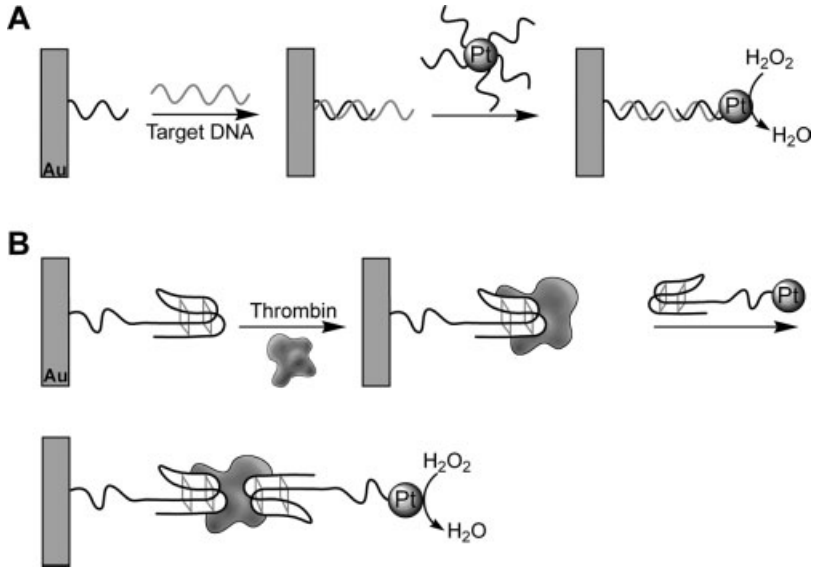

Figure 6.8 (A) Amplified electrochemical analysis of a DNA by nucleic acid-functionalized Pt NPs acting as electrocatalysts for the reduction of H_2O_2. (B) Amplified electrochemical analysis of thrombin by an aptamers monolayer-functionalized electrode and an aptamer-functionalized Pt NP labels as electrocatalysts for the reduction of H_2O_2.

A further approach for the amplified detection of DNA or proteins by employing metal nanoparticle (Pt NP) labels as catalysts for the reduction of H_2O_2 was described [64]. Nucleic acid-functionalized Pt NPs act as catalytic labels for the amplified electrochemical detection of DNA hybridization and aptamer/protein recognition events. Hybridization of the nucleic acid-modified Pt NPs to the nucleic acid–analyte DNA complex associated with an electrode permits the amperometric, amplified, detection of the DNA through the Pt NP electrocatalyzed reduction of H_2O_2 with a sensitivity limit of 1×10^{-11} M [Figure 6.8(A)]. Similarly, the association of the aptamer-functionalized Pt NPs to a thrombin aptamer–thrombin complex associated with the electrode allowed the amplified, electrocatalytic detection of thrombin with a sensitivity limit corresponding to 1×10^{-9} M [Figure 6.8(B)].

6.4
Metal Nanoparticles as Microgravimetric Labels

Nanoparticles provide a "weight label" that may be utilized for the development of microgravimetric sensing methods [quartz crystal microbalance (QCM)] that are ideal for the detection of biorecognition events. Also, the catalytic properties of metallic NPs may be employed to deposit metals on the NP-functionalized biorecognition complexes, thus allowing enhanced mass changes on the transducers

(piezoelectric crystals) and amplified biosensing. For a quartz piezoelectric crystal (AT-cut), the crystal resonance frequency changes by Δf when a mass change Δm occurs on the crystal according to the Sauerbrey equation [65]:

$$\Delta f = -2f_0^2[\Delta m/A(\mu_q\rho_q)^{1/2}] \tag{6.1}$$

where f_0 is the fundamental frequency of the quartz crystal, Δm is the mass change, A is the piezoelectrically active area, ρ_q is the density of quartz (2.648 g cm^{-3}) and μ_q is the shear modulus (2.947×10^{11} dyn cm^{-2} for AT-cut quartz). Thus, any mass changes of the piezoelectric crystals are accompanied by a change in the resonance frequency of the crystal.

The microgravimetric QCM method was applied for the amplified detection of DNA using nucleic acid-functionalized Au NPs as "weight labels" [66–68]. A target DNA molecule (**13**) was hybridized to an Au–quartz crystal that was modified with a probe oligonucleotide (**12**) and the **14**-functionalized Au NPs were hybridized to the 3′-end of the duplex DNA associated with the crystal (Figure 6.9). The subsequent secondary dendritic amplification was achieved by the interaction of the resulting interface with the target DNA (**13**) that was pretreated with the (**12**)-functionalized Au NP [67, 69]. Concentrations of DNA (**13**) as low as 1×10^{-10} M could be detected by the amplification of the target DNA by the nucleic acid-functionalized Au NP labels.

Also, the detection of DNA using nucleic acid-functionalized Au NPs and catalytic metal deposition on the NPs labels was reported [70, 71]. The Au nanoparticles act as catalytic "seeds" and catalyze the reduction of $AuCl_4^-$ and the deposition of gold on the Au NPs. Thus, the catalytic enlargement of the nanoparticles increased the mass associated with the piezoelectric crystal and provided an active amplification route for the amplified microgravimetric detection of the DNA. For example, Figure 6.10(A) depicts the amplified detection of the 7249-base M13mp18 DNA by using the catalytic

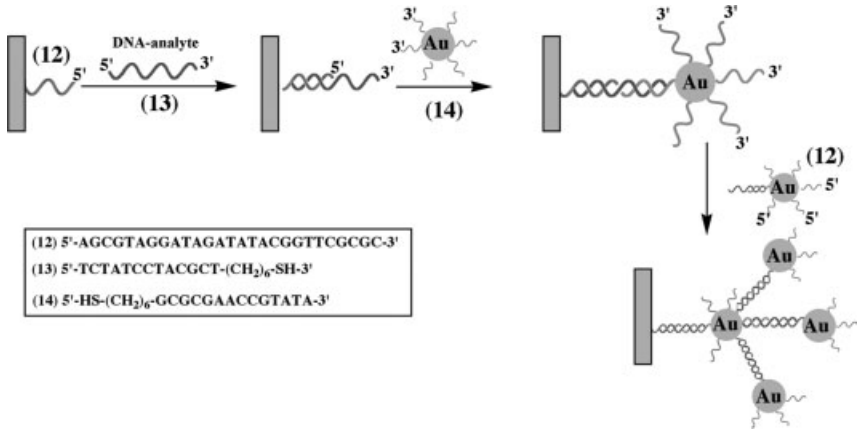

Figure 6.9 Dendritic amplified DNA sensing by the use of oligonucleotide-functionalized Au NPs, which are assembled on a quartz crystal microbalance (QCM) Au–quartz crystal (Reproduced from [67] by permission of The Royal Society of Chemistry).

deposition of gold on an Au NP conjugate [71]. The DNA primer (**15**) was assembled on an Au–quartz crystal. After hybridization with M13mp18 DNA (**16**), the double-stranded assembly was replicated in the presence of a mixture of nucleotides (deoxynucleotide triphosphates, dNTP mixture) that included dATP, dGTP, dUTP, biotinylated dCTP (B-dCTP) and polymerase (Klenow fragment). The resulting biotin-labeled replica was then treated with the streptavidin–Au NP conjugate (Sav–Au NP) (**17**), and the resulting Au-labeled replica was subjected to the Au NP-catalyzed deposition of gold by the NH_2OH-stimulated reduction of $AuCl_4^-$. The replication process represents the primary amplification step as it increases the mass associated with the crystal and simultaneously generates a high number of biotin labels for the association of the Sav-Au NP. The binding of the conjugate represents the secondary amplification step for the analysis of M13mp18 DNA. The third step, which involves the catalyzed precipitation of the metal, led to the greatest amplification in the sensing process as a result of the increase in the mass of the Au NPs. This method enabled the M13mp18 DNA to be sensed with a detection limit of $\sim 1 \times 10^{-15}$ M.

This amplification method was also applied for the analysis of a single-base mismatch in DNA as depicted in Figure 6.10(B) [70, 71]. This was exemplified with the analysis of the DNA mutant **18a**, which differs from the normal gene (**18**) by the substitution of a G base with an A base. The analysis of the mutant was performed by the immobilization of the probe DNA (**19**), which is complementary to the normal gene (**18**) and also to the mutant (**18a**) (up to one base prior to the mutation site), on the Au–quartz crystal. Hybridization of the normal gene or the mutant with this probe interface, followed by the reaction of the hybridized surfaces with biotinylated dCTP (B-dCTP) in the presence of polymerase (Klenow fragment), led to the incorporation of the biotin-labeled base only into the assembly that included the mutant **18a**. The subsequent association of the Sav–Au NP conjugate **17** followed by the catalyzed deposition of gold on the Au NPs amplified the analysis of the single-base mismatch in **18a**. Figure 6.10(C), curve a, shows the microgravimetric detection of the mutant **18a** revealing a frequency change of $\Delta f = -700$ Hz upon analyzing (**18a**), 3×10^{-9} M. The normal gene (**18**) does not alter the frequency of the crystal [Figure 6.10(C), curve b]. The mutant could be detected with a detection limit of 3×10^{-16} M.

Microgravimetric detection method was further extended to analyze proteins by aptamer-functionalized surfaces, using metal NPs as "weight labels" and as catalytic sites for enlargement of nanoparticles and the amplified sensing of the proteins. The use of metal nanoparticle labels for the amplified analysis of thrombin was reported [72]. The fact that thrombin consists of a dimer with two binding sites for aptamers [73, 74] allowed the application of aptamer-functionalized Au NPs for developing a microgravimetric QCM aptasensors for thrombin (Figure 6.11). The thiolated aptamer **20** was linked to an Au–quartz crystal. The interaction of the **20**-modified Au–quartz crystal with thrombin and the subsequent association of the aptamer **20**-functionalized Au NPs provide a primary amplification of the analysis of thrombin by applying the Au NPs as a "weight label". The secondary catalytic enlargement of the Au nanoparticles by the particle-catalyzed reduction of $AuCl_4^-$ by 1,4-dihydronicotinamide adenine dinucleotide (NADH) [75] provided a further

amplification for the sensing of thrombin. Upon analyzing thrombin at a concentration of 2×10^{-9} M, the primary amplification step resulted in a frequency change of -30 Hz, whereas the secondary amplification step altered the crystal frequency by -900 Hz.

6.5
Semiconductor Nanoparticles as Electrochemical Labels for Biorecognition Events

Other inorganic nanoparticle composites such as semiconductor NPs (or quantum dots) have been employed as labels (that substitute metallic NPs) for the amplified electrochemical detection of proteins or DNA [16, 43, 44]. The use of different semiconductor NPs allowed the parallel analysis of different targets, using the NPs as codes for different analytes. For example, CdS semiconductor nanoparticles modified with nucleic acids were employed as labels for the detection of hybridization

Figure 6.10 (A) Amplified detection of the 7249-base M13mp18 DNA (**16**) using the catalytic deposition of gold on an Au nanoparticle conjugate. events of DNA [76]. Dissolution of the CdS (in the presence of 1 M HNO_3) followed by the electrochemical reduction of the Cd^{2+} to Cd^0 accumulated the metal on the electrode. The subsequent stripping off of the generated Cd^0 (to Cd^{2+}) provided the electrical signal for the DNA analysis. This method was further developed by using magnetic particles functionalized with probe nucleic acids as sensor units that hybridize with the analyte DNA and the nucleic acid-functionalized CdS NPs labels that hybridize with the single-strand domain of the analyte DNA and trace the primary formation of the probe–analyte double-stranded complex. The magnetic separation of the magnetic particle–CdS NP aggregates crosslinked by the analyte DNA, followed by dissolution of the CdS and electrochemical collection and stripping off of the Cd metal, provide the amplified electrochemical readout of the analyte DNA. In fact, this system combined the advantages of magnetic separation of the tracers CdS NPs associated with the DNA recognition events with the amplification features of the electrochemical stripping method. Highly sensitive detection of DNA is accomplished by this method (detection limit 100 fmol, reproducibility = RSD 6%) [76].

By using different semiconductor NPs as labels, the simultaneous and parallel analysis of different antibodies or different DNAs was accomplished. A model system for multiplexed analysis of different nucleic acids with semiconductor NPs was developed [77]. Three different kinds of magnetic particles were modified by three different nucleic acids (**21a–c**) and subsequently hybridized with the complementary target nucleic acids (**22a–c**). The particles were then hybridized with three different kinds of semiconductor nanoparticles, ZnS, CdS, PbS, that were functionalized with nucleic acids (**23a–c**) complementary to the target nucleic acids associated with the magnetic particles [Figure 6.12(A)]. The magnetic particles allowed the easy separation and purification of the analyte samples, whereas the semiconductor particles provided nonoverlapping electrochemical readout signals that transduced the specific kind of hybridized DNA. Stripping voltammetry of the respective semiconductor nanoparticles yielded well-defined and resolved stripping waves, thus allowing simultaneous electrochemical analysis of several DNA analytes. The same strategy was also applied for the multiplexed immunoassay of proteins [78], with simultaneous analysis of four antigens. The arsenal of inorganic labels for the parallel multiplexed analysis of biomolecules and the level of amplification were further extended by using other metal sulfide composite nanostructures. For example, InS nanorods provided an additional resolvable voltammetric wave, while the nanorods configuration of the label increased the amplification efficiency due to the higher content of stripped-off metal from the nanorod configuration as compared with a spherical NP structure [79].

This method to encode biomolecular identity by semiconductor NPs was extended for the parallel analysis of different proteins by their specific aptamers [80]. An Au electrode was functionalized with aptamers specific for thrombin and lysozyme [Figure 6.12(B)]. Thrombin and lysozyme were labeled with CdS and PbS NPs, respectively, and the NP-functionalized proteins acted as tracer labels for the analysis of the proteins. The NP-functionalized proteins were linked to the respective aptamers and subsequently interacted with the nonfunctionalized thrombin or lysozyme. The competitive displacement of the respective labeled proteins associated with the surface by the analytes, followed by dissolution of the metal sulfides associated with the

surface and the detection of the released ions by electrochemical stripping, then allowed the quantitative detection of the two proteins [Figure 6.12(C)]. This method was further extended for coding unknown single polymorphisms (SNPs) using different encoding QDs [81]. This protocol relied on the ZnS, CdS, PbS and CuS NPs modified with four different mononucleotides and the application of the NPs to construct different combinations for specific SNPs, that yielded a distinct electronic fingerprints for the mutation sites.

Metal Nanoparticles as Optical Labels for Biorecognition Events

The unique size-controlled optical properties of the metallic NPs reflected by intense localized plasmon excitons [1, 2, 82] turn the NPs into powerful optical tags for biorecognition processes. Furthermore, the electronic interactions of the localized

plasmon with other plasmonic waves allow one not only to develop new optical amplification paths for biosensing, but also the use these electronic coupling phenomena to follow dynamic processes associated with biorecognition events. For example, surface plasmon resonance (SPR) is a common technique for following biorecognition events at metallic surfaces [83–85]. The changes in the dielectric properties of the metallic surfaces and the changes in the thickness of the dielectric films associated with the metallic surfaces alter the resonance features of the surface plasmon wave and provide the basis for SPR biosensors. The electronic coupling between an Au NP conjugated to the biorecognition complex and the plasmon wave may lead to amplification of the detection processes [86].

A colorimetric detection method for nucleic acids is based on the distance-dependent optical properties of DNA-functionalized Au NPs. The aggregation of Au NPs leads to a red shift in the surface plasmon resonance of the Au NPs as a result of an interparticle coupled plasmon exciton. Thus, the hybridization-induced aggregation of DNA-functionalized Au NPs changes the color of the solution from red to blue [3]. Changes in the optical properties of the Au NPs upon their aggregation provide a method for the sensitive detection of DNA and provide a way to design optical DNA biosensors [87–90]. Specifically, two batches of 13-nm diameter Au NPs were separately functionalized with two thiolated nucleic acids that acted as labels for the detection of the analyte DNA [Figure 6.13(A)]. Each of the NP labels is modified with nucleic acid complementary to the two ends of the analyte DNA. Since each of the nucleic acid-functionalized Au NPs includes many modifying oligonucleotides, the addition of the target DNA to a solution of the two DNA-functionalized Au NPs resulted in the crosslinking and aggregation of the nanoparticles through hybridization. Aggregation changed the color of the solution from red to purple as a result of interparticle coupled plasmon absorbance [Figure 6.13(B)]. The aggregation process was found to be temperature-dependent, and the aggregated Au NPs can reversibly dissociate upon elevation of the temperature through the melting of the double strands and reassociate with a decrease in the temperature through the rehybridization process, which results in the reversible changes of the spectrum [91]. These melting transitions, aggregation and deaggregation, occur in a narrow temperature range [Figure 6.13(C)] and allow the design of selective assays for DNA targets and high discrimination of the mismatched targets. The color changes in the narrow temperature range lies in the background of the simplest test to follow the aggregation of Au NPs, the "Northwestern" spot test [87]. This is an extremely sensitive method to discriminate between aggregated and nonaggregated gold NPs in aqueous solutions, and it relies on a detectable color change from red to blue upon aggregation. The test consists of spotting of a droplet of an aqueous solution of particles on a reversed-phase thin-layer chromatographic plate. A blue spot indicates aggregation in the presence of the target DNA, whereas a red spot indicates the presence of freely dispersed particles [Figure 6.13(C)]. The sharp melting transitions of DNA-functionalized gold nanoparticles were applied to discriminate the target DNA from DNA with single-base-pair mismatches simply by following the changes in the nanoparticle absorption as a function of temperature [87, 88]. The melting properties of DNA-linked nanoparticle aggregates are affected by a number of factors, which include DNA

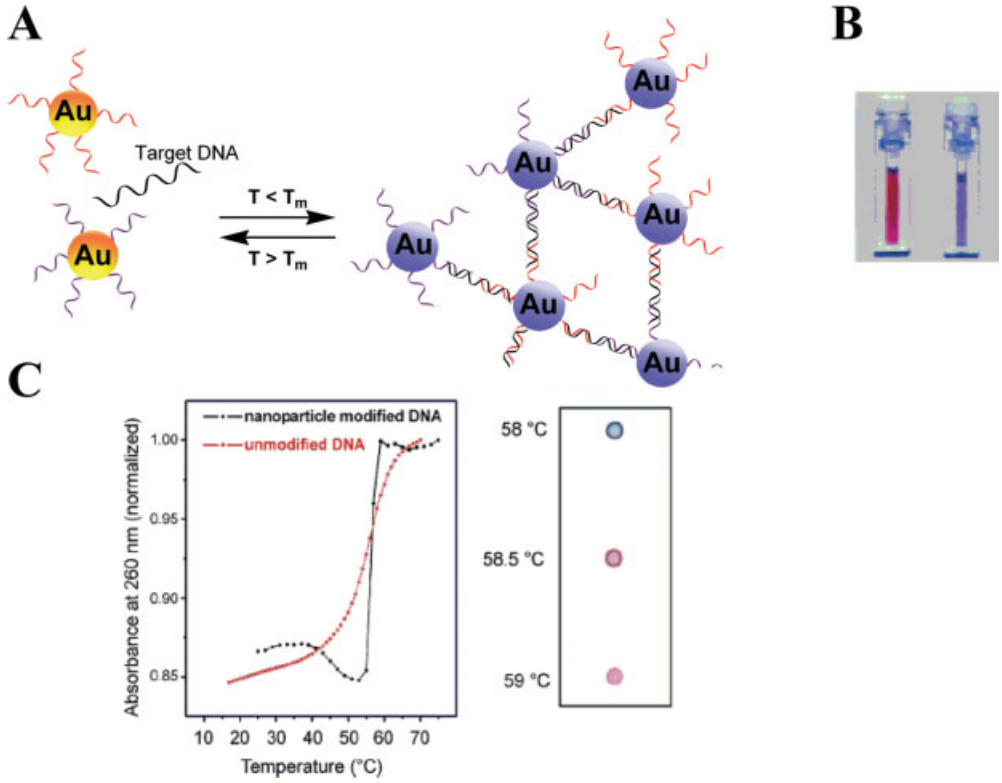

Figure 6.13 Optical detection of a target DNA through the hybridization of two kinds of nucleic acid-functionalized Au NPs complementary to the ends of the target DNA. The hybridization leads to the aggregation of the NPs (A) and to a red-to-purple color transition (B). surface density of the modifying nucleic acids, nanoparticle size, interparticle distances and salt concentration [91].

Recently, the use of DNA-based machines for the amplified detection of DNA was developed [92, 93]. The aggregation of Au NPs was used as a readout signal that follows the operation of the machine and the detection of the respective DNA [94] [Figure 6.14 (A)]. The machine consists of a nucleic acid "track" (**24**) that includes three domains, I, II and III. Domain I acts as the recognition site, and hybridization with the target DNA (**24a**) triggers, in the presence of polymerase and the dNTP mixture, the replication of the DNA track. Formation of the duplex, and specifically the formation of the duplex region II, generates the scission site for nicking enzyme Nb BbvC I. The enzyme-induced scission of the duplex activates the autonomous operation of the machine, where the replication and strand displacement of the complementary nucleic acid of region III proceed continuously. The displaced nucleic acid **25** may be considered as the "waste product". In the presence of two kinds of nucleic acids **26**- and **27**-

functionalized Au NPs, which are complementary to the two ends of the "waste product", aggregation of Au NPs proceeds. The color changes as readout method of aggregation of the Au NPs are depicted in Figure 6.14(B). The method allowed the optical detection of the target DNA with a sensitivity that corresponded to 1×10^{-12} M.

A different metal NP-induced analysis of DNA through the aggregation of the NPs employed the salt effect on the double layer potential of the NPs [95, 96]. Au NPs (15 nm) were functionalized with a probe nucleic acid, and the effect of the addition of the salt (up to 2.5 M) on the stability of the modified particles, as compared with unmodified (bare) NPs was examined. While the nucleic acid-functionalized Au NPs revealed stability in the presence of added salt, the nonfunctionalized Au NPs precipitated at a salt concentration of 0.1 M. The probe-functionalized Au NPs, when hybridized with the complementary target DNA, revealed a rapid red to purple color transition (<3 min) upon addition of 0.5 M NaCl. This color change was attributed to the lowering of the Au NP surface potential upon addition of the salt, which resulted in a decrease in the electrostatic repulsive interactions between the particles and consequently to shorter interparticle distances and a coupled plasmon absorbance.

The effect of salt on the stability of unmodified Au NP upon interaction with a probe nucleic acid before and after hybridization was used for the colorimetric detection of specific sequences in amplified genomic DNA [97, 98]. The method relied on the different effects of single- and double-stranded DNA on unmodified citrate-coated Au NPs. The adsorption of short ss-DNA probes on Au NPs stabilizes the citrate-coated NPs against salt-induced aggregation. The exposure of unmodified gold nanoparticles to a saline mixture containing amplified genomic DNA and short ss-DNA complementary to the regions in genomic DNA resulted in the aggregation of Au NPs and a color change from red to blue. If the short oligomers were not complementary to the regions in the genomic DNA, no color change occurred due to the stabilization of Au NPs by these oligomers. The method permitted the sequence-specific detection of label-free oligonucleotides at the level of 100 fmol and was adapted to detect single-base mismatches.

The hybridization-induced aggregation of metallic NPs was extended to analyze ions and small molecules using aptamers and DNAzymes. Aptamers are nucleic acids with specific recognition properties towards small molecules or proteins. They are prepared by the Systematic Evolution of Ligands by Exponential Enrichment (SELEX) procedure, which involves the selection and amplification of a sequence-specific nucleic acid to a target molecule from a library of 10^{15}–10^{16} nucleic acids [99–101]. Similarly, catalytic nucleic acids (DNAzymes or ribozymes) are prepared by eliciting

Figure 6.14 (A) Analysis of a DNA target (**24a**), by a nucleic acid "track" (**24**), consisting of regions I, II and III. The replication followed by nicking of the primary duplex (**24a**)/(**24**) yields displacement of the "waste product" (**25**). The displaced product (**25**) stimulates the aggregation of (**26**)- and (**27**)-functionalized Au NPs that are complementary to the two ends of (**25**). nucleic acids by *in vitro* selection towards transition-state analogues of chemical reactions [102] or by the selection of nucleic acids with binding affinities to metal ions [103–105] or active site analogues such as a heme [106, 107]. For example, the "8–17" DNAzyme has demonstrated high activity and specificity towards Pb^{2+} ions and revealed catalytic activity towards the specific scission of the complementary nucleic acid that included the respective cleavage site [108, 109]. Au NPs were used as optical labels for the detection of Pb^{2+} ions based on the activity of the Pb^{2+}-dependent DNAzyme that effects the separation of Au NP aggregates [110] (Figure 6.15). The method used the "8–17" DNAzyme that reveals high activity and specificity toward Pb^{2+} ions. The system consists of a substrate strand **17**DS that includes the cleavage site and is complementary to enzyme strand **17**E, which recognizes Pb^{2+} ions. The enzyme strand revealed catalytic activity in the presence of Pb^{2+} ions and resulted in scission of the substrate strand at the cleavage site. The complementary substrate strand of the DNAzyme was elongated with nucleic acid residues that are complementary to secondary nucleic acids labeled with Au NPs [Figure 6.15(A)]. Mixing of all three components of the DNAzyme – the enzyme strand, the complementary nucleic acid substrate and the nucleic acid-labeled Au NPs – resulted in the hybridization of the respective components, the aggregation of the Au NPs [Figure 6.15(A), part (c)] and the appearance of blue color, which indicated interparticle-coupled plasmon absorbance [Figure 6.15(B), part (a), curve 1]. The addition of Pb^{2+} ions resulted in the DNAzyme-assisted cleavage of the substrate strand, and this led to the separation of the Au NP aggregates and to a red color corresponding to the deaggregated Au NPs [Figure 6.15(B), part (a), curve 2]. This method allowed the colorimetric detection of Pb^{2+} ions in the concentration range 0.1–4 μM [Figure 6.15(B), part (c), curve 1]. The function of DNAzyme as an active component for the detection of Pb^{2+} ions was confirmed by using an inactive DNAzyme (**17**Ec) with poor scission activity of the substrate strand in the presence of Pb^{2+} ions [Figure 6.15(B), part (b), curves 1 and 2] and with low sensitivity [Figure 6.15(B), part (c), curve 2].

The DNAzyme-controlled aggregation of Au NPs was expanded to a broader range of analytes, and a colorimetric biosensor for adenosine was tailored on the basis of the aptazyme-directed assembly of gold NPs [111]. The aptazyme is based on an "8–17" DNAzyme that is allosterically activated by the adenosine aptamer [Figure 6.15(C), part (a)]. In the absence of adenosine, an inactive aptazyme is formed, and the substrate strand operates as a linker for the assembly of a blue colored aggregate of 13-nm Au NPs [Figure 6.15(C), part (b), route (i)]. In the presence of adenosine, however, the aptazyme is activated and the substrate strand is cleaved [Figure 6.15(C), part (b), route (ii)]. This prevents the aggregation of the Au NPs, which results in a red-colored system characteristic of the individual nonaggregated nanoparticles. Concentrations of up to 1 mM of adenosine could be semiquantitatively analyzed by the extent of blue-to-red color changes or quantitatively measured by the ratio of the absorbance values at 520 and 700 nm. The addition of guanosine, cytidine or uridine (all 5 mM) instead of adenosine did not affect the aggregation of the DNA-bound Au NPs, indicating the specificity of the system towards adenosine.

Aptamer- and oligonucleotide-induced aggregation processes of Au NPs were used to develop colorimetric sensors for low molecular weight substrates such as adenosine and cocaine [112]; for example, a nucleic acid strand (**28**) that includes the specific anti-adenosine aptamer sequence and tether units I and II complementary to two kinds of **29**- and **30**-functionalized Au NPs. The mixture of (**28**) with the functionalized Au NPs resulted in the aggregation of the Au NPs through bridging of the NPs by hybridization of **28** with the functionalized NPs (Figure 6.16). In the presence of added adenosine, the adenosine–aptamer complex folds to a configuration that destabilizes the double-stranded structure, resulting in deaggregation of the particles and a purple-to-red color transition. The method allowed the detection of adenosine in the concentration range 0.3–2 mM. The generality of this method was further demonstrated by the construction of a colorimetric sensor for cocaine based on a specific cocaine aptamer [112].

The aggregation of the Au NPs is not limited to DNA detection and the process was applied to develop optical biosensing assays for sensing enzyme activities. For example, the detection of proteases (thrombin and letal factor) by the enzyme-induced cleavage of peptides was reported [113]. In this protocol, acetylated cysteine residues were added to two termini of the peptide substrate. As the cysteine units bind to Au NPs, the intact peptide bridged the NPs, resulting in their aggregation and the formation of a violet–blue color. The pretreatment of the modified peptide with target protease led to the cleavage of the peptide to the monofunctionalized cysteine residues that did not lead to the aggregation of the NPs. The assay demonstrated high sensitivity and it allowed the sensing of thrombin with a detection limit as low as 5 nM and the detection of letal factor with a detection limit of 25 nM. An additional method for the detection of proteases (thermolysin and nACT–PSA) activity was described [114]. This method is based on the protease-induced deaggregation of Au NP clusters crosslinked by π-stacking of the Fmoc residues linked to the peptide coating of the Au NPs. The cleavage of the peptide by target protease resulted in deaggregation of NPs and a color change from blue to red. Similarly, the activity of alkaline phosphatase (ALP) was monitored through the aggregation of Au NPs [115].

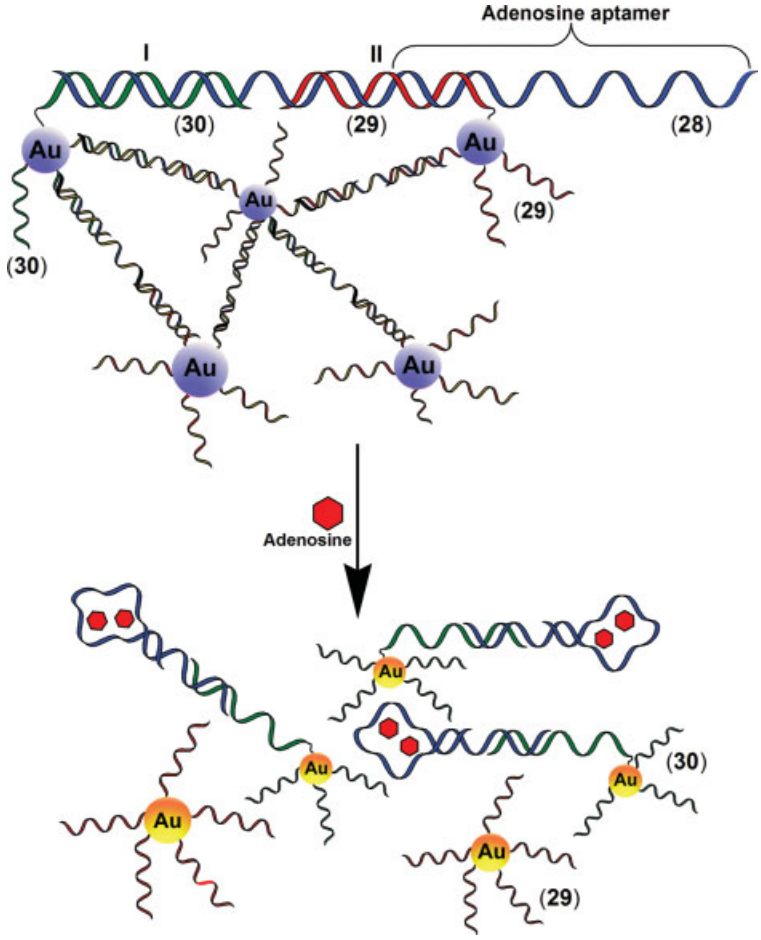

Figure 6.16 Colorimetric analysis of adenosine monophosphate through the deaggregation of Au NPs bridged by the blocked adenosine aptamer tethered to a nucleic acid (**28**), that is hybridized with nucleic acids (**29**)- and (**30**)-functionalized Au NPs. Formation of the aptamer–substrate complex separates the (**29**)-modified Au NPs and stimulates the deaggregation of the NPs.

The phosphorylated peptide H_2N-Cys-Tyr(PO_3^{2-})-Arg-OH was assembled on Au NPs through the cysteine group. Electrostatic repulsion of the negatively charged Au NPs retained the nonaggregated configuration of the NPs. The hydrolytic dephosphorylation of the peptide by ALP removed the phosphate group, thus permitting the bridging and aggregation of the NPs by the free amino group on the peptide chains.

The aggregation of Au NPs as colorimetric test for biorecognition events was extended to numerous other biorecognition complexes. For example, the process was used to detect the cholera toxin [116]. Au NPs were modified with a lactose capping

layer, and the cholera toxin (B-subunit) linked to the lactose derivative induced aggregation of the Au NPs. Upon aggregation, the color of solution of Au NPs changed from red to deep purple. The selectivity of the bioassay arises from the fact that thiolated lactose mimics the GM1 ganglioside, the native receptor of the cholera toxin. The detection limit of the assay was 54 nM. Similarly, the colorimetric sensing of platelet-derived growth factors (PDGFs) and their receptors (PDGFRs) based on aggregation of aptamer-functionalized Au NPs was also developed [117].

In addition to the absorbance features of metallic NPs that were used to follow biorecognition events in solution and on surfaces, other optical methods have been employed to detect the association of biomolecule-functionalized Au NPs on biochips. These methods included scanometric detection by light scattering, surface plasmon resonance spectroscopy, resonance-enhanced absorption by NPs and enhanced Raman scattering.

A scanometric DNA detection method was developed, and this was based on a sandwich assay format involving a DNA-functionalized glass slide, the target DNA and Au NP probes [118]. In a typical setup for scanometric detection, the modified glass slide was illuminated in the plane of the slide with white light. The slide served in such a configuration as a planar waveguide that prevents any light from reaching the microscope objective by total internal reflectance. Wherever NP probes were attached to the surface, evanescently coupled light was scattered from the slide, and the NP labels were imaged as bright, colored spots. This approach was used for the detection of target DNA molecules that were specifically bound to a DNA-functionalized surface. The resulting DNA hybrid was labeled with gold nanoparticles that allowed the scanometric detection of the DNA (Figure 6.17). At high target concentrations ($\geq$1 nM), the Au NPs on the surface could be visualized with naked eye. At low target concentrations ($\leq$100 pM), the coverage of the surface-bound Au NPs was too low, and an enhancement process was needed. Enlargement of the Au NPs by the catalytic reduction of silver ions and the deposition of silver metal on the Au NPs

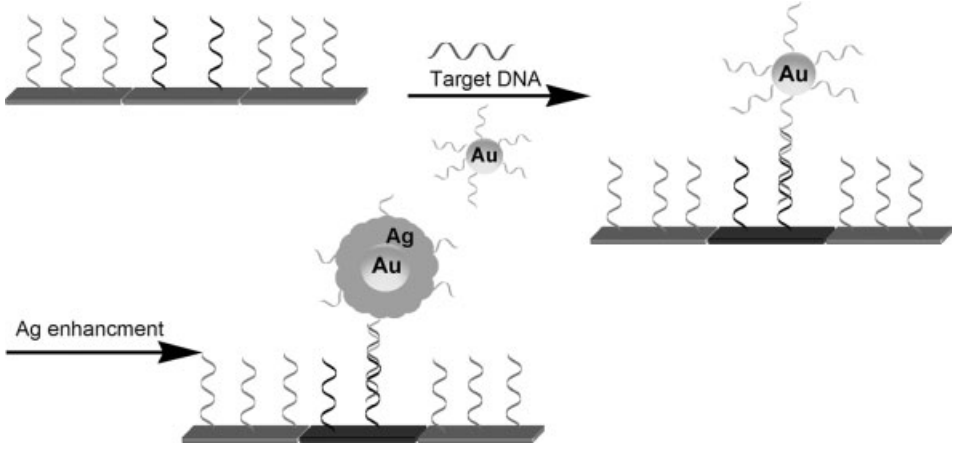

Figure 6.17 Scanometric detection of DNA on a surface using gold–silver core–shell NPs.

resulted in a 100-fold increase in the light-scattered signal and thus increased the sensitivity detection of target DNA (50 fM) [118]. This method was used to detect single-base mismatches in oligonucleotides, which were hybridized to DNA probes and were immobilized at different domains of a glass support. High sensitivities were provided by the deposition of silver, whereas the selectivity was achieved by examination of the melting properties of the spots: the mismatched spot reveals a lower melt temperature owing to its lower association constant. The scattering of light is size-dependent, and hence, by using different sized nanoparticles the simultaneous detection of different DNA sequences is feasible. Accordingly, the light scattered by DNA-functionalized 50- and 100-nm Au NP probes was used to identify two different target DNAs in solution [119]. The scanometric method was successfully applied to detect the MTHFR gene from genomic DNA at concentration as low as 200 fM without PCR amplification of the target, by the application of improved optical imaging instruments [120]. A similar approach was used to identify single nucleotide polymorphisms (SNPs) in unamplified human genomic DNA samples representing all possible genotypes for three genes involved in thrombotic disorders [121].

The scanometric method was applied as an optical detection means in a series of systems that employed nucleic acid-functionalized Au NPs as barcodes for biorecognition events such as antigen–antibody complex formation or DNA hybridization. In one system (Figure 6.18), prostate-specific antigen (PSA) was detected by nucleic acid-functionalized Au NPs that acted as signaling barcodes [122]. The Au NPs were modified with the polyclonal anti-PSA Ab that was further functionalized with thiolated nucleic acid (**31**), which were hybridized with the complementary nucleic acid (**31′**), and its sequence acted as a barcode for the sensing process. In the presence of PSA and magnetic particles functionalized with the monoclonal anti-PSA Ab, an aggregate consisting of the "sandwich" structure of the Au NPs and the magnetic particles was formed. The magnetic separation of the aggregate was followed by the thermal displacement of the barcode DNA. The released barcode nucleic acid was then amplified by the polymerase chain reaction (PCR), and the product was used to bridge the Au NPs with the complementary nucleic acid to a glass surface. The Ag-enhanced Au NPs were then analyzed by the scanometric method. Although this analytical protocol involves many steps, the PCR amplification step leads to an ultrasensitive detection method, and PSA at a level of 30 aM was analyzed.

An analogous process was used to analyze DNA (Figure 6.19) [123]. By this method, the functionalized Au NPs include the duplex DNA barcode (**32/32′**) and the nucleic acid units (**33**) that recognize the target DNA. In the presence of the target DNA (**35**), the magnetic particles modified with the nucleic acids **34** and the **32/33**-functionalized Au NPs, the magnetic particle–Au NP aggregate is formed through crosslinking the particles by **35**. The subsequent magnetic separation of the aggregate and the thermal separation of the DNA barcode were followed by scanometric detection of the released DNA code on surfaces. A PCR-like sensitivity that corresponded to 500 zM was claimed for the analysis of DNA. The DNA barcode-based sensing protocols were used to analyze protein cancer markers [124], the amyloid biomarkers for Alzheimer's disease [125] and the genes of various

pathogens, such as hepatitis B, Ebola virus, variola virus (smallpox, VV) and human immunodeficiency virus (HIV) [126]. Furthermore, different modifications of the method that use fluorescence detection [127] and colorimetric assay [128] have been reported.

The colorimetric scattering assay of gold nanoparticles was applied for the rapid detection of *mecA* gene in unamplified genomic DNA sequences [129]. The method was based on hybridization of DNA-functionalized Au NPs probes with the complementary sequences of target DNA in solution. The resulting solution was then spotted on a glass waveguide, which was illuminated with white light in the plane of the slide. The color of the light scattered by the oligonucleotide-functionalized Au NPs probes is different from that of the Au NPs aggregates generated by the hybridization process

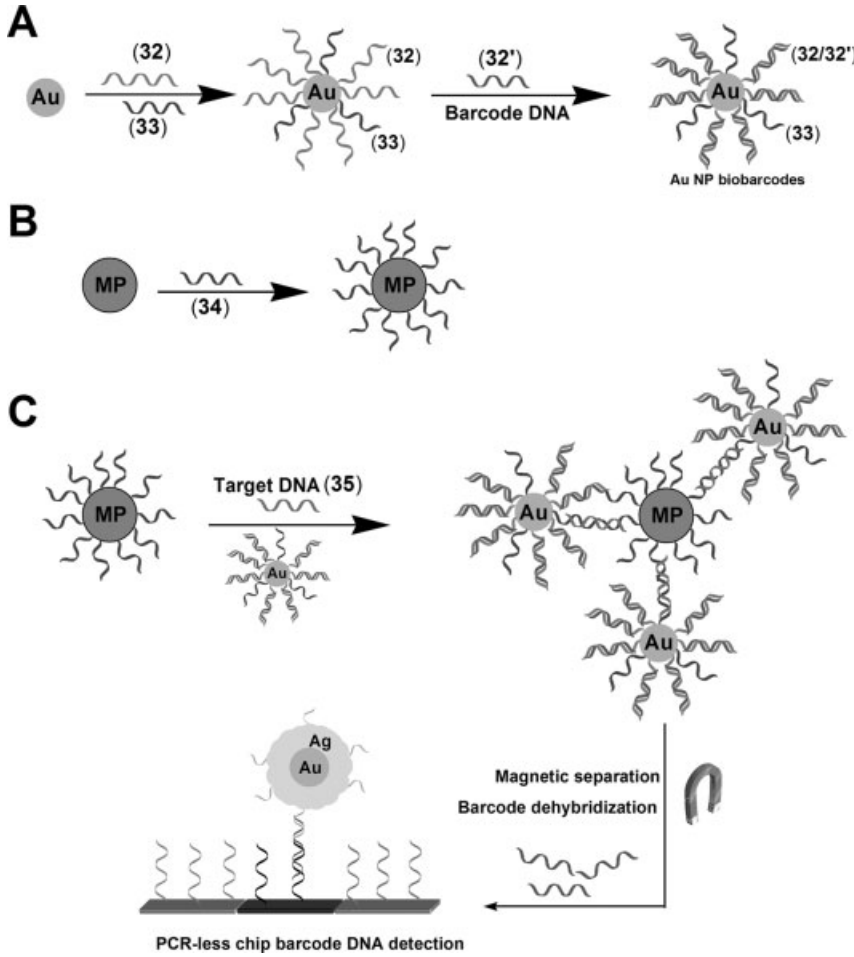

Figure 6.19 Scanometric detection of a DNA by a nucleic acid barcode-functionalized Au NP: (A) synthesis of Au NP labeled with the nucleic acid (**32**), complementary to the DNA barcode (**32′**) and the nucleic acid (**33**) complementary to the target; (B) preparation of the magnetic particles modified with the nucleic acid (**34**) complementary to the other end of the target; (C) aggregation of the functionalized Au NPs and the magnetic particles through hybridization with the target, magnetic separation of the aggregates, thermal separation of the DNA barcode and its scanometric detection.

between the probes and target DNA. In the absence of the target DNA, individual 40–50-nm Au NPs scatter green light, whereas in the presence of the target DNA aggregated nanoparticles scatter yellow to orange light. The method showed enhanced detection sensitivity (about four orders of magnitude) compared with the colorimetric assay, thus allowing the detection of zeptomole quantities of target DNA, 333 fM of synthetic DNA and 33 fM of genomic DNA. An improved light-scattering strategy using gold nanoparticles as labels for the detection of specific target DNA in a

homogeneous solution was reported [130]. The method is based on the aggregation of DNA-functionalized Au NPs through the hybridization of the target DNA with probe-labeled Au NPs and enhanced light scattering that originated from the aggregates in solution. The light-scattering assay demonstrated high sensitivity, and the human p53 gene, exon 8 DNA, was detected at a concentration as low as 0.1 pM. Moreover, the assay showed a high degree of specificity and was used for discrimination between perfectly matched targets and targets with single base-pair mismatches.

The hyper-Rayleigh scattering (HRS) technique (nonlinear light scattering) was used to monitor DNA hybridization on unmodified gold nanoparticles in a saline solution, and the target DNA was analyzed at a concentration of 10 nM [131]. The HRS assay for DNA detection was based on the differences in the electrostatic interactions between ssDNA and dsDNA with the particles. The method permitted the analysis of single-base mismatch in DNA by monitoring the HRS intensity from the different DNAs interacting with the gold nanoparticles.

Surface-enhanced Raman scattering (SERS) of nanoparticle-bound substrates allows the amplification of molecular vibrational spectra by up to 10^6-fold [132–134]. Modification of metal NPs with different Raman dyes was used to generate multiply coded NPs [135–138] and for the preparation of thousands of codes to be written and read by means of surface-enhanced Raman resonance (SERR) scattering without the need for spatial resolution of components of the code [135, 137]. The use of SERS for the analysis of biorecognition events was demonstrated with the application of Au NPs that were functionalized with Raman dyes and recognition elements [139, 140]. Formation of the complementary recognition complex on surfaces, followed by the electroless deposition of Ag on the Au NPs, allowed the enhanced readout of the biorecognition events by SERS. The concept was applied for the parallel detection of various analytes on surfaces in an array configuration [Figure 6.20(A)]. For example, six different thiol-functionalized Raman-active dyes, Cy3, Cy3.5, Cy5, TAMRA, Texas Red and Rhodamine 6G, were linked through an oligonucleotide spacer (10 adenosine units) to six different oligonucleotides and coupled to Au NPs (13 nm) to yield six different Raman dye-labeled Au NP probes [139] [Figure 6.20(B)]. These Au NP probes were then employed as labels for hybridization with the complementary targets. The capture DNA strands were spotted on a surface, and the specific binding of Au NPs by hybridization with target DNAs was followed by the silver enhancement of the Au NPs and analysis by SERS [Figure 6.20(C) and (D)]. The detection limit of this method was 20 fM. The assay demonstrated the ability to discriminate SNPs in DNA and RNA targets. A similar concept was also used to identify protein–protein and protein–small molecule interactions by using Au NPs that were functionalized with specific antibodies and encoded with specific Raman dyes [140]. Compared with colorimetric and scanometric detection methods, this method offers enhanced multiplex sensing capabilities afforded by the narrow spectral bands – fingerprints of Raman dyes. Further developments of the SERS technique allowed highly sensitive immunoassay procedures [141–143].

Au NPs have been widely employed for signal amplification of biorecognition events based on nanoparticle-enhanced SPR spectroscopy [82, 86]. The changes in the dielectric properties at thin films of metals, such as gold films, as a result of

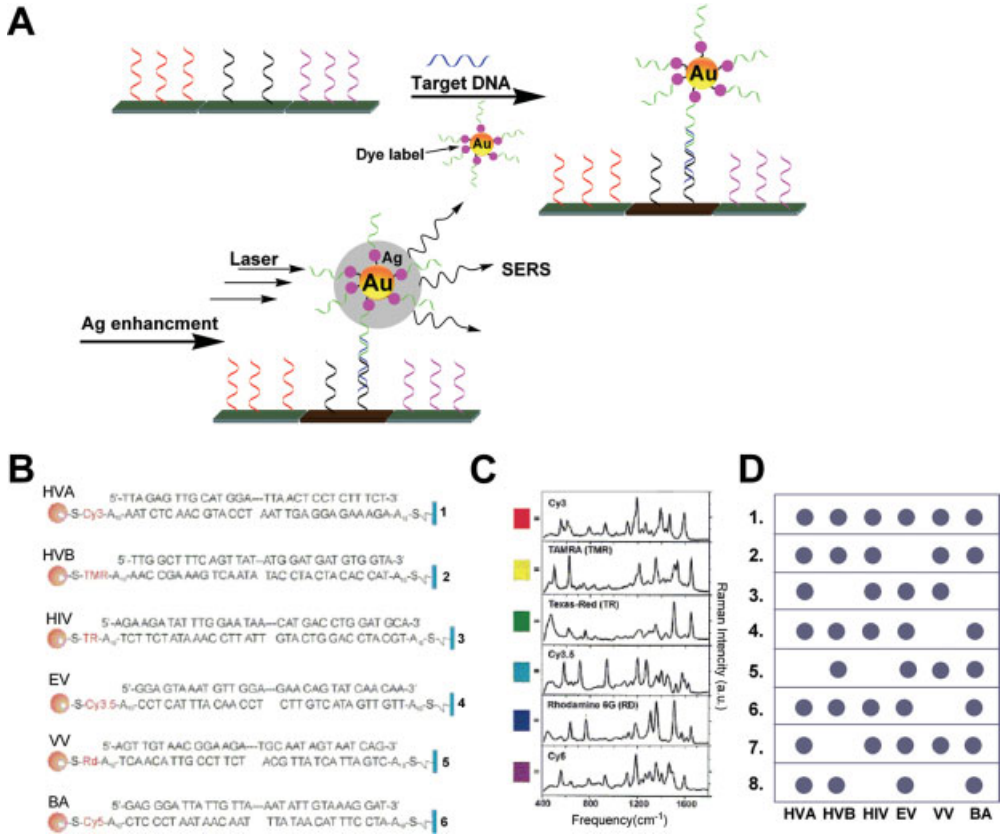

Figure 6.20 (A) Detection of a target DNA by the use of dye-functionalized Au NPs as labels for the SERS imaging. (B) Dye-labeled sequences of nucleic acids complementary to target DNAs of different pathogens. (C) Raman spectra of the dye-labeled Au NPs probes after silver enhancement upon the parallel analysis of the different pathogens on surfaces. biomolecular recognition processes, are the basis for the SPR technique. Labeling of the biorecognition complexes with Au or Ag NPs besides changing the dielectric properties, results in the electronic coupling between the localized NPs plasmon and the surface plasmon wave of the metal film. This electronic coupling significantly affects the resonance frequency of the surface wave, thus leading to the enhanced amplified optical transduction of the biorecognition events. Accordingly, Au NPs were used as labels in immunosensing [144–146] and DNA sensing [147–149] applications. The binding of Au NPs to the immunosensing interface led to a large shift in the plasmon angle, a broadening of the plasmon resonance region and an increase in the minimum reflectance, and these effects allowed the detection of the antigen with picomolar sensitivities [144]. Similarly, the sensitivity of DNA analysis was enhanced 1000-fold (10 pM) when Au NP-functionalized DNA molecules

were used as labels [147]. Also, the sensitive detection of DNA hybridization by applying catalytic growth of Au NPs as a means to enhance the SPR shifts was demonstrated [150].

The charging of Au NPs that are coupled to thin gold films affects the electronic coupling between the localized NP plasmon and the surface plasmon wave, resulting in a shift in the SPR spectra. Thus, biocatalytic electron transfer reactions that involved NP–enzyme conjugates may be monitored by SPR spectroscopy [151]. Au NPs (1.4 nm) were functionalized with N^6-(2-aminoethyl) flavin adenine dinucleotide (FAD cofactor, amine derivative; (**1**), and apo-glucose oxidase (apo-GOx) was reconstituted onto the cofactor sites. The nanoparticle–GOx conjugates were then assembled on a gold thin film (SPR electrode) by using a long-chain dithiol, HS $(CH_2)_9SH$, monolayer as a bridging linker. This yielded the biocatalytically active glucose oxidase (GOx) bound to the Au NPs in an aligned configuration [Figure 6.21 (A)]. The biocatalyzed oxidation of glucose resulted in the formation of the reduced form of the cofactor, $FADH_2$. In the absence of O_2 that acts as the natural electron acceptor for GOx, electron transfer proceeded from the reduced cofactor to the Au

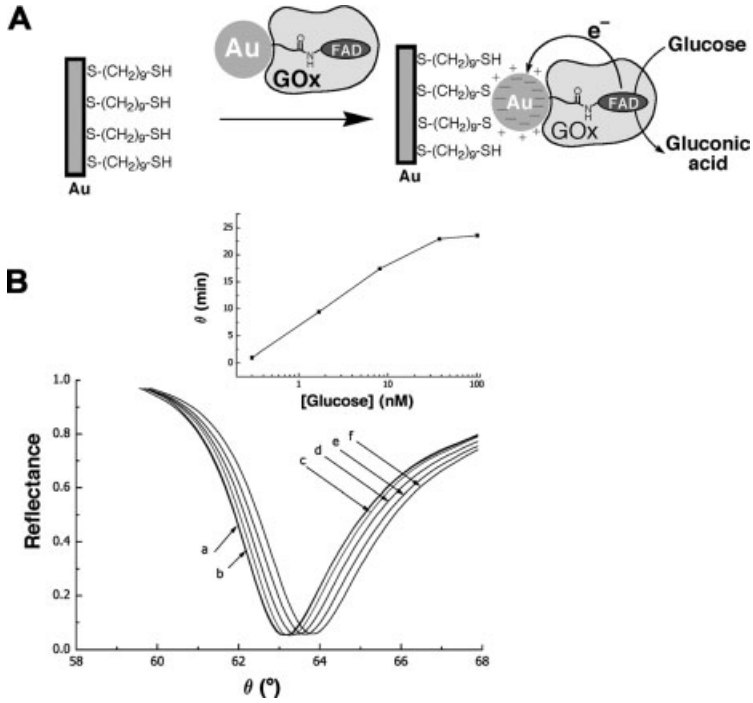

Figure 6.21 (A) Assembly of Au NP-bound reconstituted glucose oxidase (GOx) on a dithiol monolayer that is associated with an SPR-active surface and biocatalytic charging of the Au NPs in the presence of glucose. (B) SPR spectra of the Au NP–GOx hybrid system upon the addition of various concentrations of glucose: (a) 0, (b) 0.3, (c) 1.6, (d) 8, (e) 40 and (f) 100 mM. NPs, resulting in their charging. The long-chain dithiol monolayer provided a barrier for the electron tunneling from the Au NPs to the bulk Au electrode, and this preserved the electrical charge that was produced on the Au NPs. Potentiometric measurements indicated that the long-chain dithiol linkers provided a resistance layer that generated a potential gradient between the charged Au NPs and the conductive support. This potential gradient originated from the charging of the Au NPs by the biocatalytic process and thus, charge accumulated on the NPs was controlled by the biocatalytic process (the concentration of glucose). Accordingly, the plasmon coupling between the charged Au NPs and the Au support resulted in a shift of the SPR spectra, and these were dependent on the charge generated on the NPs [Figure 6.21(B)]. As the charge value was controlled by the rate of the biocatalytic reaction, the shift in the SPR spectrum was enhanced upon elevation of the glucose concentration [Figure 6.21(B), inset].

Metal nanoparticles exhibit a strong UV–visible absorption band that is not present in bulk material [1, 2, 152–154]. This absorption band, known as the localized surface plasmon resonance (LSPR), occurs when the incident photon frequency matches the collective oscillations of the conduction electrons. It is well established that the maximum extinction wavelength, λ_{max}, of the LSPR is controlled by the composition, size, shape and interparticle spacing of the nanoparticles, and also by the dielectric properties of their local environment (i.e., substrate, solvent and surface-bound molecules) [82]. The sensitivity of λ_{max} of the LSPR to the molecular environment of the NPs allowed the development of a new class of optical biosensors [155, 156] that operate in an analogous manner to their SPR counterparts by transducing small changes in the refractive index near the noble metal surface into a measurable wavelength-shift response. Triangular silver nanoparticles, ~100 nm wide and 25 nm high, fabricated by the nanosphere lithography (NSL) technique [Figure 6.22(A)], showed very unique optical properties [157, 158]. In particular, the λ_{max} of their LSPR spectrum is unexpectedly sensitive to the size, shape and local external dielectric environment of the nanoparticles (10–40 nm shift). The Ag nanotriangles were used to follow the streptavidin–biotin interactions as a model system for LSPR-based biosensors [157]. Triangular silver NPs were functionalized with biotin units and the changes in the LSPR spectra were followed upon binding of streptavidin molecules. The detection by LSPR was further amplified by the secondary coupling of biotinylated Au NPs to the streptavidin-saturated interface. A similar method was applied to design an immunosensor [158]. In addition, LSPR spectroscopy was applied for the detection and diagnosis of biomarkers, for example, the amyloid-β-derived diffusible ligands (ADDLs) that are markers for Alzheimer's disease [159, 160]. The sandwich assay composed of antibody/ADDLs/antibody was developed to amplify the LSPR response, and thus to improve the detection limit [160] [Figure 6.22(B)]. The LSPR nanosensor demonstrated sensitivity and selectivity in the detection of ultralow concentrations of ADDLs in synthetic and human samples [human brain extracts, cerebrospinal fluid (CSF)] [Figure 6.22(C)]. A detection limit corresponding to 100 fM was achieved for synthetic ADDLs. Also, modified LSPR-based biosensors consisting of gold-capped silica nanoparticle-layered substrates for monitoring DNA hybridization and antigen–antibody interactions were fabricated [161, 162].

6.7
Semiconductor Nanoparticles as Optical Labels

The unique optical properties of semiconductor nanoparticles or quantum dots, QDs, offer a number of advantages for biosensing, including size-controlled luminescence properties, impressive photostability and high quantum yields [5–7, 163, 164]. Efficient methods for the preparation of semiconductor nanoparticles

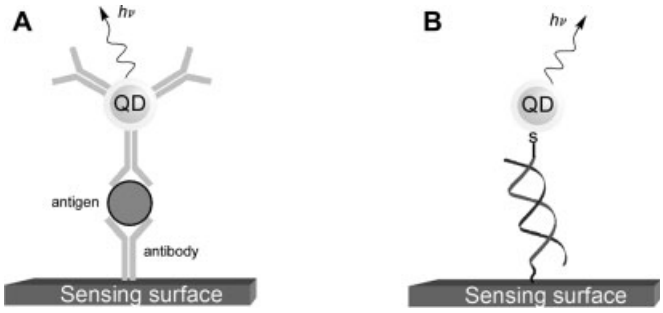

Figure 6.23 Fluorescent analysis of (A) an antigen by antibody-functionalized QDs and (B) a DNA by a nucleic acid-functionalized QD.

and their functionalization with biomolecules were developed recently [165, 166]. Unlike molecular fluorophores, which typically have very narrow excitation spectra, semiconductor QDs absorb light over a very broad spectral range. This makes it possible to excite optically a broad spectrum of quantum dot "colors" using a single excitation laser wavelength, which may enable one to probe simultaneously several markers in biosensing and assay applications. Indeed, functionalized semiconductor QDs have been used as fluorescence labels for numerous biorecognition events [9, 167–170], including their use in immunoassays for protein detection [Figure 6.23(A)] and nucleic acid detection [Figure 6.23(B)]. For example, CdSe/ZnS QDs were functionalized with avidin and these were used as fluorescent labels for biotinylated antibodies. Fluoroimmunoassays utilizing these antibody-conjugated NPs were successfully used in the detection of protein toxins (staphylococcal enterotoxin B and cholera toxin) [171, 172].

Similarly, CdSe/ZnS QDs conjugated to appropriate antibodies were applied for the multiplexed fluoroimmunoassay of toxins [Figure 6.24(A)]. Sandwich immunoassays for the simultaneous detection of the four toxins (cholera toxin, (CT), ricin, shiga-like toxin 1 (SLT), and staphylococcal enterotoxin B, (SEB)) by using different sized QDs were performed in single wells of a microtiter plate in the presence of mixture of all four QD–antibody conjugates [Figure 6.24(B)] [173], thus leading to the fluorescence that encodes for the toxin. In another example, multiplexed immunoassay formats based on antibody-functionalized QDs were used for simultaneous detection of *Escherichia coli* O157:H7 and *Salmonella typhimurium* bacteria [174] and for the discrimination between diphtheria toxin and tetanus toxin proteins [175].

Fluorescent QDs were used for the detection of single-nucleotide polymorphism in human oncogene p53 and for the multiallele detection of the hepatitis B and hepatitis C virus in microarray configurations [176]. DNA-functionalized CdSe/ZnS QDs of different sizes were used to probe hepatitis B and C genotypes in the presence of a background of human genes. The discrimination of a perfectly matched sequence of p53 gene in the presence of background oligonucleotides including different single-nucleotide polymorphism sequences was detected with true-to-false signal ratios higher than 10 (under stringent buffer conditions) at room temperature within minutes. Also, DNA–QD conjugates were used as fluorescence probes for *in situ*

hybridization assays (FISH). For example, the QD-based FISH labeling method was used for the detection of Y chromosome in human sperm cells [177]. A QD-based FISH method to analyze human metaphase chromosomes was reported [178] by using QD-conjugated total genomic DNA as a probe for the detection of EBRB2/HER2/neu gene. Also, the FISH technique was used for the multiplex cellular detection of different mRNA targets [179].

Nonetheless, the superior photophysical features of semiconductor QDs are demonstrated in organic solvents, and their introduction into aqueous media, where biorecognition and biocatalytic reactions proceed, is accompanied by a severe or even complete loss of their fluorescence properties. Different methods to stabilize the

fluorescence properties of semiconductor QDs in aqueous media were reported, including their surface passivation with protective layers [180, 181] and the coating of the QDs with protecting glass films [182, 183] or polymers [184]. Although these methods preserve the photophysical properties of the QDs, the protective layers limit important useful applications of the QDs. Quantum dots could be employed as optical labels for dynamic biological processes such as biocatalyzed transformations or structurally induced biomolecular changes, for example, opening of a hairpin nucleic acid by the hybridization of DNA, using fluorescence resonance energy transfer (FRET) or electron transfer quenching as photophysical probe mechanisms [185, 186]. The sensitivity of these photophysical processes to the distance separating the donor–acceptor or chromophore–quencher pairs prevents, however, the use of fluorescent QDs passivated by relatively thick protecting layers as optical probes for dynamic bioprocesses. Hence, a very delicate nanostructuring of the capping layer is essential to allow the use of QDs as active components in energy/electron transfer reactions.

Different sensing schemes have been developed that use QDs as a FRET donor. For example, CdSe/ZnS QDs conjugated to nucleic acids have been used to follow the biocatalyzed replication of DNA [187]. CdSe/ZnS NPs were functionalized with the DNA primer **36**, which is complementary to a domain of M13mp18 DNA. Hybridization of the M13mp18 DNA with the nucleic acid-functionalized QDs, followed by the replication of the assembly in the presence of polymerase and the nucleotide (dNTP) mixture that included Texas Red-functionalized dUTP (**37**), resulted in the incorporation of the dye labels into the DNA replica [Figure 6.25(A)]. The FRET process from the semiconductor NPs to the incorporated dye units resulted in emission from the dye with concomitant quenching of the fluorescence of the QDs [Figure 6.25(B)], and it allowed the identification of the primary hybridization.

A similar approach was used to follow telomerase activity, a biocatalytic ribonucleoprotein that is a versatile marker for cancer cells. The CdSe/ZnS QDs were modified with a nucleic acid primer that is recognized by telomerase. In the presence of telomerase and the nucleotide mixture dNTPs, that included Texas Red-functionalized dUTP (**37**), the telomerization of the nucleic acid associated with the QDs was initiated, while incorporating the Texas Red-labeled nucleotide into the telomers [Figure 6.25(C)]. The FRET process from the QDs to the dye units then enabled the dynamics of the telomerization process to be followed [187].

Also, the association of maltose with the hybrid composed of maltose-binding protein was examined by the application of a CdSe/ZnS QD linked to the maltose binding protein (MBP) [188]. CdSe/ZnS QDs were functionalized with MBP, and these were interacted with a β-cyclodextrin–QSY-9 dye conjugate [Figure 6.26(A)]. The β-cyclodextrin–QSY-9 dye conjugate resulted in quenching of the luminescence of the QDs by the dye units. Addition of maltose displaced the quencher units, and this regenerated the luminescence of the QDs [Figure 6.26(B)]. This method allowed the development of a competitive QD-based sensor for maltose in solution. Similarly, a competitive QD-based assay for the detection of the explosive trinitrotoluene (TNT) was developed [189]. CdSe/ZnS QDs were functionalized with a single-chain antibody fragment that selectively binds TNT. The analogue substrate trinitrobenzene (TNB) covalently linked to the quencher dye BHQ10 was bound to the QD–antibody conjugate and quenched the QD fluorescence. In the presence of the TNT analyte, the quencher

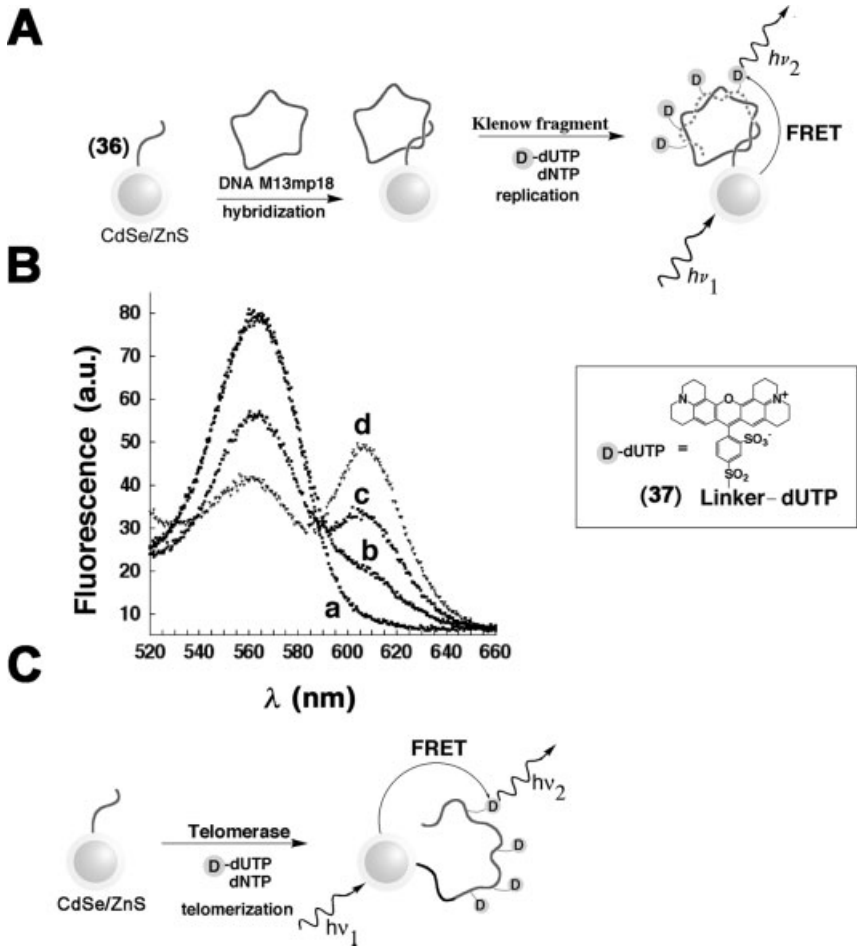

Figure 6.25 (A) Optical detection of M13 phage DNA by nucleic acid-functionalized CdSe/ZnS QDs. The replication of the analyte in the presence of the dNTP mixture that includes the Texas Red-labeled dUTP (**37**) results in the incorporation of the dye into the replica and the stimulates of a FRET process. (B) Time-dependent fluorescence changes upon incorporation of the dye (**37**) into the DNA replica and the analysis of the M13 phage DNA according to (A). TNB–BHQ10 conjugate was competitively displaced. This eliminated the FRET interactions between the QD and the dye, and the fluorescence of the QDs was restored.

The hydrolytic functions of a series of proteolytic enzymes were followed by the application of QDs modified with peptides as reporter units and the FRET process as a readout mechanism [190, 191]. CdSe QDs were modified with different peptides that included specific cleavage sequences for different proteases, and quencher units were tethered to the peptide termini. The fluorescence of the QDs was quenched in

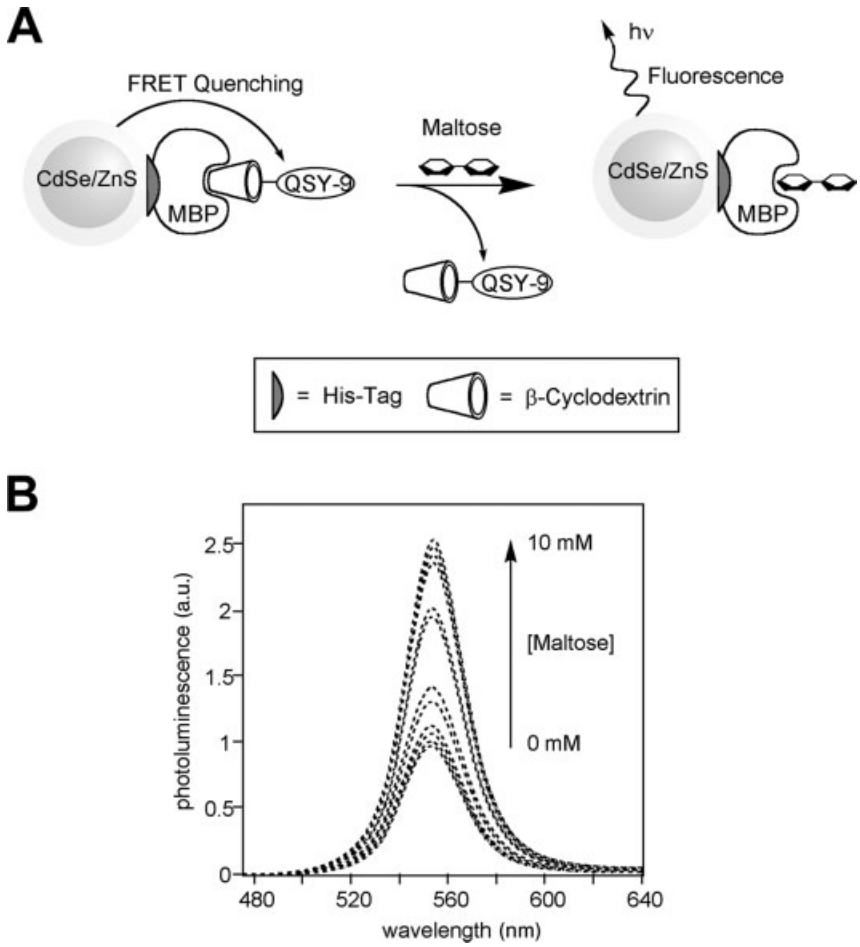

Figure 6.26 (A) Application of CdSe/ZnS QDs for the competitive assay of maltose using the maltose binding protein (MBP) as sensing material and β-cyclodextrin–QSY-9 dye conjugate, β-CD–QSY–9, as FRET quencher. the presence of the quencher–peptide capping layer. The hydrolytic cleavage of the peptide resulted in the removal of the quencher units and this restored the fluorescence of the QDs. For example, collagenase was used to cleave the Rhodamine Red-X dye-labeled peptide (**38**) linked to CdSe/ZnS QDs [Figure 6.27(A)]. While the tethered dye quenched the fluorescence of the QD, hydrolytic scission of the dye and its corresponding removal restored the fluorescence [Figure 6.27(B)].

In a related study, the activity of tyrosinase (TR) was analyzed by CdSe/ZnS QDs [192]. The QDs were capped with tyrosine methyl ester monolayer. The tyrosinase-induced oxidation of the tyrosine groups to the respective dopaquinone units generated active quencher units that suppressed the fluorescence of the QDs

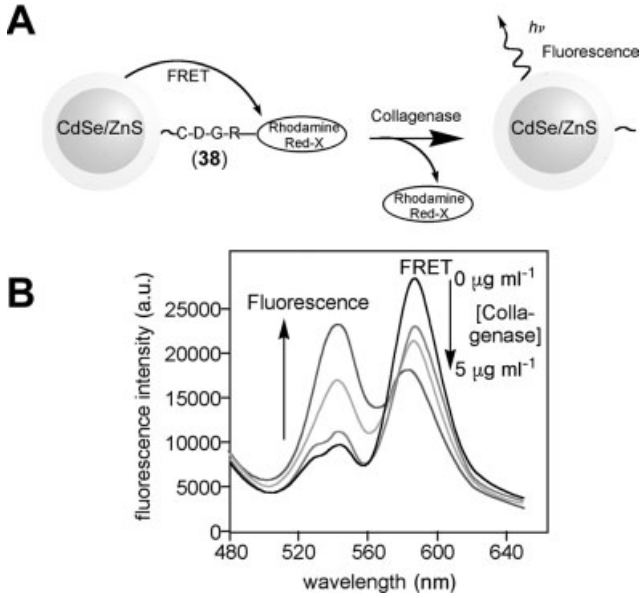

Figure 6.27 (A) Application of CdSe/ZnS QDs for the optical analysis of the protease-mediated hydrolysis of the Rhodamine Red-X-functionalized peptide (**38**). (B) Decrease in the fluorescence of the dye and the corresponding increase in the fluorescence of the QDs upon interaction with different concentrations of collagenase. [Figure 6.28(A)]. The depletion of the fluorescence of the QDs upon their interaction with different concentrations of tyrosinase (TR) is displayed in Figure 6.28(B). The tyrosinase-stimulated oxidation of phenol residues was further employed to use the QDs to monitor the activity of thrombin [192]. The CdSe/ZnS QDs were functionalized with the peptide **39** that included the specific sequences for cleavage by thrombin and the tyrosine site. The tyrosinase-induced oxidation of tyrosine yields the dopaquinone units that quenched the fluorescence of the QDs [Figure 6.29(A)]. The hydrolytic scission of the peptide by thrombin cleaved off the quinone quencher units and restored the fluorescence of the QDs [Figure 6.29(B)].

The FRET process occurring within a duplex DNA structure consisting of tethered CdSe/ZnS QDs and a dye was applied to probe DNA hybridization and the DNase I cleavage of the DNA [193]. Nucleic acid **40**-functionalized CdSe/ZnS QDs were hybridized with the complementary Texas Red-functionalized nucleic acid **41** [Figure 6.30(A)]. The time-dependent resonance energy transfer from the QDs to the dye units was used to monitor the hybridization process. Treatment of the DNA duplex with DNase I resulted in the cleavage of the DNA and the recovery of the fluorescence properties of the CdSe/ZnS QDs. After cleavage of the double stranded DNA with DNase I, the intensity of the FRET band of the dye decreased and the fluorescence of CdSe/ZnS QDs increased [Figure 6.30(B)]. The luminescence properties of the QDs were only partially recovered due to the nonspecific adsorption of the dye on QDs.

(B) Time-dependent fluorescence quenching of the QDs upon tyrosinase-induced oxidation of the tyrosine-functionalized QDs: (a) 0, (b) 0.5, (c) 2, (d) 5 and (e) 10 min. (Reprinted with permission from [192]. Copyright 2006 American Chemical Society).

The QDs were also used to probe the formation of aptamer–protein complexes [194]. An anti-thrombin aptamer was coupled to QDs, and the nucleic acid sequence was hybridized with a complementary oligonucleotide–quencher conjugate (Figure 6.31). The fluorescence of the QDs was quenched in the QD–quencher duplex. In the presence of thrombin the duplex was separated and the aptamer underwent a conformational change to the quadruplex structure that binds thrombin. The displacement of quencher units from the blocked aptamer activated the luminescence functions of the QDs, and a about 19-fold increase in their fluorescence was observed.

6.8 Semiconductor Nanoparticles for Photoelectrochemical Applications

The photoexcitation of the semiconductor quantum dots yields the transfer of an electron from the semiconductor valence band to its conduction band, to yield an electron–hole pair. The electron–hole recombination in the QD may lead to either thermal or radiative relaxation of the excited species. The immobilization of QDs

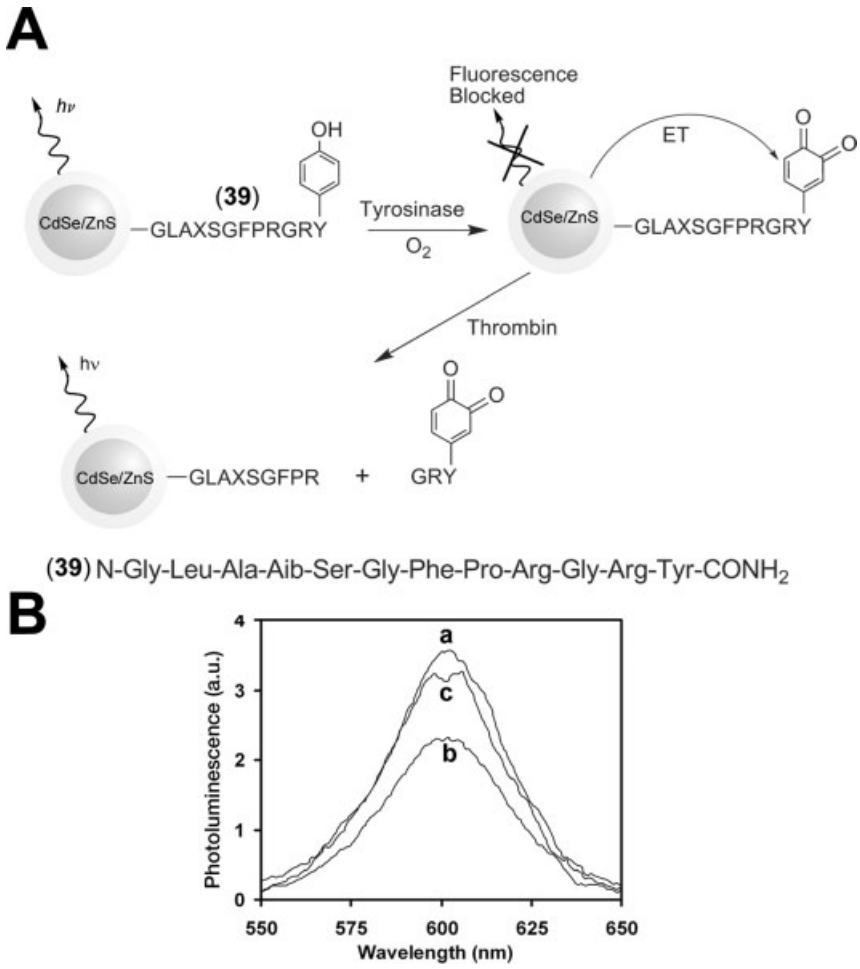

Figure 6.29 (A) Sequential analysis of tyrosinase activity and thrombin activity by the tyrosinase-induced oxidation of the tyrosine-containing peptide (**39**) associated with the CdSe/ZnS QDs that results in the electron transfer quenching of the QDs, followed by the thrombin-induced cleavage of the dopaquinone-modified peptide that restores the fluorescence of the QDs. onto electrodes permits the utilization of the photogenerated electron–hole pair for inducing the formation of photocurrents (photoelectrochemical effect). The photocurrent may be formed by the transfer of the conduction band electrons to the bulk electrode and the concomitant transfer of electrons from the electron donor to the valence band holes to yield a steady-state cathodic photocurrent. Alternatively, the photogenerated conduction band electrons may be transferred to a solution-solubilized electron acceptor, with the concomitant transfer of electrons from the

electrode to the valence band hole and the formation of an anodic photocurrent. The coupling of biomolecule–QD conjugates to electrode surfaces enables one not only to use the photoelectrochemical effect as a means to transduce biosensing processes, but also to tailor functional nano-architectures on surfaces that perform logic gate operations or act as switching systems. Different QD–DNA hybrid systems [195, 196] or QD–protein conjugates [197, 198] were assembled on electrodes, and the control of the photoelectrochemical properties of the QDs by the biomolecules was demonstrated. CdS nanoparticles were assembled on electrodes by double-stranded nucleic acids acting as bridging units, and the effect of a redox-active intercalator on the resulting photocurrent and its direction was demonstrated [196]. Dithiol-tethered single-stranded ssDNA (**42**) was assembled on an Au electrode and subsequently hybridized with a complementary dithiolated ssDNA (**43**) to yield a double-stranded DNA. The resulting surface was treated with CdS–NPs to yield a semiconductor nanoparticle interface linked to the electrode surface (Figure 6.32). Irradiation of the dsDNA–CdS NP-modified electrode in the presence of triethanolamine (TEOA) as electron donor resulted in an anodic low-intensity photocurrent. The observed generated photocurrent was attributed to an imperfect structure of the CdS NP–DNA assemblies that resulted from direct contact between the NPs and the electrode, rather then from charge transport through the DNA. The DNA duplex structure linking the CdS NPs to the electrode could be employed, however, as a medium to incorporate redox-active intercalators that facilitate electrical contact between the NPs and the electrode, resulting in enhanced photocurrents. Methylene blue (MB) (**44**) was intercalated into the (**42**/**43**)-dsDNA coupled to the CdS NPs [Figure 6.32(A) and (B)]. The cyclic voltammogram of the system implied that at potentials $E > -0.28$ V (vs. SCE) the intercalator exists in its oxidized form (**44**), whereas at potentials $E < -0.28$ V (vs. SCE) the intercalator exists in its reduced leuco form (**45**). Coulometric analysis of the MB redox wave, $E^{\circ} = -0.28$ V (vs. SCE), knowing the surface coverage of the

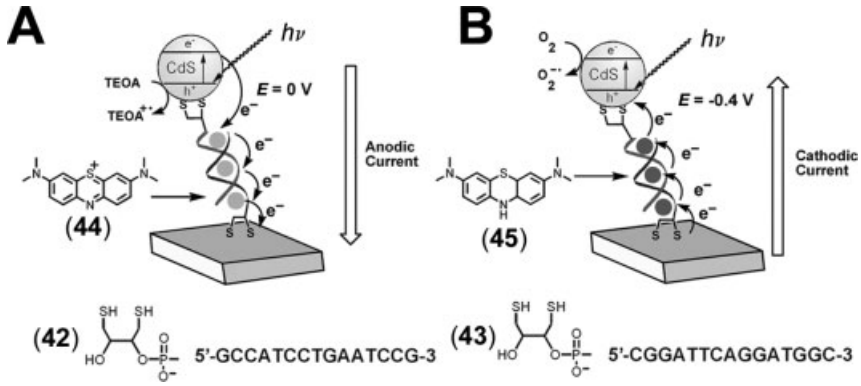

Figure 6.32 Directional electroswitched photocurrents in the CdS NP–ds-DNA–intercalator system. (A) Enhanced generation of anodic photocurrent in the presence of the oxidized methylene blue intercalator (**44**) (applied potential $E = 0$ V). dsDNA, indicated that about 2–3 intercalator units were associated with the double-stranded DNA. An anodic photocurrent was generated in the system in the presence of TEOA as electron donor and MB intercalated into the dsDNA and while applying a potential of 0 V (vs. SCE) on the electrode. At this potential MB existed in its oxidized state (**44**), which acts as an electron acceptor. The resulting photocurrent was about fourfold higher than that recorded in the absence of the intercalator.

The enhanced photocurrent was attributed to the trapping of conduction band electrons by the intercalator units and their transfer to the electrode that was biased at 0 V, thus retaining the intercalator units in their oxidized form. The oxidation of TEOA by the valence band holes then led to the formation of the steady-state anodic photocurrent. Biasing the electrode at a potential of −0.4 V (vs. SCE), a potential that retained the intercalator units in their reduced state (**45**), led to blocking of the photocurrent in the presence of TEOA and under an inert argon atmosphere. This experiment revealed that the oxidized intercalator moieties with the DNA matrix played a central role in the charge transport of the conduction band electrons and the generation of the photocurrent.

Figure 6.33(A), curve b, shows the photocurrent generated by the (**42**/**43**)–dsDNA linked to the CdS NPs in the presence of the reduced intercalator **45** under conditions where the electrode was biased at −0.4 V (vs. SCE) and the system was exposed to air (oxygen). At a bias potential of −0.4 V (vs. SCE), the intercalator units exist in their reduced *leuco* form (**45**) that exhibits electron-donating properties [Figure 6.32(B)]. Photoexcitation of the CdS NPs yields electron–hole pairs in the conduction band and valence band, respectively. The transport of the conduction band electrons to oxygen with the concomitant transport of electrons from the reduced intercalator units to the

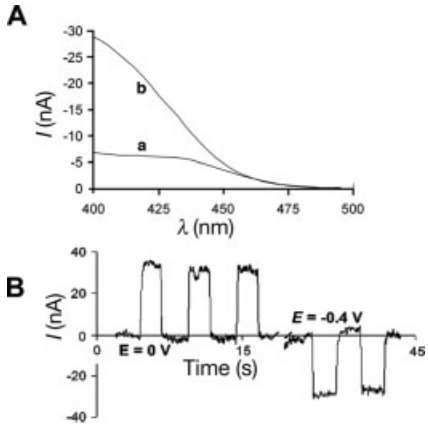

Figure 6.33 (A) Cathodic photocurrents generated in the CdS NP–dsDNA system associated with the electrode: (a) in the absence and (b) in the presence of reduced methylene blue intercalator (**45**). The data were obtained at the applied potential $E = -0.4$ V and in the presence of air. (B) Electrochemically switched anodic and cathodic photocurrents generated by the Cd NP–dsDNA–**44**/**45** systems at 0 and −0.4 V, respectively, in the presence of 20 mM TEOA and air. Photocurrents were generated with irradiation at $\lambda = 420$ nm. (Reproduced with permission from [196]. Copyright 2005 Wiley-VCH).

valence band holes completed the cycle for the generation of the photocurrent. The fact that the electrode potential retained the intercalator units in their reduced state and the infinite availability of the electron acceptor (O_2) yielded the steady-state cathodic photocurrent in the system.

The introduction of TEOA and oxygen to the electrode modified with (**42**/**43**)–DNA duplex and associated CdS NPs allowed the control of the photocurrent direction by switching the bias potential applied on the electrode. Figure 6.33(B) depicts the potential-induced switching of the photocurrent direction upon switching the electrode potential between −0.4 (cathodic photocurrents) and 0 V (anodic photocurrents), respectively. A layer-by-layer deposition of nucleic acid-functionalized CdS QDs on the electrode was followed by the photoelectrochemical transduction of the assembly process [195]. Semiconductor CdS NPs (2.6 ± 0.4 nm) were functionalized with one of the two thiolated nucleic acids **46** and **47** that are complementary to the 5′- and 3′-ends of a target DNA molecule (**48**). An array of CdS NP layers was then constructed on an Au electrode by a layer-by-layer hybridization process with the use of the target DNA **48** as crosslinker of CdS QDs functionalized with nucleic acids (**46** or **47**) complementary to the two ends of the DNA target (Figure 6.34). Illumination of the array in the presence of a sacrificial electron donor resulted in the generation of a photocurrent. The photocurrents increased with the number of generations of CdS NPs associated with the electrode, and the photocurrent action spectra followed the absorbance features of the CdS NPs, which implies that the photocurrents originated from the photoexcitation of the CdS nanoparticles. The ejection of the conduction band electrons into the electrode occurred from the QDs that were in intimate contact with the electrode support. This was supported by the fact that $Ru(NH_3)_6^{3+}$ units ($E^\circ = -0.16$ V vs SCE), which were electrostatically bound to the DNA, enhanced the photocurrent from the DNA–CdS array. The $Ru(NH_3)_6^{3+}$ units acted as charge transfer mediators that facilitated the hopping of conduction band electrons from CdS particles, which lacked contact with the electrode, due to their separation by the DNA tethers.

Enzymes or redox proteins were also linked to semiconductor QDs, and the resulting photocurrents were employed to assay the enzyme activities and to develop different biosensors. Cytochrome *c*-mediated biocatalytic transformations were coupled to CdS NPs, and the direction of the resulting photocurrent was controlled by the oxidation state of the cytochrome c mediator [198]. The CdS NPs were immobilized on an Au electrode through a dithiol linker, and mercaptopyridine units, acting as promoter units that electrically communicate between the cytochrome *c* and the NPs, were linked to the semiconductor NPs (Figure 6.35). In the presence of reduced cytochrome *c*, the photoelectrocatalytic activation of the oxidation of lactate by lactate dehydrogenase (LDH) proceeded, while generating an anodic photocurrent [Figure 6.35(A)]. Photoexcitation of the NPs resulted in the ejection of the conduction band electrons into the electrode and the concomitant oxidation of the reduced cytochrome *c* by the valence band holes. The resulting oxidized cytochrome *c* subsequently mediated the LDH-biocatalyzed oxidation of lactate. Similarly, cytochrome *c* in its oxidized form was used to stimulate the bioelectrocatalytic reduction of NO_3^- to NO_2^- in the presence of nitrate reductase (NR), while generating a cathodic

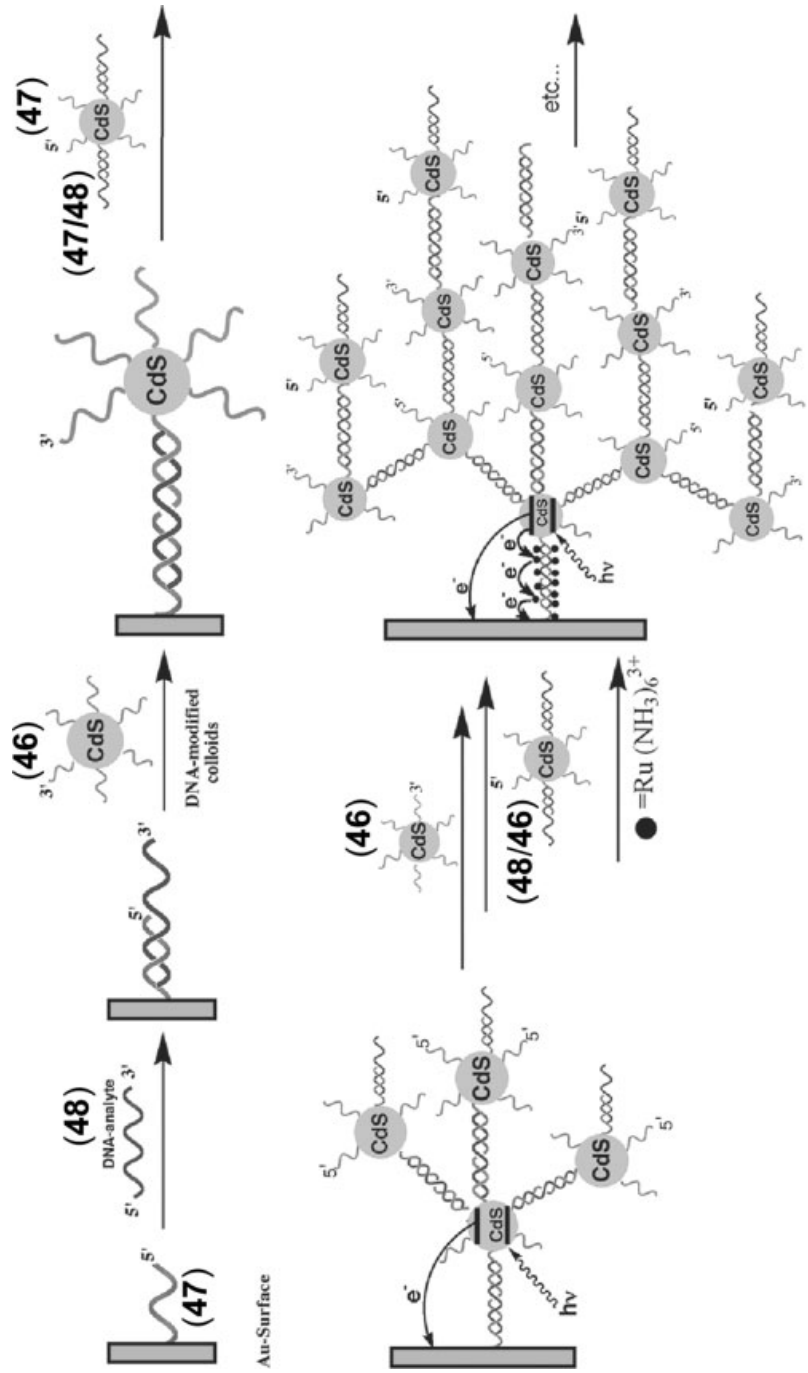

Figure 6.34 Layer-by-layer deposition of CdS NPs using **46**- and **47**-functionalized NPs and **48** as crosslinker. photocurrent [Figure 6.35(B)]. The transfer of conduction band electrons to the oxidized, heme-containing cofactor generated the reduced cytochrome *c*, while the transfer of electrons from the electrode to the valence band holes of the NPs restored the ground state of the NPs. The cytochrome *c*-mediated biocatalyzed reduction of NO_3^- to nitrite then allowed the formation of the cathodic photocurrent, while biasing the electrode potential at 0 V vs. SCE. The photocurrents generated by the biocatalytic cascades at various concentrations of the different substrates are depicted in Figure 6.35 (C). These results demonstrated that photoelectrochemical functions of semiconductor NPs could be used to develop sensors for biocatalytic transformations. A related study employed CdSe/ZnS QDs capped with mercaptosuccinic acid as a protecting layer for the generation of photocurrents in the presence of cytochrome *c* [199].

In a different study [197], CdS NPs were assembled on an Au electrode, and the NPs were further modified with acetylcholinesterase (Figure 6.36). The biocatalyzed

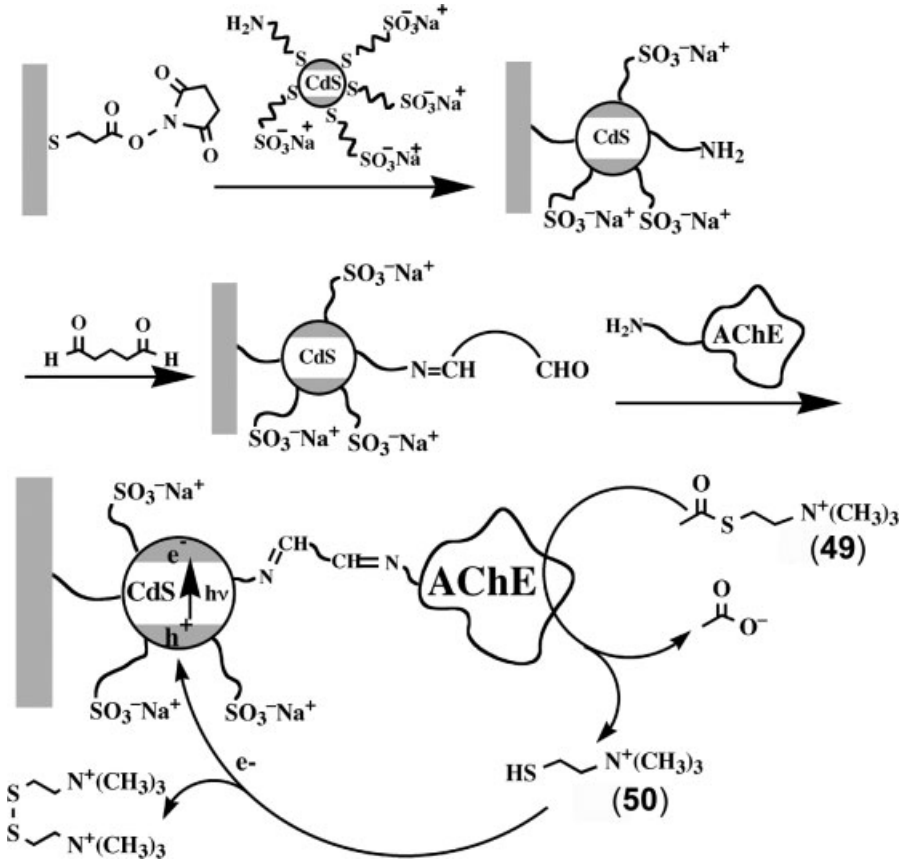

Figure 6.36 Assembly of the CdS NP–AChE hybrid system for the photoelectrochemical detection of the enzyme activity (h^+ = hole). (Reprinted with permission from [197]. Copyright 2003 American Chemical Society).

hydrolysis of acetylthiocholine (**49**) by acetylcholinesterase generated thiocholine (**50**), which acted as an electron donor for the photogenerated holes in the valence band of the CdS NPs. The resulting photocurrent was controlled by the concentration of the substrate and was depleted in the presence of inhibitors of acetylcholinesterase. The system was suggested as a potential sensor for chemical warfare agents that act as inhibitors of acetylcholinesterase.

6.9 Biomolecules as Catalysts for the Synthesis of Nanoparticles

It is well established that living organisms may synthesize NPs and even shaped metallic NPs [200–205]. For example, triangular gold nanoparticles were synthesized by using *Aloe vera* and lemongrass plant (*Cymbopogon flexuosus*) extracts as reducing agents [205, 206]. Although the mechanism of growth of the NPs is not clear, the resulting nanostructures originate from one or more products that are generated by the cell metabolism. This suggests that biomolecules might be active components for synthesizing NPs.

Indeed, a new emerging area in nanobiotechnology involves the use of biomaterials and, specifically, enzymes as active components for the synthesis and growth of particles [207]. As the enlargement of the NPs dominates their spectral properties (extinction coefficient, plasmon excitation wavelength), the biocatalytic reactions that yield the nanoparticles may be sensed by the optical properties of the generated NPs. Furthermore, enzyme–metal NP conjugates may provide biocatalytic hybrid systems that act as amplifying units for biosensing processes.

Different oxidases generate H_2O_2 upon biocatalyzed oxidation of the corresponding substrates by molecular oxygen. The H_2O_2 generated was found to reduce $AuCl_4^-$ in the presence of Au NP seeds that act as catalysts. This observation led to the development of an optical system for the detection of glucose oxidase activity and for the sensing of glucose [208] [Figure 6.37(A)]. A glass support was modified with an aminopropylsiloxane film to which negatively charged Au NPs were linked. Glucose oxidase (GOx) biocatalyzed the oxidation of glucose, and this led to the formation of H_2O_2 that acted as a reducing agent for the catalytic deposition of Au on the Au NPs associated with the glass support. The enlargement of the particles was then followed spectroscopically [Figure 6.37(B)]. Since the amount of the H_2O_2 formed is controlled by the concentration of glucose, the absorbance intensities of the resulting NPs are dominated by the concentration of glucose and the respective calibration curve [Figure 6.37(C)] was extracted. Other enzymes demonstrated, similarly, the biocatalytic generation of reducing products that grow NPs. For example, alkaline phosphatase hydrolyses *p*-aminophenol phosphate to yield *p*-aminophenol and the latter product reduces Ag^+ on Au NP seeds that act as catalytic sites [209].

Different bioactive *o*-hydroquinone derivatives such as the neurotransmitters dopamine (**51**), L-DOPA (**52**), adrenaline (**53**) and noradrenaline (**54**), were found to act as effective reducing agents of metal salts to the respective metal NPs, for example, the reduction of $AuCl_4^-$ to Au NPs without catalytic seeds [210]. For

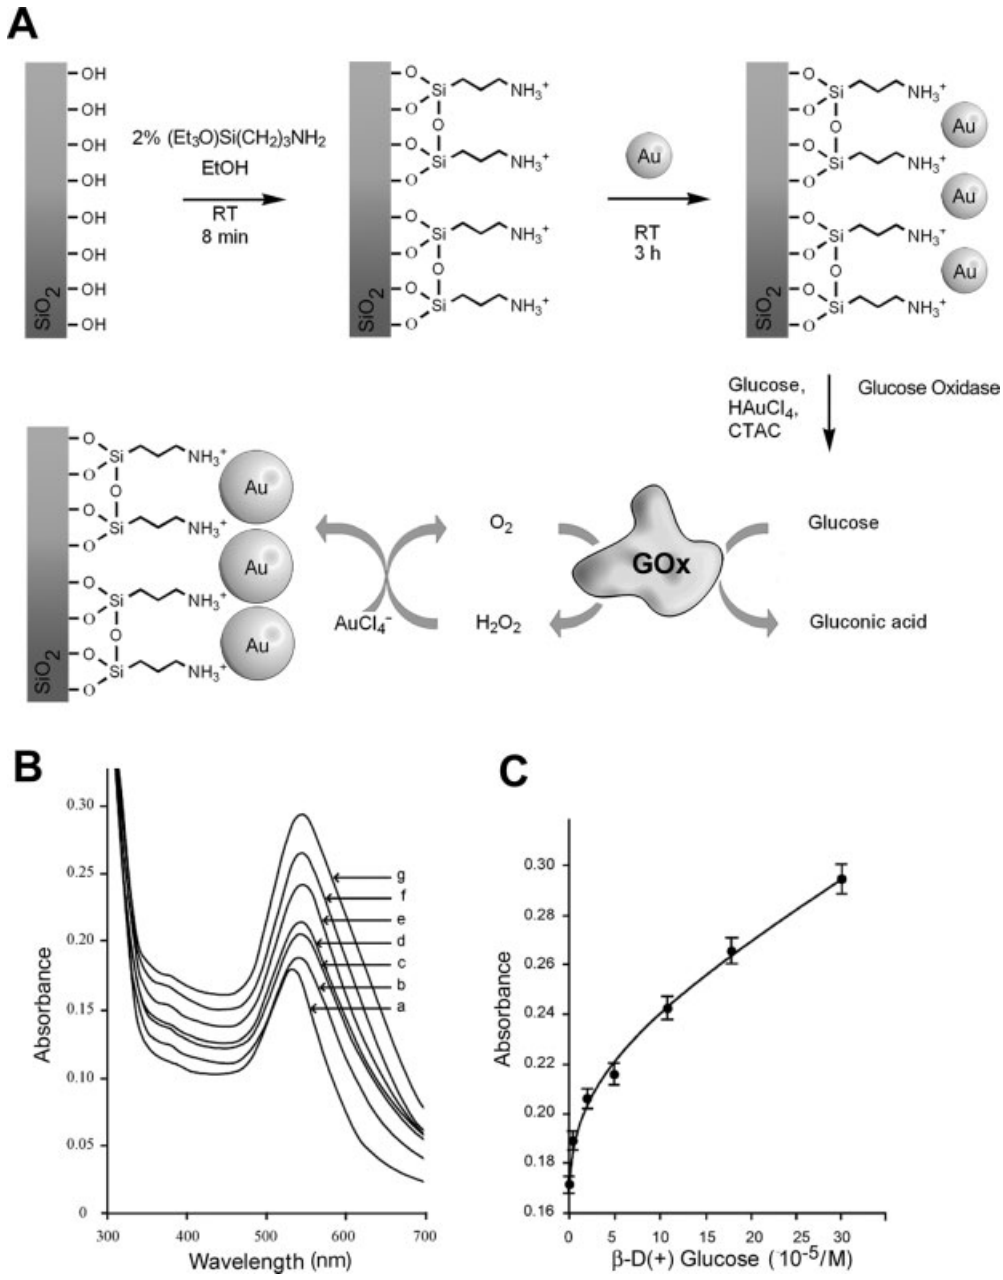

Figure 6.37 (A) Biocatalytic enlargement of Au NPs in the presence of glucose and glucose oxidase (GOx). RT, room temperature; CTAC, cetyltrimethylammonium chloride. (B) Absorbance spectra of Au NP-functionalized glass supports upon reaction with 2×10^{-4} M $HAuCl_4$ and 47 μg mL^{-1} GOx in 0.01 M phosphate buffer that includes CTAC (2×10^{-3} M) and different concentrations of β-D-(+)-glucose: (a) 0, (b) 5×10^{-6}, (c) 2×10^{-5}, (d) 5×10^{-5}, (e) 1.1×10^{-4}, (f) 1.8×10^{-4} and (g) 3.0×10^{-4} M. For all experiments, the reaction time was 10 min and the temperature was 30 °C. (Reprinted with permission from [210]. Copyright 2005 American Chemical Society).

example, Figure 6.38 depicts the absorbance features of the Au NPs generated by different concentrations of dopamine (**51**). As the concentration of dopamine increased, the plasmon absorbance of the Au NPs was intensified. Although the Au NPs were enlarged, as the concentration of dopamine was elevated, the maximum absorbance of the plasmon band was blue-shifted. A detailed TEM analysis revealed that the increase in the concentration of dopamine indeed enhanced the growth of the

Au NP. Nonetheless, the enlargement process generated on the Au NP surface small (1–2 nm) Au clusters that were detached to the solution, and these acted as additional seeds for enlargement. As a result, the absorbance spectra corresponded to the enlarged particles and to the numerous small clusters/NPs, and these led to the blue shift in the plasmon absorbance. The spectral features permitted the extraction of a calibration curve corresponding to the optical detection of dopamine (Figure 6.38, inset). Analogous results were observed for the detection of the other neurotransmitters (**52**–**54**) [210].

The optical detection of L-DOPA (**52**) by means of the Au NPs enabled the following of the activity of tyrosinase. The enzyme tyrosinase is specifically expressed by melanocytes and melanoma cells and is viewed as a specific marker for these cells [211]. Tyrosinase hydroxylates tyrosine to L-DOPA using O_2 as the oxygen source [Figure 6.39(A)]. Consequently, the biocatalytically generated L-DOPA stimulated the synthesis of the Au NPs, and these acted as optical labels for the activity of the enzyme. Figure 6.39(B) shows the absorbance spectra of the Au NPs upon analyzing different amounts of tyrosinase. It was found that tyrosinase could be detected by this method with a sensitivity limit of 10 units.

The catalytic growth of metallic NPs by enzymes and the optical monitoring of the biocatalytic transformations were extended to probe enzyme inhibition [212]. The biocatalyzed hydrolysis of acetylthiocholine (**49**) (an analog of acetylcholine) yields thiocholine (**50**), and the thiol product was found to act as a reducing agent that reduces $AuCl_4^-$ on Au NP seeds. The enlargement of the NPs was used to follow the AChE

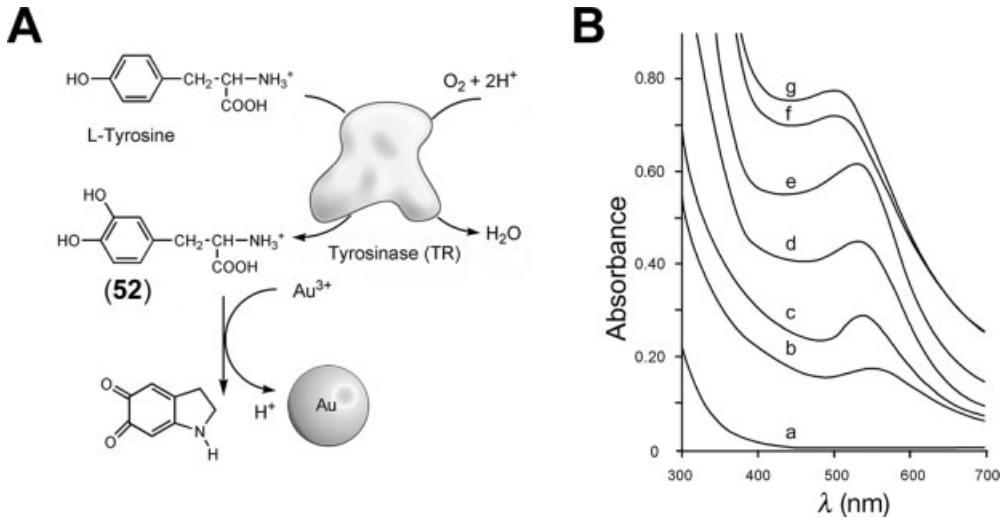

Figure 6.39 (A) Assay of tyrosinase activity through the biocatalyzed oxidation of tyrosine and the L-DOPA (**52**)-mediated formation of Au NPs. activity [Figure 6.40(A)]. The fact that the enzyme controls the absorbance of the Au NPs and thus their degree of enlargement [Figure 6.40(B)] suggested that upon inhibition of AChE the growth of the particles would be blocked. Indeed, the addition of paraoxon (**55**), a well-established AChE irreversible inhibitor that mimics the functions of organophosphate nerve gases, to the biocatalytic system that synthesizes the nanoparticles resulted in the inhibition of the growth of the Au NPs [Figure 6.40(C)]. Also, an electron-transfer mediator, Os(II) bispyridine-4-picolinic acid, was used for the enlargement of Au NP seeds through the biocatalytic oxidation of glucose by GOx [213]. A similar mediated redox mechanism was used to follow the inhibition of AChE through blocking the enlargement of the Au NPs [213].

1,4-Dihydronicotinamide adenine dinucleotide (phosphate) (NADH or NADPH) cofactors were found to enlarge Au NP seeds by the reduction of $AuCl_4^-$. The enzyme/cofactor-mediated enlargement or synthesis of metal NPs thus provides a means to follow the activities of enzymes or their substrates. Numerous biocatalyzed transformations involve NAD^+-dependent enzymes and the coupling of these biocatalysts to the growth of Au NPs allowed the development of different biosensors [75]. Figure 6.41(A) shows the absorbance spectra of a system consisting of Au NP seeds, $AuCl^{4-}$ and cetyltrimethylammonium bromide (CTAB) upon addition of various concentrations of NADH. The plasmon absorbance of the generated Au NPs is intensified as the concentration of NADH increases. Accordingly, the growth of the Au NPs allowed the quantitative optical analysis of NADH [see the calibration curve in Figure 6.41(A), inset]. The enlargement of the Au NP seeds was also examined on

surfaces. Citrate-stabilized Au NP seeds were immobilized on an aminopropylsiloxane film associated with a glass support, and the functionalized surface was treated with different concentrations of NADH in the presence of $AuCl_4^-$. The growth of the Au NPs was followed spectroscopically [Figure 6.41(B)]. The plasmon absorbance of the Au NPs increased as the concentration of NADH was elevated, consistent with the growth of the particles. The SEM images of the particles confirmed the growth of the NPs on the glass support, [Figure 6.41(C)]. The particles generated by 2.7×10^{-4}, 5.4×10^{-4} and 1.36×10^{-3} M NADH are shown in images (I), (II) and (III), which reveal the generation of Au NPs with an average diameter of 13 ± 1, 40 ± 8 and 20 ± 5 nm, respectively. The NPs generated by the high concentration of NADH (III) reveals a 2D array of enlarged particles that touch each other, consistent with the spectral features of the surface.

The quantitative growth of Au NPs by NADH allowed the assay of NAD^+-dependent enzymes and their substrates. This was demonstrated by the application of the enzyme lactate dehydrogenase (LDH) and lactate as substrate [75] [Figure 6.42(A)]. The absorbance spectra of the NPs enlarged in the presence of different concentrations of lactate, are shown in Figure 6.42(B). From the derived calibration curve, lactate

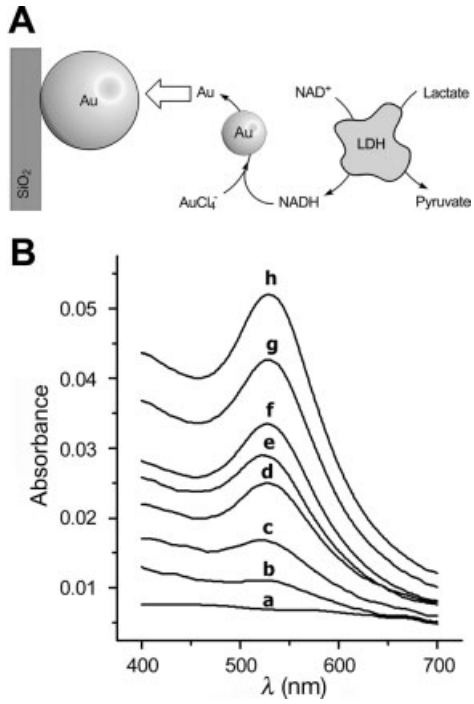

Figure 6.42 (A) Biocatalytic enlargement of Au NPs by the NAD^+–LDH–lactate system. (B) Spectral changes of the Au NP-functionalized glass supports upon interaction with the growth solution consisting of $HAuCl_4$ (1.8×10^{-4} M), CTAB (7.4×10^{-2} M) and lactate–LDH-generated NADH formed within 30 min in the presence of various concentrations of lactate: (a) 0, (b) 2.9×10^{-3}, (c) 3.6×10^{-3}, (d) 5.1×10^{-3}, (e) 5.8×10^{-3}, (f) 6.6×10^{-3}, (g) 7.3×10^{-3}, (h) 9.8×10^{-3} M. could be analyzed with a sensitivity limit corresponding to 3×10^{-3} M. Also, the reduced cofactor NADH was also employed to reduce Cu^{2+} ions to Cu^0 metal deposited on core Au NPs [214].

The NADH-induced growth of Au NPs was further developed by demonstrating that the reduced cofactor was able to synthesize, under controlled conditions, shaped NPs (in the form of dipods, tripods and tetrapods). These shaped particles exhibit unique optical properties (color) as a result of their high aspect ratio and the existence of a longitudinal plasmonic exciton [215]. It was demonstrated that in basic aqueous solution (pH = 11) that included ascorbate and NADH as reducing agents and CTAB as surfactant, the rapid formation of the shaped Au NPs was observed. The Au NP shapes consisted of dipods (12%), tripods (45%), tetrapods (13%) and spherical particles (30%) (Figure 6.43). The shaped particles were made of "arms" about 20–25 nm long and with a width of 2–5 nm (Figure 6.43). The development of the shaped particles was controlled by the concentration of NADH. At low NADH concentrations, "embryonic-type" shapes were observed, and at high cofactor concentrations, well-shaped particles were detected [Figure 6.43(A)–(C)]. A series of experiments indicated that the particles were formed in two steps. In the primary step, ascorbate reduced, at pH 11, $AuCl_4^-$ to Au NP seeds. These particles acted as catalysts for the rapid NADH-mediated reduction of $AuCl_4^-$ to Au^0 that was deposited on the seeds. High-resolution transmission electron microscopy (HRTEM) allowed

the detailed analysis of the growth directions of the shaped NPs, and this enabled the growth mechanism to be proposed. For example, HRTEM images of tripod particles are given, Figure 6.43(D) and (E). The lattice planes exhibit an inter-planar distance of 0.235 nm that corresponds to the {1 1 1} type planes of crystalline gold. The pods, separated by 120°, revealed a crystallite orientation of [0 1 1] with growth directions of the pods of type <211>; namely the pods are extended the direction $[1\bar{1}\bar{2}]$, $[\bar{2}\bar{1}1]$ and [1 2 1] [Figure 6.43(D), inset]. The shaped Au NPs revealed a red-shifted plasmon absorbance band at $\lambda = 680$ nm, consistent with a longitudinal plasmon exciton in the "rod-like" structures. The blue color of the shaped Au NPs distinctly differs from the red spherical Au NPs.

The fact that the degree of shaping and the absorbance spectra of the resulting Au NPs were controlled by the concentration of NADH allowed the development of an ethanol biosensor based on the shape-controlled synthesis of NPs. The biocatalyzed oxidation of ethanol by AlcDH yields NADH, and the biocatalytically generated NADH acted as an active reducing agent for the formation of blue shaped Au NPs. As the amount of NADH is controlled by the concentration of ethanol, the extent of the structurally developed shaped nanoparticles exhibiting the red-shifted longitudinal plasmon was then controlled by the substrate concentration. Figure 6.43(F) shows the absorbance spectra resulting from the gradual development of the shaped Au NPs formed in the presence of different concentrations of ethanol. The derived calibration curve corresponding to the optical analysis of ethanol by the shaped Au NPs is depicted in Figure 6.43(F), inset.

6.10
Biomolecule Growth of Metal Nanowires

The synthesis of nanowires is one of the challenging topics in nanobiotechnology [216, 217]. The construction of objects at the molecular or supramolecular level could be used to generate templates or "seeds" for nanometer-sized wires. Nanowires are considered as building blocks for the self-assembly of logic and memory circuits in future nanoelectronic devices [218]. Thus, the development of methods to assemble metal or semiconductor nanowires is a basic requirement for the construction of nanocircuits and nanodevices. Furthermore, the nanowires should include functional sites that allow their incorporation into structures of higher complexity and hierarchical functionality. The use of biomaterials as templates for the generation of nanowires and nanocircuitry is particularly attractive. Biomolecules exhibit dimensions that are comparable to those of the envisaged nano-objects. In addition to the fascinating structures of biomaterials that may lead to new inorganic or organic materials, templates of biological origin may act as "factories" for the production of "molds" for nanotechnology. The replication of DNA, the synthesis of proteins and the self-assembly of protein monomers into sheets, tubules and filaments all represent biological processes for the high-throughput synthesis of biomolecular templates for nanotechnology. Specifically, the coupling of NPs to biomolecules might yield new materials that combine the self-assembly properties of the biomolecules with the catalytic functions of the NPs. That is, the catalytic

enlargement of the NPs associated with the biomolecules might generate the metallic nanowires.

Among the different biomaterials, DNA is of specific interest as a template for the construction of nanowires [219–221]. The ease of synthesis of DNA of controlled lengths and predesigned shapes, together with the information stored in the base sequence, introduce rich structural properties and addressable structural domains for the binding of the reactants that form nanowires. Also, numerous biocatalysts such as endonucleases, ligase, telomerase and polymerase can "cut", "paste", elongate or replicate DNA and may be considered as nanotools for shaping the desired DNA and, eventually, for the generation of nanocircuits. In addition, the intercalation of molecular components into DNA and the binding of cationic species such as metal ions to the phosphate units of nucleic acids allow the assembly of chemically active functional complexes, which may be used as precursors for the formation the nanowires.

One of the early examples that demonstrated the synthesis of Ag nanowires [222] is depicted in Figure 6.44. Two microelectrodes, which were positioned opposite one

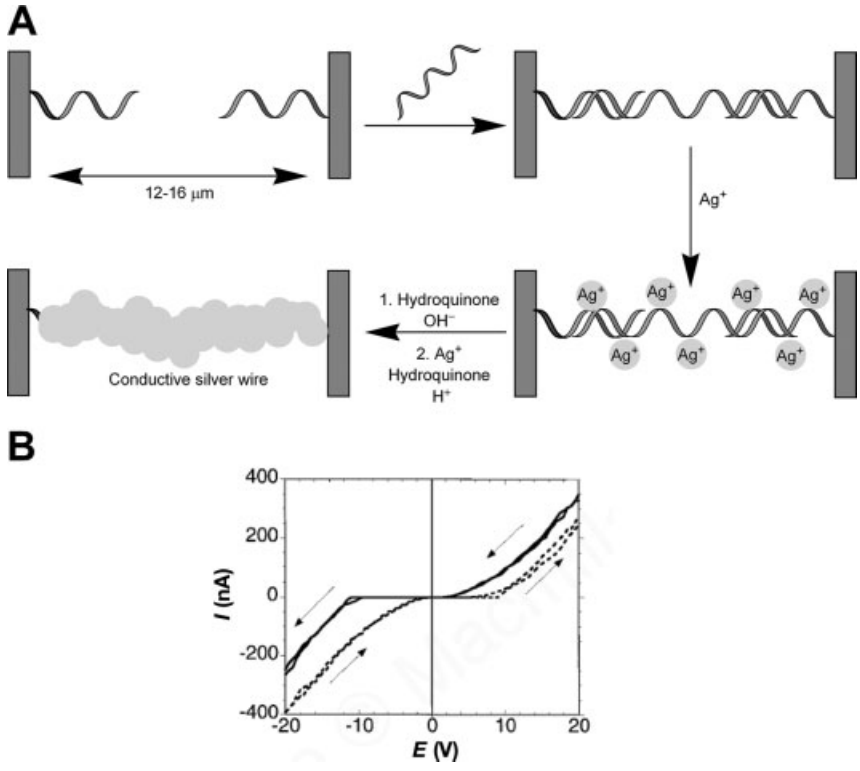

Figure 6.44 (A) Construction of a nanowire that bridges two microelectrodes by the deposition of Ag^+ ions on a bridging DNA strand followed by the chemical reduction of the Ag^+ ions to the metallic agglomerate. (B) Current versus voltage (*I*–*V*) curves obtained with the structures produced. (Reprinted with permission from Macmillan Publishers Ltd: Nature [222]. Copyright 1998).

another with a 12–16-μm separation gap, were functionalized with 12-base oligonucleotides that were then bridged with a 16-μm long λ-DNA [Figure 6.44(A)]. The resulting phosphate units of the DNA bridge were loaded with Ag^+ ions by ion-exchange and the bound Ag^+ ions were reduced to Ag metal with hydroquinone. The resulting small Ag aggregates along the DNA backbone were further reduced by reducing Ag^+ under acidic conditions and catalytic deposition of Ag on the Ag aggregates formed metallic nanowires. The resulting Ag nanowires exhibited dimensions corresponding to micrometer long and about 100 nm wide nanowires. The conduction properties of the nanowires revealed non-ohmic behavior and threshold potentials were needed to activate electron transport through the wires [Figure 6.44 (B)]. The potential gap in which no current passes through the nanowires was attributed to the existence of structural defects in the nanowires. The "hopping" of electrons across these barriers requires an overpotential that is reflected by the break voltage. This study was extended with the synthesis of many other metallic nanowires on DNA templates, and Cu [223], Pt [224] and Pd [225] nanowires were generated on DNA backbones.

The use of DNA and metallic NPs as templates and NPs as building blocks of nanowires was further demonstrated by using telomers synthesized by HeLa cancer cell extracts [226]. The constant repeat units that exist in the telomers provided addressable domains for the self-assembly of the NPs and the subsequent synthesis of the nanowires. By one approach, the primer **56** was telomerized in the presence of the dNTPs nucleotide mixture, which contained (aminoallyl)-dNTPs (**57**) [Figure 6.45(A)]. The resulting amine-containing telomers were treated with Au NPs (1.4 nm) (**58**), which were functionalized with the single *N*-hydroxysuccinimidyl ester groups, to yield Au NP-modified telomers. The Au NP-decorated DNA wires were then enlarged by electroless gold deposition to generate metallic nanowires [Figure 6.45(B) and (C)]. A second approach involved the telomerase-induced generation of telomers that included constant repeat units. The hybridization of the Au NPs functionalized with nucleic acids complementary to the telomer repeat domains, followed by electroless enlargement of the NPs, yielded Au nanowires.

The binding of proteins, such as RecA, to DNA has been used as a means for the patterning of nanoscale DNA-based metal wires with nonconductive or semiconductive gaps [227]. The metallization of the free, non-protein-coated DNA segments permitted the sequence-specific biomolecular lithography of DNA-based nanowires [228]. A single-stranded nucleic acid sequence was complexed with RecA and was carried to a double-stranded duplex DNA, a process that led to the nanolithographic patterned insulation of the DNA template by the protein [Figure 6.46(A)]. A carbon nanotube was then specifically attached to the protein patch using a series of antigen–antibody recognition processes: The anti-RecA antibody (Ab) was bound to the protein linked to the DNA duplex and the biotinylated anti-antibody was then linked to the RecA Ab. The latter Ab was used to bind specifically the streptavidin-coated carbon nanotubes on the protein patch. Ag^+ ions were bound to the free DNA domains and these were reduced to Ag clusters that were associated with the DNA assembly. The dsDNA was modified with aldehyde groups prior to this process to allow the chemical reduction of the electrostatically bound Ag^+ ions to Ag clusters. The

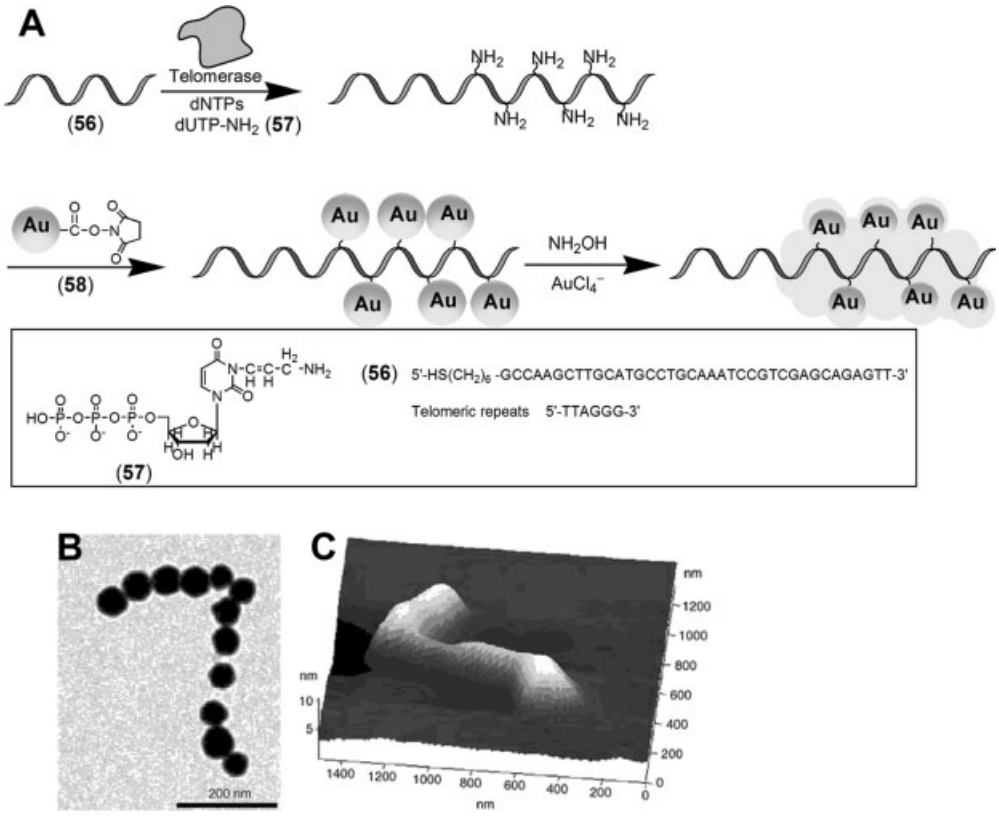

Figure 6.45 Assembly of Au nanowires on a telomer template. (A) Covalent attachment of Au NPs to amine groups, which were introduced into the telomer structure during the telomerization step, followed by catalytic enlargement of the NPs. subsequent catalytic electroless enlargement of the Ag^0 nanoclusters with gold generated the device where the two Au contacts were bridged by the carbon nanotubes. A representative SEM image of the device is depicted in Figure 6.46(B). The resulting device deposited on a Si substrate acted as a field-effect nanotransistor, where the gold contacts bridged by the CNT acted as the nanoscale source and drain electrodes, and the current flow through the CNT was gated by the applied potential on the Si support [Figure 6.46(C)]. Other DNA–protein arrays based on streptavidin and biotinylated DNA were used to organize tailored NP nanostructures that were subsequently metallized to composite architectures of nanowires [229].

Proteins may be applied as templates for the deposition of metal nanoparticles and for the formation of metal nanowires. For example, aromatic short-chain peptides, such as the Alzheimer's diphenylalanine β-amyloid (**59**), form well-ordered nano-

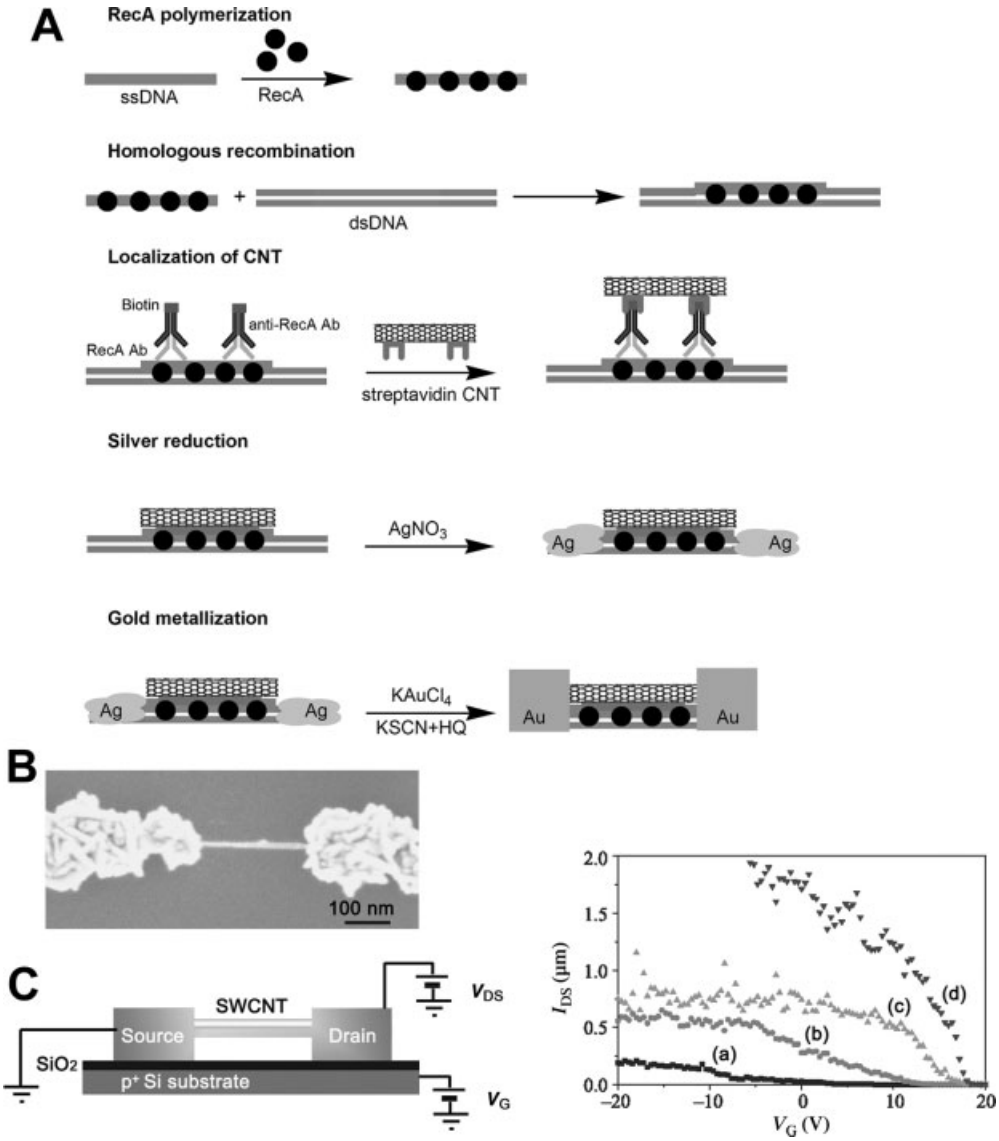

Figure 6.46 (A) Construction of a DNA-templated CNT FET. (B) SEM image of a rope of CNTs and metallic wires contacting it. tubes that were used as templates for growing Ag nanowires [230] [Figure 6.47(A)]. The peptide nanotubes were loaded with Ag^+ ions, which were reduced with citrate to yield metallic silver nanowires inside the peptide nanotubes [Figure 6.47(B)]. The peptide coating was then removed by enzymatic degradation in the presence of proteinase K to yield micrometer-long Ag nanowires with a diameter of 20 nm [Figure 6.47(C)]. Upon application of D-phenylalanine-based peptide fibrils, which are resistant to proteinase K, the peptide coating of the Ag nanowires was preserved. Peptide nanotubes were also used to generate coaxial metal–insulator–metal nanotubes [231] [Figure 6.48(A)]. The D-phenylalanine peptide **59** assembled nanotube was interacted with Ag^+ ions and the resulting intra-tube-associated ions were reduced to form the Ag^0 nanowire. The resulting composite was further modified by tethering of a thiol-functionalized peptide to the nanowire peptide coating. The association of Au NPs with the thiol groups followed by deposition of gold on the Au NP seeds generated the resulting coaxial metal nanowires [Figure 6.48(B)].

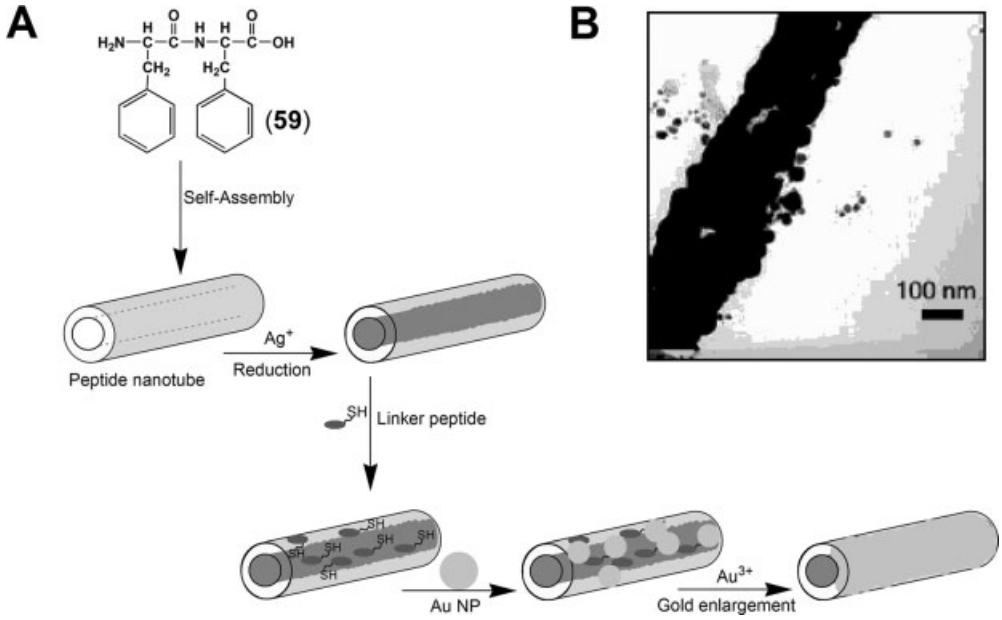

Figure 6.48 (A) Stepwise synthesis of coaxial Ag/Au nanowires in a peptide template. (B) TEM image of the coaxial wire formed in the peptide template. (Reproduced with permission from [231]. Copyright 2006 American Chemical Society).

The specific assembly of protein subunits into polymeric structures could provide a means for the patterning of the generated metal nanowires. The f-actin filament provides specific binding for the biomolecular motor protein myosin, which forms a complex with the filament, where the motility of myosin along the filament is driven by ATP [232, 233]. The f-actin filament is formed by the reversible association of g-actin subunits in presence of ATP, Mg^{2+} and Na^{+} ions. Accordingly, the f-actin filament was used as a template for the formation of metallic nanowires [234]. The f-actin filament was covalently modified with Au NPs (1.4 nm) that were functionalized with single *N*-hydroxysuccinimidyl ester groups, and the Au NP-functionalized g-actin subunits were then separated and used as versatile building blocks for the formation of the nanostructure. The Mg^{2+}/Na^{+}/ATP-induced polymerization of the functionalized monomers yielded the Au NP-functionalized filaments [Figure 6.49(A)], and electroless catalytic deposition of gold on the Au NP-functionalized f-actin filament yielded 1–3-μm long gold wires of height 80–150 nm. The gold wires revealed metallic conductivity with a resistance similar to that of bulk gold. By the sequential polymerization of naked actin filament units on the preformed Au NP–actin wire and the subsequent electroless catalytic deposition of gold on the Au NPs, patterned actin–Au wire–actin filaments were generated [Figure 6.49(C)]. A related approach was applied to yield the inverse Au wire–actin–Au wire patterned filaments [Figure 6.49(B)]. The nanostructure consisting of actin–Au nanowire–actin was used

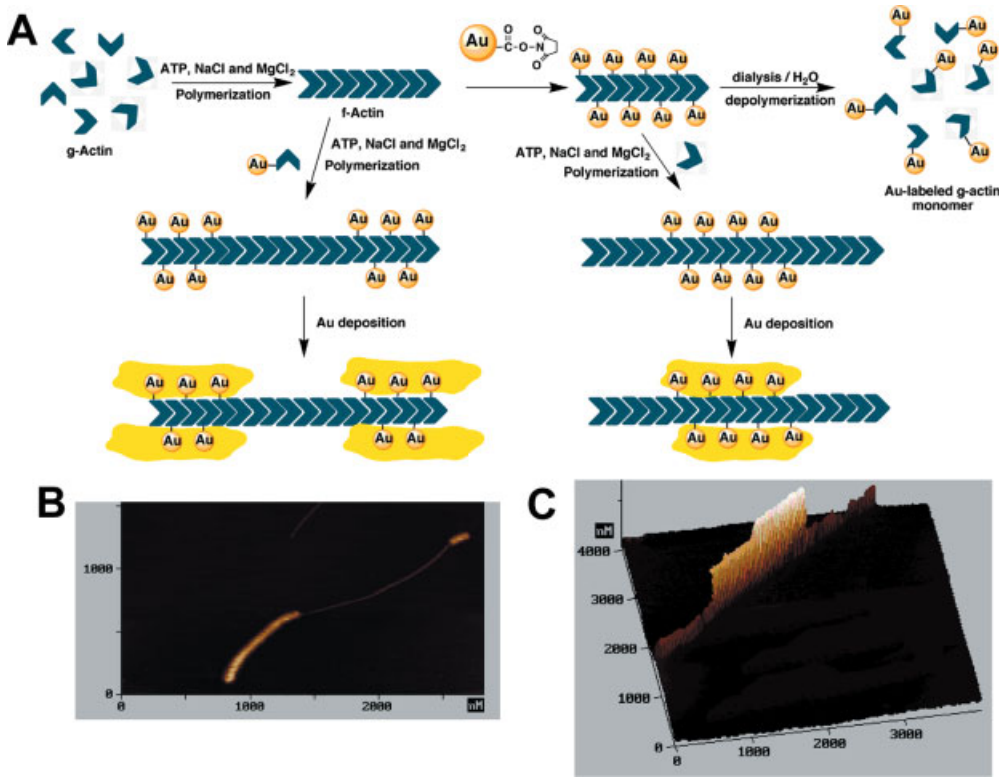

Figure 6.49 (A) Assembly of patterned actin-based Au nanowires: Left: an Au wire–actin–Au wire filament; Right: an actin–Au wire–actin filament. (B) AFM image of the Au wire–actin–Au wire filament. (C) AFM image of the actin–Au wire–actin filament. (Reprinted by permission from Macmillan Publishers Ltd: Nature Materials 234, Copyright (2004)).

as a nanotransporter driven by an external fuel. The actin–Au nanowire–actin nanostructure was deposited on a myosin-modified glass surface. Addition of ATP resulted in the motility of the nanostructures on the surface of $250 \pm 50\,\mathrm{nm\,s^{-1}}$. Thus, such metallic nano-objects conjugated to motor proteins were suggested as potential nanotransporters, where chemicals deposited on the Au cargo are carried by the proteins.

In contrast with the use of proteins as passive templates for the growth of nanowires, one can use enzymes and NPs as active hybrid systems for the synthesis of nanocircuitry and for the preparation of patterned nanostructures. The participation of enzymes in growing metal NPs and particularly the biocatalytic enlargement of metal NP seeds suggests that metal NP–enzyme hybrids could be used as active components for the synthesis of metallic nanowires. The flavoenzyme glucose oxidase was functionalized with Au NPs (1.4 nm, average loading of 12 NPs per

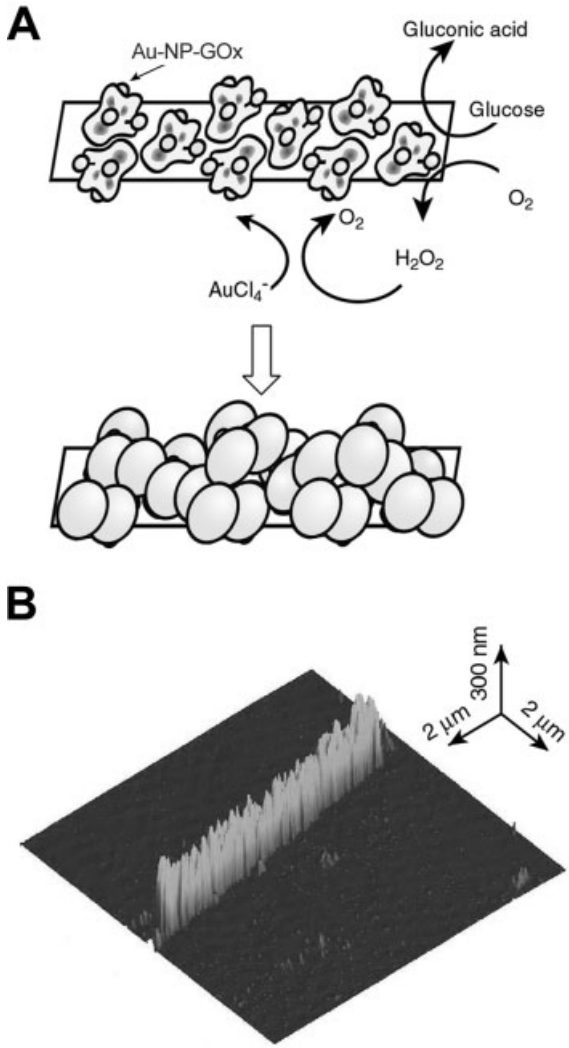

Figure 6.50 (A) Generation of an Au nanowire by the biocatalytic enlargement of an Au NP functionalized GOx line deposited on a silicon support by DPN. (B) Atomic force microscopy (AFM) image of the Au nanowire generated by the Au NP-functionalized GOx "biocatalytic ink". (Adapted with permission from [209]. Copyright 2006 Wiley-VCH).

enzyme unit) and the biocatalytic–NP hybrid material was used as a template for the stepwise synthesis of metallic nanowires [209] [Figure 6.50(A)]. The enzyme–Au NP hybrid was used as a "biocatalytic ink" for the pattering of Si surfaces using dip-pen nanolithography (DPN). The subsequent glucose-mediated generation of H_2O_2 and the catalytic enlargement of the NPs resulted in the catalytic growth of the particles,

and this yielded micrometer-long Au metallic wires exhibiting heights and widths in the region of 150–250 nm, depending on the biocatalytic "development" time interval [Figure 6.50(B)].

This process is not limited to redox enzymes, and NP-functionalized biocatalysts that transform a substrate to an appropriate reducing agent may be similarly used as "biocatalytic inks" for the generation of metallic nanowires. This was exemplified with the application of Au NP-functionalized alkaline phosphatase, AlkPh (average loading of 10 NPs per enzyme unit) as "biocatalytic ink" for the generation of Ag nanowires [209] [Figure 6.51(A)]. The alkaline phosphatase-mediated hydrolysis of *p*-aminophenol phosphate (**60**) yielded *p*-aminophenol (**61**), which reduced Ag^{+} to Ag^{0} on the Au NP seeds associated with the enzyme. This allowed the enlargement of the Au particles acting as a core for the formation of a continuous silver wires exhibiting height of 30–40 nm, on the protein template [Figure 6.51 (B)]. The method allowed the stepwise, orthogonal formation of metal nanowires composed of different metals and controlled dimensions [Figure 6.51(C)]. Furthermore, the biocatalytic growth of the nanowires exhibited a self-inhibition mechanism and upon coating of the protein with the metal no further enlargement occurred. This self-inhibition mechanism is specifically important since the dimensions of the resulting nanowires are controlled by the sizes of the biocatalytic templates.

6.11 Conclusions and Perspectives

Nanobiotechnology, and particularly, biomolecule–NP hybrid systems, that represent the functional elements of nanobiotechnology, provide an emerging interdisciplinary scientific discipline. This chapter has addressed these scientific areas by discussing numerous biomolecule–NP conjugates as functional units for biosensing, building elements of nanocircuitry and devices and composite materials for intracellular diagnostics or medical therapeutics. Biomolecule–NP hybrid systems combine the evolution-optimized recognition and reactivity properties of biomolecules with the unique electronic, catalytic and optical properties of metallic or semiconductor NPs. The biomolecule–NP hybrids provide new materials that reveal unique properties and functions as a result of the composite structures and the quantum size effects accompanying the different nano-assemblies.

The analytical applications of biomolecule–NP systems have seen tremendously advances in the last decade. The electronic properties of metallic NPs were used to electrically communicate redox proteins with electrodes and to develop amperometric biosensors. The catalytic functions of metallic NPs were broadly applied to develop amplification methods for biosensing events, and the localized plasmonic features of NPs were extensively used to develop new optical methods that probe biorecognition events and design novel biosensor configurations. Optical phenomena such as the surface-enhanced fluorescence or Raman signals by dye-modified metallic NPs, the coupling of the localized plasmon of metallic NPs with surface plasmonic waves,

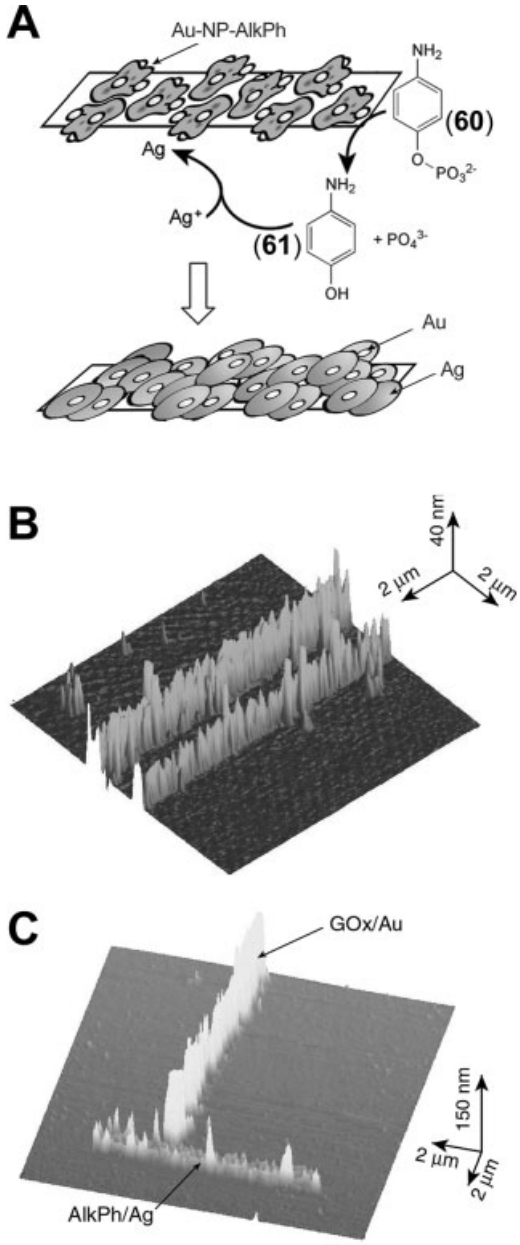

Figure 6.51 (A) Biocatalytic enlargement of Au NP-modified AlkPh with silver and fabrication of silver lines on a support using DPN and the "biocatalytic ink". (B) AFM image of Ag nanowires generated on the Au NP–AlkPh template deposited on the silicon support by DPN after 40 min of enlargement in the Ag growth solution. (C) AFM image of Au and Ag nanowires generated by deposition and enlargement of the Au NP–GOx template, followed by the passivation of the Au nanowire with mercaptoundecanoic acid and the subsequent deposition of Au NP–AlkPh template and its enlargement to the Ag nanowire. the interparticle plasmon coupling in metallic NP aggregates and the reflectance of NPs were creatively used to image biorecognition events and to develop optical biosensors. Similarly, the coupling of biomolecules to semiconductor NPs (quantum dots) demonstrated the utility of these systems to assemble new optical and photoelectrochemical biosensor systems. The size-controlled emission properties of semiconductor QDs, as a result of the quantum confinement of the electronic levels in the nanoparticles, allow the multiplexed analysis of different targets and the design of high-throughput analyses in array formats. The development of photoelectrochemically based biosensors by the use of biomolecule–semiconductor hybrid systems highlights the bridge between the optical and electronic applications of biomolecule–NP hybrids for biosensing.

The development of biomolecule–NP-based sensors reached the level of practical applicability, and various analytical systems for clinical diagnostics, the analysis of food products, environmental pollutants and homeland security biosensors are expected to emerge from these hybrid nanocomposites. Some new challenging research directions in the analytical applications of biomolecule–NP hybrid systems can be identified, however. The unique optical properties of metal or semiconductor nanorods [235, 236] pave the way to new optical applications of these nano-objects. Composite nanorods may act as optical barcodes for biosensing events and could provide a rich library of labels for the parallel analysis of complex mixtures. Similarly, metal NP–semiconductor quantum dot (dumbbell) nanostructures [237] may provide new composites to assemble biomolecule hybrid systems of tailored electronic and optical functions.

Significant progress in the use of biomolecules as templates for the synthesis of nanostructures and nanocircuitry has been achieved in recent years. DNA and proteins act as efficient nanoscale templates for the synthesis of metallic or semiconductor nanowires. Although the scientific approaches to construct the nanowires are innovative, important challenges in this field are still ahead of us. The non-ohmic behavior of the conductance through nanowires and the difficulties in electrically wiring the nanowires to micro-contacts requires a fundamental experimental and theoretical understanding of charge transport phenomena across these nanostructures. The use of enzymes as catalysts that grow nanowires of predesigned structures [209] represents an important path to the further development of nanocircuitry and devices.

Numerous other applications of biomolecule–NP hybrid systems may be envisaged. The use of such systems in nanomedicine [238] has attracted increasing interest, and different applications such as photodynamic anticancer therapy [239], targeted delivery of radioisotopes [240], drug delivery [241] and gene therapy [242] have been demonstrated.

Physicists, chemists, biologists and material scientists have already recognized the limitless scientific opportunities and challenges in the applications of biomolecule–NP hybrid systems. The rapid progress in the field suggests that these interdisciplinary efforts will lead to exciting new science of immense practical and technological utility.

7
Philosophy of Nanotechnoscience

Alfred Nordmann

7.1
Introduction: Philosophy of Science and of Technoscience

One way or another, the philosophy of science always informs and reflects the development of science and technology. It appears in the midst of disputes over theories and methods, in the reflective thought of scientists and since the late nineteenth century also in the analyses of so-called philosophers of science. Four philosophical questions, in particular, are answered implicitly or contested explicitly by any scientific endeavor:

- How is a particular science to be defined and what are the objects and problems in its domain of interest?
- What is the methodologically proper or specifically scientific way of approaching these objects and problems?
- What kind of knowledge is produced and communicated, how does it attain objectivity, if not certainty, and how does it balance the competing demands of universal generality and local specificity?
- What is its place in relation to other sciences, where do its instruments and methods, its concepts and theories come from and should its findings be explained on a deeper level by more fundamental investigations?

When researchers publish their results, when they review and critique their peers, argue for research funds or train graduate students, they offer examples of what they consider good scientific practice and thereby adopt a stance on all four questions. When, for example, there is a call for more basic research on some scientific question, one can look at the argument that is advanced and discover how it is informed by a particular conception of science and the relation of science and technology. Frequently it involves the idea that basic science identifies rather general laws of causal relations. These laws can then be applied in a variety of contexts and the deliberate control of causes and effects can give rise to new technical devices. If one encounters such an argument for basic science, one might ask, of course, whether this picture of

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

basic versus applied science is accurate. While it may hold here and there, especially in theoretical physics, it is perhaps altogether inadequate for chemistry. And thus one may find that the implicit assumptions agree less with the practice and history of science and more with a particular self-understanding of science. According to this self-understanding, basic science disinterestedly studies the world as it is, whereas the engineering sciences apply this knowledge to change the world in accordance with human purposes.

Science and scientific practice are always changing as new instruments are invented, new problems arise, new disciplines emerge. Also, the somewhat idealized self-understandings of scientists can change. The relation of science and technology provides a case point. Is molecular electronics a basic science? Is nanotechnology applied nanoscience? Are the optical properties of carbon nanotubes part of the world as it is or do they appear only in the midst of a large-scale engineering pursuit that is changing the world according to human purposes? There are no easy or straightforward answers to these questions and this is perhaps due to the fact that the traditional ways of distinguishing science and technology, and basic and applied research, do not work any longer. As many authors are suggesting, we should speak of "technoscience" [1, 2] which is defined primarily by the interdependence of theoretical observation and technical intervention [3].[1)] Accordingly, the designation "nanotechnoscience" is more than shorthand for "nanoscience and nanotechnologies" but signifies a mode of research other than traditional science and engineering. Peter Galison, for example, notes that "[n]anoscientists aim to build – not to demonstrate existence. They are after an engineering way of being in science" [5]. Others appeal to the idea of a "general purpose technology" and thus suggest that nanotechnoscience is fundamental research to enable a new technological development at large. Richard Jones sharpens this when he succinctly labels at least some nanotechnoscientific research as "basic gizmology."[2)]

Often, nanoscience is defined as an investigation of scale-dependently discontinuous properties or phenomena [6]. This definition of nanoscience produces in its wake an ill-defined conception of nanotechnologies – these encompass all possible technical uses of these properties and phenomena. In its 2004 report on nanoscience and nanotechnologies, the Royal Society and Royal Academy of Engineering defines these terms as follows:

1) This is in reference to Ian Hacking's distinc-tion of "representing" and "intervening" [4]: In technoscientific research, the business of theoretical representation cannot be dissociated, even in principle, from the material conditions of knowledge production and thus from the interventions that are required to make and stabilize the phenomena. In other words, technoscience knows only one way of gaining new knowledge and that is by first making a new world. If the business of science is the theoretical representation of an eternal and immutably given nature and if the business of technology is to control the world, to intervene and change the "natural" course of events, "technoscience" is a hybrid where theoretical representation becomes entangled with technical intervention.

2) Jones used this term in conversation (and on his web site, www.softmachines.org) and referred, for example, to Nadrian Seeman's systematic exploration of DNA as a building block or component of future technical systems.

> "*Nanoscience is the study of phenomena and manipulation of materials at atomic, molecular and macromolecular scales, where properties differ significantly from those at a larger scale. Nanotechnologies are the design, characterisation, production and application of structures, devices and systems by controlling shape and size at the nanometre scale" [7].*

The notion of "nanotechnoscience" does not contradict such definitions but assumes a different perspective – it looks from within the organization of research where fundamental capabilities are typically acquired in the context of funded projects with a more or less concretely imagined technical goal. This is what Galison means by an engineering way of being in science. Even though a great deal of scientific knowledge and experience goes into the acquisition of such capabilities and the investigation of novel phenomena, it is not quite "science" because the point of this investigation is not normally to question received conceptions and to establish new truths, nor is it to produce and test hypotheses or to develop theories that close important gaps in our understanding of the world. And even though nanoscale research practice involves a good bit of tinkering and pursues technological challenges and promises, it is also not "engineering" because most researchers are not in the business of building devices for more or less immediate use. At best, they lay the groundwork for concrete engineering projects in the future.

For this "engineering way of being in science", a philosophy of technoscience is needed that asks for nanotechnological, biomedical or semiconductor research the four questions that were identified above: what is the role of theory and theory-development in nanoscale research and what kinds of theories are needed for nanotechnological development?; what are the preferred methods and tools and the associated modes of reasoning in nanoscientific research?; what is nanotechnoscience and how are its objects constituted?; and what kind of knowledge do technoscientific researchers typically produce and communicate? The four main sections of this chapter will address these questions – and in all four cases, strictly philosophical considerations will shade into societal dimensions and questions of value. That this is so is due to the fact that there may have been "pure science" but that there is no such thing as "pure technoscience." Indeed, one way of characterizing technoscience is by noting that academic laboratory research is no longer answerable just to standards of peer researchers but has entered the "ethical space" of engineering with its accountability also to patrons and clients, to developers and users [8, 9].

7.2
From "Closed Theories" to Limits of Understanding and Control

7.2.1
Closed Relative to the Nanoscale

In the late 1940s, the physicist Werner Heisenberg introduced the notion of "closed theories". In particular, he referred to four closed theories: "Newtonian mechanics,

Maxwell's theory with the special theory of relativity, thermodynamics and statistical mechanics, non-relativistic quantum mechanics with atomic physics and chemistry". These theories he considered to be closed in four complementary respects:

1. Their historical development has come to an end, they are finished or have reached their final form.
2. They constitute a hermetically closed domain in that the theory defines conditions of applicability such that the theory will be true wherever its concepts can be applied.
3. They are immune to criticism; problems that arise in contexts of application are deflected to auxiliary theories and hypotheses or to the specifics of the set-up, the instrumentation, and so on.
4. They are forever valid: wherever and whenever experience can be described with the concepts of such a theory, the laws postulated by this theory will be proven correct [10].[3)]

All this holds for nanotechnoscience: It draws on an available repertoire of theories that are closed or considered closed in respect to the nanoscale, but it is concerned neither with the critique or further elaboration of these theories, nor with the construction of theories of its own.[4)] This is not to say, however, that closed theories are simply "applied" in nanotechnoscience.

When Heisenberg refers to the hermetically closed character of closed theories (in condition 2 above), he states merely that the theory will be true where its concepts *can* be applied and leaves quite open how big or small the domain of its actual applicability is. Indeed, he suggests that this domain is so small that a "closed theory does not contain any absolutely certain statement about the world of experience" [10]. Even for a closed theory, then, it remains to be determined how and to what extent its concepts can be applied to the world of experience.[5)] Thus, there is no pre-existing domain of phenomena to which a closed theory is applied. Instead, it is "a question of success",

3) Heisenberg's notion of closed theories influenced Thomas Kuhn's conception of a paradigm [11]. It also informed the so-called finalization thesis, one of the first systematic accounts of technoscience [12]. Heisenberg also emphasized a fifth and especially contentious aspect of closed theories: an expansion of their domain of application will not introduce a change to the theory. This aspect and Heisenberg's particular list of closed theories plays no part in the following discussion.

4) In the case of nanotechnoscience, this repertoire includes far more than the four theories singled out by Heisenberg. It is a bold claim, to be sure, that nanotechnoscience is not concerned with the construction of theories of its own. One counterexample might be the discovery and subsequent theoretical work on the giant magnetoresistance effect [13]. Also, there are certain isolated voices who call for the development of theory specifically suited to the complexities of the nanocosm [14, 15]. These voices are isolated, indeed, and the consensus appears to be that the development of nanotechnologies can do without such theories – which might be hard to come by anyway [16].

5) Here, Heisenberg might have been inspired by Heinrich Hertz, who formulated the *Principles of Mechanics* as a closed theory [17]. He defined as mechanical problems all those phenomena of motion that can be accounted for by his fundamental law, albeit with the help of additional assumptions. Phenomena that cannot be accounted for in such a way, are not mechanical problems and simply outside the domain of mechanics (for example, the problems of life).

that is, of calibration, tuning or mutual adjustment to what extent phenomena of experience can be assimilated to the theory such that its concepts can be applied to them.

7.2.2 Applying Theory to the Nanoscale: Fitting Versus Stretching

This notion of "application" has been the topic of many recent discussions on modeling[6] – but it does not capture the case of nanotechnoscience. For in this case, researchers are not trying to bring nanoscale phenomena into the domain of quantum chemistry or fluid dynamics or the like. They are not using models to extend the domain of application of a closed theory or general law. They are not engaged in fitting the theory to reality and *vice versa*. Instead, they take nanoscale phenomena as parts of a highly complex mesocosm between classical and quantum regimes. They have no theories that are especially suited to account for this complexity, no theories, for example, of structure–property relations at the nanoscale.[7] Nanoscale researchers understand, in particular, that the various closed theories have been formulated for far better-behaved phenomena in far more easily controlled laboratory settings. Rather than claim that the complex phenomena of the nanoscale can be described such that the concepts of the closed theory now apply to them, they draw on closed theories eclectically, stretching them beyond their intended scope of application to do some partial explanatory work at the nanoscale.[8] A certain measurement of a current through an organic–inorganic molecular complex, for example, might be reconstructed quantum-chemically or in the classical terms of electrical engineering – and yet, the two accounts do not

6) See the work, in particular, of Nancy Cartwright, Margaret Morrison and Mary Morgan [18, 19].

7) Note that the term "complexity" is used here in a deliberately nontechnical manner. It does not refer to phenomena that fit the constraints of nonlinear complex dynamics, "complexity theory" or the like. The complexity at the nanoscale is one of great messiness, too many relevant variables and properties and multiple complicated interactions. This becomes apparent especially in contrast to the comparatively neat world of the laboratory phenomena that underwrite classical and quantum physics. In its complexity, the "real-world situation" of the nanoworld is precariously situated between classical and quantum regimes.

8) Here is another way to characterize this contrast between "applying" theory by fitting and by stretching: In the standard case of fitting theory to reality and vice versa, the problem concerns ways to compensate for the idealizations or abstractions that are involved in formulating a theory and constructing a model. However, classical theories do not abstract from nanoscale properties and processes, nor do they refer to idealizations of nanoscale phenomena. In this case, the challenge is that of crossing from the intended domain of a classical theory into quite another domain. – like all attempts to distinguish systematically the new nanotechnoscience from old-fashioned "science and engineering," this one is vulnerable to the critique that the two notions of "application" (bringing phenomena into the domain of application, stretching the domain of application to areas for which the theory has not been made) are not categorically distinct but differ only by degree. I thank Eric Winsberg for suggesting this line of thought.

compete against each other for offering a better or best explanation [20]. Armed with theories that are closed relative to the nanoscale, researchers are well equipped to handle phenomena in need of explanation, but they are also aware that they bring crude instruments that are not made specifically for the task and that these instruments therefore have to work in concert. Indeed, nanoscale research is characterized by a tacit consensus according to which the following three propositions hold true simultaneously:

1. There is a fundamental difference between quantum and classical regimes such that classical theories cannot describe quantum phenomena and such that quantum theories are inappropriate for describing classical phenomena.
2. The nanoscale holds intellectual and technical interest because it is an "exotic territory" [14] where classical properties such as color and conductivity emerge when one moves up from quantum levels and where phenomena such as quantized conductance emerge as one moves down to the quantum regime.
3. Nanoscale researchers can eclectically draw upon a large toolkit of theories from the quantum and classical regimes to construct explanations of novel properties, behaviors or processes.

Taken together, these three statements express a characteristic tension concerning nanotechnology, namely that it is thought to be strange, novel and surprising on the one hand, familiar and manageable on the other. More significantly for the present purposes, however, they express an analogous tension regarding available theories: they are thought to be inadequate on the one hand but quite sufficient on the other. The profound difference between classical and quantum regimes highlights what makes the nanocosm special and interesting – but this difference melts down to a matter of expediency and taste when it comes to choosing tools from classical or quantum physics. Put yet another way: what makes nanoscale phenomena scientifically interesting is that they cannot be adequately described from either perspective, but what makes nanotechnologies possible is that the two perspectives make do when it comes to accounting for these phenomena.

Available theories need to be stretched in order to manage the tension between these three propositions. How this stretching actually takes place in research practice needs to be shown with the help of detailed case studies. One might look, for example, at the way in which theory is occasionally "stuck in" to satisfy an extraneous explanatory demand.[9] A more prominent case is the construction of simulation

9) See, for example, a publication in Science on observed effects (large on–off ratios, negative differential resistance) in a molecular device. Asked by peer reviewers to offer an explanation of the observed effect, the authors suggest a somewhat arbitrary but plausible candidate mechanism and call for theories and future experimental work to "elucidate the transport mechanisms" [21]. This discussion was introduced reluctantly since it is clearly unnecessary for the point they wish to make (namely that they can consistently pass a current where no one had done so before) and because it is obviously easy to come up with a sufficiently credible explanation from the toolkit of available theory. The authors implicitly acknowledge that another explanation could easily substitute for theirs.

models where integrations of different levels of theoretical description are tuned to the actual behavior of a nanoscale system or process [22, 23]. This implies also that the very meaning of theories is stretched, especially where they account for the causal structure behind the observed phenomena: as these theories are applied in situations that are taken to be far more complex than the one for which the theories were developed, the causal story offered by them takes a backseat to the contributions they can make towards a description of the phenomena. In other words, algorithms descriptive of a certain dynamics become detached from the causal explanation they originally helped to provide, since it is the initial or structural conditions precisely that are not thought to hold continuously from macro to nano to quantum regimes.[10)]

There is quite another symptom of the ways in which theories and concepts are stretched as they are applied to the nanoscale. The nanoworld is taken to be complex, self-organizing, full of surprises – a world characterized by chemical and biological activity. The aspirations of nanotechnologies therefore emphasize the construction of active rather than merely passive devices.[11)] The so-called first generation of nanotechnological achievements was limited to the generation of new materials (passive structures), the second generation is supposed to incorporate molecular activity into nanotechnical systems.[12)] However, from the point of view of theories that are closed relative to the nanoscale, one cannot "see" any of that novel activity and liveliness but only what has become stabilized in the formulations and formalisms of those theories. Several descriptive or programmatic terms for nanoscale phenomena therefore strain to reach beyond their actual meanings. A prime example of this is the term "selective surface" which attributes agency to something that remains quite passive: Cells may attach to a given surface differentially, but the surface is not therefore doing anything to favor or disfavor certain cells; the selection is entirely on the side of the engineer who selects that surface in order to achieve some functionality. The same holds for

10) At the panel "Ontologies of Technoscience" at the October 2006 Bielefeld Conference ("Science in the Context of Application"), Bernadette Bensaude-Vincent showed that in the development of materials science and nanotechnologies the focus on structure–function relations (Crick's dogma that scientific understanding requires that function is referred to underlying structure) gives way to analyses of dynamic patterns in the observed functions and properties. Davis Baird offered as an example of this a particular nanotechnological detection device that physically instantiates factor analysis and therefore statistically infers underlying causes from observed properties (in other words, it does not perform a physical or chemical analysis to identify the presence of what is measured). Nicole Karafyllis finally suggested that (nano)technologies are now entering into a novel relation to biology as they design function not through construction (e.g. from structural principles) but by way of growth (e.g. by way of harnessing of self-organization).

11) Regarding the prestige of the device *vis-à-vis* the material, see [23a] on Herbert Gleiter as a pioneer of nanotechnology.

12) The notion of first/second generation passive/active devices was established and promoted especially by Mihail Roco of the National Nanotechnology Initiative. This paper is agnostic as to whether the second generation will ever be attained.

"self-cleaning surfaces", "smart materials", "autonomous (self-propelled) movement", the different conceptions of "self-assembly" or "soft machines".[13] All these terms have a specific meaning and at the same time refer to something more visionary, more genuinely "nano" that goes beyond their origin in theories that come from outside the nanoworld.[14]

7.2.3 Mute Complexity

So far, the notion of stretching what we know in one regime to phenomena in another one has been taken descriptively to characterize nanoscale research. Here, however, arises an occasion for critical questioning by scientists, citizens, concerned policy makers. To the extent that one cannot see the specific complexity from the point of view of theories closed relative to the nanoscale, we may find that the difficulties of understanding and controlling nanoscale phenomena are not adequately expressed. By stretching closed theories one recovers partial explanations of phenomena and thereby partial stories only of success. In other words, the assurance that much is amenable to explanation from the large toolkit of available theories finds ample expression, but there is no theoretical framework for the actual struggle of taming and controlling nanoscale phenomena – this part of the story remains untold, locked up in the laboratory.[15] Put bluntly, one might be doing years and years of interesting research only to discover that most of the phenomena one is tinkering with, that one is stabilizing and probing in the laboratory, will never be robust enough to serve as components in nanotechnological devices. There is no language, in other words, to identify specific limits of knowledge and control.

Having arrived at this point in a rather roundabout manner, one might ask whether the limited ways to speak of limits of understanding and control can be shown more straightforwardly. A telling illustration or example is provided by

13) Since the publication of Richard Jones's book on Soft Machines, that concept has been the subject of an emerging discussion [25, 26]. It concerns the question of whether the term "machine" retains any meaning in the notion of a "soft machine" when this is thought of as a non-mechanical, biological machine (while it clearly does retain meaning if thought of as a "concrete" machine in the sense of Simondon).

14) This is especially true, perhaps, for the concept "self-assembly", which has been cautiously delimited, for example, by George Whitesides [27], but which keeps escaping the box and harks backwards and forwards to far more ambitious notions of order out of chaos, spontaneous configurations at higher levels, etc.

15) To be sure, it is a commonplace that laboratory practice is more complex than the stories told in scientific papers. Traditional scientific research often seeks to isolate particular causal relations by shielding them against interferences from the complex macroscopic world of the laboratory. Whether it is easy or difficult to isolate these relations, whether they are stable or evanescent, is of little importance for the scientific stories to be told. The situation changes in respect to nanotechnoscience: its mission is to ground future technologies under conditions of complexity. In this situation, it is more troubling that scientific publications tell stories only of success.

nanotoxicology. It is finding out the hard way that physico-chemical characterization does not go very far, and that even the best methods for evaluating chemical substances do not REACh all the way to the nanoscale [28].[16] In other words, the methods of chemical toxicology go only so far and tell only a small part of the toxicological story – though regarding chemical composition, at least, there are general principles, even laws that can be drawn upon. With regard to the surface characteristics and shape of particles of a certain size, one has to rely mostly on anecdotes from very different contexts, such as the story of asbestos. For lack of better approaches, therefore, one begins from the vantage point of chemical toxicology and confidently stretches available theories and methods as far as they will go – while the complexities of hazard identification, let alone risk assessment (one partially characterized nanoparticle or nanosystem at a time?!) tend to be muted.[17]

There is yet another, again more general, way to make this point. Theories that are closed relative to the nanoscale can only introduce nonspecific constraints. The prospects and aspirations of nanotechnologies are only negatively defined: Everything is thought to be possible at the nanoscale that is not ruled out by those closed theories or the known laws of nature. This, however, forces upon us a notion of technical possibility that is hardly more substantial than that of logical possibility. Clearly, the mere fact that something does not contradict known laws is not sufficient to establish that it can be realized technically under the complex conditions of the nanoregime. Yet once again, there is no theoretical framework or language available to make a distinction here and to acknowledge the specificities and difficulties of the nanoworld – since all we have are theories that were developed elsewhere and that are now stretched to accommodate phenomena from the nanosphere.[18] However, failure to develop an understanding also of limits of understanding and control at the nanoscale has tremendous cost as it misdirects expectations, public debate and possibly also research funding.

16) The pun is intended: REACh refers to the new style of regulating chemical substances in and by the EU. It is widely acknowledged that it does not apply where properties depend not only on chemical composition but also on surface characteristics, size, shape, perhaps also engineered functionality and the specificities of their environments. (Along similar lines, Joachim Schummer [29] has argued that REACh does not even reach the products of conventional synthetic chemistry.)

17) Sabine Maasen and Monika Kurath have shown that this difficulty for chemical toxicology creates interesting new opportunities for nanotoxicology [31]. For another illustration of the predicament, one might recall that carbon nanotubes were "discovered" in the 1980s, that for a good number of years they have been being commercially manufactured and that researchers are still complaining that no two batches are alike.

18) I have been urging that more attention should be paid to limits of understanding and control at the nanoscale. If I am right in this section, I have been asking for something that cannot be done (as of now) in a straightforward way.

7.3
From Successful Methods to the Power of Images

7.3.1
(Techno)scientific Methodology: Quantitative Versus Qualitative

As was shown above, Heisenberg considered "a question of success" the extent to which phenomena of experience can be fitted to closed theories [10]. This suggests the question what "success" amounts to in nanoscale research, that is, what it takes to satisfy oneself that one has reached a sufficiently good understanding or control of the phenomena under investigation.

For Heisenberg and any philosopher of science who is oriented towards theoretical physics, this question boils down to the predictive success of a quantitative science. Here, "quantitative" means more than the employment of numbers and even of precision measurements. The characteristics of quantitative approaches include the following. First, predicted numerical values are compared with values obtained by measurement. The reasonably close agreement between two numbers thus serves to establish the agreement of theory and reality. Second, this quantitative agreement emphatically makes do without any appeal to a likeness or similarity between theoretical models and the real-world systems they are said to represent. Quantitative science rests content if it reliably leads from initial conditions to accurate predictions, it does not require that all the details of its conceptual apparatus (every term in its algorithms) has a counterpart in reality. Both characteristics of quantitative science are familiar especially from twentieth century theoretical physics – but do they serve to characterize also nanotechnoscience [31]?

In the light of the extremely heterogeneous research practices under the general heading of "nanoscience and nanotechnologies" there may not be a general answer to this question. Yet it is fair to say that much nanotechnoscientific research is qualitative. Its epistemic success consists in constructions of likeness.[19)]

The shift sounds innocent enough but may have significant consequences: the agreement of predicted and measured quantities is being displaced by an agreement of calculated and experimental images. The latter qualitative agreement consists

19) Here, a case study of Jan Hendrik Schön might show that he was caught between quantitative and qualitative methodologies. He was "caught cheating", after all, when it was discovered that for different experiments he included an exactly identical plot of current flow. This diagram is supposed to be generated from a series of measurements but the characteristic shape of the curve is also a qualitative short-hand expression for "current is flowing." In a culture of research that is moving increasingly to produce effects, Schön may well have "written" this diagram as it is generally "read" – without regard to the particular values but as a symbol for a certain type of event. Overall, Schön's case is less innocent and more complicated than this [32]. But perhaps in other regards, too, it is symptomatic of the ambivalence that results from the transdisciplinary qualitative orientation of nanotechnoscience even as nanoscale research continues to be informed mostly by rigorously quantitative disciplinary traditions.

primarily in the absence, even deliberate suppression of visual clues by which to hold calculated and experimental images apart. Indeed, the (nano)technoscientific researcher frequently compares two displays or computer screens. One display offers a visual interpretation of the data that were obtained through a series of measurements (e.g. by an electron or scanning probe microscope), the other presents a dynamic simulation of the process he might have been observing – and for this simulation to be readable as such, the simulation software produces a visual output that looks like the output for an electron or scanning probe microscope. Agreement and disagreement between the two images then allows the researchers to draw inferences about probable causal processes and to what extent they have understood them. Here, the likeness of the images appears to warrant the inference from the mechanism modeled in the simulation to the mechanism that is probably responsible for the data that were obtained experimentally. Accordingly (and this cannot be done here), one would need to show how nanoscale researchers construct mutually reinforcing likenesses, how they calibrate not only simulations to observations and visual representations to physical systems but also their own work to that of others, current findings to long-term visions. This kind of study would show that unifying theories play little role in this, unless the common availability of a large tool-kit of theories can be said to unify the research community. Instead of theories, it is instruments (STM, AFM, etc.), their associated software, techniques and exemplary artefacts (buckyballs, carbon nanotubes, gold nanoshells, molecular wires) that provide relevant common referents [33–35].

7.3.2 "Ontological Indifference": Representation Versus Substitution

This is also not the place to subject this qualitative methodology to a sustained critique. Such a critique is easy, in fact, from the point of view of rigorous and methodologically self-aware quantitative science [31]. Far more interesting is the question of why, despite this critique, a qualitative approach appears to be good enough for the purposes of nanoscale research. As Peter Galison has pointed out, these purposes are not to represent the nanoscale accurately and, in particular, not to decide what exists and what does not exist, what is more fundamental and what is derivative. He refers to this as the "ontological indifference" of nanotechnoscience [5]. Why is it, then, that nanotechnological research can afford this indifference? For example, molecular electronics researchers may invoke more or less simplistic pictures of electron transport but they do not need to establish the existence of electrons. Indeed, electrons are so familiar to them that they might think of them as ordinary macroscopic things that pass through a molecule as if it were another material thing with a tunnel going through it [20]. Some physicists and most philosophers of physics strongly object to such blatant disregard for the strangely immaterial and probabilistic character of the quantum world that is the home of electrons, orbitals, standing electron waves [36, 37]. And indeed, to achieve a practical understanding of electron transport, it may be necessary to entertain more subtle accounts. However, it is the privilege of ontologically indifferent technoscience that it

can always develop more complicated accounts as the need arises. For the time being, it can see how far it gets with rather more simplistic pictures.[20)]

Ontological indifference amounts to a disinterest in questions of representation and an interest, instead, in substitution.[21)] Instead of using sparse modeling tools to represent only the salient causal features of real systems, nanoresearchers produce in the laboratory and in their models a rich, indeed oversaturated substitute reality such that they begin by applying alternative techniques of data reduction not to "nature out there" but to some domesticated chunk of reality in the laboratory. These data reduction and modeling techniques, in turn, are informed by algorithms which are concentrated forms of previously studied real systems, they are tried and true components of substitute realities that manage to emulate real physical systems [38].[22)] In other words, there is so much reality in the simulations or constructed experimental systems before them, that nanotechnology researchers can take them for reality itself [39]. They study these substitute systems and, of course, have with these systems faint prototypes for technical devices or applications. While the public is still awaiting significant nanotechnological products to come out of the laboratories, the researchers in the laboratories are already using nanotechnological tools to detach and manipulate more or less self-sufficient nanotechnological systems which "only" require further development before they

20) A particularly interesting and challenging example of this is Don Eigler's famous picture of a quantum corral that confines a standing electron wave. The picture's seemingly photographic realism suggests that the quantum corral is just as thing-like as a macroscopic pond. It brazenly bypasses all discussions regarding the interpretation of quantum mechanics and thus displays its ontological indifference. Nevertheless, it is an icon of nanotechnoscience, testimony to new capabilities of manipulation and visualization and a down-payment of sorts on the promise that technical control does not stop at the threshold to quantum effects.

21) Compare Peter Galison's suggestion above that the relevant contrast is that between demonstrating existence and building things. Yet, as will be shown in Section 7.5 below, "building" is too narrow and too "technical" a notion. It does not do justice to the intellectual engagement, even passion for the challenges encountered at the nanoscale.

22) Rom Harré contrasts scientific instruments that serve as probes into causal processes and modeling apparatus (including simulations) that domesticates or produces phenomena. It is this modeling apparatus that underwrites epistemic success in constructions of likeness: Instruments typically obtain measurements that can be traced back down a causal chain to some physical state, property or process. As such, the instruments are detached from nature – measurements tell us something about the world. Physical models, in contrast, are part of nature and exhibit phenomena such that the relevant causal relations obtain within the apparatus and the larger apparatus–world complex. Whether it domesticates a known phenomenon such as the rainbow or elicits an entity or process that does not occur "naturally", it does not allow for straightforward causal inference to the world within which the apparatus is nested [38]. As the metaphor of domestication and Harré's conception of an apparatus–world complex suggest, causal inference from the apparatus to the world may be required only for special theoretical purposes that are characterized by a specific concern for reality (for example, when something goes wrong and one wants to explore the reasons for this). At the same time, the very fact that the apparatus is nested in the world delivers an (unarticulated) continuity of principles and powers and the affordance of ontological indifference.

can exist as useful devices outside the laboratory, devices that not only substitute for but improve upon something in nature.

7.3.3 Images as the Beginning and End of Nanotechnologies

Again, it may have appeared like a cumbersome path that led from qualitative methodology and its constructions of likeness to the notion that models of nanoscale phenomena do not represent but substitute chunks of reality and that they thereby involve the kind of constructive work that is required also for the development of nanotechnological systems and devices. For a more immediate illustration of this point, we need to consider only the role of visualization technologies in the history of nanotechnological research.[23)] Many would maintain, after all, that it all began for real when Don Eigler and Erhard Schweizer created an image with the help of 35 xenon atoms. By arranging the atoms to spell "IBM" they did not represent a given reality but created an image that replaces a random array of atoms by a technically ordered proto-nanosystem. Since then, the ability to create images and to spell words has served as a vanguard in attempts to assert technical control in the nano-regime – the progress of nanotechnological research cannot be dissociated from the development of imaging techniques that are often at the same time techniques for intervention. Indeed, Eigler and Schweizer's image has been considered proof of concept for moving atoms at will. It is on exhibit in the STM web gallery of IBMs Almaden laboratory and is there appropriately entitled "The Beginning" – a beginning that anticipates the end or final purpose of nanotechnologies, namely to directly and arbitrarily inscribe human intentions on the atomic or molecular scale.

Images from the nanocosm are at this point (early 2008) still the most impressive as well as popular nanotechnological products. By shifting from quantitative coordinations of numerical values to the construction of qualitative likeness, from the conventional representation of reality to the symbolic substitution of one reality by another, nanotechnoscience has become beholden to the power of images. Art historians and theorists like William Mitchell and Hans Belting, in particular, have emphasized the difference between conventional signs that serve the purpose of representation and pictures or images that embody visions and desires, that cannot be controlled in that they are not mere vehicles of information but produce an excess of meaning that is not contained in a conventional message [40, 41].

The power of images poses some of the most serious problems of and for nanoscience and nanotechnologies. This is readily apparent already for "The Beginning". As mentioned above, it is taken to signify that for the first time in history humans have manipulated atoms at will and thus as proof of concept for the most daring nanotechnological visions and by the most controversial nanotechnological visionaries such as Eric Drexler. This was not, of course, what Eigler and

23) It is no accident that this is perhaps the best-studied and most deeply explored aspect of nanotechnologies.

Schweizer wanted to say. Their image is testimony also to the difficulty, perhaps the limits of control of individual atoms. But the power of their image overwhelms any such testimony.

Here arises a problem similar to the one encountered in Section 7.2.3. The specificity, complexity and difficulty of work at the nanoscale do not have a language and do not find expression. The theories imported from other size regimes can only carve out an unbounded space of unlimited potential, novelty, possibility. And the pictures from the nanocosm show us a world that has already been accommodated to our visual expectations and technical practice.[24] Ontologically indifferent, nanotechnoscience may work with simplistic conceptions of electron transport and it produces simplistic pictures of atoms, molecules, standing electron waves which contradict textbook knowledge of these things. For example, it is commonly maintained that nanosized things consist only of surface and have no bulk. This is what makes them intellectually and technically interesting. But pictures of the nanocosm invariably show objects with very familiar bulk-surface proportions, a world that looks perfectly suited for conventional technical constructions. And thus, again, we might be facing the predicament of not being told or shown what the limits of nanotechnical constructions and control might be.

The power of images also holds another problem, however. In the opposition of conventional sign and embodied image the totemistic, fetishistic, magical character of pictures comes to the fore. To the extent that the image invokes a presence and substitutes for an absence, its kinship to voodoo-dolls, for example, becomes apparent. This is not the place to explore the analogy between simulations and voodoo-dolls [31], but it should be pointed out that nanotechnologies in a variety of ways cultivate a magical relation to technology – and their imagery reinforces this. Indeed, in the history of humankind we might have begun with an enchanted and uncanny nature that needed to be soothed with prayer to the spirits that dwelled in rocks and trees. Science and technology began as we wondered at nature, became aware of our limits of understanding and yet tamed and rationalized nature in a piece-meal fashion. Technology represents the extent to which we managed to defeat a spirited, enchanted world and subjected it to our control. We technologized nature. Now, however, visitors to science museums are invited to marvel at nanotechnologies, to imagine technological agency well beyond human thresholds of perception, experience and imagination and to pin societal hopes for technological innovation not on intellectual understanding but on a substitutive emulation that harnesses the self-organizing powers of nature. We thus naturalize technology, replace rational control over brute environments by a magical dependency on smart environments and we may end up rendering technology just as uncanny as nature used to be with its earthquakes, diseases and thunderstorms [42, 43].[25]

24) Compare footnote 20 above.

25) This is a strong indictment not of particular nanotechnologies but of certain ways of propagating our nanotechnological future. Considered another way, it is simply an engineering challenge to design nanotechnology for the human scale.

7.4
From Definitions to Visions

7.4.1
Wieldy and Unwieldy Conceptions

The first two sections gave rise to the same complaint. After surveying the role of theories and methodologies for the construction of technical systems that can substitute for reality, it was noted that this tells us nothing about the specificity, complexity and difficulty of control at the nanoscale. The nanocosm appears merely as that place from where nanotechnological innovations emanate and so far it appears that it can be described only in vaguely promising terms: the domain of interest to nanoscience and nanotechnologies is an exotic territory that comprises all that lies in the borderland of quantum and classical regimes, all that is unpredictable (but explicable) by available theories and all that is scale-dependently discontinuous, complex, full of novelty and surprise.[26)]

However, as one attempts a positive definition of nanotechnoscience and its domain of phenomena or applications, one quickly learns how much is at stake. In particular, definitions of "nanotechnology" suggest the unity of a program so heterogeneous and diverse that we cannot intellectually handle or manage the concept any more. By systematically overtaxing the understanding, such definitions leave a credulous public and policy makers in awe and unable to engage with "nanotechnology" in a meaningful manner. The search for a conceptually manageable definition is thus guided by an interest in specificity but also by a political value – it is to facilitate informed engagement on clearly delimited issues. In purely public contexts, therefore, it is best not to speak of nanotechnology in the singular at all but only of specific nanotechnologies or nanotechnological research programs [44]. In the present context, however, an effort is made to circumscribe the scope or domain of nanotechnoscience, that is, to consider the range of phenomena that are encountered by nanoscience and nanotechnologies. This proves to be a formidable challenge.

7.4.2
Unlimited Potential

There is an easy way to turn the negative description of the domain into a positive one. One might say that nanoscience and nanotechnologies are concerned with everything molecular or, slightly more precisely, with the investigation and manipulation of molecular architecture (as well as the properties or functionalities that depend on molecular architecture).

26) Tellingly, the most sophisticated definition of nanoscience is quite deliberate in saying nothing about the "nanocosm" at all. Indeed, this definition is not limited to nanoscale phenomena or effects but intends a more general nanoscience of scale-dependently discontinuous behaviors at all scales: nanoscience is everywhere where one encounters a specific kind of novelty or surprise [6].

Everything that consists of atoms is thus an object of study and a possible design target of nanoscale research. This posits a homogeneous and unbounded space of possibility, giving rise, for example, to the notion of an all-powerful nanotechnology as a combinatorial exercise that produces the "little BANG" [45] – since bits, atoms, neurons, genes all consist of atoms, since all of them are molecular, they all look alike to nanoscientists and engineers who can recombine them at will. And thus comes with the notion of an unlimited space of combinatorial possibilities the transgressive character of nanotechnoscience: categorial distinctions of living and inanimate, organic and inorganic, biological and technical things, of nature and culture appear to become meaningless. Although hardly any scientist believes literally in the infinite plasticity of everything molecular, the molecular point of view proves transgressive in many nanotechnological research programs. It is particularly apparent where biological cells are redescribed as factories with molecular nanomachinery. Aside from challenging cultural sensibilities and systematic attempts to capture the special character of living beings and processes, nanotechnoscience here appears naively reductionist. In particular, it appears to claim that context holds no sway or, in other words, that there is no top–down causation such that properties and functionalities of the physical environment partially determine the properties and behaviors of the component molecules.[27)]

This sparsely positive and therefore unbounded view of nanoscale objects and their combinatorial possibilities thus fuels also the notion of unlimited technical potential along with visions of a nanotechnological transgression of traditional boundaries. Accordingly, this conception of the domain of nanoscience and nanotechnologies suffers from the problem of unwieldiness – it can play no role in political discourse other than to appeal to very general predispositions of technophobes and technophiles [46].

Three further problems, at least, come with the conception of the domain as "everything molecular out there." And as before, internally scientific problems are intertwined with matters of public concern. There is first the (by now familiar) "scientific" and "societal" problem that there is no cognizance of limits of understanding and control – as evidenced by a seemingly naive reductionism. There is second the (by now also familiar) problem that technoscientific achievements and conceptions have a surplus of meaning which far exceeds what the research community can take responsibility for – the power of images is dwarfed by the power of visions (positive or negative) that come with the notion of unlimited potential. And there is finally the problem of the relation of technology and nature.

27) I cannot pass judgement on these claims. However, even Richard Jones's Soft Machines [32] with its vivid appreciation of the complexities of "biological nanotechnology" does not reflect the findings of developmental biologists regarding environmental stimuli to gene expression. Recent work on adult stem cells appears to reveal that they can be reverted to earlier states but that they nevertheless "remember" what they were. Such findings complicate immensely the apparently unbounded promise that nanotechnology can solve all problems at the level of molecules.

Martin Heidegger, one of the sharpest critics of modern technology, chastised it for treating all of nature as a mere resource that is "standing in reserve" to be harnessed by science and industry [47]. The power of his argument derives precisely from the fact that he saw all of modern technoscience as one: it is a scaffolding or harness (the German word is *Gestell*) that recruits humans and nature into a universal scheme of production. Rather than accept as a gift what nature, poetry or craft brings forth, it demands the deliverance of what it has learned rationally to expect from the study of nature as a calculable system of forces. Conceived as a unified enterprise with an unbounded domain of "everything molecular", nanotechnology fits the bill of such an all-encompassing modern technology. It does so because it employs what one might call a thin conception of nature. According to this conception, nature is circumscribed by the physical laws of nature. All that accords with these laws is natural. Thus, nanotechnology can quickly and easily claim for itself that it always emulates nature, that it manufactures things nanotechnologically just as nature does when it creates living organisms. This conception, however, is too "thin" or superficial to be credible and it suffers from the defect that the conditions of (human) life on earth have no particular valence in it: from the point of view of physics and the eternal laws of nature, life on Earth is contingent and not at all necessary. The laws predate and will outlive the human species. In contrast, a substantial, richly detailed or "thick" conception of nature takes as a norm the special evolved conditions that sustain life on Earth. Here, any biomimetic research that emulates nature will be characterized by care and respect as it seeks to maintain these special conditions. This involves an appreciation of how these conditions have evolved historically. On this conception, context holds sway and a molecule that occurs in a technical system will not be the same as one in a biological system, even if it had the same chemical composition.

It is an open question and challenge to nanoscience and nanotechnologies, however, whether it can embrace such a thick or substantial conception of nature.

7.4.3
A Formidable Challenge

It was not very difficult to identify at least four major problems with the commonly held view that the domain of nanotechnological research encompasses "everything molecular" It proves quite difficult, in contrast, to avoid those problems. In particular, it appears to defy common sense and the insights of the physical sciences to argue that molecules should have a history or that they should be characterized by the specific environments in which they appear. Is it not the very accomplishment of physical chemistry ever since Lavoisier that it divested substances of their local origins by considering them only in terms of their composition, in terms of analysis and synthesis? [48]. And should one not view nanoscience and nanotechnologies as an extension of traditional physics, physical chemistry and molecular biology as they tackle new levels

of complexity? All this appears evident enough, but yet there are grounds on which to tackle the formidable challenge and to differentiate the domain of nanoscientific objects.[28)]

As noted above, bulk chemical substances are registered and assessed on the grounds of a physico–chemical characterization. Once a substance has been approved, it can be used in a variety of contexts of production and consumption. On this traditional model, there appears no need to consider its variability of interactions in different biochemical environments (but see [29, 30]). Although the toolkit of nanotoxicology is still being developed, there is a movement afoot according to which a carbon nanotube is perhaps not a carbon nanotube. What it is depends on its specific context of use: dispersed in water or bound in a surface, coated or uncoated, functionalized or not – all this is toxicologically relevant. Moreover, a comprehensive physico-chemical characterization that includes surface properties, size and shape would require a highly complex taxonomy with too many species of nanoparticles, creating absurdly unmanageable tasks of identification perhaps one particle at a time. Instead, the characterization of nanoparticles might proceed by way of the level of standardization that is actually reached in production and that is required for integration in a particular product – with a smaller or larger degree of variability, error tolerance, sensitivity to environmental conditions, as the case may be for a specific product in its context of use. Nanotoxicology would thus be concerned with product safety rather than the safety of component substances. On this account, the particles would indeed be defined by their history and situation in the world and thus thickly by their place within and their impact upon nature as the specific evolved conditions of human life on Earth.[29)]

There is another, more principled, argument for a thickly differentiated account of the objects that make up the domain of nanoscience and nanotechnologies. The unbounded domain of "everything molecular" includes not only the objects and properties that we now have access to and that we can now measure and control. It also includes those objects and properties that one may gain access to in the future. This way of thinking is indifferent to the problem of actual technical access also in that it does not consider how observational instruments and techniques structure, shape and perhaps alter the objects in the domain. On this account, the domain appears open and unlimited because

28) One might argue that a definition requiring scale-dependent discontinuities already does offer such a differentiation [6]. This is not the case, however. It is a beginning at best. As shown above, this definition excludes certain phenomena and processes from nanoscience and thus claims specificity, but it leaves nanotechnology entirely undetermined: nanoscience tends to certain novel or surprising properties and processes, nanotechnology is whatever one can make of these properties and processes. More significantly, however, the appearance of scale-dependent novel properties can be claimed rather generically. Not every property at the nanoscale is discontinuous in respect of scale. However, for every substance one can claim that it may or will have some such properties simply by virtue of the proportion of atoms in the boundary layers.

29) Nanotoxicology in particular, and nanotechnological research in general, might thus become a "social science of nature" [49].

it refers to an imaginary (future) state of total information and the nonintrusive and presence of observers in the nanoworld. In contrast to this account, the domain could be delimited more concretely and its visionary surplus could be contained more effectively if it did not include all nanoscale objects "out there" but considers how these objects are constituted, how they become accessible to nanoscale research. Accordingly, the domain of objects and processes would consist of just those phenomena and effects that are revealed by scanning tunneling microscopy and other specifically nanotechnological procedures [50, 51].

However, more so than the current attempt to formulate a philosophy of nanotechnoscience, this proposal by Peter Janich ascribes to nanotechnoscience a methodological unity or basis in common practice. He suggests a philosophical program of systematizing the operations by which nanoscale objects become amenable to measurement and observation. Such a systematic reconstruction of the domain of objects of nanotechnological research might begin by looking at length measurement or scanning probe microscopy. However, research practice is not actually unified in this manner. Even scanning probe microscopy – to many a hallmark or point of origin for nanotechnologies – plays a minor role in the work of many nanoscale researchers [52]. Also, the above-mentioned struggles to attain standard measures or to characterize nanomaterials testify to the unruliness of the objects of research. They are not constituted through methodical procedures that individuate objects and make them comparable throughout the scientific community. Instead, it appears that they are constituted through complicated interactions that are difficult to reproduce and that rely on proximate likeness.

Since Janich's approach faces considerable odds, all one can do perhaps is to generalize the previous lesson from nanotoxicology: The objects of nanoscale research are constituted through their specific histories – histories that concern their origin (in a tissue sample, in the soil, in a chemically produced batch), that include nanotechnological interventions as well as their location finally in a technical system. This would promote, of course, the fragmentation of "nanotechnology" into as many "nanotechnologies" as there are nanotechnological devices or applications. A nightmare vision for some, others may consider this an intellectual requirement. If this is so, it becomes impossible to uphold the idea of carbon nanotubes as all-purpose technical components. If they contribute to the performance of some product, then they are individuated or characterized as being carbon-nanotubes-in-that-product and they are as safe or unsafe as that product is. By the same token, they are no longer conceived as molecular objects that are combinable in principle with just about any other. The open space of unlimited potential differentiates into a manifold of specific technological trajectories.

The formidable challenge has not been met by this proposal. It does help dramatize, however, the inherent tension in the commonly held view of nanotechnological objects, as well as the difficulties (once again) of prediction and control at the nanoscale.

7.5
From Epistemic Certainty to Systemic Robustness

7.5.1
What Do Nanoscientists Know?

The previous sections considered research practices of nanotechnosciences – how theories are stretched to the complexities at the nanoscale, how a qualitative methodology serves the construction of likeness and inferences from that likeness, how the research objects are individuated and encountered. All these practices contribute to the generation of knowledge but it remains to be explored in which sense this is "objective knowledge." As in traditional science, the findings of nanotechnoscientific research are published in scientific journals, so the questions is, more concretely, what kind of knowledge is expressed or communicated in a nanoscientific journal article? To answer this question properly, contrasts need to be established and particular publications compared. Here, a summary must suffice.

A typical research article in classical science states a hypothesis, offers an account of the methods, looks at the evidence produced and assesses the hypothesis in the light of the evidence. It participates in a public process of evaluating propositions, of finding certain statements true or false and of seeking certainty even where it is impossible to attain. In contrast, a technoscientific research article provides testimony to an acquired capability. It offers a sign or proof of what has been accomplished in the laboratory and tells a story of what has been done. The telling of the story does not actually teach the capability but it offers a challenge to the reader that they might develop this capability themselves. As opposed to epistemic knowledge (concerned with truth or falsity of propositions), nanoscale research produces skill knowledge. This is not an individualized skill, however, or tacit knowledge. Acquired capabilities can be objective and public, specifically scientific and communicable. They grasp causal relations and establish habits of action. They are assessed or validated not by the application of criteria or norms but by being properly entrenched in a culture of practice. One cannot judge their truth or falsity (skills are not true or false) but one can judge the robustness of demonstrability: If one has acquired a capability, one can more or less consistently do something in the context of an "apparatus–world complex" [38]. As opposed to the truth or falsity, certainty or uncertainty of hypotheses, the hallmarks of technoscientific knowledge are robustness, reliability, resilience of technical systems or systematic action.

7.5.2
The Knowledge Society

This account of skill knowledge presses the question of where the "science" is in "technoscience". The answer to this question can be found in the first section of this chapter: it is in the (closed) theories that are brought as tools to the achievement of partial control and partial understanding. Nanotechnoscience seeks not to improve theory or to change our understanding of the world but primarily to manage

complexity and novelty. As such, nanotechnoscience is just technical tinkering, just product development, just an attempt to design solutions to societal problems or to shape and reshape the world. However, the conceptual and physical tools it tinkers with do not come from ordinary experience, from common sense and a craft tradition but concentrate within them the labors of science. So, the "science" of "nanotechnoscience" is what goes into it. What comes out is skill knowledge and this knowledge does not rely on a corresponding scientific understanding. As long as one can produce an effect in a reasonably robust manner, it does not really matter whether scientific understanding catches up. Indeed, the complexities may be such that it cannot fully catch up.[30)]

The standard example of technology being ahead of science is the steam engine, which was developed without a proper understanding of the relation between heat and work [53]. This understanding came much later and, indeed, was prompted by the efficient performance of the steam engine. The steam engine itself was therefore not applied science but the result of technical tinkering. It was made of valves, pumps, gears, and so on, of which there was good nonscientific craft-knowledge – and it worked just fine before the advent of thermodynamics. In a sense, it did not need to be understood.

As opposed to the steam engine, nanotechnological devices (whatever they may be), genetically modified organisms, drug delivery systems are offsprings of the knowledge society. They are not made of valves and pumps but assembled from highly "scientized" components such as algorithms, capabilities acquired by scientifically trained researchers who are using measuring and monitoring devices that have plenty of knowledge built in [39]. The science that goes into the components is well understood, not so the interactions of all the components and their sensitivities in the context of the overall technical system. Still, like the steam-engine, it may work just fine without being fully understood. And although one cannot attain positive knowledge from which to derive or predict its performance, we may learn to assess its robustness.

7.5.3 Social Robustness

The shift from hypotheses that take the form of sentences to actions within technocultural systems, from epistemic questions of certainty to systemic probes of robustness has implications also for the "risk society" that looks to government mostly for protection from risk [54].[31)]

30) This diagnosis is not entirely novel or surprising. Technology, writes Heidegger, is always ahead of science and, in a deep sense, science is only applied technology [47]. By this he means not only that laboratory science requires instruments and experimental apparatus for stabilizing the phenomena. He means more generally that a technological attitude informs the scientific way of summoning phenomena to predictably appear once certain initial conditions are met.

31) The precautionary principle refers to the certainty and uncertainty of knowledge regarding risks. Where technology assessment shifts from truth of sentences about risk to the robustness or resilience of emerging technical systems and their interaction with other technical systems. In this case, a different kind of prudential approach is required – for example, Dupuy and Grinbaum's "ongoing normative assessment" [55].

Expectations of certainty and assurances of safety will not be met by nanotechnologies. Other technologies already fail to meet them. Certainty about the safety of a new drug, for example, is produced by the traditional method of a clinical trial that establishes or refutes some proposition about the drug's efficacy and severity of side-effects. A far more complex and integrated mechanism is required where such certainty is unattainable and where robustness needs to be demonstrated. Here, several activities have to work in tandem, ranging from traditional toxicology, occupational health and epidemiology all the way to the deliberate adoption of an unknown risk for the sake of a significant desired benefit. If this integration works, social robustness will be built into the technical system along with the robustness of acquired skills, tried and true algorithms, measuring and monitoring apparatus. The fact that nanoscale researchers demonstrate acquired capabilities and that they thus produce "mere" skill knowledge creates a demand for skill knowledge also in a social arena where nanotechnological innovations are challenged, justified and appropriated.

7.6 What Basic Science Does Nanotechnology Need?

The preceding sections provided a survey of nanotechnoscience in terms of disciplinary questions (a complex field partially disclosed by stretching closed theories), of methodology (constructions and qualitative judgments of likeness), of ontology (a thin conception of nature as unlimited potential) and of epistemology (acquisition and demonstration of capabilities). This does not exhaust a philosophical characterization of the field which would have to include, for example, a sustained investigation of nanotechnology as a conquest of space or a kind of territorial expansion.[32] Also, nothing has been said so far about nanotechnology as an enabling technology that might enable, in particular, a convergence with bio- and information technologies. Finally, it might be important to consider nanotechnoscience as an element or symptom of a larger cultural transition from scientific to technoscientific research.

This survey is limited in other ways. It glossed over the heterogeneity of research questions and research traditions. And it focused exclusively on the way in which nanotechnological research has developed thus far. There is nothing in the preceding account to preclude a profound reorientation of nanoscience and nanotechnologies. Indeed, one reorientation might consist in the whole enterprise breaking apart and continuing in rather more traditional disciplinary settings – with "nano" ceasing to be a funding umbrella but becoming a prefix that designates a certain approach. Thus, under the sectoral funding umbrellas "food and agriculture", "energy", "health", "manufacturing" or "environment" researchers with the "nano" prefix would investigate how problems and solutions can be viewed at the molecular level. Their work

32) One implication of this is that nanotechnology should not be judged as the promise of a future but, instead, as a collective experiment in and with the present [56].

would then have to be integrated into more comprehensive approaches to the problem at hand.

Alternatively, nanotechnological researchers may pursue and promote disciplinary consolidation and unification.[33] In that case, they might be asking the question, "what kind of basic science does nanotechnology need?". From quantum mechanics, hydrodynamics, and so on, derive the (closed) theories that serve as the toolkit on which nanoscale research is drawing. While these are basic sciences, of course, they are not therefore the basis of nanoscience. What, then, is the basic scientific research that needs to be done in order to ground nanotechnologies properly or to establish nanoscience as a field in its own right? There have been no attempts so far to address this question in a systematic way.[34] And obviously, one should not expect any consensus regarding the following list of proposed basic research for nanotechnology.

In terms of empirical grounding or a theoretical paradigm, some call for general theories of (supra-)molecular structure–property relations, others imagine that there will be a future science of molecular and nanotechnical self-organization.[35] Following the suggestion of Peter Janich (see above, Section 7.4.3), one might identify and systematize how nanoscale phenomena are constituted through techniques of observation and measurement – this might render theories of instrumentation basic to nanoscience.[36]

Another kind of basic research entirely would come from so-called *Bildwissenschaft* (image or picture science) that could provide a foundation for image-production and visualization practice in nanotechnoscience. Such investigations might contribute visual clues for distinguishing illustrations from animations, from simulations, from visualizations of microscopically obtained data. They might also turn to image–text relations or develop conventions for reducing the photographic intimations of realism while enhancing informational content.[37]

33) The field of "nanomedicine" appears to be moving in that direction by distinguishing its research questions and paradigms from "medical nanotechnologies." It is not at all clear yet whether nanomedicine will emerge from this with a disciplinary identity of its own, including perhaps a unique body of theory.

34) To be sure, there are piecemeal approaches. One might say, for example, that a theory of electron transport is emerging as a necessary prerequisite for molecular electronics (but see [57]). Also, the giant magnetoresistance effect might be considered a novel nanotechnological phenomenon that prompted "basic" theory development [13].

35) See, for example, [15]. In [14] Michael Roukes calls for the identification of the special laws that govern the nanoscale. To be sure, there is profound skepticism in the scientific community (a) that there can be laws of structure-property relations at the nanoscale and (b) that they are needed in order to pursue nanotechnological research. On this latter view, the account provided in the first four sections of this paper provides sufficient "grounding" of nanotechnology.

36) See, for example, [58] on modeling of measurements at the nanoscale. Can this kind of theory development and modification serve to constitute a nanoscale research community – or does it belong to a special tribe of instrument developers that merely enters into a trade with other nanotechnology researchers? [59].

37) Compare the suggestion by Thomas Staley (at the conference on Imaging Nanospace) that visualizations of data could be constructed like maps with graphic elements even text imposed upon the quasi-photographic image [60]. This might break the spell of the powerful image (see above, Section 7.3.3) and return ownership of the image to the scientific community.

Finally, one might ask whether nanotechnoscience can and should be construed as a "social science of nature".[38] As an enabling, general-purpose or key technology it leaves undetermined what kinds of applications will be enabled by it. This sets it apart from cancer research, the Manhattan project, the arms race, space exploration, artificial intelligence research, and so on. As long as nanotechnoscience has no societal mandate other than to promote innovation, broadly conceived, it remains essentially incomplete, requiring social imagination and public policy to create an intelligent demand for the capabilities it can supply. As research is organized to converge upon particular societal goals [61], nanoscience and nanotechnology might be completed by incorporating social scientists, anthropologists and philosophers in its ambitions to design or shape a world atom by atom.

Nanotechnologies are frequently touted for their transformative potential, for bringing about the next scientific or industrial revolution. This chapter did not survey a revolutionary development, but pragmatic and problematic integrations of pre-existing scientific knowledge with the novel discoveries at the nanoscale. If one expects science to be critical of received theories and to produce a better understanding of the world, if one expects technology to enhance transparency and control by disenchanting and rationalizing nature, these pragmatic integrations appear regressive rather than revolutionary. If one abandous these expectations and makes the shift from epistemic certainty to systemic robustness, these pragmatic integrations hold the promise of producing socially robust technologies. In the meantime, there is no incentive for researchers and hardly any movement on the side of institutions to consider seriously the question of a disciplinary reorientation and consolidation of the nanosciences and nanotechnologies. A nanotechnological revolution has not happened yet: we may be waiting for it in vain and this is probably a good thing.[39]

38) See footnotes 3 and 29. The term Soziale Naturwissenschaft was coined in the context of the finalization thesis and could be designated more literally as a social natural science – science of a nature that is socially shaped through applied science, technology and human action. It is thus not social science but an integrated approach that acknowledges the social character of the world. Here, this proposal is taken up in two ways. Materials (as opposed to matter) and molecules defined by their history and situation are social entities, as such objects of this socials science of nature. Second, nanotechnoscience is a program for shaping and reshaping, for designing and redesigning, for reforming the world. To the extent that this is also a social reform it is systematically incomplete without societal agenda setting: What are the projects, the problems to be solved, the targets and design norms of nanotechnoscience?

39) Some are waiting, of course, not for a radically new and progressive way of doing science but for the far-off scientific breakthroughs that inspire speculations about human enhancement and mind–machine interfaces. However, in the context not of pure philosophy but of supposed implications of current research, "revolutionary" human enhancement is a non-issue that can only distract from more urgent questions [62].

Ethics of Nanotechnology. State of the Art and Challenges Ahead

Armin Grunwald

8.1
Introduction and Overview

In view of the revolutionary potentials attributed to nanosciences and nanotechnology with respect to nearly all fields of society and individual life [1, 2], it is not surprising that "nano" has attracted great interest in the media and in the public. Parallel to high expectations, for example in the fields of health, growth and sustainable development, there are concerns about risks and side-effects. Analyzing, deliberating and assessing expectable impacts of nanotechnology on future society are regarded as necessary parts of present and further development. There have already been commissions and expert groups dealing with ethical, legal and social implications of nanotechnology (ELSI) [3, 4]. An ethical reflection on nanotechnology emerged and has already led to new terms such as "nano-ethics" and the recent foundation of a new journal *Nano-Ethics*. The quest for ethics in and for nanotechnology currently belongs to public debate in addition to scientific self-reflection. The ethical aspects of nanotechnology discussed in the (so far few) treatises available show broad evidence of this relatively new field of science and technology ethics.

Nanotechnology has been attracting increasing awareness in practical philosophy and in professional ethics. However, there has been some time delay compared with the development of nanotechnology itself: "While the number of publications on NT [nanotechnology] *per se* has increased dramatically in recent years, there is very little concomitant increase in publications on the ethical and social implications to be found" [5, p. R10]. Certain terms, such as privacy, man–machine interface, the relationship between technology and humankind or equity are often mentioned.

In the last few years, ethical reflection on nanotechnology developed quickly and identified many ethically relevant issues [6, 7]. However, well-justified criteria for determining why certain topics, such as nanoparticles or crossing the border between technology and living systems, should be ethically relevant are mostly not given and there is no consensus yet. In particular, the *novelty* of the ethical questions touched by developments emerging from nanotechnology compared with ethical issues in

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

well-known fields of technology is often not clear. Furthermore, although ethical aspects of nanotechnology have been identified, their analysis and the elaboration of proposals for how to deal with them in society is still at the beginning. Ethics of nanotechnology is, therefore, still an emerging field, in spite of the thematic broadness and the scientific awareness of the ongoing discussion.

In view of this situation, the purpose of this chapter consists primarily in studying current and foreseeable developments in nanotechnology from the viewpoint of philosophical ethics. Which developments are ethically relevant? Are there ethical questions which have already been tackled by current or recent discussions in the ethics of technology or in bioethics? Could the analysis of ethical aspects of nanotechnology benefit from other ethical discussions? Are there developments which pose completely new ethical questions? To this end, it is necessary to clarify the understanding of the notion of "ethics" to be used in order to look for criteria for deciding when something is ethically relevant in a transparent way (Section 8.2). These criteria are then applied to the field of nanotechnology and the ethical challenges are "mapped out" and described briefly, in order to give a broad overview (Section 8.3). This overview is complemented by two in-depth case studies of ethical aspects in nanotechnology: the challenge of dealing with possible risks of nanoparticles and the role of the precautionary principle (Section 8.4) and the human enhancement case, which is directly related to nanotechnology via the debate on "converging technologies" (Section 8.5). Dealing constructively and in a rational way with these ethical challenges requires specific conceptual and methodical developments. In particular, some effort has to be invested into handling the dimension of the future in normative as well as in epistemological regard in a non-partisan way (Section 8.6).

8.2 The Understanding of Ethics[1)]

In modern discussion, the distinction between factual morals on the one hand and ethics as the reflective discipline in cases of moral conflicts or ambiguities on the other has widely been accepted [10]. This distinction takes into account the plurality of morals in modern society. As long as established traditional moral convictions (e.g. religious ones) are uncontroversial and valid among all relevant actors and as long as they are sufficient to deal with the respective situation and do not leave open relevant questions, ethical reflection is not in place. Morals are, in fact, the action-guiding maxims and rules of an individual, of a group or of society as a whole. Ethical analysis, on the other hand, takes these morals as its subjects to reflect on. Ethics is concerned with the justification of moral rules of action, which can lay claim to validity above and beyond the respective, merely particular morals [8]. In

1) This chapter summarises general work of the author in the field of ethics of technology [8, 9] in order to introduce the basic notions to be used in the following in a transparent way. See also [1, Section 6.2].

particular, ethics serves the resolution of conflict situations which result out of the actions or plans of actors based on divergent moral conceptions by argumentative deliberation only, which is grounded in philosophical ideas such as the Categorical Imperative by Immanuel Kant, the Golden Rule or the Pursuit of Happiness (Utilitarianism).

Normative aspects of science and technology lead, in a morally pluralistic society, unavoidably to societal debates at the least and often also to conflicts over technology. We can witness recent examples in the fields of nuclear power and radioactive waste disposal, stem cell research, genetically modified organisms and reproductive cloning. As a rule, what is held to be desirable, tolerable or acceptable is controversial in society. Open questions and conflicts of this type are the point of departure for the *ethics of technology* [10, 11]. Technology conflicts are, as a rule, not only conflicts over technological means (e.g. in questions of efficiency), but also include diverging ideas over visions of the future, of concepts of humanity and on views of society. Technology conflicts are often controversies about *futures*: present images of the future – which are considerably influenced by our illustrations of the scientific and technological advance – are highly contested [12]. The role of the ethics of technology consists of the analysis of the normative structure of technology conflicts and of the search for rational, argumentative and discursive methods of resolving them. In this "continental" understanding, ethics is part of the philosophical profession. In ethical reflection in the various areas of application, however, there are close interfaces to and inevitable necessities for interdisciplinary cooperation with the natural and engineering sciences involved as well as with the humanities. Even transdisciplinary work might be included in cases of requests for broad participation, for example in the framework of participatory technology assessment [13].

Technology is not nature and does not originate of itself, but is consciously produced to certain ends and purposes – namely, to bring something about which would not happen of itself. Technology is therefore always embedded in societal goals, problem diagnoses and action strategies. In this sense, there is no "pure" technology, that is a technology completely independent of this societal dimension. Therefore, research on and development of new technologies always refer to normative criteria of decision-making including expectations, goals to be reached and values involved [14].

But even if technology is basically beset with values, this does not imply that every decision in research and technology development must be scrutinized in ethical regard. Most of the technically relevant decisions can, instead, be classified as a "standard case" in moral respect in the following sense [6, 9]: they do not subject the normative aspects of the basis for the decision (criteria, rules or regulations, goals) to specific reflection, but assume them to be given for the respective situation and accept the frame of reference they create. In such cases, no explicit ethical reflection is, as a rule, necessary, even if normative elements self-evidently play a vital role in these decisions – the normative decision criteria are clear, acknowledged and unequivocal. It is then out of the question that this could be a case of conflict with moral convictions or a situation of normative ambiguity – the information on the normative framework can be integrated into the decision by those affected and by

those deciding on the basis of axiological information, without analyzing it or deliberating on it. The (national and international) legal regulations, the rules of the relevant institutions (e.g. corporate guidelines), where applicable, the code of ethics of the professional group concerned, as well as general societal usage, are elements of this normative framework [14]. The requirements to be fulfilled in the affected normative framework in order that the respective moral situation can be assumed to be a "standard case" can be operationalized according to the following criteria [6, 11]:

- *Pragmatic completeness:* the normative framework has to treat the decision to be made fully with regard to normative aspects.
- *Local consistency:* there must be a "sufficient" measure of consistency between the normative framework's elements.
- *Unambiguity:* among the relevant actors, there must be a sufficiently consensual interpretation of the normative framework.
- *Acceptance:* the normative framework must be accepted by those affected as the basis for the decision.
- *Compliance:* the normative framework also has to be complied with in the field concerned.

Standard situations in moral respect in this sense are governing decision-making in many fields (e.g. in many cases of laboratory work, in public administration or in private businesses). Technical innovations and scientific progress, however, can challenge such situations by presenting new questions or by shaking views previously held to be valid. This is then the entry point for ethical reflection in questions of science and engineering, for the explicit confirmation, modification or augmentation of the normative framework [15] but also for influencing the direction of further development. This conceptual framework provides a point of departure to identify ethically relevant aspects in new technological developments. Whether there are new challenges for ethics in nanotechnology and which ethical questions will be addressed will be investigated against this background.

8.3 Ethical Aspects of Nanotechnology – an Overview

Ethical challenges of nanotechnology are, following the preceding section, challenges of the existing normative frameworks including the social values represented by them by emerging nanotechnological innovations. The task of identifying ethical challenges emerging from nanotechnology, therefore, can be transformed into the search for affected normative frameworks and social values. Because of the novelty of nanotechnology, which still consists mostly of nanoscience [1, 2], corresponding technology development will frequently take place in form of "radical design processes" rather than as "normal design processes" which may be characterized by more incremental approaches (following [14]). Therefore, we can expect that ethical challenges will be relevant in many cases [15]. Establishing a "map" of the

"landscape" of ethical questions caused by nanotech innovation means answering the following questions:

- Which are the ethical aspects of nanotechnology and related innovations in the sense defined above?
- Which of the identified ethical aspects of nanotechnology are *specific* for nanotechnology and *novel* to ethics?
- Where are relations to recent or ongoing ethical debates in other technology fields, if any?

The resulting "map" of ethical aspects described in the following is organized with reference to existing ethical debates (e.g., debates on privacy, equity or human nature). This classification has the advantage that it automatically allows one to refer to normative frameworks and therefore enables us to investigate whether (a) existing frameworks are sufficient to deal with the value problems involved and (b) if not, whether there are new challenges to the frameworks which are specifically caused by nanotechnology. In this way, it is possible to arrive at a structured and well-founded picture of ethical aspects in nanotechnology.[2)]

8.3.1
Equity: Just Distribution of Opportunities and Risks

A first type of ethical aspects of nanotechnology might result from considerations of equity and distributional justice. Ethical questions concern the *distribution* of the benefits of nanotechnology among different groups of the population or among different regions of the world, as well as the spatial and temporal distribution of the risks of nanotechnology [16]: "Nanotech offers potential benefits in areas such as biomedicine, clean energy production, safer and cleaner transport and environmental remediation: all areas where it would be of help in developing countries. But it is at present mostly a very high-tech and cost-intensive science and a lot of the current research is focused on areas of information technology where one can imagine the result being a widening of the gulf between the haves and the have-nots" [5].

Problems of distributive justice are inherent to many fields of technical innovation. Because scientific and technical progress requires considerable investment, it usually takes place where the greatest economic and human resources are already available. Technical progress does, by its nature, tend to increase existing inequalities of distribution. For example, nanotechnology-based medicine will, in all probability, be rather expensive. Questions of equity and of access to (possible) medical treatments could become urgent in at least two respects: *within* industrialized societies, existing inequalities in access to medical care could be exacerbated by a highly technicized medicine making use of nanotechnology and – with regard to *less developed societies* – because likewise, already existing and particularly dramatic inequalities between industrialized and developing nations could be further increased. Apprehensions

2) This analysis builds on earlier work in the field [1, 6] and goes beyond the state reached. In particular, the categorical classification in fields of ethical interest has been improved.

with regard to both of these types of a potential "nano-divide" (after the well-known "digital divide") are based on the assumption that nanotechnology can lead not only to new and greater options for individual self-determination (e.g. in the field of medicine), but also to considerable improvement of the competitiveness of national economies. Current discussions on distributive justice on both national and international levels (in the context of sustainability as well) are therefore likely to gain increased relevance with regard to nanotechnology.

A specific future field of debate with respect to equity will be the "human enhancement" issue ([17]; see Section 8.5 of this chapter). If technologies of improving human performance were to be available then the question arises of who will have access to those technologies, especially who will be able to pay for them and what will happen to persons and groups excluded from the benefits. There could develop a separation of the population into "enhanced" and "normal" people where a situation is imaginable with "normal" to be used as a pejorative attribute [18] and a coercion towards enhancement might occur: "Merely competing against enhanced co-workers exerts an incentive to use neuro-cognitive enhancement and it is harder to identify any existing legal framework for protecting people against such incentives to compete" [19, p. 423]. Special problems can be expected for disabled persons [20].

Equity aspects, however, are not really new ethical aspects caused by nanotechnology, but are rather intensifications of problems of distribution already existing and highly relevant. Problems of equity belong indispensably to modern technology in general and are leading to ongoing and persistent debates in many fields. The digital divide [21] is, perhaps, the best-known example. But also in military respects or with regard to access to medical high-tech solutions these inequalities exist and are debated in many areas. There is no new ethical question behind them but there might be new and dramatic cases emerging driven by nanotechnological R&D. This point has already arrived at the international level of the nanotech debate [22].

8.3.2 Environmental Issues[3)]

Technology is of major importance for the sustainability of humankind's development. On the one hand, technology determines to a large extent the demand for raw materials and energy, needs for transport and infrastructure, mass flows of materials, emissions and amount and composition of waste. Technology is, on the other hand, also a key factor of the innovation system and influences prosperity, consumption patterns, lifestyles, social relations and cultural developments. Therefore, the development, production, use and disposal of technical products and systems have impacts on the ecological, economic and social dimensions of sustainable development. In most cases, these impacts are ambivalent with regard to sustainable development [23]: there are both positive contributions and negative consequences. The overall concept of

3) A detailed analysis of nanotech potential with regard to sustainable development can be found in [26] and the respective Special Issue of the *Journal of Cleaner Production*.

sustainable development requires production and consumption patterns to be shaped in a manner such that the needs of the current generations can be satisfied in a way that they do not limit or threaten opportunities of future generations for satisfying their needs [24, 25]. Of special relevance in this respect are (following [26]):

- The *limited availability of many natural resources* such as clean water, fossil fuels and specific minerals highlights the importance of the efficiency of their use, of recycling and of substituting non-renewable resources by renewable ones.
- The *limited carrying capacity of the environment* (atmosphere, groundwater and surface water, oceans and pedosphere, ecosystems) emphasizes the necessity for limiting or reducing emissions and for regenerating damaged environments.
- The postulate of *intergenerational equity* as a core part of the idea of sustainable development requires consideration of the distribution of risks and benefits of new technologies among the population and in the global dimension ([22]; see also the preceding section of this paper).
- The sustainability issue of *participation* leads to consequences for the processes of opinion-forming and decision-making in shaping technology and its interfaces with the public (e.g., by means of participatory technology assessment [13]).

Many scientists and engineers claim that nanotechnology promises less material and energy consumption and less waste and pollution from production. Nanotechnology is also expected to enable new technological approaches that reduce the environmental footprints of existing technologies in industrialized countries or to allow developing countries to harness nanotechnology to address some of their most pressing needs [22]. Nanoscience and nanotechnology may be a critical enabling component of sustainable development when they are used wisely and when the social context of their application is considered [26]. There are a lot of high expectations concerning positive contributions of nanotechnology to sustainable development.

However, all the potential positive contributions to sustainable development may come at a price. The ambivalence of technology with respect to sustainable development also applies to nanotechnology [27]. The production, use and disposal of products containing nanomaterials may lead to their appearance in air, water, soil or even organisms [1, Chapter 5, 28]. Nanoparticles could eventually be transported as aerosols over great distances and be distributed diffusely. Despite many research initiatives throughout the world, only little is known about the potential environmental and health impacts of nanomaterials. This situation applies also and above all for substances which do not occur in the natural environment, such as fullerenes or nanotubes. The challenge of acting under circumstances with high uncertainties but with the nanoproducts already at the marketplace is the heart of the ethical challenges by nanoparticles (because of the high relevance and because nanoparticles and their possible risks are under intensive public observation today [29, 30], this topic will be dealt with in-depth (see Section 8.4).

Questions of eco- or human toxicity of nanoparticles, on nanomaterial flow, on the behavior of nanoparticles in spreading throughout various environmental media, on

their rate of degradation or agglomeration and their consequences for the various conceivable targets are, however, not ethical questions (see Section 8.2). In these cases, empirical–scientific disciplines, such as human toxicology, eco-toxicology or environmental chemistry, are competent. They are to provide the knowledge basis for practical consequences for working with nanoparticles and for disseminating products based on them. However, as the debate on environmental standards of chemicals or radiation has shown [31, 32], the results of empirical research do not determine how society should react. Safety and environmental standards – in our case for dealing with nanoparticles – are to be based on sound knowledge but cannot logically be derived from that knowledge. In addition, normative standards, for example concerning the intended level of protection, the level of public risk acceptance and other societal and value-laden issues enter the field. Because of this situation, it is not surprising that frequently conflicts about the *acceptability* of risks occur [33, 34] – and this is obviously a non-standard situation in moral respect (see Section 8.2). Therefore, the field of determining the acceptability and the tolerability of risks of nanoparticles is an ethically relevant issue.

In particular, there are a lot of sub-questions where ethical investigation and debate are asked for in the field of nanoparticles. Such questions are [1, Section 6.2]:

- What follows from our present lack of knowledge about the possible side-effects of nanoparticles? This is a challenge to acting rationally under the condition of high uncertainty – a common problem in practical ethics.
- Is the precautionary principle [35] relevant in view of a lack of knowledge and what would follow from applying this principle [28, 31, 32] (see Section 8.4)?
- Which role do the – doubtlessly considerable – *opportunities* of nanoparticle-based products play in considerations of this sort? According to which criteria may benefits and hazards be weighed against each other, especially in cases when the benefits are (relatively) concrete, but the hazards are hypothetical?

A further question would be by which means such balancing could be performed in an inter-subjectively valid and commonly acceptable way. The quantification of risks and benefits by using utility values might be very difficult or even impossible in cases of high uncertainty about the probability, the kind and the extent of a possible damage as well as in cases of ethical problematic procedures of quantification (such as expressing the value of human life in monetarian units).

Are comparisons of the possible risks of nanoparticles with other types of risk possible, in order to learn from them? Can criteria for assessing the nanoparticle risks be gained from experience in developing new chemicals or medicines? Are we allowed to look at risks of our daily life in order to determine what nanoparticle risk should be acceptable in general [31]? Which normative premises enter into such comparisons and by which argumentative means could they be morally justified?

The questions of the acceptability and comparability of risks, the advisability of weighing up risks against opportunities and the rationality of action under uncertainty are, without doubt, of great importance in nanotechnology. A new field of

application is developing here for the ethics of science and technology. The type of questions posed, however, is well known from established discussions on risks (e.g. risks by exposure to radiation or by new chemicals). Really novel ethical questions are not to be expected in spite of the high practical relevance of the field.

From an ethical point of view this situation is well known: there are, on the one hand, positive expectations with regard to sustainable development which legitimate a moral postulate to explore further and to exhaust those potentials. On the other hand, there are risks and uncertainties. This situation is the basic motivation of technology assessment (TA) as an operationalization of ethical reflections on technology [36]. The basic challenge with strong ethical support is *shaping* the further development of nanotechnology in the direction of sustainable development [25, 37].

8.3.3 Privacy and Control

Another field regularly mentioned among the ethical aspects of nanotechnology is the threat to privacy through new monitoring and control technologies. Nanotechnology offers a range of possibilities for gathering, storing and distributing personal data to an increasing extent. In the course of miniaturization, a development of sensor and memory technology is conceivable which, unnoticed by its "victim", drastically increases the possibilities for acquiring data. Furthermore, miniaturization and networking of observation systems (e.g., in the framework of "pervasive" or "ubiquitous" computing) could considerably impede present control methods and data protection regulations or even render them obsolete [38]. Passive observation of people could, in the distant future, be complemented by actively manipulating them – for instance, if it would be possible to gain direct technical access to their nervous system or brain [19, 39].

Within the private sphere, health is a particularly sensitive area. The development of small analyzers – the "lab on a chip" – can make it possible to compile comprehensive personal diagnoses and prognoses on the basis of personal health data. This technology can facilitate not only medical diagnoses, but can also make fast and economical comprehensive screening possible. Everyone could let him- or herself be tested, for example, for genetic dispositions for certain disorders – or could be urged by his/her employer or insurance company to do so. In this manner, individual persons could find themselves put under social pressure. Without sufficient protection of their private sphere, people are rendered manipulable, their autonomy and freedom of action are called into question. Stringent standards for data protection and for the protection of privacy therefore have to be set.

Questions of privacy, of monitoring and controlling people are doubtlessly ethically relevant. But all of these questions of monitoring and of data and privacy protection are not posed exclusively by nanotechnology. Even without nanotechnology, observation technologies have reached a remarkable stage of development which poses questions on the preservation of the private sphere. Even today, so-called smart tags, based on RFID technology (radiofrequency identification), are being employed for access control, such as ticketing, for example, in public transportation and in

logistics. These objects have at present a size of several tenths of a millimeter in each dimension, so that they are practically unnoticeable to the naked eye. Further miniaturization will permit further reductions in size and the addition of more functions – without nanotechnology being needed – but nanotechnology will promote and accelerate these developments.

The ethically relevant questions on a right to know or not to know, on a personal right to certain data, on a right to privacy, as well as the discussions on data protection and on possible undesirable inherent social dynamisms and, in consequence, of a drastic proliferation of genetic and other tests, have been a central point in bio- and medical-ethical discussions for some time. Nanotechnological innovations can accelerate or facilitate the realization of certain technical possibilities and therefore increase the urgency of the problematics of the consequences; in this area, however, they do not give rise to qualitatively new ethical questions.

8.3.4
Military Use of Nanotechnology

Nanotechnology can improve not only multiple peaceful uses but also military and future arms systems. The foundation of the so-called Institute for Soldier Nanotechnologies (http://web.mit.edu/isn/) to enhance soldier survivability makes it clear that nanotechnology has applications in the military field. It is predicted that nanotechnology will bring revolutionary changes in this areas as well [40–42]. Nevertheless, progress in a military technology will not only improve survival and healing, it always implies its use to enhance the efficacy of weapons, surveillance systems and other military equipment. As nanotechnology will provide materials and products that are stronger, lighter, smaller and more sensitive, there may be projectiles with greater velocity and smaller precision-guidance systems. Moreover, nanotechnology will influence the processing in energy generation and storage, displays and sensors, logistics and information systems, all being important elements of warfare. A particular point of interest is the use of BCI (brain–computer interaction) for navigation support for jet pilots, which is being researched by many projects funded by the US defense agency DARPA [43]. In several countries the Departments or Ministries of Defense have arranged nanotechnological programs. No one wants to be left behind [42].

The ethical concerns related to these developments mentioned in the available literature may be classified into the following points [41, 42]:

- An arms race similar to that of nuclear weapons cannot be excluded.
- Present asymmetric power relation could be increased or intensified, for instance to the disadvantage of developing countries [7].
- Some nanobased weapons might be much smaller and, perhaps, cheaper that traditional ones. This could increase the risks of proliferation and of terrorist usage of those weapons.

As long as the military in general is regarded as ethically allowed – and this is the case in most concepts of ethics as far as the military is used for legitimate purposes

such as self-defense of democratic states or legitimate interventions into totalitarian states or for humanitarian reasons – there is little reason to investigate ethical aspects of the use of new technologies in the military areas as a specific topic. At any time, technology has been an important factor in military affairs and had a decisive influence on power relations. Nations with highly developed industrial capacities will be able to exploit the military possibilities of scientific and technological advances to a greater extent than less developed nations.

However, the developments must be observed carefully from the standpoint of peace-keeping and arms control. Possibly areas of international agreements must be reconsidered [41], above all the arms control agreements (e.g. Biological Weapons Convention; limits on conventional forces by new weapons types outside of treaty definitions) or the international laws of warfare (e.g. through the introduction of autonomous fighting systems not reliably discriminating between combatants and non-combatants). There is a certain risk that military "facts" could be created before an open debate about such developments has been launched. In this way, awareness in ethical regard is required in this field but novel ethical questions are not in view at present.

8.3.5 Health

Miniaturization is an essential means of progress in many medical areas. Smaller samples for *in vitro* analysis allow less invasive and less traumatic methods of extraction. Better interfaces and biocompatible materials provide new occasions for implants and restoring damaged organic facilities. The field of medical application seems to be the largest area of future nanotech applications [2]. Nanomedicine is defined as "(1) the comprehensive monitoring, control, construction, repair, defense and improvement of all human biological systems; working from the molecular level, using engineered nanodevices and nanostructures; (2) the science and technology of diagnosing, treating and preventing disease and traumatic injury, of relieving pain and of preserving and improving human health, using molecular tools and molecular knowledge of the human body; (3) the employment of molecular machine systems to address medical problems, using molecular knowledge to maintain and improve human health at the molecular scale" [44, p. 418].

With the help of nanotechnology-based diagnostic instruments, diseases or predispositions for diseases could possibly be discovered earlier than at present [45]. Through the development of "lab-on-a-chip"-technology, the emerging tendency towards personalized medicine would be further promoted. In therapy, there is the prospect, with the help of nanotechnology, of developing targeted treatments free of side-effects. The broad use of nanoparticle dosage systems could lead to progress in medicinal treatment. Through nanotechnological methods, the biocompatibility of artificial implants can be improved. Drug delivery systems could considerably enhance the efficiency of medication and minimize side-effects: "Although many of the ideas developed in nanomedicine might seem to be in the realm of science fiction, only a few more steps are needed to make them come true, so the 'time-to-market' of

these technologies will not be as long as it seems today. Nanotechnology will soon allow many diseases to be monitored, diagnosed and treated in a minimally invasive way and it thus holds great promise of improving health and prolonging life. Whereas molecular or personalized medicine will bring better diagnosis and prevention of disease, nanomedicine might very well be the next breakthrough in the treatment of disease" [46, p. 1012).

Addressing symptoms more efficiently or detecting early onsets of diseases is without doubt recommended by ethics. These potentials are so remarkable that ethical reflection almost seems to be superfluous – if one looks solely at the potentials. A comprehensive analysis, however, has to include – as noted above – also possible side-effects, especially risks [48–50]. New types of responsibility and new tasks for weighing up pros and cons might occur. For example, new forms of drug delivery based on nanotechnology (using fullerenes, nanostructured membranes, gold nanoshells, dendrimers [1, Section 3.3]) could also have consequences which are not expected and might not be welcome. Careful observations of the advance of knowledge and early investigations of possible side-effects have to be conducted. HTA (Health Technology Assessment) offers several established approaches for early warning. The ethically relevant issues are [7]:

- the gulf between diagnostic and therapeutic possibilities and the problem of undesirable information;
- data protection and the protection of privacy (see Section 8.3.3), especially the danger of genetic discrimination;
- preventive medicine and screening programs;
- increases in costs through nanomedicine and problems of access and equity (see Section 8.3.1);
- deferment of illness during the lifetime of humans;
- changes in the understanding of illness and health [52].

However, there is probably no field of science in which dealing with risks is so well established as in medicine and pharmaceutics. Advances in medicine (diagnosis and therapy) are evidently related to risks and there are a lot of established mechanisms such as approval procedures for dealing with them. There is nothing new about this situation. Therefore, using nanotechnology for medical purposes is a standard situation in moral respects (following the notion introduced in Section 8.2). Against this background, it seems to be improbable that direct applications of nanotechnology for medical purposes might lead to completely new ethical questions [47, 51]. The ethical topics to be aware of are not specific for the use of nanotechnology but are also valid for a lot of other advances in medical science and practice.

The boundaries of such a standard situation in moral respects would, however, be transgressed in some more visionary scenarios as in the vision of longevity or the abolition of aging. Nanotechnology could, in connection with biotechnology and, perhaps, neurophysiology, build the technological basis for realizing such visions. In this respect, the idea has been proposed that nanomachines in the human body could permanently monitor all biological functions and could, in case of dysfunction, damage or violation, intervene and re-establish the "correct" status. In this way, an

optimal health status could be sustained permanently [53] which could considerably enlarge the human lifespan. Such methods, however, would require dramatic technological progress [2, Section 7.2.3]. According to the state of present knowledge, neither the prediction of the time needed for such developments nor an assessment of their feasibility at all can seriously be given.

A new area that is both practically and ethically interesting and much closer to realization consists of creating direct connections between technical systems and the human nervous system [39, 54, 55]. There is intensive current work on connecting the world of molecular biology with that of technology. An interesting field of development is nanoelectronic neuro-implants (neurobionics), which compensate for damage to sensory organs or to the nervous system [43]. Micro-implants could restore the functions of hearing and eyesight. Even today, simple cochlear or retina implants, for example, can be realized. With progress in nano-informatics, these implants could approach the smallness and capabilities of natural systems. Because of the undoubtedly positive goals of healing and restoring damaged capabilities, ethical reflection could, in this case, concentrate above all on the definition and prevention of misuse. Technical access to the nervous system, because of the possibilities for manipulation and control which it opens up, is a particularly sensitive issue. A more complex ethical issue would be neuro-cognitive *enhancement* of functions of the brain [19] (see Section 8.5).

Summing up, in the field of medical applications of nanotechnology there are, considered from the standpoint of today's knowledge, no ethical concerns which are specifically related to the use of nanotechnology. There are a lot of positive potentials which probably also will bear risks – these risks, however, might be dealt with by "standard" measures of risk analysis and management established in medical practice [48]. However, things might change in the more distant future (e.g., if there were to be a shift from the classical medical viewpoint to the perspective of "enhancing" human performance; see Section 8.5).

8.3.6
Artificial Life

Basic life processes take place on a nanoscale, because life's essential building blocks (such as proteins) have precisely this size. By means of nanobiotechnology, biological processes will, due to frequently expressed expectations, be made technologically controllable. Molecular "factories" (mitochondria) and "transport systems", which play an essential role in cellular metabolism, can be models for controllable bio-nanomachines. Nanotechnology on this level could permit the "engineering" of cells and allow a "synthetic biology" constructing living systems "from the bottom" or modifying existing living systems (such as viruses) by technical means. An intermeshing of natural biological processes with technical processes seems to be conceivable. The classical barrier between technology and life is increasingly being breached and crossed.

The technical design of life processes on the cellular level, direct links and new interfaces between organisms and technical systems portend a new and highly dynamic scientific and technological field. Diverse opportunities, above all, in the

field of medicine, but also in biotechnology, stimulate research and research funding [1, Section 3.3]. New ethical aspects are certainly to be expected in this field. They will possibly address questions of artificial life and of rearranging existing forms of living systems by technical means, for example the reprogramming of viruses. Their concrete specification, however, will only be possible when research and development can give more precise information on fields of application and products.

Without knowing much about products and systems emerging from the mentioned developments, there is one thing which seems clear already today. We can surely expect discussions about risks because technically modifying or even creating life is morally and with respect a very sensitive field [56]. The corresponding discussions of risks will have structural similarities to the discussion on genetically modified organisms (GMOs) because in both cases the "source code of life" is attached by technical means. It could come to discussions about safety standards for the research concerned, about containment strategies, about "field trials" and release problems. The danger of misuse will be made a topic of debate, such as technically modifying viruses in order to produce new biological weapons that could possibly be used by terrorists. In this area of nanotechnology, opposition, rejection and resistance in society could be feared, comparable to the GMO case. There will be a demand for early dealing with possible ethical and risk problems and for public dialogue and involvement.

In spite of the partly still speculative nature of the subject, ethical reflection of the scientific advance on crossing the border between technology and life does not seem to be premature [49, 50]. There are clear indications that scientific and technical progress will intensify the – at present non-existent – urgency of these questions in the coming years. However, against the questions to be answered in this section, it has to be stated that these ethical questions are not really specific to nanotechnology. The slogan "shaping the world atom by atom" [57] does not make a difference between technology and life and is, therefore, background to crossing the border between technology and life. But the ethical debates to be expected can rely on preceding investigations. Since the 1980s, these subjects have been repeatedly discussed in the debates on GMO, on artificial intelligence and on artificial life. There is a long tradition of ethical thought which has to be taken into account when facing the new challenges in the field.

8.3.7
Human Enhancement[4)]

Within the tradition of technical progress, that has, at all times, transformed conditions and developments – which, until then, had been taken as given, as unalterable fate – into influenceable, manipulable and formable conditions and developments, the human body and its psyche are rapidly moving into the dimension of the formable. The vision of "enhancing human performance" has been conjured

4) Because of the high relevance in current debates and the challenge to traditional thinking involved, this topic has been selected for an in-depth investigation (see Section 8.5).

up, above all, in the field of "converging technologies" [17]. Nanotechnology, in combination with biotechnology and medicine, opens up perspectives for fundamentally altering and rebuilding the human body. At present, research is being done on tissue and organ substitution, which could be realized with the help of nano- and stem cell technologies. Nano-implants would be able to restore human sensory functions or to complement them, but they would also be able to influence the central nervous system (for an overview on types of enhancement, see [20]).

While the examples of medical applications of nanotechnology cited above [45] remain within a certain traditional framework – because the purpose consists of "healing" and "repairing" deviations from an ideal condition of health, which is a classical medical goal –chances (or risks) of a remodeling and "improvement" of the human body are opened up. This could mean extending human physical capabilities, for example to new sensory functions (e.g., broadening the electromagnetic spectrum that the eye is able to perceive). It could, however, also – by means of the direct connection of mechanical systems with the human brain – give rise to completely new interfaces between humans and machines. Even completely technical organs and parts of the body (or even entire bodies) are being discussed, which, in comparison with biological organisms, are supposed to have advantages such as – perhaps – increased stability against external influences [17].

There are initial anthropological questions of our concept of humanity and of the relationship between humanity and technology. With them, however, and at the same time, the question poses itself of how far human beings *can*, *should* or *want to* go in remodeling the human body and to what end(s) this should or could be done. The practical relevance of such ethical questions in view of a possible technical improvement of human beings (with the substantial participation of nanotechnology) may, at first sight, seem limited. Three considerations, however, contest this estimation. First, the vision of the technical enhancement of human beings is actually being seriously advocated. Research projects are being planned in this direction and milestones for reaching this goal are being set up, whereby nanotechnology takes on the role of an "enabling technology". Second, the visions of human enhancement show consequences by merely communicating them – they currently modify the *conditio humana* [58]. Third, technical enhancements are by no means completely new, but are – in part – actually established, as the example of plastic surgery as a technical correction of physical characteristics felt to be imperfections shows, and as is the case in the practice of administering psycho-active substances. It is not difficult to predict that the possibilities and the realization of technical improvements of human beings will increase; demand is conceivable. In view of the moral questions connected with this development and of their conflict potential, ethical reflection is needed in this field already today although the feasibility of the enhancement technologies at all and the time scale of their availability cannot be assessed with any certainty. Because nanotechnology is seen as the "enabling technology" of these developments, the emerging ethical questions can be related to nanotech developments. However, we have to keep in mind that there is a tradition of ethical thought in anthropology, bioethics, medicine ethics and ethics of technology which provides a lot of argumentations and analyses for the field of "human enhancement".

8.4
Nanoparticles and the Precautionary Principle[5)]

Nanoparticles and nanomaterials are among the first outcomes of nanotechnology to enter the marketplace and can already be found in everyday products [59]. From the "imperative of responsibility" [60] or the quest for "projected futures" [61, 62], philosophical conclusions have been drawn for slowing the process of bringing more and more nanoparticles into the environment and the human body without knowing much about possible side-effects. Ethical reflection is asked for concerning the question of how to deal responsibly with this situation involving high uncertainties of knowledge.

8.4.1
The Risk Debate on Nanoparticles

Currently, special attention in public risk debate is being paid to synthetic nanoparticles. A vast potential market for nano-based products is seen in this field. By means of admixtures or specific applications of nanoparticles, for example, new properties of materials can be brought about, for instance, in surface treatment, in cosmetics and in sunscreens. Consumers and citizens could easily come in contact with nanoparticles already today and the probability of directly having contact with synthetic nanoparticles will increase considerably in the next few years because of the expanding market for the respective products [59]. In spite of this situation, there is still little knowledge about possible impacts of nanoparticles on human health and the environment. In order to allow rational risk management strategies, knowledge about ways of spreading, behavior in the atmosphere or in fluids, lifetime of nanoparticles *as* nanoparticles until agglomeration to form other (larger) particles, their behavior in the human body and in the natural environment, and so on, would be needed. Such knowledge, however, is currently not available to an extent which would allow for classical risk management strategies [1, Section 5.2, [27, 28]].

The growing awareness of this risk issue in combination with the fact of having nearly no knowledge available about side-effects of nanotechnology led to severe irritations and to a kind of helplessness in the early stages of that debate. Some statements from that time will illustrate that situation. A re-assurance company stated: "The new element with this kind of loss scenario is that, up to now, losses involving dangerous products were on a relatively manageable scale whereas, taken to extremes, nanotechnology products can even cause ecological damage which is permanent and difficult to contain. What is therefore required for the transportation

5) Parts of this work have been performed within the expert group "Nanotechnology. Assessment and Perspectives" of the European Academy Bad Neuenahr-Ahrweiler [1]. I would like to thank the group members for many fruitful discussions. More specifically, I am deeply indebted to Harald Krug, who introduced the knowledge available in human and eco-toxicology about impacts of nanoparticles into those discussions. An extended version of this chapter is currently being published [66].

of nanotechnology products and processes is an organizational and technical loss prevention programme on a scale appropriate to the hazardous nature of the products" [64, p. 13]. The ETC group postulated a ban on the commercial use of nanoparticles until more knowledge was available: "At this stage, we know practically nothing about the possible cumulative impact of human-made nanoscale particles on human health and the environment. Given the concerns raised over nanoparticle contamination in living organisms, the, ETC group proposes that governments declare an immediate moratorium on commercial production of new nanomaterials and launch a transparent global process for evaluating the socio-economic, health and environmental implications of the technology" [29, p. 72]. A completely different but also far-reaching recommendation aims at "containing" nanotech research: "CRN has identified several sources of risk from MNT (molecular nanotechnology), including arms races, gray goo, societal upheaval, independent development and programmers of nanotech prohibition that would require violation of human rights. It appears that the safest option is the creation of one – and only one – molecular nanotechnology programme and the widespread but restricted use of the resulting manufacturing capability" [65, p. 4]. This containment strategy would imply a secret and strictly controlled nanotech development, which seems to be unrealistic and unsafe as well as undemocratic. These different proposals have enriched (and heated) public and scientific debate on possible nanoparticle risks. Nanotechnology, itself still in an embryo state, experienced itself, at that time, more or less suddenly, as a subject of public risk debate. The actors in the field seemed not to be prepared for this case. Against this background, it is understandable that the first years of the nanotech risk debate may be characterized mainly by mere suspicions, speculations and uncertainties rather than by knowledge-based and rational deliberation.

In analyzing this situation with respect to conclusions for risk management, careful normative reflection is required [35]. More precisely, thinking about the precautionary principle implies the absence of a standard situation in moral, in epistemic and in risk respect ([6]; see also Section 8.2 of this chapter). Ethical reflection is needed to shed light on the normative premises of the options at hand as well as on the criteria of decision-making. Such an ethical "enlightenment" is a necessary precondition of deliberative procedures within which society could identify adequate levels of protection, threshold values or action strategies. Questions of the acceptability and comparability of risks, the advisability of weighing up risks against opportunities and the rationality of action under uncertainty are, without doubt, of great importance in the field of nanoparticles (for the general challenge related to rationality and risk, see [33]). A new field of application is developing here for the ethics of technology, where close cooperation with toxicology, social sciences and jurisprudence is necessary [63].

8.4.2
The Precautionary Principle

Risk management strategies accompanying the implementation of new technologies and the introduction of new materials are standing in a long tradition. In earlier

times, often a "wait-and-see" approach had been taken. New substances have been introduced assuming that either probably no negative developments and impacts at all would occur or that, in case of adverse effects, *ex post* repair and compensation strategies would be appropriate. The asbestos case is one of the best-known experiences where this approach failed and where the failure had dramatic consequences [67].

Such experiences with hazards caused by new materials, by radiation or by new technologies (see [68] for impressive case studies) led to risk regulations in different fields, in order to prevent further negative impacts on health and the environment. Important areas are [1, Section 5.1]:

- regulations for working places with specific risk exposures (nuclear power plants, chemical industry, aircraft, etc.) to protect staff and personnel;
- procedural and substantial regulations for nutrition and food (concerning conservation procedures, maximum allowed concentrations of undesirable chemicals such as hormones, etc.) to protect consumers;
- environmental standards in many areas to sustain environmental quality (concerning ground water quality, maximum allowed rate of specific emissions from fabrication plants, power plants, heating in households, etc.);
- safety standards and liability issues to protect users and consumers (in the field of automobile transport, for power plants, engines, technical products used in households, etc.).

There are established mechanisms of risk analysis, risk assessment and risk management in many areas of science, medicine and technology, for example in dealing with new chemicals or pharmaceuticals. Laws such as the Toxic Substance Control Act in the USA [69] constitute an essential part of the normative framework governing such situations. This "classical" risk regulation is adequate if the level of protection is defined and the risk can be quantified as the product of the probability of the occurrence of the adverse effects multiplied by the assumed extent of the possible damage. In situations of this type, thresholds can be set by law, by self-commitments or following participatory procedures, risks can be either minimized or kept below a certain level and also precautionary measures can be taken to keep particular effects well below particular thresholds by employing the ALARA (as low as reasonably achievable) principle [63]. Insofar as such mechanisms are able to cover challenges at hand to a sufficient extent, there is a standard situation in moral respect (see Section 8.2) regarding the risk issue. As the ongoing debate shows (which will be explained in more detail below), the field of risks of nanoparticles will not be a standard situation in this sense.

As soon as the conditions for the classical risk management approach are no longer fulfilled, uncertainties and ambivalent situations are the consequence. This is the case if, on the one hand, scientific knowledge concerning possible adverse effects is not available at all or is controversial or highly hypothetical or if empirical evidence is still missing. On the other, classical risk management might not be applicable if adverse affects could have catastrophic dimensions with respect to the extent of possible damage, also in case of (nearly) arbitrary small probabilities of their

occurrence. In the field of nuclear power plants, scenarios of this type have been used as counter-arguments against that technology. The catastrophic dimension of possible, at least thinkable, accidents should, in the eyes of opponents, be a decisive argument even in case of an extreme low probability of such events. This type of situation motivated, for example, Hans Jonas [60] to postulate a "heuristics of fear" and the obligation to use the worst scenario as orientation for action.

In the philosophical debate, however, it became clear that Jonas's approach – besides inherent philosophical problems of the naturalistic and teleological approach – might be very appropriate to raise awareness with regard to precautionary situations but completely inadequate to be operationalized by regulation. Jonas's approach missed completely a legitimate procedure for deciding about the applicability and adequacy of precautionary strategies. What can still be learned from Jonas's work is the high relevance of normative reflection in cases where classical risk management would no longer be adequate [35]. Such situations often are welcomed entry points for ideology and interest-driven statements in arbitrary directions. In fact, it is very difficult to identify what a "rational" approach to dealing with non-classical situations could be and in which way it could be proven to be rational [33].

The observation that in many cases severe adverse effects in the course of the introduction of new materials had not been detected in an early stage but rather led to immense damage to human health, the environment and also the economy [68] motivated debates about precautionary regulation measures which could be applied *in advance* of having certain and complete knowledge – because it might then be too late to prevent damage. Wide international agreement on the precautionary principle was reached during the Earth Summit [United Nations Conference on Environment and Development (UNCED)] in Rio de Janeiro in 1992 and became part of Agenda 21: "In order to protect the environment, the precautionary approach should be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation" [70]. The precautionary principle was incorporated in 1992 in the Treaty on the European Union: "Community policy on the environment shall aim at a high level of protection taking into account the diversity of situations in the various regions of the Community. It shall be based on the precautionary principle . . ." (Article 174).

The precautionary principle substantially lowers the (threshold) level for action of governments (see [35] for the following). It considerably alters the situation in comparison with the previous context in which politicians could use (or abuse) a persistent dissent among scientists as a reason (or excuse), simply *not to take action at all*. In this way, political action simply could come much too late. It is, however, a difficult task to establish legitimate decisions about precautionary measures without either to run into the possible high risks of a "wait-and-see" strategy or to overstress precautionary argumentation with the consequence of no longer to be able to act any more or to cause other types of problems (e.g., for the economy) without need. The following characterization of the precautionary principle shows – in spite of the fact that it still does not cover all relevant aspects – the complex inherent structure of the precautionary principle:

> "*Where, following an assessment of available scientific information, there is reasonable concern for the possibility of adverse effects but scientific uncertainty persists, measures based on the precautionary principle may be adopted, pending further scientific information for a more comprehensive risk assessment, without having to wait until the reality and seriousness of those adverse effects become fully apparent*" *(modified from [35])*.

Thinking about applying the precautionary principle generally starts with a *scientific examination*.

An assessment of the state of the knowledge available in science and of the types and extents of uncertainties involved is needed. In assessing the uncertainties involved, *normative* qualifiers come into play [35]. It has to be clarified whether there is *reasonable concern* in this situation of uncertainty. The qualifier "reasonable concern" as employed by the EC guidelines makes no prejudice about the degree of likelihood, but this qualifier relates to a judgment on the quality of the available information [35]. Therefore, the assessment of the knowledge available including its uncertainties is crucial to precautionary reflections.

8.4.3 The Precautionary Principle Applied to Nanoparticles

Following the preceding analysis, the central questions in the current situation concerning the use of nanoparticles and the knowledge about possible impacts are as follows [66]:

1. Is there a precautionary situation at all, characterized by *epistemic uncertainty* or *unquantifiable risk*?
2. Is there "*reasonable concern* for the *possibility* of adverse effects" in the field of nanoparticles to legitimate the application of the precautionary principle?
3. If yes, what would follow from this judgment with respect to adequate precautionary measures?

The first question has to be answered *positive* (e.g. [1, Section 5.2, 27]). There are unknown or uncertain cause-effect relations and still unknown probabilities of risks resulting from the production, use and proliferation of nanoparticles. The scope of possible effects, their degrees and the nature of their "seriousness" (in relation to the chosen level of protection) can currently, even in the best cases, only be estimated in qualitative terms. Therefore, we are witnessing a typical situation of uncertainty where established risk management strategies are not to be applied [3, p. 4f, 27].

The answer to the second question, whether there is "*reasonable concern* for the *possibility* of adverse effects" in the field of synthetic nanoparticles is also to be answered positive. There are first toxicological results from the exposure of rats to high concentrations of specific nanoparticles which showed severe up to lethal consequences. Because the exposure concentrations were extremely high and the transfer of knowledge achieved by the exposure of rats to the situation of humans is

difficult, these results do not allow for the conclusion of evidence of harm to human health – but they support assuming "reasonable concern for the *possibility* of adverse effects" caused by synthetic nanoparticles. There is a strict difference from classical risk management where *evidence of adverse effects* is required, not evidence of their *possibility* (only).

The third question is the most difficult one. In the precautionary situation given by positive answers to the first two questions, the challenge is to identify a "rational" course of action. The suspicion of adverse effects of nanoparticles could serve as a legitimating reason for very strict measures such as a moratorium on nanoparticle use [29, 30]. However, a mere suspicion – this would be sufficient in the above-mentioned Jonas scenario – does not legitimate strict precautionary measures. Instead, this would depend on a scientific assessment of the state of the art and that the quality of the information available [35]. This scientific assessment of the knowledge available for the nanoparticle case has recently been performed [1, Section 5.2] in a comprehensive manner. It resulted that there are indications for nanoparticle risks for health and the environment in some cases but that there is, based on the state of the art, *no reason for serious concern* about adverse effects but well-grounded serious concern about the *possibilities* of such effects. In the same direction: "Taking into account our present-day knowledge, there is, with regard to nano-specific effects (excluding self-organization effects and cumulative effects of mass production), no reason for particularly great concern about global and irreversible effects of the specific technology 'per se', with it being on a par with the justifiable apprehension concerning nuclear technology and genetic engineering" [27, p. 16].

The mere *possibility* of serious harm implied by a wider use of nanoparticles, however, *does not legitimize* using the precautionary principle as an argument for a moratorium or other prohibitive measures. However, because the state of knowledge permanently changes, continuous monitoring and assessment of the knowledge production concerning impacts of nanoparticles on human health and the environment are urgently required. One of the most dramatic lessons which can be learned from the asbestos story is exactly the lesson about the crucial necessity for such a systematic assessment [67].

The next question is what other (and weaker) types of measures are required in the present (precautionary) situation. These could, for example, be self-organization measures in science, such as the application of established codes of conduct or the adaptation of existing regulation schemes to special features of nanoparticles. It seems helpful to reconsider, as an example, the implementation of the precautionary principle in the genetically modified organisms (GMOs) case: "The European Directive 2001/18 (superseding Directive 90/220), concerning the deliberate release of GMOs into the environment, is the first piece of international legislation in which the precautionary principle is translated into a substantial precautionary framework. ... In the framework of this Directive the precautionary principle is translated into a regulatory framework which is based on a so-called *case-by-case* and a *step-by-step* procedure. The case-by-case procedures facilitates a mandatory scientific evaluation of every single release of a GMO. The step by step procedure facilitates a progressive line of development of GMOs by evaluating the

environmental impacts of releases in decreasing steps of physical/biological containment (from greenhouse experiments, to small-scale and large-scale fields tests up to market approval). This procedural implementation of the precautionary principle implies an ongoing scientific evaluation and identification of possible risks" [35]. The application of the precautionary principle would, in this argument, imply "that there is a need for a cautious step-by-step diffusion of risk-related activities or technologies until more knowledge and experience is accumulated" [27, p. 6].

Against this background there is a wide consensus that no really new regulatory measures are needed: ". . . the existing regulative framework is adequate to deal with the introduction of new substances in the nanotechnology sector" [27, p. 27]. There are particular points of criticism concerning existing regulatory systems [69]; these points may be taken into account by modifications and supplements. Treating nanoparticles as new chemicals seems to be the adequate risk management approach [1].

In the framework of the precautionary principle, there are urgent tasks to be done by science [66], especially in order to close the still large knowledge gaps [27]. A second line of activities required consists of systematically collecting all relevant knowledge and of regularly conducting comprehensive evaluations of the respective state of knowledge. A third field of activities should be directed to contributing to public debate and to improving communication at the interface between science and society. The following steps for further action, thereby meeting several of recommendations by other groups [3, 27, 71], have been proposed [1]:

- develop a nomenclature for nanoparticles and assign a new Chemical Abstracts Service (CAS) registry number to engineered nanoparticles;
- group and classify nanomaterials with respect to categories of risk, toxicity and proliferation;
- treat nanoparticles as new substances and develop and approve tools for screening and testing;
- improve the knowledge base in toxicology;
- develop guidelines and standards for good practices in cautiously dealing with nanoparticles;
- avoid or minimize production and unintentional release of waste nanoparticles;
- establish comprehensive evaluation of the state of knowledge and its evaluation with respect to implications for risk management as well as for identifying knowledge gaps which should urgently be closed;
- create institutions to monitor nanotechnologies and the knowledge about possible risks;
- establish a permanent and open dialogue with the public and with industry.

This step-by-step approach conforms to present knowledge and seems to be an adequate way of applying the precautionary principle in a pragmatic way. However, there is no guarantee of preventing all kinds of possible risks by applying these steps. To repeat an important lesson from the asbestos story, the present situation which

may be characterized by "no evidence of harm" must not be reinterpreted as "evidence of no harm" [67].

With respect to the "reasonable concern for the possibility of hazards", specific caution in dealing responsibly with synthetic nanoparticles is required. Such particles should be handled analogously to *new* chemicals even in the case that the chemical composition is well known beyond the nano character. Dealing with new nanoparticles is still based on a case-by-case approach because established nomenclature and classification schemes are not well prepared to be applied to nanoparticles. This situation should be changed as soon as possible [1, 63].

Beyond risk management and regulation, public risk communication has to be observed carefully because irritations in this communication could have a dramatic impact on public acceptance and political judgment. Denying the existence of risks of new technologies often causes mistrust and suspicion instead of creating optimism. To speak frankly about possible risks increases the chance of a trusty relationship between science and society. Building trust in public debate needs an open debate about chances and risks and often requires schemes for comparing different types and amounts of risk to be available [56, 63]. Transparency about the premises of different risk assessment exercises is urgently required. Knowledge about risks includes knowledge about the validity and the limits of that knowledge. Communicative and participative instruments of technology assessment [13, 72] could help improve mutual understanding and public risk assessment.

8.5
Human Enhancement by Converging Technologies

The report "Converging Technologies for Improving Human Performance" [17] caused a worldwide wave of intensive debate about the future of human nature and on the current agenda of science [71]. It was based on earlier debates in the context of biotechnical and genetic improvement strategies [73, 74]. The idea of NBIC (Nano–Bio–Info–Cogno) convergence [1], however, led to a new degree of intensity. Nanotechnology has been seen as the "enabling technology" of such new strategies of enhancement which allows the "converging technologies" to be given a place in a book on nanotechnology. Without any doubt the question for human enhancement will not be covered by a standard situation in moral respect.

In this section, we will use a topic-oriented approach, starting by discussing the "human enhancement" topic first in general and then mentioning the contributions to this old topic of nanotechnologies and the converging technologies (Section 8.5.1). The implications of the human enhancement idea by NBIC technologies for the need for orientations will be discussed (Section 8.5.2), followed by addressing specific ethical questions (Section 8.5.3). As a result, a rather probable scenario of the further development will be given and discussed in an ethical respect (Section 8.5.4).

8.5.1
Human Enhancement: Visions and Expectations

Human enhancement is a very old theme. Mankind's dissatisfaction with itself has been known from ancient times – discontent with mankind's physical endowments, its physical and intellectual capabilities, with its vulnerability to exogenic eventualities such as disease, with the inevitability of aging and, finally, of death, dissatisfaction with its moral capacities or – and this will probably be particularly frequent – with one's physical appearance. Various methods have been developed and established in order to give certain wishes for improvement a helping hand. Today's esthetic surgery, as a kind of business with considerable and further growing returns, is at present the probably most widespread method of human enhancement. Pharmaceuticals enhancing the performance of the mind or preventing tiredness are increasingly used [19]. Extending the physical limits of human capabilities through intensive training in competitive sports can also be understood as enhancement. Making use of *technical means* for improving performance in sport (doping), however, is being practiced as we often can read about in newspapers but is still held to be unsportsmanlike and unethical.

If the types of enhancement just listed apply to individuals (high athletic performance, individual beauty), *collective* human enhancement is, in its turn, also no new topic. Humankind's often deplored defects in terms of morals or civilization led, for example, in the – with regard to morality as well – progress-optimistic European Enlightenment to approaches towards trying to improve humankind *as a whole* through education. Beginning with the individual, above all, in school education, far-reaching processes towards the advancement of human civilization were to be stimulated and supported.

In the twentieth century, the totalitarian regimes in the Soviet Union and in the German Nazi Reich also applied strategies for improvement – due to the respective ideologies, either related to ideas of socio-Darwinist racism and anti-Semitism or to the orthodox communist and anti-bourgeois ideology. These historical developments show that strategies of improvement must be scrutinized very careful with respect to possibly underlying totalitarian ideologies.

In the current discussion of human enhancement, it is neither a question of an improvement through education and culture nor by indoctrination or power, but of *technical* improvement. Initiated by new scientific visions and utopias which are under discussion, completely new possibilities of human development have been proposed. The title of the report of an American research group to the National Science Foundation conveys its program: "Converging Technologies for Improving Human Performance" [17]. Nanotechnology and the Converging (NBIC) Technologies offer, according to this report, far-reaching perspectives for perceiving even the human body and mind as formable, to improve them through precisely targeted technical measures, and, in this manner, also to increase their societal performance. Strategies of enhancement start at the individual level but are aiming, in the last consequence, at the societal level: "Rapid advances in convergent technologies have the potential to enhance both human performance and the nation's productivity. Examples of payoff

will include improving work efficiency and learning, enhancing individual sensory and cognitive capacities, revolutionary changes in healthcare, improving both individual and group efficiency, highly effective communication techniques including brain to brain interaction, perfecting human–machine interfaces including neuromorphic engineering for industrial and personal use, enhancing human capabilities for defense purposes, reaching sustainable development using NBIC tools and ameliorating the physical and cognitive decline that is common to the aging mind" [17, p. 1]. Among these proposed strategies of enhancement are the following:

- *The extension of human sensory faculties:* the capabilities of the human eye can be augmented, for example, with respect to visual acuity ("Eagle Eye") or with regard to a night vision capability by broadening the electromagnetic spectrum visible in the infrared direction; other sensory organs, such as the ear, could likewise be improved, or completely new sensory capabilities, such as the radar sense of bats, could be made accessible to human beings.
- *Expanding memory through technical aids:* it would be conceivable, by means of a chip which could be directly connected to the optic nerve [43], to record all of the visual impressions perceived in real time and to store them externally. In this manner, all of the visual impressions which accumulate in the course of a lifetime could be recalled at any time. In view of our forgetfulness, this could be an attractive idea for many people. Also the human memory could be enhanced by technical means (neuro-cognitive enhancement [19]).
- *Retardation of aging:* according to our present knowledge, aging can, roughly speaking, be interpreted as a form of degradation on the cellular level. If one could succeed in discovering and repairing immediately all forms of such degradation, aging could be greatly delayed or even abolished. For example, the famous nanorobots acting as "submarines" in our bodies could detect and eliminate pathogens: "In the hunt for pathogens, doctors send tiny machines into the furthest recesses of the body. These 'mini-submarines' are so small that they are not visible to the naked eye even as a speck of dust. Rotating cutting devices from the same dwarf world burrow their way through blocked blood vessels to eliminate the causes of heart attacks and strokes" [64, p. 3]. Overcoming aging with the help of nanotechnology would, then, in the sense of medical ethics, be nothing other than fighting epidemics or other diseases.

This thinking aims at broadening human capabilities in comparison with those we traditionally ascribe to a healthy human being. It is obvious that an entire series of ethical or anthropological questions are associated with these visionary expectations (or even just possibilities), which increase the contingency of the *conditio humana* [58, 76]. These questions pertain to the moral *permissibility* or *forbiddenness* of enhancement, to a possible *duty* to enhancement (if such a duty were possible), to the consequences of enhancement with regard to distributive justice (who can afford to have him- or herself enhanced [18]), to the *consequences* for our *concept of humankind* and for the *society of the future*, to the questions of the possible limits of technical enhancement and to legitimizing criteria for drawing such a boundary line. Without any doubt it seems clear that these challenges demarcate a non-standard situation in

moral respect (see Section 8.2) and that, therefore, this is a field where ethical reflection is required in spite of the partially speculative status (see Section 8.3.7).

8.5.2 Occasions of Choice and Need for Orientation

Scientific and technical progress leads to an increase in the options for human action and has therefore at first sight an *emancipatory function*: an augmentation of the possibilities for acting and deciding and a diminution of the conditions which have to be endured as unalterable takes place. Whatever had been inaccessible to human intervention, whatever had to be accepted as non-influenceable nature or as fate becomes an object of technical manipulation or shaping. This is an increase of contingency in the *conditio humana*, a broadening of the spectrum of choices possible among various options [58].

Influencing the faculties of the "healthy" human body in the form of an improvement can be shown to be the *logically consistent continuation of* scientific and technical progress [76]. Up to now the physical capabilities of healthy humans have to be taken as given, as a heritage of the evolution of life. The sensoric capabilities of the eye or the ear, for example, cannot be extended (except by technical means outside the human body, such as microscopes). It would be an act of emancipation from Nature to be able to influence these capabilities intentionally by technical means. New occasions of choice would appear: in which directions would an enhancement be sensible, which additional functions of the human body should be realized, and so on? Also, more individuality could be the result if decisions on specific enhancements could be made at the individual level. In this way, human enhancement seems to contribute further to realizing grand normative ideas of the Era of Enlightenment.

However, there is also another side of the coin. The first price to be paid is the dissolution of established self-evidence about human beings and their "natural" capabilities. The increase of contingency is also an increased need for orientation and decision-making [58]. Second, the outcomes of those decisions about technical improvements can then be attributed to human action and decision – increased accountability and responsibility are the consequence [77]. Third, not only are new options opened but existing ones might be closed. For example, it is rather probable that disabled persons in a society using enhancement technologies to a large extent would have greater problems of conducting their life [20]. Furthermore, problems of access and equity would arise in increasing amount [18]. This ambivalent situation is characteristic of many modern technologies and does not per se legitimize arguments against enhancement but calls for attention and awareness and also for rational debates about dealing with the "dark side" of enhancement technologies.

8.5.3 Human Enhancement – No Simple Answers from Ethics

Increasing humankind's occasions of choice and its emancipation from the givenness of its biological and intellectual constitution also bring about uncertainties, a loss

of security which have been unquestioned up to now and the need for new orientation to answering the above-mentioned general questions, as well as other, more specific questions, for example concerning neuro-implants: "However, ethical dilemmas regarding the enhancement of the human brain and mind are potentially more complex than, for example, genetically enhancing one's growth rate, muscle mass or even appearance because we primarily define and distinguish ourselves as individuals through our behavior and personality" [55]. This diagnosis poses the question of how far humans *may, should, want* to go in the (re-)construction of the human body and mind with the aim of enhancement [18, 74]. In advance of identifying the ethical questions involved, it seems appropriate to highlight an anthropological aspect affected: the difference between healing and enhancement.

Legitimate interventions into the human body and mind are at present carried out with the aims of healing or preventing disease or deficiencies. *Improving* human beings is, as yet, not a legitimate aim of medicine. Although the borderline between healing and enhancing interventions can hardly be drawn unambiguously [74] and although the terms "health" and "illness" are not well clarified [20, 52], there is obviously a categorical difference between the intentional enhancement of human beings and healing disorders [20]. Healing orients itself conceptually on a condition of health held to be ideal. This can either be explicitly defined or merely implicitly understood – in both cases, healing means closing the gap between the actual condition and the assumed ideal condition. What is to be understood under the ideal condition has certainly been defined culturally in different manners in the course of history. In each individual case, however, this is, at least in context, obvious enough. The ophthalmologist who subjects his patient to an eye-test has a conception of what the human eye should be able to perceive. He or she will propose technical improvements of the current state (e.g. a pair of spectacles) only for deviations from this conception and only from a certain degree of deviation on. The purpose of such measures is restoring the normal state, which succeed may more or less well. Traditional medical practice is probably unimaginable without the manner of thinking that a normal or ideal state serves in the background as a normative criterion for defining deviation. Medical treatment does not extend beyond this normal or ideal state. Just this – for medical practice, essential – way of thinking would, in view of the possible technical improvement of human beings, probably become meaningless. A situation would develop where normative frameworks for technical interventions into the human body and mind would be needed but will not be available because this is a completely new situation in moral respects. This poses the question of how far humans *may, should, want* to go in the (re-)construction of the human body and mind with the aim of improving them.

Ethical issues raised by this situation have been characterized with regard to neuro-cognitive enhancement [19]. This classification can be extended to other forms of enhancement also:

- *Safety:* risks of enhancement might consist of unintended side-effects for the brain of the person to be enhanced (e.g., by unsuccessful technical interventions or in the long term).

- *Coercion:* the use of enhancement technologies by parts of the population might exert force on others also to enhance themselves. Otherwise disadvantages in professional or private life might be the consequence.
- *Distributive justice:* access to enhancement technologies might be distributed over the population or between different regions of the world in a very inequitable way, for example because of high costs of enhancement ([18]; for the topic of equity in general, see Section 8.3.2).
- *Personhood and intangible values:* the way in which we see ourselves as humans and our imagination of a "good life" could be changed.

First we have to draw our attention to the fact that the spontaneous rejection with which the concept of human enhancement is often confronted in the population is, in itself, no ethical argument *per se*. The fact that we are not accustomed to dealing with the enhancement issue and the cultural alien-ness of the idea of technically enhanced human beings are social facts and are quite understandable – but they have only limited argumentative force as such. Spontaneous rejection might occur only because of feeling uncomfortable and unfamiliar in thinking about technical enhancement and could be changed by getting more familiar with it. Therefore, feeling and intuition are factual but still have to be scrutinized for whether there are ethical arguments hidden behind them at all and how strong these arguments would be.

The often-mentioned assertion that a human being's "naturalness" would be endangered or even be eliminated by technical improvement is also no strong argument *per se*. Humankind's naturalness or culturality are competing and partially linked patterns of interpretation of the human condition. Using humankind's naturalness as an argument in the sense that we should not technically improve the evolutionarily acquired faculties of sight, hearing, thinking, and so on, just because they are naturally developed and evolutionarily adapted, would be a naive naturalistic fallacy: out of the fact that we find ourselves to be human beings, for instance, with eyes which function only within a certain segment of the electromagnetic spectrum, nothing follows – normatively –directly at all. Limiting human capabilities to the naturally given properties would reduce humans to museum pieces and would blind out the cultural aspects of being humans, to which also belongs transcending the status quo, that is thinking beyond what is given, as has been the thesis of many writers on philosophical anthropology such as Arnold Gehlen.

From these considerations it cannot be concluded that human enhancement is permitted or even imperative. It merely follows that one should not make it too easy on oneself with an ethical repudiation. Strong imperative arguments are, in fact, not in sight [18]. However, argumentatively, the repudiation front also is not very strong. It points to a great extent to the *consequences* of enhancement – consequences which, like the fears of an increasing separation of society [18], are, to a great extent, hypothetical and which can therefore provide only very general and provisional orientation. In the final analysis, the ethical debate seems to narrow itself down to single-case argumentation: which concrete improvement is meant, which goals and

purposes are connected with it, which side-effects and risks are to be apprehended and the question of weighing up these aspects against the background of ethical theories, such as Kantianism or utilitarianism. *Universally* applicable verdicts such as a strong imperative duty or a clear rejection of any improvement whatsoever seem at present to be scarcely justifiable. What follows from this situation for the future is the responsibility to reflect on the *criteria* for the desirability or acceptability of concrete possibilities for enhancement. A lot of work is still in front of ethics [75, 78].

Recently, it has been proposed to structure the field of possible ethical standpoints and perspectives with regard to enhancement technologies ([79, p. 9], applied to cognitive enhancement, but the scheme seems to be more generally usable) in the following, instructive way:

- *Laissez-faire* – emphasizes freedom of individuals to seek and employ enhancement technologies based on their own judgment.
- *Managed technological optimism* – believes that although these technologies promise great benefits, such benefits cannot emerge without an active government role.
- *Managed technological skepticism* – views that the quality of life arises more out of society's institutions than its technologies.
- *Human essentialism* – starts with the notion of human essence (whether God-given or evolutionary in origin) that should not be modified.

The decision to take one of these perspectives and to work with it in conceptualizing future developments in this field depend on the assessment of the strength of ethical arguments pro and con and also on images of "human nature".

8.5.4 Enhancement Technologies – A Marketplace Scenario Ahead?

What would follow from the description of the current debate given above? In order to give an answer we should take a brief look at the field of human cloning, which is not a technical enhancement of humans but would be a deep technical intervention into human life. Human cloning is regarded against the background of many ethical positions, for example Kantian ethics [74] as a form of instrumentalization of humans. The genetic disposition of an individual would be intentionally fixed by cloning. The persons affected would not be able to give their agreement to be cloned in advance. Cloning means an intentional and external determination of the genome of a later individual. An "informed consent", the information of the affected person about the cloning process and its impacts as well as the agreement of that person, would not be possible because the cloning has to be done at the early embryo phase. Therefore, human (reproductive) cloning and research to this end were banned in many countries soon after the clone sheep "Dolly" had been presented.

The ethical debate about human enhancement is, so far, completely different from the debate about human cloning. A restrictive regulation for human enhancement technologies and the research which could enable it, similar to the ban on human cloning technologies, has not been postulated yet. What makes the difference in debating about regulation while the intuitive and spontaneous public reactions are

similar in both fields? The thesis is that the situation in ethical respect itself is completely different.

In the debate on human cloning, there is a strong ethical argument which motivated severe concern. The postulate of human dignity implies, in many interpretations, the idea that humans must not be instrumentalized without their consent. But cloning means determining *intentionally* the genome of an individual without any chance of consent in advance. In contradiction to the usual fertilization, which includes a high degree of statistical influence, cloning would double or multiply a well-known genome. This would imply a determination of the developing persons without any chance of reversibility [74, 80, 81]. This point seems to be the ethical reason behind the strong regulatory measures which have been taken extremely quickly.

In the field of human enhancement, however, things are completely different in this respect. Human enhancement in the fields mostly mentioned [1] would be applied to adults. Additional or improved sensory capabilities, for example, would be implemented in the same way as other medical procedures today: the candidates would be informed about the operational approach, about costs, about the process of adapting the new features, as well as about possible risks and side-effects. After having received such information, the enhancement candidates would either leave the "enhancement station" (in order not to use the term "hospital") or would sign a letter of agreement and, thereby, would give their "informed consent".

Ethical argumentation, therefore, will be performed by using different types of arguments. The arguments given so far are mostly concerned with possible *impacts* of technical enhancement. Expectable problems of distributive justice and equity are often mentioned [18, 50, 75]. Such argumentations, however, work with highly uncertain knowledge about future impacts of enhancement technologies. As can be learned from the history of technology assessment, it is very difficult to assess the consequences of completely new technologies where no or only little experience would be available as a basis for projections. In such cases, normative biases, pure imagination and ideology are difficult to separate from what could be derived from scientific knowledge. Often, an argument can be countered by a contradicting argument – for example, in the case of coercion mentioned above: "The straightforward legislative approach of outlawing or restricting the use of neurocognitive enhancement in the workplace or school is itself also coercive. It denies people the freedom to practice a safe means of self-improvement, just to eliminate any negative consequences of the (freely taken) choice not to enhance" [19, p. 423]. Another example would be the problem of equity: "Unequal access is generally not grounds for prohibiting neurocognitive enhancement, any more than it is grounds for prohibiting other types of enhancement, such as private tutoring or cosmetic surgery . . . . In comparison with other forms of enhancement that contribute to gaps in socioeconomic achievement, from good nutrition to high-quality schools, neuro-cognitive enhancement could prove easier to distribute equitably" [19, p. 423]. Or take arguments which make use of a possible change of the personhood of people by enhancement: "And if we are not the same person on Ritalin as off, neither we are the same person after a glass of wine as before or on vacation as before an exam"

19, p. 424]. Therefore, ethical analysis building on such highly uncertain assumptions about possible impacts could only constitute weak ethical arguments, pro enhancement as well as contra.

In this situation, it is rather probable that the introduction of enhancement technologies could happen according to the *economic market model*. Enhancement technologies would be researched, developed and offered by science and transferred to the marketplace. History shows (see Section 8.5.1) that a demand for such enhancement technologies is imaginable, as is currently the case in the field of esthetic surgery. Public interest would be restricted to possible situations of market failure. Such situations would be of the types discussed above: problems of equity, prevention of risks, questions of liability or avoidance of misuse. This scenario could be perceived as defensive with respect to current ethical standards, as cynical or as poor in ethical respects. Many people might feel uneasy about it. However, at the moment, such a scenario would fit the state of ethical analysis of technical enhancement of the human body and mind.

Such a scenario, however, has not to be equivalent to a *laissez-faire* model of the use of enhancement technologies [79; see the quotation at the end of Section 5.3]. Also, a marketplace scenario would have to be embedded in a societal environment, consisting of normative frameworks [15], ethical standards and regulation. To clarify the ethical issues involved in enhancement technologies and their relations to social values and to regulation is, to a large extent, still a task ahead.

8.6
Conceptual and Methodical Challenges

It is a characteristic trait of modern societies that they draw the orientation needed for opinion formation and decision-making increasingly from debates about future developments and less and less from existing traditions and values [77, 82]. Modern secular and scienticized society generally orients itself, instead of on the past, more on wishes and hopes, but also on fears with regard to the future. The notion of a "risk society" [77] and the global movement towards sustainable development [25] are examples of this approach. Ethical reflection, therefore, has to be related to communication about those future prospects. The necessity of providing orientation in questions such as human enhancement leads to the methodical challenge of applying the "moral point of view" on non-existing but only *projected* ideas with their own uncertainties and ambiguities.

8.6.1
Ethical Assessments of Uncertain Futures

Ethical analysis on nanotech issues is to a large extent confronted with the necessity to deal with, in part far-reaching, future projections [58, 76]. Ethical inquiry in fields such as artificial life or human enhancement takes elements of future communication like visions as its subject. Providing orientation then means to analyze, assess

and judge those far-reaching future prospects on the basis of today's knowledge and seen from the today's moral point of view.

Frequently, the "futures" used in the debate on nanotech and society differ to a large extent and, sometimes, waver between expectations of paradise and fears of apocalyptic catastrophes. Expectations which regard nanotech as the anticipated solution of all of humanity's problems standing in Drexler's [53] technology-optimistic tradition contrast radically with fears expressed in the technology-skeptical tradition of Joy's [83] line of argumentation where self-reproducing nanorobots are no longer simply a vision which is supposed to contribute to the solution of humanity's gravest problems [53], but are communicated in public partially as a nightmare. The visionary pathos in many technical utopias is extremely vulnerable to the simple question of whether everything could not just be completely different – and it is as good as certain that this question will also be asked in an open society. But as soon as it is posed, the hoped effect of futuristic visions evaporates and can even turn into its opposite [1, Section 5.3].

The general problem is that the spectrum of proposed future projections often seems to be rather arbitrary, for example between expectations of paradise and apocalypse, warning against catastrophes in completely diverging directions. One example will be given: the uncertainty of our knowledge about future developments of nanotechnology and its consequences in connection with the immense imagined potential for damage, of possibly catastrophic effects, are taken as an occasion for categorizing even the precautionary principle (see Section 8.4) as insufficient for handling these far-reaching future questions [61, 62]. Instead, the author's view of society's future with nanotechnology leaves open solely the *existential renunciation* of nanotechnology as the only solution, going beyond even Hans Jonas' *Imperative of Responsibility* [60], inasmuch as they formulate a "duty to expect the catastrophe" in order to prevent the catastrophe (an analysis of the inherent contradictory structure of this argument is included in [76]). It seems interesting that the argumentative opponents, the protagonists of human enhancement by converging technologies, also warn against catastrophes, but only in the opposite sense: "If we fail to chart the direction of change boldly, we may become the victims of unpredictable catastrophe" [17, p. 3]. If, however, the ultimate catastrophe is cited in both directions as a threat, this leads to an arbitrariness of the conclusions. Ethics, therefore, is confronted not only with problems of judging states or developments by applying well-justified moral criteria but also with the necessity to assess the "futures" used in these debate with respect to their "rationality".

This situation leads to new methodical challenges for ethical inquiry. Especially the uncertainty of the knowledge available standing behind the future prospects makes it difficult to assess whether a specific development at the human–machine interface or concerning the technical improvement of the human body should be regarded as science fiction (SF), as technical potential in a far future, as a somewhat realistic scenario or as probably becoming part of reality in the near future. Ethical analysis has to take into account this uncertainty and has to be combined with an "epistemology" of future projections [76] and with new types of a future knowledge assessment [84]. In the following, we will propose an "Ethical

Vision Assessment" and an "Ethical Foresight Approach" which would be parts of a concomitant ethical reflection parallel to the ongoing scientific advance, in close relation to that advance but also in a distance which allows independent assessments and judgments.

8.6.2 Ethical Vision Assessment

Far-reaching visions have been put forward in the nanotech debate since its very beginning. A new paradise has been announced since the days of Eric Drexler's book *Engines of Creation* [53]. This line of story-telling about nanotech has been continued in the debate on human enhancement by converging technologies: "People will possess entirely new capabilities for relations with each other, with machines and with the institutions of civilization. ... Perhaps wholly new ethical principles will govern in areas of radical technological advance, such as the routine acceptance of brain implants, political rights for robots and the ambiguity of death in an era when people upload aspects of their personalities to the Solar System Wide Web" [17, p. 19]. It might seem that such speculations should not or could not be subject to ethical inquiry at all.

Because of the "power of visions" in the societal debates – for examples for research funding, motivating young scientists and for public acceptance – it is of great importance to scrutinize such visions carefully instead of denoting them as obscure and fantastic. In spite of the "futuristic" and speculative nature of those visions (see [85] for the notion of "futuristic visions" and [76] and [1] for first steps toward an epistemological analysis of future knowledge), an early ethical dealing with nanotech visions would be an important and highly relevant task in order to allow more transparent debate, especially about science's agenda [1, 71]. There is a need to make those visions more specific, to extract their epistemic and normative key assumptions and ideas and to relate them to other key issues in public debate. Visions in nanotechnology are very different in nature and often refer to more general ideas, such as [49]

- the notion of free and curiosity-driven research as justification and paradigm in itself;
- the Enlightenment ideology of human-centered and emancipatory progress;
- a transhumanist dogma driving forward human evolution by physically changing humans and transforming them into technology;
- the aims and emphases of different religious belief systems including different ideas about the "quality of life";
- the promotion of global development, health and sustainable development, partially following goals of environmentalism, movements for social justice or particular campaign groups in the framework of the civil society;
- a neo-liberal winner-takes-all capitalist system;
- compassion, motivated by the desire to alleviate human suffering;
- a "medical success" culture driven by the felt obligation or goal to leave no disease or condition without a technical solution and to correct every physical disadvantage.

Scrutiny of nanotech visions could be done in the framework of an "ethical vision assessment" [1, Section 8.6]. Vision assessment can be analytically divided in several steps which are not sharply separated and not linearly ordered but which serve different sub-objectives and involve different methods [85]:

1. With respect to analysis (*Vision Analysis*), it would be a question of disclosing the *cognitive and normative* contents of the visions and of judging epistemologically the extent of their reality and practicability, self-evidently on the basis of current knowledge. Then, an important aspect, the prerequisites for the visions' realizability and the time spans involved would have to be investigated. In both analytical steps, observing the language used on the one hand and the question of the antecedents of the predictive statements play a special role: " ... the nanoethics researcher must be attentive to the twists and turns of language which can be symptoms bringing light to the most hidden layers of the scientific or technological imagination" [61]. Further, the visions' *normative* contents have to be reconstructed analytically: the visions of a future society or of the development of human beings, as well as possible diagnoses of current problems, to the solution of which the visionary innovations are supposed to contribute. For a "rational" discussion, the transparent disclosure of the stocks of knowledge, uncertainties and values involved is necessary, above all, with regard to the relationship of fact to fiction [86]. The contribution of such reflective analyses could consist in this respect in the "clarification" of the pertinent communication: the partners in communication should know explicitly what they are talking about as a prerequisite for more rational communication. It is a matter of society's "self-enlightenment" and of supporting the appropriate learning processes.

2. Vision Assessment would, further, include evaluative elements (*Vision Evaluation*). These are questions of how the cognitive aspects are to be categorized, how they can be judged according to the degree of realization or realizability, according to plausibility and evidence and which status the normative aspects have, for example relative to established systems of values or to ethical standards. The purpose is the transparent disclosure of the relationship between knowledge and values, between knowledge and the lack of it and the evaluation of these relationships and their implications. On the one hand, one can draw upon the established evaluation methods of technology assessment, which often include a participative component [13, 72]. On the other, in the field of human enhancement there are some far-reaching questions in a normative respect which stand to discussion and which require ethical and philosophical reflection (see Section 8.5 and [18, 73, 74]).

3. Finally, it is a matter of deciding and acting (*Vision Management*). The question is how the public, the media, politics and science can be advised with regard to a "rational" use of visions. The question of alternatives, either already existing or to be developed, to the visions already in circulation, stands here in the center of interest, in accordance with the basic position of technology assessment, of always thinking in terms of alternatives and options. In this manner, visions

based on technology can be compared with one another or with non-technological visions.

In particular, it would be the assignment of Vision Assessment in an ethical respect to confront the various and, in part, completely divergent normative aspects of the visions of the future directly with one another. This can, on the one hand, be done by ethical analysis and desk research; on the other, however, the representatives of the various positions should discuss their differing judgments in workshops directly with and against one another, in order to lay open their respective premises and assumptions (e.g., using technology assessment procedures [72]).

8.6.3 Ethical Reflection in Technology Foresight

In the last consequence, it would be necessary to transform the future prospects of nanotech visionarists [17] into more negotiable and communicable, transparent scenarios of the future. This could be realized by using the toolbox of (technology) foresight [87]. According to the above-mentioned ideas and challenges, ethical reflection of far-ranging future visions should be combined with research on and procedures for making the various future prospects more transparent. A close relation between an epistemology of future knowledge [84] ethical deliberation emerges. This situation motivates having a brief look into the field of "technology foresight" which has been developed in the last 10 years, especially at the European level [87]. It seems to be possible to benefit from experiences which have been made there in dealing with different kinds of future knowledge and assessments concerning the agenda-setting processes. In particular, it adds to the previously mentioned dimensions of epistemology and ethics possibilities for public debate and involving actors other than researchers and philosophers.

Foresight is the process of looking systematically into the longer-term future of science, technology, the economy and society with the aim of identifying the areas of strategic research (agenda setting) and the emerging generic technologies likely to yield the greatest economic and social benefits at low risk [87]. As the term implies, these approaches involve thinking about emerging opportunities and challenges, trends and breaks from trends, future risks and ways of dealing with them, and so on. Foresight involves bringing together key actors of change and sources of knowledge, in order to develop *strategic visions* and to establish networks of knowledgeable actors who can respond better to policy challenges in awareness of each others' knowledge resources, values, interests and strategic orientations. The contexts in which foresight can be employed are equally wide-ranging: much work to date has focused on national competitiveness and especially the prioritization and development of strategic goals for areas of research in science and technology. Foresight thus occupies the space in which planning, future studies, technology assessment, strategic deliberation and policy development overlap. It is not a matter of academic- or consultancy-based forecasts of the future (though it has to take these into account as necessary knowledge grounds).

As can easily be seen, there are some similarities to the situation described above in the field of nanotech: far-reaching visions and expectations, uncertainty of knowledge, diverse positions of different actors and the aim at influencing agenda setting. Obviously, there are also differences: usually, in foresight processes ethical reflection is not part of the game whereas regional cooperation, creation of new networks, mobilization and contributing to economic welfare by exploiting chances of new technologies and of regional resources are major issues. The reason for bringing the more philosophical issue of assessing and reflecting nanotech visions with respect to epistemological and ethical questions with established foresight methodologies lies in the common challenge of being confronted with the necessity to deal "rationally" with highly uncertain future knowledge and the inseparably interwoven normative elements of expectations, desires and fears often involved. Giving advice to the scientific agenda, for example via contributing to the processes of defining issues and priorities of the public funding of science and technology, following an open and democratic debate, is, therefore, difficult to achieve.

In various foresight exercises, it has been a common experience that in order to arrive at a workable view on the future in the respective field it is crucial to focus on a concrete and tangible topic. Compared with this experience, it seems impossible to apply a foresight exercise to such a broad and grand topic like nanotechnology. On the contrary, more specific subtopics should be addressed such as the use of nanoparticles in cosmetics, developments towards artificial life or opportunities or threats concerning the equity of access to nanotech benefits. Then it is imaginable to set up a foresight process which would

- include research and reflection parts as the vision assessment activities described above;
- involve other societal groups (stakeholders, customers, policymakers, regulators, business people, etc.);
- provide a balanced and ethically as well as epistemologically reflected view on the respective part of the nanotech field which then could be used as a valuable input for debates about science's agenda in this field.

The task of such a foresight exercise would consist, first, of a "rationalization" of diffuse future prospects in a double manner: rationalization concerning the epistemic contents as well as concerning the normative aspects involved. Second, the resulting images of the future should be communicated to and debated with a broader audience in society. In this way, there could be a success in transforming the rather diffuse visionary prospects of nanotechnology into more specific scenarios in specific areas, for instance of the human–machine interface.

8.6.4 Concomitant Ethical Reflection on Nanotechnology

Since the very beginning of ethical reflection in science and technology, there has been an ongoing discussion about an adequate relation in time between scientific–technological advances and ethics. Ethics often seems to pant helplessly behind

technical progress and to fall short of the occasionally great expectations [88]. The rapid pace of innovation in technicization has the effect that ethical deliberations often come too late: when all of the relevant decisions have already been made, when it is long since too late for shaping technology. Technological and scientific progress sets facts which, normatively, can no longer be revised [74]: "It is a familiar cliché that ethics does not keep pace with technology" [38]. This "ethics last" model means that first there have to be concrete technological developments, products and systems which then could be reflected by ethics. Ethics in this perspective, could, at best, act as a repair service for problems which are already on the table.

In contrast, the "ethics first" model postulates comprehensive ethical reflection on possible impacts already *in advance* of technological developments. Ethics actually can provide orientation in the early phases of innovation, for example because future projections and visions emerging on the grounds of scientific and technical advances may be subject to ethical inquiry. Because there are early ideas available about the scientific and technical knowledge and capabilities as well as about their societal impacts – risks as well as chances – long before market entry, it is possible to reflect and discuss their normative implications. For example, Jonas worked on ethical aspects of human cloning long before cloning technology was available even in the field of animals. Obviously, ethical reflection in this model has to deal with the situation that the knowledge about technology and its consequences is uncertain and preliminary.

This does not necessarily mean that ethical deliberations have to be made for absolutely every scientific or technical idea. The problems of a timely occupation with new technologies appear most vividly in the diverse questions raised by the visions of salvation and horror as regards nanotechnology and human enhancement. What sense is there in concerning oneself hypothetically with the ethical aspects of an extreme lengthening of the human life span or with self-replicating nanorobots [38]? The "ethics first" perspective is exaggerated in these cases to such an extent that any relevance will be lost. Most scientists are of the opinion that these are speculations which stem much rather from the realm of science fiction than from problem analysis which is to be taken seriously: "If discussions about the ethics and dangers of nanotechnology become fixated on a worry that exists only in science fiction, we have a serious problem" [89]. We should not forget that ethical reflection binds resources and there should therefore be certain evidence for the "validity" of these visions, if resources are to be invested in them which could then be lacking elsewhere. Therefore, methods of assessing visions of human enhancement are required which allow for an epistemological investigation of the visions under consideration (see the sections above).

Ethical judgment in very early stages of development could provide orientation for shaping the *process* of scientific advance and technological development (e.g., with regard to questions of equity or of risks of misuse). In the course of the continuing concretization of the possibilities for application of nanotechnologies, it is then possible continuously to concretize the – at first abstract – estimations and orientations on the basis of newly acquired knowledge and finally to carry out an ethically reflected technology assessment. In this way, ethical analysis is an ongoing process, accompanying the scientific and technological advance.

Due to nanotechnology's and the converging technologies' early stage of development, we have here a rare case of an advantageous opportunity: there is the chance and also the time for concomitant reflection, as well as the opportunity to integrate the results of reflection into scientific agenda and technology design and thereby to contribute to the further development of science and technology [38]. In view of the visionary nature of many the prospects in nanotechnology and of long and longer spans of time within which the realization of certain milestones can be expected, there is, in all probability, enough time to analyze the questions posed. In general, it applies in this case that this reflective discussion should take place already in the early phases of development, because then the greatest possibilities for influencing the process of scientific development are given. The chances are good that, in the field of nanotechnology, ethical reflection and the societal discussion do not come too late, but can accompany scientific–technical progress critically and can, in particular, help to influence science's agenda by ethically reflected advice.

9
Outlook and Consequences

Günter Schmid

"Nanotechnology could become the most influential force to take hold of the technology industry since the rise of the Internet. Nanotechnology could increase the speed of memory chips, remove pollution particles in water and air and find cancer cells quicker. Nanotechnology could prove beyond our control and spell the end of our very existence as human beings. Nanotechnology could alleviate world hunger, clean the environment, cure cancer, guarantee biblical life spans or concoct super weapons of untold horror .... Nanotechnology could spur economic development through spin-offs of the research. Nanotechnology could harm the opportunities of the poor in developing countries .... Nanotechnology could change the world from the bottom up. Nanotechnology could become an instrument of terrorism. Nanotechnology could lead to the next industrial revolution .... Nanotechnology could change everything."

This only incompletely cited collection of meaningful as well as senseless predictions is listed in a brochure on "The Ethics and Politics of Nanotechnology" by UNESCO published in 2006 [1]. It impressively demonstrates how the understanding of nanotechnology depends from the observer's individual opinion, the spreading medium or from the different political trends. Depending on the respective author's personal attitude, hopes are raised or catastrophes are predicted.

In spite of the variations of the definition of nanotechnology (see Chapters 1 and 2), from a scientific point of view, strictly observed in this and the other books in this series, we must refrain from unserious promises, but also from scenarios drawing the decline of mankind. Both belong to the field of science fiction and are not based on scientific findings. Indeed, there are enough scientifically substantiated facts making nanotechnology one of the most influential technologies we have ever had, in agreement with the very first of the UNESCO headlines cited above. This can be followed from the few examples given in Sections 2.2.1–2.2.7 in Chapter 2, but even more from the following volumes that deal with information technology, medicine, energy and instrumentation on the nanoscale, making observations in the nanoworld possible. Without entering science fiction fields, our present knowledge in nanoscience allows the prognosis that nano-based data storage systems will offer

Nanotechnology. Volume 1: Principles and Fundamentals. Edited by Günter Schmid

ISBN: 978-3-527-31732-5

capacities to store the whole of the world's literature on a single chip and to construct notebooks with the capacity of a computer center of today. Low-priced solar cells, moldable accumulators of high capacities, highly efficient fuel cells and hydrogen storage systems will become available. Last but not least, progress to be expected in medical diagnosis and therapy will revolutionize health care, beginning with enduringly working drug delivery systems, diagnostic potentials, improved by orders of magnitude, up to individual cancer therapies, based on the personal genome of a patient.

These few examples indeed demonstrate the innovative power of nanoscience and -technology. On the other hand, we should not close our eyes to possible dangers linked with the expansion of nanotechnology. From experiences in the past, for instance in the cases of nuclear energy and genetically modified organisms, we should avoid similar mistakes in the case of nanotechnology. Especially scientists are asked to contribute to an objective discussion in public, free of ideologies and pre-opinions.

An indispensable condition to discuss chances and risks of nanotechnology, free from any prejudice, is a minimum knowledge about nanotechnology by the public. This is not easy to achieve, due to the very complex nature of nanotechnology extending from physics to the life sciences. Therefore, education processes have to start as early as possible in primary and secondary schools, in colleges and universities. This is especially necessary in order to protect people from wrong prophets, in a positive as well as in a negative sense. There is no doubt that nanotechnology will change our lives, but it depends on us what this change will look like.

1
Pollution Prevention and Treatment Using Nanotechnology

Bernd Nowack

1.1
Introduction

Environmental nanotechnology is considered to play a key role in the shaping of current environmental engineering and science. Looking at the nanoscale has stimulated the development and use of novel and cost-effective technologies for remediation, pollution detection, catalysis and others [1]. However, there is also a wide debate about the safety of nanoparticles and their potential impact on environment and biota [2, 3], not only among scientists but also the public [4, 5]. Especially the new field of nanotoxicology has received a lot of attention in recent years [6, 7]. Nanotechnology and the environment – is it therefore a Janus-faced relationship? There is the huge hope that nanotechnological applications and products will lead to a cleaner and healthier environment [8]. Maintaining and re-improving the quality of water, air and soil, so that the Earth will be able to support human and other life sustainably, are one of the great challenges of our time. The scarcity of water, in terms of both quantity and quality, poses a significant threat to the well-being of people, especially in developing countries. Great hope is placed on the role that nanotechnology can play in providing clean water to these countries in an efficient and cheap way [9]. On the other hand, the discussion about the potential adverse effects of nanoparticles has increased steadily in recent years and is a top priority in agencies all over the world [10, 11]. Figure 1.1 shows the hits for a search for "risk" related to nanotechnology in the Web of Science. Publications that deal in one way or other with "risk" have skyrocketed in the last few years since 2002.

The same properties that can be deleterious for the environment can be advantageous for technical applications and are exploited for treatment and remediation. Figure 1.2 shows a few examples of this Janus face of nanotechnology: engineered particles with high mobility are needed for efficient groundwater remediation, but at the same time this property will render a particle more difficult to remove during water treatment. The toxicity of some nanoparticles can be used for water disinfection where killing of microorganisms is intended, whereas the same property is unwanted

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

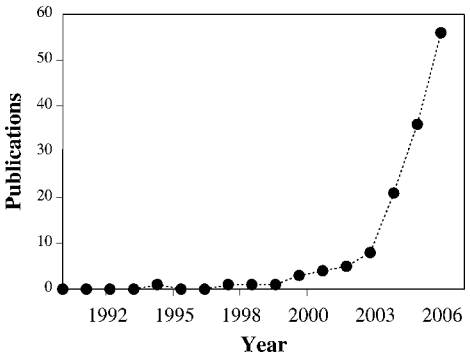

Figure 1.1 Hits in the Web of Science for the search terms "(nanotechnol* OR nanopart* OR nanotub*) AND risk" for the years 1990–2006.

when nanoparticles eventually enter the environment. The catalytic activity of a nanoparticle can be advantageous when used for the degradation of pollutants, but can induce a toxic response when taken up by a cell. The high sorption capacity of certain nanoparticles is exploited for the removal of organic and inorganic pollutants while this property may also mobilize sequestered pollutants in the environment. The engineering of nanoparticles that are easily taken up by cells will have a huge impact on medicine and pharmacological research, but the dispersion of such particles in the environment can lead to unwanted and unexpected effects. Also the

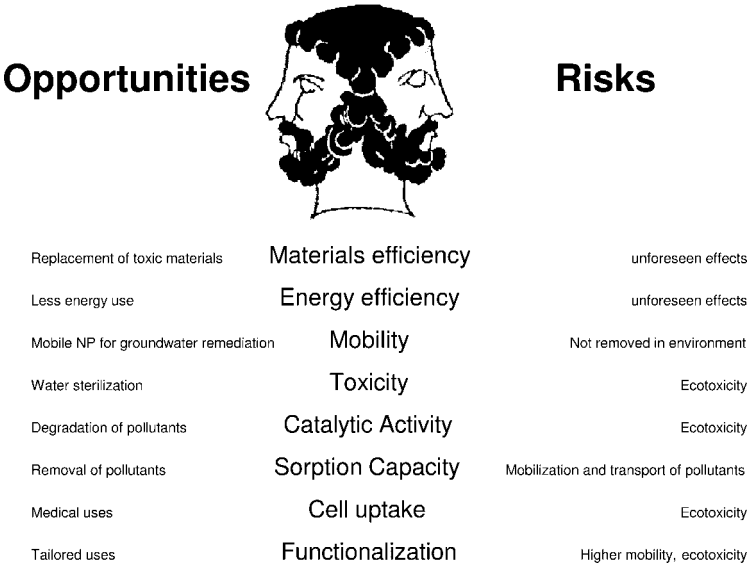

Figure 1.2 The Janus face of nanotechnology.

fact that many engineered nanoparticles are functionalized and therefore have a different surface activity from pristine particles is pivotal for many applications where a tailored property is needed, but such particles may behave in a completely different way from standard particles in the environment and may, for example, be much more mobile or show an increased (or decreased, as the case may be) toxicity. This short list of properties exemplifies the fact that engineered nanoparticles or nanotechnological applications make use of the same properties that are looked for by environmental scientists.

This chapter will give a general overview of potential environmental applications of nanotechnology and nanoparticles and will also give a short overview of the current knowledge about possible risks for the environment.

1.2 More Efficient Resource and Energy Consumption

Pollution prevention by nanotechnology refers on the one hand to a reduction in the use of raw materials, water or other resources and the elimination or reduction of waste and on the other hand to more efficient use of energy or involvement in energy production [1]. The implementation of green chemistry principles for the production of nanoparticles and for nanotechnological applications in standard chemical engineering will lead to a great reduction in waste generation, less hazardous chemical syntheses, improved catalysis and finally an inherently safer chemistry [12]. However, there are very few data that actually show quantitatively that these claims are true and that replacing traditional materials with nanoparticles really does result in less energy and materials consumption and that unwanted or unanticipated side effects do not occur.

Nanomaterials can be substituted for conventional materials that require more raw material, are more energy intensive to produce or are known to be environmentally harmful [8]. Some new nanocatalysts can be used at much lower temperatures than conventional catalysts and therefore require less energy input [13]. The capacity of nanocatalysts to function at room temperature opens the way for broad applications of nanomaterials in many consumer products. Another example of how nanotechnology can reduce energy costs is nanomaterial coatings on ships, which are expected to realize fuel savings on the order of $460 million per year for commercial shipping in the USA [13]. Nanodiamonds are expected to increase the life expectancy of automotive paints and therefore to reduce material costs and expenditure [14]. Nanotechnology may also transform energy production and storage by providing alternatives to current practices. One example is nanoparticulate catalysts for fossil fuels [15], which will lead to reduced emissions or better energy efficiency, higher storage capacity for hydrogen [16, 17], biohydrogen production [18] and more effective and cheaper solar cells or coatings on windows that reduce heat loss [19]. Nanoparticles can increase the storage capacity of batteries and rechargeable batteries [20–22] or are used in flat screens where they reduce the amount of heavy metals [8].

1.3 Pollution Detection and Sensing

Various nanostructured materials have been explored for their use in sensors for the detection of different compounds [23]. An example is silver nanoparticle array membranes that can be used as flow-through Raman scattering sensors for water quality monitoring [24]. The particular properties of carbon nanotubes (CNTs) make them very attractive for the fabrication of nanoscale chemical sensors and especially for electrochemical sensors [25–28]. A majority of sensors described so far use CNTs as a building block. Upon exposure to gases such as NO_2, NH_3 or O_3, the electrical resistance of CNTs changes dramatically, induced by charge transfer with the gas molecules or due to physical adsorption [29, 30]. The possibility of a bottom-up approach makes the fabrication compatible with silicon microfabrication processes [31]. The connection of CNTs with enzymes establishes a fast electron transfer from the active site of the enzyme through the CNT to an electrode, in many cases enhancing the electrochemical activity of the biomolecules [27]. In order to take advantage of the properties of CNTs, they need to be properly functionalized and immobilized. CNT sensors have been developed for glucose, ethanol, sulfide and sequence-specific DNA analysis [27]. Trace analysis of organic compounds, e.g. for the drug fluphenazine, has also been reported [32]. Nanoimmunomagnetic labeling using magnetic nanoparticles coated with antibodies specific to a target bacterium have been shown to be useful for the rapid detection of bacteria in complex matrices [33].

1.4 Water Treatment

Clean water is a requirement for all properly functioning societies worldwide, but is often limited. New approaches are continually being examined to supplement traditional water treatment methods. These need to be lower in cost and more effective than current techniques for the removal of contaminants from water. In this context also nanotechnological approaches are considered. In this section the following application areas will be covered: nanoparticles used as potent adsorbents, in some cases combined with magnetic particles to ease particle separation; nanoparticles used as catalysts for chemical or photochemical destruction of contaminants; nanosized zerovalent iron used for the removal of metals and organic compounds from water; and nanofiltration membranes.

1.4.1 Adsorption of Pollutants

Sorbents are widely used in water treatment and purification to remove organic and inorganic contaminants. Examples are activated carbon and ion-exchange resins. The use of nanoparticles may have advantages over conventional materials due to

the much larger surface area of nanoparticles on a mass basis. In addition, the unique structure and electronic properties of some nanoparticles can make them especially powerful adsorbents. Many materials have properties that are dependent on size [34]. Hematite particles with a diameter of 7 nm, for example, adsorbed Cu ions at lower pH values than particles of 25 or 88 nm diameter, indicating the uniqueness of surface reactivity for iron oxides particles with decreasing diameter [35]. However, another study found that normalized to the surface area the nanoparticles had a lower adsorption capacity than bulk TiO_2 [36]. Several types of nanoparticles have been investigated as adsorbents: metal-containing particles, mainly oxides, carbon nanotubes and fullerenes, organic nanomaterials and zeolites.

For the removal of metals and other inorganic ions, mainly nanosized metal oxides [37, 38] but also natural nanosized clays [39] have been investigated. Also, oxidized and hydroxylated CNTs are good adsorbers for metals. This has been found for various metals such as Cu [40], Ni [41, 42], Cd [43, 44] and Pb [45, 46]. Adsorption of organometallic compounds on pristine multi-walled CNTs was found to be stronger than for carbon black [47].

Chemically modified nanomaterials have also attracted a lot of attention, especially nanoporous materials dues to their exceptionally high surface area [48]. The particle size of such materials is, however, not in the nano-range but normally 10–100 μm. Another option is to modify chemically the nanoparticle itself [49]. TiO_2 functionalized with ethylenediamine was, for example, tested for its ability to remove anionic metals from groundwater [50].

CNTs have attracted a lot of attention as very powerful adsorbents for a wide variety of organic compounds from water. Examples include dioxin [51], polynuclear aromatic hydrocarbons (PAHs) [52–54], DDT and its metabolites [55], PBDEs [56], chlorobenzenes and chlorophenols [57, 58], trihalomethanes [59, 60], bisphenol A and nonylphenol [61], phthalate esters [62], dyes [63], pesticides (thiamethoxam, imidacloprid and acetamiprid) [64] and herbicides such as sulfuron derivatives [65, 66], atrazine [67] and dicamba [68]. Cross-linked nanoporous polymers that have been copolymerized with functionalized CNTs have been demonstrated to have a very high sorption capacity for a variety of organic compounds such as *p*-nitrophenol and trichloroethylene [69]. It was found that purification (removal of amorphous carbon) of the CNTs improved the adsorption [54]. The available adsorption space was found to be the cylindrical external surface; neither the inner cavity nor the inter-wall space of multi-walled CNT contributed to adsorption [70]. Unlike the case with fullerenes, no adsorption–desorption hysteresis was observed, indicating reversible adsorption [70].

Fullerenes have also been tested for adsorption of organic compounds. Adsorption depends to a great extent on the dispersion state of the C_{60} [71], which is virtually insoluble in water [72]. Because C_{60} forms clusters in water, there are closed interstitial spaces within the aggregates into which the compounds can diffuse, which leads to significant adsorption–desorption hysteresis [70, 73]. Fullerenes are only weak sorbents for a wide variety of organic compounds (e.g. phenols, PAHs, amines), whereas they are very efficient for the removal of organometallic compounds (e.g. organolead) [74].

An interesting application is oxide–CNT composites, which have been explored for the removal of metals [75] and also of anions such as arsenate and fluoride [76, 77]. Specially designed polymers and dendrimers are exploited for their potential removal of metals and organics [78, 79].

1.4.2 Magnetic Nanoparticles

Magnetic nanoparticles offer advantages over non-magnetic nanoparticles because they can easily be separated from water using a magnetic field. Separation using magnetic gradients, the so-called high magnetic gradient separation (HGMS), is a process widely used in medicine and ore processing [80]. This technique allows one to design processes where the particles not only remove compounds from water but also can easily be removed again and then be recycled or regenerated. This approach has been proposed with magnetite (Fe_3O_4), maghemite (γ-Fe_2O_3) and jacobsite ($MnFe_2O_4$) nanoparticles for removal of chromium(VI) from wastewater [81–83]. Water-soluble CNTs have been functionalized with magnetic iron nanoparticles for removal of aromatic compounds from water and easy separation from water for re-use [84].

1.4.3 Nanofiltration

Nanofiltration membranes (NF membranes) are used in water treatment for drinking water production or wastewater treatment [85]. NF membranes are pressure-driven membranes with properties between those of reverse osmosis and ultrafiltration membranes and have pore sizes between 0.2 and 4 nm. NF membranes have been shown to remove turbidity, microorganisms and inorganic ions such as Ca and Na. They are used for softening of groundwater (reduction in water hardness), for removal of dissolved organic matter and trace pollutants from surface water, for wastewater treatment (removal of organic and inorganic pollutants and organic carbon) and for pretreatment in seawater desalination.

Carbon nanotubes have been arranged to form a hollow monolithic cylindrical membrane [86], which was efficient for the removal of bacteria or hydrocarbons and that can easily be regenerated by ultrasonication or autoclaving.

1.4.4 Degradation of Pollutants

The semiconductor TiO_2 has been extensively studied for oxidative or reductive removal of organic pollutants [49, 87]. Illumination promotes an electron to the conduction band, leaving a hole in the valence band. This process produces a potent reducing and oxidizing agent. In water, photo-oxidation occurs primarily through hydroxyl radicals. Because TiO_2 requires ultraviolet light for excitation, it has been sensitized to visible light by dyes, through incorporation of transition metal ions [49]

or by doping with nitrogen [88]. The degradation rate of several dyes by nanosized TiO_2 was found to be 1.6–20 times higher than for bulk TiO_2 particles [89]. Several types of compounds such as dyes [88, 90] and organic acids [91] have been shown to be rapidly degraded. A special type of TiO_2 photocatalysts are titania nanotube materials, which were shown to have superior activity [92, 93].

1.4.5 Zerovalent Iron

Laboratory research has established that nanoscale metallic iron is very effective in destroying a wide variety of common contaminants such as chlorinated methanes, brominated methanes, trihalomethanes, chlorinated ethenes, chlorinated benzenes, other polychlorinated hydrocarbons, pesticides and dyes [94]. The basis for the reaction is the corrosion of zerovalent iron in the environment:

$$2Fe^0 + 4H^+ + O_2 \rightarrow 2Fe^{2+} + 2H_2O$$

$$Fe^0 + 2H_2O \rightarrow Fe^{2+} + H_2 + 2OH^-$$

Contaminants such as tetrachloroethane can readily accept the electrons from iron oxidation and be reduced to ethene:

$$C_2Cl_4 + 4Fe^0 + 4H^+ \rightarrow C_2H_4 + 4Fe^{2+} + 4Cl^-$$

However, nanoscale zerovalent iron (nZVI) can reduce not only organic contaminants but also the inorganic anions nitrate, which is reduced to ammonia [95, 96], perchlorate (plus chlorate or chlorite), which is reduced to chloride [97], selenate [98], arsenate [99, 100], arsenite [101] and chromate [102, 103]. nZVI is also efficient in removing dissolved metals from solution, e.g. Pb and Ni [102, 104]. The reaction rates for nZVI are at least 25–30 times faster and also the sorption capacity is much higher compared with granular iron [105]. The metals are either reduced to zerovalent metals or lower oxidation states, e.g. Cr(III), or are surface complexed with the iron oxides that are formed during the reaction. Some metals can increase the dechlorination rate of organics and also lead to more benign products, whereas other metals decrease the reactivity [106].

The reaction rates for nZVI can be several orders of magnitude faster on a mass basis than for granular ZVI [107]. Because the reactivity of ZVI towards lightly chlorinated and brominated compounds is low and because the formation of a passivating layer reduces the reactivity with time, many approaches have been explored where the surface is doped with a catalyst (e.g. Pd, Pt, Cu, Ni) to reduce the activation energy. The same approach has also been tested for nZVI. Surface-normalized reaction rates for such materials were found to be up to 100 times faster than for bulk ZVI [108–111].

The nanoscale iron particles can be produced either by a top-down approach (e.g. milling of iron filings) or by direct chemical synthesis [105]. A common method for synthesis of iron nanoparticles is by reduction of an aqueous ferric solution by reducing agents such as sodium borohydride or sodium hypophosphite [49].

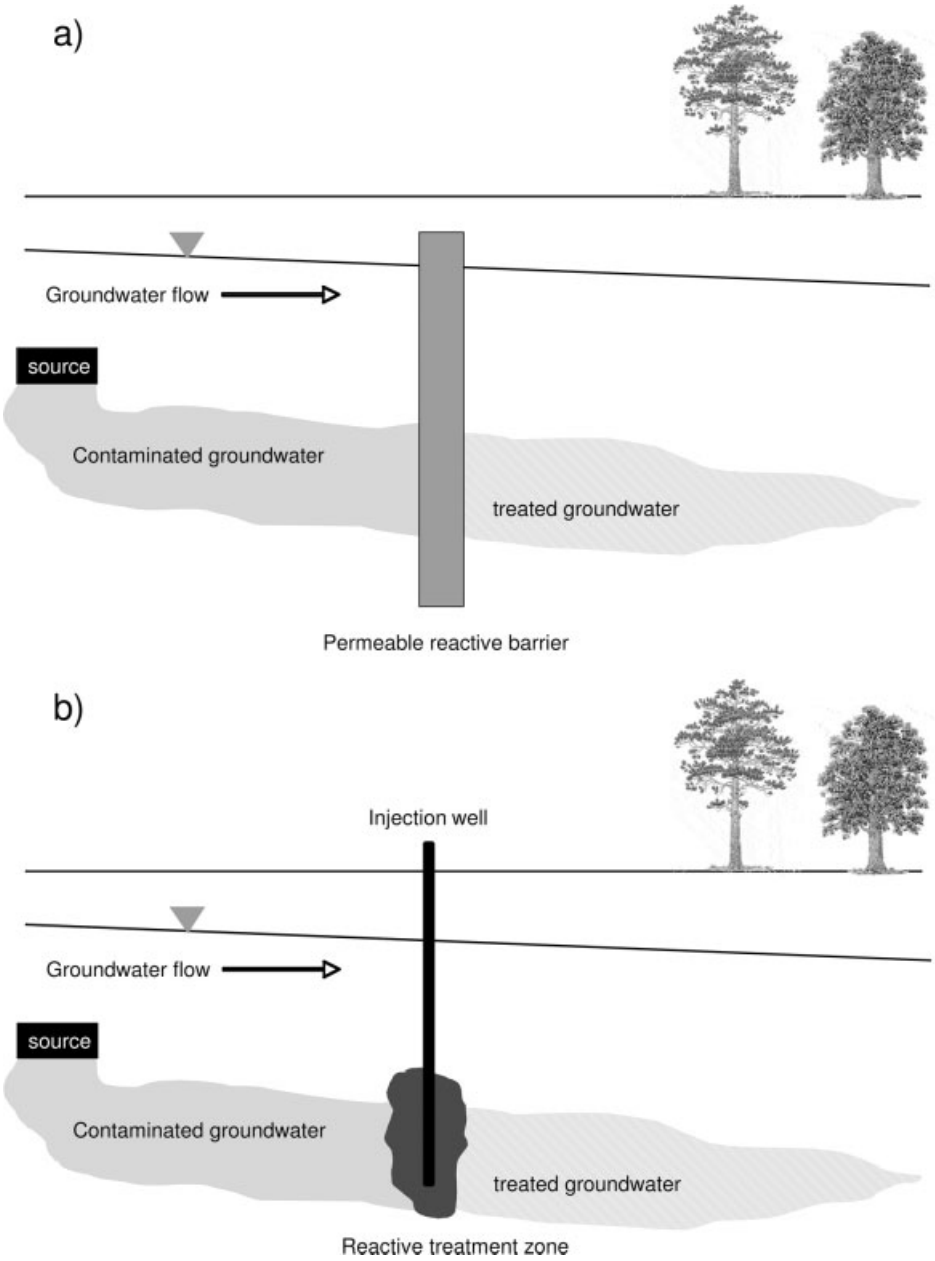

Figure 1.3 Three approaches to application of ZVI for groundwater remediation: (a) conventional reactive barrier using granular ZVI; (b) injection of nZVI to form an immobile reaction zone; (c) injection of mobile nZVI. Modified after [107].

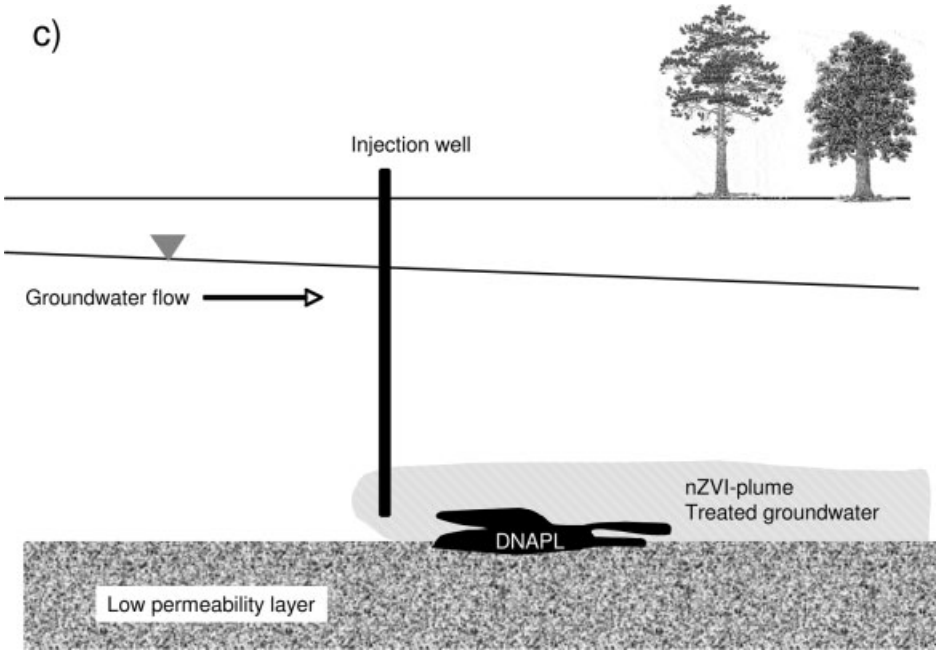

Figure 1.3 *(continued)*

1.5 Soil and Groundwater Remediation

The use of nZVI for groundwater remediation represents the most widely investigated environmental nanotechnological technique. Granular ZVI in the form of reactive barriers has been used for many years at numerous sites all over the world for the remediation of organic and inorganic contaminants in groundwater (see Figure 1.3a). With nZVI, two possible techniques are used: immobile nZVI is injected to form a zone of iron particles adsorbed on the aquifer solids (Figure 1.3b) or mobile nZVI is injected to form a plume of reactive Fe particles that destroy any organic contaminants that dissolve from a DNAPL (dense non-aqueous phase liquid) source in the aquifer (Figure 1.3c). With this technique, the formation of a pollutant plume is inhibited. The successful results of field demonstrations using nZVI have been published, with reported reductions in TCE of up to 96% after injection of 1.7 kg of nanoparticles into the groundwater [112]. A larger test was conducted where 400 kg of nZVI was injected and significant reductions in TCE soil concentration (>80%) and dissolved concentrations (57–100%) were observed [113]. To date approximately 30 projects are under way in which nZVI is used for actual site remediation [105].

Whereas most research using nZVI has been devoted to groundwater, much less has been published about soil remediation. These studies have mostly been done in soil slurries and efficient removal of PAHs by nZVI has been reported [114, 115]. For

PCBs, a removal of only about 40% was attained, caused by the very strong adsorption of PCBs to the soil matrix and limited transfer to the nZVI particles [116]. nZVI has also been used to immobilize Cr(VI) in chromium ore processing residue [117].

Because the iron particles have a strong tendency to aggregate and adsorb on surfaces of minerals, much effort has been directed towards methods to disperse the particles in water and render them mobile. In one approach, water-soluble starch was used as a stabilizer [118], and in another, hydrophilic carbon or poly(acrylic acid) delivery vehicles were used [119]. Modified cellulose, sodium carboxymethylcellulose (CMC), was found to form highly dispersed nZVI [120] and also several polymers have been tested and found to be very effective [121]. In this stabilized form the nZVI was up to 17 times more reactive in degrading trichloroethene than non-stabilized material. However, for other stabilizing agents a decrease in reactivity of up to 9- [121] or 2–10-fold was observed [121]. To deliver the nZVI to the oil/water interface in the case of DNAPL contamination, a copolymer was used to increase colloid stability and at the same time increase phase transfer into the organic phase [122].

1.6 Environmental Risks

1.6.1 Behavior in the Environment

The use of nanoparticles in environmental applications will inevitably lead to the release of nanoparticles into the environment. Assessing their risks in the environment requires an understanding of their mobility, bioavailability, toxicity and persistence. Whereas air-borne particles and inhalation of nanoparticles have attracted a lot of attention [123], much less is known about the possible exposure of aquatic and terrestrial life to nanoparticles in water and soils [2]. Nanoparticles agglomerate rapidly into larger aggregates or are contained within other materials (e.g. polymers). Cations, for example, are able to coagulate acid-treated CNTs with critical coagulation concentrations of 37 mM for Na, 0.2 mM for Ca and 0.05 mM for trivalent metals (e.g. La^{3+}) [124]. Aggregation of CNTs added as a suspension to filtered pond water has been reported [125]. Sedimentation and therefore removal from water can be expected under such conditions. The coagulation and interception by surfaces also determine the fate of nanoparticles in porous media and rapid removal has been observed in many, but not all, cases [126, 127]. However, a recent study shows that humic and fulvic acids are able to solubilize CNTs under natural conditions and that stable suspensions are obtained [128].

Most nanoparticles in technical applications are functionalized and therefore studies using pristine nanoparticles may not be relevant for assessing the behavior of the actually used particles. As mentioned above in Section 1.5 on groundwater remediation, functionalization is often used to decrease agglomeration and therefore increase mobility of particles. Very little is known to date about the influence of functionalization on the behavior of nanoparticles in the environment.

1.6.2 Ecotoxicology

A consistent body of evidence shows that nanosized particles can be taken up by a wide variety of mammalian cell types, are able to cross the cell membrane and become internalized [6, 7, 129–131]. The uptake of nanoparticles is size dependent [132, 133]. Most of the toxicological studies have been carried out with mammalian cells and therefore were carried out in a cell culture medium containing a mixture of proteins and other biological compounds. In this medium, nanoparticles are coated with proteins and have a negative surface charge irrespective of the charge of the pristine particles [132]. Results from such studies therefore cannot be directly transferred to environmental conditions.

Ecotoxicological studies show that nanoparticles are also toxic to aquatic organisms, both unicellular (e.g. bacteria or protozoa) and animals (e.g. daphnia or fish). Whereas bulk TiO_2 is considered to have no health effects on aquatic organisms, this is clearly not the case for nanosized TiO_2 [134]. This was found both for inorganic nanoparticles such as TiO_2 [134–136], CeO_2 [137] and ZnO [136, 138] and for carbon-containing particles such as fullerenes [139–143] and CNTs [144]. The observed effects ranged from higher activity of certain stress-related genes, lipid peroxidation and glutathione depletion and antibacterial activity (growth inhibition) for microorganisms to increased mortality and reduced fertility at high particle concentrations. Inorganic nanoparticular TiO_2 had a toxic effect on bacteria and the presence of light was a significant factor increasing the toxicity [136]. In copepods purified CNTs did not show any effect whereas unpurified CNTs with all their byproducts increased mortality [144]. Organisms are able to use a lipid coating of CNTs as a food source and therefore alter the solubility and toxicity of the CNT in the organism [145].

Nanosized CeO_2 particles were adsorbed on the cell wall of *E. coli* but the microscopic methods were not sensitive enough to discern whether internalization had taken place [137]. Nanosized ZnO was internalized by bacteria [138]. Nanoparticles that damage bacterial cell walls have been found to be internalized, whereas those without this activity were not taken up [146]. CNTs have been shown to be taken up by a unicellular protozoan [125] and they induced a dose-dependent growth inhibition. The CNTs were localized with the mitochondria of the cells.

These results from ecotoxicological studies show that certain nanoparticles will have effects on organisms on the environment, at least at elevated concentrations. The next step towards an assessment of the risks of nanoparticles in the environment will therefore be to estimate the exposure to the different nanoparticles.

1.7 Conclusions

This chapter was intended to give an overview of the various aspects of nanotechnology and the environment, mainly looking at it from the side of applications rather than from the risk side. It should have become clear that nanotechnology in general

and nanoparticles in particular will have important impacts on various fields of environmental technology and engineering. However, we should always keep in mind that nanotechnology has a Janus face and that each positive and desired property of nanomaterials could be problematic under certain conditions and pose a risk to the environment. A careful weighing up of the opportunities and risks of nanotechnology with respect to their effects on the environment is therefore needed.

Photocatalytic Surfaces: Antipollution and Antimicrobial Effects

Norman S. Allen, Michele Edge, Joanne Verran, John Stratton, Julie Maltby, and Claire Bygott

2.1
Introduction to Photocatalysis: Titanium Dioxide Chemistry and Structure–Activity

For many years, titanium dioxide pigments have been used successfully for conferring opacity and whiteness to a host of different materials. Their principal usage is in applications such as paints, plastics, inks and paper, but they are also incorporated into a diverse range of products, such as foods and pharmaceuticals. The fundamental properties of titanium dioxide have given rise to its supreme position in the field of white pigments. In particular, its high refractive index permits the efficient scattering of light. Its absorption of UV light has conferred durability on products. Its non-toxic nature has meant that it can be widely used in almost any application without risk to health and safety. However, the primary reason for its success is the ability to reflect and refract or scatter light more efficiently than any other pigment, due to its high refractive index in comparison with extenders, fillers and early pigments [1–5] (see Table 2.1).

Titanium dioxide exists in three crystalline modifications, rutile, brookite and anatase, all of which have been prepared synthetically. In each type, the titanium ion coordinates with six oxygen atoms, which in turn are linked to three titanium atoms and so on. Anatase (Figure 2.1) and rutile (Figure 2.2) are tetragonal whereas brookite is orthorhombic. Brookite and anatase are unstable forms. Brookite is not economically significant since there is no abundant supply in nature.

Examination (Table 2.2) of the basic properties of the two main crystal forms shows differences in specific gravity, hardness, refractive index and relative tint strength. The oil absorption of commercial anatase and rutile pigments also varies, in part due to the different types of surface treatments applied to them.

Titanium dioxide has the highest average refractive index known. For anatase, it is 2.55 and for rutile it is 2.76. These high values account for the exceptional light scattering ability of pigmentary titanium dioxide when dispersed in various media, which in turns yields the high reflectance and hiding power associated with this pigment. Although single-crystal titanium dioxide is transparent, as a finely divided

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

Table 2.1 Refractive index of TiO_2 in comparison with extenders, filler and other pigments.

Material	Refractive index
Rutile TiO_2	2.76
Anatase TiO_2	2.52
Lithopone	2.13
Zinc oxide	2.02
White lead	2.00
Calcium carbonate	1.57
China clay	1.56
Talc	1.50
Silica	1.48

powder it has a very high reflectance and it is intensely white because its high reflectance is substantially uniform throughout the visible spectrum. This white color is different in tone for the two crystal structures due to their different reflectance curves across the visible and near-visible spectrum (Figure 2.3).

From examination of Figure 2.3, is evident that:

- Rutile TiO_2 reflects the radiation slightly better that anatase and is therefore brighter.
- The higher absorption of rutile at the very blue end of the visible spectrum and in the UV region accounts for the yellower tone of rutile pigment. This higher UV

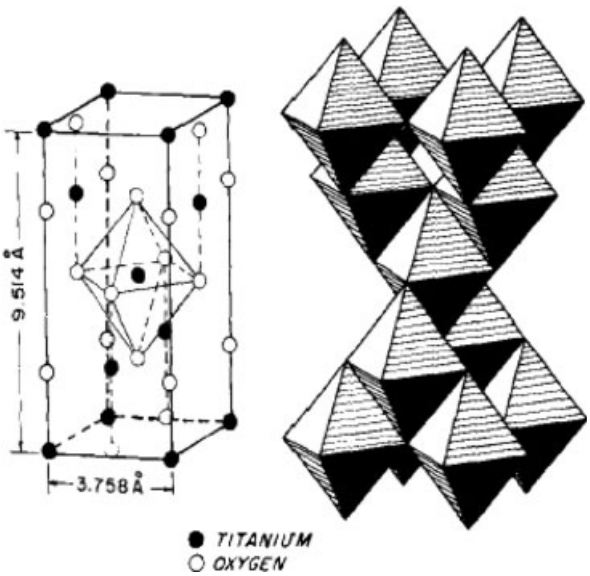

Figure 2.1 Crystal structure of anatase.

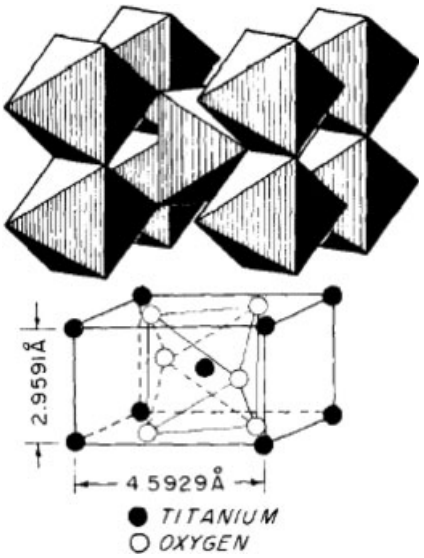

Figure 2.2 Crystal structure of rutile.

absorption also provides relatively better durability to a system as it reduces the amount of energy available to degrade the binder.

Although the difference in refractive index gives rutile pigments up to 15% opacity benefit over the anatase pigment, the bluer tone and lower hardness of anatase pigments are beneficial in some applications, especially where low abrasivity may be an issue. Where the highest possible optical efficiency (opacity) and durability are required, rutile pigments are superior.

Refractive index varies with wavelength and for titanium dioxide the refractive index is greater for shorter wavelengths (blue region) and lower for longer wavelengths (red region) of the visible spectrum.

Table 2.2 Typical properties of anatase and rutile polymorphs.

Property	Anatase	Rutile
Pigment form		
Appearance	Brilliant white powders	
Density ($g\,cm^{-3}$)	3.8–4.1	3.9–4.2
Refractive index	2.55	2.76
Oil absorption (1b/100b)	18–30	16–48
Tinting strength (Reynolds)	1200–1300	1650–1900
Crystal form		
Density ($g\,cm^{-3}$)	3.87	4.24
Hardness (Moh)	5–6	6–7

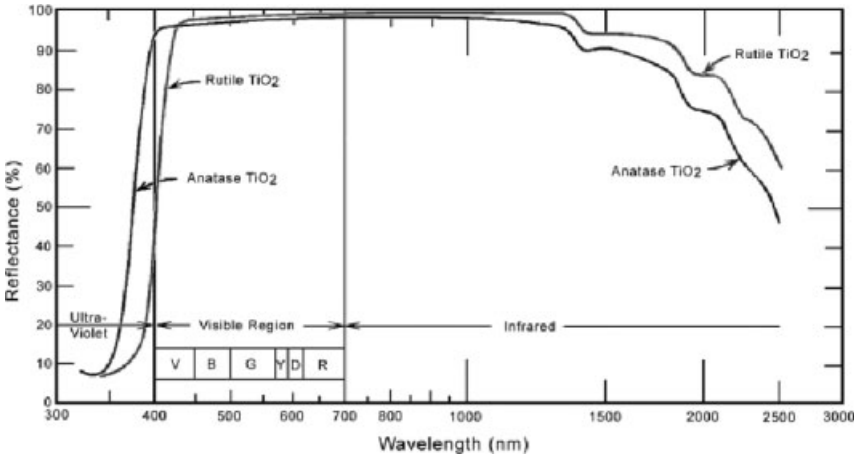

Figure 2.3 Reflectance of anatase and rutile pigments through the near-UV, visible and IR regions.

The performance of a pigment in a surface coating is significantly affected by the interaction of the medium with the pigment surface. The consequences are felt at all stages, but are particularly relevant for dispersion, shelf stability and exterior durability. Treated TiO_2 absorbs UV radiation and protects the polymer photochemically; untreated TiO_2, however, is itself photocatalytic. Although it converts most of the UV energy into heat, the remaining energy creates radicals, which accelerate the breakdown of the polymer. Almost all titanium dioxide used in plastics applications is surface treated. Treatments are essentially the same, whether the base pigment is produced by the chloride or the sulfate route. The level of photocatalytic activity may be reduced by surface treatment of the base pigment with suitable inorganic compounds [1]. The most common precipitates are oxyhydrates of aluminum and silicon. Also used are oxides and oxyhydrates of zirconium, tin, zinc, cerium and boron. The treatment functions by placing a physical barrier between the pigment surface and the polymer matrix, blocking the active sites and minimizing degradation. The treatment may also aid and reduce the requirements of power and shear when mixing. Many TiO_2 pigments also have a final organic treatment, such as with trimethylolpropane or pentaerythritol. Its primary function is to modify the interfacial region between the hydrated inorganic oxide TiO_2 particle surface and various less polar organic polymers.

During the manufacturing process of TiO_2, the pigment is formed as discrete particles of around 0.2–0.4 μm. The titanium dioxide manufacturers control the operational variables to produce particles of a uniform size and distribution. These 0.2–0.4 μm particles have been engineered to maximize the scattering of light, resulting in optimum brightness and opacity.

However, as soon as the particles are manufactured, they begin to combine into aggregates, agglomerates and flocs. *Aggregates* are associations of pigment particles that are fixed together along the crystal faces. Bonds between particles are strong and cannot be broken by conventional grinding devices. *Agglomerates* are associations of pigment particles and aggregates that are weakly bonded together. *Flocs* are

associations of crystallites, aggregates and agglomerates joined across corners or held together by short range attractive forces. These flocs disperse under moderate shear (Figure 2.4).

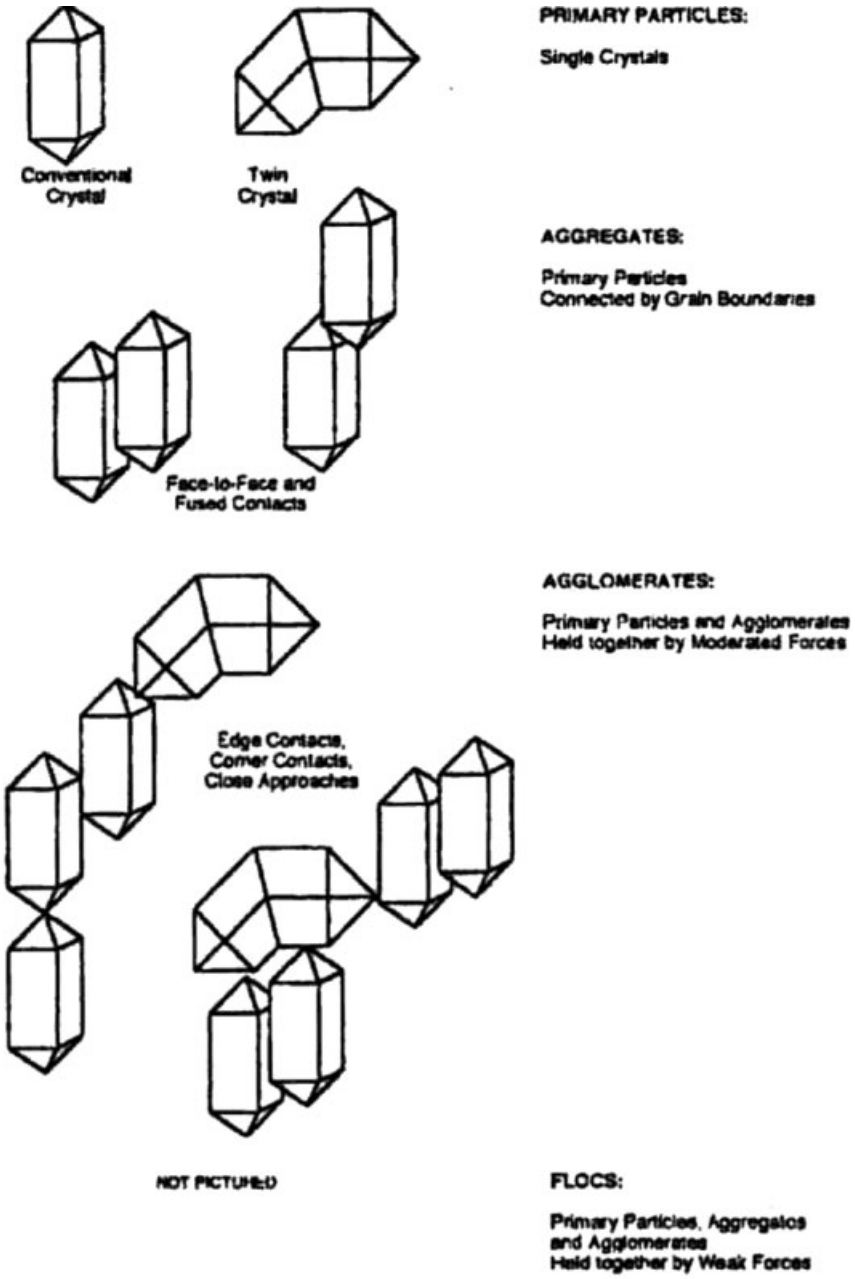

Figure 2.4 Aggregates and agglomerates.

Aggregates can only be broken into individual pigment particles with intensive milling. One of the last manufacturing steps performed by the TiO_2 manufacturer is micronization and/or milling to dissociate as many aggregates as possible. Aggregates will not reform unless the pigment is heated to over 500 °C. Agglomerates are also broken up in the milling step. However, agglomerates will easily re-form during packing, storage and transportation. The disruption of these inter-particle bonds is generally understood to be the dispersion that needs to be performed by the TiO_2 consumer.

It is possible to manipulate the TiO_2 particle size to within a very narrow range around a predetermined optimum. Generally, in paint applications this optimum is approximately 0.2–0.3 μm, as it is within this range that TiO_2's light scattering ability is at its peak, which in turn maximizes the level of gloss finish.

TiO_2 pigment particles are submicroscopic with size distributions narrower than many so-called monodisperse particulates. Appropriately ground, pigment dispersions contain less than 5 wt.% of particles smaller than 0.10 μm and larger than 1.0 μm. Optical effectiveness, that is, light scattering is controlled by the mass/volume frequency of particles in the size range from 0.1 to 0.5 μm. Gloss is diminished by a relatively small mass/volume fraction of particle larger than about 0.5 μm. Dispersibility and film fineness is degraded by a very small mass/volume fraction of particles larger than about 5 μm. Important optical properties such as opacity, hiding power, brightness, tone, tinting strength and gloss are all dependent upon the particle size and particle size distribution.

Pure titanium dioxide possesses by nature an internal crystal structure that yields an innately high refractive index. When the particle size and particle size distribution are to be optimized so as to contribute along with its high refractive index to a maximum light scattering, *conventional or pigmentary* titanium dioxide is obtained. It reflects all the wavelength of the visible light to the same degree, producing the effect of whiteness to the human eye. All these attributes, together with its opacity, are achieved for an optimal particle diameter which is approximately 0.2–0.4 μm, that is, in the order of half the wavelength of visible light. This fact can also be demonstrated on the basics of Mie theory [6].

There exists, however, another type of titanium dioxide whose median crystal size has been explicitly reduced up to 0.02 μm. This is the so-called *nanoparticles or ultrafine* TiO_2 and will be the subject of this chapter.

The history of nanoparticle titanium dioxide dates back to the late 1970s when the first patent on the preparation of these materials was issued in Japan. It is in principle possible to obtain nanoparticle TiO_2 by simple milling of the pigmentary TiO_2 to a finer particle [4]. However, the properties of the fine powders in terms of purity, particle size distribution and particle shape remain highly unsatisfactory.

Several wet-chemical processes were developed during the 1980s by TiO_2 pigment manufacturers such as Ishihara, Tioxide and Kemira. The first part of the process, the production of the nanoparticle base material, uses after-wash titanium hydroxylate as the raw material. After subsequent process steps involving the decomposition of the hydroxylate crystal structure and the reprecipitation of the TiO_2, the product is calcined to obtain oval-shaped particles with a desired primary crystal size and narrow

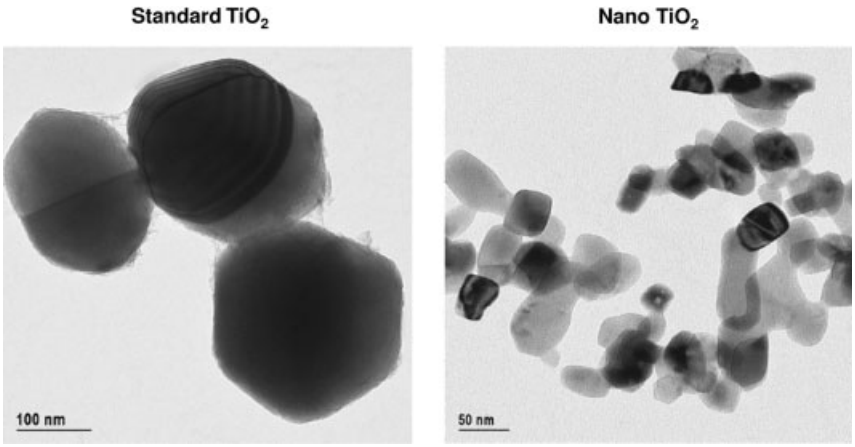

Figure 2.5 Typical TEM images of pigmentary and nanoparticles.

size distribution. The base crystals are coated in the after-treatment unit according to the requirements of the end-use. One of the primary tasks of the after-treatment is to ensure good dispersibility of extremely fine particles in the final application.

TiO_2 nanoparticles are also routinely produced by the gas-to-particle conversion in flame reactors because this method provides good control of particle size, particle crystal structure and purity [4].

Typically, the crystal size of these products is about one-tenth of the size of the normal pigmentary grade. Figure 2.5 shows typical transmission electron micrographs for pigmentary and nanoparticulate titanium dioxide at the same magnification.

Table 2.3 shows a comparison of some typical values of the physical properties of nanoparticle and conventional titanium dioxide products.

The smaller crystal size influences various properties and leads to higher values for the surface area and oil absorption. Lower values for specific gravity and bulk density are also achieved. Otherwise, it has many of the properties of conventional TiO_2 pigments: non-toxic, non-migratory, inert and stable at high temperatures.

The optical behavior of ultrafine TiO_2 differs dramatically from that of conventional TiO_2 pigment. The optical properties of nanoparticle TiO_2 are governed by the

Table 2.3 Typical properties of nanoparticle and conventional titanium dioxide.

Property	Nanoparticle	Pigmentary
Appearance	White powder	White powder
Crystal structure	Anatase or rutile	Anatase or rutile
Crystal size (μm)	0.005–0.05	0.15–0.3
Specific surface area ($m^2\,g^{-1}$)	50–>300	15
Bulk density ($g\,mL^{-1}$)	3.3	4.0
Oil absorption (g per 100 g)	30	16

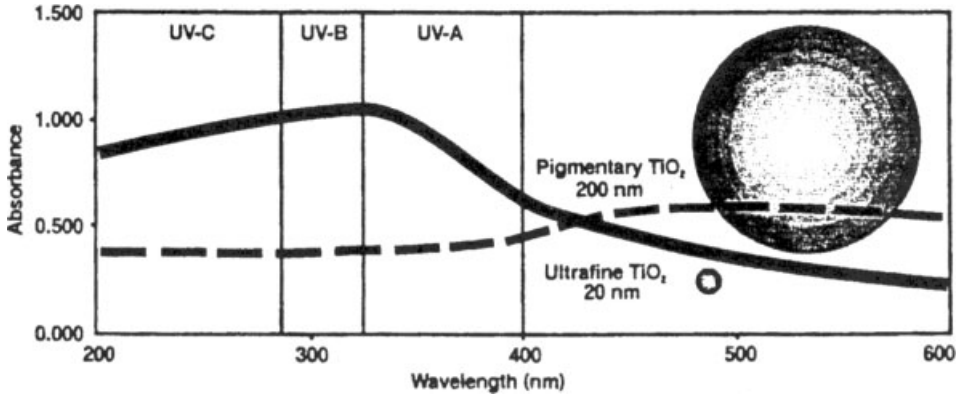

Figure 2.6 Comparison of the optical behavior of ultrafine TiO_2 and pigmentary TiO_2.

Rayleigh theory of light scattering. A simple interpretation of this theory is that the shorter wavelengths of light are more efficiently scattered by very small particles. The intensity of the scattered light is inversely proportional to the fourth power of the wavelength. In practical terms, a reduction in the crystal size of a TiO_2 product leads to an optimum size of TiO_2 of the order of 20–50 nm where the UV spectrum of light (200–400 nm) is effectively scattered from the particles while the visible wavelengths are transmitted through the material. The material thus appears virtually transparent to the naked eye. The behavior is demonstrated in Figure 2.6, which shows the difference between pigmentary and nanoparticle TiO_2.

The complete picture of the optical behavior of TiO_2 becomes more complete by recognizing that TiO_2 is a semiconductor. TiO_2 exhibits a characteristic energy gap of 3.23 or 3.06 eV between the valence band and the conduction band for anatase and rutile, respectively. Wavelengths shorter than 390 nm for anatase and 405 nm for rutile – corresponding to higher energy than the threshold energy – will excite electrons from the valence to the conduction band. Summarizing, titanium dioxide exhibits various mechanisms on exposure to light depending on the wavelength and the particle size: (see Table 2.4 and Figure 2.7). Electron–hole pairs are formed, giving rise to various sensitization processes.

Based on the light scattering property described earlier, nanoparticle titanium dioxide can be used to impart excellent UV protection. Compared with the available

Table 2.4 Optical behavior of pigmentary and nanoparticle TiO_2 under visible and UV light.

Particle size	Wavelength $<$400 nm	Wavelength $>$400 nm
Pigmentary TiO_2	Semiconductor absorption	Scattering and reflection (Mie scattering)
Nanoparticle TiO_2	Semiconductor absorption Scattering and reflection (Raleigh's theory)	Transmission of light Particle diameter $\ll$ wavelength

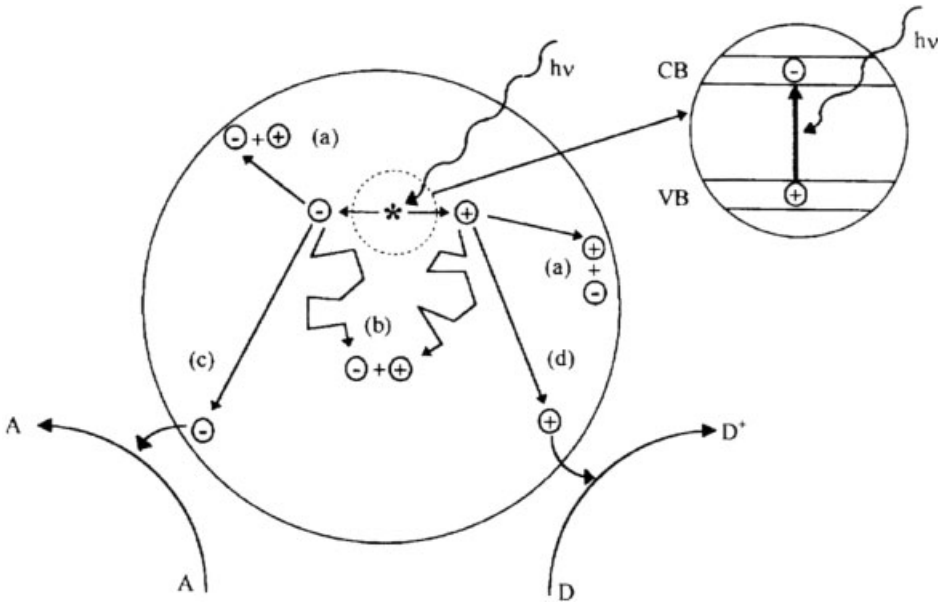

Figure 2.7 Illustration of the major processes occurring on a semiconductor particle following electronic excitation. Electron –hole recombination can occur at the surface [reaction (a)] or in the bulk [reaction (b)] of the semiconductor. At the surface of the particle, photogenerated electrons can reduce an electron acceptor A [reaction (c)] and photogenerated holes can oxidize an electro donor D [reaction (d)]. The combination of reactions (c) and (d) represent the semiconductor sensitization of general redox reactions given later in the text.

UV absorbers, ultrafine TiO_2 possesses effective UV filter properties over the entire UV spectrum (UVC + UVB + AVA). For example, it is gaining wide acceptance for use in sun creams. Nanoparticle TiO_2, apart from its effective attenuating characteristics, is extremely inert and, therefore, safe to use next to the skin [5]. Nanoparticle TiO_2 can also be used in clear plastic films to provide UV protection to foodstuffs. UV radiation from artificial lighting in a grocery store induces auto-oxidation in, e.g., meat and cheese, resulting in discoloration. In this regard it also exhibits antibacterial behavior, which will be discussed later.

It is also possible to use ultrafine TiO_2 as a light stabilizer in plastics to protect the material itself from yellowing and to retard the deterioration of the mechanical properties. A further example of the potential of nanoparticle TiO_2 as a UV filter is found in clear wood finishes. The original color of wood panels can be retained by a clear lacquer made with 0.5–4% nanoparticle TiO_2 [7]. In addition to preventing wood from darkening, ultrafine TiO_2 also enhances its lifetime.

An exciting and increasing popular application of the optical properties of ultrafine TiO_2 is found in automotive coatings, where the ultrafine powder is used as an effect pigment in combination with mica flakes to create the so-called titanium opalescent effect. For UV protection applications and due to the intrinsic photoactivity of TiO_2 pigments, mainly, *nanoparticle surface-treated rutile* pigments are used. *Nanoparticle anatase TiO_2* finds applications in the field of photocatalysis.

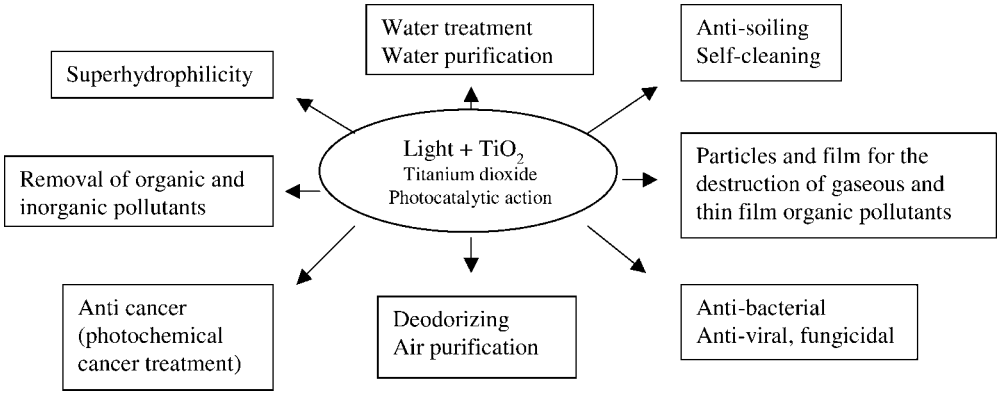

Figure 2.8 Major areas of activity in titanium dioxide photocatalysis.

2.2 Applications

The field of heterogeneous photocatalysis is very diverse and involves many research groups throughout the world. A number of research themes have emerged which offer real potential for commercial developments and merit much greater research.

Figure 2.8 displays and summarizes many of the major fields in which TiO_2 is used as a photocatalyst, all related in a sense towards solving environmental issues.

For the purpose of this chapter, we will just focus on our application studies of TiO_2 for antibacterial, self-cleaning and depollution [atmospheric contaminants such as volatile organic compounds (VOCs) and nitrogen oxides]. For example, in indoor environments, most surfaces, e.g. ceramic tiles, window glass or paper, are gradually covered with organic matter such as oils, dirt and smoke residue and become fouled [8]. Transparent TiO_2 coatings can be completely unobtrusive, causing no readily discernible changes in the substrate color or transparency, but they can decompose organic matter as it deposits. Thus, various types of surfaces with TiO_2 can be covered to make them self-cleaning under sunlight as well as room light (Figure 2.9). Thus, surfaces based on paints, ceramics, glass and cementitious materials containing active photocatalytic titania nanoparticles have widespread applications to create environmentally clean areas within their proximity.

2.3 Photocatalytic Chemistry

The overall catalytic performance of titanium dioxide particles has been found to be dependent on a number of parameters, including preparation method, annealing temperature, particle/crystal size, specific surface area, ratio between the anatase and rutile crystal phases, light intensity and the substrate to be degraded [9]. Furthermore, the electrons confined in the nanomaterial exhibit a different behavior to that in the

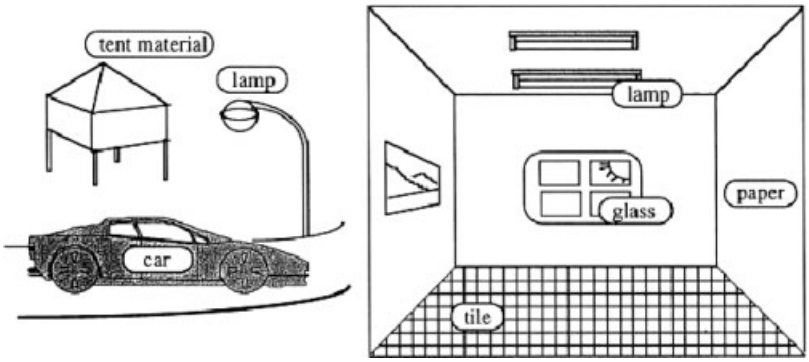

Figure 2.9 Schematic representation of the possible applications of transparent TiO_2 thin film photocatalyst in the indoor and outdoor environments.

bulk materials. The properties of the electrons in small semiconductors should be dependent on the crystallite size and the shape due to quantized motion of the electron and hole in a confined space. This phenomenon is called the quantum size effect. However, the quantization effect does not exist in amorphous phases [10]. As a result of the confinement, the bandgap increases and the band edges shift to yield larger redox potentials. Hence the use of size-quantized semiconductor TiO_2 particles may result in increased photoefficiencies [11].

However, other workers [12] reported that the photocatalytic activity increased greatly and the blue shift was significant only at particle diameters less than 10 nm. On the other hand, the small size effect can improve the photocatalytic activity of the TiO_2 due to the increasing specific surface area, which gives more reactive sites to absorb pollutants. Meanwhile, the diffusion of the photoinduced electrons or holes from bulk to surface becomes fast with a decrease in the particle size [13], which will also lead to an enhancement of the photocatalytic activity. On the other hand, the surface tension increases and causes a crystal lattice distortion with decreasing particle size [14] and consequent change in the structure of the energy band.

The anatase TiO_2 phase is more active than the rutile phase in photocatalysis. The reason for the lower photocatalytic efficiencies in the rutile TiO_2 phase is because the recombination of the electron-hole pair produced by UV irradiation occurs more rapidly on the surface of the rutile phase and the amounts of reactants and hydroxides attached to the surface of the rutile phase are smaller than those of the anatase TiO_2 phase [17]. However, according to other work, the decrease in the photocatalytic effect during the transformation from the anatase to rutile TiO_2 phase was not due to the change in the crystalline structure, but mainly to changes in the specific surface area and porosity [16]. The photocatalytic processes on a titanium dioxide particle are displayed simply in Figure 2.10. Primarily following photoexcitation, a number of surface processes can take place providing activation and further reactions depending on the nature of the environment in question. Holes can generate active hydroxyl radicals whereas active oxygen species are generated through electron transfer processes. All exhibit high activity that can react with surrounding organic and gaseous environments.

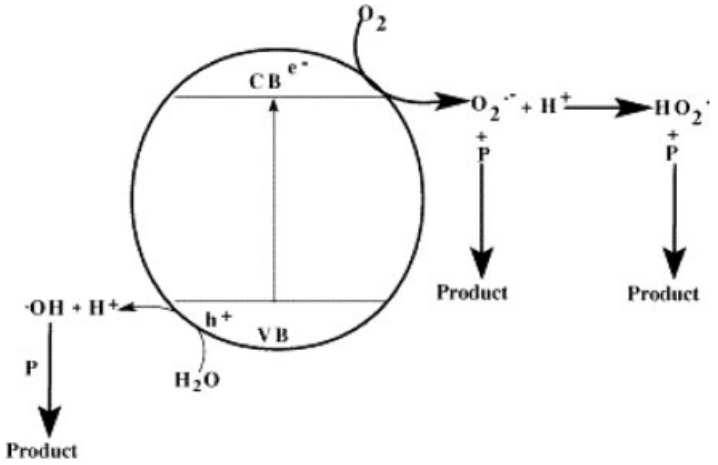

Figure 2.10 Surface photocatalytic activity of titanium dioxide.

Polymeric and organic coatings systems are commonly utilized by titania doping for various applications. In outdoor applications all polymers degrade. The degradation rate depends on the environment (especially sunlight intensity, temperature and humidity) and on the type of polymer. This so-called photo-oxidative degradation is due to combined effects of photolysis and oxidative reactions. Sunlight photolytic degradation and/or photo-oxidation can only occur when the polymer contains chromophores which absorb wavelengths of the sunlight spectrum on Earth (>290 nm). These wavelengths have sufficient energy to cause a dissociative (cleavage) processes resulting in degradation.

Chromophores that can absorb sunlight are:

- internal in-chain impurities such as hydroperoxides or carbonyls formed during storage, processing or weathering;
- external impurities such as polymerization catalyst residues, additives (e.g. pigments, dyes or antioxidants), pollutants from the atmosphere or metal traces from processing equipment;
- parts of the molecular structure of the polymer, i.e. polyaromatics;
- charge-transfer complexes between oxygen and the polymer chain.

Photo-oxidative degradation is due to a radical-based auto-oxidative process (Figure 2.11), which can be divided into four stages.

In the initiation step. free radicals are generated. During photo-oxidation these radicals are formed due to a photolysis reaction of one of the chromophores present. The propagation reactions are thermal reactions and these have been studied in more detail. The rate of the reaction of oxygen with alkyl radicals is very high and that is why the rate of the propagation is largely determined by the ease of hydrogen atom abstraction in the second step of the propagation. The propagation reaction is a repeating reaction; photochemically, hydroperoxides can decompose

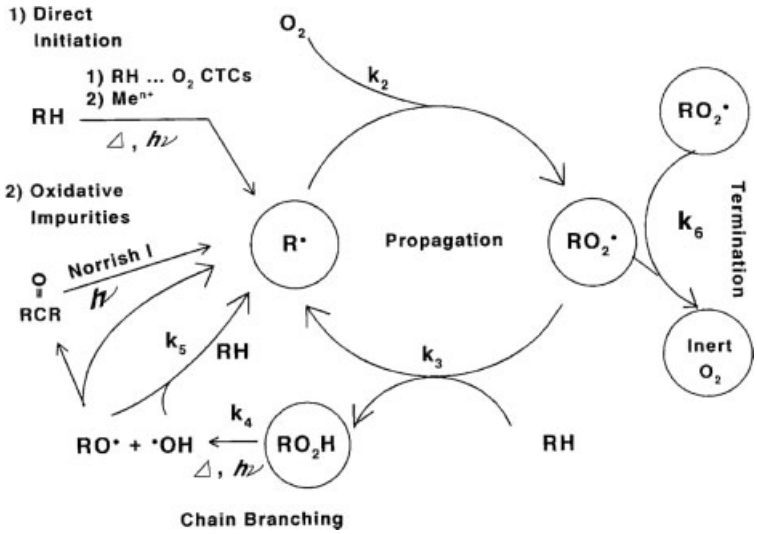

Figure 2.11 Auto-oxidation mechanism for almost all polymers (R = polymer chain, H = most labile hydrogen, $X^{\bullet}$ = any radical, k_i = reaction rate).

homolytically into alkoxy and hydroxy radicals, which can initiate another propagation cycle [18, 19]. Termination reactions are bimolecular. In the presence of sufficient air, which is normally the case for the long-term degradation of polymers, only the reaction of two peroxy radicals has to be considered. Here the reaction depends on the type of peroxy radical present. Aside from these processes, polyaromatics and heterochain polymers exhibit further complex reactions but for the purposes of this chapter the main processes of concern are those induced by the catalytic effect of the titanium dioxide.

The ability of pigments to catalyze the photo-oxidation of polymer systems has also attracted significant attention in terms of their mechanistic behavior. In this regard, much of the information originates from work carried out on TiO_2 pigments in both polymers and model systems [20–27]. To date their are three current mechanisms of the photosensitized oxidation of polymers by TiO_2 and, for that matter, other white pigments such as ZnO:

1. The formation of an oxygen radical anion by electron transfer from photoexcited TiO_2 to molecular oxygen [20]. A recent modification of this scheme involves a process of ion annihilation to form singlet oxygen, which then attacks any unsaturation in the polymer [28].

$$TiO_2 + O_2 \xrightarrow{h\nu} {TiO_2}^{+\bullet} + {O_2}^{-\bullet}(I)$$

$$(I) \rightarrow TiO_2 + {}^1O_2(\text{ion annihilation})$$

$$(I) + H_2O \rightarrow TiO_2 + HO^{\bullet} + HO_2^{\bullet}$$

$$2HO_2^{\bullet} \rightarrow H_2O_2 + O_2$$

$$RCH_2 = CHR' + {}^1O_2 \rightarrow RCH = CHCH(OOH)R'$$

2. Formation of reactive hydroxyl radicals by electron transfer from water catalyzed by photoexcited TiO_2 [29]. The Ti^{3+} ions are reoxidized back to Ti^{4+} ions to start the cycle over again.

$$H_2O \xrightarrow{(TiO_2)h\nu} H^+ + e'(Aqu) + rOH$$

$$[Ti^{4+}] + e' \rightarrow [Ti^{3+}]$$

$$[Ti^{3+}] + O_2 \rightarrow [Ti^{4+}]$$

3. Irradiation of TiO_2 creates an exciton (p) which reacts with the surface hydroxyl groups to form a hydroxyl radical [20]. Oxygen anions are also produced, which are adsorbed on the surface of the pigment particle. They produce active perhydroxyl radicals.

$$TiO_2 \xrightarrow{h\nu} e' + (p)$$

$$OH^{\bullet} + (p) \rightarrow HO^{\bullet}$$

$$Ti^{4+} + e' \rightarrow Ti^{3+}$$

$$Ti^{3+} + O_2 \rightarrow [Ti^{4+} \cdots O^{2-}]_{adsorbed}$$

$$[Ti^{4+} \cdots O^{2-}]_{adsorbed} + H_2O \rightarrow Ti^{4+} + HO^{\bullet} + HO_2^{\bullet}$$

As mentioned previously, titanium dioxide particles are often coated with various media. For example, to improve pigment dispersion and reduce photoactivity, the surface of the pigment particles is coated with precipitated aluminosilicates. Zirconates are also used in some instances whereas for other applications such as in nylon polymers and fibers the anatase is coated with manganese silicates or phosphates. Anatase will photosensitize the oxidation of a polymer, the effect being dependent on the nature and density of the coating and increasing with pigment concentration. Uncoated rutiles are also photosensitizers but again the effect is reduced and proportional to the effectiveness of the coating. In this case, stabilization increases with increasing coated rutile concentration. Thus, the surface characteristics of the titania pigment are an important factor in controlling photoactivity. As discussed for Figure 2.11, the surface is covered with hydroxyl groups of an amphoteric character formed by the adsorption of water. These groups are more acidic in character on the surface of anatase and less effectively bound than those on rutile. The surface carriers

(excitons) therefore react more slowly with the hydroxyl groups in the case of rutile. Infrared analysis has been used to characterize the different species on the particle surfaces. At 3000–3700 cm^{-1} free and hydrogen-bonded OH groups can be detected whereas in the region 1200–1700 cm^{-1} H−O−H bending and carbonates can be seen.

Surface modifications of the TiO_2 particles with inorganic hydrates may reduce the photochemical reactivity of titanium pigments. This can reduce the generation of free radicals by physically inhibiting the diffusion of oxygen and preventing release of free radicals. The often simultaneous chemical effects of surface modification can involve provision of hole and electron recombination sites or hydroxyl radical recombination sites. In addition to the latter effects, the surface treatment or coating, as mentioned above, can improve other properties such as wetting and dispersion in different media (water, solvent or polymer), to improve compatibility with the binder and dispersion stability and color stability. The photosensitivity of titanium dioxide is considered to arise from localized sites on the crystal surface and occupation of these sites by surface treatments inhibits photo-reduction of the pigment by UV radiation and hence the destructive oxidation of the binder is inhibited. Coatings containing 2–5 wt.% of alumina or alumina and silica are satisfactory for general-purpose paints. If greater resistance to weathering is desired, the pigments are coated more heavily to about 7–10 wt.%. The coating can consist of a combination of several materials, e.g. alumina, silica, zirconia, aluminum phosphates or other metals. For example, the presence of hydrous alumina particles lowers van der Waals forces between pigment particles by several orders of magnitude, decreasing particle–particle attractions. Hydrous aluminum oxide phases appear to improve dispersibility more effectively than most of the other hydroxides and oxides. Coated and surface-treated nanoparticles of titania also have commercial uses in, for example, enhanced stabilization of polymers and coatings [7].

During the weathering of commercial polymers containing white pigments such as titania, oxidation occurs at the surface layers of the material, which eventually erode away, leaving the pigment particles exposed. This phenomenon is commonly referred to as “chalking” and has been confirmed by scanning electron microscopy. Methods of assessing pigment photoactivities have attracted much interest from both scientific and technological points of view. Artifical and natural weathering studies are tedious and very time consuming. Consequently, numerous model systems have been developed to assess their photochemical activities rapidly. Most of these systems undergo photocatalytic reactions to give products which are easily determined, usually by UV absorption spectroscopy, HPLC, GC, microwave spectroscopy, etc.

2.4
Photoactivity Tests for 2-Propanol Oxidation and Hydroxyl Content

These are specific tests to ascertain titanium dioxide photoactivity. The various types and grades of titania discussed in this chapter are listed in Table 2.5. The oxidation of 2-propanol to yield acetone is a specific methodology and this has been related to

Table 2.5 Properties of pigmentary and nanoparticulate titanias.

Sample	BET surface area ($m^2 g^{-1}$)	Particle size	Surface treatment	% Surface treatments
A anatase normal	10.1	0.24 μm	None	
B rutile normal	6.5	0.28 μm	Al	1
C rutile normal	12.5	0.25 μm	Al	2.8
D rutile normal	12.5	0.29 μm	Al	3.4
E nano anatase	44.4	20–30 nm	None	
F nano anatase	77.9	15–25 nm	None	
G nano anatase	329.1	5–10 nm	None	
H nano anatase	52.1	70 nm	Hydroxyapatite	5
I nano rutile	140.9	25 nm	None	
J nano rutile	73.0	40 nm	Al, Zr	13
K nano anatase	190.0	6–10 nm	Al, Si, P	20
L nano rutile	73.0	30–50 nm	Al, Zr	13
M nano anatase	239.0	71 nm	Al, Si, P	12
N nano anatase	190.0	92 nm	Al, Si, P	20
O rutile normal	12.5	250 nm	Al, Si, P	3.5

oxygen consumption during irradiation of the medium in the presence of the titania particles [30]. The hydroxyl content relates to the concentration of hydroxyl functionalities present on the pigment particles and is often related to activity [31]. The data for both tests are compared in Figure 2.12. There are a number of correlations and trends within the data. First, all the nanoparticle grades exhibit higher photoactivities than the pigmentary grades. Thus, for oxygen consumption the anatase A is more active than the rutile types B and D, the last being the least active and most

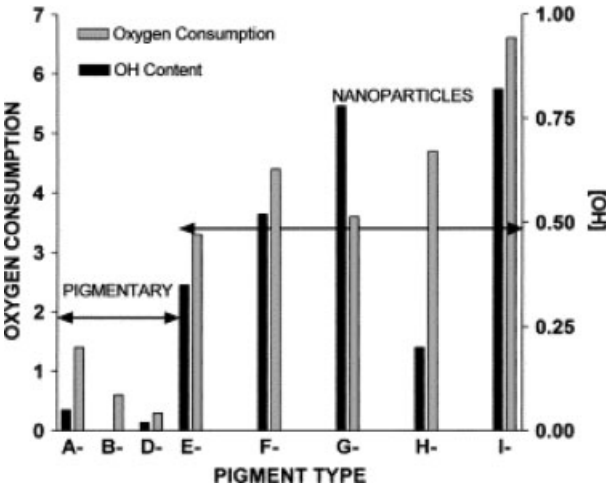

Figure 2.12 Comparison of hydroxyl content and oxygen consumption rates for 2-propanol oxidation with pigmentary and nanoparticle titanium dioxide.

durable pigment. Second, of the nanoparticles the rutile grade I is the most active in both tests. The three anatase grades E, F and G exhibit increasing activity with hydroxyl content whereas for oxygen consumption F is the greater. It is nevertheless clear from the data that nanoparticulates are significantly more active.

Environmental issues play an important role in the applications of titania fillers. These include the use of their photocatalytic behavior in the development of self-cleaning surfaces for buildings, i.e. antisoiling and antifungal growth and VOC/NO_x reduction (emissions). The latter can cause lung damage by lowering resistance to diseases such as influenza and pneumonia whereas in combination with VOCs it produces smog and contributes to acid rain, causing damage to buildings. From a commercial point of view, such benefits have enormous implications. Japanese scientists [32] have been actively exploiting the development of a variety of materials and a number of European ventures have followed suit, most notably in Italy, with Global Engineering and Millennium Chemicals as examples, and the European-funded PICADA Consortium [33]. Here, developments range from self-cleaning and depolluting surfaces and facades based on nano-titania activated coatings and cementitious materials. These applications include antisoiling, depollution of VOCs and NO_x contaminants and antifungal/microbial activities. Numerous reports have appeared in newspapers and magazine articles highlighting such applications, e.g. self-cleaning paving and building blocks and facades that can also depollute the surrounding atmosphere, internal coatings and paints for sanitization and elimination of MRSA and also, for example, clothes and textiles that supposedly never need cleaning (although in many cases this is undoubtedly an exaggeration and was promoted for public awareness of the potential). The cements are normally loaded up to 3% w/w for optimum activation and cost efficiency.

2.5
Self-Cleaning Effects: Paints/Cementitious Materials

The relative photoactivities of the nanoparticles and pigments may be compared by measuring their influence in the first instance, on the durability for example, of an 18% w/w PVC-based alkyd paint matrix. Mass loss and gloss loss are the two industrial parameters often used and the former is compared in Figure 2.13 for the range of pigments and nanoparticles given here. These results clearly show that photoactivity is divided into two main trends. For mass loss, all four nanoparticle anatase pigments are the most photoactive. The rutile pigments B and D and the anatase pigment A exhibit similar activity to that of the nanoparticle rutile grade I.

In terms of self-cleaning, this can be described in a number of formats. For cementitious materials this would imply a surface which under light activation would have the ability continuously to destroy or "burn off" by oxidation the surface dirt layers, whether they be carbonaceous, oil or soil. This can be clearly seen visually in some of the commercial trials undertaken by Millennium Chemicals in tunnels in Italy (in conjunction with Global Engineering, Milan). The photocatalytic activity of Eco-cements can be measured by, for example, determining the fading rate of an

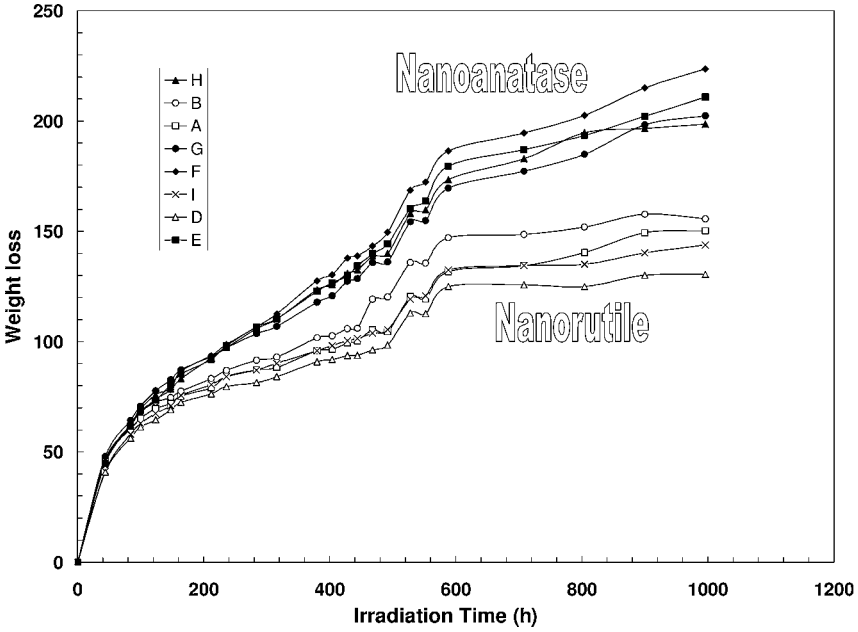

Figure 2.13 Weight loss (mg per 100 cm^2) of PVC alkyd paint films during irradiation in an Atlas Weatherometer containing equivalent amounts of titania pigments.

impregnated dye such as Rhodamine B. This is illustrated in Figure 2.14, where over a given period of light exposure the cement with photocatalyst exhibits a rapid dye fade compared with the undoped material. In reality, this is further illustrated by the photographs of real trials in Milan (shown in Figure 2.15), where the photocatalytic cement remains clean after a period of use compared with that for undoped cement.

For paints and coatings, the idea is to limit the oxidation and chalking of the paint film to the very near surface layers such that over time with weathering rain water will

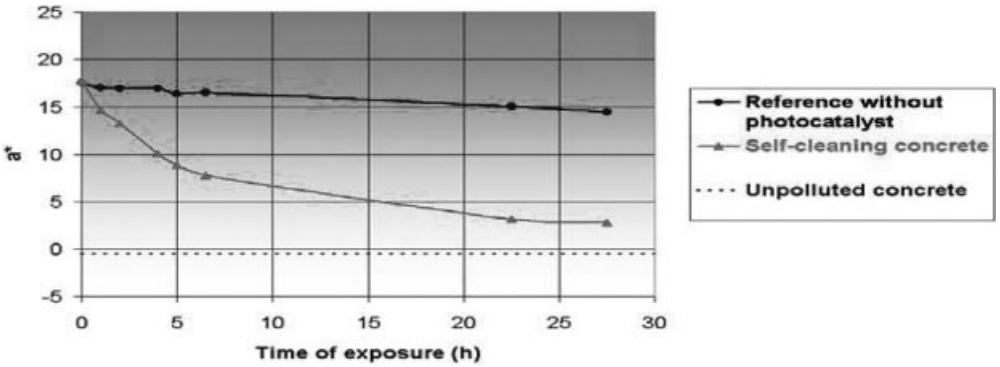

Figure 2.14 Fading rate of Rhodamine B dye impregnated into concrete with and without titania photocatalyst.

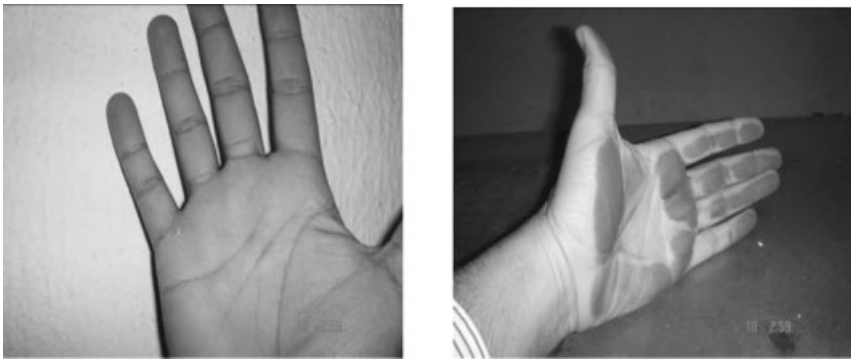

Figure 2.15 Cementitious materials with and without photocatalyst in a motorway tunnel in Italy after 3 months of exposure.

wash the top layer, leaving an underlying clean, fresh surface. The other is like the cementitious materials the surface deposits are oxidized or "burnt off" leaving the surface layer clean. In the former case it is important that the coating exhibits high durability for a reasonably cost-effective stable system. Also, the paints chosen must be stable to flocculation and viscosity changes, cure or dry at ambient temperature and ideally be water based to avoid further environmental problems. Most polymers are carbon based and are unlikely to be photo-resistant, but water-based acrylic latex paints have been evaluated. In the first instance four types of acrylic water-based paints were evaluated in terms of relative stability toward photoactive nanoparticles. Here a special sol–gel grade of anatase was prepared in the laboratory with no post-firing. Particles of varying sizes were also prepared via this route. The relative paint stabilities with and without the anatase sol particles (10–20 nm) at 5% w/w after 567 hours of weathering are shown in Table 2.6. Of these paint formulations, only the polysiloxane BS45 (Wacker) proved to be resistant to the photocatalytic effects of the titania particles. The styrene–acrylic, poly(vinyl acetate) and acrylic copolymers all showed high degrees of chalking (weight loss).

Table 2.6 Weight loss for paints after 567 h of Atlas exposure: various polymers plus 5% anatase sol particles, 10–20 nm.

Paint composition	Weight loss (%)
Styrene acrylic	12.2
Styrene acrylic + anatase sol	97.3
PVA copolymer	11.4
PVA copolymer + anatase sol	97.9
Acrylic copolymer	7.4
Acrylic copolymer + anatase sol	101.0
Polysiloxane BS45	23.3
Polysiloxane BS45 + anatase sol	13.6

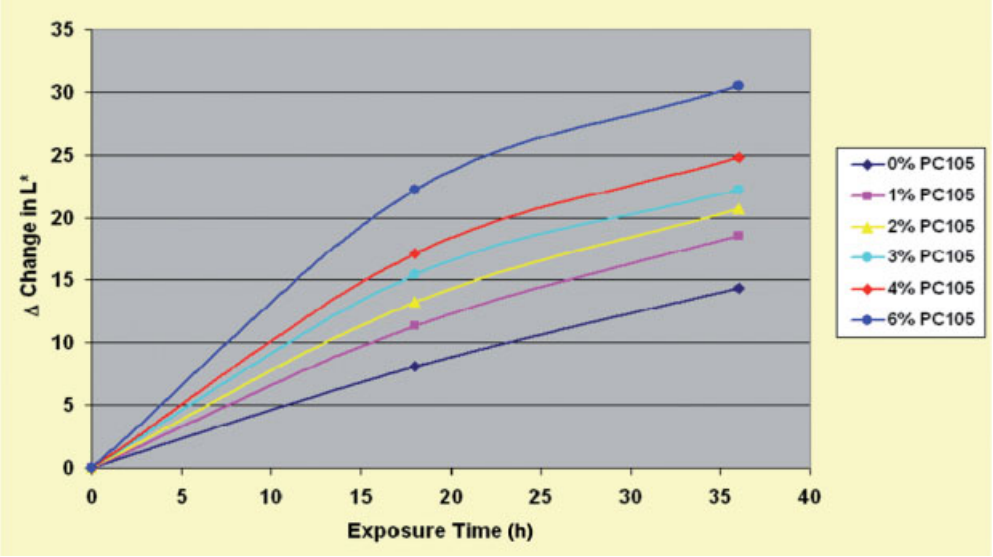

Figure 2.16 Change in color difference factor L* with exposure time for methylene blue-impregnated silicate paint films with increasing nanoparticle titanium dioxide PC105.

From the point of view of surface cleaning, paint films can also be impregnated (like cement) with dyes and fading rates measured. Aside from organic-based paints, a number of inorganic paints are commercially available, a number made from complex alkali metal silicates. Because of their inorganic nature, they tend to be significantly light stable. An example of the self-cleaning effect of a typical silicate-based paint is demonstrated by the fading data on methylene blue dye in Figure 2.16. It is seen that photobleaching of the dye occurs more rapidly in film with photocatalyst than an undyed (undoped) film and that this increases with increasing concentration of PC105 nanoparticles.

Another method used potentially to enhance the durability of a substrate while simultaneously controlling photocatalytic activity is to dope the paints with mixtures of durable and catalytically active grades of titanium dioxide. In this regard, mixtures of pigmentary rutile O and nanoparticle anatase F pigments appear to provide one interesting illustration option, with the former inducing some level of base stability while the presence of the latter gives rise to surface activity. Figures 2.17 and 2.18 illustrate this effect for a siliconized polyester coating exposed in a QUV weatherometer for gloss and mass loss, respectively. Gloss loss is seen to be gradually reduced with time the effect increasing with increasing loading of anatase nanoparticle F. Mass loss is also seen to increase gradually with increasing levels of the same nanoparticle. In this case, it is evident that only low levels of shedding/chalking occur with time such that the paint film retains some level of durability except for the very near surface layer.

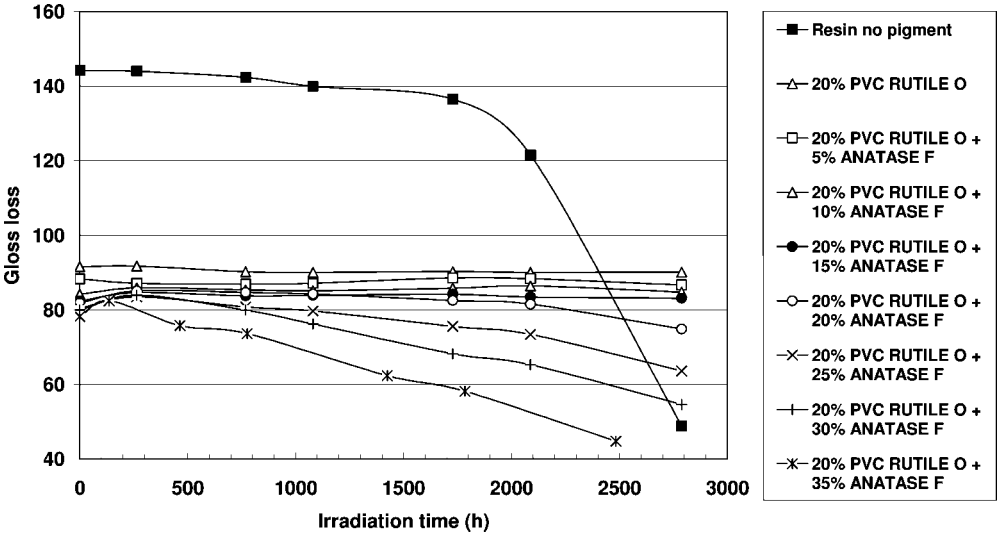

Figure 2.17 Gloss loss versus irradiation time in a QUV weatherometer for a DSM siliconized polyester resin with 20% w/w rutile pigment O plus increasing levels of 5, 10, 15, 20, 25, 30 and 35% w/w of nanoparticle anatase F.

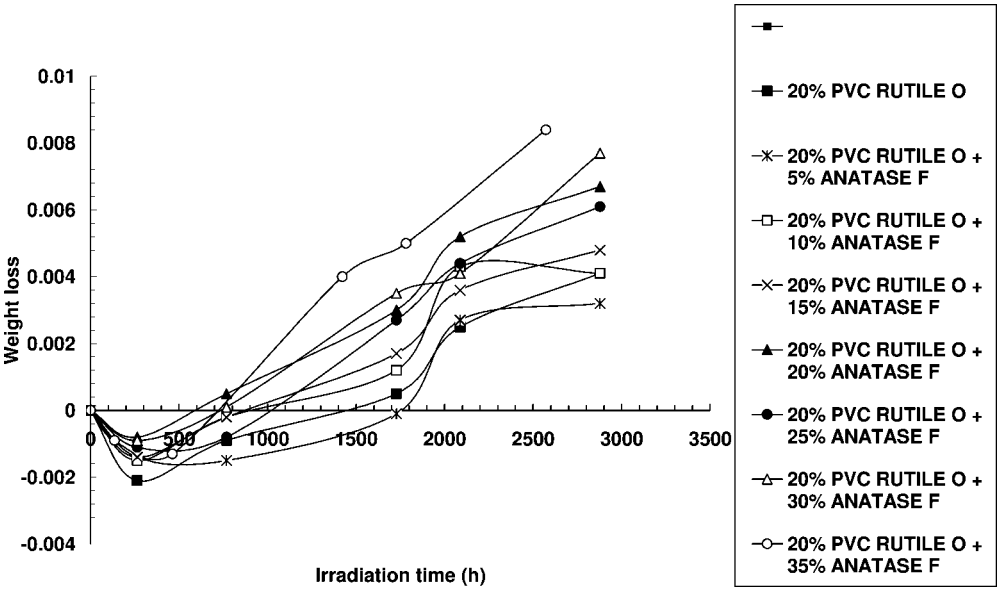

Figure 2.18 Mass loss versus irradiation time in a QUV weatherometer for a DSM siliconized polyester resin with 20% w/w rutile pigment O plus increasing levels of 5, 10, 15, 20, 25, 30 and 35% w/w of nanoparticle anatase F.

Table 2.7 Weight loss for Lumiflon paint pigmented with RCL-696/nano-TiO_2 after 546 h of Atlas exposure.

Nano-TiO_2	Pigmentary TiO_2	Weight loss (%)
10 wt.% PC500	RCL-696	19.0
20 wt.% PC500	RCL-696	66.5
10 wt.% PC105	RCL-696	31.0
20 wt.% PC105	RCL-696	62.8

20 wt.% AT1	RCL-696	43.2
20 wt.% PC500	None	97.6
20 wt.% PC105	None	128.7
20 wt.% PC50	None	121.4
20 wt.% Showa Denko	None	146.8
20 wt.% AT1	None	138.7
None	RCL-696	4.7
Clear resin blank	None	5.4

A similar but perhaps more extreme effect is shown in Table 2.7 for a Lumiflon fluorinated acrylic paint film. At 10 and 20% concentrations of the nanoparticles G, F, E and H, chalking is fairly high, whereas the pigmentary rutile O at 20% w/w only gives a 4.7 mass loss value. The pigmentary uncoated anatase A is also an option, giving high levels of chalking at 10 and 20% w/w. Thus, control of pigment type and particle size in addition to their concentrations is a critical area of development for effective self-cleanable paint surfaces, the effect varying also with the paint formulation. In this regard, coatings could effectively be developed to suit a particular type of environment.

2.5.1 Antibacterial Effect

The ability of the nanoparticles to destroy bacteria and fungi has also been actively pursued and some data from our laboratories are demonstrated. The type of photocatalytic medium, nanoparticle and bacteria/fungi all play an intimate key role in performance. There are a number of tests one can apply [34–36], the simplest evaluation being the typical zone of inhibition on agar plates where the growth of bacteria is measured around a paint film. *Staphylococcus aureus* growth is shown on agar plates in Figure 2.19 for typical silicate paint films with and without PC105 nanoparticles. On the right-hand picture plate a clear zone of inhibition is seen to develop compared with that for the undoped film.

Similar tests have also been undertaken in our laboratories on titanium dioxide powders. Here *E. coli* were used where their destruction (measured in terms of

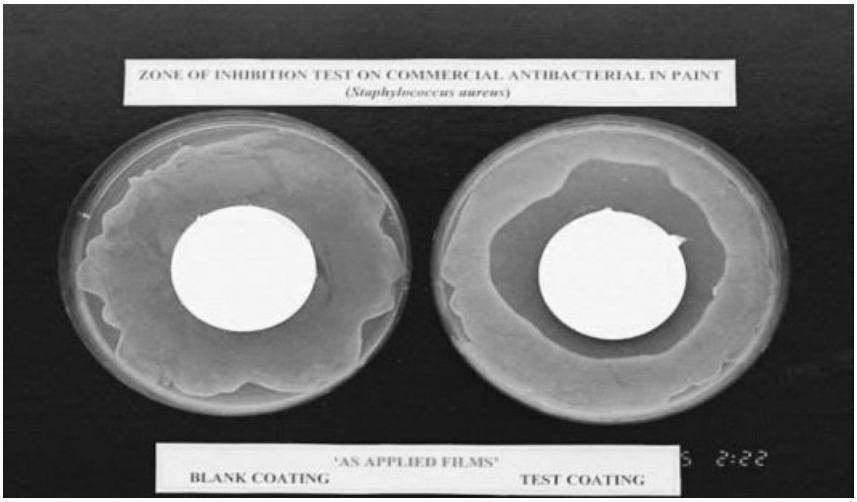

Figure 2.19 A typical antibacterial evaluation on an agar plate medium for Eco-paint films with and without nanoparticulate photocatalyst titania.

colony-forming units) after irradiation with UV light in the presence of the titania particles is plotted against irradiation time. A study on the range of titania powders showed (Figure 2.20) that there was an inverse relationship between antibacterial activity and particle size: for the pigment powders, pigment E > H > F > G = A, with a

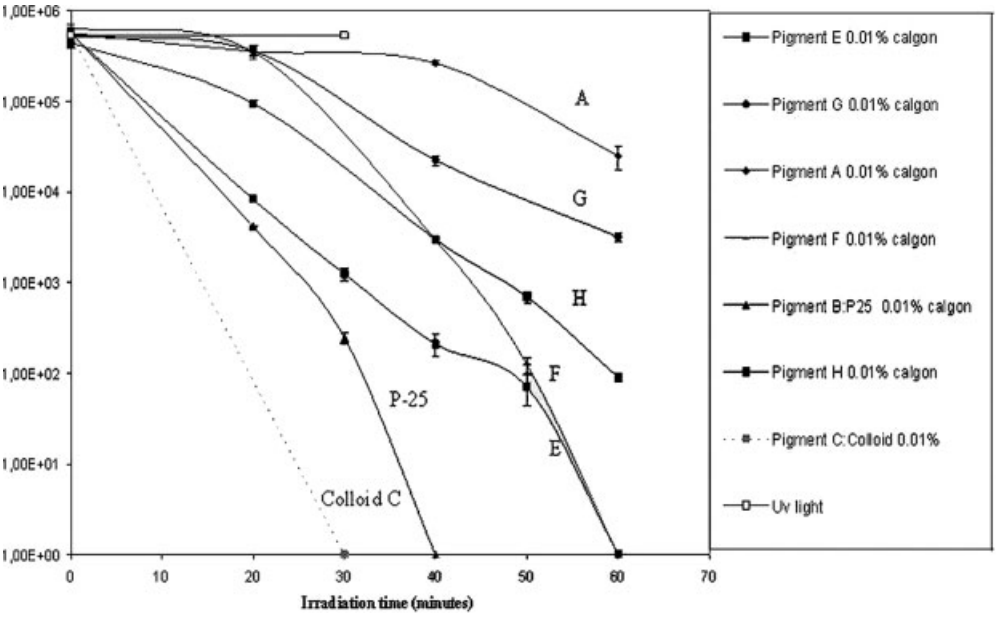

Figure 2.20 Photocatalytic bactericidal effect of pigments A, B, E, F, G and H powders and C (colloid) at 0.01% in stirred conditions, using unwashed cell suspensions.

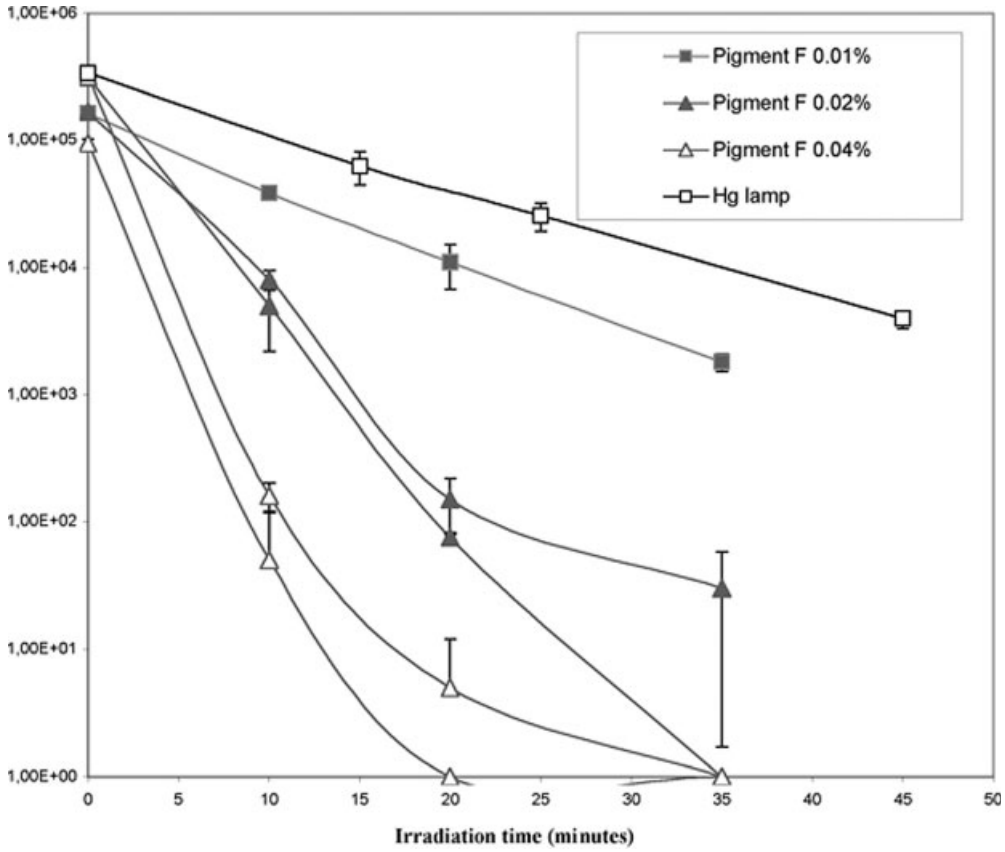

Figure 2.21 Effect of concentration of pigment F on photocatalytic bactericidal effect.

sol–gel colloid dispersion C and Degussa P25 having the greatest effects. However, the experimental conditions used provided some confounding factors which required clarification in order to identify the best experimental method and the most effective pigments in terms of antibacterial activity, as mentioned previously. Here the particles were dispersed in a Calgon medium and this evidently reduced activity on the plate.

In general, the antimicrobial effect increased with increasing concentration of nanoparticles (Figure 2.21) up to 0.04%. In the absence of any dispersion effect, the activity of the nanoparticle E was comparable to that of the Degussa P25, followed by F and G and with little difference between A, H and D and the mercury lamp control (Figure 2.22). Similar results were observed at 0.02% in our work. For the nanopigments E, F and G, a further enhanced effect was noted at 0.1%, but the effect of P25 was reduced.

The enhanced activity of C over its derivative pigment G was lost when C was dried and ground (Figure 2.23). This finding demonstrates that the drying process has a

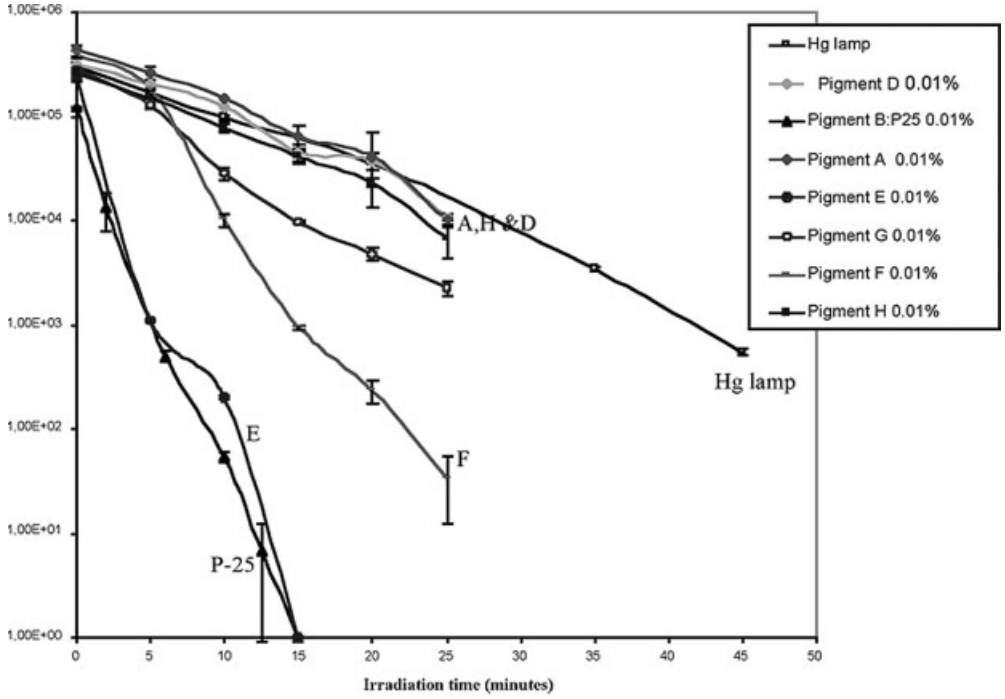

Figure 2.22 Photocatalytic bactericidal effect of pigments A, B D, E, F, G and H at 0.01%, using washed cell suspensions.

marked effect on activity, due to a decrease in surface area during aggregation and to a decrease in dispersion stability in water.

Pigment E has the most reactive surface because it has fewer defects, which increases the efficiency of the photogenerated radicals form our microwave analysis [33]. Thus pigments calcined at higher temperatures (E > F > G) have better crystallinity and therefore higher antibacterial activities.

The UV light itself has little effect on the bacteria; the pigmentary grade of anatase A has a small effect whereas the nanoparticle G has a somewhat greater effect. However, the most interesting feature of these data is the very high destructive effect of the mixed phase nanoparticle grade made by Degussa (P25). This nanoparticle grade of titania is well established is the literature in terms of its high photoactivity [32]. In this work, a grade of nanoparticle anatase G was prepared in the laboratory whereby the particles were seeded form solution and then dried but not subsequently oven fired. This so-called washed form of titania is seen in the data to be higher in activity than that of the Degussa material. This effect is currently being investigated further in terms of hydroxyl content and hydrogen peroxide generation.

The overall effect of activity will depend on whether more TiO_2 is activated as a consequence of increased surface area or whether less TiO_2 is activated because less light passes through the suspension due to light scattering. Larger aggregates of particles sediment in a liquid system and an increased concentration of pigments

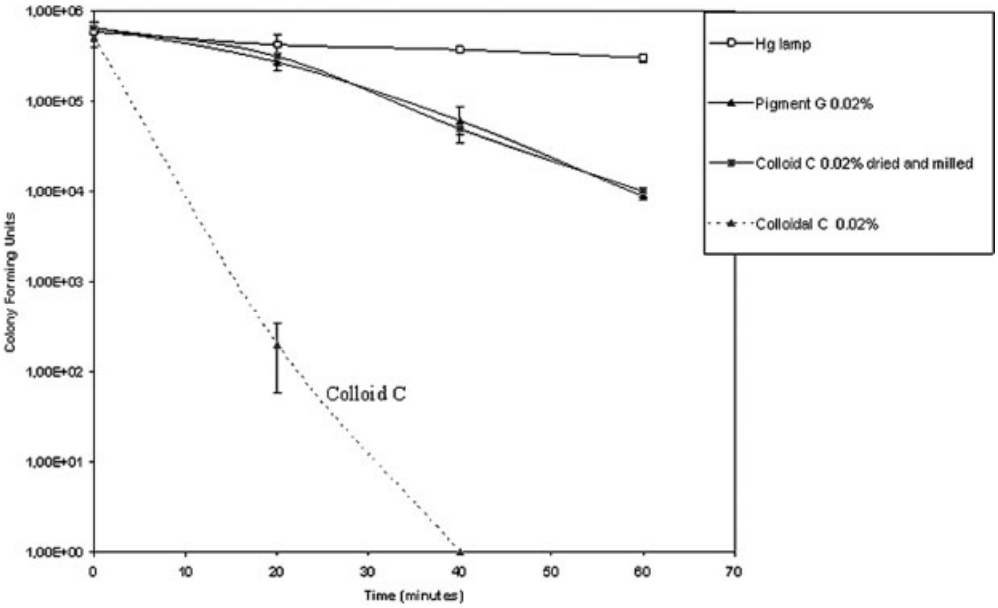

Figure 2.23 Photocatalytic bactericidal effect for C colloid suspension, C dried and milled and pigment G powder (unstirred).

shows less of an antimicrobial effect since less light passes through the suspension if the cell–particle mixture is not stirred. Conversely, Calgon milled pigments, which are nanometer sized, also scatter light significantly at high concentrations and decrease activity (optimum loading 0.01%), hence the optimum activity is presented by nanoparticle powder aggregates in this work. The most important aspect to consider in terms of antibacterial inactivation is the relative sizes of the titanium particles/aggregates and the bacterial cell. *E. coli* measures approximately $1 \times 3\ \mu m$; a benzene molecule is $0.00043\ \mu m$. The porosity of the pigment has no bearing on the antimicrobial effect, whereas the chemical pollutant can diffuse into the porous particle structure. Thus, the higher surface area of pigment G did not enhance any antibacterial effect. It has been verified using a disc centrifuge in our study that the three nanoparticulate powder pigments E, F and G were aggregated into $0.7\ \mu m$ particles. In this case, they would all offer comparable active areas to bacteria. Only the inherent ability of the pigments to generate radicals will affect antibacterial activity. Hence the process is more sensitive to structure (crystallinity) than to texture (surface area) and follows a clear inverse relationship with particle surface area.

2.5.2
Depollution: NO_x/VOC Removal

The ability of photocatalytic surfaces to depollute the surrounding atmosphere with a certain radius has been well documented recently in the literature [32, 33, 36].

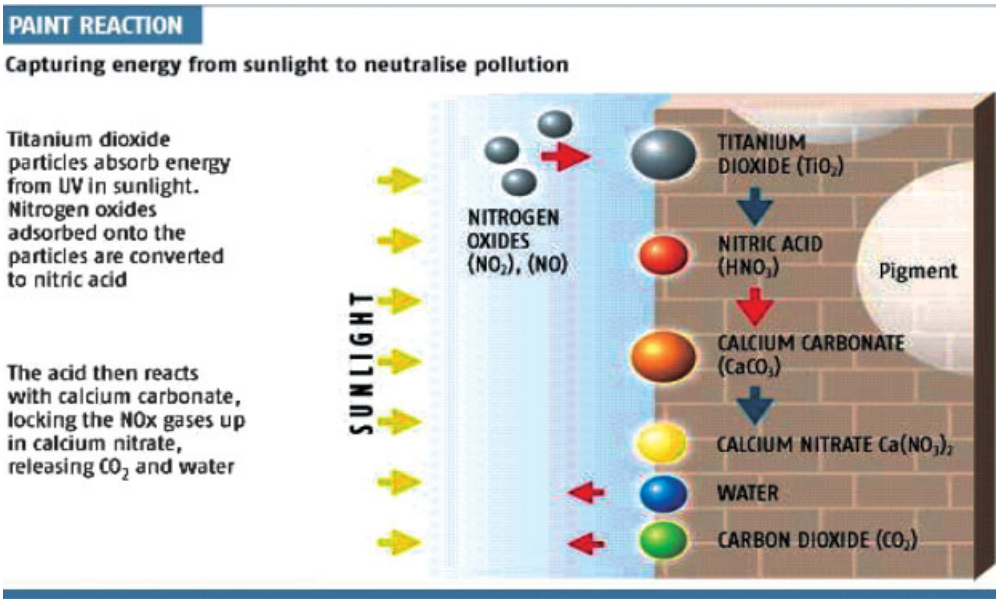

Figure 2.24 Depollution scheme for photocatalytic paints and surfaces.

Japanese scientists have been particularly prolific in this area for some time now. In this part of the research work it was important to be able to develop coatings and cementitious materials that remove NO_x, SO_2, VOCs and potentially ozone especially in areas where such contamination is likely to be above recommended standards. Examples include motorway tunnels, underground car parks, busy highways, chemical factories and city dwellings such as schools. A pictorial representation of the key mechanistic features of the depolluting paint coatings is illustrated in Figure 2.24.

The materials should in this regard be durable and show little or no loss in activity with aging, in addition to having the ability to inactivate nitric acid reaction products. Also, as above it should be self-cleaning. The coating may also, in some cases, need to be translucent so that existing coatings or stonework can be over-coated without any change in appearance. To some extent the coating must be photo-resistant to the effects of the nano-TiO_2 and would probably need to be porous to allow contact between the TiO_2 surface and the gaseous pollutants. Nano-TiO_2 is an excellent scatterer of light and if the coating is porous this further increases light scatter. Some potential problems in the design of such coatings have been circumvented in our laboratories, such as poor adhesion and poor durability. Also, the nitric acid formed in the reaction could damage the substrate or poison the catalytic reaction. A suitable test method was developed to measure the efficacy of the coatings studied via a "Signal" detection system (Figure 2.25).

In the diagram shown, test films of paint are irradiated in a cell through which a standard flow rate of nitrogen is passed with a set concentration of NO_x gases. NO_x

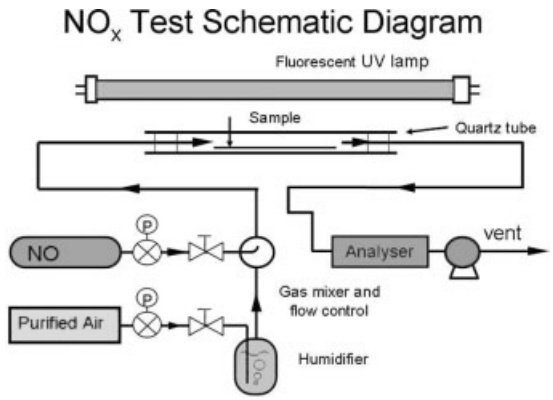

Figure 2.25 Schematic diagram of NO_x gas detection system for irradiated photocatalytic surfaces.

levels are measured via a chemiluminescence detector system before and after irradiation to give a measure of depollution.

Commercial dry nano-TiO_2 products with a range of particle size and surface area were developed with surface areas ranging from 20 to 300 $m^2 g^{-1}$ for evaluation as indicated in Table 2.5. In addition to these, colloidal sol–gel particle media were also developed for easy dispersion. Even with the smallest crystallite size it is difficult to eliminate light scattering at levels above 5% at conventional coatings thickness (25 μm) due to aggregation. With special non-dried sol–gel nano-TiO_2 there is less light scattering because of reduced particle aggregation. It appeared that the coatings had to be porous before there was a significant activity towards gaseous reductions such as NO_x.

From the data in Figures 2.26 and 2.27, the efficacy of NO_x removal increases significantly with both an increase in particle surface area and concentration of nanoparticle titania (anatase) in a polysiloxane paint substrate. Porosity can also be introduced by using materials other than TiO_2 itself. Nanoparticle calcium carbonate offered the possibility of high translucency and the ability to react with nitric acid. The results are confirmed in Figure 2.28, where it is seen that the NO_x is reduced

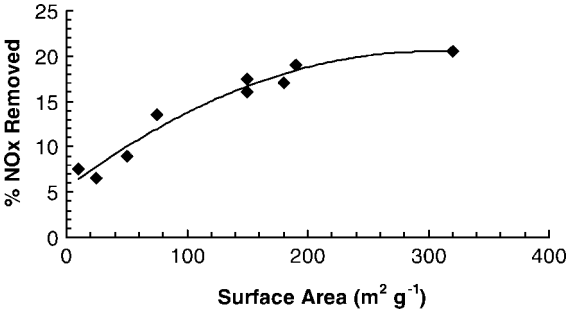

Figure 2.26 Percentage concentration of NO_x removed versus the surface area of anatase sol–gel particles at 5% w/w in a polysiloxane Wacker BS 45 paint system.

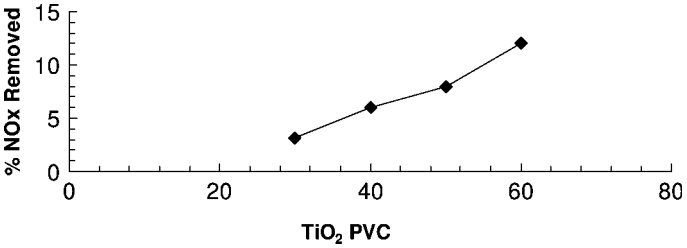

Figure 2.27 Percentage concentration of NO_x removed versus the concentration of anatase sol–gel particles (10–20 nm) at 5% w/w in a polysiloxane Wacker BS 45 paint system.

not only with increasing titania doping but also with increasing levels of calcium carbonate addition.

The most interesting feature of the results however, is the influence of titania and calcium carbonate loading on the extent of degradation of the polysiloxane paint films as measured by percentage weight loss. The data in Figure 2.29 show that in the absence of calcium carbonate the extent of degradation is low, as indicated above, whereas in its presence the rate of degradation increases with concentration from 2.5 to 5.0% w/w. At 10% w/w of titania the extent of degradation is significant in the presence of the calcium carbonate. In this case the access of both moisture and oxygen through the film matrix will be enhanced. Film translucency also decreases with increasing loadings of titania and calcium carbonate particles, as shown by the data on contrast ratio in Figure 2.30.

Measurements on NO_x reductions have also been obtained in terms of NO and NO_2 gases, where it is seen that the rate of NO_x destruction is clearly greater in the presence of the nanoparticles alone whereas the paint matrix gives rise to a barrier effect, as might be expected (Table 2.8, Figure 2.31). Nevertheless, the efficacy of the paint films in destroying the NO_x gases is high. The durability of a paint film in terms of NO_x reduction is also important and this is illustrated by the plot in Figure 2.32 for a typical Eco-silicate paint system. Here the percentage reduction in NO_x ability is reduced by only about 10% and thereafter stabilizes after 12 months.

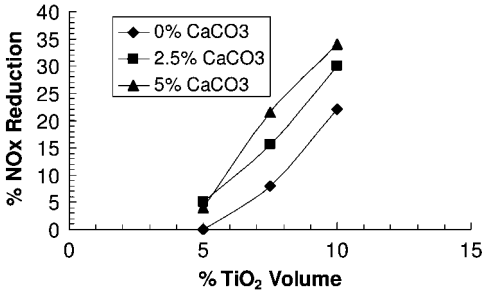

Figure 2.28 Percentage NO_x reduction versus volume of titania (anatase 10–20 nm) for a polysiloxane BS 45 paint substrate with 0, 2.5 and 5.0% w/w of nanoparticle calcium carbonate.

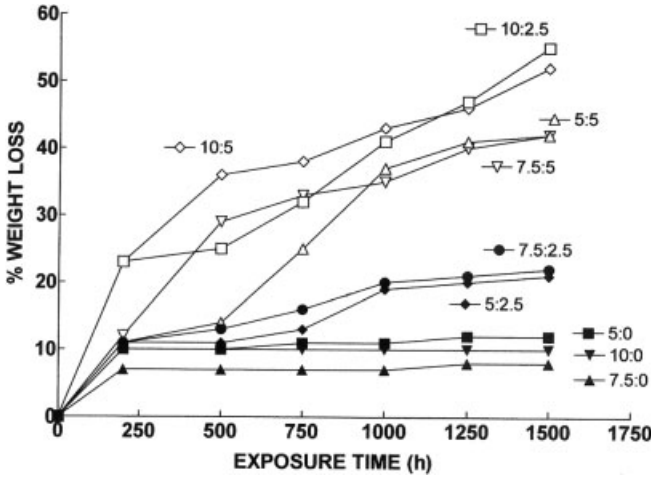

Figure 2.29 Percentage weight loss versus exposure time in an Atlas Ci65 weatherometer for polysiloxane paint films (BS 45) containing different ratios of nanoparticle anatase (10–20 nm) sol–gel titania (5/7.5/10) to calcium carbonate (0/2.5/10) particles.

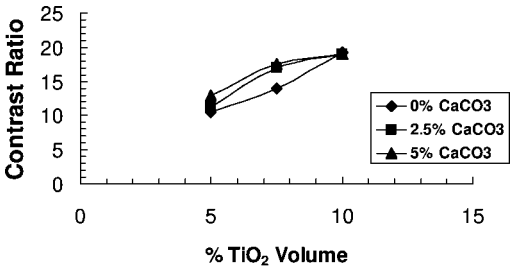

Figure 2.30 Translucency (contrast ratio) for BS 45 paint films with volume addition of sol–gel anatase titania (10–20 nm) particles versus calcium carbonate addition.

Table 2.8 NO_x reduction comparisons for polysiloxane latex with and without titania sol–gel and sol–gel alone using steady-state signal detection apparatus.

Composition	NO_x reduction (%)		NO_x reduction ($\mu g\, m^{-2}\, s^{-1}$)	
	NO	NO_2	NO	NO_2
BS45 latex	0	0	0	0
BS45 latex + 5% sol	84.9	9.3	0.060	0.055
Sol	84.9	55.8	0.320	0.409

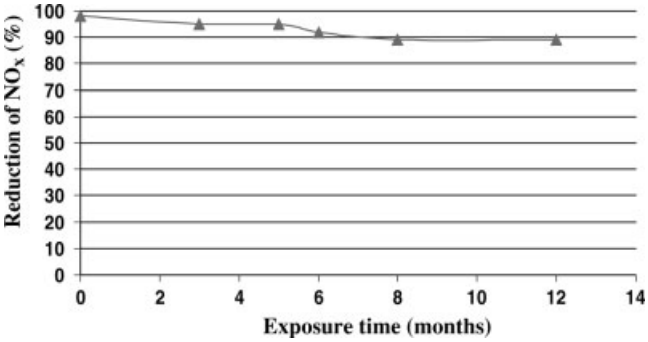

Figure 2.31 Plot of reduction of NO_x versus exposure time.

Another important factor is irradiation power or light flux density. Optimum power appears to be achieved at 0.6 $mW\,cm^{-2}$ of film, as shown in Figure 2.32.

The effectiveness of the Eco-paint and cemetitious materials in terms of depollution in surrounding areas is also important and effectively demonstrated by the tunnel experiment in Figure 2.33. Here one wall is effectively coated with a titania-doped cement whereas the other is undoped. NO_x measurements under stedy-state irradiation show significantly less ppb concentrations for the titania-doped left wall under both actual conditions and also via mathematical modeling experiments. With the same experiment using the Eco-cement coating, VOC reductions can also be measured in relation to the air velocity. The data in Figure 2.34 shows that as the air velocity is reduced so the VOC concentrations are effectively reduced. The benzene being unsubstituted is more difficult to decompose photocatalytically and therefore requires a slower abatement air speed for effective decomposition. The greater the degree of alkyl group substitution, the more effective and easier is the decomposition rate. Alkyl groups are more easily oxidized than benzene rings.

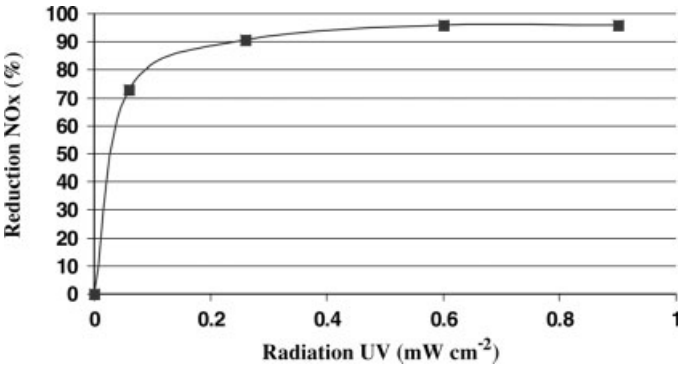

Figure 2.32 Reduction in NO_x with UV radiation intensity for a typical Eco-silicate paint film.

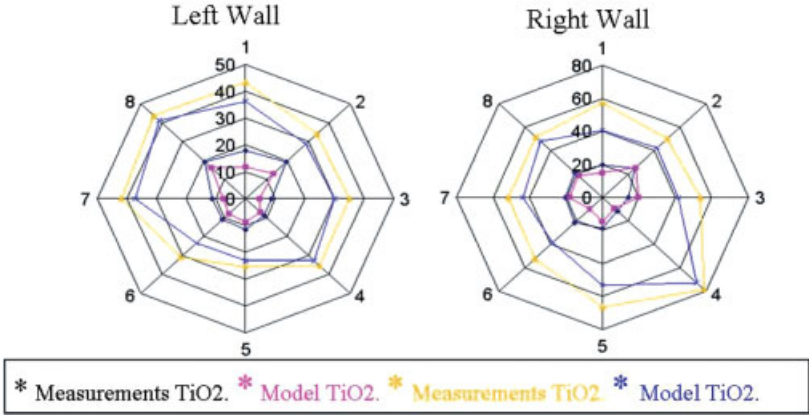

Figure 2.33 NO_x concentrations around a tunnel wall with and without photocatalytic titanium dioxide doping for a cementitious facade. NO_x mean concentrations (ppb) per sector with TiO_2 (period A) and without TiO_2 (period B) for the right wall.

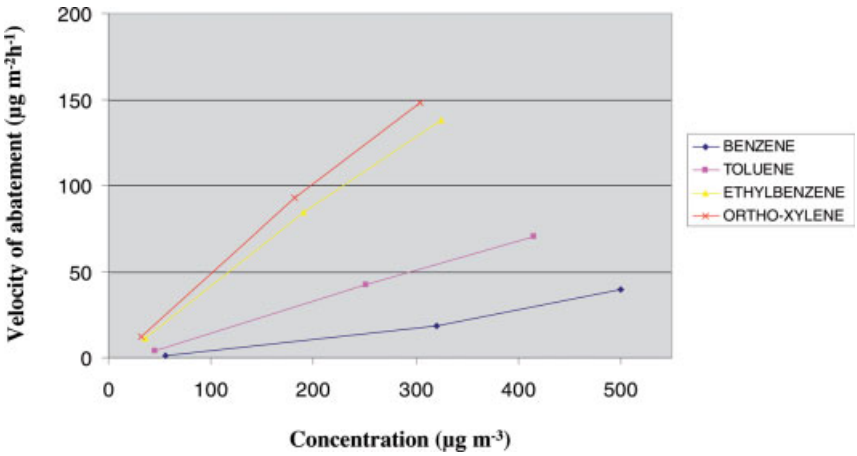

Figure 2.34 Steady-state concentration of aromatics in the vicinity of an Eco-cement wall coating with a change in surrounding air velocity.

2.6 Conclusions

Photo-oxidation studies on paint films show a clear demarcation between nanoparticle and pigmentary grade titanium dioxide, with the former being more active. Model system studies based on 2-propanol oxidation and hydroxyl analysis go some way to predicting pigment activities but precise correlations do not always exist in the real world.

The use of nanoparticle anatase in conjunction with pigmentary rutile grades is also a viable option for the development of self-cleaning paint surfaces. For

antibacterial surfaces nanoparticles are effective, whereas pigmentary grades are ineffective. Highly effective photocatalytic grades of nanoparticles can also be prepared through control of the preparation and subsequent drying operations.

The antibacterial activity of the nanoparticle pigments was inversely proportional to particle size and relates to their intrinsic ability to generate active carriers giving rise to active surface species. Pigments calcined at higher temperatures, consequently with fewer structural defects, are more active, because defects act as recombination centers for the electrons and holes. Hence the antibacterial efficiency of TiO_2 is not determined by surface area but by the ability to generate active carriers, resulting eventually in the formation of effective chemical species such as peroxides (hydrogen peroxide). This is not surprising because of the size of bacteria relative to the pigments: the majority of the surface area offered by a pigment is sterically unavailable to the bacterial cells. In terms of future building developments, especially in the medical world, this would offer significant advantages for eliminating the potential of MRSA.

The paint coatings are also active to NO_x and VOCs, particularly once UV irradiated, with high levels of TiO_2 and $CaCO_3$ enhancing activity. This effect is associated with increased porosity of the paint system induced by both the titania and calcium carbonate particles. Unfortunately, higher levels of TiO_2 and $CaCO_3$ impart lower durability to the paint matrix. Higher levels of TiO_2 and $CaCO_3$ also reduce the translucency of the paint films, thus increasing absorptivity. On a positive note, higher levels of $CaCO_3$ would react with more HNO_3.

Photocatalytic cementitious materials offer significant advantages from an environmental point of view on all issues associated with long-term activity, durability, self-cleaning and depollution of NO_x and VOCs.

Acknowledgment

The authors would like to thank the PICADA consortium Global Engineering, Milan, Italy for the use of some of the data in this chapter.

3
Nanosized Photocatalysts in Environmental Remediation

Jess P. Wilcoxon and Billie L. Abrams

3.1
Introduction

3.1.1
Global Issues

Modern industrial economies have developed approaches to manufacturing, utilization and disposal of chemical and biochemical products which have inflicted considerable damage on our air and water environments. As such, advances in technology, medicine, mining, transportation, agricultural practices and military practices have not come without a price. Although the quality of human life has benefited in many ways from advances in these areas, the anthropogenic impact on the aquatic and terrestrial biosphere has been substantial, leading to pollution of the world's drinking water, soils and air. Unfortunately, the adverse anthropogenic effects on the environment are increasing [1]. This poses an undeniable threat to the ecosystem, biodiversity and ultimately human health and life.

Industry produces an estimated 300 million tons of synthetic compounds annually, a large percentage of which ends up as environmental pollutants [2]. As of 2001, approximately 100 000 metric tons of chemicals were released into surface waters and more than 720 000 metric tons were released into the atmosphere [3]. Table 3.1 shows the 2001 toxic release inventory (TRI) figures [3]. The numbers specifically for surface water and air pollution have not changed significantly for the 2004 TRI [4, 5]. However, as of the 2004 TRI, the total amount (including underground injection, landfills and wastewater) of toxic chemical released into the environment as a result of industrial practices stands at over 1.9 million metric tons [4, 5].

Accidental oil and gas spills on the order of 0.4 million tons have also resulted in significant damage to the aquatic ecosystem [2]. In the Niger Delta alone, more than 6800 spills have been documented (approximately one spill per day for the past 25 years); however the real number is thought to be much higher [6].

Historically, environmental protection regulations were lax, which encouraged disposal of many chemicals in landfills, with little documentation of the types and amounts of chemicals present. The worst of these sites became Superfund sites, requiring billions of dollars of expenditure to treat using existing technologies. These Superfund sites in the USA arose mainly as a result of industrial waste spills, abandoned mines, landfills and contamination of groundwater and soil due to abandonment of environmentally hazardous or controlled areas [7, 8]. As of the most recent US Environmental Protection Agency (EPA) release, there are more than 1600 Superfund sites across the USA [7]. The average cost of cleaning up one of these

sites is on the order of $25 million [8]. These Superfund sites are only a small sampling exemplifying the extent of pollution in the USA. The Department of Energy (DOE) along with other US government agencies are also responsible for billions of cubic meters of toxic contaminants affecting groundwater and soil [8]. Along these lines, the US military stock piles contain approximately 3×10^8 kg of munitions waste [9]. Generally these munitions wastes, such as RDX and HMX (hexahydro-1,3,4-trinitro-1,3,5-triazine and octahydro-1,3,5,7-tetratrinitro-1,3,5,7-tetrazocine, respectively), are difficult to break down and thus linger in soil and groundwater, posing significant health threats [9].

Agricultural activities also contribute to environmental contamination since they rely on nitrogen- and phosphorus-based compounds for crop fertilization. They also employ herbicides and pesticides to control weed and insect damage and to improve crop yields. The run off from these activities contaminates aquifers used for human water supply, damage coral reefs and contribute to algal blooms in costal areas and inland water bodies.

From the above discussion, it is evident that the impact of pollution by humans on the biosphere is extensive and perhaps overwhelming. However, as the scientific community assesses the problem(s) at hand, new approaches to remediation will emerge. This chapter outlines one possible approach to dealing with water and air pollution: photocatalysis, specifically using nanosized semiconductors. It is by no means an all-encompassing solution since there is no single approach that can address the problems noted above. However, it has a lot of potential in several specialized areas, especially where visible light illumination, a free energy source, can be utilized.

3.1.2 Scope

Since the topic of environmental remediation has been a focus in the scientific community for many decades, there are numerous reviews in this field. For a broader scope in the general field of environmental remediation, we refer the reader to some of these publications [2, 3, 10–12]. This is just a small sampling of the literature in this field and should not be regarded as a complete list.

Heterogeneous photocatalysis of pollutants is just one approach to environmental remediation and has also been reviewed by numerous authors [13–17]. TiO_2 has been the standard material for photocatalysis since its initial use in the photoelectrocatalytic generation of hydrogen reported by Fujishima and Honda in 1972 [18]. Since this time, the field of photocatalysis has grown significantly and over 2000 papers have been published [13, 17].

In recent years, with the avid interest in nanomaterials, there is also extensive literature addressing the effects of size on photocatalytic behavior [13, 14, 16, 17, 19–35]. There is good evidence showing that size effects play a role in photocatalysis. Accompanying a decrease in size is the increase in surface area with subsequent changes in surface chemistry, both of which are critical in photocatalysis. Most of the studies on nanosized photocatalysis for environmental remediation use TiO_2

as the photocatalyst material. However, different conclusions are often obtained because of differences in photocatalyst preparation, size determination and reaction rate methodologies used by various groups. There are large variations between findings where some groups claim enhancement in photocatalytic activity as a function of size and others claim the opposite.

With so many complete reviews in the field, it is difficult to present very new information to guide people in the field. However, we can present alternative perspectives that may aid in the thought processes needed to solve problems involving the search for new materials to enhance photocatalytic efficiency. Therefore, in this chapter, we focus on some important aspects relating the physical and chemical properties of nanoparticles to their photocatalytic behavior. Also, since most reviews in this field focus on TiO_2 as the photocatalyst, we will include detailed discussion of novel photocatalysts such as MoS_2 and other dichalcogenides, while discussing TiO_2 in a selective and critical manner.

Our technological focus concerns the application of nanosized photocatalysts in environmental remediation. Photocatalysis, the light-driven oxidation of organic and inorganic pollutants, can be an effective approach for the treatment of dilute, large-volume chemical contamination since visible sunlight is the most inexpensive and largest energy source available on the planet. Hence the limiting factor in this remediation method is the development of robust, inexpensive, environmentally benign photocatalysts.

This chapter emphasizes the key approaches to photocatalyst synthesis and characterization and the most salient research issues for the future. Following a review of the general field of environmental remediation, we give a historical background of the field with emphasis on the properties of titanium dioxide, since studies of the photophysical properties of this material have dominated the literature.

We then discuss selected photocatalysis studies and research findings associated with TiO_2. We next discuss research concerning layered semiconductors such as MoS_2 as photocatalysts. The ability to adjust the absorption onset and redox potential with size and surface chemistry in nanosized materials provide new opportunities in photocatalysis. Finally, we give examples of recent technical applications of TiO_2 semiconductors such as self-cleaning tiles and windows enabled by scientific research on TiO_2 photocatalysis.

3.2 General Field of Environmental Remediation

The best way to treat the pollution problem is to use conservation and preventive measures such as recycling to limit emissions into air and water sources. Steps are already being taken by industry to limit their emissions through optimization of manufacturing practices in addition to recycling and regeneration of chemicals, which also lead to economic savings in the long run [36]. Governments have also initiated legislation putting constraints on the permissible emissions. However, the fact remains that there is an abundance of toxic pollutants present in our water

systems, soil and air. As such, the challenge for environmental remediation is substantial.

Scientific and technical methods to mitigate environmental pollution rely on many approaches and vary for the cases of soil, water and air purification. The remediation approach chosen depends on the complexity and nature of the contaminated media and economic costs of the treatment. Often there are limited acceptable treatment approaches, as is the case with DDT contamination of sediments off the coast of California. Mixed wastes consisting of both radiological and chemical toxins are especially difficult and costly to separate and treat. The lack of documentation of the types and amounts of chemicals in many waste sites makes the remediation process especially costly.

The most common environmental remediation techniques traditionally used to treat large volumes of water intended for municipal water supplies include carbon adsorption, air stripping, oxidation through ozonation or chlorination and incineration, ultrafiltration and sedimentation [13, 34, 35]. These approaches are generally used for large-scale pollutant removal. The main drawbacks of these techniques are that most of them are transfer methods, where the pollutant is moved from one place to another or transformed from one phase to another. Activated carbon adsorption is a common and generally effective way to capture both airborne [such as volatile organic compounds (VOCs)] and waterborne contaminants. However, disposal of the saturated carbon is an issue [13].

On a smaller scale, water purifiers for home use utilize activated carbon absorbents to remove organic contaminants at the point-of-use. This point-of-use application is especially useful for rural locations lacking central waste treatment facilities. However, disposal of the concentrated activated carbon in a safe manner is still problematic.

Air stripping involves the removal of VOCs from wastewater, converting the pollutant from waterborne to airborne, necessitating the treatment of the resulting gaseous products. Outside Western countries, air stripping is often used to dilute airborne contaminants from industrial waste effluents. However, this approach again simply transfers the pollution problem from the liquid phase to the gas phase without destroying the chemical and is therefore banned in Western countries [13].

If this stripping process is accompanied by adsorption of the stripped pollutants and photocatalytic oxidation using a high surface area mesh containing a photocatalyst and a light source, the process is still very useful. Such an approach is being implemented commercially in Japan, as discussed in a later section.

Some of the other techniques such as incineration do lead to partial mineralization of the pollutants; however, they require high temperatures and again can result in unwanted gaseous by-products. Oxidation and chlorination are usually not capable of mineralizing all types of organic wastes completely. These techniques often lead to the formation of secondary pollutants, which can be just as toxic as the original pollutant.

Biological degradation processes in the presence of natural sunlight is an inexpensive, common route to degradation of certain noxious materials. The process is sometimes called the activated sludge process and relies primarily on bacteria [13]. It

is somewhat slow and efficient only at low toxin levels. It also requires that pH and temperature levels be controlled for the health of the bacteria. Also, many toxic chemicals, especially herbicides and pesticides, have low solubility in water and these pollutants are found primarily in sediments where sunlight does not penetrate. Therefore, although pesticides such as DDT have been banned in Western countries for decades, they are still ubiquitous in riparian and coastal environments.

Chlorination is a good process for killing viruses and bacteria; however, side chlorination reactions with organics present in the water may produce chlorinated species which are known to be carcinogens. In the presence of nitrates the chlorination efficiency decreases and nitrates are fairly common in many water sources.

Complete mineralization of organic pollutants is necessary and can be achieved by advanced oxidation processes (AOPs). This terminology is used to describe a group of photochemical techniques that lead to rapid and complete mineralization of a variety of organic compounds [13, 27, 37]. These techniques include UV ozonation, UV peroxidation (using H_2O_2) and heterogeneous photocatalysis. Use of ozone as an oxidant and disinfecting chemical is effective but can also produce unwanted by-products such as bromate ions, which are suspected carcinogens. Thus, current research in advanced oxidation techniques has emphasized combining photocatalysis with ozone treatment [38]. Generally, heterogeneous photocatalysis is preferable over the other two processes. It uses air (O_2) as opposed to O_3 or H_2O_2, which are relatively expensive reactants. Also, depending on which photocatalyst is employed, excitation wavelengths are in the near-UV (TiO_2 as photocatalyst) to visible range (sensitized or doped TiO_2, metal dichalcogenides as photocatalyst), whereas O_3 and H_2O_2 require short UV excitation wavelengths. However, all three methods are really only applicable to small-scale waste treatment sites where there is a low concentration of contaminant present. Large-scale waste remediation has yet to be demonstrated for these AOP techniques [13, 37].

Photo-oxidation of organic and biological pollutants can be implemented along with conventional methods using strong oxidants such as ozone and hydrogen peroxide. However, this is really only viable for high pollution levels. Typically, this treatment requires the concomitant use of short-wavelength UV lamps that increases the cost and restricts its application to point-of-use, small volume, water and air treatment. A strong motivation for the development of photocatalysts such as TiO_2 is to decrease economic costs by using at least a small portion of available solar light to photo-oxidize organic chemicals and convert them to harmless by-products in dilute volumes of water and air.

It has been shown that photocatalysts such as titania in combination with oxidants such as peroxide or ozone can also disinfect water by killing pathogens and oxidizing even stable contaminants. At present the costs of this combined advanced oxidation process are too great to be implemented on a large scale, but may be viable in point-of-use applications for smaller volumes in rural settings. Since titanium is the ninth most abundant metal [39] on Earth, the cost of producing titania photocatalysts is not likely to be the limiting factor for its application in environmental remediation.

Heterogeneous photocatalysis has a lot of potential in the field of environmental remediation, mainly due to the prospects of complete pollutant mineralization.

As such, it has been the focus of research for some time, with TiO_2 as the most studied photocatalyst. For economic viability, however, new photocatalysts which can use visible light must be developed. Even the UV efficiency of the best TiO_2 photocatalysts in water is only around 4%, which is too low to be economically competitive with existing approaches. The efficiency for gas-phase reactions, fortunately, is higher and therefore treatment of air contamination has been the first commercial application of TiO_2 photocatalysts.

Economic considerations in environmental remediation play a pivotal role in the decision to employ a particular technology. This point needs to be emphasized when comparing conventional treatment approaches with proposed methods such as photocatalytic oxidation using nanosized catalysts. However, these nanosized catalysts provide the possibility for accessing a much larger portion of the solar spectrum (i.e. the visible portion). This in itself would be very cost-effective, leading to a great step forward in the field of photocatalysis for environmental remediation.

No single remediation technology can be expected to address the diverse global problems outlined above. However, to be widely implemented any approach will have to possess economic advantages and be scaleable to deal with large volumes of contaminated solids, liquids and gasses. In the next 10–20 years it is possible that photocatalytic oxidation will play a significant role in environmental remediation if appropriate new materials such as nanosized photocatalysts can be developed and optimized for specific reactions. In the interim, as stated above, the best approach is resource conservation and recycling of materials so that waste generation is minimized. Societies and their governments should provide tax incentives to promote such approaches.

3.3 Photocatalysis

3.3.1 History and Background

A large surge in research and interest in the fields of photochemistry and photocatalysis was initiated by the oil crisis in the early 1970s, leading to a search for alternative energy sources. Of special interest was the generation of hydrogen from the photochemical splitting of water. Following the demonstration of photocatalytic water splitting on a TiO_2 electrode (in a photoelectrochemical cell) in 1972 by Fujishima and Honda, the field of photocatalysis and photoelectrochemistry flourished [18, 40, 41].

It is worth highlighting some of the initial achievements that participated in developing photocatalysis as a field. The photocatalytic properties of wide-bandgap metal oxide semiconductors such as ZnO and TiO_2 were first discussed in a tutorial article by Markham published in 1955 [42]. The first example of using light-driven catalysis in environmental remediation was that of Frank and Bard, who described the photo-reduction of cyanide ions in solution [43, 44]. The Ollis group reported the

first photo-oxidation of several types of organic toxins using TiO_2 in 1983 and this work initiated many other studies of this process [45, 46]. The first application of photocatalytic oxidation using TiO_2 to kill bacteria such as *Lactobacillus acidophilus*, *Saccharomyces cerevisiae* and *Escherichia coli* was reported in 1985 [47]. A group led by Fujishima demonstrated the first use of TiO_2 semiconductor powders to photo-oxidize HeLa tumor cells [48]. Eventually, extensive research on photocatalysis in the 1990s, particularly in Japan, led to the first report by Wang and co-workers of surface coatings of TiO_2 powders which had self-cleaning properties [49]. These surfaces were also superhydrophilic, which prevents water droplets from forming. This work would eventually lead to the commercial production of anti-fogging glass in Japan.

As the above historical timeline indicates, nearly all reviews of photocatalysis using semiconductors are dedicated to the properties of titania. [13, 17, 22, 28, 50]. TiO_2 is the most widely investigated material due to its ready availability, lack of toxicity and photostability. However, due to its wide optical gap of 3–3.2 eV, which precludes full use of the solar spectrum, research to develop alternative materials continues actively. Nevertheless, in Japan, commercial use of titania films in self-cleaning tiles and air filters has been shown to be economically viable. Self-cleaning construction materials such as tiles are sold by several Japanese companies and these developments are a subject of a recent review which we discuss in more detail at the end of this chapter [50].

The search for new materials or ways to improve visible light absorption of TiO_2 through sensitization and bandgap manipulation via doping continues. Improvements in the synthesis, characterization and processing of semiconductor nanoclusters is a major focus of this chapter. Recent developments in the last decade allow photocatalysis using new nanomaterials such as WS_2 and MoS_2, which in the bulk have near-IR bandgaps that are too small to drive many photo-oxidation processes. Nanoclusters of these materials have been demonstrated to have bandgaps which red shift into the visible region with decreasing size [51]. This permits the application of a wider range of semiconductors as candidates for viable photocatalytic processes in environmental remediation [52].

3.3.2 Definitions

Photocatalysis is the acceleration of a light-driven chemical reaction due to the presence of a chemical called a catalyst. By definition, the catalyst simply lowers that activation energy required for the process and the catalyst itself remains unchanged by the reaction [53]. Determining that a catalyst really remains unchanged after the reaction can be difficult and will be discussed in later sections. The specific photoreaction which is the subject of this chapter is the creation of electron–hole pairs in a semiconductor material. The electrons and holes interact with oxygen and water, resulting in the formation of free radicals such as dioxygen radical anions and hydroxyl groups. These radicals then begin a chain of "dark reactions", ultimately oxidizing chemicals in either the solid-, solution- or gas-phase environments, resulting in CO_2 and dilute mineral acids such as HCl. The complete reaction

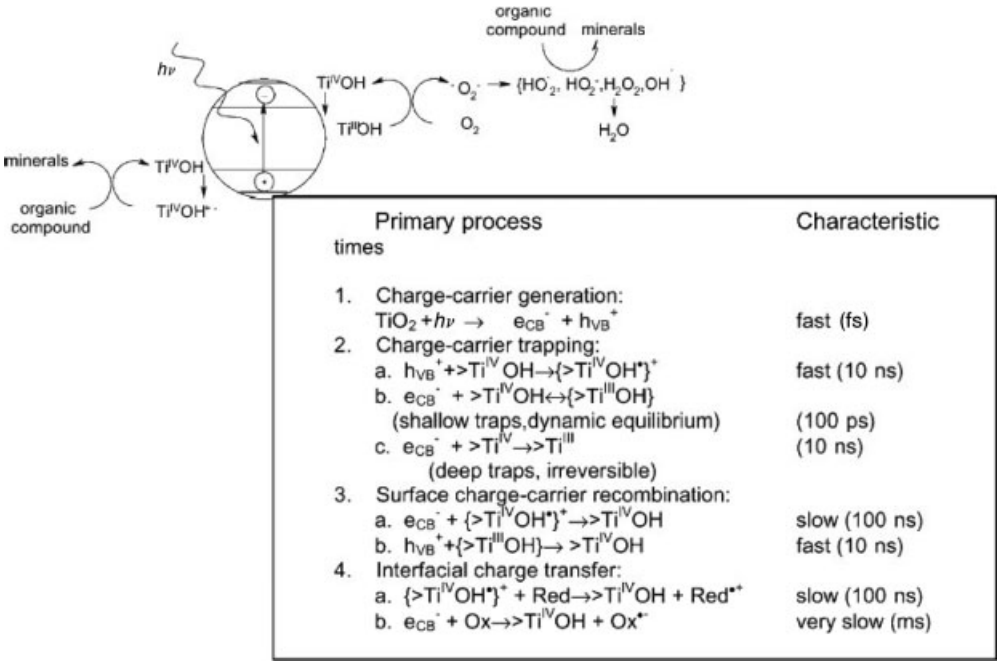

Figure 3.1 Light-activated photocatalysis in a TiO_2 particle. (Reprinted with permission from O. Carp, C. L. Huisman, A. Reller, *Progress in Solid State Chemistry* **2004**, *32*, 33 and A. Hagfeldt, M. Gratzel, *Chemical Reviews* **1995**, *95*, 49).

is often called total mineralization. A scheme for these processes using TiO_2 photocatalysts and the time scales associated with various steps is shown in Figure 3.1 [13] and Figure 3.2 [37]. Note the key role of hydroxyl radicals in both figures. Also, depending on the chemical, there are many possible rate-limiting steps in the photocatalysis reaction.

Laser photolysis and transient absorption experiments have allowed the time identification and time scales shown in Figure 3.1 to be determined [54]. Both trapped holes and electrons have distinct absorbance spectra in the visible region and the decay rate of these absorbance features following photoexcitation allows the carrier transfer kinetics to be followed. The selectivity and efficiency of these processes depends on many factors that we review in more detail subsequently.

3.3.3
Well-Known Example – Water Splitting Reaction

A light-driven electrochemical photocell to split water into hydrogen and oxygen was first described by Fujishima and Honda in 1972 and was a key result motivating interest in titania as a photocatalyst [18]. Although the oxidation and reduction potentials of TiO_2 are sufficient to drive this reaction, the kinetics are difficult,

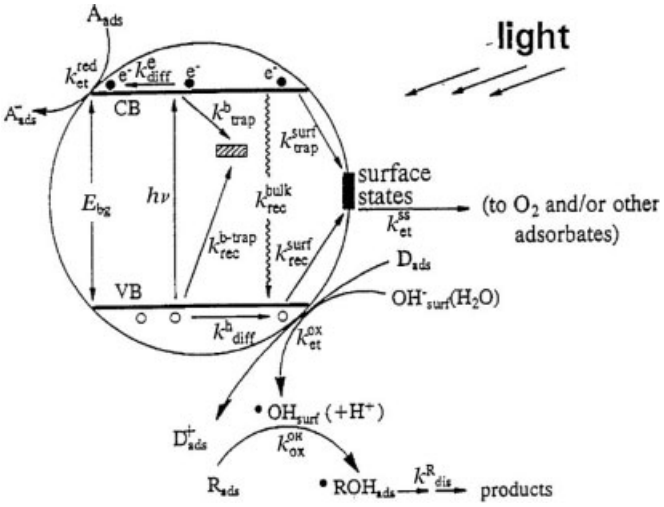

Figure 3.2 Photophysically and photocatalytically possible events on a heterogeneous photocatalyst. (Reprinted with permission from N. Serpone, *Solar Energy Materials and Solar Cells* **1995**, *38*, 369).

requiring four electrons to be transferred. Hence the efficiency of the process is low, estimated at less than 0.1%. This low UV light efficiency combined with the fact that TiO_2 absorbs only small amounts of the total solar spectrum means that most of the absorbed light simply generates heat. A lesson learned from these experiments is that although the thermodynamics for photocatalytic oxidation may be favored for a chosen chemical, competing pathways may limit the efficiency and these pathways must be eliminated by careful design of the nanocatalyst (see Section 3.4). It is unlikely that a single type of photocatalyst will suffice for all oxidations of interest.

Many later reports of direct, fully catalytic water cleavage are doubtful since chemicals present during the preparation of the particles (alcohols in the case of the TiO_2 synthesis), can act as electron donors, allowing hydrogen evolution to occur. However, the electrons are not furnished by the conduction band of the TiO_2 in this case. One must also be cautious regarding the contributions of reactor cell leaks to the observation of oxygen in these reactions. Mills and Le Hunte provide a good critique of these experiments [17].

3.4
Design Issues for Environmental Remediation Photocatalysts

3.4.1
Introduction

The factors affecting photocatalysis when using bulk semiconductors such as TiO_2 will also need to be considered when working with nanosized photocatalysts.

The important processes outlined in Figure 3.1 can be viewed as design parameters requiring optimization in order to have an efficient photocatalytic reaction.

3.4.2 Charge Separation

For the size range of nanoparticle photocatalysts discussed in this chapter, photogenerated charges rapidly diffuse to the particle surface and are trapped. Many TiO_2 surfaces, for example, have oxygen vacancies that function as electron traps. However, the electrons in these traps have lower energies than the initially photoexcited conduction band electrons and so are less likely to be transferred to oxidants. It is possible to modify a nanocluster surface to improve the electron transfer process as we discuss in the synthesis section of this chapter (Section 3.6). A longer electron lifetime improves the generation of hydroxyl radicals from surface Ti–OH species. Spatially separating the electrons from the holes by introduction of metal or semiconductor islands on the TiO_2 surface is a good approach for increasing the electron lifetime and the photocatalytic efficiency since the electron transfer is usually the rate-limiting step. This is why most reactions are conducted in oxygen-saturated water since oxygen is a good electron scavenger.

Several approaches to improving charge separation in titania photocatalysts have been suggested and implemented. Deposition of metal islands such as Ag or Pt on TiO_2 clusters has been shown to facilitate the electron charge-transfer process, which is kinetically the slowest redox event [55, 56]. The metal islands are thought to function as sinks for electrons, reducing the recombination of the photogenerated charges. The presence of Ag on the TiO_2 was shown to enhance dye photo-oxidation compared with the TiO_2 particles alone in a batch slurry-type reactor. Orlov and coworkers [55] used a flow-through reactor design with immobilized Au-coated TiO_2 particles to improve photoactivity for two common pollutants, methyl *tert*-butyl ether (MTBE) and 4-chlorophenol.

In general, not all dopants will enhance charge separation and the subsequent quantum yield of all reactions. For example, Fe^{3+}, which is one of the most common dopants, is capable of enhancing the photodegradation of certain pollutants (CCl_4, $CHCl_3$ [57, 58]) while negatively impacting the photo-oxidation of other pollutants (e.g. 4-nitrophenols [58, 59]). It has also been reported that there is an optimum dopant concentration which depends on TiO_2 particle size [58]. Particularly for Fe^{3+}, the necessary doping level was found to increase with decreasing TiO_2 particle size where sizes $\leq$11 nm showed enhanced behavior for photodegradation of $CHCl_3$ [58]. However, it is not clear that the particle size and size distribution were controlled, so specific conclusions based on size may be difficult.

Alternatively, coupling two semiconductors can be used to improve charge separation by transfer of one of the charges, say the electron, from the semiconductor with the higher potential to the lower one. This leaves the hole on the original semiconductor and can achieve better spatial charge separation. An example of this is TiO_2–CdS, where CdS can absorb visible light and transfer its electron to TiO_2 [60].

3.4.3
pH of Solution

The solution pH has an important effect on the adsorption of organic molecules on the catalyst surface, particularly if the chemical to be oxidized has a net charge or is very polar. For example, since the oxidation depends exponentially on the distance of the chemical from either the holes or the surface hydroxyl radicals, if the organic molecule has a positive charge (such as a quaternary ammonium salt), low pH values, where a metal oxide like TiO_2 will be positively charged, are less favorable than slightly alkaline values (e.g. $pH \approx 9$). The opposite will hold for anionic contaminants. For neutral organic substrates, the more important effect of pH is to increase the activity at higher pH values by producing a more hydroxylated surface. This sort of surface is more effective in trapping photogenerated holes. As an example, the pH corresponding to neutrality in Degussa P25 TiO_2 is around 6.2 [17], so for values less than this, the surface is charged and cationic chemicals are repelled, whereas for values greater than 6.2, anionic species are repelled. Despite these facts, most photocatalysis reactions using TiO_2 have a weak pH dependence.

3.4.4
Charge Transfer

The initial carrier generation process important in photocatalysis is the photogeneration of electrons and holes, which occurs on the femtosecond time scale [24], as shown in Figure 3.1. The carriers then diffuse to the cluster surface in less than 10 ns and are trapped. The holes can be trapped at Ti(IV)–OH^+ sites and the electrons at Ti(III)–OH sites in around 10 and 0.1 ns, respectively. Interfacial charge transfer of the Ti(IV)–OH^+ holes to adsorbed organic molecules and Ti(III)–OH to molecular oxygen then can occur on time scales of around 100 ns (holes) to milliseconds. The slow time for the latter means that methods to accelerate the transfer of electrons are important to minimize undesired surface trapped carrier recombination.

3.4.5
Presence of Simple and Complex Salts

Metal salts, especially simple ones such as NaCl, are present in most wastewater and many natural aquifers. As such, they affect both photocatalytic activity and selectivity. Most common anions found in water systems such as chloride, nitrate, phosphate and sulfate decrease the catalytic oxidation of organic compounds [13, 61–63]. The presence of ions during water purification using photocatalysis is an important research topic since some present and future sources of water will require desalination and this source of salt water also contains organic pollutants from off-shore dumping, etc. If brackish water must first be completely desalinated to avoid poisoning of the photocatalyst, the cost of environmental remediation of organic contaminants will not be economically competitive with carbon adsorption

approaches that do not have this requirement. Hence the ability to formulate a photocatalyst which is somewhat salt tolerant is important.

Certain anions, such as sulfate and phosphate ions, can form reactive species such as H_2PO_4, which are good oxidants, thus improving the photo-oxidation rate. However, their other effect is to adsorb on the photocatalyst surface, which can block active catalytic sites. This adsorption is strong enough that washing with an alkaline solution is necessary to restore the photocatalytic activity. For example, phosphate adsorption at low concentrations of only 1 mM has been reported to reduce the photo-oxidation of organics such as ethanol and aniline by around 50% [61].

The effect of cations on the photoactivity is more varied and dependent on the type of organic molecule considered in addition to the metal ion type and concentration [13, 31, 64, 65]. At high concentrations, their presence is mostly unfavorable since they may undergo photo-reduction by the photocatalyst itself and deposit on the surface, blocking active sites. By maintaining the reaction media at low pH, the positively charged photocatalyst surface will repel cations, lessening their negative impact.

Photo-reduction, however, can be useful in improving activity in the case of metals such as Pt, Ag or Pd, provided that full coverage of the catalyst surface does not occur. Instead, metal islands are formed, which function as electron storage sinks and facilitate charge separation and transfer. This topic is discussed in more detail in the section on synthesis and photocatalyst surface modification. Certain types of metal ions such as Cu(II) and Fe(II) can enhance photocatalysis by limiting carrier recombination through trapping either electrons or holes. The facile ability to change oxidation state is critical to this function. However, many metals, including Fe, are prone to hydroxide formation and deposition of these metal hydroxides on the photocatalyst surface is almost always detrimental. This means that an optimal metal ion concentration in the range 100–500 ppm (0.01–0.05%) should be determined and used for a chosen photocatalytic reaction.

There is a close connection between the pH of the solution and whether an ion such as Cu(II) accelerates photocatalysis or not. For example, in the photo-oxidation of aliphatic acids by TiO_2 in the presence of Cu(II), it was reported that for pH values <4 Cu(II) forms complexes which are active intermediates, trapping holes, whereas copper diacetate complexes form at higher pH values and poison the photocatalyst [66, 67].

In our work on the photo-oxidation of pentachlorophenol, we demonstrated that nanosized TiO_2 and SnO_2 synthesized by ambient temperature hydrolysis, followed by dialysis to remove unwanted by-products, was quenched by the addition of simple salts such as NaCl at concentrations of only 10 mM [68]. These low concentrations of NaCl have a poisoning effect on the catalyst, although it is mild in this case. Similar observations have been made in field tests of TiO_2 where deionization of the aqueous waste stream has been found to be necessary [69]. This is an important consideration when estimating costs of remediation using photocatalysts, since desalination is a costly process. In other studies by Barbeni *et al.*, no inhibition of the PCP photocatalysis by TiO_2 in the presence of NaCl at 1 mM occurred, so the presence of low level salts is acceptable [70].

3.4.6
Effect of Surfactants

In our work, we investigated not only the effect of simple salts on the rate of photo-oxidation of PCP, but also that of complex, surface-active salts/surfactants such as dodecyltrimethylammmonium chloride (DTAC), a cationic quaternary ammonium salt with an organic, hydrophobic tail group. Using this surfactant, we could isolate the effects of the common anion chloride from that of its ion pair, NaCl in one case and dodecyltrimethylammonium chloride for the other. To our surprise, this complex cationic surfactant significantly accelerated the rate of photo-oxidation of PCP by Degussa P25 titania in addition to our nanosized photocatalysts [68]. Two explanations of these experiments are reasonable:

1. Binding of PCP at photocatalytic surface sites by the presence of a bulky surfactant such as DTAC is not the rate-determining factor in the photo-oxidation of PCP by TiO_2. Instead, this surfactant either aids hole or electron transfer to PCP or electron-accepting species such as oxygen. Possibly free hydroxyl radicals are formed, which can diffuse to the PCP so that direct hole transfer to bound PCP is not required.
2. The sodium cation in NaCl is mainly responsible for the strong quenching of the photo-oxidation. This contradicts other studies cited above, however.

The significant enhancement (note the logarithmic scale on the vertical axis) due to the presence of a surfactant is shown in Figure 3.3. Note that at similar concentrations of NaCl the rate of PCP photo-oxidation is significantly slower. A common argument against using surfactant-stabilized nanoclusters as catalysts is that the surfactant will block access to the cluster surface and thus poison the catalyst. Our study shows this is not the case for DTAC. We also discovered that substitution of a bromide counterion for the chloride in DTAC does not increase the photo-oxidation of PCP as greatly as for DTAC. It is also worth noting that the surfactant peaks in the

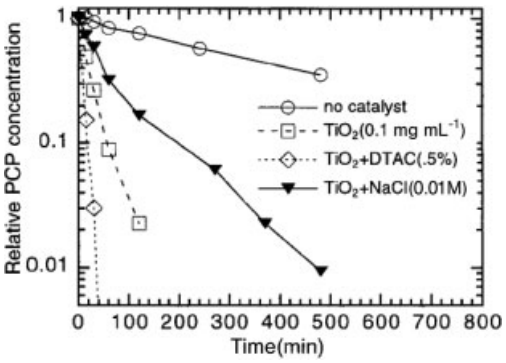

Figure 3.3 Relative PCP concentration vs. irradiation time, showing the effect of surfactant type on photocatalytic destruction of PCP. (Reprinted with permission from J. P. Wilcoxon, *Journal of Physical Chemistry B* **2000**, *104*, 7334).

chromatograms [high-performance liquid chromatography (HPLC) was used to monitor reactant and product species throughout all photocatalysis experiments; see Section 3.6.2) did not decrease in area during the photo-oxidation of PCP, indicating that both DTAC and DTAB are resistant to photo-oxidation.

In studies of the reduction of nitrate ions by nanosized CdS which was surface stabilized by charged organic thiols, Korgel and Monbouquette also found significant photocatalytic activity despite the strong surface binding of thiols to CdS [71]. The best way to rationalize this result is to remember that the surfactant used to stabilize a nanocluster in solution is in dynamic equilibrium with the surface. By this we mean a free stabilizer is constantly being exchanged with bound surfactant, thus allowing other chemicals transient access to the photocatalyst surface. So, binding of other chemicals is not statically blocked by the surfactant. In fact, the surfactant might increase the local concentration of organic chemical near the photocatalyst surface since its hydrophobic tail groups have much more favorable interactions with non-polar organic chemicals than does the continuous phase, water. An enhancement of the local concentration of pollutants will increase the reaction rate.

3.4.7
Effect of Solvent and Dissolved Oxygen

Most photocatalysis studies have been performed in aqueous solution. An observation common to photo-oxidation of most organics in water is that dissolved oxygen plays a vital role in the oxidation process by forming first dioxygen radical anions by abstraction of the electron formed upon photoexcitation of the semiconductor and then peroxides by reaction with the water [72]. Many researchers deliberately aerate their photocatalyst slurry suspensions in order to optimize the photo-oxidation process and claims have been made numerous times that nearly total quenching of the photo-oxidation process occurs when inert gas purging is employed [70]. Thus, the use of aprotic organic solvents should cause a severe quenching of the photo-oxidation due to both the lack of OH radicals and reduced oxygen levels because of decreased oxygen solubility.

Molecular oxygen has a strong affinity for electrons and its presence should reduce undesired carrier recombination, thus increasing the effectiveness of the photocatalyst [73]. However, there is evidence that at high concentrations of oxygen the photocatalytic activity is reduced, possibly due to changes to the TiO_2 surface such as hydroxylation, which could interfere with the adsorption of the organic on catalytic sites [74].

If water and dissolved oxygen play critical roles in the photocatalysis process using TiO_2, then carrying out these reactions in a polar, but aprotic solvent such as acetonitrile (ACN) would be expected to quench the process and could alter the photo-oxidation pathway. However, complete quenching is not observed in anaerobic catalytic photo-oxidation of pentachlorophenol by Degussa TiO_2 in the aprotic solvent ACN (filled triangles, Figure 3.4). Uncatalyzed photo-oxidation in ACN, which occurs by a different mechanism, is quenched, however (open diamonds, Figure 3.4) [68]. In Figure 3.4, it can be observed that although the rate of catalytic photo-oxidation is 2–5

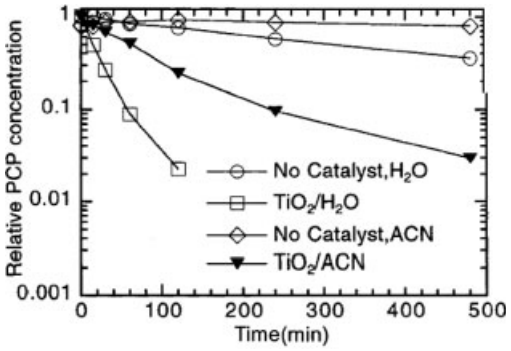

Figure 3.4 Relative PCP concentration (10 ppm at $t = 0$) vs. irradiation time using a xenon arc lamp. Significant photocatalysis occurs in oxygen-free solutions of acetonitrile (ACN). (Reprinted with permission from J. P. Wilcoxon, *Journal of Physical Chemistry B* **2000**, *104*, 7334).

times slower in nitrogen = purged ACN than water, photocatalysis does occur. Also, the mechanism for PCP photo-oxidation in water and in ACN is similar, as verified by the presence of common elution peaks for the main photo-oxidation intermediate in the HPLC traces for both solvents.

3.4.8
Light Intensity

For low light intensity, up to around 25 mW cm^{-2} at 365 nm (depending on reactor geometry and nanoparticle concentration), the rate of electron–hole transfer is fast enough to allow each photocatalyst particle to absorb photons and create electron–hole pairs. Hence the rate is first order or proportional to the light intensity. At higher intensities, the existence of an electron–hole pair on a particle prevents the photogeneration of another one on the same particle and full utilization of the incident photons cannot be realized. The photocatalysis rate is found to be proportional to the square root of the intensity in this regime [73]. The practical aspect of this observation is that slurry-type batch reactors are best operated at low light intensity such as found in natural sunlight, which provides 2–3 mW cm^{-2} in the absorbance region of TiO_2. It also indicates that schemes for concentrating sunlight to higher fluxes to increase the rate of photo-oxidation will be of limited utility.

3.5
Potential for Nanomaterials in Environmental Remediation

3.5.1
Introduction

Nanosized materials for photocatalysis and photo-oxidation have evolved from conventional bulk metals and semiconductors to colloidal (large cluster, ~10–100 nm

in size) materials and, most recently, to nanosized materials or small clusters (1–10 nm). We distinguish these classes of materials by the way in which physical properties depend on surface area and the significant changes in electronic and photocatalytic behavior with decreasing size. In the nanosize regime, quantum confinement and cluster surface chemistry dominate materials properties.

Nanoparticles of a given material can exhibit very different behavior to their bulk counterpart. For example, the potential for oxidation and reduction could become stronger with decreasing size, so more types of organic or inorganic materials can be photo-oxidized or photo-reduced at faster rates. Since the specific surface area is so much greater, more economical use of material reduces costs. Also, the large surface to volume ratio means that subtle changes to the surface due to addition of other atoms or molecules can lead to dramatic alterations of physical properties such as substrate binding. A number of fields, including magnetism, luminescence and renewable/alternative energy to sensors/taggants as well as photocatalysis, will benefit from capitalizing on the surface–size relationship. The unifying theme in these disparate fields is controlled alteration and possible enhancement of physical properties due to quantum size and cluster interface effects.

Semiconductor surfaces in small clusters can be considered defective relative to perfect micron-sized crystals of the same material. This can be a major advantage in photocatalysis since either electron or hole traps at the surface will determine the recombination time, in many instances reducing the recombination rate and increasing the probability of carrier transfer to an adsorbed organic molecule. The effect is that the efficiency for catalytic photo-oxidation can increase with decreased size in addition to being strongly influenced by substitutional ions such as iron [58].

In the last 20–30 years, scientific interest in the properties of nanosized materials and the need for new materials for photocatalysis applications such as environmental remediation and renewable energy has motivated research in both fields. As mentioned above, several reviews relating nanoparticles and photocatalysis have already appeared. The effects of size quantization using colloidal materials was reviewed in 1988 and 1989 by Henglein [75, 76]. A large motivation for new developments in colloidal science was the investigation of particle size effects on optical properties and photocatalysis. Complementing Henglein's viewpoint, other reviews provided a detailed overview of colloidal semiconductors and their photochemical properties [23]. The photo-redox reactions in nanocrystalline systems were subsequently reviewed by Hagfeldt and Gratzel [24]. This early research by Henglein and Hagfeldt and Gratzel (along with others) emphasized the use of optical techniques to learn about the size-dependent behavior of semiconductors. Techniques such as transient absorbance to monitor electrons and holes and their recombination kinetics guided future research in photocatalysis. Several reviews (1995–98), by Howe [16], Hoffmann *et al.* [26] and Linsebigler *et al.* [40], analyzed the effect of carrier confinement and size effects in TiO_2. Other reviews have focused more specifically on the use of nanomaterials in environmental and energy applications [30, 32, 35]. Beydoun *et al.* presented a broad overview of the nanoparticles in photocatalysis [21]. They reported many instances where nanoparticles, especially TiO_2, enhance the photocatalytic process. It is difficult to separate the effects of carrier

confinement due to decreased particle size from surface chemistry changes which occur in the same size range. We will give examples of both types of size-dependent changes in this chapter.

3.5.2 Nanomaterials and Advantages in Photocatalysis

3.5.2.1 Semiconductor Nanoclusters

As in the case of their bulk counterparts, nanosized semiconductors have a range of forbidden energy states whose most important effect for photocatalysis is to allow the creation of valence band holes and conduction band electrons using light. Fast recombination of these photoexcited holes and electrons is an undesirable effect for photocatalysis. Hence nanosized semiconductors with strong photoluminescence are poor candidates as photocatalysts. Fortunately, the diffusion time for electrons or holes in nanoclusters is so fast that the normal bulk recombination process is not important. The most important effect is trapping of the carriers at the surface. This trapping can be influenced by cation or anion vacancies [e.g. Ti(IV) or O^{2-}] at the surface which are deliberately or accidentally introduced during the synthesis. It is also possible to use surface-active molecules such as surfactants, certain ions and the general solvent environment to change the carrier lifetime at the cluster surface and improve the oxidation process for adsorbed organic chemicals. Deposition of metal islands such as Pt that improve charge separation by serving as electron traps is another avenue for enhancing charge separation. Each of these synthetic strategies will be illustrated in more detail later with examples from the literature. Many of these effects are simply due to the different geometry and chemical bonding in a cluster surface at small dimensions (1–3 nm) and would occur even in the absence of quantum confinement of the electron–hole pair.

3.5.2.2 Quantum Confinement

The quantum size effect was first discussed by Frohlich in 1937 [77, 78]. The concept of quantum confinement that he described evolved from a series of observations where light interactions with certain materials varied as a function of form. Frohlich discussed quantum size effects in the context of observed differences in light-scattering behavior between small particles and corresponding thin films of the same material [77, 78]. The quantum confinement model is similar to the particle-in-a-box model where an electron is confined in a finite volume in space and the number and energy levels of the possible states is determined by the confining potential. In an aromatic molecule, for example, this electron confinement or delocalization is determined by the degree of bond conjugation setting a length scale over which the electron is confined by the electrostatic potential. In such a system only a discrete number of energy states are possible and as the physical size or delocalization of the electron increases so does the number of states, eventually becoming so closely spaced as to be essentially continuous.

In a semiconductor, the states which make up the valence and conduction bands are also so closely spaced as to appear continuous. However, as the semiconductor

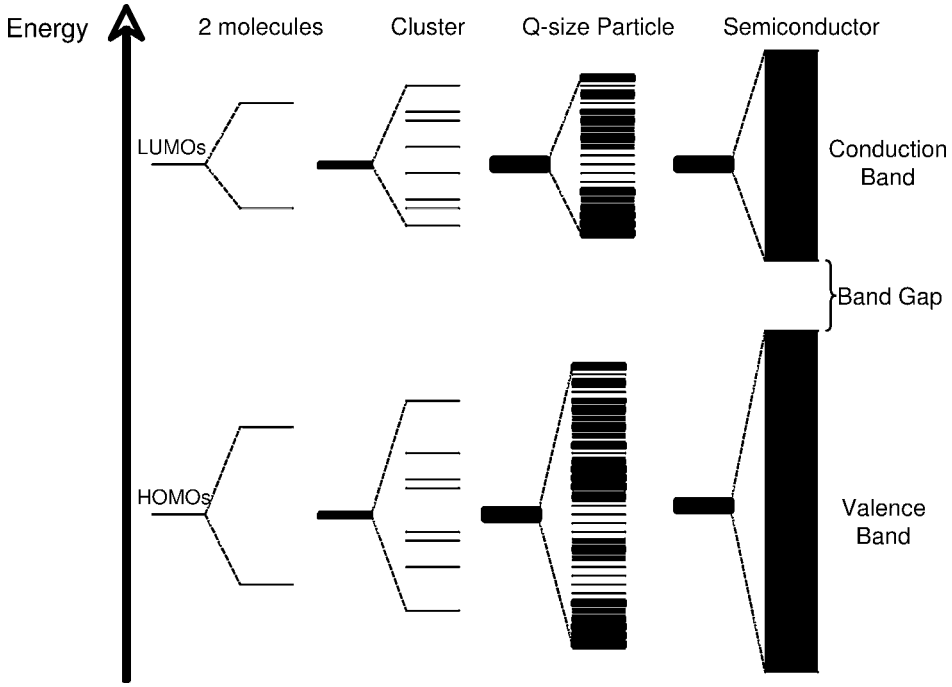

Figure 3.5 Molecular orbital schematic showing the development of bands as a function of increasing particle size. (Reprinted with permission from D. W. Bahnemann, *Israel Journal of Chemistry* **1993**, *33*, 115).

size decreases to a length scale comparable to the confinement potential of the electron–hole pair or exciton, (the Bohr radius), the particle size strongly influences the exciton energy, increasing the energy as the size decreases. Thus, the onset of light absorption shifts to the blue with decreasing size. The continuous bands become discrete states (as in a molecule) and discrete absorption bands emerge (Figure 3.5). Since such a nanosized semiconductor lacks the long-range translational symmetry of its bulk counterpart, the distinction between light-driven direct (momentum conserving) and indirect transitions (requiring phonon assistance) between the highest energy states in the valence band and the lowest energy states in the conduction band is lost. This means that optical transitions with a low probability or oscillator strength in an indirect semiconductor such as silicon or MoS_2 are likely and the extinction coefficient is strong in nanoclusters of these materials. As the semiconductor size approaches molecular dimensions, it is most appropriate to model the valence band as consisting of the highest occupied molecular orbital(s) (HOMO) and the conduction band as the lowest unoccupied molecular orbital(s) (LUMO). In order to model these states properly, chemical bonding at the surface must be understood and included. Ligands bound to surface atoms should also be included. This is nearly impossible to do properly, so quantum confinement

predictions of energy shifts with size are qualitative, rarely agreeing with experiments for sizes less than 4–5 nm.

Discussions of quantum confinement have been the subject of several reviews [13, 15, 17, 34, 75, 76, 79–81]. Many reviews have considered the effects of quantum confinement on electrical, optical and photocatalytic properties. In particular, Brus modeled the shift in redox potential with decreasing particle size for CdS and InSb [82]. Brus's model is based on a description of bulk state behavior in the limit of small crystallite size. It uses approximations from band theory of perfect lattices and assumes a crystal structure matching that of the bulk material. As a result, it could not account for surface states. In general, this model predicts fairly mild quantum effects as a function of size, especially when the crystallite sizes are larger than 5 nm.

Some of the predictions are based on the relationship between the particle size and the effective mass of the exciton [i.e. the effective mass model (EMM)]. There is some controversy as to whether the effective mass model should be used to make quantitative estimates of particle sizes based on absorption spectra shifts and the use of the same exciton effective mass as that for the bulk counterpart [79]. The actual value for the exciton effective mass is itself dependent on size and shape.

Both cluster size and shape influence the energy shifts observed in nanoparticles. A rod-like cluster will have different confinement potentials for the longitudinal and transverse directions, for example. Also, the confining potentials for electrons and holes are typically different, as reflected in the different effective mass of the electrons and holes or curvatures of the potential surfaces for the valence and conduction bands. In most materials, electrons are much more mobile than holes and the conduction band will shift more strongly than the valence band with decreasing size. As noted by Wise [83], the particle size at which confinement effects become prominent is greatly influenced by whether or not the charge carrier mobilities are similar. Certain materials such as PbS and PbSe satisfy this requirement, but most others such as CdS and TiO_2 do not. Chemically, this is due to the unequal sharing of electrons in polar semiconductors such as metal oxides and sulfides.

The blue shift of the bandgap absorption onset impacts the design of nanosized photocatalysts in several ways and the length scale at which such effects are first observed is materials dependent. This increase in the bandgap as a function of decreasing size allows the possible use of a wider range of materials as photocatalysts. Many of materials are not catalytically active in their bulk form. For example, semiconductors such as MoS_2 and WS_2, which have near-IR absorption onsets, can be shifted into the visible region by decreasing the cluster size. Both valence and conduction bands shift in energy, the valence band becoming more positive and thus the holes more strongly oxidizing. The photoexcited electrons in the conduction band are shifted to more negative potentials, also improving their transfer to such species as molecular oxygen. In general, the greater the effective mass of the holes compared with the electrons, the larger is the shift in the conduction band energy with decreasing size. The amount of the shift can be estimated by measuring the rate of hole or electron transfer to fluorescent hole or electron acceptor molecules as a function of cluster size [84].

The interplay between quantum size effects and surface chemistry changes with decreasing particle size can be optimized in order to enhance the activity of a particular catalytic reaction. However, in order to do this, there must be fairly good synthetic control over particle size and monodispersity. This size control is not available through all synthesis techniques and seems to be difficult in the case of TiO_2. As a result, many conclusions relating photocatalytic activity to size may seem contradictory. More often than not, other factors such as photocatalyst environment or synthetic protocol dominate the changes in the observed reactivity.

3.5.2.3 **Surface Chemistry**

In addition to increasing the strength of the confining potential and shifting the light absorption onset, decreasing particle size results in a larger fraction of atoms which are in surface sites with bonding differing from the interior atoms. For small clusters (1.5–2 nm), ~70–80% of all the atoms reside on the surface [85]. Sometimes cluster surface structures are considered defective. However, these defects may be useful for photocatalysis. For example, a metal oxide defect structure (e.g. TiO_2) with oxygen vacancies can enhance both the adsorption of water on the surface and the dissociation rate of water into hydroxyl groups and protons. This water dissociation process requires the presence of paired acid–base sites that are situated in close proximity. Surface sites with acid character such as titanium cations initially bind water molecules, whereas neighboring sites with basic characteristics such as Ti–O–Ti structures can accept a proton from the water molecule. In nanosized materials, the structural arrangement of interior atoms that is simply the phase structure as determined by diffraction methods, is less significant than the surface chemistry. For example, in the case of titania, the surface hydroxyl groups play a critical role in initiating the oxidation process by both influencing the adsorption of organic chemicals and aiding the dissociation of adsorbed water into hydroxyl radicals and hydrogen ions. Free hydroxyl radicals are very good at attacking and oxidizing a wide range of organic groups and, with a potential of around 2.8 V, are more effective than any radical except fluorine. Even surface-bound hydroxyl radicals with a potential of 1.5 V can be effective oxidants [86].

Synthetic changes of the surface properties of nanosized catalysts can also be used to modify redox potentials and substrate binding, independent of quantum confinement effects. Kamat and Meisel have taken advantage of this effect through alterations of the interface of nanosized TiO_2 particles deposited on Au [27]. The intimate contact between the metal and the surface of the nanosized TiO_2 was reported to be crucial in improving charge transfer. Additional examples of the effect of ions and metals on the surface of semiconductor photocatalysts will be given later.

3.5.2.4 **Other Unique Materials Properties**

Since most of the atoms in a nanocluster can reside at accessible surface positions, very small changes in the chemistry of the cluster surface can significantly alter its photocatalytic properties. For example, in a 50–60 atom cluster with a diameter of around 1.6 nm, the addition of a single foreign atom can change the interatomic spacing and thus the binding energy between the catalyst nanoparticle and an organic

substrate. The restructuring of a highly curved nanocluster surface due to other atoms, surfactants or ions also fundamentally alters the optical and binding properties compared with micron-sized powders, allowing a wider range of materials to be utilized as photocatalysts. An example emphasized in this chapter is nanosized metal dichalcogenides such as MoS_2.

3.5.2.5 Importance of Nanocluster Photostability

There are only certain types of materials which have suitable stability as nanosized clusters to be considered as useful photocatalysts. One group includes materials which are already oxidized, such as metal oxides. Even among this group, only titania is readily regenerated during the photocatalytic oxidation process, thus acting as a true catalyst. Other oxides such as ZnO are partially consumed upon use as photocatalysts [87].

Metal sulfides such as CdS or ZnS are not generally photostable in the presence of either water or oxygen. The reason for this is the polar nature of their bonds which make them subject to oxidation by the holes created upon photoexcitation. However, in certain specialized reactions such as the oxidation of H_2S, the presence of anions such as HS^- at the hole sites of the cluster surface prevents the holes from simply oxidizing the lattice. This allows typically unstable polar semiconductors such as CdS to be used as photocatalysts [60].

A class of photostable materials are metal dichalcogenides such as MoS_2 whose stability is due to their anisotropic structure. These materials have a two-dimensional layered structure with catalytically active metal edge sites located at the cluster surface protected by adjacent sulfurs (Figure 3.6). Photoexcitation occurs primarily within the metal d-bands and doesn't weaken the bonds responsible for the lattice. The resulting electronic structure makes them quite photostable in water.

3.6
Nanoparticle Synthesis and Characterization

3.6.1
Introduction

Research concerning nanocluster optical properties and photocatalysis has focused on a limited number of readily available materials such as TiO_2, ZnO or ZnS. Development of new synthetic methods should allow studies involving a much broader range of materials, increasing the efficiency and selectivity of nanosized photocatalysts. Furthermore, the ability to form alloys and later alter the cluster surface properties will give researchers further control of the photophysical properties.

Both solution-based and gas-phase syntheses of nanoparticles are used to prepare photocatalytic materials. Solution-based methods for the formation of metal oxide semiconductors rely primarily on the base- or acid-catalyzed hydrolysis of metal organic precursors such as titanium isopropoxide. These syntheses are generally executed by rapid mixing or co-injection of two solutions, one containing the metal organic in a polar organic and the second solution containing the acid catalyst. The resulting colloids are stabilized by charge in water at low pH. Some additional details about size and nanostructure control in these formation approaches are provided below in our discussion of TiO_2 synthesis.

Many commercial micro- and nanosized metal oxide powders are formed by proprietary methods which generally involve gas-phase hydrolysis of inexpensive compounds such as $TiCl_4$ (fumed silica powers are prepared in this manner from $SiCl_4$ also). A good example of a photocatalytically active material prepared by this method is Degussa type P25 TiO_2 (primary particle size $\sim$25 nm), which consists of roughly 80% anatase (the allegedly photoactive form) and 20% rutile phase. Because so much of the literature uses this material, we discuss some of its special properties in more detail below. It is generally more active and broadly effective for photo-oxidation than most other TiO_2 formulations [13].

Since Degussa P25 TiO_2 has both high activity and commercial availability, it has been employed in the majority of studies of photocatalytic activity described below. This material is formed by the high-temperature (>1200 °C) flame hydrolysis of $TiCl_4$. $TiCl_4$ is a very inexpensive but air-sensitive chemical precursor, so the presence of oxygen and hydrogen during the reaction produces both TiO_2 and HCl. The latter by-product is removed by treating the TiO_2 with steam. Nanosized Degussa TiO_2 has a BET surface area of $50\,m^2\,g^{-1}$ and consists of submicron- to micron-sized aggregates of 10–40 nm primary particles Another commonly used commercial TiO_2 photocatalyst, Sachtlebem Hombikat UV 100, consisting only of anatase, also has high photoactivity, which is believed to be due to a fast interfacial electron transfer rate resulting from its smaller particle size [54].

In general, gas-phase aggregation methods have a production cost advantage over solution-based methods since they use less expensive chemical precursors. However, the colloids or clusters formed in the gas phase cannot be dispersed as stable sols in

water. Degussa P25 powder, for example, consists of "popcorn-ball"-like 3–5 μm sized aggregates of roughly 20–30 nm diameter spheres and hence is not soluble in water, instead being used exclusively as a suspension or slurry in photocatalysis experiments. The slurry must be agitated (usually with a magnetic stirrer), under most conditions. Light does not penetrate into this opaque solution compared with a transparent solution of fully dispersed nanoclusters.

Solution-based methods for preparing the third class of semiconductors to be discussed, metal sulfides, are typically based on reaction of metal salts (e.g. $MoCl_4$) in non-aqueous solutions with a sulfur source (e.g. H_2S, NH_4S) under anaerobic conditions in the presence of a surfactant stabilizer [51]. A special method based on the use of inverse micelles as nanosized reactors to control the growth of semiconductor metal sulfide clusters is particularly useful for control of size, crystallinity and size dispersion, and we discuss certain aspects of this approach in more detail in a later section on MoS_2 and WS_2 photocatalysts.

Solution-based semiconductor clusters generally have a net charge since it is almost impossible to match exactly the bulk stoichiometry in a small nanocluster. These clusters are typically synthesized using non-polar solvents such as hexane, allowing extraction of the charged clusters into polar organic phases such as acetonitrile or tetrahydrofuran. These solvents are fully miscible with water. Once the extracted clusters have been dispersed in water, purification methods such as dialysis may be used to remove ions and organic by-products and also to change the surfactant used to stabilize the cluster solution in water.

The stability of a metal sulfide nanocluster in the presence of air and water depends critically on its nanostructure and only a certain class of layered dichalcogenides such as MoS_2 are stable against photo-oxidation in water. Accordingly, we focus on the synthesis of these clusters later in this chapter.

3.6.2 Characterization

Understanding the effect of photocatalyst size, structure, crystallinity and chemical composition requires a variety of characterization techniques from both surface science and analytical chemistry. Selection of appropriate characterization methods accelerates the pace of development of new photocatalysts by providing feedback to the synthetic chemist. Methods such as transmission electron microscopy (TEM) and selective area electron diffraction (SAD) can yield insights into the average particle size, size dispersion, nanocrystallinity and phase. Techniques such as X-ray photoelectron spectroscopy (XPS) and extended X-ray absorbance fine structure (EXAFS) are frequently used to determine oxidation state, elements and elemental ratios present in a photocatalyst. X-ray diffraction (XRD) provides information regarding average crystallite size and phase structure and small-angle X-ray scattering (SAXS) can also provide the average particle size and size dispersion. Since all these techniques require a high-vacuum environment for their application, the information that they provide needs to be complemented by analytical chemical methods allowing the photocatalyst to be studied in the liquid state, which is the environment where photocatalysts are typically used.

An important point about utilizing electron microscopy to study cluster size is that only a small portion of the sample (e.g. a few hundred particles) is analyzed. Therefore, if an unrepresentative portion of the TEM grid is chosen, conclusions regarding the average size and size dispersion for the entire sample are not warranted. Instead, SAXS is a more objective measurement since $\sim 10^{12}$ clusters are contributing to the SAXS signal. The drawback of SAXS measurements for the smallest photocatalysts (1–3 nm) is that the scattering is very weak and conclusions regarding size dispersion are more problematic. Since this size regime corresponds to the size of photocatalysts that are typically the most active, one must use analytical methods designed for the study of large molecules and polymers such as size-exclusion chromatography (SEC) to obtain precise size and size dispersion data for such nanoclusters.

For fully dispersed nanosized photocatalysts, it is possible to use HPLC to separate both chemicals and photocatalysts in complex mixtures and study each component by various analytical methods such as optical absorbance or photoluminescence. There are two mechanisms for separation. The first, SEC, depends on the degree of permeation of clusters into a porous chromatographic medium which is packed into a column of a given length. Clusters are injected into a flowing mobile phase such as toluene in which they are soluble and then transported through the porous medium. A good example of a hydrophobic porous medium suitable for SEC is microgels of cross-linked polystyrene. Chromatographic columns packed with microgel particles are designed to separate chemicals by size. The smallest chemicals can penetrate a larger fraction of these channels and therefore take a longer time to elute. Using molecules of a known size, one can calibrate the column so a given elution peak time can be used to obtain the hydrodynamic size of a nanocluster [88]. Figure 3.7 gives an example of the effect

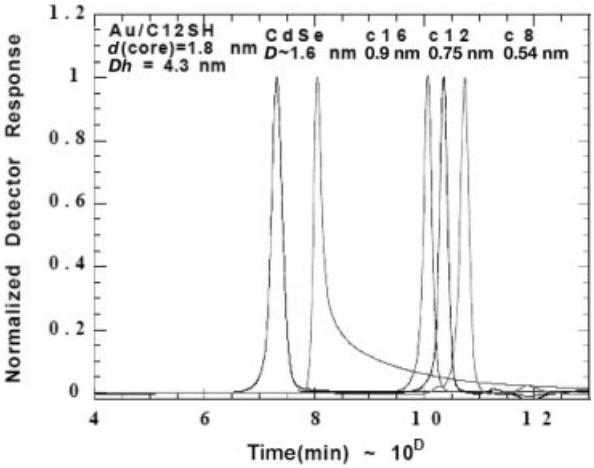

Figure 3.7 HPLC of monodisperse nanoclusters of Au and CdSe compared with three alkane standards: octane, C8 (0.54 nm), dodecane, C12 (0.75 nm), and hexadecane, C16 (0.9 nm). (Reprinted with permission from J. P. Wilcoxon, P. Provencio, *Journal of Physical Chemistry B* **2005**, *109*, 13461).

of chemical size on the elution time for three calibration standards consisting of aliphatic hydrocarbons labeled C16 (hexadecane), C12 (dodecane) and C8 (octane). Larger metal (Au) and semiconductor (CdSe) nanoclusters are included in this chromatogram. The time axis is proportion to the hydrodynamic size, $D \sim \log t$ as shown. This hydrodynamic size includes surfactants which are on the surface of the nanoclusters.

The simple relation between elution time and hydrodynamic size breaks down when the chemical or nanocluster interacts chemically with the column material. Examples of materials which have strong chemical affinities for metal oxide clusters are silica- and alumina-based columns which may be modified with various types of organic moieties to make them more or less hydrophilic. If a nanocluster is somewhat hydrophilic, e.g. a metal oxide like TiO_2, and the column is also hydrophilic (e.g. also a metal oxide such as alumina), the cluster will interact or stick and then release constantly as it moves down the column. How strongly the molecule sticks to the column will influence its elution time, with the most hydrophilic clusters eluting at the longest time. This affinity chemistry can be used to separate and study clusters based on cluster surface chemistry. Since surface chemistry is so vital to photocatalytic activity and selectivity, this type of chemical affinity chromatography provides a useful complement to SEC.

Various types of detectors may be used in-line with the separation column to detect the elution time of chemicals. In Figure 3.7, the detector response has been normalized by its peak, but the total area under the elution peak is proportional to the amount of chemical and is a very useful piece of information. If the chemical or cluster absorbs light, an absorbance spectrometer which can detect both the complete spectrum or just a single wavelength can be used [89]. Since semiconducting clusters such as MoS_2 absorb in the visible region, monitoring the absorbance provides a signature for the elution of a cluster. Most organic pollutants absorb light only in the UV or near-UV range, so monitoring the light absorbance in this region allows the detection of these species. For non-absorbing chemicals, the change in the refraction of light when a chemical is present in the mobile phase can be used to detect the elution. Fluorescent molecules or nanoclusters (most semiconductor nanoclusters used as photocatalysts are at least weakly fluorescent and emit in the visible region) can be detected with an in-line fluorescence spectrometer. The entire absorbance spectrum corresponding to an elution peak can be used to distinguish different clusters or chemicals [90]. The width and degree of shape homogeneity of the spectra of the elution peak can also be used to gauge the size dispersion of the clusters.

Collection of an eluting peak allows further identification of the chemical or cluster by other analytical methods such as gas chromatography–mass spectrometry (GC–MS). Elemental composition can be quantified by using X-ray fluorescence, (XFS). The latter technique is non-destructive and can be used for either solutions or solid films. The collected solution can be dried out and the resulting powder subjected to gas adsorption measurements to determine the available area per unit mass. Comparisons of such data with the geometric area based on the particle size are useful for inferences regarding geometry.

Dynamic light scattering (DLS) measures the diffusion rate of particles in dilute solution, where by dilute we mean that the particles are separated from each other by many particle diameters. This is the case for most photocatalysis studies. DLS is very useful for monitoring particle photocatalyst size changes and aggregation which might occur as a result of the photocatalytic reaction. If aggregation of the colloids occurs, for example, less catalyst surface area will be available to substrates, lowering the photoactivity of the nanomaterial. It is important to establish that the nanosized photocatalyst average size remains unchanged as a result of the reaction.

Studies of TiO_2 synthesis in water–alcohol mixtures sometimes use DLS to measure the particle size in solution and to follow changes with time, since these clusters are not agglomerated and are fully dispersed. This is rarely done for most experiments using commercial gas-synthesized TiO_2 nanocluster photocatalysts since slurries or suspensions of these clusters in water are turbid. This means that light is multiply scattered, precluding DLS measurements of cluster diffusion. For example, the strongly turbid solutions formed by commercial powders of TiO_2 such as Degussa P25 are unfortunately unsuitable for DLS studies.

3.6.3 Detailed Examples of Nanocluster Synthesis and Photocatalysis

3.6.3.1 Semiconductor Nanoclusters

Photocatalysts based on semiconductor nanoclusters must have certain chemical, electronic and optical properties to be useful in environmental remediation. Other properties include low synthesis cost, photostability in water over a wide range of pH values and a light absorption range that includes a significant portion of the solar spectrum. In addition, the oxidation potential of the valence band hole must be sufficiently positive to form free radicals from adsorbed organics and/or create hydroxyl radicals from adsorbed water. Ideally, the reduction potential of the conduction band electrons must be negative enough to transfer electrons to dissolved oxygen or other electron acceptor molecules. No single material of a fixed size can satisfy all of these conditions, but as many reviews have noted, titania comes the closest [13, 17, 34]. It is photostable under near-UV illumination conditions, rendering it environmentally benign, and its redox potentials can drive photooxidation reactions for a variety of organic and biotoxins [13, 17]. It suffers primarily from too wide a bandgap, which requires that UV light excitation be used, corresponding to only 2–5% of the solar spectrum.

Many complete reviews focusing only on titania have appeared addressing its photophysical and photocatalytic properties [13, 14, 16, 17, 20, 22, 24, 26, 34, 40]. We shall selectively and critically review some of its properties based on these studies. We then discuss in more detail nanosized semiconductors which have received less attention, such as MoS_2 and WS_2. In our discussions we will emphasize the connection between synthesis, size, nanostructure and photocatalytic properties and also the characterization methods best suited to study this relationship.

3.6.3.2 TiO_2

Synthesis, Nanostructure and Electronic Properties The growth of a solid, colloidal material such as TiO_2 or SnO_2 from chemical precursors consisting of metal alkoxides can be catalyzed by acid hydrolysis. The hydrolysis is a stepwise process which initially produces TiO_2 molecules during the induction period. Over time, an increase in concentration of these molecules creates a condition of supersaturation, at which point nucleation occurs to form small agglomerates (typical sizes are 1–2 nm). It is generally known that a relatively short nucleation period removes the supersaturation condition and results in a narrow size distribution. Following the nucleation events, growth continues until all the precursor is exhausted.

Over the years, protocols have been empirically developed to synthesize TiO_2 colloids in the nanosize regime. Unfortunately, reviews and papers discussing the use of nano-TiO_2 as a photocatalyst usually give very little or no specific information regarding the many details of the synthesis, particularly the important issue of colloid size control. Research suggests that particle size is important for the photocatalytic activity of TiO_2 [58]. Hence it is worthwhile to give some synthesis examples from our laboratory discussed in a previous paper [68].

Our method is based on slow injection of a solution of either titanium or tin isopropoxide in 2-propanol into a rapidly stirred acidic solution (pH = 1.5). The ratio of 2-propanol to water was fixed at 1:10. Under these conditions, we observed that smaller sizes are favored by higher precursor concentrations and faster rates of injection for colloid sizes between 10 and 100 nm. A plausible rationalization of this observation is that higher titanium isopropoxide concentrations will produce larger numbers of critically sized nuclei of TiO_2, with less available precursor left to add to these nuclei, so growth will both be faster and end more quickly.

A systematic increase in final colloid size occurs upon increasing the pH of the acidic solution. However, this size increase is accompanied by a loss of long-term stability against aggregation. A critique of this explanation of the observed smaller sizes at higher concentrations is that it ignores the possible sintering and/or exchange of atoms between clusters which may occur after all the precursor is exhausted. This can result in changes in the colloid size distribution and even the average size. Our conclusions regarding size control differ from those of other workers who synthesized larger (400–500 nm) TiO_2 colloids by a similar process and found no systematic dependence of final colloid size on initial precursor concentration [91]. However, these experiments did not use acid-catalyzed hydrolysis and so the nucleation process was slower for an equivalent precursor concentration and resulted in colloids 400–500 nm in size. The small specific surface area of such colloids makes them unsuitable for efficient photocatalysis.

Nanostructure, Surface Structure and Photocatalytic Activity Although the TiO_2 anatase phase is favored thermodynamically, the solution growth process that we described can produce a mixed anatase–rutile phase and also amorphous material. Degussa P25 photocatalyst, for example, has a 70 : 30 anatase:rutile composition. Both anatase and rutile phases have tetragonal lattices with a rock salt-like structure.

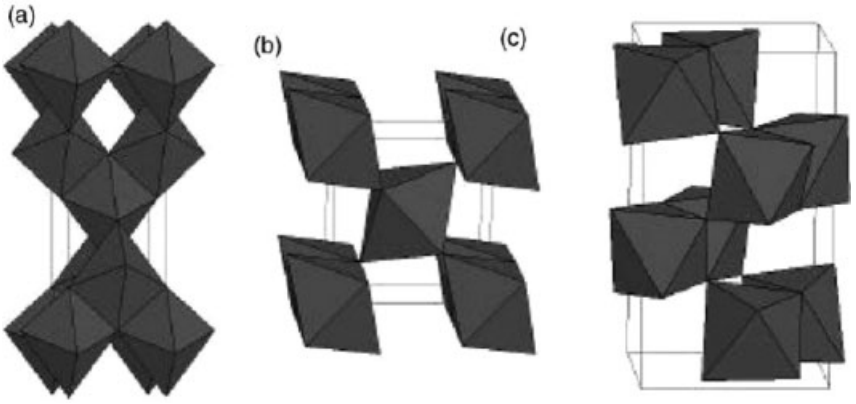

Figure 3.8 Crystal structure of (a) anatase, rutile (b) and (c) brookite showing the connections between TiO_6^{2-} octahedral subunits which distinguish the crystal structure of TiO_2 (Reprinted with permission from O. Carp, C. L. Huisman, A. Reller, *Progress in Solid State Chemistry* **2004**, *32*, 33).

If one views the structure as consisting of TiO_6^{2-} octahedral subunits, then these octahedra are connected by their edges in rutile and their vertexes in anatase as shown in Figure 3.8. Hence the latter has slightly less symmetry. Subsequent thermal treatments are generally used to maximize the anatase phase and improve crystallinity. Due to oxygen vacancies in the structure, the conductivity mechanism is n-type.

Many accounts in the literature assert that the anatase phase has greater photocatalytic activity than rutile [40, 92]. However, it is likely that the internal phase of nanocrystals of TiO_2 is less important to its photoactivity than the arrangement of the atoms at the surface, since these are the only atoms which interact directly with the substrate organic molecules. The number of hydroxyl groups present at the surface, which depends on the details of the synthesis, is also critical to the activity. It is worth noting that a mixed anatase–rutile–amorphous phase as found in Degussa P25 is, for most oxidation reactions, the most active known TiO_2 photocatalyst. This observation argues against an explanation of photoactivity solely in terms of internal phase. Instead, in this case improved charge separation has been invoked [93]. However, in our opinion, known impurities such as Fe(III) in Degussa P25 may actually be a better explanation.

When TiO_2 is used to photo-oxidize chemicals in water or air, water molecules rapidly adsorb on the surface. It has been estimated that there are about 5–15 hydroxyl groups for every square nanometer of TiO_2 surface [13, 94]. In addition to changing the adsorption characteristics of the catalyst surface, higher pH values increase the concentration of hydroxyl radicals, increasing the photo-oxidation rate of many organic chemicals. The adsorbed water molecules at the surface are also chemically important since they can form hydroxyl radicals upon reaction with photogenerated holes. These latter reactive species are key to the photo-oxidation of organic molecules in both the liquid and gas phase.

Substitutional Doping by Nitrogen The small amount (2–5%) of sunlight which is absorbed by TiO_2 limits its practical application in many circumstances. Thus, researchers have explored various synthetic strategies to increase the amount of light absorbed while still retaining the low cost and high stability of this material. A promising approach is to substitute nitrogen or sulfur atoms for oxygen in the TiO_2 lattice. Nitrogen doping has been shown to increase the absorbance onset of titania from 390 to almost 520 nm [95]. Nitrogen is introduced by exposure of the TiO_2 powder to ammonia gas at around 600 °C for several hours. This reduces the area as measured by the BET method by a factor of almost four. Perhaps related to this reduced surface area, it has been reported that the photocatalytic efficiency using these doped materials is only 14% of that found for the same photocatalytic reactions conducted at 351 nm, so most of the absorbed visible photons are not contributing to the desired photo-oxidation [96]. To overcome this deficiency, Morikawa *et al.* examined the effect of deposition of metals such as Cu, Ni, Pt, Zn and La on nitrogen-doped TiO_2 [97]. The ions were impregnated into the N-doped powders from aqueous solution, followed by evaporation of the water at 150 °C and calcinations at 300 °C for 2 h. They studied the oxidation of acetaldehyde using only light with wavelengths exceeding 410 nm. They reported that only Cu and Pt significantly enhanced the photocatalytic oxidation rate. They also found an optimal concentration of Cu of around 0.5 wt.%, at which the rate was enhanced by roughly a factor of two compared with the nitrogen-doped powder control. They hypothesized that the role of the Cu islands on the TiO_2 is to increase the carrier lifetime on the impregnated powders. It is worth noting that acetaldehyde was oxidized by TiO_2 doped with Cu at 0.5% continuously for 100 days without degradation of the catalyst, so this approach may work in practical photoreactors for indoor air purification.

Deposition of Metals An important factor for enhancing photocatalytic efficiency in small particles, noted previously in this chapter, is increasing the electron and hole lifetimes by improved charge separation. The deposition of noble metals on TiO_2 can reduce carrier recombination by serving as electron traps. The general synthetic approach used to deposit metals such as Pt on TiO_2 surfaces is photo-reduction of Pt salts such as chloroplatinic acid (H_2PtCl_6) in the presence of stirred slurries of the TiO_2 and near-UV light. The electrons promoted to the conduction band of the TiO_2 reduce the Pt salt which deposits on the TiO_2 surface. The amount of light exposure can be used to control the amount of Pt deposited [22].

As noted in a recent review by Choi, there are conflicting reports concerning the photocatalytic benefits of depositing Pt on the surface of TiO_2 [22]. The conflicting results can be traced to the different types of powders used, the loading level of the metal and the fact that different organic chemicals have been studied by each group. For example, Choi [22] found that the length of irradiation time used to deposit Pt on the TiO_2 affected not just the amount of metal deposited but also its oxidation state. Shorter photo-reduction times favored the presence of Pt(II) and Pt(IV) in addition to metallic Pt. Only Pt(0) was found to enhance the photocatalytic activity, which makes sense if the metal islands serve as electron storage sinks and reduce the recombination kinetics. Pt atoms in higher oxidation states may only serve to block access to

active sites and thus reduce the photo-oxidation of organic chemicals. One might also expect the physical size and adsorption mechanism to be strongly affected by the type of organic, which explains several of the conflicting reports concerning the efficacy of Pt deposition [69, 98].

An additional example of the use of metal island deposits in commercial anatase powders is the use of Ag/TiO_2 powders prepared by the photo-reduction of Ag ions by suspensions of TiO_2 [56]. The deposition of the Ag on TiO_2 was accompanied by increased absorption of the Ag/TiO_2 in the visible range (400–600 nm) where Ag clusters have significant absorbance. However, the absorbance was much broader than would be observed in isolated spherical clusters. This visible absorbance increased as the fraction of the Ag deposited increased from 0.5 to 2.0 wt.% relative to TiO_2. The catalytic photo-oxidation of two dyes was studied using a batch slurry reactor illuminated with UV light. Both dyes were photo-oxidized at substantially faster rates compared with the naked TiO_2 powder and, as in the Pt/TiO_2 studies described above, an optimal Ag loading of around 1.5% was found. The fast photo-oxidation of dyes by TiO_2 prevents the use of the dyes themselves to enhance the absorption of TiO_2 into the visible region. However, as discussed below, this dye sensitization has been proposed as a method of increasing the efficiency of TiO_2 photocatalysts.

The use of TiO_2 with deposited noble metals can be studied with either batch slurry reactors as described above and shown in Figure 3.9, in studies of TiO_2/Pt and TiO_2/Ag or using more practical flow reactors whose walls are coated with the catalyst material. A good example of the last reactor design was given by Orlov *et al.* [55]. In this work, the photo-oxidation of two significant types of environmental pollutants was studied using both Degussa P25 TiO_2 and the same material modified by deposition of gold particles.

The method for deposition of the Au nanoparticles on the TiO_2 was taken from that described by Haruta [99]. This method produces hemispherical gold islands with a large contact area along the perimeter between the TiO_2 support and the Au. This large contact area is considered critical in the activity for oxidation reactions since the TiO_2 will adsorb oxygen and water while the Au can serve as a reservoir of electrons. The synthesis method described by Haruta can produce small Au islands on any form

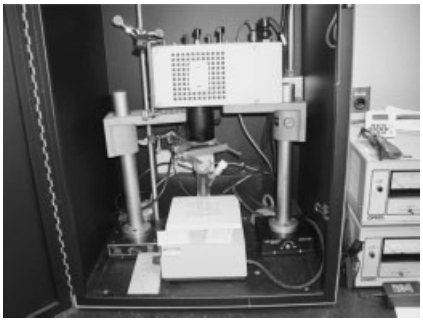

Figure 3.9 Photochemical reactor with overhead xenon lamp illumination, magnetic stirring, sampling sidearm.

of substrate, including powders, honeycombs and thin films. An ionic solution of a gold precursor such as $HAuCl_4$, when aged for about 1 h at a pH > 6 in the presence of a high surface area powder such as Degussa P25 TiO_2, forms deposits of $Au(OH)_3$ on the powder surface. Calcination can then be used to transform this coating into metallic Au islands. Control of the particle size is not critical to this method since only the perimeter Au atoms are believed to be catalytically active. In fact, Haruta showed that the rather large 4.6 nm diameter particles deposited by this method for pH > 6 are more active for the photocatalytic oxidation of CO than 2 nm Pt particles.

In the photocatalysis studies described by Orlov *et al*. [55], the Au islands on Degussa P25 TiO_2 were first formed at ~1 wt.% Au, followed by dip coating of the resulting slurry on the inner cylinder of a photochemical reactor to form a film. Heating the inner cylinder of the reactor to ~300 °C for 30 min created good film adhesion and a uniformly thick coating with good longevity. Axial illumination through the clear outer cylinder of the reactor permitted good light penetration, and air flow from the bottom of the reactor provided both mixing and ample dissolved oxygen. This fixed-bed reactor design could be used in the field by flowing contaminated water through the coaxial cylinders.

The reactor design and Au/TiO_2 catalysts was tested for two common pollutants, chlorophenols, which originate from agricultural run-off of insecticides and fungicides, and methyl *tert*-butyl ether (MTBE). MTBE has been used as a gasoline additive to improve wintertime combustion and is now banned in the USA due to leaks from storage tanks into the water system in the past. MTBE is carcinogenic at only a few parts per billion. Both compounds are relatively robust and novel treatment methods such as photocatalytic oxidation are being explored [100].

A significant finding of Orlov *et al*.'s work [55] was that the reaction rate for the mineralization of 4-chlorophenol was increased by 50% over that of Degussa P25 TiO_2 by use of the TiO_2 with Au deposited at 1 wt.%. A doubling of the reactivity was shown for the destruction of MTBE. The reactor design used was also shown to allow removal of either pollutant at water flow rates required to treat contaminated water pools. The temperatures required to form stable films of Au/TiO_2 on the reactor inner walls did lead to some loss of surface area and thus lower activity than a slurry reactor using the same Au/TiO_2 photocatalyst, but the activity was still greater than that of pure Degussa P25 TiO_2 powders. The long-term application and stability of the photocatalyst in real-world conditions still requires more testing. The additional cost of the Au would be acceptable provided that the catalyst stability can be shown to be exceptional.

Dye Sensitization [$Ru(pyr)_3$] Although several experiments indicate that organic dyes adsorbed on the surface of TiO_2 undergo photo-oxidation, certain reactions involving chlorinated hydrocarbons and aromatics can be extended to the visible region using dyes which are adsorbed on the surface of the TiO_2 particles. The basic idea is that the dye absorbs visible light and if the energy level of the photoexcited electron on the dye molecule is higher than that of the TiO_2 conduction band the electron will be transferred into the conduction band of the TiO_2 semiconductor. The oxidized dye is then capable of capturing another electron (i.e. oxidizing) from a pollutant and being regenerated. The

increased physical separation of electron and hole due to this transfer process can improve the efficiency of the photo-oxidation. Examples of dyes which are effective and reasonably stable for this process are ruthenium–bipyridine complexes [101, 102]. The cost of such complexes due to the expensive Ru may make such modifications impractical for large-scale systems, however.

An interesting method of extending the absorbance onset via electron transfer while avoiding the problems with degradation of the organic part of a dye is to deposit transition metal salts such as Pt, Rh or Au chloride on the surface of TiO_2. It has been demonstrated that photo-oxidation of chlorinated compounds such as 4-chlorophenol using only visible light at 455 nm is then possible [65, 103–105]. The metal chloride complex absorbs visible light and undergoes M−Cl bond breakage, leaving the metal in an oxidized state and the chlorine atom on the cluster surface. Then electron transfer from this chlorine atom to a chlorine atom in the organic compound also adsorbed on the TiO_2 occurs and regenerates the metal, making the reaction catalytic. There are less possibly adverse reaction pathways in this approach compared with the use of organic dyes as sensitizers.

Research Needs for Future Improvements The key to further improvements in TiO_2-based photocatalysts is to develop synthetic methods extending the light absorption into the visible region so that UV lamps and their costs can be eliminated. These new photocatalysts may have to be based on new nanosized materials as described in the next section. Also, not enough is known concerning the true longevity of TiO_2 when used under real conditions of salts and other inorganic metal ions in the presence of organic pollutants. Since any particulate photocatalyst must be immobilized to prevent contamination of the water and loss of the catalyst, high surface area flow reactors which allow light to reach all the photocatalyst surface are critical. Methods of inexpensively regenerating the active surfaces of such reactors will also have to be developed.

3.6.3.3 Alternative Photocatalytic Materials

Introduction Several alternatives to TiO_2 as potential photocatalytic materials have also been investigated in an attempt to access more of the visible portion of the solar spectrum and potentially to enhance the photocatalytic efficiency for different reactions. Some of these alternative materials include ZnO, SnO_2, CdS, MoS_2, WS_2 and, more recently, nitrides and oxynitrides such as TaN and TaON, respectively. Of the oxide materials (other than TiO_2), ZnO has been the most studied. Along with ZnO, we also review the newer nitrides, specifically TaN, as part of a small sampling of the materials that have been investigated. MoS_2 is outlined in detail in the latter part of Section 3.6.

ZnO ZnO is another wide-bandgap material which has been explored as a photocatalyst by several groups. One concern with this material is its photostability for certain reactions in aqueous solution [106]. For other reactions, especially photo-oxidation of dyes, ZnO may have a better efficiency than TiO_2 [107]. Since the cost and absorbance characteristics of the two photocatalysts are similar, ZnO in nanosize form may be a useful alternative photocatalyst.

ZnO can be made by acid-catalyzed hydrolysis of zinc acetate in ethanol. A white gel-like material is formed by using this synthesis. A photocatalytic film on glass is formed by dip coating on to a glass substrate and calcining the film at 500 °C [87]. Typical ZnO particle sizes from XRD linewidths are about 35 nm with a BET surface area of around 27 $m^2 g^{-1}$ (For comparison, Degussa P25 TiO_2 has a 25 nm particle size and a BET surface area of 50 $m^2 g^{-1}$). It was found that the ZnO fluorescence was quenched in the presence of chlorinated aromatics, which indicates the hole was being transferred to the aromatic. The most strongly absorbed compounds were chlorinated aromatics compared with chlorinated aliphatics. Photocatalysis studies confirmed that the more strongly adsorbed aromatic compounds were also photo-oxidized at a faster rate.

By monitoring the rate of disappearance of these compounds under 365 nm illumination, it was asserted that the ZnO efficiency was larger than films of Degussa P25 TiO_2 under the same conditions. However, this efficiency was obtained from the initial slope of the kinetic data showing the rate of disappearance versus irradiation time. Despite the rapid initial disappearance, mineralization of widely investigated compounds such as 4-chlorophenol was incomplete after 250 min of irradiation. Our photocatalytic studies of 4-chlorophenol using slurry reactors of Degussa P25 TiO_2 showed complete degradation of this compound within this irradiation time of 250 min [52]. It is possible that immobilization of the ZnO and TiO_2 on the glass slide used in these studies decreases the available surface area, making their photocatalytic reactor design the limiting factor. The authors did not explain how the total surface area and light flux were measured to allow a direct comparison of the two photocatalysts. Hence it is difficult to see how their conclusions regarding the superior efficiency of ZnO are supported.

ZnO fluorescence and its sensitivity to hole scavengers can be used to monitor the presence and the destruction of organic molecules as reported by Kamat's group [108]. The sensitivity to the presence of chlorinated aromatics is about 1 ppm using the fluorescence emission at typical concentrations of nanosized ZnO (1 mg mL^{-1}). The recovery of the fluorescence as the chlorinated aromatic is photo-oxidized allows the reaction kinetics to be monitored. This method also allows researchers to follow the state of the ZnO since any degradation or activity loss will lower the total fluorescence from the solution. An example of this behavior for 4-chlorocatechol is shown in Figure 3.10. Successive additions of 4-chlorocatechol do not cause loss of total fluorescence with time, indicating good ZnO stability.

Research suggests that ZnO probably does not provide any significant photocatalytic advantages compared with TiO_2, since it also fails to absorb a significant portion of sunlight. To bypass this shortcoming, other materials must be developed. An example of photocatalysts which absorb a significant fraction of visible light is given in the following section.

Ta_3N_5 and TaON Nanoparticles of nitrides and oxynitrides present two other potential classes of materials for photocatalysis. Specifically, Ta_3N_5 and TaON with bandgaps of ~2.07 and 2.4 eV, respectively, appear to be appropriate for visible light

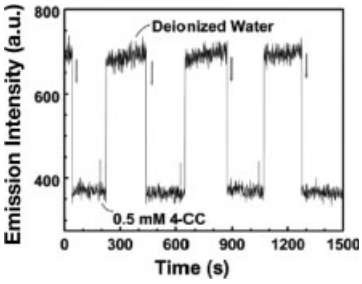

Figure 3.10 The fluorescence emission intensity from ZnO nanoparticle when exposed to aliquots of .5 mM 4-chlorocatechol (4-CC). The destruction of the 4-CC by the UV-driven photocatalysis requires about 200 s to restore the fluorescence. (Reprinted with permission from P. V. Kamat, R. Huehn, R. Nicolaescu, *J. Phys. Chem. B* **2002**, 106, 788).

photocatalysis and have been shown to be fairly active for the photocatalytic destruction of methylene blue (MB) [109]. Zhang and Gao synthesized nanosized Ta_3N_5 through high-temperature (600–1000 °C for 5–8 h) nitridation of Ta_2O_5 nanoparticles. The Ta_3N_5 crystallite size, which was determined by XRD, appeared to depend on the nitridation temperature, which was also critical in determining the extent of nitride formation (i.e. complete nitridation only occurred at higher temperature starting at 900 °C). Thus, smaller sized crystallites (~18 nm) nitrided at 700 °C often also contained the tantalum oxynitride phase. It therefore follows that with the higher temperatures needed for complete nitridation, that larger crystallite sizes on the order of 75 nm formed at 900 °C. However, there seems to be some variation in the resulting nitride formation based on temperature as a parameter since, according to the authors, pure phases of Ta_3N_5 also occurred at 700 °C but with resulting crystallite sizes of ~26 nm. Control over the synthesis parameters for this materials system seems to be difficult. Thus, the formation of a pure nitride phase also proved difficult.

In studying the photocatalytic degradation of MB, Zhang and Gao compared the reactivity of Ta_3N_5 nanoparticles with standards such as Degussa P25 TiO_2 and TiO_2 doped with N ($TiO_{2-x}N_x$) for visible light reactions using batch slurry-type reactors [109]. Compared with the $TiO_{2-x}N_x$ under UV/Vis illumination, the authors found a faster rate of photodegradation of MB by the 18 nm Ta_3N_5–TaON phased nanoparticles and also the 26 nm nanoparticles consisting of pure Ta_3N_5. The comparison with the $TiO_{2-x}N_x$ is perhaps slightly misleading since, as we discussed above, this form of TiO_2 has been shown to have decreased photocatalytic efficiency compared with pure TiO_2. The main role of the N doping is to extend the absorption into the visible region. A fairer comparison under the UV/Vis conditions would be with Degussa P25, which the authors did not show. The authors performed the comparison with Degussa P25 only under visible light conditions where it has minimal absorption and subsequently suppressed photoactivity. Accordingly, the Ta_3N_5 systems perform better than both the Degussa P25 and $TiO_{2-x}N_x$ under visible light illumination for the photo-oxidation of MB. The

authors also claimed that a size dependence to this photocatalytic activity exists where smaller Ta_3N_5 crystallites (~18 nm) are more active than larger ones (~75 nm). It is important to distinguish, as the authors did, between crystallite size and particle size. There may be some evidence of varying photoactivity as a function of crystallite size, but this cannot be translated into particle size since, as can be seen from their TEM images, there is a significant particle size distribution where large aggregates have formed. Also, as stated by the authors, the 18 nm sample was not a pure phase of TaN, but consisted of a Ta_3N_5–TaON mixture whereas the 75 nm samples were pure Ta_3N_5. It is therefore difficult to conclude that the photocatalytic activity of these materials is size dependent. It could very well be a case similar to TiO_2, where phase plays a very important role depending on the specific reactions of interest. Regardless of size dependence, these systems do show potential for visible light photocatalysis, but it is not clear that they are better than TiO_2, especially Degussa P25.

3.6.3.4 MoS_2 and Other Metal Dichalcogenides

High surface area TiO_2 powders in nanosized form such as Degussa P25 TiO_2, $d \sim 25$ nm, as mentioned above, are the most studied photocatalysts. However, TiO_2 has a significant disadvantage due to its large bandgap of ~3.2 eV. This means that it can only be excited by UV illumination of ~390 nm or shorter wavelength, thus requiring the use of UV lamps, increasing the cost of detoxification. If sunlight is used as the light source, TiO_2 absorbs only 3–7% of the solar spectrum, as illustrated in Figure 3.11 [52]. Also shown in Figure 3.11 is the absorption edge of bulk TiO_2 compared with three sizes of MoS_2: bulk, 8 nm and 4.5 nm. Research and analysis by Tributsch [110] has revealed that in order for photocatalysts to be useful in solar fuel production and chemical waste detoxification, the semiconductor material must meet the following requirements: (1) have a bandgap matched to the solar spectrum, (2) have valence and conduction band energy edges compatible with the desired redox potentials, (3) be resistant to photochemical degradation and (4) have a short carrier diffusion time leading to faster energy transfer for the surface compared with electron–hole recombination times [52]. All of these properties can be achieved through tailoring of the optical and electronic properties of MoS_2 nanoclusters based on the size. Prior to discussing MoS_2 nanoclusters, it is worthwhile reviewing the properties and uses of bulk MoS_2.

MoS_2 Bulk Properties and Historical Background MoS_2 and its structural isomorphs such as WS_2, MoS_2 and WSe_2 have excellent corrosion resistance, which has resulted in a variety of high-temperature catalytic and lubrication applications. This resistance to oxidation comes from the two-dimensional structure of these materials and the resultant electronic properties shown in Figures 3.12 and 3.13. In Figure 3.12, it is observed that the valence band is composed of Mo d_{z^2} states and the conduction band of Mo d_{xy} and $d_{x^2-y^2}$ states, so that excitation of an electron across the 1.75 eV gap doesn't weaken any chemical bonds.

Human use of Mo from MoS_2 has a long history. The mineral form of MoS_2, known as molybdenite, is a naturally occurring mineral and one of the most abundant

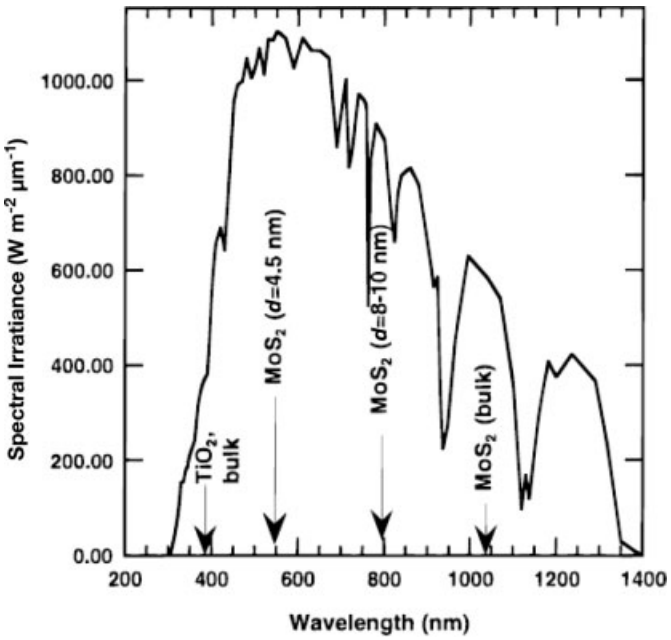

Figure 3.11 Solar spectral irradiance (AMD 1.5D) showing the radiation reaching the Earth's surface as a function of wavelength. Included in this spectrum are the absorption edges of bulk TiO_2 and MoS_2 in various forms. (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

forms found in the Earth's crust. This contrasts with most other metal sources such as Fe, Al and Ti, which occur naturally as oxides [111]. Due to its long history and the fact that molybdenite occurs naturally as a mineral in the Earth's crust, it is thought to have been used in very early times, such as in 14th century Japanese swords [111]. Initially, MoS_2 was thought to be the same as other ores such as lead or graphite and was named "molybdos", meaning "lead-like", by the ancient Greeks [111]. In 1778, Karl Scheele, a Swedish chemist, demonstrated that molybdenite was actually a sulfide mineral [112, 113] and that it contained molybdenum metal [111]. Extraction of the Mo was also later performed by Peter Jacob Hjelm in 1782 by reducing molybdenite with carbon [111]. Throughout the 19th century, interest in Mo was primarily non-commercial.

Commercial and technical applications of Mo were enabled by mining and extraction improvements, allowing the extraction of molybdenite in commercial quantities. The use of Mo in metal alloys steadily increased with time with the increased demands beginning around World War I. Most of molybdenite is MoS_2 and the rest consists of silicates and other rare metals such as Re [113]. To extract a purer form of MoS_2 from molybdenite, the mineral is subjected to a series of crushing, cleaning and purification steps [113]. The use of MoS_2 as a hydrotreating catalyst [114] for removal of heteroatoms from crude oil in fuel refining and as a high-temperature

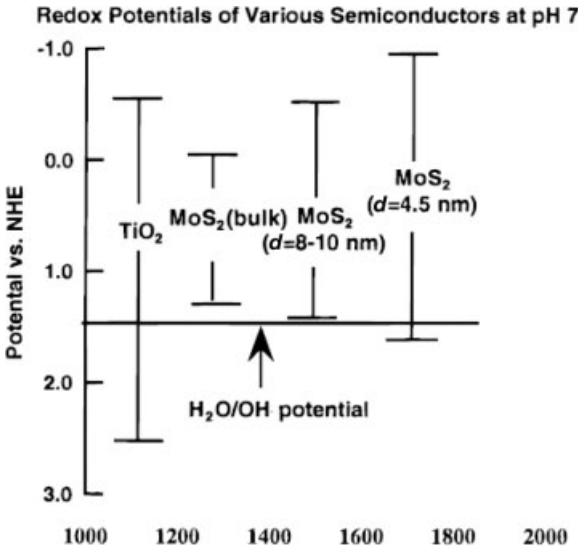

Figure 3.13 Conduction and valence band edge positions relative to the normal hydrogen electrode (NHE) for bulk TiO_2, bulk MoS_2, MoS_2 ($d = 8$–10 nm) and MoS_2 ($d = 4.5$ nm). (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

lubricant also increased rapidly during the 20th century. Research in Germany around the time of World War II identified formulations of MoS_2 on alumina supports capable of removing heteroatoms such as S, N and O from crude oil feedstocks, allowing subsequent refining operations using transition metal catalysts to be conducted without poisoning of these materials by sulfur. MoS_2 has been studied extensively both in the purified form and in its natural state. It was found to be easy to study using optical and electrochemical methods since it can be cleaved to very thin layers, making it suitable for optical and electronic studies [115].

Roscoe Dickinson and Linus Pauling elucidated the anisotropic crystal structure of MoS_2 in 1923 [116]. In this work, they noted that by 1904 Hintze had discovered that MoS_2 occurred as hexagonal crystals with complete basal cleavage planes. Dickinson and Pauling showed that Mo has six S atoms surrounding it in an equidistant manner at the corners of a triangular prism. They determined this through the use of Laue photographs and the theory of space groups [116]. Following this, they also showed that the S and Mo were stacked in S–Mo–S sandwiches along the *c*-axis and that there were two sandwiches per unit cell where $c = 12.3$ Å [116]. Later, Hultgren [117] and Pauling [118] showed that trigonal bonding in MoS_2 and WS_2 was due to d^4sp hybridization of atomic wavefunctions. The bonding within the MoS_2 sheet was determined to be covalent and the trilayer sheets were held together by weak van der Waals forces. Figure 3.6 shows a schematic of the MoS_2 sandwich structure. The most stable form of MoS_2 is the 2H-MoS_2 structure. Two other metastable polytypes also exist: 1T-MoS_2 and 3R-MoS_2[119]. The space group for the stable 2H-MoS_2 is $P6_3/mmc$ [120]. The quasi-2D, graphite-like structure where the trilayers consisting of S–Mo–S sandwiches held together by weak van der Waals forces allows the facile shearing reported by Dickinson and Pauling. MoS_2 has many applications in lubrication, especially in space applications and at high temperatures where its solid state form is an advantage [121, 122]. Other industrial applications include catalytic hydrodesulfurization (HDS) [114, 123]. It has also been proposed as a possible solar photoelectrochemical electrode for hydrogen generation from water [124].

MoS_2 is a semiconductor with an n-type conduction mechanism. Its optical absorbance properties are due to both direct and indirect transitions, which have been investigated by a variety of measurement techniques, including optical absorption and transmission [115, 125–127], reflectivity measurements [128, 129], electron energy loss measurements [130] and electron transport measurements [131]. For example, Goldberg *et al.* [127] measured the optical absorption coefficient, emphasizing the features below the first exciton [115] located at ∼680 nm. The lowest energy absorption at 1.24 eV (∼1000 nm) at room temperature was forbidden (i.e. indirect) and thus weak. [127]. Using photocurrent measurements, Kam and Parkinson obtained similar values of 1.23 eV for the indirect E_g of MoS_2 and 1.69–1.74 eV for the direct gap [132]. Roxlo *et al.* used photothermal deflection and transmission spectroscopy [133] to obtain a highly precise value of the indirect bandgap of 1.22 ± 0.01 eV. Using the augmented spherical wave method, Coehoorn and co-workers calculated detailed band structures for MoS_2, $MoSe_2$ and WSe_2 [120, 134].

It is possible to determine the valence and conduction band levels of bulk n-type MoS_2 using cyclic voltammetry. For example, Schneemeyer and Wrighton studied the oxidation reactions of biferrocene and *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine using an MoS_2 electrode and found that the flat-band valence band potential was $+1.9$ V vs. SCE, demonstrating that the direct transition of around 1.7 eV controls the oxidizing power of the holes [135]. They noted that this potential should allow most of the oxidation reactions possible at TiO_2 to take place for MoS_2 also.

To test this hypothesis without the competing reaction of water oxidation, they studied the oxidation of Cl^- ion in an oxygen-free solvent, acetonitrile. They found that a sustained evolution of chlorine gas was indeed observed upon visible illumination of the MoS_2 electrode with no loss of photocurrent for over 8 h of continuous operation. During this experiment, many moles of electrons were generated without any visible (i.e. microscopic) evidence for oxidation of the MoS_2 electrode. Their results support the results predicted by Tributsch for the electrochemical photo-oxidation of water described in the next section [110].

Photocatalytic Properties of MoS_2 A detailed and systematic search for photocatalysts allowing the photo-oxidation of water using visible light was reported by Tributsch in 1977 [110, 124]. The principles he outlined for successful water photo-oxidation should also apply to photo-oxidation of organic molecules. For example, a suitable photocatalyst must be capable of absorbing visible light, have valence and conduction band potentials appropriate for the substrate molecule to be oxidized, have an efficient mechanism for electron–hole separation, be chemically stable (i.e. exciton creation must not weaken the chemical bonds in the structure) and be inexpensive and/or easy to synthesize [110].

Based on the first requirement, oxide compounds were determined to be unsuitable since they absorb mostly in the UV region (e.g. TiO_2, ZnO, SnO_2). Polar semiconductors such as CdS were also ruled out since they are unstable as the photogenerated electrons weaken the chemical bond. Transition metal dichalcogenides appeared to be the most suitable candidates [110]. Tributsch investigated a large number ($\sim$70) of metal dichalcogenides and concluded that the most favorable materials were WS_2, MoS_2 and TcS_2. Due to its lack of abundance and high cost, TcS_2 was deemed unsuitable. WS_2 was also ruled out since it was difficult to obtain as large crystals at that time. MoS_2 was readily available and easy to process, becoming the obvious final choice.

A detailed analysis of the MoS_2 band structure was also reported (Figure 3.12) [110]. Optical transitions occur between the d states, as shown in Figure 3.12. Since the formation of the exciton pair occurs via the metallic d states, light absorption has no adverse affect on the Mo–S chemical bonds. It is this phenomenon that accounts for the stability of MoS_2 against photocorrosion and accounts for the widespread use of MoS_2 as a stable, high-temperature solid-state lubricant and its applications as an electrode material with good corrosion resistance in water.

Tributsch demonstrated the oxidation of water with the formation of molecular oxygen and hydrogen using MoS_2 as an electrode [110]. However, the reaction needed

to be assisted by a redox catalyst such as tris(2,2′-bipyridine)ruthenium (II), since the rate of O_2 generation was low. This was probably due to the inherent limitations of MoS_2 in the bulk form and a kinetic bottleneck for transfer of the conduction band electrons to form hydrogen gas by reduction of water. Also, being an indirect bandgap semiconductor with a small bandgap (~1.22 eV) in the near-IR region, the potential may not be large enough to drive the necessary redox chemistry. This is important for other photocatalytic applications also, such as the photodestruction of toxic chemicals, since the valence and conduction band edges may not match the redox potentials sufficiently.

Motivated by Tributsch's calculations, other groups explored the use of bulk transition metal dichalcogenides in photoelectrochemical applications and in photocatalysis. The behavior of n-WSe_2 and $MoSe_2$ single crystals as photoanodes in regenerative photoelectrochemical cells [136] was compared with the behavior of WS_2 and MoS_2 [137]. The diselenides were reported to have conversion efficiencies of ~10% using a sodium iodide electrolyte. However, the conversion efficiencies for the disulfides were considerably lower. Other groups were subsequently able to increase the conversion efficiency to >14% using nanosized WSe_2 in a polyiodide solution [138]. A still higher conversion efficiency (17%) was achieved using WSe_2 through enhancement of the crystal quality using an etching technique developed by Tenne [138, 139].

Some work has been reported on the use of bulk dichalcogenide powders for photodestruction of chemical wastes. DiPaola *et al.* studied WS_2 and WO_3 and also mixtures of the two materials in the photocatalytic degradation of phenol [140]. They discovered that the mixed system had a much higher rate of phenol conversion than the individual pure bulk powders. It is unlikely that simply mixing two bulk powders would affect the recombination kinetics as their interfaces are not in physical contact, so this result is difficult to rationalize. Our work with bulk powders of MoS_2 and WS_2 [52, 68] contradicts the above report of photocatalytic activity for either phenol or pentachlorophenol. On the contrary, we found that slurries of these powders and also other layered materials such as PtS_2 inhibit the near-UV photo-oxidation process compared with solutions containing no catalyst. However, nanosized MoS_2 shows considerable photocatalytic activity.

Nanosized Photocatalysts of MoS_2 and WS_2 One key to the photocatalytic activity observed in nanosized MoS_2 is the effect of size on the optical and electronic properties of nanosized semiconductors. The confinement of holes and electrons to a reduced size particle results in a blue shift of the absorption onset compared with the bulk material. For example, as shown in Figure 3.11, the absorbance onset of MoS_2 blue shifts from the bulk value of ~1040 nm to ~550 nm for 4.5 nm sized clusters in solution. Just as significant for photocatalytic redox reactions, the increase in bandgap with decrease in cluster size causes the valence band to shift to more positive values and the conduction band to more negative values. Both shifts enable photo-oxidation of organic chemicals to occur more readily. By measuring the rate of transfer of holes and electrons, one can estimate the energy levels as a function of cluster size, as shown in Figure 3.13, where the potentials are measured at

pH 7 versus NHE [52]. It should be noted that the pH of a solution of a metal sulfide has a different chemical effect on the cluster surface compared with a metal oxide such as TiO_2, where low pH tends to make the surface positive and change its substrate binding properties. For example, the formation of $Ti–OH_2^+$ structures, which is important at typical pH values of around 1 used in many photocatalytic studies, is not possible for MoS_2.

An advantage of MoS_2 nanoclusters over bulk MoS_2 is the increased surface to volume ratio (S/V), allowing for more efficient surfaces traps per volume. In addition to lowering the cost of the photocatalyst by reducing the amount of material required, the high S/V ratio increases the likelihood of surface trapping of the photogenerated carriers and so increases the lifetime of the charge carriers prior to recombination. This increases the probability of successful hole transfer to an organic pollutant. Also, since nanocluster solutions scatter a negligible amount of light, simplified analysis of the photocatalytic behavior of the system is possible. As in the case of TiO_2, the method of nanocluster synthesis is likely to have a significant effect on the cluster photocatalytic properties.

MoS_2 Nanocluster Synthesis Since photocatalytic applications of MoS_2 often require solution processing methods to form either films or disperse solutions, liquid-phase synthesis has some advantages compared with vacuum or gas-phase methods. Monodispersed solutions of MoS_2, $MoSe_2$, WS_2 and WSe_2 nanoclusters were first synthesized by Wilcoxon and co-workers using an inverse micelle approach [51, 52, 68, 141–144]. In this method, surfactant molecules are dissolved in a suitable non-polar organic such as toluene or octane. The surfactants are chemically bipolar with a water-loving or hydrophilic head group joined to a hydrophobic or water-hating tail group. Their bipolar nature causes the surfactants to associate and form droplet-like aggregates as shown schematically in Figure 3.14. The non-polar organic tail groups prefer to form an interface with the non-polar solvent, which allows the hydrophilic head groups to be shielded from the solvent and lowers the free energy of the solution. These aggregates are called inverse micelles since the curvature of the interface is the opposite to that of normal micelles that form in water with the hydrophilic head groups interfacing with a continuous water phase. The reader may be familiar with normal micelle aggregates as they are critical to allowing solubilization of hydrophobic entities such as oil and permitting detergent action, which gives soaps the ability to remove oil from clothes and skin.

Inverse micelles have a water-like interior volume which can dissolve ionic metal salts just as water does. However, the absence of water means that undesired chemical reactions such as hydrolysis to form metal hydroxides cannot occur. The dissolved metal ion pairs interact and are stabilized by the hydrophilic head groups instead of water, and these head groups are not reactive chemically. When this metal salt solution is then mixed with another inverse micelle solution containing an ionic sulfiding agent, such as a metal sulfide or H_2S, a controlled aggregation to form a nanocrystal of MoS_2 ensues [52]. The cluster growth process is relatively slow compared with the same reaction in a continuous, homogeneous medium since it requires diffusion and collisions between micelles to allow exchange of the growing

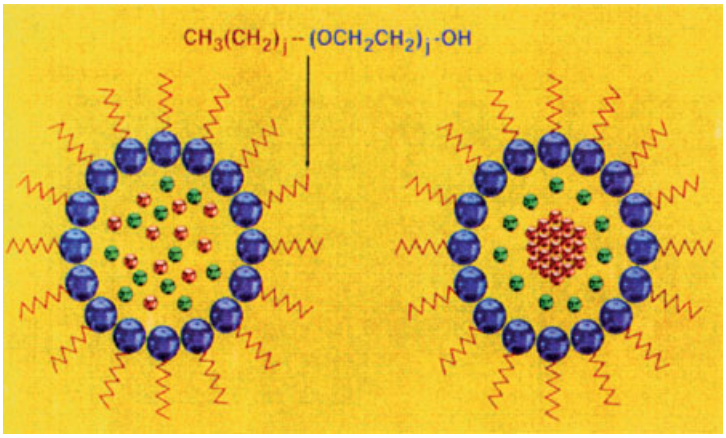

Figure 3.14 Schematic showing a two-dimensional drawing of a spherical inverse micelle with hydrophobic tail groups (red) forming an interface with a continuous oil medium (yellow). The hydrophilic head groups shown in blue provide a water-like environment which permits ionic metal salts such as $MoCl_4$ to dissolve and form ion pairs shown in red [Mo(IV) cations] and green (Cl^- anions) in the micelle interior. Reaction of the metal ions with a sulfur source such as H_2S results in the growth of a nanocrystal of MoS_2 as shown on the right. The surface of the nanocrystal is stabilized against aggregation by the surfactants which are later removed via an extraction process described in the text.

nanocrystals. The kinetics of this process are controlled by the size of the inverse micelle cage that is used to dissolve the Mo salt and also the initial salt concentration. The slow nanocrystal growth allows good ordering of the atoms even at room temperature and this is confirmed by HRTEM, showing atomic lattice planes and facets on the nanocrystals and also selected area electron diffraction (SAD). Figure 3.15 shows a SAD pattern of a 4.5 nm MoS_2 cluster, revealing the same hexagonal crystal structure as the bulk [51]. Figure 3.16 shows an HRTEM image of a MoS_2 cluster ~3 nm in size. This image reveals that the cluster is highly crystalline with no defects. The lack of defects in nanoclusters of this size is perhaps not surprising since any defect that may form has a very short distance to diffuse out to the nanocluster surface.

MoS_2 clusters synthesized in inverse micelles in non-polar oils such as decane can be extracted into immiscible polar organic solvents such as dry acetonitrile or methanol. In this process most of the ionic by-products and free surfactant is removed and the resulting solutions can be dissolved in water. Figure 3.17 shows a photograph of these solutions with each solution having a distinct color and absorbance onset determined by the average cluster size. Since acetonitrile can be obtained in high purity with no absorbance above 200 nm, detailed complete absorbance spectra on purified MoS_2 clusters are readily collected.

Optical absorption spectra of nanosized MoS_2 (4.5, 3 and 2.5 nm) compared with the bulk are shown in Figure 3.18 [51]. Curves 3, 4 and 5 correspond to solutions of 4.5 nm, 3 nm and 2.5 nm MoS_2, respectively (note the logarithmic scale of the absorbance axis). The absorption features in the bulk spectra can be traced to the

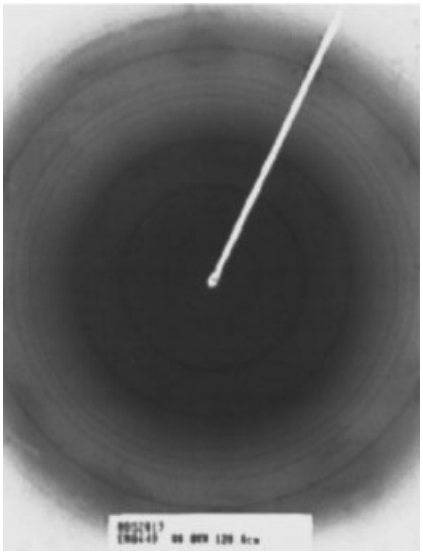

Figure 3.15 SAD pattern of 4.5 nm MoS_2 clusters showing a hexagonal structure. (Reprinted with permission from J. P. Wilcoxon, P. P. Newcomer, G. A. Samara, *Journal of Applied Physics* **1997**, *81*, 7934).

different transitions in the band structure as shown in Figure 3.19 [51]. There is a weak absorption onset at ~1040 nm (~1.2 eV) (Figure 3.18), which is attributed to the indirect bandgap occurring between the Γ point and the middle of the Brillouin zone between Γ and K [51]. The direct bandgap occurring at the K point is represented by the next absorption onset at ~700 nm (~1.8 eV). There are actually two peaks that correspond to this direct transition, labeled A_1 and B_1. The energy separation of these two peaks is most likely due to spin–orbit splitting of the valence band at the K point [51, 120, 126, 134]. There is another direct transition originating deep within the

valence band, corresponding to the absorption onset at ~500 nm (~2.5 eV). This transition is labeled C and D.

As semiconductor clusters become molecular in size, the continuous bands due to the translational symmetry develop molecule-like structure and discrete bands. The valence band evolves into the highest occupied molecular orbital (HOMO) and the conduction band evolves to become lowest unoccupied orbital (LUMO). These bands are seen in the absorbance peaks of Figure 3.18. Photoexcitation leads to electron

promotion from the HOMO to the LUMO. Some weak luminescence is observed from these cluster solutions due to radiative recombination from the LUMO to the HOMO. This luminescence can be used to monitor the transfer rate of the electrons or holes to other adsorbed species and roughly estimate the size-dependent conduction band energy levels [84].

It is worth noting that other synthetic methods for the formation of MoS_2 nanoclusters result in clusters with metallic properties. For example, ultrahigh vacuum methods have been employed to deposit 2D Mo nanoclusters on gold surfaces followed by sulfidization of Mo metal islands [123, 145–147]. As a result of this synthetic route, the formation of triangular clusters through analysis using scanning tunneling microscopy (STM) [123, 145] was discovered (Figure 3.20). The

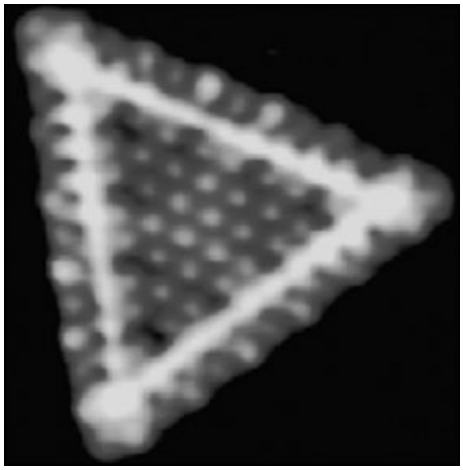

Figure 3.20 STM image of a triangular MoS_2 nanocluster with dimensions of 48 × 53 Å. (Reprinted with permission from M. V. Bollinger, K. W. Jacobsen, J. K. Norskov, *Physical Review B* **2003**, *67*, 085410).

STM image in Figure 3.20 shows a single layer of MoS_2. These triangular clusters were shown to have metallic conducting properties for the atoms at the edges. Since these clusters were grown on a support, it is not certain that free clusters would have the same geometry and electronic properties.

More recently, Lauritsen *et al*. showed that excess sulfur can be present at the edges depending on the cluster size [148]. They also showed that there is a tendency for the preferential formation of particular sizes, suggesting the formation of "magic sizes" that are thermodynamically favored. This is an important observation under these synthesis conditions since this phenomenon is observed in many other materials systems and under various synthetic routes. It also leads to better size control and, with this control, the authors were able to link atomic-scale structural analysis to cluster size using STM. The subsequent implications for enhanced catalytic activity, particularly for hydrodesulfurization (HDS), are thus promising.

Accordingly, Bertram *et al*. investigated both MoS_2 and WS_2 clusters formed in the gas phase and used mass and photoelectron spectroscopy to show that these clusters have planar platelet structures [149]. The platelet structures were shown to stack just as in the bulk to form larger clusters.

These MoS_2 clusters from Bertram *et al*.'s work were grown by evaporation of bulk MoS_2 using a pulsed electric arc. Both charged and neutral M_nS_m clusters grow within an inert seeding gas of helium. To study the effect of extra sulfur on the structure, they also vaporized Mo and W metal, allowing metal clusters to form of various sizes which were then exposed to controlled amounts of H_2S gas. The smallest platelets formed had a metallic character and were chemically inert. They began stacking just as in the bulk structure since multiples of fundamental platelet masses were observed. Mass analysis was consistent with extra sulfur atoms at edge sites. Simulations indicated these extra sulfur atoms stabilized the structures and a "magic sized" cluster of WS_2 is shown in Figure 3.21 taken from [149]. (The phrase "magic sized" derives from the larger abundance of certain masses of clusters observed due to extra stability for special numbers of metal atoms.) Clusters were stable over a wide range of M:S ratios. This was explained by the hypothesis that polysulfide chains could grow near the edges of the cluster. Their observation of $S : Mo > 2$ is consistent with our observations of excess sulfur in clusters grown in inverse micelles, purified by chromatography and analyzed using X-ray fluorescence (XRF) spectroscopy. The nature of the bonding at the catalytically active Mo edge sites which are protected by sulfur atoms is likely critical to the photocatalytic activity, as is known in the case of HDS catalysis, the major catalytic application of MoS_2 [148].

The small triangular cluster shown in Figure 3.21 has a nearly zero bandgap (i.e. is metallic) and only the edge W atoms are metallic, whereas the states near the HOMO (the Fermi level) are delocalized over the entire plane of W atoms. Furthermore, this metallic character is due to the excess of sulfur at the edges and, as the clusters are grown larger and approach the 2 : 1 S : W ratio of the bulk, a gap develops. The optical properties such as absorbance and luminescence of our larger 2.5, 3 and 4.5 nm MoS_2 and WS_2 clusters grown in inverse micelles are consistent with an energy gap

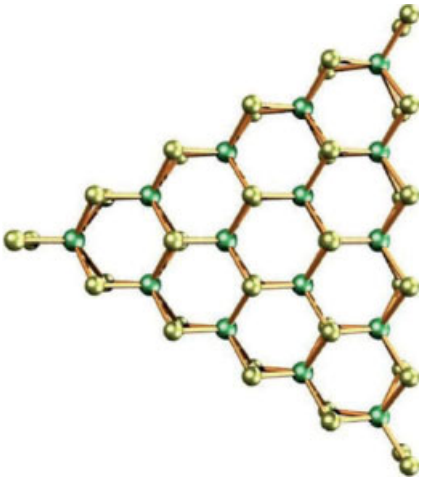

Figure 3.21 Structure of $W_{15}S_{42}$ platelet calculated by Bertram *et al.* (Reprinted with permission from N. Bertram, J. Cordes, Y. D. Kim, G. Gantefor, S. Gemming, G. Seifert, *Chemical Physics Letters* **2006**, *418*, 36).

between HOMO and LUMO states, indicating that they are semiconducting. Furthermore, the onset of the absorbance is consistent with an indirect optical transition even for the smallest 2.0 nm clusters studied by our group [144]. Indications are that clusters grown in free space differ in structure and electronic properties from those grown on substrates, possibly due to the significant interaction energies between the Au atoms in the substrate and the Mo atoms.

Quantum Size Effects in MoS_2 The effect of decreased cluster size and higher energy carrier confinement in both the in-plane and out-of-plane, transverse or *c*-axis direction of platelet stacking are important for the electronic properties of metal dichalcogenides. Studies of size-related phenomena were reported by Consadori and Frindt in 1970 through investigations of thin layers (13 Å, corresponding to a thickness of one unit cell) of WSe_2 [150]. They found that the optical absorption onset depended on sample thickness and showed a very small shift to higher energies with decreasing thickness. These effects were attributed to quantum size effects [150]. This was not the first observation of the effect of carrier confinement in small semiconductors; however, it may have been the first observation of quantum size effects in layered dichalcogenides. These effects were actually due to two-dimensional (2D) confinement in an infinitely large sheet and the shift in the energy of the A_1 exciton (E_{A_1}) was only 0.15 eV compared with infinitely thick samples.

As described below, compared with the shifts observed for metal dichalcogenide clusters in solution due to in-plane carrier confinement, the transverse out-of-plane confinement for thin layers is very weak. Lateral confinement of the carriers appears to be necessary in order to observe strong size effects. This result is consistent with the d–d band optical transitions which dominate the photoexcitation behavior of MoS_2. The energy shifts reported on thin WSe_2 reported by Consadori and

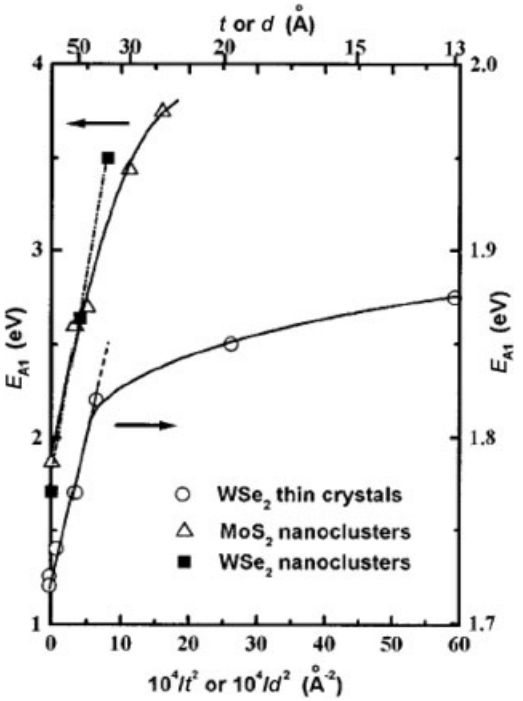

Figure 3.22 Influence of metal dichalcogenide layered structure dimensionality (2D vs. 3D) on the strength of quantum confinement of the A_1 exciton in WSe_2 and MoS_2. 2D confinement represents thin crystals and 3D confinement represents clusters. (Reprinted with permission from J. P. Wilcoxon, P. P. Newcomer, G. A. Samara, *Journal of Applied Physics* **1997**, *81*, 7934).

Frindt [150] are compared with the transverse confinement of MoS_2 and WSe_2 clusters demonstrated by Wilcoxon *et al.* [51] in Figure 3.22. In this figure, first exciton energy E_{A_1} is plotted as a function of $1/t^2$ for the 2D thickness study (right axis) and as a function of $1/d^2$ (where d = diameter) for the 3D cluster study (left axis). This $1/t^2$ dependence of ΔE_{A_1} is obeyed to $t \approx 40$ Å but then deviates significantly as the thickness decreases. The shift in E_{A_1} as sizes approach 40 Å in-plane carrier confinement is over an order of magnitude larger in the transverse direction. This deviation is even stronger at smaller sizes, which demonstrates the large difference between transverse and longitudinal confinement.

The absorption spectra of Figure 3.18 have structured features such as minima and maxima whose positions shift to the blue with decreasing cluster size. Figure 3.23 provides an examination of these peaks for MoS_2 clusters in dilute acetonitrile solution. The absorption edge shifts correspond to changes in the size-dependent bandgap and the density of energy states as the clusters become molecular in size. The effects of quantum confinement depend on the cluster dimension relative to the bulk excitonic Bohr radius (r_B). This dimension defines a cross-over from a strong to a

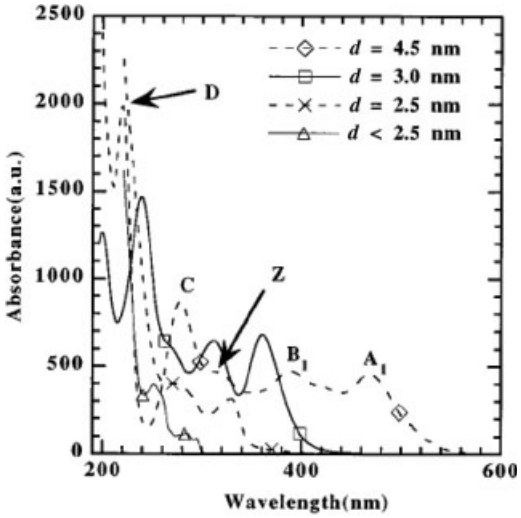

Figure 3.23 Optical absorption spectra of MoS_2 clusters ranging from <2.5 to 4.5 nm. The corresponding band structure transitions are shown, compare with Figure 3.17. (Reprinted with permission from J. P. Wilcoxon, P. P. Newcomer, G. A. Samara, *Journal of Applied Physics* **1997**, *81*, 7934).

weak regime. In 1938, Mott proposed a model of the hydrogen-like exciton for the $n = 1$ Rydberg states of the A_1 and B_1 excitonic peaks [151]. He thus determined that r_B for MoS_2 is 2 nm [51, 115, 151]. The 4.5 nm diameter MoS_2 clusters ($R = 2.25$ nm) are thus slightly larger than the bulk exciton, whereas 3.0 nm ($R = 1.5$ nm) and 2.5 nm ($R = 1.25$ nm) clusters should exhibit strong carrier confinement. Although $D = 4.5$ nm clusters are slightly larger than the r_B for MoS_2, they still exhibit properties vastly different from the bulk, which can be verified by the large blue shift in the absorption spectra shown in Figures 3.18 and 3.23.

The extent of carrier confinement manifests itself through the effect of particle size on spin–orbit splitting of the absorbance peaks. Decreasing cluster size is accompanied by an increase in the spin–orbit splitting of the A_1 and B_1 excitonic peaks. Effective mass theory (EMM) defines quantum confinement as the shift in the absorption edge or bandgap, $E_g(R)$, for a cluster with radius R, to be proportional to $1/2\,\mu R^2$, where μ is the reduced exciton mass [79]. When $E_g(R)$ is plotted against $1/R^2$, a straight-line plot should result with a slope proportional to $1/(2\,\mu)$ [51]. However, deviations from linearity for each excitonic peak occur as the cluster size decreases (Figure 3.24). The increase in spin–orbit splitting between the Wannier excitonic peaks, A_1 and B_1, as a function of decreasing cluster size also occurs [51]. The difference between peaks A_1 and B_1 is 0.67 eV for MoS_2 clusters of 2.5 nm [51] compared with ~0.20 eV for the bulk [120, 126, 134].

When $R/r_B > 4$, the quasi-particle nature of the excitons is predicted to be preserved [81]. The quasi-particle characteristics are lost, however, when $R/r_B < 2$ and the charge carriers are confined, leading to independent carrier behavior. The

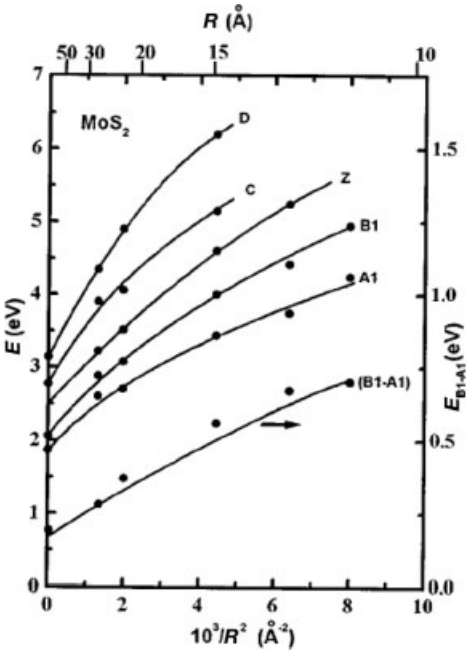

Figure 3.24 E(R) vs. $1/R^2$ showing deviations from linearity for each excitonic peak with decreasing MoS_2 cluster size. Increase in spin–orbit splitting is also represented by the right axis. presence of specific excitonic peaks in the absorption spectrum of MoS_2 is preserved for clusters sizes of $\leq$2.5 nm, while the significant blue shifts remain consistent with strong quantum confinement. This could be due to the 2D nature of the strong bonding in MoS_2 [51]. Since the hole and electron confinement radii differ, the true picture is more complicated. Bulk values for hole and electron masses may not apply to very small cluster sizes where the confining potentials are dependent on the cluster surface structure and chemical nature of the adsorbed ligands. For example, the presence of excess sulfur at the edge sites may increase or decrease the electron density on the Mo atoms and thus affect catalytic activity.

Photocatalysis Using MoS_2 Nanoclusters Nano-MoS_2 is suitable as a visible light photocatalyst due to the effects of strong quantum confinement on its optical properties. For example, the blue shift of the absorbance onset with decreasing cluster size increases the oxidation (valence band holes) and reduction (conduction band electrons) potentials (Figure 3.13). Photocatalysis experiments reported using either MoS_2 or WS_2 are much more limited than TiO_2 and date only to around 2000. Since photoexcitation can be driven with visible radiation, unlike most metal oxides, lower costs are potentially possible since a larger portion (visible) of the solar spectrum is accessible.

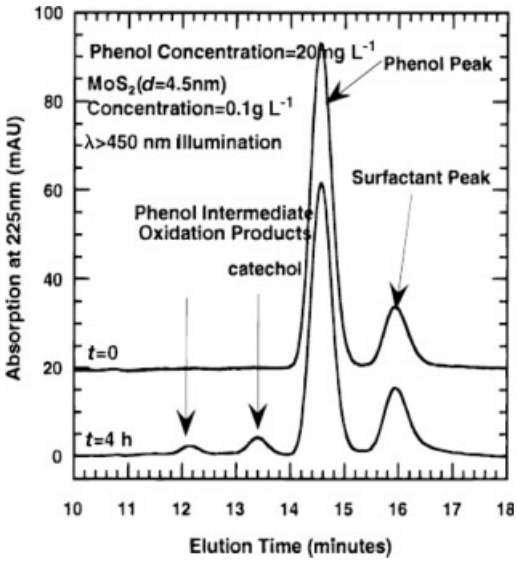

Figure 3.25 HPLC absorption trace showing phenol destruction with visible light ($\lambda > 455$ nm) using 4.5 nm MoS_2 clusters as the photocatalyst. (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

Thurston and Wilcoxon published some of the first reported photocatalysis using nanosized MoS_2 in the late 1990s [52]. They investigated the effect of MoS_2 cluster size on the efficiency of phenol photo-oxidation. A xenon lamp with appropriate band pass filters allowed comparisons with Degussa P25 TiO_2 photocatalyst [52]. A short-pass filter cutting off IR radiation above 1000 nm to minimize heating of the solution was used. HPLC using a reversed-phase octadecyl-terminated silica column and a mixture of water and acetonitrile as the mobile phase was utilized to analyze the phenol concentration as a function of illumination time. To study the MoS_2 cluster solutions, which were optically transparent, a long-pass filter limited the xenon arc lamp output to wavelengths greater than 455 nm. Figure 3.25 shows an absorption chromatogram for an experiment using 4.5 nm MoS_2 obtained using 455 nm light where the phenol elutes at ~14.6 min. After 8 h, the phenol peak area had decreased by ~25%. This was accompanied by the appearance of two phenol photo-oxidation products: catechol (13.4 min) and a possible isomer of catechol (12.2 min) [52]. Photo-oxidation using Degussa P25 TiO_2 in slurry suspension at 365 nm radiation showed similar behavior (Figure 3.26). As expected, no photo-oxidation of phenol using TiO_2 slurries illuminated with visible light occurred (Figure 3.27). The active sites on the MoS_2 clusters are possibly the empty d-orbitals accessible at the Mo metal edge sites. Phenol adsorption and hole transfer may occur at these locations and even the presence of a stabilizing cationic surfactant apparently does not prevent access to these sites. In fact, in later studies of pentachlorophenol oxidation using MoS_2 and TiO_2, certain cationic surfactants were shown to increase the rate of photo-oxidation.

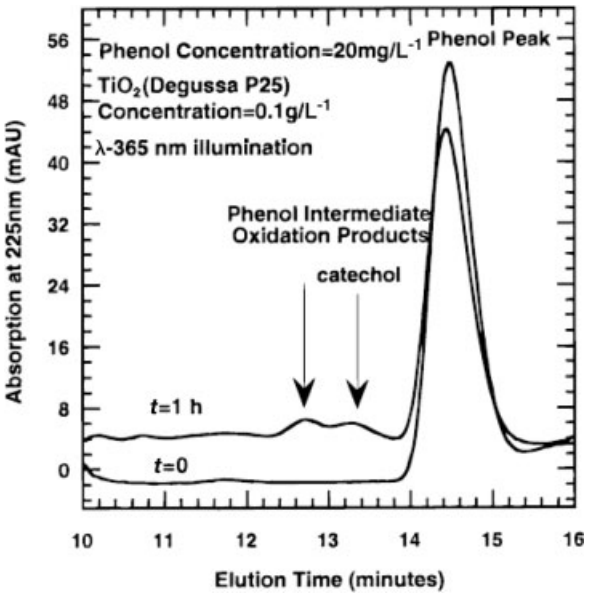

Figure 3.26 HPLC trace showing phenol destruction with 365 nm UV illumination catalyzed by Degussa P25 TiO_2. (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

Earlier we mentioned that there are technical advantages to using optically transparent solutions as compared with slurries to investigate photocatalysis. This advantage can only be realized with fully dispersed solutions of stabilized nanoclusters. Under these circumstances, analysis of the chemical state of the solution using chromatography combined with on-line optical absorbance yields the amounts of pollutant and oxidation by-products as a function of illumination time and also an elution peak corresponding to the nanosized photocatalyst. Unlike an aggregated powder such as Degussa P25 TiO_2, which is typically removed by filtration prior to chromatographic analysis, the state of the catalyst can also be determined. As an example, consider Figure 3.28, showing the absorbance spectrum collected at the elution peak of 4.5 nm MoS_2 clusters before and after photocatalysis [152]. Analysis of these spectra demonstrated that no decrease in the spectral area (proportional to the MoS_2 concentration) occurs with either visible or UV illumination. Importantly, the characteristic excitonic absorbance peaks in the MoS_2 spectra are present with no shifts in peak positions before and after the photocatalytic oxidation of phenol occurs. Since degradation would lead to a decrease in the area under the MoS_2 cluster peaks and a shift in their position, such measurements demonstrate that the phenol oxidation is catalytic. It is significantly more difficult to determine if any changes have occurred to a TiO_2 slurry catalyst.

By using larger, 8–10 nm, MoS_2 clusters, a much larger fraction of the incident light will be absorbed by the clusters. Unfortunately, the photo-oxidation was slower

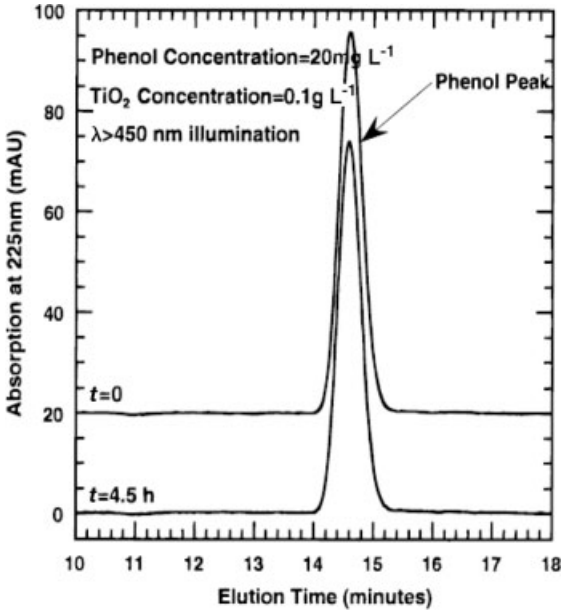

Figure 3.27 HPLC trace of attempted phenol destruction using Degussa P25 TiO_2 illuminated by visible light ($\lambda > 455$ nm). No decrease in phenol concentration is observed and no photo-oxidation products develop. (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

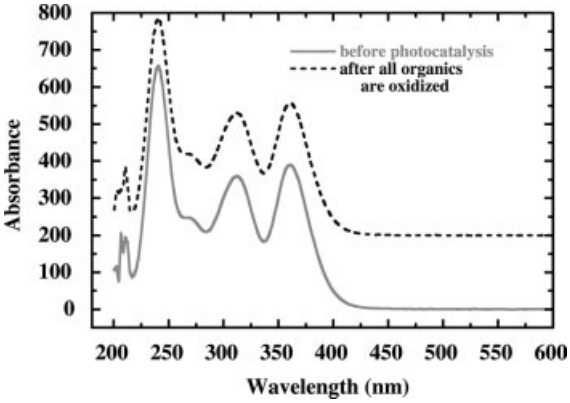

Figure 3.28 Optical absorption of MoS_2 before and after photocatalysis showing no spectral or intensity change. This suggests that nano-MoS_2 is acting catalytically with all its original properties preserved. (Reprinted with permission from J. P. Wilcoxon, T. R. Thurston, *Materials Research Society Symposium Proceedings* **1999**, *549*, 119).

in this case. Figure 3.29 shows a plot of the phenol concentration as a function of time under visible illumination for 4.5 nm MoS_2 clusters, 8–10 nm MoS_2 clusters and Degussa P25 TiO_2. These data were obtained from the calculated area under the phenol elution peaks of the chromatograms shown in Figures [25–27]. The catalytic nature of the 4.5 nm MoS_2 clusters for the phenol oxidation was verified by adding additional phenol after most of the phenol had been destroyed, repeating the reaction and observing the same reaction kinetics within the error bars indicated in Figure 3.29.

Using fully dispersed nanoclusters as photocatalysts is not practical in real environmental remediation, since it would be very difficult to remove the clusters from the purified water by filtration or other commonly used methods. Accordingly, experiments were undertaken to deposit the nanoclusters onto a TiO_2 powder which could be used as a slurry or eventually coated onto a high surface area support as has been done previously in flow reactors based upon TiO_2 catalysts. The deposited MoS_2 clusters then serve as sensitizers allowing visible light absorbance and transfer of the electron from the more negative MoS_2 conduction band to the TiO_2. Thus, both light absorbance and charge separation could be achieved. We deposited 8–10 nm MoS_2 onto several support materials: Degussa P25 TiO_2, SnO_2, WO_3 and ZnO [52]. P25 TiO_2 was the only support material that showed enhanced performance during

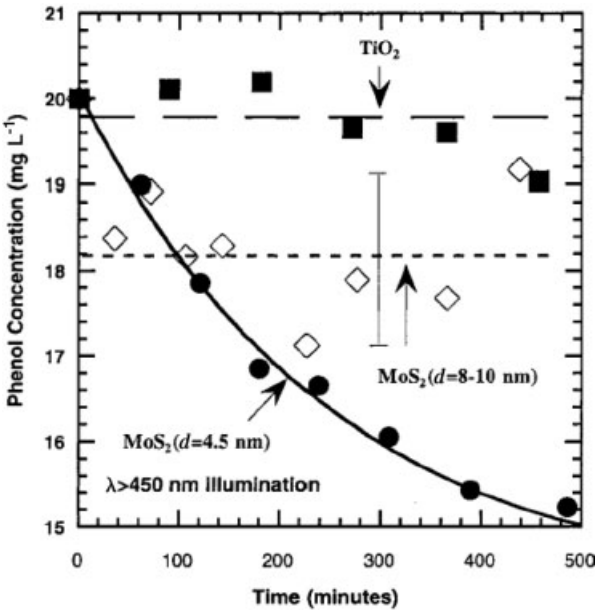

Figure 3.29 Visible light-induced photo-oxidation of phenol as a function of time as determined from HPLC. Order of phenol destruction: 4.5 nm MoS_2 > 8–10 nm MoS_2 > Degussa P25 TiO_2 (no activity). Figure 3.30 Phenol concentration as a function of time for Degussa P25 TiO_2 loaded with 8–10 nm MoS_2 at 0, 2.5 and 5 wt.%. Samples were irradiated with 365 nm light. (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

phenol destruction as a result of the MoS_2 deposition. A comparison of the phenol destruction rate under UV (365 nm) radiation for three different loadings of MoS_2 on TiO_2, 0, 2.5 and 5 wt.%, is shown in Figure 3.30. The 2.5 wt.% sample led to an increase in phenol photo-oxidation relative to TiO_2 alone whereas the 5 wt.% sample led to a decrease in the destruction rate. Hence an optimum loading is necessary for achieving the fastest phenol destruction rate for this system. This result is similar to that found for the deposition of metal clusters on TiO_2 described earlier. High concentrations of MoS_2 clusters may block critical phenol adsorption sites on the TiO_2, for example. Figure 3.31 shows a plot of the destruction rate of phenol as a function of MoS_2 loading on TiO_2. This figure reveals that once the optimum loading of 2.5 wt.% has been reached, there is a decrease in the phenol destruction rate.

Studies of the photocatalysis of pentachlorophenol (PCP) using 8–10, 4.5 and 3 nm MoS_2 clusters dispersed in water and also acetonitrile showed a strong size dependence of the rate of PCP destruction [68]. PCP is a very toxic chlorinated aromatic molecule. It belongs to the family of chlorinated phenols which are found widely in the environment due their widespread use as fungicides for wood preservation. Unfortunately, it has a very slow natural degradation rate. Also, direct photolysis of PCP has been reported to result in even more toxic by-products such as octachlorodibenzo-*p*-dioxin [17, 68]. Several studies have utilized TiO_2 as a photocatalyst and demonstrated that total mineralization of PCP to CO_2 and HCl is possible [26, 153, 154]. However, as discussed above, the limitation of TiO_2 is that it

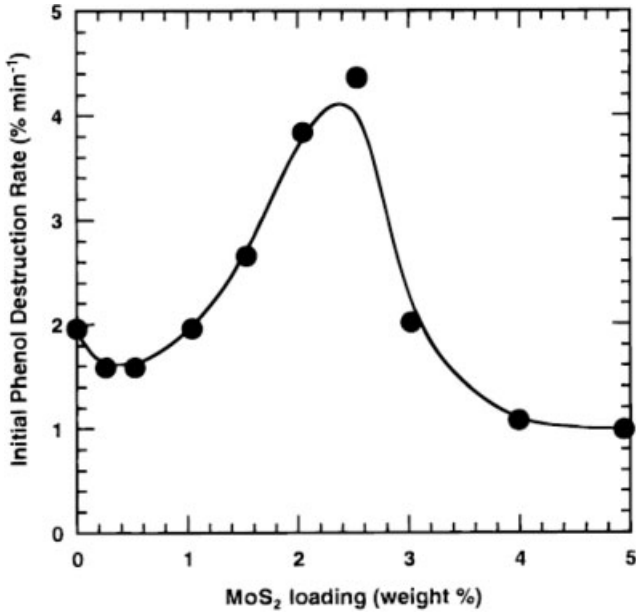

Figure 3.31 Initial phenol destruction rate dependence on 8–10 nm MoS_2 loading of Degussa P25 TiO_2 using 365 nm irradiation. (Reprinted with permission from T. R. Thurston, J. P. Wilcoxon, *Journal of Physical Chemistry B* **1999**, *103*, 11).

must be excited by UV light, which is only ~3% of the solar spectrum, probably requiring the use of lamps for a practical TiO_2 photoreactor.

It was necessary to use bulk CdS powder as a reference photocatalyst since TiO_2 is not active under visible illumination [68]. CdS has a similar absorbance onset (~525 nm) to MoS_2 nanoclusters [68]. The elution peak area from absorbance chromatograms was used to determine the PCP concentration as a function of illumination time. The decrease in PCP concentration as a function of time for 4.5 and 3 nm MoS_2 clusters, bulk CdS powder, bulk MoS_2 powder and bulk TiO_2 illuminated with visible light is shown in Figure 3.32 [68]. As might be expected, there was no change in PCP concentration using either bulk powders of MoS_2 or Degussa P25 TiO_2 under visible light radiation. Some decrease in PCP concentration was observed with bulk CdS powder. However, both sizes of MoS_2 clusters were more active than the CdS slurry powder.

The most interesting result of these studies (Figure 3.32) is the dramatic increase in PCP destruction rate for the 3 nm MoS_2 compared with the 4.5 nm MoS_2. In fact by 120 min, complete photo-oxidation of PCP occurs and there is no detectable PCP [68] (the sensitivity was 20 ppb). Although the 4.5 nm clusters absorb significantly more of the incident visible light, the most important size effect appears to be the more energetic electrons and holes created in the smaller 3 nm MoS_2 clusters. It is also possible that some of the activity increase is due to more favorable surface chemistry and binding properties of the 3 nm clusters compared with the 4.5 nm clusters. It is

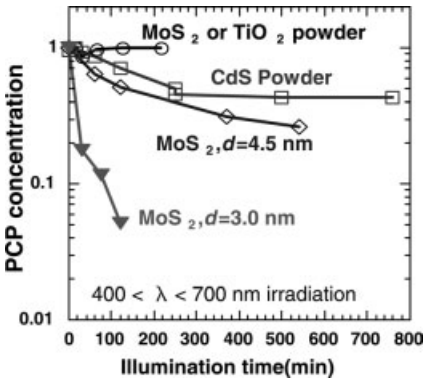

Figure 3.32 Semi-logarithmic plot of pentachlorophenol (PCP) concentration vs. visible light illumination time. Nanosized MoS_2 photocatalysts are compared with conventional semiconductor powders: MoS_2, TiO_2 and CdS. The smallest MoS_2 clusters (3 nm) with the most positive oxidation potential are the most active. (Reprinted with permission from J. P. Wilcoxon, *Journal of Physical Chemistry B* **2000**, *104*, 7334).

worth noting that this high rate of PCP oxidation also occurs in the presence of stabilizing surfactants and that PCP photo-oxidation using only visible light excitation of 3 nm MoS_2 clusters is higher than that observed for Degussa P25 TiO_2 using full lamp irradiation ($300\,nm < \lambda < 700\,nm$) [68].

The stability of the 3 nm MoS_2 clusters during photocatalysis reactions was also tested by Wilcoxon *et al.* [152]. The photo-oxidation of an alkyl chloride using visible light and 3 nm MoS_2 is shown in Figure 3.33. In this figure, the HPLC absorption chromatogram shows a peak at ~4.1 min (3 nm MoS_2), a peak at ~4.65 min (free surfactant) and a peak at ~5.2 min (organic impurity) at four different stages of the reaction: $t = 0$, 15, 30 and 60 min [152]. There is no evidence of the organic impurity left after 60 min. The surfactant that does not participate in cluster stabilization (i.e. free surfactant) present in the solution also photo-oxidizes as a function of continued irradiation and after 3 h is completely gone. However, the MoS_2 peak remains unchanged, demonstrating, again, the photocatalytic property of this material.

Electron transfer (ET) rates from MoS_2 clusters to electron acceptor molecules such as bipyridine (bpy) can be estimated by monitoring the change in the fluorescence decay rates as a result of ET [84]. For example, time-resolved fluorescence measurements showed a dramatic decrease in ET rates to bpy as the size of the clusters increased. The ET rates were fastest for 3 nm MoS_2 clusters, which is consistent with a more negative conduction band potential due to increased quantum confinement compared with 4.5 nm clusters. By using electron acceptor molecules with known redox potentials, one can also estimate how much the conduction band shifts with cluster size by such measurements. Similar experiments using hole acceptor molecules allow one to estimate the shift in valence band position with cluster size.

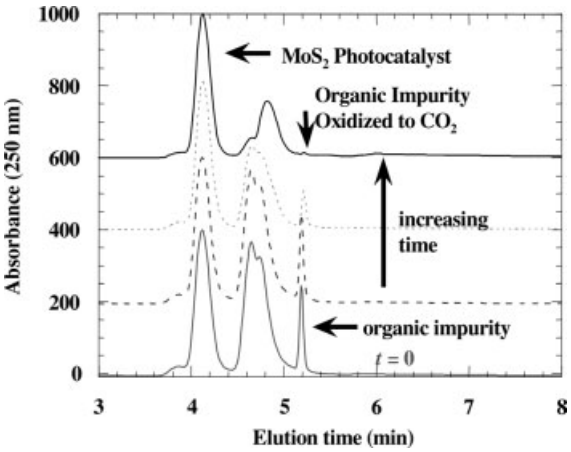

Figure 3.33 Liquid chromatographic analysis of a fully dispersed solution of MoS_2 containing an organic impurity. The absorbance at 250 nm vs. elution time is used to monitor the disappearance of the organic and the integrity of the MoS_2 nanocatalyst as a function of visible illumination time. (Reprinted with permission from J. P. Wilcoxon, T. R. Thurston, *Materials Research Society Symposium Proceedings* **1999**, *549*, 119).

ET to an acceptor in a photoredox reaction is preceded by electron–hole (e–h) separation. In order to have increased ET rates, there must be efficient e–h separation compared with e–h recombination. The small size of the MoS_2 clusters guarantees fast diffusion of the electron to the surface. This can be enhanced further through surface modification of the clusters. Wilcoxon *et al*. demonstrated that the deposition of gold (Au) cluster islands on the surface of 3 nm MoS_2 clusters suppressed e–h recombination with the possible outcome of enhancing e–h separation [51]. Evidence of this phenomenon is shown in Figure 3.34, where the decrease in photoluminescence (PL) as a function of the amount of Au on the cluster surface is demonstrated. As the Au content increases, the PL decreases. A decrease in PL represents a decrease in the e–h recombination rate relative to other non-radiative processes such as e–h transfer. This result implies that the photocatalytic properties of already active nanosized MoS_2 (4.5 nm or less) could be enhanced further with charge separation strategies that have proved useful for photocatalysts such as TiO_2.

One useful synthetic approach to improving the photocatalytic properties of nanosized MoS_2 is to form clusters of MoS_2 on the surface of another semiconductor such as TiO_2. By using MoS_2 as the light-absorbing component in such a coupled semiconductor system, visible light may be used to drive the photoredox reaction. This was first demonstrated, as noted above, in Thurston and Wilcoxon's work [52] on phenol photo-oxidation on MoS_2/TiO_2. The conduction band of bulk MoS_2 is not sufficiently negative to drive electron transfer from MoS_2 to TiO_2, but decreasing the MoS_2 cluster size will make the reduction potential more negative, suggesting that this strategy can be implemented using nanosized clusters of MoS_2 grown on TiO_2.

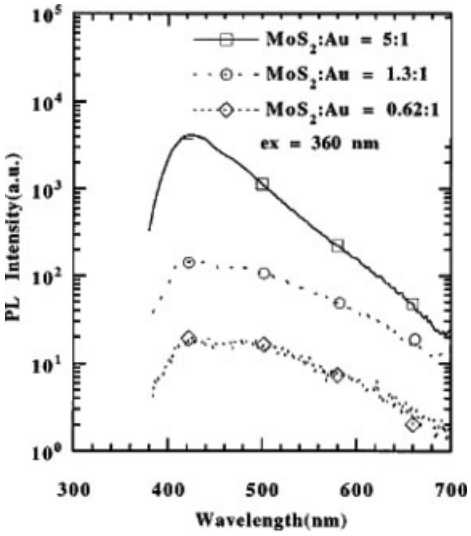

Figure 3.34 Influence of Au on the PL of 3 nm MoS_2. (Reprinted with permission from J. P. Wilcoxon, P. P. Newcomer, G. A. Samara, *Journal of Applied Physics* **1997**, *81*, 7934).

Ho *et al.* reported a new approach to making such a coupled semiconductor photocatalyst [155]. The approach mimics that used to deposit islands of Pt on TiO_2 by using the photogenerated electrons on TiO_2 to reduce a suitable Mo salt precursor and form islands of MoS_2. The metal precursor used was $(NH_4)_2MS_4$, where M = Mo, W. To maximize the transfer of photogenerated electrons from the Degussa P25 TiO_2 slurry, hydrazine was added to react with the holes and oxygen was removed by continuous nitrogen purging during illumination by a UV mercury lamp. The MS_2 islands that were formed were not nanocrystalline and needed to be calcined under nitrogen to create photoactive materials. XPS was used to determine the Ti:M ratios, which were 0.3 mol% (WS_2) and 0.6 mol% (MoS_2).

The absorbance of the coupled MS_2/TiO_2 systems was measured using diffuse reflection methods to minimize the effect of multiple scattering by the TiO_2. The measurements, shown in Figure 3.35, demonstrate that the growth of MS_2 clusters on the TiO_2 surface enhances the visible absorbance substantially. Their results suggest that MoS_2 clusters are more effective than WS_2 at enhancing the visible absorbance. Also, note that the absorbance onsets for both MoS_2 and WS_2 are blue shifted relative to the bulk.

Slurries of the MS_2/TiO_2 were tested for the photocatalytic oxidation of a dye, methylene blue, and 4-chlorophenol. In both experiments, a stirred batch reactor was used and oxygen was bubbled through the solution during the experiment. The concentrations of the organic molecules were monitored using HPLC absorbance measurements. The state of the photocatalyst following reaction was not investigated. For both methylene blue and 4-chlorophenol, significant photo-oxidation of the organic occurred using only visible light (400–700 nm). The results from their work

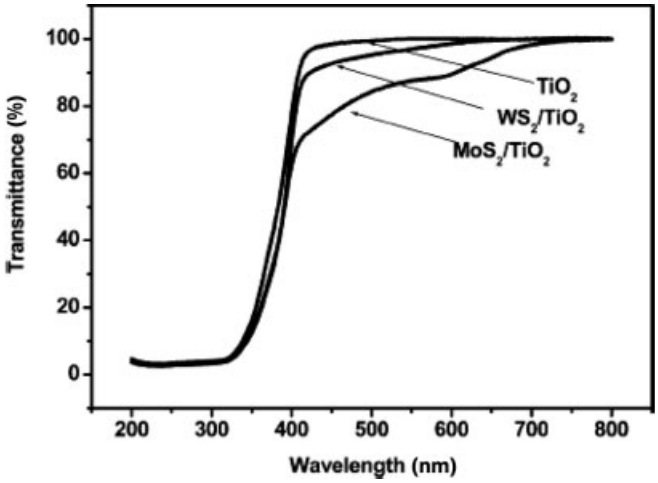

Figure 3.35 Diffuse reflectance spectra of TiO_2, 0.3 mol% of WS_2 on TiO_2 and 0.5 mol% of MoS_2 on TiO_2. (Reprinted with permission from W. K. Ho, J. C. Yu, J. Lin, J. G. Yu, P. S. Li, *Langmuir* **2004**, *20*, 5865).

are shown in Figure 3.36. Either WS_2/TiO_2 or MoS_2/TiO_2 seem equally effective for these photo-oxidation reactions.

They concluded that the effectiveness of the coupled system was indeed due to electron transfer from the MS_2 to the TiO_2 by measurements using electron spin resonance (ESR), where they observed a signal corresponding to Ti(III) radical.

3.7 Current and Future Technological Applications of Photocatalysts for Environmental Remediation

The photocatalytic reactions discussed thus far occur in water, but the same materials, especially TiO_2, have proved useful for photo-oxidation of VOCs in the air. In fact, this application represents the first commercial use of photocatalysts, which in Japan amounts to nearly US$300 million in revenue and about 2000 companies as of 2003 [50]. Air purification using TiO_2 photocatalysts is very dependent on reactor design, the most common configurations being annular plug flow reactors [156] and honeycomb reactors [157]. The oxidation process functions most efficiently at low concentrations and relatively low air flow rates. High flow rates may be limited by mass transport considerations. For flow rates of less than $20\,000\,ft^3\,min^{-1}$ may suggest that photocatalysis is more cost-effective than carbon adsorption or incineration of VOCs.

Because light penetrates long distances through air, the illumination of the photocatalyst in gas reactors is simplified compared with aqueous phase reactors, especially the most efficient opaque, slurry-type reactors. Also, higher reaction temperatures and pressures are possible, unlike in water purification where the boiling point of water is a limitation. In fact, a combination of air stripping of VOCs combined with gas-phase photocatalytic destruction is likely a viable approach to water purification.

An advantage of photocatalytic gas purification of VOCs is that relatively low levels of light are required. For outdoor applications, for example, ambient conditions of around 2–3 $mW\,cm^{-2}$ are available in the near-UV (UVA) region of the spectrum that can be absorbed by TiO_2. These levels are sufficient for many applications such as self-cleaning tiles and windows [50]. For indoor applications, fluorescent lighting of around 1 $\mu W\,cm^{-2}$ in the UVA region is available in most offices. The efficiency of the photocatalysis has actually been shown to be superior at these levels. For example, the quantum efficiency for photo-oxidation of 2-propanol by TiO_2 was ~28% and for the common indoor pollutant acetaldehyde it was nearly 100%, due to an autocatalytic process producing a free radical chain in the air [50]. Since gas-phase diffusion of both reactants and products takes place continuously, gas-phase photocatalytic processes can be self-cleaning, preserving the integrity of the catalytic surface. It also appears that free radical scavengers such as chlorine ions and electron scavengers such as oxygen are not as significant a problem in air as in water [158]. However, incomplete mineralization of some chemicals can lead to loss of efficiency with time due to build-up of intermediates at the catalyst surface. Water is not available in most indoor applications to wash these away, but the best outdoor designs take advantage of rain to preserve an active catalyst surface [50].

Gas-phase photoreactors may be incorporated into existing heating and air conditioning systems, where they are often utilized in combination with more traditional approaches such as HEPA filters and carbon adsorption. For example, Ao and Lee recently described experiments in which a commercial air cleaner was modified to incorporate TiO_2 on activated carbon filter illuminated using a 6 W UV

lamp (254 nm) to remove nitrous oxide and toluene at ppb levels [159]. The high efficiency of the combined activated carbon–TiO_2 photocatalyst was attributed to the ability of the carbon to adsorb and concentrate the NO pollutant, which then diffuses to the TiO_2 where it is photo-oxidized.

A recent review of the gas-phase photocatalysis by Fujishima and Zhang summarizes some of the most interesting results on gas-phase photo-oxidation using TiO_2 photocatalysts [50]. We will now examine some results from that review for both indoor and outdoor air cleaning.

3.7.1 Indoor Air Purification

The labor costs associated with keeping indoor surfaces free from bacteria and other contamination can be significant in the case of hospitals and nursing homes. With this application in mind, Fujishima's group was able to demonstrate that low UV light levels of around 1 mW cm^{-2} could destroy *E. coli* cells placed on a TiO_2-coated glass plate in <1 h. For comparison, they found that only 50% of the cells were dead following 4 h of illumination under the same conditions. This laboratory work was tested in several operating rooms in the form of antibacterial tiles with a TiO_2 coating. Tests showed that the bacterial levels were negligible after 1 h of illumination under the ambient fluorescent illumination. The bacterial levels in the surrounding air also decreased significantly [50].

The latter result is consistent with observations by Choi that OH radicals generated on the TiO_2 diffuse a significant distance through air and can oxidize soot many microns away from the active surface [22]. The evidence for this is shown in Figure 3.37, where soot was deposited on the surface of a glass substrate coated with TiO_2 photocatalyst. This SEM image shows that a gap develops at the interface between the TiO_2 and the soot. The width, *d*, of this gap was reported to increase continuously with UV illumination time, indicating that the active oxidants formed at the TiO_2 surface desorb and migrate across the glass to reach the soot.

Fujishima's group has investigated self-cleaning surfaces as possible interior wall materials for buildings and homes [160]. Build-up of indoor air pollution in modern, highly insulated homes and offices combined with out-gassing of chemicals such as formaldehyde and urethane used in building materials make such self-cleaning surfaces very attractive. They were able to demonstrate that many volatile organic compounds could be completely mineralized to CO_2 using weak (1 mW cm^{-2}) UV illumination.

Indoor air cleaners based on HEPA and activated carbon adsorption are commonly used to remove foul-smelling VOCs which exist in most indoor environments. They are readily adapted to use photocatalytic oxidation to extend filter life by the self-cleaning property of TiO_2. To maximize the surface area, a honeycomb-type filter which minimizes back-pressure is coated with TiO_2. A picture of such a filter taken from Fujishima and Zhang's review [50] is shown in Figure 3.38. TiO_2 nanoparticles can be embedded in activated carbon as described by Ao and Lee [159] and used in modified air conditioners or air cleaners. This approach permits the adsorbing

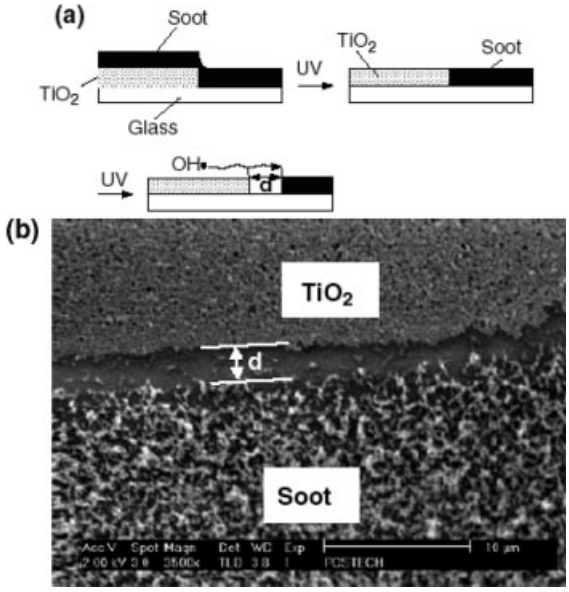

Figure 3.37 (a) Schematic diagram showing the photocatalytic degradation process of soot. Initially the soot is in contact with the TiO_2 catalyst. A gap, of width *d*, develops and grows as a function of irradiation time. (b) SEM of the gap, *d*, after 6 h of irradiation. (Reprinted with permission from W. Choi, *Catalysis Surveys from Asia* **2006**, *10*, 16).

carbon to regenerate itself by mineralization of the adsorbed pollutants. These types of filters can also kill airborne bacteria and viruses.

TiO_2 surfaces have another useful property that was accidentally discovered in the laboratories of TOTO Inc. in 1995. It was found that TiO_2 films having an appropriate

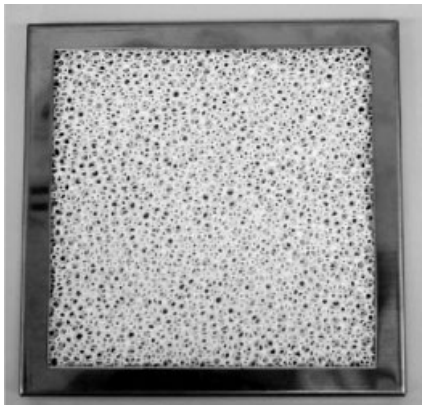

Figure 3.38 TiO_2-coated porous ceramic filters for use as air filters. (Reprinted with permission from A. Fujishima, X. T. Zhang, *Comptes Rendus Chimie* **2006**, *9*, 750).

fraction of SiO_2 incorporated and the exposed to UV light became superhydrophilic, having a zero contact angle with water (i.e. no droplet formation, perfect wetting) [50]. The restructuring of the surface which makes the surface superhydrophilic was subsequently elucidated [49]. This property eventually led to commercial windows coated with very thin, optically transparent TiO_2 films which were both self-cleaning and non-fogging. This is useful for both interior and exterior surfaces of windows.

3.7.2
Outdoor Air Purification

The application of TiO_2 photocatalytic films in exterior construction materials such as tiles is the largest commercial application of photocatalysts at the present time. These materials remain free of contamination by a combination of photocatalytic oxidation driven by sunlight and washing of the breakdown products by rain. The latter is made facile by the excellent wetting properties of the superhydrophilic surface of TiO_2 [50]. Fujishima and Zhang [50] estimated that self-cleaning tiles have been applied to over 5000 buildings in Japan as of 2003. The Japanese company TOTO Inc., which markets these tiles, estimates that the tiles need to be cleaned manually only every 20 years, compared with ordinary tiles which must be cleaned every 5 years. An added benefit is that the tiles can decompose pollutants such as nitrogen oxides from automobile pollution. The tiles are fairly effective, as shown in Figure 3.39 taken from Fujishima and Zhang's review [50], which

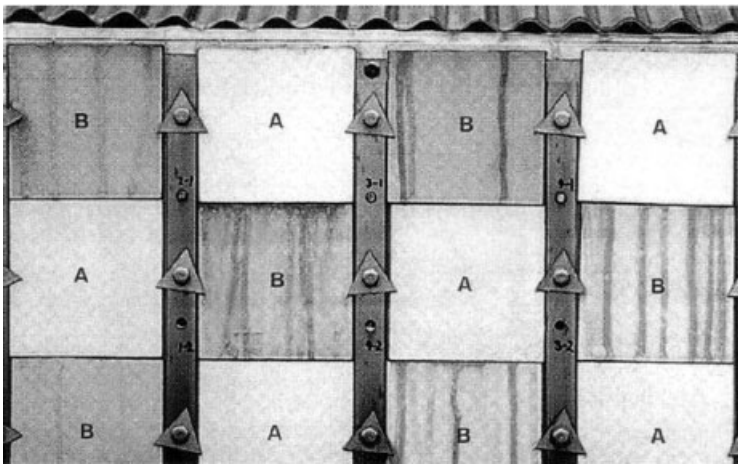

Figure 3.39 Exterior wall showing alternating self-cleaning (A) and ordinary (B) tiles. The TiO_2-coated tiles are obviously cleaner than the non-coated counterpart. (Reprinted with permission from R. Wang, K. Hashimoto, A. Fujishima, M. Chikuni, E. Kojima, A. Kitamura, M. Shimohigoshi, T. Watanabe, *Advanced Materials* **1998**, *10*, 135, and A. Fujishima, X. T. Zhang, *Comptes Rendus Chimie* **2006**, *9*, 750).

shows alternating tiles with and without TiO_2. Water from the roof runs over both types of tiles but the photocatalytic surfaces are much cleaner, as shown in this photograph.

Window glass (SiO_2) can also be made self-cleaning by embedding nanoparticles of TiO_2 in an SiO_2 matrix. An added benefit of this composite material is that water droplet formation does not occur on rainy days due to the superhydrophilic properties of TiO_2. This property is also very useful for the windshields of cars and motorcycles. With just a little rainfall a thin, uniform film forms which rapidly evaporates. Even in heavy rainfall droplet formation that causes light scattering is avoided since a uniform film of water forms on the glass. Since TiO_2 has a much higher refractive index than glass, with a continuous film on glass (i.e. SiO_2) the composition of the TiO_2/SiO_2 film can be carefully controlled to avoid excess refraction of light and which results in visual clarity [50].

Plastic tents made of materials such as PVC are also widely used in outdoor applications such as temporary buildings for exhibits or storage. Their flexible surfaces are difficult to clean, so Kangyo Co. in Japan coated PVC tents with TiO_2, leading to the formation of an inorganic/organic interfacial microstructure between the TiO_2 layer and the PVC to prevent photo-oxidation of the PVC. This approach is fairly effective, as shown in Figure 3.40 taken from Fujishima and Zhang's review [50], where a tent made partly of ordinary PVC and TiO_2-coated PVC was photographed by Taiyl Kangyo Co. after 2 months of exposure to air contamination [50].

Common construction materials such as cement can also be modified by the addition of TiO_2 photocatalysts [161]. Provided that the addition of the photocatalyst particles does not adversely affect the curing and final strength of the material, this modification is inexpensive and reduces maintenance costs by its self-cleaning ability. The preservation of ancient Greek statues against urban air pollutants is one novel example of the utility of these composite materials [13, 162].

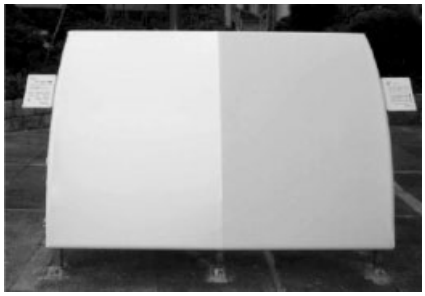

Figure 3.40 Photograph of a tent made by Taiyo Kangyo Co. where the left half was coated with TiO_2 and the right half was not coated. The left half is clearly cleaner after 2 months of outdoor exposure. (Reprinted with permission from A. Fujishima, X. T. Zhang, *Comptes Rendus Chimie* **2006**, *9*, 750).

3.8 Conclusion

Nanosized photocatalysts for environmental remediation can be a viable approach to photo-oxidation and removal of organic and inorganic pollutants in water and air. This process for photocatalytic oxidation of pollutants produces relatively benign products such as CO_2 and dilute mineral acids under ambient conditions. Potentially, it can be driven entirely by sunlight, minimizing its economic costs. Since very broad classes of chemicals can be destroyed, this approach is quite general. However, two main future research challenges were identified in our review, improvement of the photocatalyst efficiency and practical reactor designs for specific remediation problems.

In this chapter, we have emphasized the interaction of new synthetic methods for the production of nanosized semiconductors. Our review focused most on two photocatalytic materials. The first is TiO_2, which has been investigated as a photocatalyst for over 30 years and has an extensive literature with several excellent reviews. The other material, MoS_2, has been investigated for this application for only around 10 years but its structural and size-dependent optical and electronic properties suggest that it may prove as useful as TiO_2 in the future. It is an excellent example of how new nanomaterials can dramatically affect technical progress in environmental remediation.

The main limitation of TiO_2 as a photocatalyst has been identified as its wide bandgap, which limits its absorbance to 3–5% of the solar spectrum. Much effort has been made to improve its absorption efficiency through substitutional doping with elements such as nitrogen to extend its absorption range into the visible region. Unfortunately, a loss of efficiency accompanies the use of these longer wavelength photons and this has not yet been overcome. Other synthetic modifications to TiO_2 which were reviewed included deposition of metal islands and the use of sensitizers such as dyes or inorganic ions such as Fe(III) to extend its light absorption range. No single method was effective for all types of reactions. However, the use of metal island deposits on TiO_2 was shown to improve the efficiency of photo-oxidation for several types of difficult pollutants such as chlorinated aromatics. The key observation was that an optimum metal loading exists to optimize the photocatalytic activity. Mechanistically, it appears that atoms at the perimeter between metal islands and TiO_2 play a key role in the activity. Various experiments including transient absorption and electron spin resonance indicate that the role of the metal islands is to facilitate the transfer of electrons to species such as molecular oxygen, thus reducing the recombination of electron–hole pairs. This indicates how the proper choice of characterization methods can lead to insights into and better scientific understanding of the photocatalytic process.

It would be surprising if a single material such as TiO_2 could serve as a universal photocatalyst despite its low cost and photochemical stability. We demonstrated that layered metal dichalcogenides such as MoS_2 share its photochemical stability and low costs and have the additional feature of having size-tunable light absorption and redox potentials. The size-dependent electronic properties of nanosized semiconductors arise from carrier confinement in the small particle. We showed that such photocatalysts that normally absorb light in the near-IR region have a blue shift of their absorbance onset into the visible region and their redox potentials become favorable

enough to allow the complete mineralization of a toxic chlorinated organic such as pentachlorophenol using only visible light. The rate of photo-oxidation was shown to depend on photocatalyst size. A surprising observation was that the presence of a stabilizing surfactant on the cluster surface did not quench the photo-oxidation. In fact, addition of this surfactant to a common, very active TiO_2 photocatalyst also improved its photocatalytic activity. We recommend such surface modifications of nanosized semiconductors as a fruitful avenue for future research. Clusters in the size range 1–3 nm should be the best candidates for such surface tuning of their electronic states, since 60–90% of all their atoms reside in surface positions.

Synthetic strategies can be facilitated by feedback from traditional and novel characterization methods. As an example of the latter, we demonstrated how liquid chromatography could be used to follow the course of a photo-oxidation reaction and also to characterize the chemistry and size of the MoS_2 photocatalyst as a function of illumination time. Such *in situ* photocatalyst characterization is not possible with agglomerated slurry photocatalysts and is an advantage of fully dispersed nanoclusters as photocatalysts. The absorption spectra of nanosized photocatalysts is so sensitive to changes in the size or cluster surface chemistry that deactivation of the catalyst from agglomeration or surface changes can be rapidly monitored. We also discussed the use of techniques such as dynamic light scattering to follow photocatalyst agglomeration, a common process which reduces the available surface area and photoactivity.

We reviewed experiments in which two coupled nanosized semiconductors in physical contact can transfer photogenerated carriers from one to the other, leading to improved charge separation, reduced recombination and improved photocatalytic oxidation. Two example systems of MoS_2/TiO_2 were discussed. In these systems, the presence of nanosized MoS_2 on the TiO_2 surface allowed visible light to be used for the photo-oxidation. Such a scheme exploits the best characteristics of each material in addition to providing for sensitive tuning of the chemical adsorption properties. It is also a requirement for a practical reactor since nanosized photocatalysts must be immobilized to prevent them from acting as pollutants themselves. In the future we anticipate more studies of such composite systems as they allow scientists great latitude in photocatalyst design.

We described photocatalysis experiments using two types of reactor design: batch slurry reactors and fixed-bed flow reactors. Most basic research has used the slurry type since this design is not as sensitive to illumination geometry and exposes the maximum amount of catalyst surface to the pollutant. It is also the simplest design. However, such a design cannot be used in the field for large-scale treatment due to the costs and complexities associated with recovering the photocatalyst from the treated water. Instead, immobilization of the catalyst nanoparticles as a porous film on a high surface area support material is required. A honeycomb design is a common choice but ensuring complete illumination of the photocatalyst is difficult. The best geometry and light illumination for such a reactor and also optimal flow rates are specific to a given remediation problem and chemical. Since the kinetics of photo-oxidation will depend on chemical type and concentration, the ability to vary the flow rate and monitor the treated water are key aspects of reactor design. More research

into reactor design will be required before photocatalytic remediation can compete with current methods for water treatment. High surface area materials such as carbon aerogels are worthy of consideration as supports.

Even though remediation schemes using TiO_2 to treat liquid-phase pollutants are not currently economically viable, we presented recent technological applications of TiO_2 porous films to the continuous treatment of indoor and outdoor air pollution. The key observation for these gas-phase reactions was the high efficiency for gas-phase reactions at low light levels. This is fortunate since the light flux available in the near-UV region in natural sunlight can be used with TiO_2 films in a variety of outdoor applications, including self-cleaning tiles and glass. In indoor applications, there is sufficient near-UV light available due to fluorescent lighting that air cleaning and purification using TiO_2 impregnated on carbon is a useful method of removing noxious odors and killing bacteria. The combination of conventional carbon adsorption with the ability of TiO_2 photocatalysts to oxidize the adsorbed chemicals extends the life of the filters and invigorates and extends an older technology. Such applications should dominate the short-term uses of photocatalysts in environmental remediation.

As a final note, not only is environmental remediation a technical and scientific problem, it is also a social problem. The general population also needs to evaluate their habits and curb any contributions they may be making to the pollution problem. Environmental pollution is very much related to many other issues such as habitat destruction, overpopulation, lack of education, excessive consumerism, extreme poverty and corruption within governments and corporations. None of these problems can be solved in a completely isolated manner. Scientific and technical solutions exist in many of these areas and particularly, as outlined here in this chapter, for environmental remediation through photocatalysis. The use of nanomaterials as photocatalysts is certainly promising. However, we must be careful that we do not merely exchange one problem for another when using nanomaterials if there is a possibility that they may also become future pollutants. Evaluating the actual impact of new discoveries is the responsibility of all researchers if they wish to utilize their discoveries in any applied systems.

4
Pollution Treatment, Remediation and Sensing

Abhilash Sugunan and Joydeep Dutta

4.1
Introduction

Environmental monitoring is becoming increasingly critical to protect the public and the environment from toxic contaminants and pathogens released into air, soil and water from toxic chemical wastes, spills, manufacturing waste and even underground storage tanks. The US Environmental Protection Agency (EPA) has imposed strict regulations on the maximum allowable concentrations of many environmental contaminants in air and water and is reported to have been monitoring over two million underground storage tanks containing hazardous (and often volatile) contaminants from as early as 1992 [1]. Nanotechnology has the potential to bring in solutions to minimize or eliminate the use of toxic materials and the generation of undesirable by-products, and also sensitively detect (and monitor) specific polluting agents well before any major environmental catastrophes occur. Research related to improved industrial processes and starting material requirements, development of new chemical and industrial procedures and materials to replace current hazardous constituents and processes, resulting in reductions in energy, materials and waste generation are being supplemented by the application of nanotechnology to control and predict the potential damage to the environment.

Futuristic examples of types of nanotechnology applications that may lead to reduction or elimination of pollutants of concern include atomic-level synthesis of new and improved catalysts for industrial processes; adding information into molecules (analogous to DNA) that senses toxic molecules; self-assembling molecules as the foundation for new chemicals and materials for toxic waste detection and prevention; and building molecules "just in time" in microscale reactors and on-line sensitive sensors for monitoring and catastrophe prediction and prevention. More contemporary possibilities include facile and accurate detection/monitoring of common airborne pollutants such as NO_x and CO [2], waterborne harmful agents such as pathogens [3] and metal ions [4, 5], amongst others. Monitoring hazardous materials with current methods is costly and time intensive and several limitations in sampling and testing with analytical

techniques have been identified. The time and expense involved in the detection of environmental pollutants (i.e. sample acquisition, sample preparation and laboratory analysis) have led to renewed interest in finding newer solutions to analyze contamination in order to prevent, to seek remedial action for or to destroy the contaminants prior to pollution of the environment. Fast and cost-effective field-analytical technologies that can increase the number of analyses and drastically reduce the time required to perform them will help in the prevention of environmental catastrophes. Increasing the amount of analytical data tends to improve the accuracy of hazardous waste site characterization, leading to better management of the problems and the risk assessments can be improved by efficient clean-up procedures [6]. The different analytical techniques for contamination monitoring and testing that are widely used today are listed in Table 4.1 [7].

Environmental monitoring is a complex process involving hundreds of different substances that are deemed to pose a threat to the environment and can occur in the gaseous, liquid or solid phases with concentrations varying from a few percentage levels down to a few parts per trillion (ppt). Monitoring in both the external environment and at the point of discharge and sometimes in real time is necessary to prevent pollution, find remedial effects or decide when to destroy environmentally dangerous substances. There is a critical and growing need for more cost-effective and rapid techniques for the identification and quantification of pollutants in complex environmental matrices and for the conversion of contaminants into benign forms or their complete elimination, and nanotechnology has the promise to fill this need. Nanotechnology is being applied to bridge the need for accurate, inexpensive, sensitive and real-time, *in situ* analyses using robust sensors based on advantages delivered by the new techniques which can be remotely operated through satellite signals.

Although a number of chemical sensors are commercially available for field measurements of chemical species (e.g. portable gas chromatographs, surface-wave acoustic sensors, optical instruments), few are really suitable for continuous environmental and pollution control applications (Table 4.1). Detection of low concentrations for the monitoring of volatile organic compounds (VOCs) such as aromatic hydrocarbons (e.g. benzene, toluene, xylenes), halogenated hydrocarbons [e.g. trichloroethylene (TCE), carbon tetrachloride] and aliphatic hydrocarbons (e.g. hexane, octane) in air, groundwater and other saturated environments is

[b]Contribution to the US hazardous waste problem from a human exposure perspective.

urgently needed for the proper monitoring of the environment and prevention of further pollution. Volatile organic compounds from cigarette smoke, building materials, furnishings, cleaning compounds, dry cleaning agents, paints, glues, cosmetics, textiles and combustion sources are also a major source of indoor air pollution [8]. Nanotechnology has already been applied to remove some of these VOCs; it has already been reported that an ultraviolet (UV) illuminated titanium dioxide (TiO_2) catalytic surface can produce an overall reduction in air VOC levels [9]. Low-temperature activity of gold catalysts has been employed by Mintek in South Africa to construct a prototype air purification unit which removes carbon monoxide from the air at room temperature [10].

Over 700 chemical species have been identified at hazardous waste sites and the still unidentified compounds may number in the thousands [6]. All of the 600 compounds regulated under the Toxics Release Inventory (TRI) of these chemical species and numerous other agricultural and industrial compounds that are regulated under waste disposal and treatment regulations, however, pose similar risks to human health and ecosystems. The Agency for Toxic Substances and Disease Registry (ATSDR) in the USA has ranked 275 priority hazardous substances based on the frequency of occurrence at sites present on the National Priorities List, available toxicity data and the potential for direct or indirect human exposure [6]. The different chemical classes of hazardous substances of concern to human health are shown in Table 4.2

4.2
Treatment Technologies to Remove Environmental Pollutants

Cost-effective treatment of environmental pollutants requires the transformation of hazardous substances into benign forms and the subsequent development of

Table 4.3 Chemical processes that are the largest users of heterogeneous catalysts at present.

Reactions	Catalysts
CO, HC oxidation in car exhaust	Pt, Pd on alumina
NO_x reduction in car exhaust	Rh on alumina, V oxide
Cracking of crude oil	Zeolites
Reforming of crude oil	Co–Mo, Ni–Mo, W–Mo

Acrylonitrile from propylene	Bi, Mo oxides
Vinyl chloride from ethylene	Cu chloride
Hydrogenation of oils	Ni
Polyethylene	Cr, Cr oxide on silica

effective risk management strategies for the harmful effects of pollutants that are highly toxic, persistent and difficult to treat. Several new methodologies have been utilized to address new waste treatment approaches that are more effective in reducing contaminant levels that are commercially viable compared with the currently available techniques. Application of nanotechnology that results in improved waste treatment options might include removal of the finest contaminants from water (<300 nm) and air (<50 nm) and "smart materials" or "reactive surface coatings" with engineered specificity to a certain pollutant that destroy, transform or immobilize toxic compounds. Nanomaterials have been attracting increasing interest in the area of environmental remediation, mainly due to their enhanced surface and also other specific changes in their physical, chemical and biological properties that develop due to size effects. The development of novel materials with increased affinity, capacity and selectivity for heavy metals, which are a major pollutant source, has been actively studied because conventional technologies are often inadequate to reduce concentrations in wastewater to acceptable regulatory standards. Commercially available ion-exchange sorbents such as Duolite GT-73, Amberlite IRC-718, Dowex SBR-1 and Amberlite IRA 900X are limited in their ability to remove heavy metal contaminants and are often inadequate for most applications. Genetic and protein engineering have emerged as the latest tools for the construction of nanoscale materials that can be controlled precisely at the molecular level. With the advent of recombinant DNA techniques, it is now possible to create "artificial" protein polymers with fundamentally new molecular organization capabilities that are allowing targeted removal of toxic waste [11].

One of the major environmental pollution sources is automobile exhaust, consisting of harmful emission gases including NO_x, carbon monoxide and unburned

hydrocarbons (HCs), causing smog and acid rain. Most biological reactions that build the human body are catalytic, but application of catalysis in the manufacturing sector in our industrialized world started in the early 1800s and began to be used extensively (listed in Table 4.3) following the discovery of the platinum surface-catalyzed reaction of H_2 and O_2 in 1835 [12].

Since 1975, automobile manufacturers have taken a variety of steps to reduce the level of emission of these harmful emission gases which can be reduced by catalytic reactions in the catalytic converter via the following chemical reactions:

$$CO + O_2 \rightarrow CO_2 \quad \text{CO oxidation}$$

$$HC + O_2 \rightarrow CO_2 + H_2O \quad \text{HC oxidation}$$

$$NO_x + HC \rightarrow N_2 + H_2O + CO_2 \quad NO_x \text{ reduction by HC}$$

$$NO_x + CO \rightarrow N_2 + CO_2NO_x \quad \text{Reduction by CO}$$

The harmful pollutants are converted into relatively benign molecules such as CO_2, N_2 and H_2O through reactions that occur inside the automobile catalytic converters in the presence of catalysts, which consist of mixtures of platinum-group metals such as rhodium (Rh), platinum (Pt) and palladium (Pd). The future targets for the reductions of emission gases from automobile exhaust are very demanding and the requirement on NO_x has been proposed to be 0.05 g per mile, which is about one-quarter of the values that can be achieved through current catalytic converter technology. Transition metal carbides and oxycarbides are being considered as a replacement for the expensive Pt-group metals (Ru, Rh, Ir, Pd and Pt), since recent results that show strong similarities in the catalytic properties between transition metal carbides and the less abundant Pt-group metals. In addition to offering a very high surface-to-volume ratio, nanoparticles offer the flexibility of tailoring the structure and catalytic properties on the nanometer scale.

Nanocrystalline materials composed of crystallites in the 1–10 nm size range possess very high surface-to-volume ratios because of the fine grain size. These materials are characterized by a very high number of low coordination number atoms at edge and corner sites, which can provide a large number of catalytically active sites. For example, gold catalyst systems, consisting of gold nanoparticles on oxide supports, can be used for a wide variety of reactions [13, 14] and many of these have potential for applications in pollution control. Supported gold catalysts are active for the oxidation of methane and propane and the removal of NO_x has also been demonstrated. In exploratory work, gold on a transition metal oxide catalyst system has shown potential as a low-temperature three-way catalyst for automobile emission control [15, 16] with the "light-off" temperatures lowered for both hydrocarbons and carbon monoxide when fresh catalyst is used. A further automotive use for gold catalysts could be in the decomposition of ozone [17]. Consequently, the number of patents related to gold catalysis has shown an upward trend, with close to one-third of such granted patents involving pollution control (Table 4.4) for the period 1991–2001 [18].

Table 4.4 Comparative (%) number of patents granted in the field of catalytic gold nanoparticles[a].

Subject area	% (1991–2001)
Chemical processing	46
Pollution control	29
Catalyst manufacture	15
Fuel cells	10

[a]Adapted from Ref. [18].

In the area of pollution control, some patents [19, 20] have been filed claiming the use of gold catalysts in automotive emissions. Some promise for applications in motor vehicle emission devices most likely in the exhaust treatment of gasoline and diesel cars running at lower temperature ranges and for low light off applications, such as cold start conditions in gasoline engines, has been demonstrated [16]. The use of gold on a clay mineral containing magnesium silicate hydrate has been patented by Toyota for use with ozone to destroy odors [21].

Another promising technology, utilizing the enhanced surface properties of inorganic nanoparticles, involves photocatalytic degradation of organic pollutants in water. Figure 4.1 shows a schematic of this technique. It is based on irradiation of a semiconductor surface with light having energy greater than the semiconductor bandgap exciting electrons from their valence band to the conduction band. This generates electron–hole pairs on its surface. These electron–hole pairs are consumed by either recombination or surface trapping. However, the presence of organic molecules on the surface of the semiconductor material results in a catalytic redox reaction through interfacial charge transfer [22]. Semiconductor materials of choice are II–VI materials such as TiO_2 and ZnO. Noble metals such as gold and platinum on II–VI semiconductor nanoparticles act as a sink for photogenerated charge carriers and promote an interfacial charge-transfer process that leads to an increase in photocatalytic efficiency of metal oxide semiconductors. Under UV illumination, electrons accumulate on the metal surface (making electron–hole pair separation

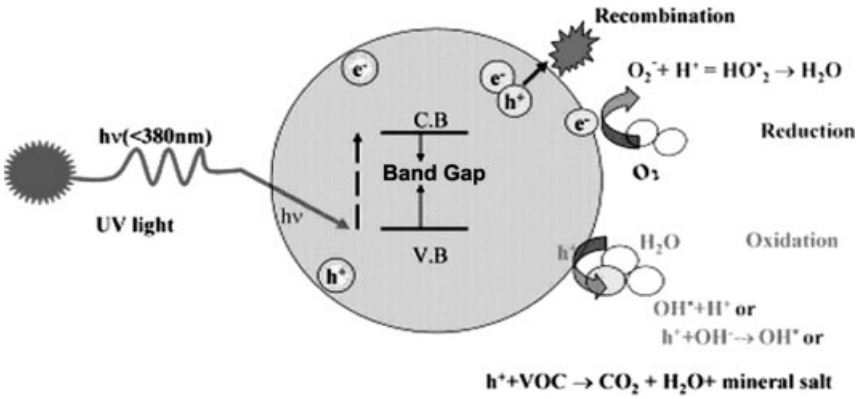

Figure 4.1 Schematic diagram of the photocatalysis on semiconductor surface.

possible, decreasing the recombination of surface charges) and the hole oxidizes absorbed species [23]. This technique has been demonstrated in degrading 4-chlorophenol [24] and chloroform [25] as models of harmful organic chemicals.

4.3 Remediation Technologies to Clean Up Environmental Pollutants Effectively

The likely first impact of nanotechnology research will be in remediation (clean-up of pollution) and end-of-pipe treatment technologies that include nanoscale materials. Substances of significant concern, both cancer causing and otherwise toxic, include heavy metals (e.g. mercury, lead) and organic compounds (e.g. benzene, chlorinated solvents, creosote, toluene). Substances such as DDT and chlordane that are no longer produced or used commercially, but persist in the environment, are also targeted for treatment.

Increased public concern for environmental clean-up has promoted the development of highly efficient photocatalysts that can participate in detoxification reactions. Environmental remediation by photocatalysts comes with several advantages: direct conversion of pollutants to non-toxic by-products without the necessity for any other associated disposal steps; use of oxygen as oxidant and elimination of expensive oxidizing chemicals; potential for using free and abundant solar energy; self-regeneration and recycling of the photocatalyst, etc. It is therefore no surprise that the research and development activities in this field have been very vigorous in recent years [26]. A significant amount of research on semiconductor-catalyzed photooxidation of organic chemicals has been carried out during the past 15 years [27]. The ability to catalyze the destruction of a wide variety of organic chemicals and complete oxidation of organics to CO_2 and dilute mineral acids in many cases, lack of inherent toxicity and resistance to photodegradation at low cost render this process highly suitable for environmental remediation [28].

Two major disadvantages of semiconductor-based photocatalysis techniques, however, are the lack of adequate fixed-bed reactor designs and the large bandgap of metal oxides (e.g. TiO_2 ~3.2 eV). For bulk TiO_2, this wavelength is in the near-UV region, ~390 nm, which means that only a tiny fraction (~3%) of the solar spectrum can be harvested. This high photon energy requirement can be overcome by doping the semiconductor material to produce tail-states in the energy bands, leading to visible light absorption and photocatalytic degradation of any adsorbed organic species on the nanoparticle [22]. Figure 4.2 shows the photocatalytic degradation of methylene blue, used as a test organic compound, with visible light by using doped ZnO as the oxide semiconductor. Using this approach, it becomes possible to utilize effectively 46% of the solar energy in the form of visible light, making photocatalytic degradation techniques more efficient than the conventional UV photon catalysis techniques.

Contamination of sediments and aqueous water systems by halogenated organic compounds presents a serious environmental threat due to their toxicity and resistance to biodegradation. These chemicals are widely employed as pesticides,

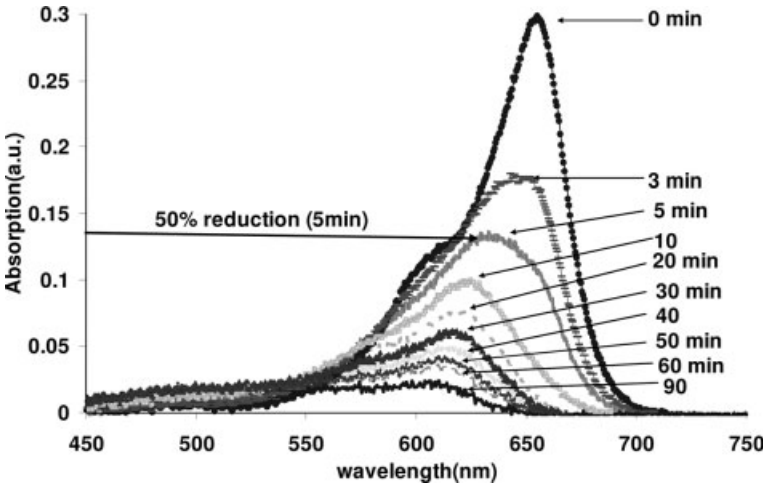

Figure 4.2 Visible light photocatalytic degradation of methylene blue with manganese-doped zinc oxide nanoparticles under 60 lux illumination (tungsten–halogen lamp).

insecticides and wood preservatives and are ubiquitous in the environment of both industrialized and agrarian nations. A subgroup of these chemicals, referred to as chlorinated aromatics, includes chlorinated benzenes, polychlorinated biphenyls (PCBs), pentachlorophenol (PCP) and insecticides such as DDT. Microbial degradation and naturally occurring hydrolysis of these compounds are very slow processes (e.g. for 4-chlorophenol at 9 °C the half–life is nearly 500 days). Some direct photodegradation also occurs, although the limited optical absorbance of chlorinated aromatics at wavelengths above 350 nm slows the process drastically. Sometimes this direct photolysis can actually lead to more toxic products; e.g. direct photolysis of PCP has been reported to lead to octachlorodibenzo-*p*-dioxin, an even more toxic species than its precursor [29]. It is clear that more effective methods of treatment of these chlorinated aromatics must be sought [30, 31]. To this end, a few groups have been investigating the photocatalytic oxidation of these compounds to form harmless CO_2 and HCl, a process referred to as total mineralization [32]. Photocatalysis is needed to reduce toxic pollutants in the atmosphere and water [33], VOCs in the atmosphere and also for reduction of NO_x [34] molecules (largely from vehicle exhausts) into N_2, N_2O, NO_2 and O_2 over semiconductor and zeolite catalysts at ambient temperature. Photocatalytic reaction between ammonia and nitric oxide has been investigated on a TiO_2 wafer under near-UV illumination [35]. Using a novel, integrated, nanobiotechnological approach comprising catalytic dechlorination using FeS nanoparticles followed by microbial degradation, it has been reported that complete removal of 5 mg L^{-1} of lindane (γ-hexachlorocyclohexane), which is an organochlorine pesticide and a persistent organic pollutant (POP), occurs from an aqueous solution in less than 10 h [36].

A variety of photocatalyst nanoparticles have been synthesized, such as oxides (TiO_2, ZnO, Fe_2O_3, WO_3, SnO_2, Ag_2O, V_2O_5, $SrTiO_3$), sulfides (ZnS, CdS, MoS_2,

Cu_xS, Ag_2S, PbS), selenides (CdSe, PbSe, HgSe), iodides (AgI) and modified systems such as coupled semiconductor systems (CdS/TiO_2, $CdSe/TiO_2$, SnO_2/TiO_2, ZnO/TiO_2, ZnO/CdS). Among them, TiO_2 nanoparticles and modified TiO_2 nanoparticles are the most extensively studied and considered to be the most efficient photocatalysts [37]. Other semiconductor nanoparticles generally have lower photocatalytic activity than TiO_2 and some have problems associated with stability, reactivity, etc. [26]. Fe_2O_3 easily undergoes photocathodic corrosion [38] and its active form α-Fe_2O_3 also has high selectivity for the reactant [39].

Many chlorinated aromatics and aliphatics are toxic, even at low concentrations, and exert a cumulative, deleterious effect on river basins and other streams that enter the environment from manufacturing operations and user applications. Reductive dechlorination of organics by various bulk metals (particularly Fe) in the aqueous phase has been well documented. Although nanoparticles possess several advantages (e.g. high surface area and surface energy), sustainability requires particle immobilization on a base membrane to avoid particle loss and agglomeration. Nanostructured metals immobilized in membrane phase leads to high reaction rates at room temperature, significant reduction of metal usage, minimizing the need for the recovery of non-chlorinated products (e.g. ethylene from TCE), leading to a subsequent improvement in water quality. Chlorinated organics and many pesticides and herbicides are toxic to aquatic life, even at low concentrations, and exert a cumulative, effect on receiving streams. The use of non-toxic, polypeptide-based membrane assemblies to create nano-sized metal domains has significant environmental importance [40]. Nanoscale bimetallic (Fe/Pd, 99.9% Fe) particles are considered as a new generation of remediation technology that could provide cost-effective remedial solutions to some of the most difficult waste dumping sites [41]. The complete reduction of aqueous perchlorate to chloride by nanoscale iron particles over a wide concentration range (1–200 mg L^{-1}) has been observed. The reaction is temperature sensitive, as evidenced by progressively increasing rate constant values of 0.013, 0.10 and 1.52 mg perchlorate per gram of iron per hour at temperatures of 25, 40 and 75 °C, respectively. The high activation energy of 79.02 ± 7.75 kJ mol^{-1} partially explains the stability of perchlorate in water. Iron nanoparticles may represent a feasible remediation alternative for perchlorate-contaminated groundwaters.

4.4 Sensors

The categorization of environmental sensors is based primarily on the physics involved and their operating mechanisms. For example, chromatography relies on the separation of complex mixtures by percolation through a selectively adsorbing medium, with subsequent detection of compounds of interest. Electrochemical sensors include sensors that detect signal changes (e.g. resistance) caused by an electric current being passed through electrodes that interact with chemicals. Mass sensors rely on disturbances and changes to the mass of the surface of the sensor

during interaction with chemicals. Optical sensors detect changes in visible light or other electromagnetic waves during interactions with chemicals. Within each of these categories, some sensors may exhibit characteristics that overlap with those of other categories. For example, some mass sensors may rely on electrical excitation or optical settings. Nevertheless, these four broad categories of sensors are sufficiently distinct for the purposes of this chapter. The following sections provide a summary and assessment of the sensors reviewed in each of the four categories.

4.4.1 Biosensors

Biosensors have been reported to detect compounds in several classes of concern, including phenols/phenoxy acids (e.g. phenol and catechol [42]), polyaromatic compounds (e.g. benzo[*a*]pyrene [43]), halogenated pesticides (e.g. triazines [44]), VOCs (e.g. benzene [45]) and inorganic substances (e.g. mercury [46]).

Biosensors typically consist of an enzyme (e.g. acetylcholinesterase, which binds with high affinity to organophosphate insecticides, and Japanese pine-comb fish luciferase, which has been used to measure Hg^{2+}), a receptor [e.g. γ-aminobutyric acid receptor (GABA), which binds to cyclodienes, pyrethroids, bicyclophosphates and orthocarboxylates; the muscarinic receptor, which binds organophosphate insecticides; and the aryl hydrocarbon receptor, which binds with high affinity to dioxins], antibody {e.g. antibodies bind to dozens of insecticides and herbicides and also environmental pollutants such as polychlorinated biphenyls (PCBs), dioxins, pentachlorophenol, benzo[*a*]pyrene and benzene, toluene and xylene (BTX)} or a microbe (e.g. cyanobacteria have been used to measure herbicides, *Trichosporon* cells have been used to measure biochemical oxygen demand and a genetically altered *Pseudomonas* has been used to measure naphthalene), which form the biological sensing element that is in intimate contact with a chemical or physical transducer (electrochemical, optical, mass or thermal). Selectivity and high binding affinities of biological macromolecules towards some environmental pollutants render them useful candidates as sensing elements for environmental biosensors [47]. For environmental monitoring, there are several general areas in which biosensors may have distinct advantages over current analytical methods. Recently, sensors using DNAzymes (segments of DNA with enzymatic activities) that can bind selectively to analytes of interest have been coupled with fluorophores or gold nanoparticles, to form sensitive and selective fluorescent or colorimetric sensors for a variety of analytes [48].

4.4.2 Electrochemical Sensors

Electrochemical sensors represent a key area where the use of nanotechnology (e.g. nanopowders), innovative materials and nano- and micro-fabrication techniques can give sensor products that offer significant enhancements with respect to sensitivity, selectivity, power consumption and reproducibility. The idea of using semiconductors as gas-sensitive devices dates back to the early 1950s when Brattain first reported

gas-sensitive effects on germanium [49]. The gas detection technique is primarily based on a change in the electrical resistance of the semiconducting metal oxide films [50]. The principal detection process is the change of the oxygen concentration at the surface of these metal oxides, caused by the adsorption and heterogeneous catalytic reaction of oxidizing and reducing gaseous species. The electrical conductivity depends on the gas atmosphere and on the temperature of the sensing material exposed to the test gas [51]. Crystallite size effects in resistive sensors are one of the most important factors affecting the sensing properties. The first evidence was obtained in 1982 by Ogawa *et al*. [52] from the measurements of the Hall parameters on SnO_2 nanoparticles. In that report, it was demonstrated that, when the grain size approaches about double the Debye length, the space-charge region can develop in the whole crystallite, which results in a higher sensitivity to adsorbed gas species. For example, the sensitivity of sensors based on tin oxide nanoparticles dramatically increases when the particle size is reduced to 6 nm [2]. Further, the surface reactivity of particles is known to increase rapidly with increase in the surface-to-bulk ratio because the strong curvature of the particle surface generates a higher density of defects which are the most reactive surface sites [12].

Selectivity has always been a major hurdle for solid-state gas sensors. A number of approaches have been developed to improve the selectivity of gas sensors, including doping metal impurities [53], using impedance measurement [54], modulating operating temperature [55] and surface coating [56], and there are some reports on the use of metal oxide-based gas sensors for air pollution monitoring [57].

4.4.3 Mass Sensors

Other strategies for sensing include nanomechanical sensors [3]. Cantilever sensors have also been used for detecting chemicals, such as volatile compounds [58], warfare pathogens [59], explosives [60] and glucose [61] and ionic species, such as calcium ions [62]. The key to using microcantilevers for the selective detection of molecules is the ability to functionalize one surface of the silicon microcantilever in such a way that a given target molecule will be preferentially bound to that surface upon its exposure. The bending and the changes in resonant frequency can be monitored by several techniques, with optical beam deflection, piezoresistivity, piezoelectricity, interferometry, capacitance and electron tunneling among the most important [63]. This strategy allows microcantilever sensors to measure extremely small changes due to molecular adsorption and, for that reason, they are extremely sensitive biosensors; with the cantilever technique, it is possible to detect surface stress as small as about $10^{-4}\,N\,m^{-1}$. Such measurement is also quantitative, related to the concentration of the analyte being detected [64]. Nonetheless, the factors and the phenomena responsible for the surface stress response during molecular recognition remain unclear. Electrostatic interaction between neighboring adsorbates, changes in surface hydrophobicity and conformational changes of the adsorbed molecules can all induce stresses, which may compete with each other and mean that the change in stress is not directly related to the receptor–ligand binding energy.

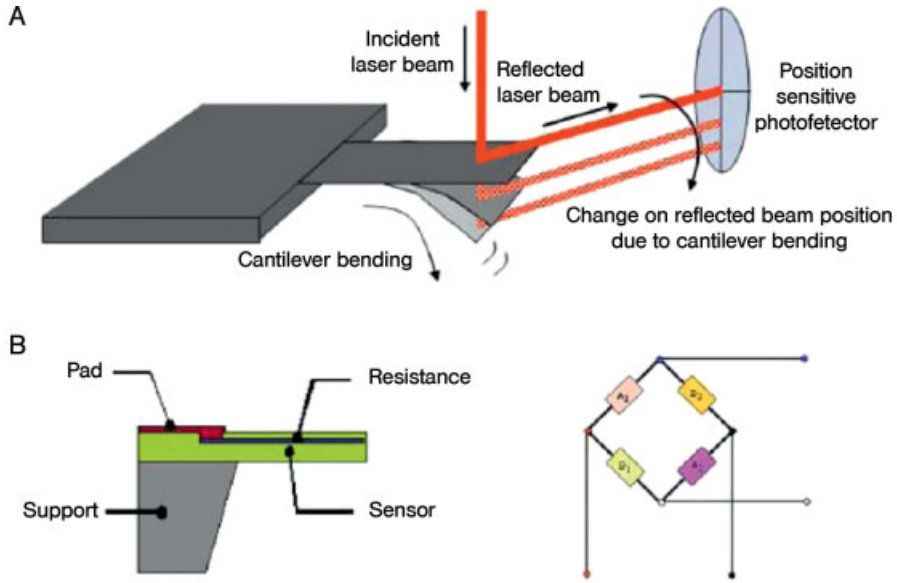

Figure 4.3 Mass sensors using microcantilevers: working mechanism. From Ref. [3].

Silicon, silicon nitride and silicon oxide cantilevers are available commercially with different shapes and sizes, analogous to AFM cantilevers, with typical lengths of 10–500 μm and ultra-thin cantilevers up to 12 nm thick. However, for specific applications (e.g. highly sensitive biosensors), cantilevers must be designed and fabricated to satisfy their requirements. Cantilever sensitivity depends critically on the spring constant: the lower the constant, the higher is the sensitivity for measurements in liquids based on the static method. Figure 4.3 shows a schematic of the working mechanism of a microcantilever sensor.

For accurate functioning of such sensors based on microcantilevers, the immobilization process should:

- avoid any change in the mechanical properties of the cantilever;
- be uniform, in order to generate a surface stress as large as possible; and
- allow accessibility by the target molecule.

Depending on the surface coating of the cantilevers, selectivity for various chemical and biological species can be achieved. Commercially available polymers have been used to coat cantilevers for differentiating between different VOCs in air. Baller *et al*. developed a Nanotechnology Olfactory SEnsor (NOSE) to characterize and to identify gaseous analytes [58]. In the field of explosives, Pinnaduwage and co-workers reported measurement of trinitrotoluene (TNT) in a small, localized explosion on an uncoated piezoresistive microcantilever [60, 65]. Heavy metal ions and ions in general have also been studied. Ji and co-workers used thiol-derivatized calixarene and crown ether macrocycle-functionalized cantilevers to detect Cs^{2+} ions in the range $10^{-11} - 10^{-7}$ M and K^{+} in the 10^{-4} M range [66]. Other functionalization

schemes have shown that cantilevers were able to detect, with great accuracy and selectivity, different ions, such as CrO_4^{2-} [67], Ca^{2+} [62] and Pb^{2+} [68].

Biological applications of cantilever based mass sensors include the detection of different pathogens, such as *Salmonella enterica* by Weeks *et al.* [59], *Vaccinia* virus by Gunter *et al.* [69] and fungal spores from *Aspergillus niger* by Nugaeva *et al.* [70]. Monitoring concentrations of specific pesticides plays an essential role in the environmental control field. An example of the application of a cantilever-based biosensor in this area was reported by Alvarez *et al.* [71] for the detection of the organochlorine insecticide dichlorodiphenyltrichloroethane (DDT). A synthetic hapten of the pesticide, conjugated with bovine serum albumin (BSA), was covalently immobilized on the gold-coated side of the cantilever; specific detection was then achieved by exposing the cantilever to a solution containing the specific monoclonal antibody to the DDT–hapten derivative. The specific binding of the antibodies on the sensitized side of the cantilever was measured with nanomolar sensitivity. Finally, a competitive assay was performed, with the cantilever exposed to a mixed solution of the monoclonal antibody and DDT and direct detection was achieved. With this detection strategy, DDT concentrations as low as 10 nM were detected, involving deflection signals in the 50 nm range. Many other applications have been described for the detection of pesticides and avidin– streptavidin [72].

4.4.4
Optical Sensors

For realizing sensitive chemical sensors and biosensors, optical methods employing optical fibers or integrated optics (IO) and, in the case of remote sensing, by connecting fiber pigtails, offer high sensitivity and fast responses. Contemporary methods for optical sensing of chemical and biological species at present are based mainly on interferometry, surface plasmon resonance (SPR) and luminescence. The relatively recent technique of luminescence quenching [73] is a new alternative. The photoluminescent (PL) properties of nanocrystalline (porous) silicon depend on the chemical nature of its surface; for example, metal ions can quench PL from porous Si [74], as can inorganic molecules [75–77]. The nanoscale size permits *in vivo* monitoring of processes within individual cells. Concentrations of toxic chemicals within carcinoma cells [78] have already been achieved. PEBBLE (probe encapsulated by biologically localized embedding) nanosensors have been prepared for the analytes oxygen [79, 80], potassium [81], zinc [82] and magnesium [83]. The wide variation of the optical properties of gold nanoparticles with particle size, interparticle distance and the dielectric properties of the surrounding media due to SPR [84–86] permits the construction of simple but sensitive colorimetric sensors for various analytes. Highly sensitive colorimetric sensors for biomolecules [87–89] and metal ions [4, 5], amongst others, have been devised using SPR of gold nanoparticles. In the example of sensing heavy metal ions, well-known metal ion chelators, such as chitosan, can be coated on the nanoparticle surfaces, such that the ligand changes its dielectric properties upon chelating the metal ions, resulting in an optical (colorimetric) signal (Figure 4.4).

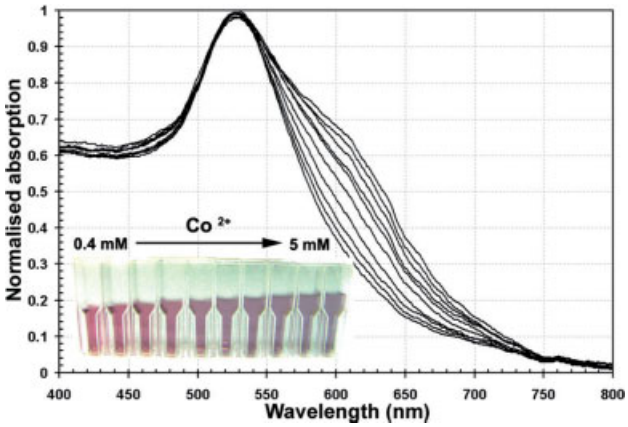

Figure 4.4 Colorimetric sensing of cobalt ions using gold nanoparticles.

4.4.5 Gas Sensors

Gas sensors for detecting air pollutants must be able to operate stably under deleterious conditions, including chemical and/or thermal attack. Therefore, solid-state gas sensors appear to be the most appropriate in terms of their practical robustness. The sensors used for detecting air pollutants are usually produced simply by coating a sensing (metal oxide) layer on a substrate with two electrodes. Typical materials are tin (IV) oxide (SnO_2), zinc oxide (ZnO), titanium dioxide (TiO_2) and tungsten oxide (WO_3), with typical operating temperatures of 200–400 °C [90]. When the active surface of a metal oxide (e.g. zinc oxide) grain is exposed to the ambient oxygen, the oxygen atoms are adsorbed on the surface as shown in Figure 4.5 and the adsorbed oxygen acts as an

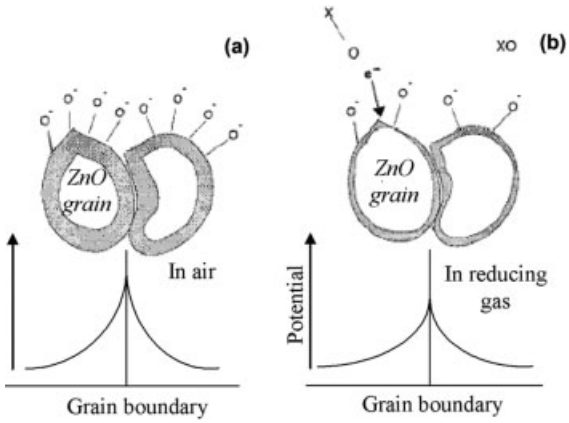

Figure 4.5 Surface effect on gas sensing including potential barrier at the grain boundary of ZnO nanoparticles: (a) in air and (b) in a reducing gas.

acceptor state. Being ionized, a depletion layer is formed on the surface of the grains and also in the neck regions, which raises the height of the potential barrier [91]. In the presence of a reducing gas, the adsorbed oxygen can easily react with the gas molecules and exit from the lattice, thus reducing the concentration of acceptors, which in turn lower the voltage barrier height. When the metal oxide sensor absorbs a reducing gas (CO, H_2), the depletion area at the surface will be decreased, leading to increased conductivity. On the other hand, if a metal oxide sensor absorbs an oxidizing gas (NO_2), the depletion zone at the surface will be increased, meaning decreasing conductivity. A change in conductivity/resistance is related to gas concentration. In the case of a ZnO sensor, conductivity decreases, which means resistance increases when the sensor absorbs NO_x, depending on the NO_x concentration [90].

A host of sensing materials are available to be used as the sensing layer for solid-state gas sensors so far reported, as shown in Table 4.5. Despite their simplicity and

Table 4.5 Materials for Solid-state sensors.

Sensing materials	Target gases
SnO_2	AsH_3, H_2S, NO_2, H_2, NH_3, SO_2, NO_x, CO, CH_3COOH, CCl_4, $C_2H_2O_4$, CH_4, CO_2
SnO_2, Fe_2O_3, La_2CuO_3, Ga_2O_3, ZnO, In_2O_3, V_2O_5, $Bi_2Sn_2O_7$, GaAs, Bi_2Sr_2	CO, CH_4, NO_x, H_2, C_2H_2, C_6H_6

$YBa_2Lu_3O_7$-d, In_2O_3, $LnCoO_{3-x}$, Sm, Eu, La, $Bi_xMo_yO_z$, $Cr_{0.8}Ti_{0.2}O_3$, ZnO, ITO, $CdIn_2O_4$, In_2O_3, $Sn_{1-x}Fe_xO_y$	NO, O_3, CO, alcohols, ketones, NH_3, H_2, CH_4, C_4H_{10}, C_2H_5OH, NO_2, ethanol
SnO_2(Pd), Ag/SnO_2, SnO_2(Ag), SnO_2(ZrO$_2$), SnO_2(Al_2O_3), SnO_2(CuO), SnO_2(Pt), WO_3(Au), $Ti_{0.9}Cr_{0.1}O_2$, $IrTiO_2/In_2O_3$(MgO), Pt/In_2O_3(MgO), Ru/TiO_2, In/TiO_2, ZnO(Al_2O_3), SnO_2(La_2O_3), Er_2O_3/ZnO, Rh/WO_3	H_2S, CH_3SH, NH_3, dimethylamine, trimethylamine, capronaldehyde, 2-methylpyrazine

low production cost, solid-state gas sensors (SGS) usually exhibit drifts and variations in behavior. After the introduction of nanoparticles, sensitivity in gas sensors has improved. The use of nanoscale materials exposes a higher surface area of the sensing element to gas and hence the physicochemical reaction that proceeds at the surface is increased [92].

4.4.6 Novel Sensing Technologies and Devices for Pollutant and Microbial Detection

Protection of human health and ecosystems requires rapid, precise sensors capable of detecting pollutants up to the molecular level. Examples of research into sensors include the development of nanosensors for efficient and rapid *in situ* biochemical detection of pollutants and specific pathogens in the environment; sensors capable of continuous measurement over large areas, including those connected to nanochips for real-time continuous monitoring; and sensors that utilize lab-on-a-chip technology. Research may also involve sensors that can be used in monitoring or process control to detect or minimize pollutants and their impact on the environment.

4.4.6.1 Real-Time Chemical Composition Measurements of Fine and Ultrafine Airborne Particles

New technologies need to be developed that will permit the chemical composition of airborne nanoparticles (down to about 5 nm in diameter) to be determined. Knowledge of the chemical composition will provide a better understanding of the sources of these particles and how to control their formation in a manner that reduces their impact on human health. It is now well established that long-term exposure to fine particulate matter is a significant risk factor for cardiopulmonary and lung cancer mortality in humans [93]. In urban air, fine particulates typically exhibit a maximum in both number and mass in the 100–300 nm diameter range. Most of these particles are produced directly from combustion sources. However, a significant fraction of particles in this size range may also arise from growth and/or coagulation of much smaller particles. The mechanism of particle formation is difficult to assess without chemical composition measurements during these events. Technology already exists for chemical analysis of fine particles [94].

4.4.6.2 Ultrasensitive Detection of Pathogens in Water

The primary water quality problem in the developing world is waterborne diseases [95]. Table 4.6 lists some common waterborne pollutants. Conventional tests for the problem count indicator bacteria – *E. coli* (coliform counts) – and require a laboratory facility and trained personnel, with the only alternative to laboratory methods being the simple Colilert test kit [96]. The need for rapid, simple tests for fecal contamination of water is not confined to developing countries. In coastal areas of the USA, for example, monitoring beaches for the indicator species *E. coli* and *Enterococcus* by laboratory analysis can take more than 1 day. During that time, conditions can change and swimmers can be put at risk.

Table 4.6 Selected waterborne contaminants in developing countries [95].

Problem	Occurrence
Pathogens	Most significant risk to water quality
Metals, e.g. arsenic	Associated with certain geological conditions or with agricultural or industrial use
Pesticides	Localized areas of agricultural use; runoff; aerial transport
Algal toxins	An array of neuro-, hepato- and cytotoxins are produced by a range of cyanobacteria; typically found in water with elevated nutrient levels
Nitrates	Widespread; natural and agricultural sources
Fluoride	Localized areas, depending on geology
Organic compounds	Common sources are industry and transport; includes aromatic and aliphatic hydrocarbons, halogenated compounds and persistent organic pollutants

Current developments in pathogen detection in water rely on filtration culture methods and fluorescence-based methods (e.g. fluorescence probe methods and DNA microarray methods). These techniques, however, are not effective for *in situ*, rapid, quantitative measurements. With filtration culture methods, sample water is passed through a filter that is pretreated for visualization of the target pathogen. Growth of colonies on the filter indicates the presence of the target pathogen in the test water. Both the fluorescently labeled probe methods and the DNA microarray methods rely on detection using fluorescence spectroscopy, which is not quantitative. There is a need for rapid, quantitative and specific pathogen detection to ensure the safety of natural and man-made water supplies, including source, treated, distributed and recreational waters. Arrays of a highly piezoelectric (e.g. strontium-doped lead titanate) microcantilever smaller than 10 μm in length coupled to antibody proteins immobilized at the cantilever tip for *in situ* rapid, simultaneous multiple pathogen quantification in source water have been used [97].

4.4.6.3 Detection of Heavy Metals in Water

Arsenic is a well-known toxic chemical that the EPA and the World Health Organization (WHO) [98] list as a known carcinogen. Arsenic is found in a wide variety of chemical forms throughout the environment and can be readily transformed by microbes, changes in geochemical conditions and other environmental processes [99]. Although arsenic occurs naturally, it may also be found as a result of a variety of industrial applications [100], including leather and wood treatments [101] and pesticides [102]. Anthropogenic arsenic contamination results mainly from manufacturing metals and alloys, refining petroleum and burning fossil fuels and wastes. These industrial activities have created a strong legacy of arsenic pollution throughout the world. Unlike organic pollutants, arsenic cannot be transformed into a non-toxic material, but can only be transformed into a form that is less toxic when

exposed to living organisms in the environment. Because arsenic is a permanent part of the environment, there is a long-term need for regular monitoring at sites where arsenic-containing waste has been disposed of and at sites where it occurs naturally at elevated levels.

Fixed laboratory assays are generally required to measure arsenic accurately in an environmental sample to parts per billion (ppb) levels, defined as $\mu g\,L^{-1}$ for water or $\mu g\,kg^{-1}$ for solids. The preferred laboratory methods for the measurement of arsenic involve pretreatment, either with acidic extraction or acidic oxidation digestion of the environmental sample. Pretreatment transfers all of the arsenic in the sample into an arsenic acid solution, which is subsequently measured using any one of several accepted analytical methods, such as atomic fluorescence spectrometry (AFS) [103], graphite furnace atomic absorption spectrometry (GFAAS), hydride generation atomic absorption spectrometry (HGAAS), inductively coupled plasma atomic emission spectrometry (ICP-AES) and inductively coupled plasma mass spectrometry (ICP-MS) [104]. The instruments involved are bulky, expensive to operate and require fully equipped laboratories to maintain and operate. Field assays, in which lower sensitivities may be acceptable for purposes of sample screening or site surveys, strive for similar detection goals as fixed laboratory methods are relatively inexpensive and can produce a large number of screening results in a short time.

A considerable amount of research has been dedicated to developing an arsenic detection colorimetric solution that matches or exceeds the sensitivity of the Gutzeit method while improving safety, accuracy and reproducibility. One research group electrochemically reduced the arsenite ion to arsine gas. They found that the arsenic reduction by this electrochemical method compared favorably with reduction by sodium borohydride. They were able to achieve detection limits down to 50 ppb arsenite using this method. Gold, copper and iron(III) species were found to interfere with the sample reduction [105]. One such system reduces arsenic compounds to arsine gas, which then bleaches a dye in a solution containing detergents and metal particles. This system has been shown to be effective, with limits of detection for arsenic as low as 30 ppb [106].

Accurate, fast measurement of arsenic in the field still remains a technical challenge. Selective solid-state sensors for carcinogenic and toxic chromium(VI) and arsenic(V) in water based on redox quenching of the luminescence from nanostructured porous silicon and polysiloles has been undertaken [107]. Sensors based on silicon wafer and polymer technologies are readily adaptable to fabrication. The fluorescence quenching detection modality also is manufacturable. The essential electronics require a blue or UV LED as the excitation source and an inexpensive photodiode detector. Potential applications of such real-time solid-state sensors include remote sensing and industrial process control. The focus on chromium(VI) and arsenic(V) detection is dictated by the redox quenching mechanism that is being used, and also by the importance of chromium(VI) and arsenic(V) as regulated chemicals under the Safe Drinking Water Act. Chromium(VI) detectors need to be developed that can sense the analyte at concentrations at least as low as the 0.1 ppm action levels with at least 10% accuracy. For arsenic(V), the target range is 10–50 ppb at the same level of analytical accuracy.

4.5 Conclusions

Environmental protection and pollution issues are frequently discussed worldwide as topics that need to be addressed sooner rather than later. Nanotechnology can strive to provide and fundamentally restructure the technologies currently used in environmental detection, sensing, remediation and pollution removal. Some nanotechnology applications are near commercialization: nanosensors and nanoscale coatings to replace thicker, more wasteful polymer coatings that prevent corrosion, nanosensors for detection of aquatic toxins, nanoscale biopolymers for improved decontamination and recycling of heavy metals, nanostructured metals that break down hazardous organics at room temperature, smart particles for environmental monitoring and purification, nanoparticles as novel photocatalysts for environmental catalysts, etc. New advances have emerged in the use of nanotechnology in environmental protection, and these been discussed in this chapter. Strategies involved in detecting markers/tracers of "substances of interest" are a very important part of preventing, remediation or sensing pollution for prevention of major catastrophes. For example, quantum dots functionalized with an appropriate molecule could be tuned to detect hazardous materials selectively by simply looking for fluorescence signals from these detector dots. A host of applications, similar or very different from this, are actively being pursued worldwide, as discussed in this chapter. This review provides just a small beginning to the exciting new applications envisaged for the "small world" of nanotechnology for preventing environmental pollution.

5
Benefits in Energy Budget

Ian Ivar Suni

5.1
Introduction

Nanomaterials in the 1–100 nm size range have unusual potential for applications within a wide variety of existing and emerging technologies. Nanomaterials have several intriguing properties that may be exploited for technological applications. Due to quantum confinement effects, when their dimensions are comparable to the electron mean free path or the optical wavelength, the electronic and optical properties of nanomaterials become size dependent. This is of course the origin of the unique properties of the widely popularized "quantum dots", which exhibit quantum confinement in all three dimensions. Another interesting property of nanomaterials, and in particular nanoparticles, is their unusually high chemical reactivity. This has led to the widespread use of metal and metal oxide nanoparticles as commercial catalysts in the chemical and petrochemical industries. Metal nanoparticles are also currently employed within catalytic converters in automobiles as three-way catalysts. Three-way catalysts catalyze the following three reactions: oxidation of unburned hydrocarbons, oxidation of CO, and reduction of nitrogen oxides.

Another interesting aspect of nanomaterials is their unusually high surface area per unit mass. Many potential applications that exploit the high surface area of nanomaterials involve their use within compacted solids as what are termed nanostructured materials, which in many cases are composite materials. Nanostructured materials thus have extremely high internal surface areas, although these may not be chemically accessible. Composite nanomaterials can be fabricated from nanowires or nanotubes of extremely high aspect ratio, allowing for low percolation thresholds. This means that high aspect ratio nanomaterials can more easily form interacting networks within a composite material to form a conductive electrical pathway or to increase mechanical strength.

Although nanomaterials have several existing applications, their potential for the development of new technologies is the main source of the excitement within academia, government and industry. Among the most widely anticipated applications of nanomaterials is the development of more environmentally friendly and more efficient energy sources. Interest in sustainable energy is driven in part by long-term concerns

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

about the scarcity of hydrocarbon fuels, which are in increasingly great demand with the rapid industrialization of China, Russia, Brazil and other emerging economies. In addition, concerns about greenhouse gas emissions such as CO_2 that arise from combustion of hydrocarbons are generating interest in cleaner energy sources.

Applications of nanomaterials in the field of energy include fuel cell catalysts, fuel cell support materials, hydrogen storage, solar cells, lithium ion batteries and supercapacitors. The current discussion will focus on recent results, on clear demonstrations of the utility of nanomaterials and on the scientific basis for these applications. In low-temperature fuel cells, Pt and other noble metal nanoparticle catalysts have been widely studied for their ability to catalyze efficiently the electrochemical reduction of oxygen and the electrochemical oxidation of both hydrogen and methanol. Because these nanoparticle catalysts may be interspersed with less conductive materials, carbon nanotubes have been widely investigated as catalyst support materials to improve catalyst utilization in fuel cells. The development of fuel cells and other energy sources powered by molecular hydrogen, with water as the only chemical product, is an important goal for sustainable energy. One of the critical issues limiting hydrogen energy is the need for an infrastructure and new technology for hydrogen storage and distribution. Although early results have now been shown to be misleading, carbon nanotubes have been widely investigated for their hydrogen storage properties.

Further applications for nanomaterials can be envisioned in the area of solar energy cells. The classical example of nanotechnology is the variation in optical absorption/emission of semiconductor nanostructures with dimension. These size-dependent properties have been exploited to alter the wavelength of optical absorption to match the terrestrial window. In addition, nanostructured TiO_2 in dye-sensitized solar cells (DSSCs) has been widely investigated due to its high internal surface area, which increases the available dye for optical absorption and maximizes internal reflections within the DSSC.

Nanomaterials have also been employed within Li ion batteries, particularly as materials for anode construction. Many materials have been demonstrated to have higher Li capacities than the prototypical graphite anode material, but they have been prone to mechanical failure due to repeated expansion (contraction) during Li insertion (removal) as the battery is charged (discharged). Intensive research efforts have been expended to use these alternative Li anode materials in the form of nanoparticles, nanowires or nanotubes to minimize mechanical strain during Li insertion and removal.

5.2
Nanomaterials in Fuel Cells

5.2.1
Low-Temperature Fuel Cell Technology

The development of fuel cells as a clean, environmentally friendly energy source is widely anticipated. The use of a hydrogen as a fuel is particularly attractive, since the

main product produced would be H_2O, with effectively zero emissions. Even the economical use of other hydrocarbon fuels beyond gasoline and natural gas may have global benefits, as this may lessen the demands for hydrocarbon fuels. Fuel cells operate by converting chemical potential energy directly into a current or voltage by coupling an electrochemical oxidation reaction with an electrochemical reduction reaction. A wide variety of fuel cells have been investigated, including proton exchange membrane, direct methanol, molten carbonate, solid oxide and phosphoric acid fuel cells.

High-temperature fuel cells such as molten carbonate, solid oxide and phosphoric acid fuel cells have recently been employed for several applications, particularly those where waste heat can be employed to reach and maintain the operating temperature. For example, waste heat is widely generated throughout industrial chemical plants, sometimes making fuel cells an economical energy source. At the operating temperature of these fuel cells, the anode and cathode reactions are typically fairly facile, making the use of electrocatalysts, which are often in the form of nanoparticles, unnecessary. In addition, nanomaterials may be subject to grain growth, sintering, dissolution and other unwanted chemical reactions at high temperature.

On the other hand, nanomaterials are much more compatible with low-temperature fuel cells, which are needed for many transportation and consumer applications where intermittent operation is typical and power requirements are relatively modest. The most common low-temperature fuel cells are the polymer electrolyte membrane fuel cell (PEMFC) and the direct methanol fuel cell (DMFC), where the following reactions occur:

$$\text{Anode (PEMFC):} \quad H_2 \rightarrow 2H^+ + 2e^- \tag{5.1}$$

$$\text{Anode (DMFC):} \quad CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^- \tag{5.2}$$

$$\text{Cathode (PEMFC and DMFC):} \quad O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \tag{5.3}$$

The structure of a typical proton exchange membrane fuel cell (PEMFC) is illustrated in Figure 5.1. The cathode in a DMFC has a similar structure, whereas the anode structure depends on whether the methanol feed stream is in liquid or vapor form. In both electrodes of a PEMFC, the metal nanoparticle catalyst is dispersed atop larger carbon particles that are combined into a porous structure that allows mass transport of both reactants and products. Sandwiched between the two electrodes is a Nafion-type polymer material that serves as a proton conductor between the anode, where protons are produced and the cathode, where protons are consumed. Nafion, a perfluorosulfonated polymer, facilitates proton "hopping" along its sulfonate backbone through a series of electrostatic interactions.

Several technological challenges remain for commercialization of PEMFCs and DMFCs. For economic reasons, the use of precious metal catalysts should be reduced or eliminated. The cost of Nafion polymer membranes may also need to be reduced and their durability improved. Nafion membranes are employed for proton transport in both PEMFCs and DMFCs and are only conductive within a narrow temperature

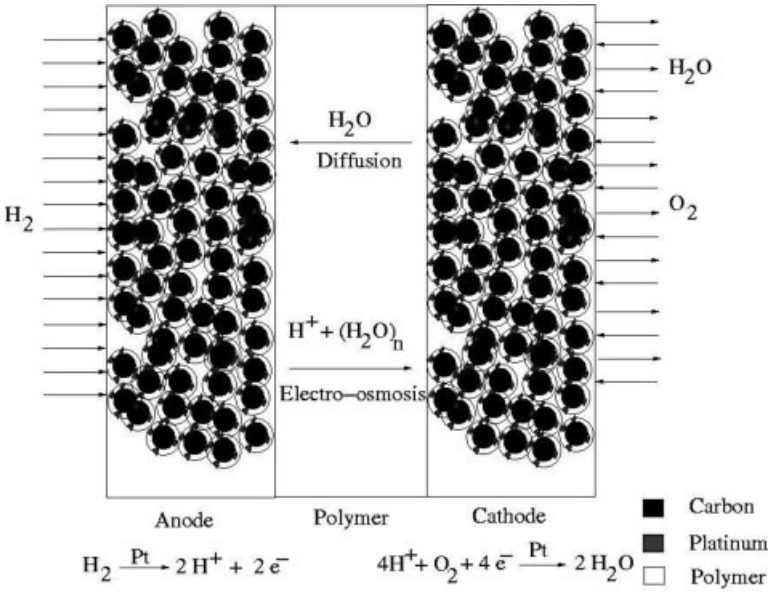

Figure 5.1 Schematic illustration of a typical proton exchange membrane fuel cell (PEMFC). (Courtesy of Renganathan Rengaswamy, Department of Chemical and Biomolecular Engineering, Clarkson University, Potsdam, NY, USA).

range, where the membrane is neither dried out nor flooded. In an H_2-fueled PEMFC, the need to maintain an appropriate humidification level throughout the fuel cell creates a complex water management problem. The local humidification depends on a complex balance between water production at the cathode, water consumption at the anode, water diffusion from the cathode to the anode, and water electro-osmosis from the anode to the cathode [1]. The durability of PEMFCs and DMFCs must also be improved, since Nafion degradation, catalyst agglomeration and dissolution and carbon corrosion can all occur upon prolonged operation at high current density.

5.2.2
Nanoparticle Catalysts in Low-Temperature Fuel Cells

When considering the use of nanomaterials in fuel cells, many observers would first consider the use of nanoparticle catalysts in both the anode and cathode. However, nanoparticle fuel cell catalysts will be discussed only briefly, since these reactions have been widely studied and the interested reader can consult recent reviews [2–9]. Hydrogen reduction by Reaction (5.1) at the anode of a PEMFC is the most facile due to its simple reaction mechanism, and Pt nanoparticles are widely used as electrocatalysts for this reaction. The main complication is that Pt catalysts can be easily poisoned by trace CO in the H_2 fuel, and so far the best performance has been attained by PtRu bimetallic nanoparticle catalysts, preferably with a 1 : 1 ratio of

Pt : Ru, that facilitate CO desorption. Ternary and quaternary catalysts have also been widely investigated.

The two cathode reactions above, methanol reduction by Reaction (5.2) and O_2 reduction by Reaction (5.3), involve more complex mechanisms and multi-step electron transfer, making electrocatalysis more difficult. O_2 reduction is most facile on Pt nanoparticle catalysts, and the use of Pt alloys with transition metals such as Co, Cr, Ti and Zr has been thoroughly investigated. However, for catalysts tested to date, the overpotential loss of 300–400 mV for O_2 reduction still accounts for about 80% of the voltage loss in a typical PEMFC [10]. Similarly, methanol oxidation has been widely studied on Pt nanoparticle catalysts alloyed with a wide variety of different transition metals, including Ru, Os and Sn. Given that the expensive Pt catalyst contributes significantly to the overall fuel cell cost, non-Pt catalyst materials are also under intensive investigation for both PEMFCs and DMFCs [11, 12]. However, Pt and its alloys in nanoparticle form remain the best catalysts for reactions (5.1)–(5.3) in low-temperature fuel cells.

5.2.3
Fuel Cell Catalyst Support Materials

Both PEMFCs and DMFCs employ porous catalyst support structures, typically some form of carbon, that perform multiple functions. The catalyst support material must be porous enough to provide a pathway for inlet and outlet of gaseous reactants and products, but it must also maintain electrical conductivity so that the voltage (current) created across the fuel cell can be captured for use or storage. The requirement to maintain electrical conductivity is complicated by the presence of Nafion polymer, which is typically far less conductive than the carbon support material.

Carbon nanotubes and carbon nanofibers have been widely investigated for possible application into the catalyst supports shown in Figure 5.1 for the PEMFC [10]. The main improvement that is envisioned is increased utilization for the Pt catalyst supported on carbon nanotubes. The high nanotube aspect ratio increases the likelihood that Pt catalyst will have direct electrical contact to the desired electrode, without electrical blockage by intervening Nafion particles. Another potential advantage of carbon nanotubes as catalyst supports is their improved resistance to oxidation. One of the primary barriers to commercialization of both PEMFCs and DMFCs is their poor durability. During long-term usage, catalyst agglomeration, catalyst dissolution and carbon corrosion all occur, resulting in a gradual loss of performance.

Wang *et al.* recently reported that the corrosion current for carbon nanotube catalyst support materials in a PEMFC cathode is 30% lower than that from Vulcan XC-72 carbon catalyst support materials [13]. In addition, these authors noted that the supported Pt catalyst better maintains its activity for the oxygen reduction reaction. Li and Xing recently used cyclic voltammetry to compare corrosion currents for carbon nanotube and Vulcan XC-72 carbon catalyst supports following prolonged oxidation [14]. They found that for the carbon nanotube-based support material, the

corrosion current eventually disappeared, whereas the corrosion current continued indefinitely for the standard carbon support material.

5.2.4 Carbon Nanotubes: Science and Technology

Carbon nanotubes, which are allotropes of carbon from the fullerene structural family, have been the most widely studied nanomaterial. They can be conceived as all-sp^2 carbons arranged in graphene sheets that have been rolled up into hollow tubes. The nanotubes can be capped at the ends by a fullerene-type hemisphere and can range in length from tens of nanometers to several micrometers. Carbon nanotubes can be subdivided into two categories, single-wall carbon nanotubes (SWNTs) and multi-wall carbon nanotubes (MWNTs). As the name suggests, SWNTs consist of a single hollow tube with a diameter of 0.4–3 nm, whereas MWNTs are composed of multiple concentric nanotubes spaced by 0.34 nm, with overall diameters of 2–200 nm.

Research interest in carbon nanotubes arises from several of their extraordinary properties. For example, their mechanical strength per unit weight is 100 times greater than that of steel, their electrical conductivity is similar to that of Cu and their thermal conductivity is comparable to that of diamond [15]. MWNTs have electrical conductivities greater than those of metals, but depending on the tube diameter and chirality, SWNTs can behave electronically as either metals or semiconductors. In addition, the aspect ratios of both SWNTs and MWNTs can be as high as 10^3–10^5, allowing for low percolation thresholds when they are employed in composite materials. Thus carbon nanotubes have been proposed for a diverse range of applications, including nanoscale transistors, chemical sensors, high-strength composites, hydrogen storage, and fuel cell electrode supports.

Carbon nanotubes can be made by laser ablation, electric arc discharge and chemical vapor deposition. The detailed synthesis conditions, such as temperature, pressure, or the presence of an inert gas, strongly influence the properties of the resulting carbon nanotubes, as does the presence and type of metal catalyst employed. One of the primary difficulties with these synthetic methods is that all create a complex mixture of different carbon forms, including amorphous carbon, graphite particles and carbon nanotubes. Thus synthesis must typically be followed by a difficult separation process.

For applications as fuel cell catalyst support materials, one should also consider the chemical reactivity of carbon nanotubes, since they must first be functionalized with metal nanoparticle catalysts and then formed into porous support materials. Both of these processes involve solution-phase chemistry, preferably aqueous chemistry. Dispersion of carbon nanotubes into aqueous solvents is difficult given their hydrophobicity, so the use of organic solvents is often required. In addition, carbon nanotubes are highly chemically inert, so chemical or electrochemical methods must be employed to attach the catalyst, typically Pt or its alloys.

Among the methods that have been employed for catalyst deposition are electroless deposition, otherwise known as chemical impregnation, electrodeposition, microwave

techniques, sputtering, and several different colloidal techniques [10]. Electroless impregnation methods are most commonly employed and involve surface oxidation/activation by a strong acid, Pt salt adsorption and Pt salt reduction by a reducing agent such as formaldehyde. Surface activation is necessary to increase the number of reactive hydroxyl, carbonyl, carboxylate and phenolic sites on the surface of the carbon nanotubes. The use of ultrasound during the surface oxidation/activation step has recently been shown to increase the Pt content by increasing the number of reactive sites generated.

The use of electrodeposition for Pt particle formation on carbon catalyst supports is attractive in that very small nanoparticles (<5 nm diameter) can be formed with very high activity [16, 17]. However, limited diffusion of Pt ions into the channels within carbon nanotube/Nafion composites severely restricts the Pt loading that may be attained. Several groups have electrodeposited Pt nanoparticles on carbon nanotube support materials through an alternative process, whereby application of a cathodic potential is preceded by metal salt precipitation on to the support surface [18–20]. This greatly enhances the catalyst loading that can be attained.

Although functionalization of carbon nanotubes with Pt catalyst nanoparticles is likely needed for creating an efficient PEMFC, carbon nanotubes also have intrinsic electrochemical behavior that may be beneficial for such applications. Electron transfer associated with different electrochemical reactions, including oxygen reduction, has been shown to be intrinsically more rapid at carbon nanotube electrodes than at electrodes made from other forms of carbon [21, 22]. For example, the oxygen reduction peak is shifted quite strongly in the anodic direction for an MWNT electrode prepared by an electric arc discharge process relative to a carbon paste electrode. Alternatively, one can compare the magnitude of the exchange current density for this reaction, which is about 5 times higher on an MWNT electrode than on a graphite electrode [21].

In addition, the electrochemical behavior of carbon nanotube electrodes is in general highly surface dependent and the introduction of certain functional groups, such as those introduced by oxidation treatments, can increase the rate of electron transfer dramatically [23]. For example, very different results can be obtained depending on whether the walls or the ends dominate the electrochemical nature of carbon nanotubes. The walls exhibit electrochemistry similar to that of basal planes of pyrolytic graphite, while the ends exhibit electrochemistry similar to the edges of pyrolytic graphite [23]. In addition, the electrochemical behavior of carbon nanotubes varies considerably with the methods used for purification and preparation [23].

5.2.5
Carbon Nanotubes within Operating PEMFCs

Many research groups have reported electrochemical studies of Pt and Pt alloy nanoparticles dispersed on to carbon nanotubes or graphite nanofibers. Given the size of this literature, discussion here will focus on results reported within an operating DMFC or an operating PEMFC or on those who have made direct comparisons to standard carbon support materials. This ensures that the electrochemical behavior

reported is retained following construction of a membrane electrode assembly (MEA), which involves the application of elevated temperature and pressure. In addition, carbon nanotubes will likely change their relative orientation during MEA fabrication, possibly affecting their behavior as catalyst support materials.

Results have been reported for oxygen reduction at carbon nanotube-supported cathode catalysts in both DMFCs and PEMFCs. Li and co-workers reported detailed studies of DMFCs in which carbon nanotubes are used to support Pt cathode catalysts [24, 25]. This group appears to have published the earliest report of the use of carbon nanotubes for fuel cell catalyst support materials. They compared two DMFCs with Pt nanoparticles as cathode catalysts, in one case supported on MWNTs and in the other case supported on Vulcan XC-72 carbon [24, 25]. Both DMFCs contained about 1.0 mg cm^{-2} Pt at the cathode and both employed commercial anode catalysts containing about 2.0 mg cm^{-2} PtRu. The carbon nanotubes were grown by electric arc discharge in a vacuum chamber, and Pt loading was accomplished by reduction of H_2PtCl_6 with ethylene glycol, yielding Pt particles of 2–5 nm diameter. Reduction with ethylene glycol was reported to yield much higher catalyst dispersion than reduction with formaldehyde.

Their best MWNT-supported cathode catalyst exhibited a limiting current density and maximum power density of 434 mA cm^{-2} and 103 mW cm^{-2}, respectively, while the corresponding Vulcan XC-72-supported catalyst yielded values of 309 mA cm^{-2} and 70 mW cm^{2-}, respectively [25]. Their results are shown in Figure 5.2 for two different preparations (A and B) of MWNT supports. In addition to the enhanced conductivity and connectivity of the carbon nanotubes, the authors also suggested

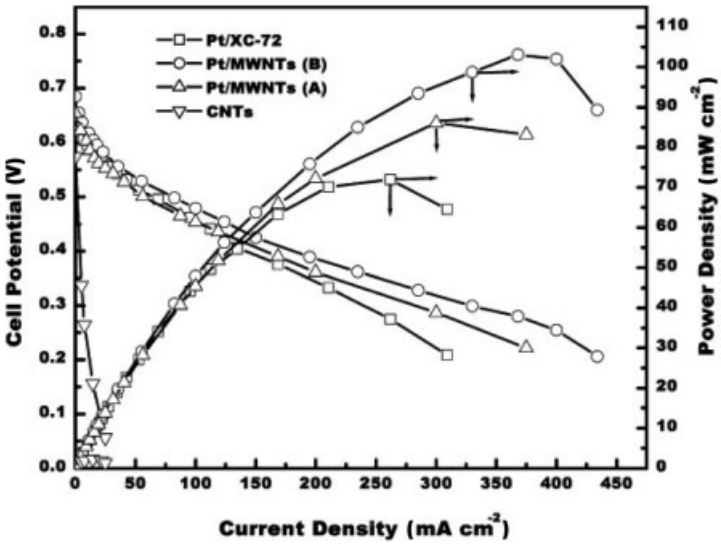

Figure 5.2 Current–voltage response and power density for a DMFC containing four different cathode catalysts supports. (From Ref. [25]).

that the catalyst activity on the standard support material may be compromised by trace amounts of organosulfur compounds, common catalyst poisons [24].

Not surprisingly, several reports have also appeared of carbon nanotube supports for Pt cathode catalysts in H_2-fueled PEMFCs, where the oxygen reduction reaction is the same [26–29]. Shaijumon *et al*. recently reported interesting results for an operating PEMFC with composite carbon catalyst supports containing a mixture of Pt-decorated MWNTs and commercial Pt/C samples from E-Tek [29]. MWNTs were fabricated by catalytic decomposition of acetylene in a CVD reactor and decorated with Pt nanoparticles by impregnation with H_2PtCl_6 followed by reduction with $NaBH_4$. This yields Pt particles of size 5–8 nm. Composite cathodes were fabricated by using 0, 25, 40, 50, 60, 75 and 100 wt.% Pt/MWNT, with the remainder of the catalyst as commercial E-Tek 20 wt.% Pt/C, with a total Pt loading of 0.5 mg cm^{-2}. The anode of the PEMFC was constructed from commercial E-Tek 20 wt.% Pt/C, with a loading of 0.25 mg cm^{-2}. Surprisingly, an optimum performance was observed with a composite catalyst support composed of a 50:50 wt.% mixture of the two carbon forms. This yielded a current density of 535 mA cm^{-2} at a voltage of 540 mV [29]. This is considerably higher than the corresponding current densities for pure E-Tek and pure MWNT catalyst supports of 258 and 362 mA cm^{-2}, respectively [29].

Waje *et al*. recently reported the PEMFC performance of CVD-grown carbon nanotubes that are pretreated by electrochemical reduction in a diazonium–acetonitrile electrolyte and then decorated with Pt nanoparticles by standard impregnation and reduction methods [27]. This treatment yields uniform Pt particles of about 2–2.5 nm diameter, with a mass loading of about 0.09 mg cm^{-2} [27]. This Pt/carbon nanotube catalyst layer was then employed as the cathode in a H_2-fueled PEMFC with a standard E-Tek/Vulcan XC-72 anode catalyst, and its performance was compared with that of a reference E-Tek/Vulcan XC-72 cathode catalyst with a slightly lower loading, about 0.075 mg cm^{-2}. The maximum power density obtained for the Pt/nanotube cathode catalyst was about 290 mW cm^{-2}, whereas that obtained from the reference cathode catalyst was about 160 mW cm^{-2} [27]. The authors contend that the superior performance at high current densities arises from the more open structure of the Pt/nanotube cathode catalyst, which enhances mass transport of reactants and products [30].

Several research groups have investigated the use of carbon nanotube catalyst supports on the anode side of an H_2-fueled PEMFC [31–34]. Li *et al*. recently described a filtration method for incorporating a Pt/carbon nanotube film into a PEMFC so that it is partially oriented [31]. These authors started with commercial MWNTs, oxidized them in a nitric acid–sulfuric acid mixture, and deposited Pt nanoparticles by ethylene glycol reduction of H_2PtCl_6, producing Pt nanoparticles of 2–5 nm diameter. The Pt/MWNT suspension was then filtered through a hydrophilic nylon filter-paper, which apparently forces the hydrophobic MWNTs to stand up and self assemble on the filter-paper [31]. These can then be pressed onto a Nafion membrane to create a partially oriented but somewhat loosely packed Pt/MWNT film. This Pt/MWNT film was then used as the cathode catalyst layer in an operating PEMFC and compared with two reference cathode catalysts, one made from a

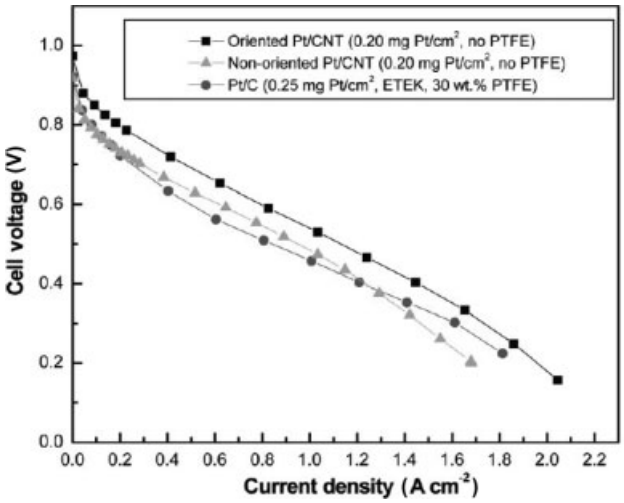

Figure 5.3 Current–voltage response for a PEMFC containing oriented nanotube, non-oriented nanotube and E-Tek cathode catalysts supports. (From Ref. [31]).

non-oriented Pt/MWNT film and one made from E-Tek Pt/C. All cathodes had approximately the same Pt loading, 0.20–0.25 mg cm^{-2}. The best performance was observed for the cathode catalyst containing oriented Pt/MWNT, which the authors argue arises partly from improved mass transport [31]. The results of Li *et al.* are shown in Figure 5.3, which compares oriented carbon nanotube cathode catalyst support materials with non-oriented carbon nanotube supports.

Carmo *et al.* also studied carbon nanotube catalyst supports for PEMFC anode fabrication using nanotubes grown by chemical vapor deposition [32]. Both Pt and PtRu nanoparticle catalysts were deposited by impregnation of H_2PtCl_6, with and without $RuCl_3$, followed by reduction at elevated temperature in an H_2 atmosphere. This produced an average Pt particle size of about 3.6 nm and an average PtRu particle size of about 4.6 nm, whereas the corresponding particle sizes on Vulcan XC-72 carbon were 6.8 and 6.4 nm, respectively. As is typically observed, the particle sizes measured by different techniques varied somewhat. The metal loading in all cases was approximately 0.4 mg cm^{-2}. At the anode side, the Pt/carbon nanotube catalyst showed significantly better performance than the Pt/Vulcan XC-72 catalyst, suggesting that carbon nanotubes may have some intrinsic role in suppressing CO poisoning [32]. However, the authors noted that this may be due to trace presence of the metal catalysts used for carbon nanotube growth. The same group also investigated the same set of catalysts and supports for the anode reaction in a direct methanol fuel cell, finding that the best performance was obtained for a PtRu catalyst supported on MWNTs [32].

Liang *et al.* reported a study of carbon nanotube anode catalyst supports that compared different techniques for PtRu nanoparticle formation [33]. They found that reduction of mixtures of H_2PtCl_6 and $RuCl_3$ in ethylene glycol yielded a much higher nucleation density of nanoparticles than reduction in aqueous solutions of

formaldehyde. This was attributed to the lower polarity of ethylene glycol, which therefore does not interfere with ion exchange reactions that deposit Pt and Ru [33]. The ethylene glycol reduction formed 2–8 nm diameter PtRu catalyst particles on MWNTs that were purchased commercially and purified before use. Anode catalysts with a loading of 0.22–0.32 mg cm^{-2} were then compared with commercial catalysts with a loading of 0.39 mg cm^{-2} in an operating hydrogen fuel cell. On a per weight basis, the MWNT-supported catalyst exhibited superior performance in the middle to high current density regime [33].

Several groups have studied the use of carbon nanotubes as anode catalyst supports in DMFCs [35–39]. Understanding of these studies is complicated by the need to separate effects associated specifically with the catalyst support from those associated with the exact catalyst composition.

5.3 Hydrogen Storage

The efforts to develop energy sources powered by molecular hydrogen, rather than by hydrocarbons, are motivated primarily by the desire to minimize the production of greenhouse gases. Carbon dioxide, which is one of the common greenhouse gases, is the inevitable product of energy sources fueled by hydrocarbons. By comparison, energy sources fueled by hydrogen would produce mainly water, dramatically reducing greenhouse gas emissions. The development of hydrogen-powered energy sources encompasses a number of technical challenges, including the development of low-cost, efficient fuel cells powered by hydrogen, in addition to low-cost, efficient methods for producing and storing hydrogen. One of the greatest challenges for applications in transportation is the lack of an infrastructure to store and distribute hydrogen. The infrastructure for storing and distributing hydrocarbons is well developed and the development of an alternative infrastructure for hydrogen is a daunting economic and technological obstacle. Hydrogen storage for vehicular applications has challenging constraints of weight and space.

Proposed hydrogen storage methods include compression, liquefaction, hydride formation and adsorption on carbon and other nanomaterials, although all currently have significant shortcomings [40]. Although hydrogen compression is the simplest method for hydrogen storage, the energy density is not high enough for most applications that are envisioned. In addition, this approach is thought to be more expensive than hydrogen liquefaction. On the other hand, hydrogen liquefaction is limited by the large energetic requirement for the liquefaction process and by the continuous loss of hydrogen due to boiling.

For systems based on hydrogen adsorption, the simplest way to compare their hydrogen storage capabilities is the weight percent of hydrogen that they are capable of adsorbing. In addition to the storage capacity, another important issue for hydrogen storage is reversibility. Practical hydrogen storage systems need to be reversible at moderate temperatures and pressures. Hence the mechanism of hydrogen storage is extremely important. Hydrogen chemisorption can likely only

be reversed at elevated temperature, whereas hydrogen physisorption is more likely to be readily reversible. The two main obstacles to commercialization are the low hydrogen storage capacity and the reversibility of the hydrogen storage process over a great many hydrogen adsorption/desorption cycles.

Two types of metal hydrides have been studied for hydrogen storage applications, metal hydrides and complex hydrides. The prototypical metal hydrides are formed from binary intermetallic compounds, A_xB_y [40]. Some examples include $LaNi_5$, TiFe, Ti_2Ni and $CeNi_3$. A is typically a rare earth or alkaline earth metal that tends to form a stable hydride, whereas B is typically a transition metal and does not form stable hydrides. The function of metal B, often Ni, is to catalyze hydrogen dissociation. The most studied metal hydrides that form from A_xB_y intermetallic compounds have relatively low hydrogen storage capacity, typically less than 3 wt.%. As a result, recent attention has turned towards lighter metals such as Mg, but to date suitable Mg hydrides have not been found.

More complex metal hydrides can be formed from hydrogen and combinations of metals from Groups I, II and II such as Li, Mg, B and Al [40]. Such materials include Mg_2FeH_6, $Al(BH_4)_3$, $NaAlH_4$ and $LiBH_4$, the last of which has the highest hydrogen storage capacity yet reported, 18 wt.%. Since it is able to store hydrogen reversibly at moderate temperature, $NaAlH_4$ has received greater attention than $LiBH_4$. One difficulty with these materials is that hydrogen desorption occurs via a multi-step mechanism where the optimum conditions for each step are different. In practice, this means either that hydrogen desorption is slow or that the full hydrogen storage capacity of these materials is not utilized. In addition, their stability over many cycle periods is inadequate, with gradual changes in composition and morphology.

5.3.1
Hydrogen Storage Using Carbon Nanomaterials

The primary motivation for the use of nanomaterials for hydrogen storage is their extremely high surface area per unit weight or unit volume. Sound fundamental reasons exist for investigating carbon nanomaterials relative to nanomaterials of other compositions. Carbon is well known for its ability to adsorb gases, so carbon materials are already widely employed as adsorbents. Carbon-based nanomaterials proposed for hydrogen storage include carbon nanotubes and graphite nanofibers. As discussed above, carbon nanotubes can be prepared either as SWNTs or MWNTs. SWNTs, which have the strong adsorption capability of carbon materials coupled with an enormous surface area per unit weight, are therefore promising as hydrogen storage materials.

Despite the widespread use as carbon as an adsorbent, the precise mechanism by which carbon nanomaterials adsorb hydrogen is not completely understood. For gases above the critical temperature, the expected adsorption mechanism is monolayer adsorption. Simple calculations based on the known surface area of different nanomaterials and the known dimensions of hydrogen molecules yield maximum hydrogen storage capacities in the range 2–4 wt.% [41]. More complex calculations are not substantially different. Such values are considerably less than the benchmark values provided by the US Department of Energy (DOE), which projects requirements

of 4.5 wt.% by 2007, 6 wt.% by 2010 and 9 wt.% by 2015 [42]. However, the existence of more complex hydrogen storage mechanisms, such as those involving defects, cannot be discounted.

The highest hydrogen storage capacities reported to date for carbon nanotubes are in the 5–10 wt.% range. However, the upper end of this range is now treated with considerable skepticism, since other investigators have had difficulty reproducing these results [43–45]. Instead, it has become generally accepted that room temperature hydrogen storage capacity is limited to less than 1 wt.%, although up to 6 wt.% hydrogen storage capacity can be attained at cryogenic temperatures [46]. Since hydrogen monolayers are generally bound by physisorption, hydrogen storage capacity typically decreases dramatically as the temperature is raised.

It should be noted that measurements of hydrogen adsorption are complicated by the very small extent of hydrogen adsorption relative to other gases, so experimental measurements are sensitive to the detailed procedures of how they are performed [45, 47, 48]. Agreement among reports of hydrogen storage capacity from different laboratories is often hampered by the lack of reliable methods for producing, purifying and quantifying carbon nanotubes. Indeed, if defects are critically involved in hydrogen storage, slight differences in preparation techniques may even result in intrinsic differences in hydrogen storage capacity [49].

One focus of current research efforts is on methods for improving the hydrogen storage capacity of carbon nanomaterials by treatments to increase its surface reactivity. Such treatments include reactive ball-milling [50–52], oxidation [53], acid treatment [47] and doping with transition metals such as Pd [54–58]. These transition metals serve a catalytic purpose of breaking the chemical bond in molecular hydrogen so that it can be stored in greater quantities on a carbon surface.

Non-carbon-based nanomaterials, such as boron nitride nanotubes, have also been studied for hydrogen storage applications [59–61]. Boron nitride nanotubes are fullerene materials with similar properties to carbon nanotubes. One advantage of boron nitride nanotubes is their greater oxidation resistance with respect to carbon nanotubes.

5.4
Solar Cells

5.4.1
Solar Energy Basics, Including Quantum Confinement

Solar power is highly desirable as a sustainable energy source due to the expected long lifespan of the Sun, on the order of 10 billion years. Solar energy has long been considered an attractive alternative to hydrocarbon fossil fuels, but its widespread adoption has been hindered by the coupled problems of low efficiency and high cost, in addition to the large area required for generation of significant power. Most commercial photovoltaic cells employ either crystalline, polycrystalline or amorphous Si [62]. Photovoltaic cells based on other materials, such as CdTe, $CuInSe_2$, $CuInGaSe_2$ and TiO_2, have comparable or higher efficiencies,

Table 5.1 Reported maximum efficiencies and other data for solar cell materials (From Ref. [62]).

Material	Efficiency (%)	Area (cm^2)	V_{oc} (V)	j_{sc} ($mA\,cm^{-2}$)
a-Si	12.7	1	0.887	19.4
$CuInSe_2$	15.4	0.408	0.515	41.2
$CuInGaSe_2$	19.2	0.470	0.689	35.7
$CuInAlSe_2$	16.9	1.032	0.621	36.0
CdTe	16.5		0.845	25.9

but none is yet cost-effective in comparison with Si photovoltaic cells [62]. The highest efficiency reported for several different solar cell materials is given in Table 5.1 [62].

Nanomaterials have been employed in several reported types of photovoltaic cells, for a variety of different purposes. Probably the classic demonstration of nanotechnology is the dependence of optical bandgap of a semiconductor nanostructure on its dimensions. When the size is comparable to the exciton Bohr radius, quantum confinement effects shift the bandgap of a semiconductor nanostructure to higher energy. This has been widely popularized by the term "quantum dot". The detailed dependence of the optical bandgap on nanostructure dimensions can be determined by solving the Schrödinger equation with the appropriate boundary conditions.

Hence the most straightforward application of nanomaterials to photovoltaic technology is to tune the optical bandgap by varying the size dimensions of a nanostructure. When optical absorption occurs within a nanoparticle, nanowire, nanotube or other nanostructure, the voltage created by exciton formation is captured in an external electrical circuit. The main focus of these efforts has been the metal chalcogenides, including CdS, ZnS, PbS and CdSe. CdTe is particularly appealing as its bandgap (1.45 eV, 855 nm) is nearly ideal for solar terrestrial photoconversion. Figure 5.4 illustrates the terrestrial solar irradiance determined by several different measurements, using detectors both normal to the Earth's surface and tilted [63]. The report of a CdS/CdTe solar cell with 15.8% efficiency in 1993 stimulated an enormous literature on this type of photovoltaic cell [64].

The blue shift of the optical bandgap with decreasing nanostructure dimension has motivated the use of nanomaterials in such solar cells. For example, losses due to optical absorption in the CdS n-type window can be minimized through the use of nanocrystalline CdS, where the optical absorption is blue shifted out of the terrestrial window for light collection [65]. This allows for use of a window material that does not absorb photons, allowing subsequent collection by the absorber material.

More generally, nanostructured absorber layers have several potential advantages over bulk absorber layers. The nanostructure dimension can be adjusted to tune the optical bandgap to match the terrestrial window [66]. The variation in optical properties of chalcogenide nanostructures has been extensively characterized [67, 68]. In addition, the presence of multiple interfaces within the absorber material may increase the effective pathlength by internal light scattering, allowing the use of much

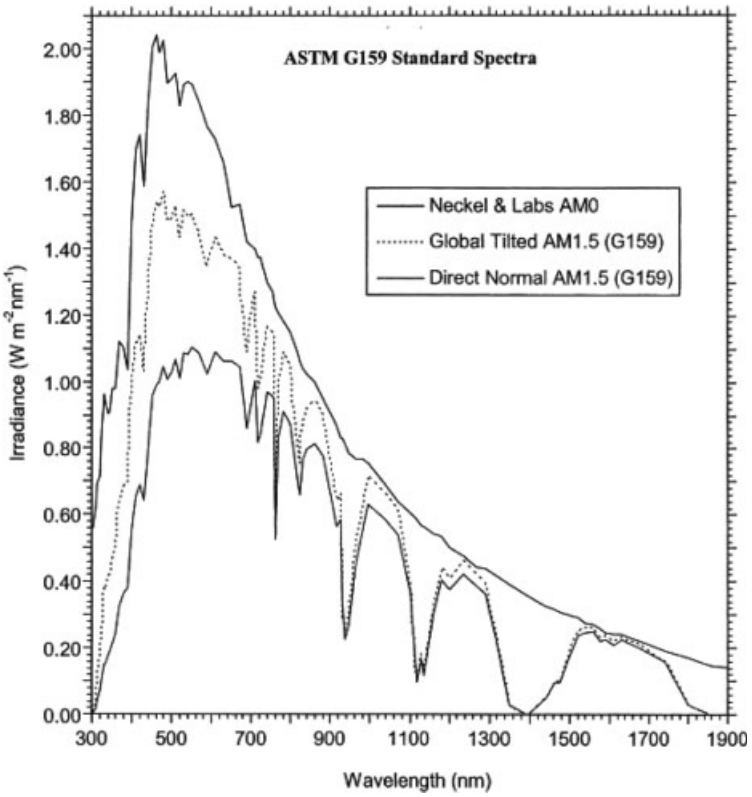

Figure 5.4 Terrestrial solar irradiance window (From Ref. [63]).

thinner absorber layers [69]. For example, the optical pathlength has been reported to increase by a factor of five in nanocrystalline TiO_2 films [70]. The competing effects of maximizing the internal surface area, which favors nanoscale particles and maximizing internal reflections, which favors microscale particles, make this a complex optimization problem [71].

5.4.2 Nanocrystalline Dye-Sensitized Solar Cells

Although TiO_2 is an effective photocatalyst for many applications, for solar cells it has the substantial drawback of an optical bandgap (3.2 eV, 387 nm) in the ultraviolet region of the spectrum, so pure TiO_2 will not absorb throughout most of the terrestrial solar irradiance window shown in Figure 5.4. The addition of a sensitizing dye, typically a transition metal complex that absorbs visible radiation, provides the necessary coverage throughout the terrestrial solar window.

The most widespread application of nanomaterials in solar cells is the use nanocrystalline TiO_2, and to a lesser extent nanocrystalline ZnO and SnO_2, as the absorber layer in DSSCs. First reported by O'Regan and Gratzel in 1991 [72],

the DSSC is an innovative, low-cost alternative to silicon-based photovoltaic cells with the absorber layer constructed from a mesoporous nanocrystalline TiO_2 film sensitized by a monolayer of dye molecules and containing an electrolyte, typically acetonitrile containing the iodide/triiodide redox couple. This can be conceptualized as two percolating continuous random networks: a network of connected TiO_2 nanoparticles and a complementary network of pores filled with organic electrolyte [73]. The dye molecules reside at the interface of these two networks. Because of the small TiO_2 nanoparticle size (~20 nm), the surface area (roughness factor) of the TiO_2 film can be more than 1000 times greater than the geometric surface area. The main obstacles to commercialization of DSSCs are their relatively low efficiency and the stability of the dye molecules during long-term usage.

The following reactions occur within a Gratzel-type DSSC:

$$TiO_2/S + h\nu \rightarrow TiO_2/S^* \tag{5.4}$$

$$TiO_2/S^* \rightarrow TiO_2/S^+ + e_{cb}^- \tag{5.5}$$

$$TiO_2/S^+ + \frac{3}{2}I^- \rightarrow TiO_2/S + \frac{1}{2}I_3^- \tag{5.6}$$

$$TiO_2/S^+ + e_{cb}^- \rightarrow TiO_2/S \tag{5.7}$$

$$\frac{1}{2}I_3^- + e_{pt}^- \rightarrow \frac{3}{2}I^- \tag{5.8}$$

$$\frac{1}{2}I_3^- + e_{cb}^- \rightarrow \frac{3}{2}I^- \tag{5.9}$$

Photon absorption by the dye monolayer (S) adsorbed at the TiO_2 surface in Reaction (5.4) creates a dye molecule in an electronically excited state (S^*). Electron transfer from this excited state to the conduction band (e_{cb}^-) of TiO_2 is shown in Reaction (5.5). The desired oxidation of I^- is shown in Reaction (5.6), while Reactions (5.7) and (5.8) represent two undesired reactions, back reaction of conduction band electrons with the dye and the reduction of I_3^- by injected electrons. An important criterion for high-efficiency operation of the DSSC is that Reaction (5.6) must occur much more quickly than Reactions (5.7) and (5.8). Reaction (5.9) describes I_3^- reduction at the counter electrode to regenerate the electron mediator, I^-. The rapidity of this reaction at the counter electrode, usually Pt, can often limit the overall cell performance, as described further below.

The main drawback of the Gratzel-type DSSC has been the low electron diffusion coefficient. Laser flash-induced transient photocurrent measurements and intensity-modulated photocurrent spectroscopy show that the electron diffusion coefficient in nanocrystalline TiO_2 films is about two orders of magnitude less than in bulk anatase TiO_2 [74–78]. More recent photocurrent transient measurements that systematically varied the average TiO_2 particle size suggest that this behavior arises from electron traps located predominantly at the TiO_2 nanoparticle surface, not within the bulk particle or at interparticle grain boundaries [79]. Ultrafast measurements using THz

spectroscopy suggest that low electron mobilities also arise from local electric field effects that are coupled to the TiO_2 morphology [80].

In analogy with the approaches described above for using carbon nanotubes as fuel cell catalyst support materials, several investigators have tried using one-dimensional TiO_2 nanostructures, such as nanotubes and nanowires, in order to obtain simultaneously both high surface area and the connectivity needed for rapid electron transfer [81]. TiO_2 nanostructures can be fabricated by a variety of different methods, including template synthesis within nanoporous membranes, hydrothermal methods and colloidal methods. Several authors have mixed TiO_2 nanowires or nanotubes with more standard TiO_2 materials, demonstrating improved energy conversion efficiency.

Yoon *et al*. reported the template synthesis of Ti nanowires and nanotubes from $TiCl_4$ within nanoporous alumina membranes [82]. Template synthesis of nanomaterials using commercially available nanoporous alumina and polycarbonate membranes has been widely employed to fabricate metal, semiconductor, ceramic and polymer nanowires and nanotubes [83]. Solar cells containing 10 wt.% of 180–250 nm TiO_2 nanowires and nanotubes with 90 wt.% Degussa P25 TiO_2 exhibited an energy conversion efficiency reported to be 42% higher than that obtained for Degussa P25 TiO_2 alone [82].

Jiu *et al*. reported the growth of TiO_2 nanowires of controlled length by a hydrothermal process in a solution containing a cetyltrimethylammonium bromide (CTAB) surfactant through addition of varying amounts of a triblock copolymer containing poly(ethylene oxide), poly(propylene oxide) and poly(ethylene oxide) [84]. The use of multiple surface-active species in such wet synthesis methods has been shown to allow for the anisotropic growth needed for nanowire formation. Surprisingly, the TiO_2 nanowire morphology survives intact following calcination at 450 °C and sintering at 550 °C, but only in the presence of the triblock copolymer. Nanowires of 20–30 nm diameter and 100–300 nm length have been produced by this method. Earlier studies from the same research group used a slightly different technique and produced TiO_2 nanotubes with diameters of 5–10 nm and lengths of 30–300 nm [85]. DSSCs with an absorber layer containing mixtures of these nanotubes and Degussa P25 TiO_2 showed superior efficiency to those containing only Degussa P25 TiO_2 [86].

Jiu *et al*. also incorporated their TiO_2 nanowires into a DSSC and compared their performance with that of Degussa P25 TiO_2 [84]. However, as these authors acknowledge, this comparison between these two materials is difficult due to their differing crystal structures, degree of crystallinity, packing orientation and porosity. For example, Degussa P25 TiO_2 contains about 80 wt.% anatase and 20 wt.% rutile phases, whereas the nanowire TiO_2 is purely in the anatase phase. Earlier studies have shown that DSSCs constructed using nanocrystalline TiO_2 in the anatase phase are more efficient that those constructed using Degussa P25 TiO_2 [87]. Despite these difficulties in comparison, the DSSC containing TiO_2 nanowires exhibited superior performance to those containing Degussa P25 TiO_2 for thick (<10 μm) absorber layers, where the advantages in terms of enhanced electron diffusion rates would be most evident.

This group has also grown TiO_2 nanowires using an "oriented attachment" method that ensures that the nanowires grow parallel to each other [88]. This process involves the use of surfactant-aided anatase crystal growth process near room temperature. This geometry is designed to maximize the rate of electron transfer in a DSSC and yielded an efficiency of 9.3%.

Several other groups have incorporated TiO_2 nanowires and/or nanotubes into DSSCs. The fabrication of TiO_2 nanowires has been demonstrated using the following sol–gel alkyl halide elimination reaction [89]:

$$TiCl_4 + Ti(OR)_4 \rightarrow 2TiO_2 + 4RCl \tag{5.10}$$

The size and the crystal phase (anatase vs. rutile) of the nanowires can be controlled to some extent by the injection rate of the titanium precursors. As the injection rate increases, the nanowire diameter decreases and the proportion of anatase phase increases. A DSSC fabricated from 81 wt.% anatase and 19 wt.% rutile TiO_2 nanowires, which is similar to the mass fraction of these phases in Degussa P25 TiO_2, exhibited a higher efficiency (3.83%) than DSSCs fabricated from purely anatase or purely rutile nanowires.

Several other examples of TiO_2 nanomaterials in DSSCs should also be noted. A DSSC has also been constructed using an absorber that contains titanate ($H_2Ti_3O_7$) nanotubes fabricated by a hydrothermal process [90]. TiO_2 nanowires have been directionally grown by electrospinning and incorporated into a DSSC with a highly viscous gel electrolyte, attaining an efficiency of 6.2% [91]. Rather than creating individual nanotubes, a Ti film can be anodized to create a continuous, oriented and highly ordered array of TiO_2 nanotubes that has been demonstrated as part of a DSSC [92].

Another intriguing example of nanomaterials in DSSCs is the fabrication of core–shell nanoparticles for use in the absorber layer. TiO_2 nanoparticles have been coated with insulating oxides or wide bandgap semiconductors. The coating is designed to prevent interfacial recombination, but must be thin enough to allow electron tunneling between the dye and TiO_2. Although this has been studied mainly with Al_2O_3 coatings [93, 94] this effect can be seen using a wide variety of oxide coatings [95, 96]. This idea has also been extended to oxide coating of ZnO nanowires [97].

5.4.3
Nanomaterials in Solar Cell Counter Electrodes

Nanomaterials are also important for other elements within a DSSC besides the absorber material. Equation (5.6) occurs at the counter electrode and is important for regenerating the electron acceptor, I^-. If the rate of I_3^- reduction is not sufficiently rapid, then this will limit the overall DSSC efficiency. Pt is typically the electrocatalytic cathode material of choice in a wide variety of electrochemical systems. However, owing to its high cost, minimizing the amount of Pt used is highly desirable. The rapidity of I_3^- reduction can be quantified by its charge transfer resistance (R_{ct}), which can be conveniently determined by electrochemical impedance spectroscopy (EIS). EIS studies of the reaction rate at the Pt counter electrode indicate that a 2–3 nm

Pt film is sufficient to obtain both rapid I_3^- reduction and adequate electrical conductivity [98, 99]. In order to reduce costs but maintain electrocatalytic activity, Pt nanoparticles dispersed within an indium tin oxide (ITO) film have also been proposed for use as the counter electrode in DSSCs [100].

5.5
Lithium Ion Battery Anode Materials

5.5.1
Lithium Ion Batteries

Lithium ion batteries have now become ubiquitous due to their high voltage (~3.6 V), high energy density (125 W h kg^{-1}) and long life cycle (>1000 cycles) relative to other battery types, such as Ni–Cd, Ag–Zn, Ni–hydride and lead acid batteries. Applications are widespread in portable consumer electronics, including notebook computers, cellular telephones, MP3 players and camcorders. Like other batteries, Li ion batteries are composed of a cathode and an anode, separated by an electrolyte. This type of battery has been called the "swing" battery because Li ions are exchanged alternately between the cathode and anode during battery charging and discharging.

The cathode material, which provides a source of Li ions during battery charging, is typically either layered $LiMO_2$, where M can be Co, Ni, Al or Mn; Li manganese oxide spinels ($LiMn_2O_4$); or other Li salts. Although $LiCoO_2$ is widely used as cathode material due to its long cycle life and reasonable energy density, the high cost and high toxicity of Co have limited its use to relatively small batteries. Efforts are under way to replace Co either partly or completely with Ni or Mn, which are less costly and less toxic. The prototypical anode material is carbon/graphite, which accepts Li ions during battery charging by intercalation between adjacent graphitic planes. Li metal was used as the anode for early Li ion batteries, but this caused safety problems due to the high activity of metallic Li. During battery discharge, the direction of Li ion migration is reversed. The electrochemical reactions at the anode and cathode are shown below for the prototypical cathode and anode materials during battery charging:

$$LiCoO_2 \rightarrow Li_{1-x}CoO_2 + xLi^+ + xe^- \tag{5.11}$$

$$6C + xLi^+ + xe^- \rightarrow Li_xC_6 \tag{5.12}$$

The intervening electrolyte material is normally a polymer material, most commonly poly(ethylene oxide) (PEO). Significant research efforts have been undertaken to find new materials for the cathode, anode and electrolyte to improve the life cycle and increase the energy density of the Li ion battery. Many of these efforts have involved the development of nanomaterials, in large part due to their higher internal surface area [101].

Nanomaterials that have been proposed as an anode material in Li ion batteries are mainly metal nanoparticles, carbon nanotubes and nanocomposites that combine

these two materials. The benchmark for comparison is intercalation of Li in graphite, where the theoretical limit is determined by the compound formed, LiC_6, which is equivalent to a storage capacity of 372 mA h g^{-1}. High Li capacity has been obtained for numerous alternative elements, including Ag, Sn, Al, Si, Sb, Bi and Pb [102]. One of the most widely studied anode materials is Sn, galvanized by researchers at Fuji Photo Film, who reported a high Li storage capacity for Sn composite electrodes [103]. The recently announced Sony Nexelion lithium ion battery is a composite containing several materials, including Sn and C. Sn has a maximum theoretical Li capacity arising from the stoichiometry $Li_{22}Sn_5$, corresponding to a storage capacity of 994 mA h g^{-1}.

The other widely studied lithium storage material is Si, which has a higher theoretical lithium storage capacity of 4200 mA h g^{-1}, arising from a stoichiometry of $Li_{22}Si_5$, than other widely studied materials. Applications of Si for lithium ion storage, which will be discussed later, are hindered by the even larger volume change upon lithiation (>300%) and by the poor electrical conductivity of Si. In addition to Sn and Si, the other alternative Li storage materials that have been studied include Sb and Cu_6Sn_5. The Li storage capacity of Sb has been reported to be 660 mA h g^{-1}, arising from the stoichiometry Li_3Sb. Another metal that has been widely investigated is Cu_6Sn_5, which first forms $Li_2Cu_6Sn_5$, which decomposes upon further lithium addition and forms $Li_{22}Sn_5$ surrounded by a Cu matrix. The Li storage capacity of Cu_6Sn_5 is about 350 mA h g^{-1}.

5.5.2
Nanomaterials for Lithium Ion Storage: Sn Nanoparticles

Unfortunately, the large volume change associated with Li compound formation during repeated cycling of these alternative lithium storage materials gradually causes a loss of electrical contact and mechanical degradation, with the anode material cracking repeatedly and eventually becoming pulverized. Graphite materials, on the other hand, show little volume change during Li cycling. In order to accommodate the volume change associated with Li storage, Li battery anodes containing micro- and nanocrystalline metals have been tested and show a greater ability to tolerate mechanical strain [102]. However, although the performance of anodes constructed from nanoparticles is greatly improved, they still suffer gradual mechanical degradation and a new problem is encountered, nanoparticle agglomeration [104].

In an elegant quantitative study, Noh *et al*. compared the capacity retention for Sn nanoparticles of various diameters, as shown in Table 5.2 [105]. They considered these results to be somewhat surprising, given that the surface area involved in the formation of the semiconductor electrolyte interface (SEI) increases with decreasing particle size, as does the extent of irreversible Li consumption during SEI formation. They reported that the initial capacity of Li anode constructed from 10 nm diameter Sn nanoparticles was as high as 1000 mA h g^{-1}, with little or no capacity fade.

Several ingenious strategies have been attempted to circumvent the problem of volume cycling during repeated Li ion battery charging/discharging. Anodes have

Table 5.2 Capacity retention for Sn nanoparticles of different diameters after 50 cycles of 0.5 C (From Ref. [105]).

Diameter (nm)	Capacity retention (%)

200	68
20	87
10	94

been constructed that are nanocomposites of active and inactive materials, with the inactive material serving as a mechanical buffer to accommodate the volume change [106–108]. For example, composites between Sn_2Fe (active) and $SnFe_3C$ (inactive) prepared by high energy ball-milling have been reported to have reversible Li capacities twice that of graphite materials [106, 107]. A serious disadvantage of this technique is that the energy density per unit mass of the anode material is reduced, sometimes dramatically, by the presence of the inactive component.

To circumvent this problem, several groups have instead created composites of Li-active nanoparticles (usually Sn) with a buffer material that is also active, usually carbon in graphitic form. Since graphite is fairly soft, it is expected to form a mechanical buffer during repeated Li insertion/removal [109–111]. One complication of this approach is that Sn nanoparticles are relatively difficult to fabricate. As is well known in colloid chemistry, formation of metal and metal oxide nanostructures requires careful control of reaction conditions, typically requiring the use of surfactants, stabilizers and/or capping agents in order both to control nanostructure growth and simultaneously to prevent aggregation [112].

Wang *et al*. have reported the fabrication of Sn nanoparticles of 2–5 and 7–13 nm diameter by reduction of $SnCl_4$ with $NaBH_4$ [110]. The Sn nanoparticles were then dispersed in graphite to form a composite Li anode containing 10.3 wt.% Sn. One of the challenges of such techniques is obtaining a high fraction of Sn in the composite anode. During both the preparation and dispersion steps, the Sn nanoparticles were protected from agglomeration by the presence of 1,10-phenanthroline, which forms a coordination compound with Sn [110]. This anode exhibited a 415 mA h g^{-1} Li storage capacity and was 91.3% reversible after 60 charge/discharge cycles.

Caballero *et al*. reported the formation of Sn nanoparticles by reduction of $SnCl_4$ by KBH_4 in the presence of cellulose fibers [111]. The Sn nanoparticles apparently nucleate and grow only on the surface of the cellulose fibers, preventing agglomeration. This cellulose–Sn nanocomposite exhibits a storage capacity of 600 mA h g^{-1} as an Li anode and was reported to exhibit reversible charge/discharge cycling, although specific numbers for capacity retention were not provided [111].

A particularly ingenious method for forming a nanocomposite anode from an Li active metal (usually Sn) and an active support (usually carbon) is to encapsulate the metal nanoparticles within carbon spheres [113–117]. This protects the metal nanoparticles both from agglomeration and from mechanical degradation arising

from volume expansion. So far, this technique has been demonstrated only for particles larger than the nanoscale (1–100 nm), but could in principle be extended to smaller particles. Unless the carbon coating can be made graphitic, the Li storage capacity will not be very high. In some cases, the addition of a conductive material such as Cu silicide within carbon coating Si particles may improve electrical contact during repeated lithium charge/discharge cycles [113].

Some of the studies that involve active metals within carbon shells provide some interesting, direct comparisons between cycling stability of these materials, with and without their carbon shells [114, 117]. Jung *et al.* created carbon encapsulation about commercial Sn particles by hydrophobization in 1-octanethiol, dispersion in a resorcinol–formaldehyde microemulsion, polymerization and carbonization of the coating by high-temperature annealing [114]. Without first making the Sn particle surface hydrophobic, the Sn particle surface will not be wetted during this synthesis. The performance of this material (CSP) as an Li anode was then compared with two control materials, Sn nanoparticles that are not encapsulated (SN) and a random mixture of spherical carbon powder with Sn particles (MIX) with the same nominal composition, 20 wt.% Sn. The results for 40 charge/discharge cycles are shown in Figure 5.5 [114]. Clearly, the cyclability of the carbon-encapsulated Sn particles is far greater than either control anode, demonstrating the stabilizing effect of the carbon encapsulation.

Another study used a similar fabrication technique to encapsulate Sn_2Sb particles with carbon through polymerization of resorcinol–formaldehyde microemulsion followed by high-temperature annealing [117]. The Li anode performance of the carbon microsphere (CM)-encapsulated Sn_2Sb particles was compared with that of Sn_2Sb powder, as shown in Figure 5.6. While the initial Li storage capacity of the Sn_2Sb powder is 689 mA h g^{-1}, only 20.3% of this capacity is retained after 60 charge/discharge cycles [117]. On the other hand, the CM-encapsulated Sn_2Sb particles retained 87.7% of their original storage capacity of 649 mA h g^{-1} after 60 charge/discharge cycles [117].

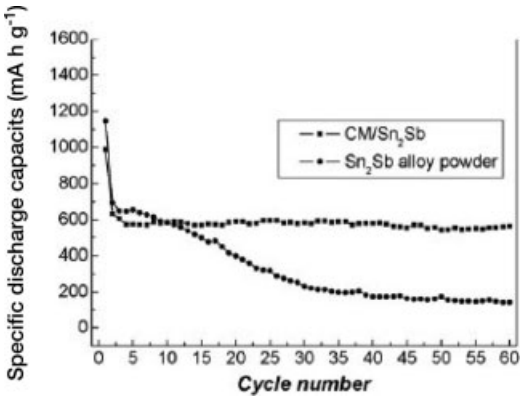

Figure 5.6 Li discharge capacity with cycle time for Sn_2Sb powder, with and without a carbon microsphere (CM) coating. (From Ref. [117]).

5.5.3
Nanomaterials for Lithium Ion Storage: Si Nanocomposites

Most of the examples given above describe ingenious techniques to improve the cycle stability of Sn-based lithium storage materials through the use of nanoparticles and nanocomposites. After Sn, the most widely studied alternative lithium storage material is Si. Si has an even higher theoretical lithium storage capacity (4200 mA h g^{-1}) than does Sn (994 mA h g^{-}), although the low conductivity of Si requires the use of some type of conductive filler. Not surprisingly, the most widely studied composite Si anode materials are Si–carbon composites [118–122]. One difficulty with Si–C composite anodes is that high-temperature processing may form the compound SiC, which is inactive for lithium storage [118].

Holzapfel *et al.* deposited nanocomposite Si–graphite films by chemical vapor deposition (CVD) of Si from SiH_4 on a graphitized fine particle carbon film, Timrex KS6 [121]. This active material was then mixed with one of two different binders, dissolved in a petroleum ether solution and dried under vacuum. The resulting electrode film contains about 7 wt.% Si in the form of Si nanoparticles ranging from 10 to 20 nm in diameter [121]. The Li storage capacity of this Si–graphite electrode declined gradually from 2500 to 1900 mA h g^{-1} during 100 charge/discharge cycles.

Wang *et al.* formed an Si–C nanocomposite by high-energy ball-milling of commercially available powders, 80 nm Si nanoparticles and 10 μm spherical mesocarbon microbeads (MCMB) [120]. MCMB represent an industry standard for lithium storage and exhibit capacities ranging from 300 to 340 mA h g^{-1} with excellent stability during cycling. After 20 h of ball-milling, the spherical MCMB lose their original structural integrity and the Si nanoparticles become dispersed within the MCMB. These composite anodes were tested and compared with Li anodes constructed from 80 nm Si powder, 10 μm MCMB and composite anodes containing much larger Si particles (20 μm). The best performance was obtained for

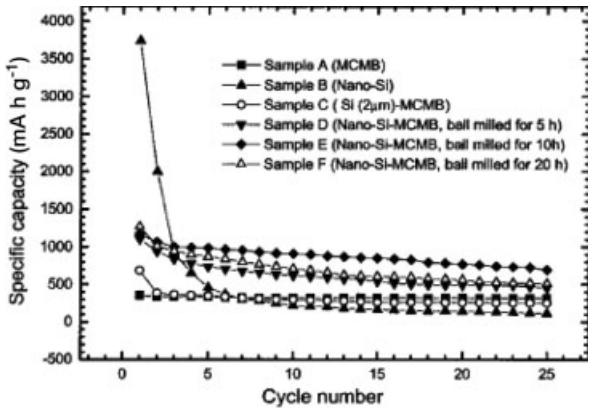

Figure 5.7 Li discharge capacity with cycle time for nanocrystalline Si, MCMB and ball-milled mixtures of the two. (From Ref. [120]).

composite anodes constructed from 20 wt.% Si and 80 wt.% MCMB, which showed good reversibility over 25 charge/discharge cycles with a capacity of 1066 mA h g^{-1}, as illustrated in Figure 5.7 [120].

5.5.4
Nanomaterials for Lithium Ion Storage: Carbon Nanotubes and Carbon Nanotube-Based Composites

MWNTs have been reported to exhibit a reversible Li capacity of 400–1000 mA h g^{-1} [123, 124], whereas SWNTs have been reported to exhibit a reversible Li capacity in the range of 450–600 mA h g^{-1}, which can be increased to 1000 mA h g^{-1} by ball-milling to increase the surface area [125]. This capacity is believed to be associated with defect sites within the nanotubes, sites between adjacent grapheme sheets within MWNTs and sites between adjacent SWNTs. Even these early reports noted significant shortcomings that would likely prevent commercialization, including an extremely high irreversible capacity, a gradual decline in reversible capacity and a strong dependence of Li capacity on carbon nanotube structure and preparation technique. Subsequent investigations concluded that carbon nanotubes alone were unlikely to provide an adequate Li anode material, but were fairly promising for the development of supercapacitors [126, 127].

Despite diminishing interest in Li anode materials constructed solely from carbon nanotubes, interest remains in the use of carbon nanotubes within nanocomposite Li anode materials. Several research groups have studied Li ion storage in nanocomposites composed of mixtures of carbon nanotubes and Sn, Sb or Ni nanoparticles [128–134]. These nanocomposite materials generally exhibit extremely high initial Li insertion capacity, which then gradually declines.

Kumar *et al*. reported a method for creating Sn–carbon nanotube nanocomposites that involves *in situ* formation of Sn nanoparticles within the carbon nanotubes [130]. Carbon nanotubes were grown by chemical vapor deposition from acetylene using a

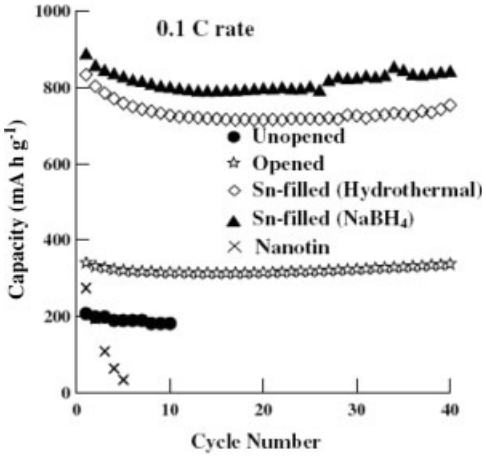

Figure 5.8 Li discharge capacity with cycle time for Sn–carbon nanotube composite with Sn reduced by two different methods. (From Ref. [130]).

ferrocene catalyst. Following removal of catalyst and amorphous carbon, the carbon nanotube ends were oxidatively opened using concentrated HNO_3. Aqueous $SnCl_2$ was introduced into the carbon nanotubes by capillary action, then reduced by either hydrothermal treatment or $NaBH_4$. The Li insertion capacity of the Sn nanoparticle–carbon nanotube composite material is shown in Figure 5.8, which illustrates that an approximately stable Li capacity on the order of 800 mA h g^{-1} is attained after 10 cycles [130].

Nanocomposites fabricated by ball-milling of carbon nanotubes with Si have also been prepared and tested for their Li insertion capacity [135, 136]. High and stable reversible Li capacity has not yet been obtained by such techniques.

5.5.5
Lithium Ion Storage: Further Considerations

An often overlooked aspect of lithium ion battery anodes is the inherent difference in electrocatalytic behavior between graphite and active metals [137]. Graphite surfaces exhibit well-known differences between the electrochemistry of basal planes and edge surfaces, whereas the surfaces of active metals appear to be more electrochemically homogeneous. The solid electrolyte interface (SEI) on basal planes of graphite is known to be relatively thin and contain many organic decomposition products, while the edge sites exhibit a thicker SEI that contains mainly inorganic species [137]. The mechanism of SEI formation is also found to differ in ethylene carbonate and propylene carbonate electrolytes, which are the two most common electrolytes in lithium ion batteries.

The studies discussed here report many impressive results for lithium battery anodes constructed from composite materials containing a variety of identifiable nanoparticle and nanotube ingredients. However, Dahn's group suggested that an

alternative approach, deposition of nearly homogeneous amorphous samples of the same materials, may provide a superior approach to obtaining the maximum lithium storage capacity [138–140]. Observations of large 10–20 μm $Si_{0.64}Sn_{0.36}$ particles suggest that they move intact over a much longer length scale during volume changes associated with lithium cycling then previously believed [140]. This supports the authors' assertion that the problem with degradation observed in metal nanoparticle lithium anodes arises not from the inability of the particles to absorb the volume change, but from the inability of their binder to absorb the volume change. In support of this argument, the cycling stability of lithium anodes containing $Si_{0.64}Sn_{0.36}$ particles was shown to be greatly improved by the use of an elastomeric binder, which provides a mechanical buffer for volume changes during charge/discharge cycling [138].

Dahn's group has also produced amorphous $Si_{1-x}Sn_x$ films with extremely high lithium storage capacity, more than 3500 mA h g^{-1}, with only 1–2% capacity fade per cycle [139]. These films have been produced by magnetron sputtering and investigated over a wide range of $Si_{1-x}Sn_x$ compositions. Amorphous films are produced for compositions with $x < 0.45$. The failure mode of such anode materials is argued to be qualitatively different than that observed for composite anodes containing metal nanoparticles [139]. Since the volume change occurs uniformly across the anode material, internal stresses at interfacial boundaries do not occur. Instead, the entire anode homogeneously expands and contracts during lithium charging and discharging. The most common failure mode is then reported to arise from an eventual loss of electrical contact [139]. One possible shortcoming of the use of amorphous thin films is that in some cases, a thermodynamic driving force may exist to form crystalline structures.

6
An Industrial Ecology Perspective

Shannon M. Lloyd, Deanna N. Lekas, and Ketra A. Schmitt

6.1
Introduction

6.1.1
Industrial Ecology

Industrial ecology (IE) is a framework for analyzing the impacts and interactions of industrial, social and ecological systems. White [1] defined IE as 'the study of the flows of materials and energy in industrial and consumer activities, of the effects of these flows on the environment and of the influences of economic, political, regulatory and social factors on the flow, use and transformation of resources'.

IE as a field is fairly young. The intellectual underpinnings of IE can be found in systems analysis research conducted by Forrester [2], research on the flows of materials in economies by Ayres and Kneese [3] and the use of systems analysis to evaluate environmental degradation trends [4, 5]. Two major developments in 1989 are generally cited as founding IE as a discipline. First, Ayres [6] developed the concept of industrial metabolism, which compares processes for converting materials, energy and labor into finished products and waste to living organisms. Second, Frosch and Gallopoulos [7] published 'Strategies for Manufacturing', in which they developed the biological analogy for industrial systems [8].

The primary objectives of IE are to understand how industrial and economic systems behave and interact with ecological and social systems, to transition from open systems to closed-loop systems where waste from one industry can be used an input for another industry and to develop industrial and regulatory strategies that function effectively with natural systems – allowing resources to be replenished and avoiding damage to biological and natural systems. The field of IE encompasses several related areas of research, practice and tools. The following list was identified by the International Society for Industrial Ecology [9].

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

- material and energy flow studies ('industrial metabolism')
- dematerialization and decarbonization
- technological change and the environment
- life-cycle planning, design and assessment
- design for the environment ('eco-design')
- extended producer responsibility ('product stewardship')
- eco-industrial parks ('industrial symbiosis')
- product-oriented environmental policy
- eco-efficiency.

The conceptual framework provided by IE and the tools listed above can be used retrospectively to evaluate the impacts of current industrial processes, consumer activities and government regulations. However, when retrospective studies identify specific changes for reducing negative ecological impact, it is often difficult to make changes to existing products or practices. For example, decisions made during product development determine what a product will be made of, how it will be produced, where it will be produced, how it will be used and how it will be disposed. Consequently, most of the costs and material, energy and environmental loadings that will be experienced during a product's life cycle are likely to be committed during product development [10–12]. Actual costs and environmental impact are not realized until later in the product life cycle. Changing a product to reduce its environmental impact after the product has been developed can cost orders of magnitude more than making the change during product development [11]. If infrastructures have been built around a commercialized product, it may be difficult to make any changes at all.

Rather than wait until a product is developed and commercialized, IE concepts and tools can be applied prospectively to provide a forward-looking analysis that allows the design and manufacture of products in a manner that prevents or reduces negative environmental impacts and interactions in nature. For example, life cycle engineering (LCE), design for the environment (Df E) and green design approaches are used during product development to estimate the environmental impacts of different product designs and support decision-making aimed at reducing the environmental impact of products [12–14].

6.1.2 Applying Industrial Ecology to Nanotechnology

Control of properties at the nanoscale offers opportunities to use materials and energy more efficiently and reduce waste and pollution. As a result, nanotechnology has the potential to provide more appealing products while also improving environmental performance and sustainability. However, a technological push towards greater investment in nanotechnology without a commensurate consideration of its potential impacts on human health and the environment could lead to new (and sometimes unforeseen) impacts or to cases where the nanotechnology substitute is inferior to the product or process replaced when evaluated over its full life cycle.

Nanotechnology offers a prime opportunity for industrial ecologists to assess an emerging technology in the nascent stages of product development. A holistic industrial ecology perspective can be used to provide a complete picture of the resource requirements and potential human health and environmental impacts associated with the full life cycle of nanotechnology-based goods and services and should reveal products and applications where a precautionary approach may be needed. In this chapter, we describe several IE concepts: life cycle assessment (LCA), material flow analysis (MFA), substance flow analysis (SFA) and corporate social responsibility – and explore their implications and application to nanotechnology.

6.2
Life Cycle Assessment

6.2.1
Background on Life Cycle Assessment

The life cycle stages associated with a product are shown in Figure 6.1. Materials, energy and labor are required to extract, process and transport raw materials and to manufacture, transport, use, dispose of, reuse and recycle products. In addition to consuming resources, the transformation of materials and energy into products results in environmental discharges and generates waste. Evaluating the total

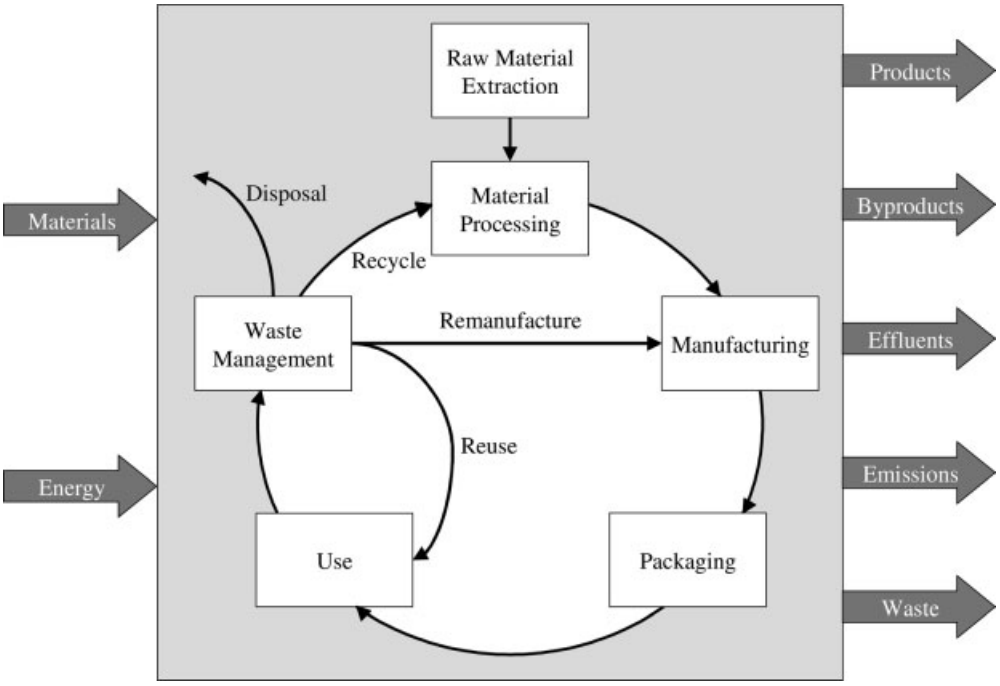

Figure 6.1 Product life cycle stages.

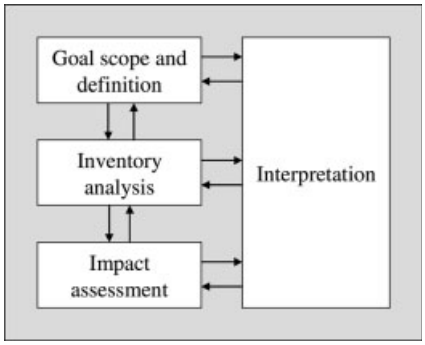

Figure 6.2 ISO 14040 life cycle assessment framework.

environmental impacts of a product requires analysis of material usage, energy usage and environmental discharges associated with each life cycle stage. This makes it possible to identify the most important environmental implications and recommend changes to design specifications, industrial processes or use activities to reduce the overall environmental impact of a product. For example, Lave *et al.* [15] found that mining and smelting lead and making and recycling a battery for early battery-powered vehicles would result in 4–60 times as much lead being discharged into the environment per vehicle mile as a comparable car using leaded gasoline. This insight arose from considering the product's entire life cycle instead of narrowly focusing on the vehicle's zero emissions during vehicle use.

LCA is a systematic, analytical process for assessing the inputs and outputs associated with each life cycle stage for a given product. The International Organization for Standardization (ISO) LCA standards describe the principles and framework for conducting an LCA [16, 17]. These stages are illustrated in Figure 6.2. The goal and scope definition phase of an LCA specifies the reason for conducting the study and identifies system boundaries, data requirements and study limitations. The life cycle inventory (LCI) analysis phase consists of collecting, validating and aggregating input and output data to quantify material use, energy use, environmental discharges and waste associated with each life cycle stage. The life cycle impact assessment (LCIA) phase consists of translating LCI results in potential environmental effects using impact categories, category indicators, characterization models, equivalency factors and weighting values. The interpretation phase occurs iteratively with other LCA phases to assess whether results are in line with defined goals and scope, provide an unbiased summary of the results, define significant impacts and recommend methods for reducing material use, energy use and environmental burdens.

6.2.2
Life Cycle Implications for Nanotechnology

In an early report on the societal implications of nanoscience and nanotechnology, Lave [18] warned that every technology has undesirable consequences and called

for a life cycle perspective in assessing the effects of nanotechnology on environmental quality and sustainability. More recently, reports published by the US National Science and Technology Council [19], the European Commission [20] and the UK Royal Society and Royal Academy of Engineering [21] recommended the use of LCA to evaluate nanotechnology products. In particular, the Royal Society and Royal Academy of Engineering report recommended that a series of LCAs be undertaken for applications arising from existing and expected developments in nanotechnologies, to ensure that the savings in resource consumption during the use of the product are not offset by increased consumption during manufacture and disposal.

Numerous projections of nanotechnology-based products and processes assert that they will use materials and energy more efficiently and reduce waste and pollution. For example, one projection estimates that nanoscale lighting technologies could reduce total global energy consumption by 10%, save $100 billion annually and reduce carbon emissions by 200 million tons per year [22]. Another projection estimates that using lightweight nanocomposites in automotive parts could save 11.5 billion liters of gasoline and reduce carbon dioxide emissions by 5 billion kilograms over the life of one year's fleet of vehicles [23].

These examples focus on the use stage of the product life cycle. In particular, environmental and resource savings are expected from improving use-phase lighting and vehicle efficiency through nanotechnology. However, a complete assessment must include an analysis of material usage, energy usage and environmental discharges associated with the full life cycle of commercialized nanotechnology products and processes. This includes extraction of raw materials, production, use and end-of-life. Table 6.1 lists several possible life cycle benefits and disadvantages of nanotechnology products. The assertions provided in Table 6.1 are generalizations, which will not likely apply to every nanotechnology-based product. Instead, LCA can be used to evaluate the net environmental impact of a specific product.

6.2.3
Life Cycle Studies Conducted to Date

To date, LCA has been used only on a limited basis to assess the potential life cycle impacts of nanotechnology products. Table 6.2 provides a summary of LCAs of nanotechnology-based products conducted to date. Additional studies have been identified by Lekas [24]. For the most part, these studies focused on the life cycle implications associated with reducing the mass of materials incorporated into products and use-phase energy consumption. Evaluation of the impacts associated with processing nanomaterials, manufacturing and retiring nanotechnology products and releasing engineered nanoparticles into the environment are limited by lack of data on producing nanomaterials, recovery of materials from nanotechnology products, fate and transport of engineered nanoparticles and risks from ecological and human exposure to the numerous types of engineered nanoparticles.

There are currently insufficient life cycle inventory data for nanoscale manufacturing processes. LCA studies of nanotechnology-based products conducted to date have relied on surrogate data for these processes. However, recent work has focused on quantifying

Table 6.1 Potential life cycle benefits and issues of nanotechnology.

	Implication	Environmental impact	Life cycle stage(s)
Potential benefits	Improved ability to detect and eliminate pollution	Improved air, water and soil quality	All
	Improved pollution control technology	Improved air, water and soil quality	All
	High-precision manufacturing	Reduced waste	Manufacturing
	Design and control chemistry	Reduced reliance on toxic and scarce materials	Materials processing, manufacturing
	More efficient processes for materials synthesis	Lower energy usage	Materials processing
	More efficient energy production and storage	Lower energy usage	All
Potential risks	Development and release of toxic engineered nanoparticles	Negative impact on human and ecosystem health	All
	Top-down methods with high waste-to-product ratios	Increase in materials required and waste during manufacturing	Materials processing, manufacturing
	High energy requirements for synthesizing nanomaterials	Increased energy usage	Materials processing
	Self-assembly reactions using toxic substances	Increase in toxic releases	Materials processing
	Complex issues with material recovery	Lower recycling rates, increased energy usage for recycling	End-of-life

the inputs and outputs associated with producing nanomaterials. For example, Zhang *et al.* [25] qualitatively examined the energy requirements for several important nanoscale manufacturing technologies. Preliminary findings indicated that bottom-up manufacturing processes are more energy intensive than top-down processes. With bottom-up approaches, nanoscale structures with fundamentally new molecular organization are built by precisely locating individual atoms and molecules where they are needed. With top-down approaches, nanoscale structures are made by reducing the dimensions of a larger structure using machining and etching techniques.

Khanna and Bakshi [26] conducted a cradle-to-gate LCA to evaluate two nanoparticles: nanoclay synthesis from montmorillonite clay and carbon nanofibers via catalytic pyrolysis of hydrocarbons on a metallic catalyst. Rather than re-lying on surrogate life cycle inventory data for nanoscale manufacturing technologies, the inputs and outputs

Table 6.2 Summary of comparative life cycle assessments.

Reference	Application	Conventional	Nanotechnology	Potential impact with nanotechnology
Lloyd and Lave [54]	Automotive body panels	Steel and aluminum	Nanoclay-based nanocomposite	Lighter automobiles, use-phase fuel savings and CO_2 emissions reduction. Perhaps not better than aluminum
Europa [55]	Coatings for magnesium alloys	Chromium-based coatings	Nano-coatings	Unknown
Beaver [56]	Inorganic sunscreens	Bulk titania	Nano-sized titania	Unknown
	Membrane	Sol–gel	Alumoxane nanoparticles	Unknown
Steinfeldt *et al.* [57]	Aluminum coating	Water, solvent and powder varnish	Sol–gel nano-varnish	Less thick coating layer, lower VOC and greenhouse gas emissions during varnish production and use
	Styrene synthesis	Iron oxide catalytic converter	Nanotube-based catalytic converter	Energy savings during synthesis and reduced heavy metals emissions. Risks of carbon nanotubes unknown
	Displays	CRT, LCD and plasma	OLED and CNT	Lower production input requirements, increased use-phase energy efficiency
	Lighting	Conventional and energy-saving bulbs	LEDs	Current LED technology less efficient than energy-saving bulbs
Lloyd *et al.* [58]	Automotive catalysts	Conventional fabrication	Nanofabrication	Reduced PGM loading levels, decreased energy consumption and lower emissions
Fluharty [59]	Copying/printing	Conventional pulverization technique	Emulsion aggregation	Reduced toner usage, emissions and waste and energy use. Increased liquid waste
Jolliet *et al.* [29]	Electronics, computing	Not specified	Not specified	Improved use-phase performance, dematerialization, higher electricity consumption during manufacturing
	Medical applications	Not specified	Not specified	Dominated by use-phase risks and benefits

associated with producing nanomaterials should be quantified and incorporated into future LCAs of nanotechnology-based products.

Efforts have also been initiated to develop a fundamental understanding of the behavior of engineered nanoparticles in natural systems and their influence on biological systems [27, 28]. This understanding should eventually improve the ability to evaluate the fate and transport of nanoparticles and their effects on ecological and human health. While current LCAs of nanotechnology-based products are not able to quantify the potential impacts of nanoparticle releases, future LCAs will incorporate findings from studies such as these to assess the potential impact of ecological and human exposure to nanoparticles during a product's life cycle.

From a life cycle perspective, the use of nanotechnology-based products will not necessarily result in environmental benefits. LCAs conducted to date indicate high potential savings from reducing use-phase energy consumption or in-product material usage and a potential increase in environmental impact from energy-intensive bottom-up nanomanufacturing processes. However, these generalizations are not the case for all nanotechnology-based products. In addition, very little is known about the environmental implications of other life cycle stages, such as the disposal of nanotechnology-based products.

Other efforts focus on developing tools and approaches for supporting LCA and engineering of nanotechnology products. Jolliet *et al.* [29] developed a matrix for identifying the additional risks and benefits of a nano-product's life cycle. DuPont and Environmental Defense have developed a framework to identify and evaluate key factors for the responsible development, production, use and disposal of nanomaterials. One of the steps associated with this framework is to profile the life cycle of the nanotechnology [30]. Using life cycle approaches to evaluate the life cycle environmental implications of alternative courses of action during nanotechnology research and development (R&D) would improve the ability to identify the potential hazards of nanotechnology, evaluate tradeoffs, establish regulatory mechanisms, optimize products for all aspects of life cycle performance and make more strategic R&D choices.

6.3 Substance Flow Analysis

6.3.1 Background on Substance Flow Analysis

While LCA helps us understand the benefits and costs of nanotechnology-based products at different life cycle stages as compared with conventional products, other tools can help us improve understanding better nanomaterials themselves and their implications at different life stages. Material flow analysis (MFA) and substance flow analysis (SFA) are used to evaluate the flows and accumulation of resources within an economy, sector or geographic region. MFA evaluates bulk flows of materials and SFA tracks flows of specific substances. SFA offers a framework for better understanding the amount, spatial location and flow of specific materials throughout the economy.

SFA evaluates the flow of specific materials from cradle to grave, quantifying the input of a substance during production, end-use applications and end-of-life. The context used for such an analysis may vary from the specific (e.g., facility level) to the broad (e.g., world scope). Udo de Haes *et al.* [31] refer to SFA as a tool for analyzing the societal metabolism of substances, whereby materials are exchanged between the anthroposphere with the environment. SFA can be used to identify potential environmental problems by quantifying the flows and accumulation of a specific substance in different environmental systems.

6.3.2
Substance Flow Analysis Implications for Nanotechnology

Faced with many unknowns about nanomaterials and their penetration into our everyday lives, SFA provides an approach for investigating the quantity and location of specific nanomaterials in the economy (e.g., the quantity of carbon nanotubes that are produced and exist in Japan versus the USA). It is less useful to compare quantities of nanomaterials in general because the properties, effectiveness and hazard potential differ by nanomaterial.

Consideration of quantity may also be useful for characterizing the dematerialization or waste reduction that may result when nanomaterials replace conventional or larger materials. For instance, a back-of-the-envelope MFA calculation on lead in cathode-ray tube (CRT) monitors revealed that disposing of one CRT monitor sends as much as 0.45 kg of lead to a landfill; switching to nanotechnology-based substitutes such as flat panel displays with organic light-emitting diodes will reduce this type of lead waste in the future [32, 33]. By finding out where nanomaterials are produced and what they are used for, we can better understand where they will ultimately end up and who will be exposed to nanomaterials during the production, distribution or use of products containing these substances.

SFA can be an appropriate tool when the material of interest is linked to a particular impact and thus warrants a more focused analysis on the stocks and flows and concentrations in the environment [34]. Additionally, by identifying large accumulations of nanomaterials, SFA may also highlight unexpected impact areas.

6.3.3
Summary of Substance Flow Analysis Work Conducted to Date

Few SFAs have been conducted on nanomaterials to date. One of the authors performed a preliminary SFA on carbon nanotubes [35]. Carbon nanotubes were chosen because of the growing interest in, manufacture, and use of these materials combined with increased concerns about their potential risks. For this analysis, carbon nanotube production and use information was gathered from the literature (both journals and news sources) and nanotube company Web sites. Information on nanotube production, raw material inputs and nanotube destination was requested from nanotube producers identified in a *Small Times Magazine* survey [36] and other producers identified during initial research.

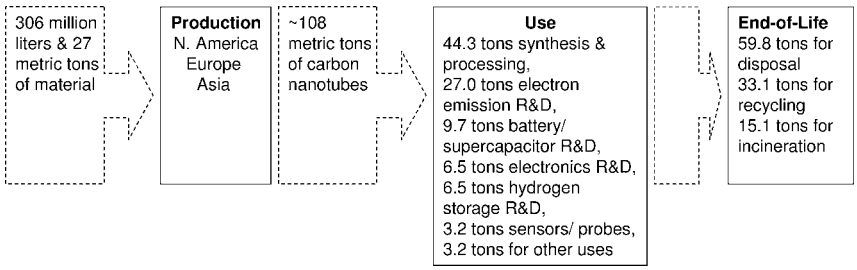

Figure 6.3 Approximate substance flow diagram for carbon nanotubes (2004).

Since nanomaterials are relatively new and information on their production and use is often proprietary, this SFA required estimation and assumptions to characterize production, use and end-of-life flows of carbon nanotubes based on available information. Since the most comprehensive data were available on production, the initial analysis focused on this life cycle stage. Information provided by one firm was used to approximate the inputs and outputs from carbon nanotube growth and then as a basis for characterizing carbon nanotubes at other life stages. The dissipation of carbon nanotubes into various end uses was estimated using carbon nanotube patent filings for eight broad application categories. Sales data or product-specific projections may also provide ways to approximate nanomaterial penetration into end uses. End-of-life outcomes for nanotubes was modeled using surrogate data from existing waste management scenarios published by the US Environmental Protection Agency (EPA) for US municipal solid waste. In reality, different products and applications will likely result in different waste management outcomes. For instance, electronics containing carbon nanotubes may be refurbished and reused, whereas carbon nanotubes in synthesis and processing may be incinerated.

The flow diagram in Figure 6.3 presents a general overview of the SFA findings on carbon nanotubes. Estimates presented here are generalized based on limited information, a small amount of nanotubes in commercial applications and a rapidly changing market. However, the findings improve our understanding of carbon nanotube flows throughout the economy. SFA provides a snapshot of a substance's flow in the economy at a given time, providing a better understanding of where these materials exist and are expected to go. Widespread projected application of these nanomaterials in many everyday products (from vehicle composites to tennis racquets and batteries) amidst uncertain risks makes the characterization of the flow of nanotubes increasingly important.

6.4
Corporate Social Responsibility

6.4.1
Background on Corporate Social Responsibility

Corporate Social Responsibility (CSR) is broadly defined as behavior by corporate entities that consider social and environmental impacts concurrently with the

economic well-being of the corporation. CSR is believed by many to pay dividends in terms of improved recruiting, branding and consumer loyalty and also through decreased risk of litigation and regulation. The following practices are often adopted by CSR-minded companies:

- Include stakeholders in decision-making.
- Maintain transparency with corporate activities affecting workers of the community.
- Seek to protect workers and their community through limiting environmental and human health impacts of products during manufacture, use and disposal.
- Use materials, labor and locations sustainably.
- Participate in CSR certification and reporting programs such as ISO 14000.

6.4.2
Corporate Social Responsibility Implications for Nanotechnology

Small Times Magazine estimated that over 3500 firms were involved in some aspect related to micro- or nanotechnology [37]. This includes companies that research and manufacture nanomaterials, nanotechnology-based products and equipment for nano-production, trade magazines and firms that offer legal expertise, venture capital investment and intellectual property strategizing on nanotechnology. Nanomaterials are used in numerous sectors, including energy, cosmetics, medicine and electronics.

Nanomaterials offer significant opportunities for decreased environmental impacts in terms of materials and energy consumption, and also the possibility of targeted human health benefits in the future. Along with the potential benefits also comes the potential for uncertain risks. Uncertainty in the risks of nanotechnology stem from scientific uncertainty in several areas, such as transport and dispersion of nanomaterials; ability of nanomaterials to enter biological systems; potential mode of action and toxicological effects of nanomaterials; suitability of traditional worker protection techniques in nano-environments; and the ability of the life cycle benefits of specific nanotechnology applications to outweigh the life cycle costs.

The level of uncertainty surrounding nanotechnology makes the work of protecting the public, workers and the environment and communicating about potential risks and benefits challenging for CSR-committed corporations. How can a corporate entity prevent or reduce exposures when the mode of exposure is not understood? How can a corporation communicate a complex, uncertain message to the public? Given the potential advantages and risks offered by nanomaterials, what is the appropriate path forward? These challenges also represent a significant opportunity for CSR-oriented firms to collaborate with regulators, non-governmental organisations (NGOs), and other firms to achieve common corporate social responsibility. By being proactive in seeking partners, sharing information and conducting research, nanofirms can hope to reduce risk and obtain competitive advantage.

Increased public awareness of the potential risks of nanotechnology, the lack of sound strategies for identifying and assessing these risks and increased production and use of nanomaterials prompted NGOs, activist groups and members of the scientific community to call for more research investigating nanotechnology's

risks [38–41]. For example, a report prepared for Greenpeace called for in-depth assessments of the environmental risks of near-term nanotechnology – specifically products or processes that might result in the release of nanoparticles into the environment [40]. The Canadian-based NGO ETC Group [38, 39] called for a global moratorium on the commercial production of nanomaterials. In particular, ETC Group [39] cautioned against scaling up of nanomaterial production without understanding the potential adverse side-effects from using them in many diverse commercial applications. Similar campaigns launched by activist groups have resulted in backlash against genetically modified (GM) crops. In the light of GM setbacks and a responsibility to balance pursuit of science with sensible precaution, editorials in *Nature* warned against leaving legitimate questions unanswered [41, 42]. Instead, they called for more research into nanotechnology risks accompanied by an open public discussion.

Companies face potential financial risks from the investment and insurance communities who are paying greater attention to the environmental, health and safety (EHS) discussions surrounding nanotechnology. Insurers are encouraging more rigorous review on both the opportunities and hazards of nanotechnology. A report by the Swiss Reinsurance Company asserts that the insurance industry should analyze nanotechnology to identify potential risks [43]. MunichRe, GenRE and Allianz have also published reports on the need for nanotechnology risk assessment [44]. Cientifica urges companies working with nanomaterials to prepare for the 'potential impact of future liabilities or changes in legislation' [53].

Companies that take the lead in dealing with EHS management and public perception concerns with nanotechnology (i.e. are 'first movers' in their industry group) may attain competitive advantage. They will not only be ready for possible regulation and may avoid retrofitting operations later (in the event of future nano-specific regulations), but they may also appeal to consumers who value CSR efforts and be in the position to influence regulatory or reporting schemes. For example, the CEO of NanoDynamics testified before Congress [45] and DuPont and Environmental Defense worked together to develop a framework for the responsible development, production, use and disposal of nanomaterials and products [30, 46]. By taking measures to consider and evaluate environmental, health and safety risks that nanomaterials may pose, corporations may avoid future risks, backlash and liability.

6.4.3
Summary of Work Conducted to Understand Nanofirm EHS Concerns and Actions

Several corporations have adopted environmental management strategies to identify, prevent or reduce the risks of nanotechnology. For example, ApNano Materials Inc. followed the European Commission's *Good Laboratory Practices Directives* to assess toxicity of its nano-based lubricant [44]. The Carbon Nanotech Research Institute adopted a policy against making products available in a powdered form in order to avoid any dispersion risks [47].

Various studies have sought to understand awareness of EHS issues at nanotechnology firms and to identify what firms are doing to deal with potential and uncertain

risks and what they could be doing to protect their workers, the environment and consumers. A few examples include the following:

- Lux Research [48] interviewed nanotechnology firms and found that companies want more certainty in the type of regulations to expect. In order to handle real, perceived and regulatory risks, Lux Research suggested that firms inventory nanomaterials, map them to exposures throughout the life cycle, characterize the risks with available knowledge and mitigate them with appropriate controls, toxicity testing and product redesigns.
- Innovest [44] reviewed hundreds of public and private nanotech companies to develop a list of best practices for offsetting potential perception risk based on product strategy, risk and stewardship.
- Lekas [49] surveyed nanotechnology startup firms in Connecticut and New York and found that they have varied concerns and degrees of progress in addressing EHS issues; they indicated that they need information and guidance and prefer communication about nanotechnology risks through an electronic or online venue from a government source.
- Lindberg and Quinn [50] surveyed nanotechnology firms in the northeastern USA and learned that small firms, in particular, need a roadmap from suppliers, industry, and government bodies to manage risks.
- A research team at the University of California, Santa Barbara [60] conducted an international survey of nanotechnology workplace safety practices for the International Council on Nanotechnology (ICON). The results of their interviews and analysis revealed that companies and laboratories recognize nanomaterial risks, but are following conventional practices faced with a lack of information.
- A European Commission survey of 380 European nanotechnology startups indicated that they do not consider social acceptance and environmental and health regulations as important barriers for the applications of nanomaterials [51].
- The European NanoBusiness Association [52] surveyed 142 European businesses (of which 18% were startups) and found that most respondents believed that health and environmental impacts of nanotechnology needed to be studied.

6.5 Conclusions

Scientific understanding of the human health and environmental impacts of nanotechnology and actions to regulate nanotechnology lag behind the research, development and commercialization of nanotechnology-based products. IE provides a framework for analyzing the impacts of nanotechnology on social and ecological systems. A number of IE tools, including LCA, MFA, SFA and CSR, can aid in assessing the potential risks and benefits of nanotechnology, in addition to developing

methods to reduce or mitigate potential risks. When applied prospectively, IE tools can be used to provide a forward-looking analysis that permits the design and manufacture of nanotechnology-based products in a manner that prevents or reduces their negative impacts. The current level of uncertainty surrounding the potential impacts and risks of nanotechnology present a significant challenge in applying IE tools. As scientific understanding of nanotechnology's environmental and health impacts evolves, the efficacy of IE in mitigating potential harm and designing more effective products using nanotechnology will continue to increase.

7
Composition, Transformation and Effects of Nanoparticles in the Atmosphere

Ulrich Pöschl

7.1
Introduction

The effects of airborne particles in the nanometer to micrometer size range (aerosols) on the atmosphere, climate and public health are among the central topics in current environmental research [1, 2]. The particles scatter and absorb solar and terrestrial radiation, they are involved in the formation of clouds and precipitation as cloud condensation and ice nuclei and they affect the abundance and distribution of atmospheric trace gases by heterogeneous chemical reactions and other multiphase processes [3–6]. Moreover, they play an important role in the spread of biological organisms, reproductive materials and pathogens (pollen, bacteria, spores, viruses, etc.) and they can cause or enhance respiratory, cardiovascular, infectious and allergic diseases [3, 7–9].

An aerosol is generally defined as a suspension of liquid or solid particles in a gas, with particle diameters in the range 10^{-9}–10^{-4} m (lower limit, molecules and molecular clusters; upper limit, rapid sedimentation) [6, 9]. The most evident examples of aerosols in the atmosphere are clouds, which consist primarily of condensed water with particle diameters on the order of $\sim$10 µm. In atmospheric science, however, the term aerosol traditionally refers to suspended particles which contain a large proportion of condensed matter other than water, whereas clouds are considered as separate phenomena [10].

Atmospheric aerosol particles originate from a wide variety of natural and anthropogenic sources. Primary particles are directly emitted as liquids or solids from sources such as biomass burning, incomplete combustion of fossil fuels, volcanic eruptions and wind-driven or traffic-related suspension of road, soil and mineral dust, sea salt and biological materials (plant fragments, microorganisms, pollen, etc.). Secondary particles, on the other hand, are formed by gas-to-particle conversion in the atmosphere (new particle formation by nucleation and condensation of gaseous precursors). As illustrated in Figure 7.1, airborne particles undergo various physical and chemical interactions and transformations (atmospheric aging),

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

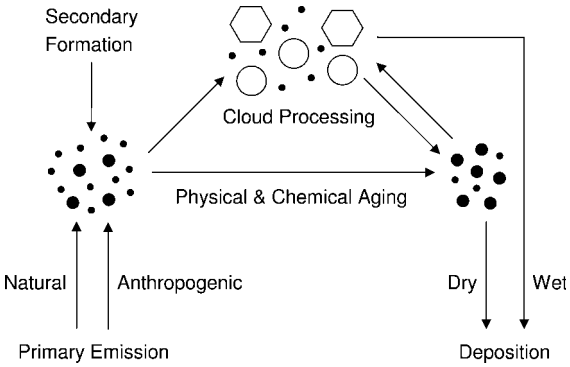

Figure 7.1 Atmospheric cycling of airborne nano- and microparticles (aerosols) [1, 2].

i.e. changes of particle size, structure and composition (coagulation, restructuring, gas uptake, chemical reaction). Particularly efficient particle aging occurs in clouds, which are formed by condensation of water vapor on pre-existing aerosol particles (cloud condensation and ice nuclei, CCN/IN). Most clouds re-evaporate and modified aerosol particles are again released from the evaporating cloud droplets or ice crystals (cloud processing). If, however, the cloud particles form precipitation which reaches the Earth's surface, not only the condensation nuclei but also other aerosol particles are scavenged on the way to the surface and removed from the atmosphere, which is actually the main sink of atmospheric aerosol particles ("wet deposition"). Particle deposition without precipitation of hydrometeors (airborne water particles), i.e. "dry deposition" by convective transport, diffusion and adhesion to the Earth's surface, is less important on a global scale, but it is highly relevant for local air quality, health effects (inhalation and deposition in the human respiratory tract) and the soiling of buildings and cultural monuments. Depending on aerosol properties and meteorological conditions, the characteristic residence times (lifetimes) of aerosol particles in the atmosphere range from hours to weeks [11, 12].

The lifetime of small nanoparticles with diameters on the order of ~10 nm or less is limited by rapid diffusion and coagulation with each other or with larger particles. Under highly polluted conditions (e.g. in exhaust plumes), it can be as short as a few seconds to minutes and in general it rarely exceeds a few hours. In contrast, large nanoparticles with diameters on the order of ~100 nm typically have the longest lifetime of all atmospheric particles. They are too small for efficient sedimentation and too large for efficient diffusion and coagulation. The only efficient removal process for these particles is wet deposition on average time scales of days to weeks.

The concentration, composition and size distribution of atmospheric aerosol particles are temporally and spatially highly variable. In the lower atmosphere (troposphere), the total particle number and mass concentrations typically vary in the approximate ranges 10^2–$10^5\,cm^{-3}$ and 1–100 $\mu g\,m^{-3}$, respectively [11–14]. In general, the predominant chemical components of air particulate matter (PM) are sulfate, nitrate, ammonium, sea salt, mineral dust, organics and black or elemental carbon, each of them typically contributing about 10–30% of the overall mass loading.

For different locations, times, meteorological conditions and particle size fractions, however, the relative abundance of different chemical components can vary by an order of magnitude or more [3, 6, 11, 15]. In atmospheric research, the term "fine air particulate matter" is usually restricted to particles with aerodynamic diameters $\leq 1\,\mu m$ or $2.5\,\mu m$ (PM_1 or $PM_{2.5}$, respectively). In air pollution control, it sometimes also includes larger particles up to $10\,\mu m$ (PM_{10}).

The total number concentration of aerosol particles in the atmosphere is usually dominated by nanoparticles with diameters up to ~100 nm, whereas the total mass concentration is generally dominated by particles with diameters >100 nm (microparticles). Characteristic examples of particle number concentration, size distribution and chemical composition of fine particulate matter in urban and high alpine air are illustrated in Figure 7.2. The displayed particle number size distributions (particle number concentration per logarithmic decade of particle diameter, $dN/d\log d_p$, plotted against particle diameter) have been observed in the city of Munich [500 m above sea level (asl); 8–14 December 2002] and at the Schneefernerhaus research station on Mount Zugspitze (2600 m asl; 6 November 2002) in Southern Germany. They correspond to total particle number concentrations of about $10^2\,cm^{-3}$ in alpine air and $10^4\,cm^{-3}$ in urban air and to particle mass concentrations of about 1

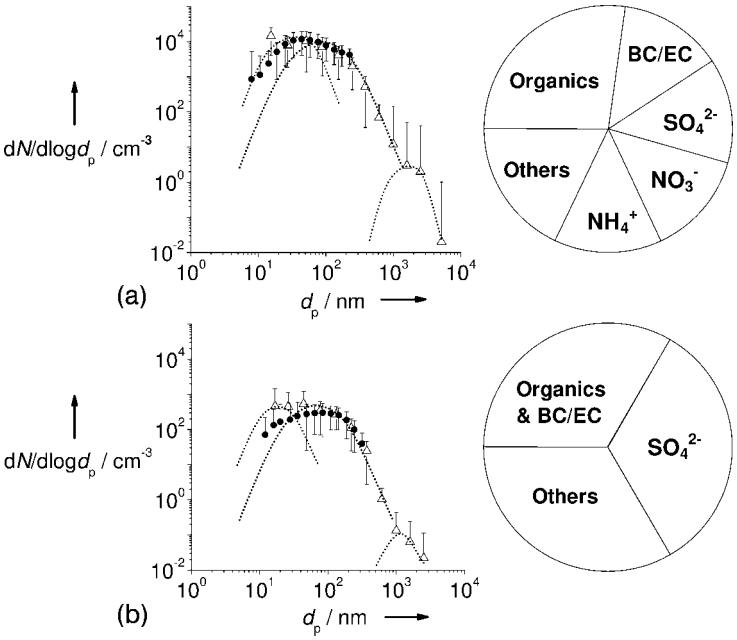

Figure 7.2 Characteristic examples of aerosol particle size distribution and chemical composition in urban (a) and high alpine air (b). Diagrams: number size distribution function $dN/d\log d_p$ (symbols and error bar, arithmetic mean values and standard deviations; open triangles, ELPI; full circles, SMPS; dotted lines, characteristic particle size modes); pie charts, typical mass proportions of main components [1].

and $10\,\mu g\,m^{-3}$, respectively. The measurements were performed with two complementary techniques, an electrical low pressure impactor (ELPI, 10 nm–10 µm, flow rate $30\,L\,min^{-1}$, measurement interval 1 min) and a scanning mobility particle sizer (SMPS, 10–300 nm, flow rate $1\,L\,min^{-1}$, measurement interval 30 min) [16, 17]. The deviations at very low particle size can be attributed to wall losses by diffusion in the SMPS system.

The dotted lines indicate characteristic particle size modes, which can be attributed to different sources, sinks and aging processes of atmospheric particles: nucleation (Aitken), accumulation and coarse mode [6, 9]. In corresponding mass size distributions, which are obtained by multiplication with particle volume ($d_p^3\pi/6$) and density (typically around $2\,g\,cm^{-3}$), the nucleation mode is usually negligible, whereas accommodation and coarse particle modes are of comparable magnitude. The composition pie charts are based on chemical analyses of $PM_{2.5}$ filter samples from the same locations and literature data for urban and remote continental background air [3, 6, 11, 15, 18–21].

Figure 7.3 illustrates the interdependencies between composition, composition-dependent properties, atmospheric interactions and transformation, climate and health effects and sources of aerosols. The resulting feedback loops are of central importance in the science and policy of environmental pollution and global change. Thus a comprehensive characterization (climatology) and mechanistic understanding of particle sources, properties and transformation is required for the quantitative assessment, reliable prediction and efficient control of natural and anthropogenic aerosol effects on climate and public health.

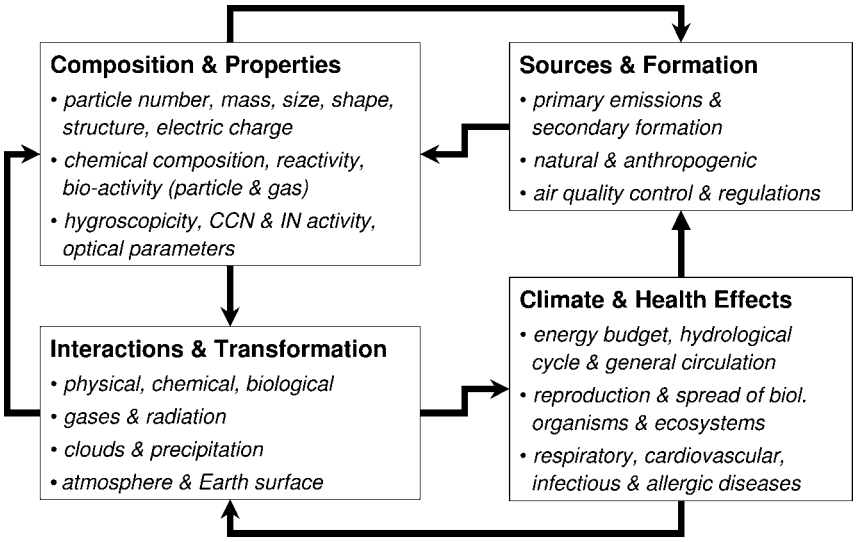

Figure 7.3 Interdependencies and feedbacks between atmospheric aerosol composition, properties, interactions and transformation, climate and health effects and sources [2].

7.2
Composition

Accurate determination of the chemical composition of air particulate matter is a formidable analytical task [1]. Minute sample amounts are usually composed of several main constituents and hundreds of minor and trace constituents. Moreover, the composition of the individual particles can be fairly uniform (internally mixed aerosols) or very different from the ensemble composition (externally mixed aerosols), depending on the involved particle sources and atmospheric aging processes (coagulation, gas–particle partitioning, chemical reactions). Especially in populated environments, air particulate matter can be pictured as the result of an "exploded pharmacy", comprising just about any non- or semi-volatile chemical compound occurring in the biosphere, hydrosphere and lithosphere or released by human activity. In addition to primary chemical components, which are directly emitted by natural and anthropogenic sources, air particulate matter mostly also contains secondary chemical components, which are formed by gas-phase reactions and subsequent gas-to-particle conversion or by chemical transformation of primary particle components in the atmosphere. By definition, an aerosol is composed of particulate and gas-phase components, i.e. the term aerosol component can refer to chemical compounds in both the condensed and gaseous state. In practice and in the remainder of this chapter, however, the term aerosol component usually refers to semi- and non-volatile particle components but not to volatile compounds residing almost exclusively in the gas phase.

7.2.1
Carbonaceous Components

Carbonaceous aerosol components (organic compounds and black or elemental carbon) account for a large fraction of air particulate matter, exhibit a wide range of molecular structures and have a strong influence on the physicochemical, biological and climate- and health-related properties and effects of atmospheric aerosols [1–3, 6, 21–25].

Traditionally, the total carbon (TC) content of air particulate matter is defined as the sum of all carbon contained in the particles, except in the form of inorganic carbonates. TC is usually determined by thermochemical oxidation and evolved gas analysis (CO_2 detection) and divided into an organic carbon (OC) fraction and a black carbon (BC) or elemental carbon (EC) fraction. Measurements of BC and EC are generally based on optical and thermochemical techniques and OC is operationally defined as the difference between TC and BC or EC (TC = BC + OC or TC = EC + OC) [21]. As illustrated in Figure 7.4, however, there is no real sharp cut but a continuous decrease in thermochemical refractiveness and specific optical absorption going from graphite-like structures to non-refractive and colorless organic compounds [26]. Both BC and EC, comprise the carbon content of the graphite-like material usually contained in soot (technically defined as the black product of incomplete hydrocarbon combustion or pyrolysis) and other combustion aerosol

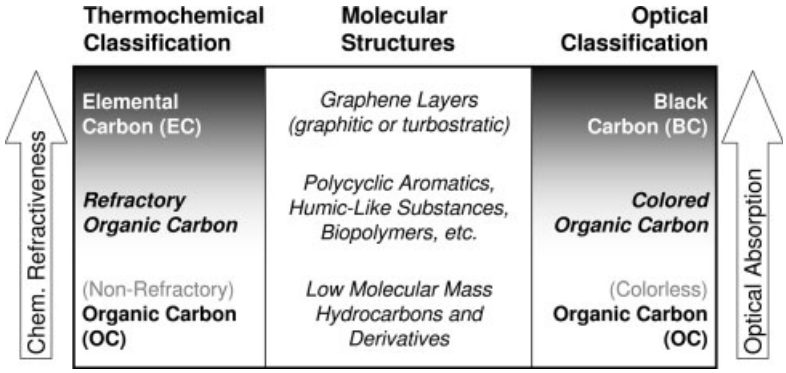

Figure 7.4 Optical and thermochemical classification and molecular structures of black carbon (BC), elemental carbon (EC) and organic carbon (OC = TC − BC or TC − EC) [26]. Depending on the method of analysis, different amounts of carbon from refractory and colored organic compounds are included in BC, EC or OC [1].

particles, which can be pictured as more or less disordered stacks of graphene layers or large polycyclic aromatics [27–29]. Depending on the applied optical or thermochemical methods (absorption wavelength, temperature gradient, etc.), however, BC and EC measurements also include the carbon content of colored and refractory organic compounds, which can lead to substantially different results and strongly limits the comparability and suitability of BC, EC and OC data for the determination of mass balances and physicochemical properties of air particulate matter.

Nevertheless, most information available on the abundance, properties and effects of carbonaceous aerosol components so far is based on measurement data of TC, BC/EC and OC [21, 25]. These data are now increasingly complemented by measurements of water-soluble organic carbon (WSOC), its macromolecular fraction (MWSOC) and individual organic compounds as detailed below. Moreover, the combination of thermochemical oxidation with ^{14}C isotope analysis (radiocarbon determination in evolved CO_2 by accelerator mass spectrometry) allows one to distinguish fossil fuel combustion and other sources of carbonaceous aerosol components. Recent results confirm that the EC is dominated by fossil fuel combustion and indicate highly variable anthropogenic and biogenic sources and proportions of OC [30].

Characteristic mass concentrations and concentration ratios of fine air particulate matter ($PM_{2.5}$) and carbonaceous fractions in urban, rural and alpine air in central Europe are summarized in Table 7.1. The reported data were obtained on an altitude transect through Southern Germany, from the city of Munich (500 m asl), via the meteorological observatory Hohenpeissenberg (1000 m asl), to the environmental research station Schneefernerhaus on Mount Zugspitze (2600 m asl) throughout the period 2001–2003. The sampling locations and measurement procedures have been described in detail elsewhere [31, 32] and the results are consistent with those of other studies performed at comparable locations [11, 13, 15, 18–21].

Table 7.1 Characteristic mass concentrations of fine particulate matter ($PM_{2.5}$) and proportions of total carbon (TC), elemental carbon (EC), organic carbon (OC), water-soluble OC (WSOC) and macromolecular WSOC (MWSOC, molecular mass >5 kDa) mass in urban, rural and high alpine air in central Europe (rounded arithmetic mean values ± standard deviation of about 30 filter samples collected at each location over the period 2001–2003).

	Urban (Munich)	Rural (Hohenpeissenberg)	Alpine (Zugspitze)
$PM_{2.5}$ ($(g\,m^{-3})$)	20 ± 10	10 ± 5	4 ± 2
TC in $PM_{2.5}$ (%)	40 ± 20	30 ± 10	20 ± 10
EC in TC (%)	50 ± 20	30 ± 10	30 ± 10
OC in TC (%)	40 ± 20	70 ± 10	70 ± 10
WSOC in TC (%)	20 ± 10	40 ± 20	60 ± 20
MWSOC in WSOC (%)	30 ± 10	50 ± 20	40 ± 20

On average, the total $PM_{2.5}$ mass concentration decreases by about a factor of two from urban to rural and from rural to alpine air, while the TC mass fraction decreases from ~40 to ~20%. The EC/TC ratios in $PM_{2.5}$ are as high as ~50% in the urban air samples taken close to a major traffic junction and on the order of ~30% in rural and high alpine air, demonstrating the strong impact of diesel soot and other fossil fuel combustion or biomass burning emissions on the atmospheric aerosol burden and composition. The water-soluble fraction of organic carbon (WSOC in OC), on the other hand, exhibits a pronounced increase from urban (~20%) to rural (~40%) and high alpine (~60%) samples of air particulate matter. This observation can be attributed to different aerosol sources (e.g. water-insoluble combustion particle components versus water-soluble biogenic and secondary organic particle components; see below) but also to chemical aging and oxidative transformation of organic aerosol components, which generally increases the number of functional groups and thus the water solubility of organic molecules.

Black or elemental carbon accounts for most of the light absorption by atmospheric aerosols and is therefore of crucial importance for the direct radiative effect of aerosols on climate [33–35]. Despite a long tradition of soot and aerosol research, however, there is still no universally accepted and applied operational definition of BC and EC. Several studies have compared the different optical and thermal methods applied by atmospheric research groups to measure BC and EC. Depending on techniques and measurement locations, fair agreement has been found in some cases, but mostly the results deviated considerably (up to 100% and more) [36–38].

Optical methods for the detection of BC are usually non-destructive and allow (near) real-time operation, but on the other hand they are particularly prone to misinterpretation. They generally rely on the assumptions that BC is the dominant absorber and has a uniform mass-specific absorption coefficient or cross-section. While these assumptions may be justified under certain conditions, they are highly questionable in the context of detailed chemical characterization of aerosol particles ("How black is black carbon?") [26]. In addition to different types of graphite-like

material, there are at least two classes of organic compounds which can contribute to the absorption of visible light by air particulate matter ("light-absorbing, yellow or brown carbon"): [21] polycyclic aromatics and humic-like substances. Therefore, optically determined BC values have to be considered as mass equivalent values but not as absolute mass or concentration values. Moreover, most conventional optical methods such as the aethalometer and integrating-sphere- and integrating-plate techniques are based on the measurement of light extinction rather than absorption. As a consequence, these methods require aerosol composition-dependent calibrations or additional sample work-up processes to compensate or minimize the influence of scattering aerosol components such as inorganic salts and acids on the measurement signal [37, 39, 40]. Alternatively, photoacoustic spectroscopy allows direct measurements of light absorption by airborne aerosol particles and in recent years several photoacoustic spectrometers have been developed and applied for the measurement of aerosol absorption coefficients and BC equivalent concentrations [41–43].

Among the few methods available for the characterization of the molecular and crystalline structures of BC and EC (graphite-like carbon proportion and degree of order) are high-resolution electron microscopy, X-ray diffraction and Raman spectroscopy [28, 29, 44]. These measurement techniques have revealed dependences of the microstructure and spectroscopic properties of flame soot, diesel soot and related carbonaceous materials on the processes and conditions of particle formation and aging. So far, however, these methods have been too labor intensive for routine investigations of atmospheric aerosol samples and their applicability to quantitative analyses remains to be proven [28, 29]. Nevertheless, recently developed measurement systems promise to allow the quantification of graphite-like carbon and soot in aerosol filter samples by Raman spectroscopy [45, 46].

7.2.2 Primary and Secondary Organic Components

The total mass of organic air particulate matter (OPM), i.e. the sum of organic aerosol (OA) components, is usually estimated by multiplication of OC by a factor of about 1.5–2, depending on the assumed average molecular composition and accounting for the contribution of elements other than carbon contained in organic substances (H, O, N, S, etc.) [21, 47]. The only way, however, to determine accurately the overall mass, molecular composition, physicochemical properties and potential toxicity of OPM is the identification and quantification of all relevant chemical components. Also, trace substances can be hazardous to human health and potential interferences of refractive and colored organics in the determination of BC or EC can be assessed only to the extent to which the actual chemical composition of OPM is known [26, 48].

Depending on their origin, OA components can be classified as primary or secondary. Primary organic aerosol (POA) components are directly emitted in the condensed phase (liquid or solid particles) or as semi-volatile vapors, which are condensable under atmospheric conditions. The main sources of POA particles and

components are natural and anthropogenic biomass burning (wildfires, slashing and burning, domestic heating); fossil fuel combustion (domestic, industrial, traffic related); and wind-driven or traffic-related suspension of soil and road dust, biological materials (plant and animal debris, microorganisms, pollen, spores, etc.), sea spray and spray from other surface waters with dissolved organic compounds.

Secondary organic aerosol (SOA) components are formed by chemical reaction and gas-to-particle conversion of volatile organic compounds (VOCs) in the atmosphere, which may proceed via different pathways:

1. new particle formation: formation of semi-volatile organic compounds (SVOCs) by gas-phase reactions and participation of the SVOCs in the nucleation and growth of new aerosol particles;
2. gas–particle partitioning: formation of SVOCs by gas-phase reactions and uptake (adsorption or absorption) by pre-existing aerosol or cloud particles;
3. heterogeneous or multiphase reactions: formation of low-volatility or non-volatile organic compounds (LVOCs, NVOCs) by chemical reaction of VOCs or SVOCs at the surface or in the bulk of aerosol or cloud particles.

The formation of new aerosol particles from the gas phase generally proceeds via the nucleation of nanometer-sized molecular clusters and subsequent growth by condensation of condensable vapor molecules. Experimental evidence from field measurements and model simulations suggest that new particle formation in the atmosphere is most likely dominated by ternary nucleation of H_2SO_4-H_2O–NH_3 and subsequent condensation of SVOCs [49–51]. Laboratory experiments and quantum chemical calculations indicate, however, that SVOCs might also play a role in the nucleation process (H_2SO_4–SVOC complex formation) [52]. The actual importance of different mechanisms of particle nucleation and growth in the atmosphere has not yet been fully unraveled and quantified. In any case, however, the formation of new particles exhibits a strong and non-linear dependence on atmospheric composition and meteorological conditions, may be influenced by ions and electric charge effects and competes with gas–particle partitioning and heterogeneous or multiphase reactions [53]. Among the principal parameters governing secondary particle formation are temperature, relative humidity and the concentrations of organic and inorganic nucleating and condensing vapors, which depend on atmospheric transport in addition to local sources and sinks such as photochemistry and pre-existing aerosol or cloud particles [23, 25, 49, 50]. The rate and equilibrium of SVOC uptake by aerosol particles depend on the SVOC accommodation coefficients and on the particle surface area, bulk volume and chemical composition (kinetics and thermodynamics of gas–particle partitioning) [54].

Most earlier studies of SOA formation had focused on pathways (1) and (2). Several recent studies indicate, however, that heterogeneous and multiphase reactions may also play an important role and substantially contribute to the overall atmospheric burden of OPM [21, 55–58]. The term "heterogeneous reaction" generally refers to reactions of gases at the particle surface, whereas the term "multiphase reaction" refers to reactions in the particle bulk involving species from the gas phase. A variety of different reversible and irreversible mechanisms of acid-catalyzed condensation and

Table 7.2 Prominent organic substance classes, characteristic magnitudes of their proportion in fine organic particulate matter (OPM; approximate upper limit of mass fraction) and their main sources.

Substance classes	Proportion	Sources
Aliphatic hydrocarbons	10^{-2}	Biomass, fossil fuel combustion
Aliphatic alcohols and carbonyls	10^{-2}	Biomass, SOA/aging
Levoglucosan	10^{-1}	Biomass burning
Fatty acids and other alkanoic acids	10^{-1}	Biomass, SOA/aging
Aliphatic dicarboxylic acids	10^{-1}	SOA/aging
Aromatic (poly-)carboxylic acids	10^{-1}	SOA/aging, soil/dust
Multifunctional aliphatics and aromatics (OH, CO, COOH)	10^{-1}	SOA/aging, soil/dust
Polycyclic aromatic hydrocarbons (PAHs)	10^{-3}	Fossil fuel combustion, biomass burning
Nitro- and oxy-PAHs	10^{-3}	Fossil fuel combustion, biomass burning, SOA/aging
Proteins and other amino compounds	10^{-1}	Biomass
Cellulose and other carbohydrates	10^{-2}	Biomass
Secondary organic oligomers/polymers and humic-like substances	10^{-1}	SOA/aging, soil/dust

radical-initiated oligo- or polymerization reactions involving organic and inorganic acids and photo-oxidants can lead to secondary formation of LVOCs and NVOCs of high molecular mass (SOA oligomers/polymers; Table 7.2). The actual atmospheric relevance and contributions of the different SOA formation pathways and involved chemical reaction mechanisms, however, still remain to be sorted out [21, 25].

Depending on local sources, meteorological conditions and atmospheric transport and thus on location, season and daytime, the composition of OPM can be dominated by POA or by SOA components. Recent studies indicate high abundance of POAs in tropical air masses due to intense biomass burning, whereas SOAs from biogenic and anthropogenic emissions of precursor VOCs seems to dominate in mid-latitude air masses. On a global scale, the formation of SOAs appears to be dominated by oxidation of biogenic VOCs (mostly by ozonolysis of terpenes) [59] and to amount to at least 50% of POA emissions [25, 60]. In the atmosphere, POA and SOA components are mixed with each other, BC/EC and inorganic aerosol components (externally and internally mixed aerosols) [61]. Moreover, both POA and SOA components can be efficiently transformed upon interaction with reactive trace gases and solar radiation (chemical aging, Section 7.3).

Hundreds of organic compounds have been detected in air particulate matter. Even in the most comprehensive investigations, however, only 10–40% of the OPM content estimated from OC measurements have been unambiguously identified on a molecular level. Prominent organic substance classes, characteristic magnitudes of their proportion in fine OPM (approximate upper limit of mass fraction) and their main sources are summarized in Table 7.2 [3, 6, 21, 25, 62–67].

Several studies have shown that macromolecules such as cellulose and proteins (molecular mass $\gg$1 kDa) and other compounds with relatively high molecular mass ($\gg$100 Da) such as humic-like substances (HULIS) account for large proportions of OPM and WSOC [21, 32, 68–72]. Obviously, biopolymers and humic substances are emitted as POA components (soil and road dust, sea-spray, biological particles), which may be modified by chemical aging and transformation in the atmosphere (e.g. formation of HULIS by oxidative degradation of biopolymers). On the other hand, organic compounds with high molecular mass can also originate from SOAs formation by heterogeneous and multiphase reactions at the surface and in the bulk of atmospheric particles as outlined above (SOA oligomers/polymers).

For the identification and quantification of individual organic compounds, filter and impactor samples are usually extracted with appropriate solvents and the extracts are analyzed by advanced instrumental or bioanalytical methods of separation and detection: gas and liquid chromatography; capillary electrophoresis; absorption, fluorescence and mass spectrometry; immunosorbent, enzyme and dye assays; etc. [26, 32, 62, 63, 66, 73–76]. Alternatively, deposited or suspended particles can be partially or fully vaporized by thermal or laser desorption and directly introduced into a gas chromatograph or spectrometer [3, 77–80].

In recent studies, nuclear magnetic resonance [18], Fourier transform infrared spectroscopy [47], scanning transmission X-ray microscopy [81] and aerosol mass spectrometry [82] have been applied to the efficient characterization and quantification of functional groups in OPM (alkyl, carbonyl, carboxyl and hydroxy groups; carbon double bonds and aromatic rings). These methods give valuable insight into the overall chemical composition, oxidation state and reactivity of OPM, but they provide only limited information about the actual identity of the individual compounds that present in the complex mixture. The molecular mass and structure of organic compounds, however, are crucial parameters for their physicochemical and biological properties and thus for their climate and health effects (volatility, solubility, hygroscopicity, CCN and IN activity, bioavailability, toxicity, allergenicity; Sections 7.3 and 7.4).

7.3 Transformation

Chemical reactions proceed at the surface and in the bulk of solid and liquid aerosol particles and can influence atmospheric gas-phase chemistry and properties of atmospheric particles and their effects on climate and human health[3, 6, 54, 83–92].

For example, aerosol chemistry leads to the formation of reactive halogen species, changes of reactive nitrogen and depletion of ozone – especially in the stratosphere, upper troposphere and marine boundary layer [93–103] On the other hand, chemical aging of aerosol particles generally changes their composition, decreases their reactivity, increases their hygroscopicity and cloud condensation activity and can change their optical properties [21, 26, 89, 104–109].

Because of their high surface-to-volume ratio, fine aerosol particles can be very efficiently transformed upon interaction with solar radiation (photolysis) and reactive trace gases (oxidation, nitration, acid–base reactions, hydrolysis, condensation or radical-initiated oligomerization, etc.). For example, oxidation and nitration reactions lead to the formation or degradation of hazardous aerosol components [8, 31, 48, 72], they cause artifacts upon collection and analysis of air particulate matter [3, 21, 110] and they play a major role in technical processes and devices for the control of combustion aerosol emissions [44, 111–113]. Moreover, the interaction with water can lead to structural rearrangements of solid aerosol particles, to the formation of highly concentrated aqueous solution droplets (hygroscopic growth) and to the formation of cloud droplets and ice crystals (Section 7.3.2).

Atmospheric aerosol transformations and gas–particle interactions generally involve multiple physicochemical processes such as mass transport, phase transition and chemical reaction at the interface or in the bulk of the gas phase, molecular clusters and liquid or solid particles, as illustrated in Figure 7.5. These multiphase processes are pivotal for the aerosol and cloud interactions and feedback loops outlined in Figures 7.1 and 7.3 and thus for the climate and health effects of atmospheric aerosols detailed below (Section 7.4).

Efficient investigation, elucidation and description of the interactions between multiple phases and chemical components of aerosols and clouds by laboratory experiments, field measurements, remote sensing and model studies require consistent terminologies and universally applicable mathematical formalisms and physical parameters. However, the current understanding of the mechanisms and kinetics of mass transport, phase transitions and chemical reactions in atmospheric aerosols and clouds is very limited. In addition to a lack of experimental data, one of the limitations is that the formalisms applied in different studies have mostly been restricted to specific systems and boundary conditions: liquid water, ice, acid

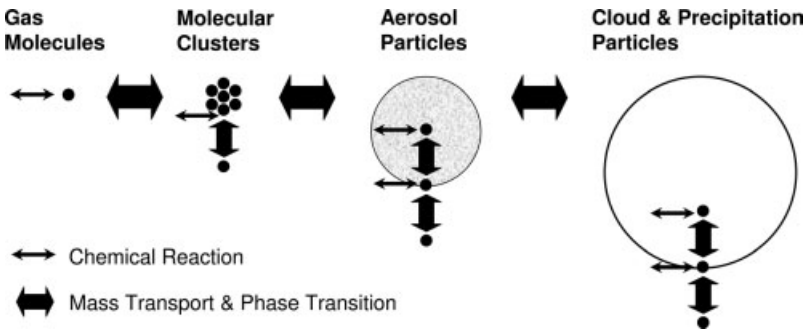

Figure 7.5 Schematic illustration of multiphase aerosol and cloud processes: mass transport and phase transitions of (semi-) volatile molecules between gas-phase, molecular clusters, aerosol particles and cloud or precipitation particles (thick arrows); chemical reactions in the gas phase, at the interface and in the particle bulk (thin arrows) [2].

hydrates, soot or mineral dust; fresh or aged surfaces; low or high reactant concentration levels, transient or (quasi-)steady-state conditions; limited selection of chemical species and reactions (see Ref. [54] and references therein). The different and sometimes inconsistent rate equations, parameters and terminologies make it difficult to compare, extrapolate and integrate the results of different studies over the wide range of reaction conditions relevant for the atmosphere, laboratory experiments, technical processes and emission control.

A comprehensive kinetic model framework for aerosol and cloud surface chemistry and gas–particle interactions has recently been proposed by Pöschl, Rudich and Ammann, abbreviated to PRA [54]. It allows to describe mass transport and chemical reactions at the gas–particle interface and to link surface processes with gas-phase and particle bulk processes in aerosol and cloud systems with unlimited numbers of chemical components and physicochemical processes. The key elements and essential aspects of the PRA framework are as follows:

1. a simple and descriptive double-layer surface model (sorption layer and quasi-static layer);
2. straightforward and additive flux-based mass balance and rate equations;
3. clear separation of mass transport and chemical reactions;
4. well-defined rate parameters (uptake and accommodation coefficients, reaction and transport rate coefficients);
5. clear distinction between different elementary and multistep transport processes (surface and bulk accommodation, etc.);
6. clear distinction between different elementary and multistep heterogeneous and multiphase reactions (Langmuir–Hinshelwood and Eley–Rideal mechanisms, etc.);
7. mechanistic description of complex concentration and time dependences;
8. flexible inclusion or omission of chemical species and physicochemical processes;
9. flexible convolution or deconvolution of species and processes;
10. full compatibility with traditional resistor model formulations.

Figure 7.6 illustrates the PRA model compartments and elementary processes at the gas–particle interface. The individual steps of mass transport are indicated by bold arrows besides the model compartments: gas-phase diffusion; reversible adsorption; mass transfer between sorption layer, quasi-static surface layer and near-surface particle bulk; diffusion in the particle bulk. The slim arrows inside the model compartments represent different types of chemical reactions: gas-phase reactions; gas–surface reactions; surface layer reactions; surface–bulk reactions; particle–bulk reactions [54]. Exemplary practical applications and model calculations demonstrating the relevance of these aspects have been presented in a companion paper [114].

The PRA framework is meant to serve as a common basis for experimental and theoretical studies investigating and describing atmospheric aerosol and cloud surface chemistry and gas–particle interactions. In particular, it will support the following research activities: planning and design of laboratory experiments for the

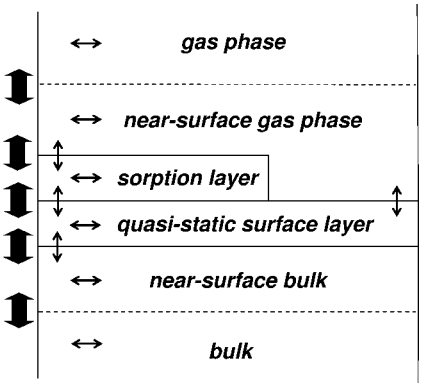

Figure 7.6 PRA framework model compartments, transport processes and chemical reactions at the gas–particle interface (double-layer surface model): fluxes of diffusion in the gas phase and particle bulk, adsorption and desorption, transfer between sorption layer and quasi-static surface layer and between quasi-static surface layer and near-surface particle bulk indicated by vertical thick arrows on the left side; elementary chemical reactions between species in the same or in different model compartments indicated by horizontal and vertical thin arrows [1, 54].

elucidation and determination of elementary processes and rate parameters; the establishment, evaluation and quality assurance of comprehensive and self-consistent collections of kinetic parameters; and the development of detailed master mechanisms for process models and the derivation of simplified but yet realistic parameterizations for atmospheric and climate models in analogy with atmospheric gas-phase chemistry [59, 115–119].

7.3.1
Chemical Transformation of Carbonaceous Aerosol Components

Organic aerosol components and the surface layers of BC or EC can react with atmospheric photo-oxidants (OH, O_3, NO_3, NO_2, etc.), acids (HNO_3, H_2SO_4, etc.), water and UV radiation. The chemical aging of OA components basically follows the generic reaction pathways outlined in Figure 7.7 and it tends to increase the oxidation state and water solubility of OC. In analogy with atmospheric gas-phase photochemistry of VOCs (methane, isoprene, terpenes, etc.) [59, 116, 117], oxidation, nitration, hydrolysis and photolysis transform hydrocarbons and derivatives with one or few functional groups into multifunctional hydrocarbon derivatives. The cleavage of organic molecules and release of SVOCs, VOCs, CO or CO_2 can also lead to volatilization of OPM. On the other hand, oxidative modification and degradation of biopolymers may convert these into HULIS (analogy with the formation of humic substances in soil, surface water and groundwater processes). Moreover, condensation reactions and radical-initiated oligo- or polymerization can decrease the volatility of OA components and promote the formation of SOAs particulate matter (SOA oligomers or HULIS, respectively; Table 7.2; Section 7.2.2).

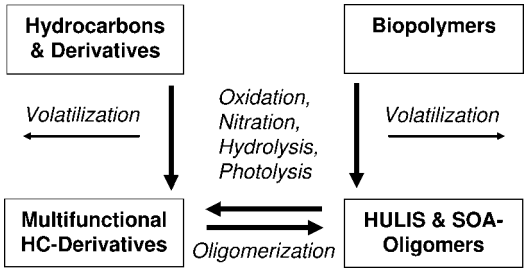

Figure 7.7 Generic reaction pathways for the atmospheric transformation (chemical aging) of organic aerosol components (left side, low molecular mass; right side, high molecular mass) [1].

The actual reaction mechanisms and kinetics, however, have been elucidated and fully characterized only for a small number of model reaction systems and components. So far, most progress has been made in the kinetic investigation and modeling of chemical reactions in cloud droplets [120, 121]. For the reasons outlined above, very few reliable and widely applicable kinetic parameters are available for organic reactions at the surface and in the bulk of liquid and solid aerosol particles [21, 54, 89, 122–124].

Several studies have shown that surface reactions of organic molecules and black or elemental carbon with gaseous photo-oxidants such as ozone and nitrogen dioxide tend to exhibit non-linear concentration dependences and competitive co-adsorption of different gas-phase components, which can be described by Langmuir–Hinshelwood reaction mechanisms and rate equations [54, 84, 89, 114, 125].

An example of such reactions is the degradation of benzo[*a*]pyrene (BaP) on soot by ozone. BaP is a polycyclic aromatic hydrocarbon (PAH) and prominent air pollutant with the chemical formula $C_{20}H_{12}$, consisting of five six-membered aromatic rings. It is one of the most hazardous carcinogens and mutagens among the 16 "priority polycyclic aromatic hydrocarbon pollutants" defined by the US Environmental Protection Agency (EPA). The main source of BaP in the atmosphere is combustion aerosols and it resides to a large extent on the surface of soot particles [48, 90, 110].

Figure 7.8 shows pseudo-first-order rate coefficients for the degradation of BaP on soot by ozone at gas-phase mole fractions or volume mixing ratios (VMR) up to 1 ppm under dry conditions and in the presence of water vapor [relative humidity (RH) 25%, 296 K, 1 atm]. These and complementary results of aerosol flow tube experiments and model calculations indicate reversible and competitive adsorption of O_3 and H_2O, followed by a slower, rate-limiting surface reaction between adsorbed O_3 and BaP on the soot surface. The kinetic parameters determined from the displayed non-linear least-squares fits (maximum pseudo-first-order rate coefficients and effective Langmuir adsorption equilibrium constants) allow the prediction of the half-life (50% decay time) of BaP on the surface of soot particles in the atmosphere. At typical ambient ozone VMR of ~30 ppb it would be only ~5 min under dry conditions and ~15 min at 25% RH.

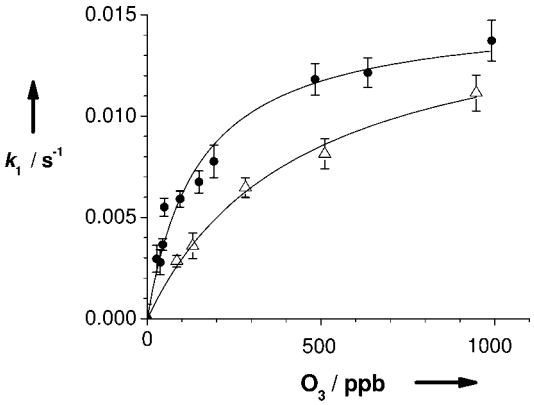

Figure 7.8 Pseudo-first-order rate coefficients (k_1) for the degradation of benzo[*a*]pyrene (BaP) on soot by ozone: measurement data from aerosol flow tube experiments under dry and humid conditions (symbols and error bars, arithmetic mean ± standard deviation; full circles, RH <1%; open triangles, RH ≈ 25%) and non-linear least-squares fit lines based on Langmuir–Hinshelwood rate equation [1, 90].

Figure 7.9 illustrates the recovery ratio (RR) of BaP from fine air particulate matter ($PM_{2.5}$) collected with a regular filter sampling system from urban air at ambient ozone VMRs up to 80 ppb (Munich, 2001–2002). The plotted RRs refer to filter samples collected in parallel with a system that removes ozone and other photo-oxidants from the sample air flow by means of an activated carbon diffusion denuder [110]. Thus deviations from unity represent the fraction of BaP degraded by reaction with ozone and other photo-oxidants from the sampled air during the

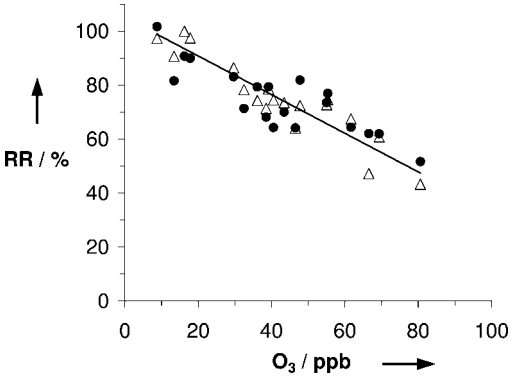

Figure 7.9 Recovery ratio for benzo[*a*]pyrene (BaP) (full circles) and the sum of all particle-bound five- and six-ring US EPA priority PAH pollutants, PAH(5,6) (open triangles), plotted against ambient ozone volume mixing ratio upon filter sampling of urban air particulate matter: measurement data points and linear least-squares fit [1, 110].

sampling process, i.e. the BaP loss by filter reaction sampling artifacts. The BaP recovery ratio is nearly identical with the recovery ratio to the sum of all particle-bound five- and six-ring US EPA priority PAH pollutants, PAH(5,6), and exhibits a negative linear correlation with ambient ozone. It decreases from unity at low ozone to ~0.5 at ~80 ppb O_3, which is a characteristic concentration level for polluted urban air in summer. Similar correlations have been observed in experiments performed at different locations and with different filter sampling and denuder systems [110].

With regard to chemical kinetics, the linear correlation between PAH recovery ratio and O_3 VMR can be attributed to the near-linear dependence of the PAH degradation rate coefficient on O_3 at low VRMs (VMR $\ll$ inverse of effective adsorption equilibrium constant; Figure 7.8) [54, 84, 90, 114]. Moreover, it indicates efficient protection and shielding of the PAH on deposited particles from further decay by coverage with subsequently collected particulate matter (build-up of "filter cake") on time scales similar to the half-life of PAH at the surface. Otherwise, the PAH recovery should be even lower and the ozone concentration dependence should be less pronounced.

In any case, the sampling artifacts observed by Schauer and co-workers and illustrated in Figure 7.9 imply that the real concentrations of particle-bound PAHs in urban air are up to ~100% higher than the measurement values obtained with simple filter sampling systems (without activated carbon diffusion denuder or equivalent equipment) as applied for most atmospheric research and air pollution monitoring purposes [48, 90, 110]. Clearly, other OA components with similar or higher reactivity towards atmospheric oxidants (e.g. alkenes) are also prone to similar or even stronger sampling artifacts, which have to be avoided or at least minimized and quantified for accurate and reliable determination of atmospheric aerosol composition and properties. These and other potential sampling and analytical artifacts caused by reactive transformation of fine air particulate matter have to be taken into account not only in atmospheric and climate research activities, but also in air pollution control. In particular, the control and enforcement of emission limits and ambient threshold level values for OA components which pose a threat to human health (Section 7.4.2) require the development, careful characterization and validation and correct application of robust analytical techniques and procedures [48].

As far as the atmospheric aerosol cycling and feedback loops are concerned (Figures 7.1 and 7.3), chemical aging and oxidative degradation of organics present on the surface and in the bulk generally make aerosol particles more hydrophilic or hygroscopic and enhance their ability to act as a CCN. Besides their contribution to the water-soluble fraction of particulate matter, partially oxidized organics can act as surfactants and influence the hygroscopic growth, CCN and IN activation of aerosol particles (Section 7.3.2).

The chemical reactivity of carbonaceous aerosol components also plays an important role in technical applications for the control of combustion aerosol emissions. For example, the lowering of emission limits for soot and related diesel exhaust particulate matter (DPM) necessitates the development and implementation of efficient exhaust aftertreatment technologies such as diesel particulate filters or particle traps with open deposition structures. These systems generally require

regeneration by oxidation and gasification of the soot deposits in the filter or catalyst structures. Usually the regeneration is based on discontinuous oxidation by O_2 at high temperatures (>500 °C) or continuous oxidation by NO_2 at moderate exhaust temperatures (200–500 °C) [29, 44, 111–113, 125]. Efficient optimization of the design and operating conditions of such exhaust aftertreatment systems requires comprehensive kinetic characterization and mechanistic understanding of the involved chemical reactions and transport processes. Recent investigations have shown that the oxidation and gasification of diesel soot by NO_2 at elevated concentration and temperature levels (up to 800 ppm NO_2 and 500 °C) follows a similar Langmuir–Hinshelwood reaction mechanism as the oxidation of BaP on soot by O_3 at ambient concentration and temperature level (up to 1 ppm O_3 and 30 °C) [29, 90, 125].

7.3.2 Restructuring, Phase Transitions, Hygroscopic Growth and CCN/IN Activation of Aerosol Particles upon Interaction with Water Vapor

Water vapor molecules interacting with aerosol particles can be adsorbed on the particles' surface or absorbed into the particles' bulk. For particles consisting of water-soluble material, the uptake of water vapor can lead to aqueous solution droplet formation and substantial increase of the particle diameter (hygroscopic growth) even at low relative humidities (RH <100%; atmospheric gas-phase water partial pressure < equilibrium vapor pressure of pure liquid water) [10].

At water vapor supersaturation (RH >100%), aerosol particles can act as nuclei for the formation of liquid cloud droplets [cloud condensation nuclei (CCN)]. For the formation of water droplets from a homogeneous gas phase devoid of aerosol particles supersaturations up to several hundred percent would be required (thermodynamic barrier for the homogenous nucleation of a new phase). In the atmosphere, however, water vapor supersaturations with respect to liquid water generally remain below 10% and mostly even below 1%, because aerosol particles induce heterogeneous nucleation, condensation and cloud formation. At low temperatures and high altitudes, clouds consist of mixtures of liquid water droplets and ice crystals or entirely of ice crystals. The formation of ice crystals is also induced by pre-existing aerosol particles, so-called ice nuclei (IN), as detailed below. Ice nucleation in clouds usually requires temperatures well below 0 °C, which can lead to high water vapor supersaturations with respect to ice [10, 126–131].

The minimum supersaturation at which aerosol particles can be effectively activated as CCN or IN is called critical supersaturation. It is determined by the physical structure and chemical composition of the particles and it generally decreases with increasing particle size. For insoluble CCN the critical supersaturation depends on the wettability of the surface (contact angle of liquid water) and for partially or fully soluble CCN it depends on the mass fraction, hygroscopicity and surfactant activity of the water-soluble particulate matter [10, 22, 24, 132, 133].

The nucleation of ice crystals on atmospheric aerosol particles can proceed via different pathways or modes. In the deposition mode, water vapor is adsorbed and immediately converted into ice on the surface of the IN (deposition or sorption

nuclei). In the condensation freezing mode, the aerosol particles act first as CCN and induce the formation of supercooled aqueous droplets which freeze later on (condensation freezing nuclei). In the immersion mode the IN are incorporated into pre-existing aqueous droplets and induce ice formation upon cooling (immersion nuclei). In the contact mode, freezing of a supercooled droplet is initiated upon contact with the surface of the IN (contact nuclei). Obviously, the IN activity of aerosol particles depends primarily on their surface composition and structure, but condensation and immersion freezing can also be governed by water-soluble bulk material [10, 130, 134–140].

Most water-soluble aerosol components are hygroscopic and absorb water to form aqueous solutions at RH <100%. The phase transition of dry particle material into a saturated aqueous solution is called deliquescence and occurs upon exceeding a substance-specific RH threshold value [deliquescence relative humidity (DRH)]. The reverse transition and its RH threshold value are called efflorescence and efflorescence relative humidity (ERH), respectively. The hygroscopic growth and CCN activation of aqueous solution droplets can be described by the so-called Köhler theory, which combines Raoult's law or alternative formulations for the activity of water in aqueous solutions and the Kelvin equation for the dependence of vapor pressure on the curvature and surface tension of a liquid droplet [10, 22, 24, 132, 141–146].

Figure 7.10a shows a typical example of the hygroscopic growth of water-soluble inorganic salts contained in air particulate matter: the hygroscopic growth curve (humidogram) of pure NaCl aerosol particles with dry particle diameters of ~100 nm measured in a hygroscopicity tandem differential mobility analyzer (H-TDMA) experiment at relative humidities up to 95%. Upon hydration (increase in RH), the crystalline NaCl particles undergo a deliquescence transition at DRH ≈ 75%. The water uptake and dependence of the aqueous solution droplet diameter on RH agree very well with Köhler theory calculations, which are based on a semi-empirical ion interaction parameterization of water activity and account for the effects of particle shape transformation (cubic crystals and spherical droplets; mobility and mass equivalent diameters) [141]. The hysteresis branch measured upon dehydration (decrease in RH) is due to the existence of solution droplets in a metastable state of NaCl supersaturation (ERH < RH < DRH). The efflorescence transition, i.e. the formation of a salt crystals and evaporation of the liquid water, occurs at ERH ≈ 40%.

Figure 7.10b displays the hygroscopic growth curve of aerosol particles composed of pure bovine serum albumin (BSA) as a model for globular proteins and similar organic macromolecules. The hygroscopic growth is much less pronounced than for inorganic salts but still significant, with deliquescence and efflorescence transitions at DRH ≈ ERH ≈ 40% (conversion of dry protein particles into saturated aqueous solution or gel-like droplets, v.v.) and no significant deviations between hydration and dehydration (no hysteresis effect). The dependence of the deliquesced particle diameter on RH is in good agreement with Köhler theory calculations based on a simple osmotic pressure parameterization of water activity, which has been derived under the assumption that the dissolved protein macromolecules behave like inert solid spheres [141].

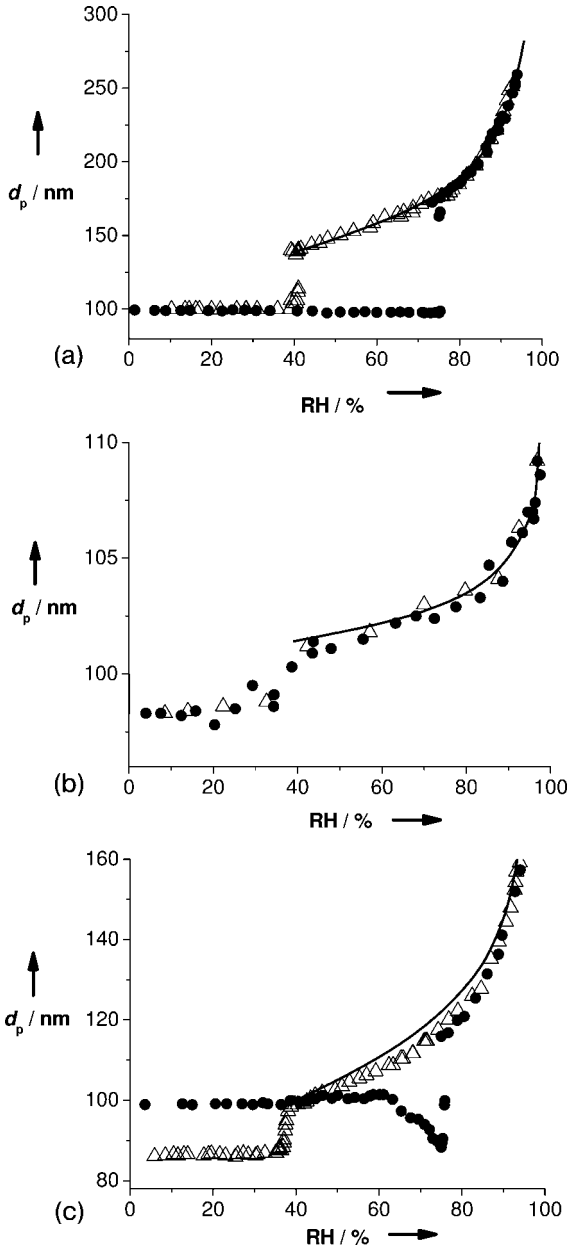

Figure 7.10 Hygroscopic growth curves for pure NaCl salt particles (a), pure BSA protein particles (b) and internally mixed BSA–NaCl protein–salt particles (c): data points measured upon hydration (full circles) and dehydration (open triangles) in H-TDMA aerosol experiments; solid lines represent Köhler theory calculations based on NaCl ion interaction and BSA osmotic pressure parameterizations for water activity [1, 141].

Figure 7.10c shows the hygroscopic growth curve of internally mixed NaCl–BSA particles (mass ratio 1:1) with dry particle diameter of ∼100 nm. The mixed aerosol particles have been generated in full analogy with the pure NaCl and pure BSA particles (nebulization of an aqueous solution). Upon hydration, however, the particles exhibit a significant decrease in the measured (mobility equivalent) diameter as the relative humidity approaches the deliquescence threshold (DRH ≈ 75%). The observed minimum diameter is ∼10% smaller than the initial diameter, indicating high initial porosity of the particles (envelope void fraction ∼30%) and strong restructuring upon humidification. Upon dehydration, the efflorescence threshold is lower than for pure NaCl (ERH ≈ 37% vs. 40%), indicating that the protein macromolecules inhibit the formation of salt crystals and enhance the stability of supersaturated salt solution droplets. The particle diameters observed after efflorescence essentially equal the minimum diameter observed prior to deliquescence. The hygroscopic growth of the deliquesced particles (aqueous solution droplets) is in fair agreement with Köhler theory calculations based on the observed minimum diameter rather than the initial diameter and on the assumption of simple solute additivity (linear combination of NaCl ion interaction and BSA osmotic pressure parameterizations of water activity) [141]. These and complementary measurement and modeling results can be explained by the formation of porous agglomerates due to ion–protein interactions and electric charge effects on the one hand and by compaction of the agglomerate structure due to capillary condensation and surface tension effects on the other.

Depending on their origin and conditioning, aerosol particles containing inorganic salts and organic (macro-) molecules can have complex and highly porous microstructures, which are influenced by electric charge effects and interaction with water vapor. Proteins and other surfactants tend to be enriched at the particle surface and form an envelope which can inhibit the access of water vapor to the particle core and lead to kinetic limitations of hygroscopic growth, phase transitions, CCN and IN activation. Formation and effects of organic surfactant films on sea salt particles have been discussed by O'Dowd *et al.* [147]. These and other effects of (non-linear) interactions between organic and inorganic aerosol components have to be further elucidated and considered for consistent analysis of measurement data from laboratory experiments and field measurements and reliable modeling of atmospheric aerosol processes (Figures 7.1 and 7.3).

Structural rearrangements, hygroscopic growth, phase transitions and CCN/IN activation of aerosol particles interacting with water vapor are not only important for the formation and properties of clouds and precipitation (number density and size of cloud droplets and ice particles; temporal and spatial distribution and intensity of precipitation). They also influence the chemical reactivity and aging of atmospheric particles (accessibility of particle components to reactive trace gases and radiation), their optical properties (absorption and scattering cross-sections) and their health effects upon inhalation into the human respiratory tract (deposition efficiency and bioavailability). Therefore, the water interactions of particles with complex chemical composition are widely and intensely studied in current aerosol, atmospheric and climate research. So far, however, their mechanistic and quantitative

understanding are still rather limited, especially with regard to carbonaceous components [5, 10, 21, 24, 25, 130, 146, 148–153].

7.4 Climate and Health Effects

Anthropogenic emissions are major sources of atmospheric aerosols. In particular, the emissions of particles and precursor gases from biomass burning and fossil fuel combustion have increased massively since pre-industrial times and account for a major fraction of fine air particulate matter in polluted urban environments and in the global atmosphere (carbonaceous components, sulfate, etc.) [3, 4, 6, 11, 154–160]. Numerous studies have shown that both natural and anthropogenic aerosols have a strong impact on climate and human health. Due to the limited knowledge of aerosol sources, composition, properties and processes outlined above, however, the actual effects of aerosols on climate and health are still far from being fully understood and quantified.

Aerosol effects on climate are generally classified as direct or indirect with respect to radiative forcing of the climate system. Radiative forcings are changes of the energy fluxes of solar radiation (maximum intensity in the spectral range of visible light) and terrestrial radiation (maximum intensity in the infrared spectral range) in the atmosphere, induced by anthropogenic or natural changes in atmospheric composition, the Earth's surface properties or solar activity. Negative forcings such as the scattering and reflection of solar radiation by aerosols and clouds tend to cool the Earth's surface, whereas positive forcings such as the absorption of terrestrial radiation by greenhouse gases and clouds tend to warm it (greenhouse effect) [4].

The optical properties relevant for the direct effects (scattering and absorption coefficient or extinction cross section and single scattering albedo, etc.) and the CCN, IN, chemical and biological activities relevant for indirect effects are determined by aerosol particle size, structure and chemical composition. Hence they are strongly influenced by the atmospheric processes outlined above (coagulation, chemical transformation, water interactions). Consequently, the actual climate system responses and feedbacks to natural or anthropogenic perturbations such as industrial and traffic-related greenhouse gas and aerosol emissions, volcanic eruptions, etc., are highly uncertain. In many cases, even the sign or direction of the feedback effect is unknown, i.e. it is not clear whether a perturbation will be reinforced (positive feedback) or damped (negative feedback) [1].

Numerous epidemiological studies have shown that fine air particulate matter and traffic-related air pollution are correlated with severe health effects, including enhanced mortality, cardiovascular, respiratory and allergic diseases [7, 161–164]. Moreover, toxicological investigations *in vivo* and *in vitro* have demonstrated substantial pulmonary toxicity of model and real environmental aerosol particles, but the biochemical mechanisms and molecular processes which cause the toxicological effects like oxidative stress and inflammatory response have not yet been resolved. Among the parameters and components potentially relevant for aerosol health effects

Table 7.3 Possible mechanisms by which aerosol particles and other air pollutants may cause adverse health effects (based on Bernstein *et al.* [7]).

(a)	Pulmonary inflammation induced by PM or O_3
(b)	Free radical and oxidative stress generated by transition metals or organic compounds (e.g. PAHs)
(c)	Covalent modification of key intracellular proteins (e.g. enzymes)
(d)	Inflammation and innate immune effects induced by biological compounds such as endotoxins and glucans
(e)	Stimulation of nocioreceptor and autonomic nervous system activity regulating heart rate variability and airway reactivity
(f)	Adjuvant effects in the immune system (e.g. DPM and transition metals enhancing responses to common environmental allergens)
(g)	Procoagulant activity by ultrafine particle accessing the systemic circulation
(h)	Suppression of normal defense mechanisms (e.g. suppression of alveolar macrophage functions)

are the specific surface, transition metals and organic compounds [7, 165–167]. Some of the possible mechanisms by which air particulate matter and other pollutants may affect human health are summarized in Table 7.3.

Ultrafine particles ($d_p < 100$ nm) are suspected to be particularly hazardous to human health, because they are sufficiently small to penetrate the membranes of the respiratory tract and enter the blood circulation or be transported along olfactory nerves into the brain [168–170]. Neither for ultrafine nor for larger aerosol particles, however, is it clear which physical and chemical properties actually determine their adverse health effects (particle size, structure, number and mass concentration, solubility, chemical composition and individual components, etc.).

Particularly little is known about the relations between allergic diseases and air quality. Nevertheless, traffic-related air pollution with high concentration levels of fine air particulate matter, nitrogen oxides and ozone is one of the prime suspects, besides unnatural nutrition and exaggerated hygiene, which may be responsible for the strong increase in allergies in industrialized countries over recent decades [7, 171–173]. The most prominent group of airborne allergens are protein molecules, which account for up to ~5% of urban air particulate matter. They are not only contained in coarse biological particles such as pollen grains (diameter >10 μm) but also in the fine fraction of air particulate matter, which can be explained by fine fragments of pollen, microorganisms or plant debris and by mixing of proteins dissolved in rain water with fine soil and road dust particles [69, 72, 174].

A molecular rationale for the promotion of allergies by traffic-related air pollution has been proposed by Franze and co-workers [72, 73], who found that proteins including birch pollen allergen Bet v 1 are efficiently nitrated by polluted urban air. The nitration reaction converts the natural aromatic amino acid tyrosine into nitrotyrosine and proceeds particularly fast at elevated NO_2 and O_3 concentrations (photo-smog or summer smog conditions), most likely involving nitrate radicals (NO_3) as reactive intermediates. From biomedical and immunological research, it is

known that protein nitration occurs upon inflammation of biological tissue, where it may serve to mark foreign proteins and guide the immune system. Moreover, conjugates of proteins and peptides with nitroaromatic compounds were found to evade immune tolerance and boost immune responses and post-translational modifications generally appear to enhance the allergenicity of proteins [72]. Thus the inhalation of aerosols containing nitrated proteins or nitrating reagents is likely to trigger immune reactions, promote the genesis of allergies and enhance the intensity of allergic diseases and airway inflammations. This hypothesis is supported by first results of ongoing biochemical experiments with nitrated proteins [175].

By means of newly developed enzyme immunoassays, nitrated proteins have been detected in urban road and window dust and fine air particulate matter, exhibiting degrees of nitration up to 0.1%. Upon exposure of birch pollen extract to heavily polluted air at a major urban traffic junction and to synthetic gas mixtures containing NO_2 and O_3 at concentration levels characteristic of intense summer smog, the degrees of nitration rose by up to 20%. The experimental results indicate that Bet v 1 is more easily nitrated than other proteins, which might be an explanation for why it is a particularly strong allergen [72]. If the ongoing biochemical experiments and further studies confirm that protein nitration by nitrogen oxides and ozone is indeed an important link between air pollution, airway inflammations and allergies, the spread and enhancement of these diseases could be encountered by the improvement of air quality and reduction of emission limits for nitrogen oxides and other traffic-related air pollutants. Moreover, it might be possible to develop pharmaceuticals against the adverse health effects of nitrated proteins.

Efficient control of air quality and related health effects requires a comprehensive understanding of the identity, sources, atmospheric interactions and sinks of hazardous pollutants. Without this understanding, the introduction of new laws, regulations and technical devices for environmental protection runs the risk of being ineffective or even of doing more harm than good through unwanted side-effects.

For example, epidemiological evidence for adverse health effects of fine and ultrafine particles has led to a lowering of present and future emission limits for soot and related DP [29, 113, 170, 176–178]. For compliance with these emission limits, different particle filter or trapping and exhaust aftertreatment technologies have been developed and are currently being introduced in diesel vehicles. Depending on the design of the particle filter or trap and catalytic converter systems, their operation can lead to substantial excess NO_2 emissions [29, 125]. If, however, elevated NO_2 concentrations and the nitration of proteins indeed promote allergies, such systems could reduce respiratory and cardiovascular diseases related to soot particles but at the same time enhance allergic diseases. Moreover, elevated NO_2 concentrations and incomplete oxidation of soot in exhaust filter systems could also increase the emissions of volatile or semi-volatile hazardous aerosol components such as nitrated PAH derivatives [31, 48]. Hence effective mitigation of the adverse health effects of diesel engine exhaust may require the introduction of advanced catalytic converter systems which minimize the emissions of both particulate and gaseous pollutants (soot, PAHs and PAH derivatives, nitrogen oxides, etc.) rather than simple particle filters.

In any case, comprehensive investigations and understanding and control of aerosol health effects need to consider both the particulate and gaseous components of aerosols in addition to their chemical reactivity and aging [48].

7.5 Summary and Outlook

Scientific investigations of and reports on atmospheric aerosols date back as long as to the 18th century and since then it has become increasingly clear that aerosol particles are of major importance for atmospheric chemistry and physics, the hydrological cycle, climate and human health [179]. Motivated by global change and adverse health effects of traffic-related air pollution, aerosol research activities have been increasingly extended and intensified over the past couple of decades [1].

These activities have led to a fairly comprehensive conceptual understanding of atmospheric aerosol sources, composition, properties, interactions and effects on climate. The parameters required for a quantitative description of the underlying physicochemical processes, however, are generally still uncertain by factors of two or more, which implies order of magnitude uncertainties for most effects involving multiple competitive or sequential processes. In some cases such as particle nucleation and reactive gas uptake, even the basic parameters are uncertain by orders of magnitude. Consequently, model calculations of atmospheric aerosol effects on future climate have to be regarded as sensitivity studies with more or less reliable qualitative and semi-quantitative results and implications rather than reliable quantitative predictions. In particular, interactions and feedback responses between aerosols and clouds, the hydrological cycle and the biosphere are difficult to quantify with the currently available information. Regardless of the rapid increase in numerical simulation capacities, this situation can hardly change before the basic physicochemical processes and properties of atmospheric aerosol particles have been elucidated to an extent comparable to the present state of knowledge of atmospheric gas-phase chemistry (universally applicable and validated master mechanisms, rate coefficients and structure–reactivity relationships, etc.).

Outstanding open questions and research aims for the elucidation of aerosol effects relevant for the science and policy of global change have been outlined in several recent monographs, reviews and research articles [4, 5, 23, 49, 50, 54]. Among these are the quantification, mechanistic elucidation and kinetic characterization of the following processes: formation of new particles and secondary organic aerosols; emission of primary organic aerosol components and black or elemental carbon; aging and deposition of aerosol particles; activation of cloud condensation and ice nuclei. As far as chemical transformation, heterogeneous and multiphase reactions and gas–particle interactions of aerosols and clouds are concerned, one of the most important prerequisites for efficient further investigation and scientific progress is the establishment of a common basis of consistent, unambiguous and universally applicable terminologies, model formalisms and kinetic and thermodynamic parameters.

With regard to atmospheric aerosol effects on human health, not only the quantitative but also the qualitative and conceptual understanding are very limited. Epidemiological and toxicological studies indicate strong adverse health effects of fine and ultrafine aerosol particles (nanoparticles) in addition to gaseous air pollutants, but the causative relations and mechanisms are hardly known [7, 164]. Their elucidation, however, is required for the development of efficient strategies of air quality control and medical treatment of related diseases, which permit the minimization of adverse aerosol health effects at minimum social and economic cost.

Particularly little is known about the relations between allergic diseases and air pollution and the interactions between natural aeroallergens and traffic-related pollutants. Several studies have shown synergistic and adjuvant effects of diesel particulate matter, O_3, NO_2 and allergenic pollen proteins, but the specific chemical reactions and molecular processes responsible for these effects have not yet been unambiguously identified. Recent investigations indicate that the nitration of allergenic proteins by polluted air may play an important role. Nitrated proteins are known to stimulate immune responses and they could promote the genesis of allergies, enhance allergic reactions and influence inflammatory processes, which is confirmed by the results of ongoing biochemical investigations [72, 175].

For efficient elucidation and abatement of adverse aerosol health effects, the knowledge of atmospheric and biomedical aerosol research should be integrated to formulate plausible hypotheses that specify potentially hazardous chemical substances and reactions on a molecular level. These hypotheses have to be tested in appropriate biochemical and medical studies, to identify the most relevant species and mechanisms of interaction and to establish the corresponding dose–response relationships. Ultimately, the identification and characterization of hazardous aerosol components and their sources and sinks (emission, transformation, deposition) should allow the optimization of air pollution control and the medical treatment of aerosol effects on human health.

List of Abbreviations, Acronyms and Symbols

asl	above sea level
BaP	benzo[*a*]pyrene
BC	black carbon
BSA	bovine serum albumin
CCN	cloud condensation nucleus
d_p	particle diameter
$dN/d\log d_p$	particle number size distribution function
DPM	diesel exhaust particulate matter
DRH	deliquescence relative humidity
EC	elemental carbon
ELPI	electrical low-pressure impactor
EPA	Environmental Protection Agency
ERH	efflorescence relative humidity

HC	hydrocarbon
H-TDMA	hygroscopicity tandem differential mobility analyzer
HULIS	humic-like substances
IN	ice nucleus
k_1	(pseudo-) first-order rate coefficient
LVOC	low-volatility organic compound
MWSOC	macromolecular water-soluble organic carbon
NVOC	non-volatile organic compound
OA	organic aerosol
OC	organic carbon
OPM	organic particulate matter
PAH	polycyclic aromatic hydrocarbon
PAH(5,6)	polycyclic aromatic hydrocarbons consisting of five or six aromatic rings
PM	particulate matter
$PM_{2.5}$ (1 or 10)	particulate matter of particles with aerodynamic diameters $\leq$2.5 μm (1 or 10 μm)
POA	primary organic aerosol
PRA	Pöschl, Rudich and Ammann
RH	relative humidity
RR	recovery ratio
SMPS	scanning mobility particle sizer
SOA	secondary organic aerosol
SVOC	semi-volatile organic compound
TC	total carbon
UV	ultraviolet
VMR	volume mixing ratio
VOC	volatile organic compound
WSOC	water-soluble organic carbon

Measurement and Detection of Nanoparticles Within the Environment

Thomas A.J. Kuhlbusch, Heinz Fissan, and Christof Asbach

8.1
Introduction

Nanotechnology opens up opportunities for new and improved products and needs tailored production tools. Nanoparticles are one of the most important building blocks, for example to develop new or improved materials, allow for higher catalytic efficiencies or reduce energy and material consumption.

Nanoparticles (NPs) are defined in this chapter as intentionally produced particles for use in products either as single particles or as agglomerates with diameters below 100 nm. Another term often used is ultrafine particles (UFPs, Figure 8.1). Ultrafine particles in this chapter denote particles in the environment which at least partially consist of unintentionally produced and/or naturally formed particles. Nanoparticles are normally solid particles whereas naturally and unintentionally manmade particles may be of solid or liquid nature. Even though particles in the sub-100-nm range can be differentiated into nanoparticles and UFPs, the measurement and detection techniques are fundamentally the same.

Figure 8.2 shows the relative scale of natural and manmade materials. This figure shows that nanoparticles are about one hundredth the size of a blood cell. The small size of nanoparticles is actually one of the important characteristics which give the free, unbound particles a generally high mobility. Particles of sizes below 100 nm are within the size of the pores of cells and hence may penetrate into cells, the blood or even end organs such as the brain [1]. Whether this may happen or is of relevance to health is still under debate and not a topic of this chapter.

Nanoparticles are mainly defined by their particle diameter being <100 nm. Other specific properties related to nanoparticles and possible concentration metrics are listed in Table 8.1.

The overview of possible particle properties of interest in view of nanoparticle effects on humans, animals and plants in Table 8.1 is not exclusive and only indicates the complexity with which nanoparticles may interact with the environment. The list of concentration metrics (Table 8.1) again is not exclusive but indicates that it is

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

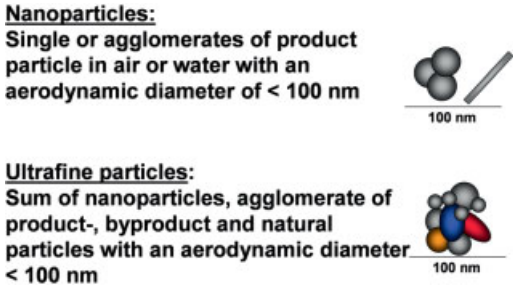

Figure 8.1 Particle definitions.

possible to use different metrics for the quantitative investigation of exposure, dose and effects. More detailed information on how the above properties are related to particle-induced negative health effects and the detection of particles in different tissues is given elsewhere [2–4].

The specific properties listed in Table 8.1 may also be used for the measurement and detection of nanoparticles in the environment.

Another issue illustrated in Figure 8.2 also is that natural and manmade nanosized particles co-exist. The properties listed in Table 8.1 may be used to determine, measure and quantify nanoparticles, but the methods generally do not differentiate manmade nanoparticle and other nanosized particles. One of the major tasks of measuring and detecting nanoparticles in the environment is the differentiation between UFPs and nanoparticles. A simple differentiation may even not be enough since a nanoparticle being attached to a larger particle will lose some of its properties, especially its size and hence its mobility. Therefore, generally three kinds of particles below 100 nm have to be differentiated.

- nanoparticles and their agglomerates (type 1)
- by-product and unintentionally produced (type 2), in addition to
- natural particles (type 3)
- mixtures of type 1 nanoparticles with type 2 or type 3 particles.

One further issue when discussing nanoparticles in the environment is the stability of nanoparticle agglomerates and agglomerates of nanoparticles with type 2 or 3 particles being larger than 100 nm. The nanoparticles will have lost their

Table 8.1 Possible nanoparticle properties and concentration metrics of interest.

Particle property	Concentration metric
Shape/morphology	Mass concentration
Chemical composition	Surface area concentration
Hygroscopicity	Number concentration
Solubility	Size distribution <100 nm

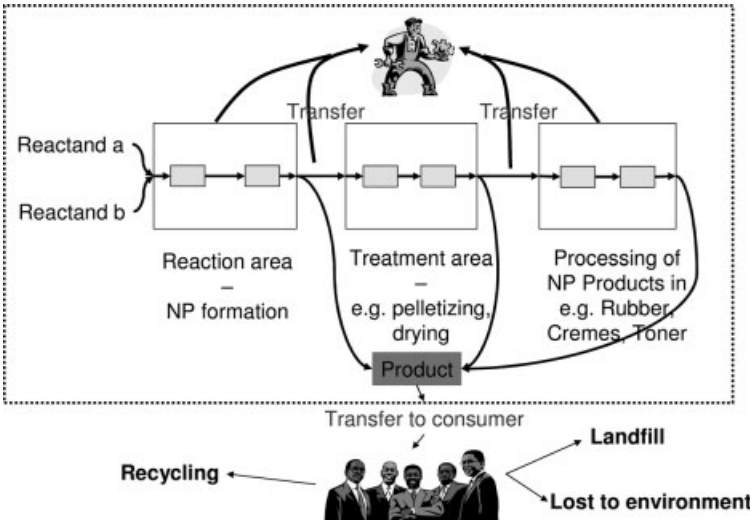

Figure 8.3 The lifecycle of nanoparticles [4].

specific nanoparticle properties but may recover some of their properties when released from the agglomerate after uptake in plants, animals or humans. This issue being specifically related to toxicology will not be further discussed here but leads to the discussion of the measurement techniques that may also include particle sizes up to about 400 nm. Still, it should be noted that to our knowledge no release of nanoparticles from agglomerates has yet been demonstrated under conditions after, for example, uptake of agglomerates in lungs.

A further point of discussion related to the detection and measurement of nanoparticles in the environment is shown in Figure 8.3. This figure shows the lifecycle of nanoparticles from production, handling and processing to the stage where they are used in products, for example for consumers, and finally to recycling, deposition in landfills or other processes. The life cycle is shown to indicate possible release of nanoparticles into the environment. They may be released during the production, handling (e.g. packing), handling during nanoparticle processing (e.g. use of carbon black nanoparticles during tire production) or use of products (e.g. paint containing nanoparticles sprayed onto surfaces).

Emissions from products containing bound nanoparticles in a fixed matrix such as carbon black in plastics of computers or in tires can generally be imagined but are not likely and cannot yet be detected. Hence the release of nanoparticles from products containing nanoparticles in a fixed matrix can be neglected, as was announced, for example, in Californian Proposition 65 [5] for carbon black. Detection of nanoparticles in most of these fixed matrices in the environment is nearly impossible.

The environment and environmental matrix containing nanoparticles are also of crucial importance for the detection and measurement of nanoparticles. Generally three matrices can be differentiated in the environment: soils, water and air. These three matrices differ not only in their physical state (solid, liquid and gas) but also in their mobility, increasing from soils to air. This mobility and the

mobility of nanoparticles dissolved in these matrices are of great importance when assessing the risk.

Figure 8.3 also differentiates workplace and public environment exposure. Possible emissions and consequently higher concentrations of nanoparticles in the environmental matrices will more likely be in work and plant areas of nanoparticle production than in the public environment. Another difference between public and workplace environments are the possible temporal changes in nanoparticle concentrations. The variance over time will be higher closer to the sources, and hence in workplace and plant areas. Therefore, the workplace and public environments are discussed separately for some cases.

8.2 Occurrence of Nanoparticles in Environmental Media

Mainly two different environments can be differentiated when discussing nanoparticles: the ambient environment and plants or workplaces in nanoparticle production, handling and processing. The environmental media in which nanoparticles may occur are the same, but the media soil and water will only be discussed for the ambient, public environment since the information given there is also valid for the work environment.

8.2.1 Ambient Environment

8.2.1.1 Water and Soils

Nanoparticles may reach waters, either by intentional use for remediation [6] or after unintentional release during/after production and subsequent wash-off. nanoparticles may also be released to water when they are produced via the liquid phase and leaks occur or the effluent is not sufficiently cleaned up. Once suspended in the liquid phase, nanoparticles will likely attach to other particles or to surfaces such as those of sand grains. No information on transport distances and the spatial distribution of nanoparticles in waters is currently available, to our knowledge.

Soils may become contaminated by nanoparticles by airborne deposition, deposition from the water phase or by direct deposition of powders and fluids, either intentionally or unintentionally. No systematic differences are made between soils and sediments in this chapter, since no information on differences in the behavior and the determination of nanoparticles is currently available.

Once nanoparticles are attached to soil surfaces, three ways of possible (re)mobilization of nanoparticles can be differentiated: (a) transport by water through the soils to the groundwater, (b) uptake by plants via roots and (c) wind erosion of soil particles containing nanoparticles.

No studies investigating the uptake of nanoparticles by plants are currently available. Lecoanet and Wiesner [7] stated that nanosized particles do not move far under environmental conditions. It was shown that the mobility of nanoparticles

correlates with size, with smaller nanosized particles being easily adsorbed on surfaces of sand grains and therefore immobilized. Biological transport may still occur from ingested sediments, but the physical movement of nanosized materials is restricted by their small size and propensity to adsorb on surfaces.

Nevertheless, taking the example of fullerenes, it could be demonstrated that the mobility of nanoparticles in water and soils is also strongly dependent on their physical–chemical properties. The mobility and behavior of three different fullerene solutions and four different oxidized materials was shown to be highly variable when changing ionic strength and pH values [7, 8]. While common models of particle transport through porous media described the behavior of mineral nanoparticles fairly well, the behavior of the fullerenes could not be modeled. Especially the latter component was found in brains of artificially exposed fish, where it induced oxidative stress [9]. Fullerenes, on the other hand, showed the lowest mobility of the substances tested, reducing the likelihood of exposure. This example demonstrates the need for knowledge of the mobility of nanoparticles.

So far, no studies have been conducted, to our knowledge, to determine nanoparticles in environmental media outside plants or experimental sites. This lack of current knowledge may be due to the low concentrations of nanoparticles in waters and soils, which make detection and quantification nearly impossible. Still, with increasing use of mobile nanoparticles, it may become important and should not be neglected in the future.

8.2.1.2 **Air**

The main matrix studied for the transport of nanoparticles so far is the air. This focus on air has several reasons, all related to the implications and use of particles in general. Some of the most important uses and effects of particles include the industrial production of particles (carbon black, titanium dioxide, etc.), horizontal dispersion in the atmosphere [10], climatic implications [11], cloud nucleation [12, 13], transport of nutrients [14] and health effects [15].

Another important reason is the high mobility of nanoparticles and UFPs in air, leading to a wide dispersion of these particles in our atmosphere. UFP number concentrations in ambient air may vary from a few hundred to over 10^5 particles per cubic centimeter, depending on the distance to sources such as incomplete combustion [16], but are determined anywhere in the Earth's atmosphere.

These UFPs are not due to nanoparticles but are mainly due to unintentionally manmade emissions in addition to natural emission. The occurrence of UFPs long before the intentional production of nanoparticles, their high mobility and ubiquitous presence and their implications for the environment and health led to the development of various measurement devices and to innumerable studies.

8.2.2
Workplace Environment

No studies investigating nanoparticle concentrations in soils and/or waters in workplaces and plant areas are known to the authors. Up to now, only very few

studies, measuring airborne nanoparticles and UFPs in workplace environments, have been published [17–19]. Sources of these small particles have to be differentiated at workplaces when detecting and measuring nanoparticles. High concentrations of particles smaller than 100 nm are commonly detected in welding and soldering workplaces or other workplaces where diesel forklifts are running. However, these particles are not termed nanoparticles since they are not intentionally produced. These are unintentional byproducts of a process or a work activity and are therefore classified as UFPs.

Nanoparticle release may occur during the production, handling and/or processing of nanoparticles. First measurements in work areas showed no detectable release of nanoparticles during normal handling and processing [17]. Nevertheless, on one occasion a leak in the production line occurred and high concentrations of nanoparticles (>100 000 cm^{-3}) were released into the work environment [19].

8.3 Nanoparticle Detection and Measurement Techniques

8.3.1 Soil

Basically no specific detection techniques for nanoparticles in soils are known. The only applicable method is the preparation of soil samples for analysis by transmission electron microscopy (TEM) coupled with, for example, energy-dispersive X-ray (EDX) analysis for the detection of nanoparticles of known chemical composition.

8.3.2 Water and Liquids

Nanoparticles can be produced in water but the detection, identification and size measurements of nanoparticles in water are still not as advanced as for airborne particles. One generally feasible way of determining nanoparticles is the filtration of waters and fluids with subsequent analysis of the deposited particles by microscopy [TEM, scanning electron microscopy (SEM), atomic force microscopy (AFM)]. This off-line technique permits the determination of nanoparticles down to diameters of a few nanometers.

No on-line technique for measurements down to a few nanometers is currently available.

8.3.2.1 Coulter Counter

The Coulter principle (electrical sensing zone method) is a widely used method for particle size analysis in liquids and is the recommended limit test for particulate matter in large-volume solutions. It sizes and counts particles based on measurable changes in electrical resistance produced by nonconductive particles suspended in an electrolyte. Suspended particles pass through the sensing zone consisting of a small

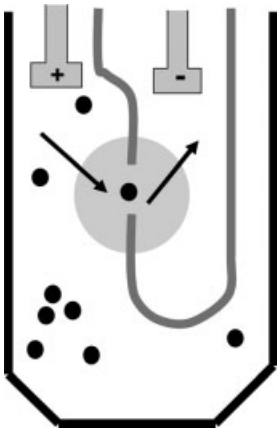

Figure 8.4 Principle setup of a Coulter Counter (Adapted from Beckman Coulter [52]).

opening (aperture) between the electrodes (Figure 8.4). Particles displace their own volume of electrolyte in the sensing zone, which is then measured as a voltage pulse. The height of each pulse is proportional to the particle volume and the number of pulses per unit time is proportional to the concentration during constant-volume flow. Several thousand particles per second can individually be counted and sized and this information is converted to particle size distributions. This method is according to its principle independent of particle shape, color and density. The detectable particle size range of the Coulter Counter extends from about 300 nm to 1200 μm, and hence not applicable to nanoparticles but to their larger agglomerates.

8.3.2.2 **Light Scattering**

Another principle in use for the detection of particles in liquids is based on light scattering. Gas molecules and atmospheric particles are smaller than the wavelengths of visible light. When light hits a gas molecule, the molecule absorbs and scatters the light in different directions. This is why a beam of a torch can be seen, for example, at night even from outside the light's path. The different colors of light are scattered differently after collision. The scattering is called Rayleigh scattering.

One of the scattering measurement techniques used for liquids is dynamic light scattering (DLS), which permits measurements of particle sizes from 2 nm to 6 μm. DLS measures the intensity fluctuations of scattered light by Brownian motion. The Brownian motion of the particles causes a Doppler shift in the incident light frequency. The magnitude of the frequency shift is related to the frequency of the Brownian motion, which on the other hand is directly related to the size of the particles.

The backscattered light (angle about 160–180° of incident light) is most commonly used for the detection and measurement of nanoparticles and their size distribution, since multiple scattering effects can be reduced and solutions with higher concentrations measured because the light does not have to go through the whole sample (Figure 8.5).

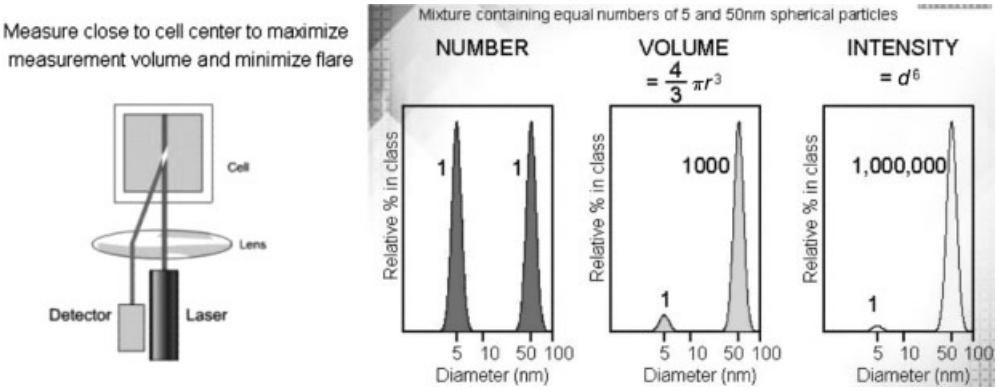

Figure 8.5 Instrumentation setup for the detection of nanoparticles in liquids by dynamic light scattering and example size distribution from Zetasizer Nano ZS90 (Rework, taken from Malvern Instruments).

A slightly different technique is also based on the illumination of particles. The viewing module of the instrument (Nanosight LM 10), in combination with a standard light microscope, uses an He–Ne laser light source to illuminate nanoscale particles. Enhanced by a near-perfect black background, particles appear individually as point scatterers, moving under Brownian motion. The tracking of individual nanoparticles and their Brownian motion in addition to the independently recorded scattering intensity is used for particle sizing by this instrument (diameter 15–500 nm). An example of the particle images is given in Figure 8.6.

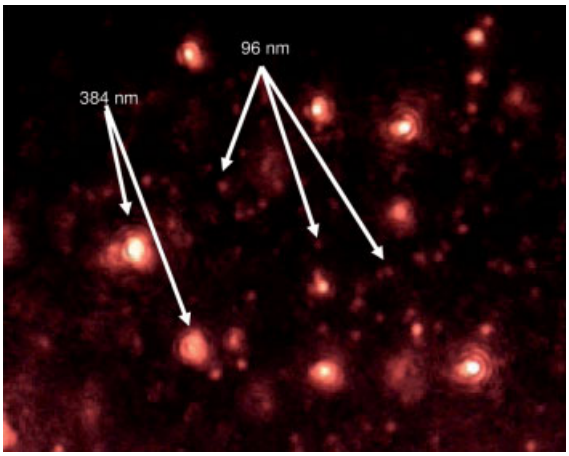

Figure 8.6 A bimodal system of 96- and 384-nm polystyrene reference spheres in water (picture: courtesy of Nanosight, UK).

8.3.3 Air

8.3.3.1 Basics

This section explains some of the basic particle and aerosol properties which are necessary to understand the measurement techniques discussed thereafter.

Mechanical Mobility The terminal settling velocity of a particle can be viewed as the velocity of a particle being released in still air undergoing gravitational settling (e.g. [20]). The terminal velocity can be calculated by a force balance, where the sum of drag force F_D and gravitational force F_G is zero:

$$F_D = F_G = mg \tag{8.1}$$

$$\frac{3\pi\eta V d}{C_C} = \frac{(\rho_p - \rho_g)\pi d^3 g}{6} \tag{8.2}$$

where η is the viscosity of air, V the particle velocity, d the particle diameter, ρ_p the particle density, ρ_g the density of the gas and g the acceleration relative to the gas due to gravity. C_C is the dimensionless Cunningham slip correction factor, which takes into account that the motion of submicrometer particles is affected by interaction with single molecules [21, 22]. C_C increases with decreasing particle diameter and approaches 1 for particle diameters above 1 µm:

$$C_C = 1 + \frac{2\lambda}{d_p}\left[\alpha + \beta \exp\left(-\frac{\gamma d_p}{2\lambda}\right)\right] \tag{8.3}$$

where λ is the mean free path of the gas molecules, $\alpha = 1.165$, $\beta = 0.483$ and $\gamma = 0.997$ are empirical constants [23].

Generally ρ_g is much smaller than ρ_p and hence can be neglected. Equation (8.2) can now be solved for the terminal settling velocity V_{TS} as used, for example, for the definition of equivalent diameters.

$$V_{TS} = \frac{\rho_p d^2 g C_C}{18\eta} \tag{8.4}$$

Stokes law, which describes the total resisting force on a spherical particle due to its velocity V relative to the fluid, can also be transformed to

$$F_D = \frac{3\pi\eta V d}{C_C} \Rightarrow B = \frac{V}{F_D} = \frac{C_C}{3\pi\eta d} \tag{8.5}$$

where B denotes the mechanical mobility of a particle. The equation now expresses the particle mobility or velocity per unit force B.

The terminal settling velocity V_{TS} [Equation (8.4)] can now be rewritten as

$$V_{TS} = F_G B \tag{8.6}$$

Equivalent Diameter The morphology of airborne particles can vary over a wide range, from spherical to needle-like in shape, from single particles to agglomerates. The latter denote small particles attached to each other by strong or weak bonds. Agglomerates usually exhibit irregular shapes with any fractal dimensions. This variance in morphology prevents easy comparisons and necessitates the use of particle models. The most commonly used models in aerosol measurement are based on equivalent spheres. One concept is the assumption of equal settling velocity of particles. In this model, each irregularly shaped particle is assigned an equivalent diameter of a sphere with the same terminal settling velocity as given in Equations (8.4) and (8.6). If the equivalent sphere is assumed to have the same density ρ_p as the irregularly shaped particle, it is referred to as the Stokes diameter d_{st}, whereas if unit density (1 g cm^{-3}) is assumed as density for the sphere, the diameter is referred to as the aerodynamic diameter d_{ae}.

This concept of equivalent diameters now allows the comparison of particles of different shape and density (Figure 8.7). Stokes and aerodynamic particle diameter can be exchanged using the following equation:

$$d_{ae} = d_{st}\sqrt{\frac{\rho_p}{\rho_0}} \tag{8.7}$$

Inertia (Impactor, Cyclone) One common principle used in aerosol measurements is the fractionation of particles according to their size by using the differences of the particle inertia. For the sake of simplicity, only impaction is discussed in more detail.

Impactors are used to remove particles of a given size from an aerosol; for example, impaction as a separation technique is used in environmental standards as a separator to remove particles larger than 10 µm d_{ae} or 2.5 µm d_{ae} (EN12341, EN14907) from the aerosol. The impaction principle is based on the acceleration of the aerosol in a nozzle and the direction of the outflow out of the nozzle onto a flat plate, called impaction plate. The flow is deflected by 90° by the impaction plate and particles above a certain size cannot follow the gas flow due to inertia and are deposited on the impaction plate. This is also exemplarily shown in Figure 8.8. It can be noted that the

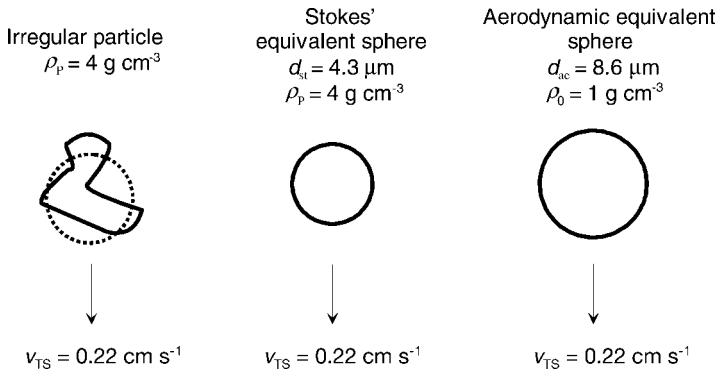

Figure 8.7 An irregular particle and its equivalent spheres (Adapted from [20]).

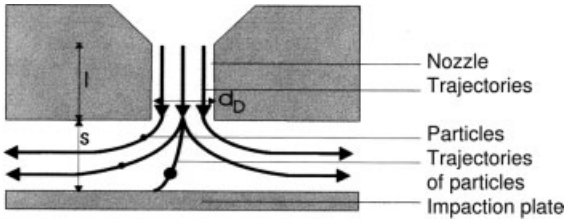

Figure 8.8 Schematic of an impactor (Adapted from [20]).

deposition of particles by impaction in the human lungs are in accordance to the aerodynamic particle equivalent diameter.

The cut-off sizes of any separating device, as for the impactor, is not a step function meaning that all particles >10 µm d_{ae} will be impacted and that all particles <10 µm d_{ae} will pass the impactor. The cut-off curve more or less has an S-shape (Figure 8.9) which is for example due to the finite dimensions of the impactor since the impaction probability is also dependent on whether the particle was released from the middle of the nozzle or the edge. The cut-off, also often called $d_{p,50}$, is therefore generally defined as the diameter at which 50% of the particles are deposited and 50% will pass the impactor.

The following equation can be used to calculate the cut-off size for a single-stage round nozzle impactor:

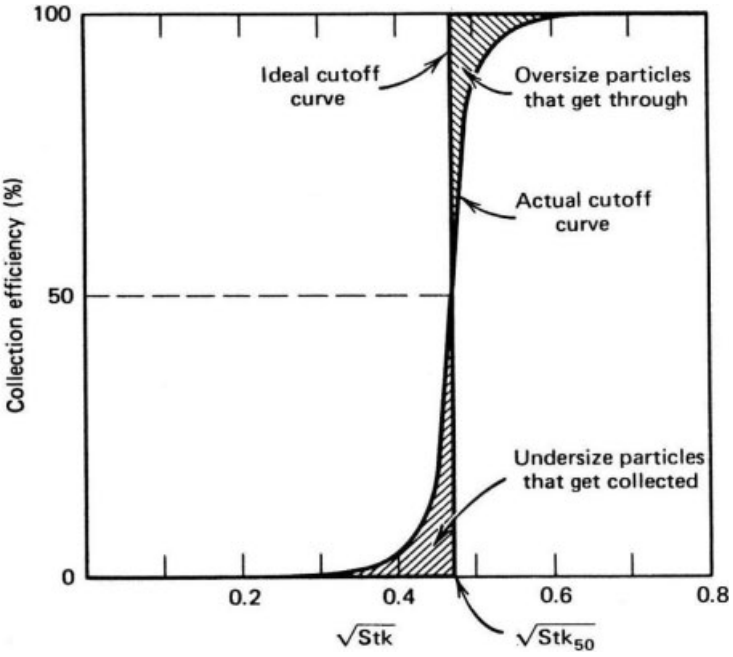

Figure 8.9 Collection efficiency curves (Adapted from [20]).

$$d_{P,50} = \sqrt{\frac{9\pi Stk_{50}\eta N d^3}{4\rho_P C_C \bar{V}}} \tag{8.8}$$

where η = viscosity of air, ρ_P = particle density, Stk_{50} = Stokes number, d = nozzle diameter, $\bar{V}$ = volumetric flow rate through impactor, N = number of nozzles and C_C = Cunningham correction factor (see Equation 8.3), also slip correction factor.

Equation (8.8) is only applicable within following limits:

- *Ratio of nozzle–impaction plate distance to nozzle diameter.* The ratio of the distance from the nozzle to the impaction plate (s) to the nozzle diameter (d_n) should be in the range $0.5 \leq s/d_n \leq 5.0$.
- *Ratio nozzle length to nozzle diameter.* The ratio of nozzle length (l) to nozzle diameter (d_D) should be in the range $0.25 \leq l/d_D \leq 2.0$. These limits ensure a homogeneous flow pattern at the exit of the nozzle, meaning the same velocity anywhere at the nozzle exit. The flow pattern will not have been well developed if the ratio is too small ($l/d_D < 0.25$) whereas distinct velocity profiles have developed with lower velocities at the edge compared with the middle of the nozzle if ratio is to large ($l/d_D > 2.0$).
- *Reynolds number.* The Reynolds number should be in the range 40–3000 to ensure laminar flow conditions.

Low-pressure conditions are necessary to allow sampling of nanoscale particles with the principle of impaction [24].

Electrical Mobility When an electric field acts upon a charged particle suspended in a gas, the particle becomes accelerated until it reaches its terminal electric migration velocity. The terminal velocity is a characteristic value for particles within a given electric field strength, which is exploited in several measurement techniques [25], such as in electrostatic classification. The ratio of the terminal migration velocity v_e and the electric field strength E is usually referred to as the 'electrical mobility' Z_p of a particle [20]:

$$Z_p = \frac{v_e}{E} \tag{8.9}$$

The electrical mobility thus expresses the ability of a charged particle to move within an electric field. This ability is dependent upon the particle charge, expressed as multiples n of the elementary charge e (1.6×10^{-19} A s) and the mechanical mobility B of the particle which represents the general ability of the particle to move in a gas:

$$Z_p = neB \tag{8.10}$$

The mechanical mobility B is a function of particle and gas properties and is explained in (8.5).

Particle Size Distributions (Mass, Surface, Number) One basic piece of information on airborne particles is their size distribution. Three modes can generally be differentiated: the nucleation mode (diameter <30 nm), accumulation mode (diameter 200–700 nm) and the coarse mode (diameter >1000 nm). The nucleation mode is

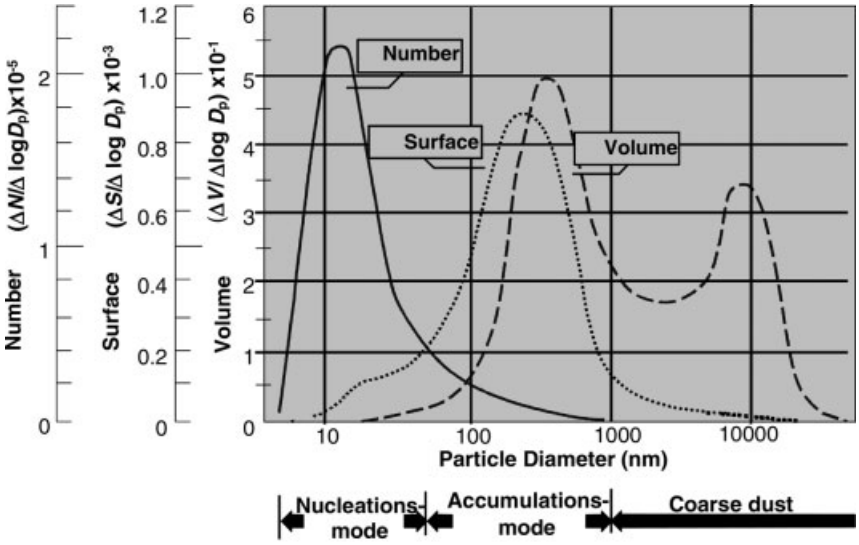

Figure 8.10 Number, surface and mass size distributions (Adapted from [56]).

determined by particles recently being formed by homogeneous nucleation. Hence nucleation mode particles are normally formed via gas to liquid or solid-phase processes. These particles, being normally <30 nm in diameter, either agglomerate with particles of their size, especially when particle concentrations exceed approximately 10^6 cm^{-3}, or with particles of the accumulation mode. The latter is due to the high surface area of accumulation mode particles. The accumulation mode particles tend to grow and their upper size range is normally limited to about 1 µm in diameter due to sedimentation. Coarse mode particles mainly stem from mechanical processes such as wind erosion and eruptions in contrast to the nucleation particles. Coarse mode particles have only a limited lifetime in the atmosphere due to sedimentation. An example of a particle size distribution is given in Figure 8.10.

Figure 8.10 also gives an example of how the modes of a given particle size distribution change when weighted according to the number concentration (d_p^0), surface area concentration (d_p^2) or mass concentration (d_p^3). In summary, the most sensitive concentration value for the determination of nucleation mode particles according to Figure 8.10 is the number size distribution, for the accumulation mode particles the surface area and for the accumulation and coarse mode particles the mass concentration.

Figure 8.11 shows the parabolic curve of the atmospheric lifetimes of airborne particles with respect to the particle size. Particles around 0.2 µm have the longest atmospheric lifetime. Atmospheric particle lifetimes are mainly governed by agglomeration (mainly small on to larger particles), sedimentation and wet deposition (wash-out by, e.g., rain). The latter process affects particles independent of their size; sedimentation is the main dry deposition process of larger particles, whereas small particles have higher agglomeration rates than larger particles. Another removal process, particle deposition by diffusion, is of lesser importance in ambient

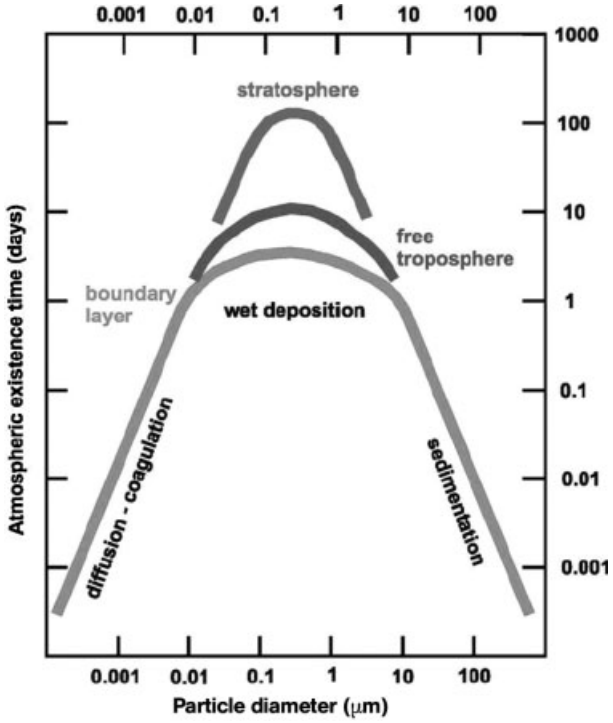

Figure 8.11 Atmospheric residence time of particles in days (Source: Jaenicke, R. (1982) Physical aspects of the atmospheric aerosol, in *Chemistry of the unpolluted and polluted troposhere* (Eds Georgii, H.W. and Jaeschke, W.), D. Reidel Publishing, Dordrecht, 341–373.).

air due to the low surface to volume ratio but becomes important when assessing indoor air and possibly workplaces (especially for nanoparticles and UFPs).

A standard way to quantify the longevity of a substance in the atmosphere is its 'lifetime' – the time that it takes for an initial amount to be cut by about two-thirds. Particle lifetimes in the atmosphere are strongly size dependent.

Figure 8.12 gives an example of particle number size distribution. Figure 8.12a shows the variance between different site types, from rural background to urban traffic sites. A clear increase in number concentrations and a shift towards UFP particles from the rural background to the urban traffic site can be seen. Figure 8.12b shows the same average urban particle number size distribution as in (a), with the only difference being that the *y*-axis is linear in scale. This example demonstrates the influence of changing scales on the perception of particle size distributions.

8.3.3.2 Online Physical Characterization

Condensation Particle Counter Condensation particle counters (CPC)s, sometimes also referred to as condensation nucleus counters (CNC)s or Aitken nucleus counters

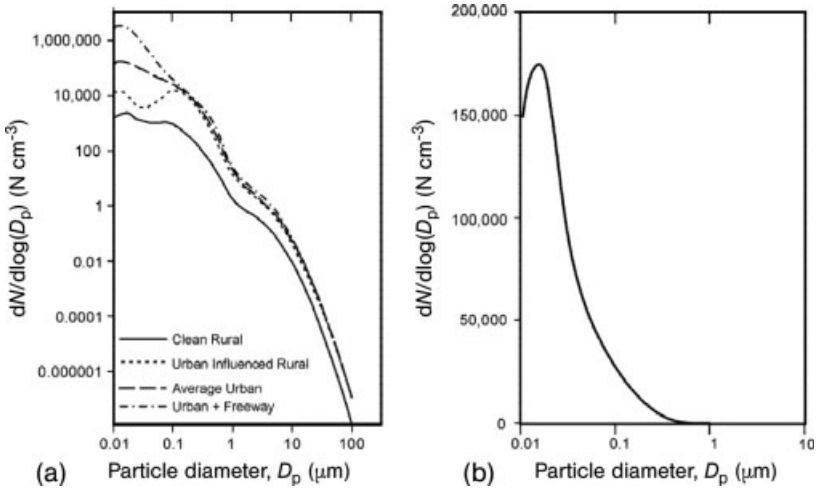

Figure 8.12 (a) Particle number size distributions for various site types in a log–log plot. (b) 'Average urban' in (a) with linear concentration axis [57].

(ANC)s, are used to measure the total number concentration of gas-borne particles larger than some minimum detectable size. No upper size limit is given for CPCs other than the collection efficiencies of the inlet system. CPCs are often used as either stand-alone instruments to measure the total concentration, for example in room or ambient air, or as detectors with other instruments, such as electrostatic classifiers (DMAs) to detect the number concentration of size-selected particles. Condensation particle counters are available as either hand-held or stationary instruments. The latter usually offer a larger liquid reservoir and can thus be used over longer periods, for example in conjunction with a scanning mobility particle sizer (SMPS). Hand-held CPCs are more mobile and are used, for instance, for the mapping of total particle concentrations in, for example, workplace environments.

In CPCs, particles are enlarged by vapor condensation and then are detected optically. Without additional preconditioning, the lowest detectable particle size would be limited to the range of the wavelength of light. Such particle counters would therefore not be suitable to detect nanoparticles. In order to grow small particles to optically detectable sizes, they are exposed to supersaturated vapor that condenses on the particle surfaces. Commonly used vapors are *n*-butanol [26] and water [27]. Diameter growth factors of 100–1000 are common [28], resulting in lower detection limits of 3 nm for *n*-butanol-based and 2.5 nm for water-based CPCs.

The fact that particles in air act as condensation nuclei was first described by Coullier in 1875 [53], who found that if air expands adiabatically the condensation effect is stronger in unfiltered compared with filtered air.

A first version of a condensation particle counter was developed by Aitken in the late 1880s [29, 30]. In his 'dust counter' as illustrated in Figure 8.13, he first flushed a test receiver (A) with particle free air, before introducing a known amount ($\sim$1 cm^3) of aerosol into the receiver. An air pump (B) was used to produce a known expansion.

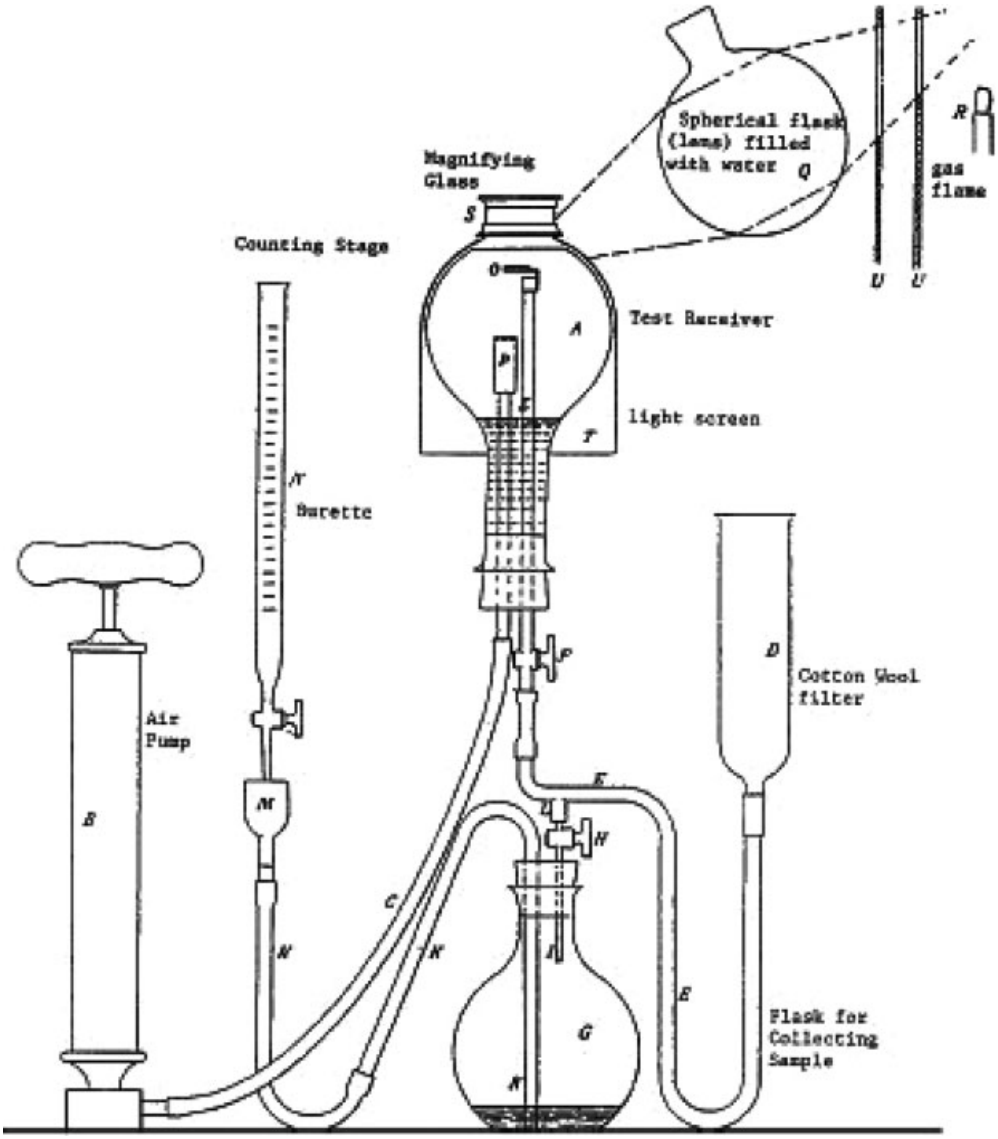

Figure 8.13 'Dust counter' as developed by Aitken [29].

The particles in the test receiver grew due to condensation, resulting in increased settling of the particles. Aitken used a magnifying glass (S) to count manually the particles settled on a deposition stage (O). Based on the assumption that the stage contained a representative sample of the particles in the receiver flask, he concluded that the total number of particles could be determined by means of the ratio of the volume above the stage and the total volume of the flask. Aitken used his dust counter and an improved portable dust counter [31] for intensive studies on atmospheric

particles and found that the particle concentrations were significantly higher when the wind was blowing from industrial sources and that the concentrations were affected by sunlight-driven photochemical reactions [32]. Based on these studies, he concluded [34]: 'Though this investigation clearly shows that the sun produces certain kinds of fogs, yet it is by no means here contended that it is to be censured for their appearance. It would rather appear that it is doing its best to show us the state of pollution into which our modern civilization has brought our atmosphere, as it only inflicts these fogs on the areas upon which man has thrown the waste products of his industries and converted the atmosphere into a vast sewer, as a penalty for something wrong in his methods'. Aitken's dust counter was thus an early instrument to help understand air pollution. Even now, well over a century later, the principle of enlarging particles by condensation remains an important tool for the determination of particle numbers. The main difference is that today particles are not grown in order to increase their settling, but to change their optical properties. CPCs can generally be distinguished into direct and indirect detection instruments [32]. While direct instruments determine the total number by counting individual droplets formed by condensation, indirect instruments measure the attenuation through or the light scattered by a population of droplets. Direct instruments usually have a lower upper concentration limit, whereas indirect instruments generally require relatively high concentrations. Modern instruments include both direct and indirect counting, depending on the particle concentration. When a certain concentration limit is exceeded, the instrument automatically switches from direct to indirect mode.

The method of producing supersaturation has changed since the Aitken's time. Whereas early instruments still used the discontinuous expansion method, modern CPCs use steady flow, forced-convection heat transfer that allows particle counting in real time. In these instruments, the saturated aerosol at ~35–40 °C enters a laminar flow condenser. The condenser walls are typically maintained at ~10 °C, causing a forced heat transfer from the warm aerosol to the cool walls [33]. Figure 8.14 shows a schematic of a modern, butanol-based ultrafine particle counter (UCPC, TSI Model 3025A) that can detect particles down to 3 nm.

Electrometer Electrometers are used to measure a current, induced by particle-borne charges. The results are integral values of the total electrical particle charge as current. Figure 8.15 shows a schematic diagram of an electrometer. The instrument consists of an absolute filter inside a grounded metal housing. The filter is connected to an electrometer and all charges are removed from the particles and led to the electrometer. The housing creates a Faraday cup that shields the electrometer input from stray electric fields. The total current measured by the electrometer can be expressed as

$$I_e = N\bar{n}_p e Q_e \tag{8.11}$$

where N is the total number of particles deposited on the filter, $\bar{n}_p$ is the average number of elementary charges on a particle, e is the elementary charge (1.602×10^{-19} A s) and Q_e is the flow rate through the electrometer.

Aged particles in ambient air are usually nearly neutralized, that is, the sum of all particle charges is close to zero, because approximately the same amount of particles

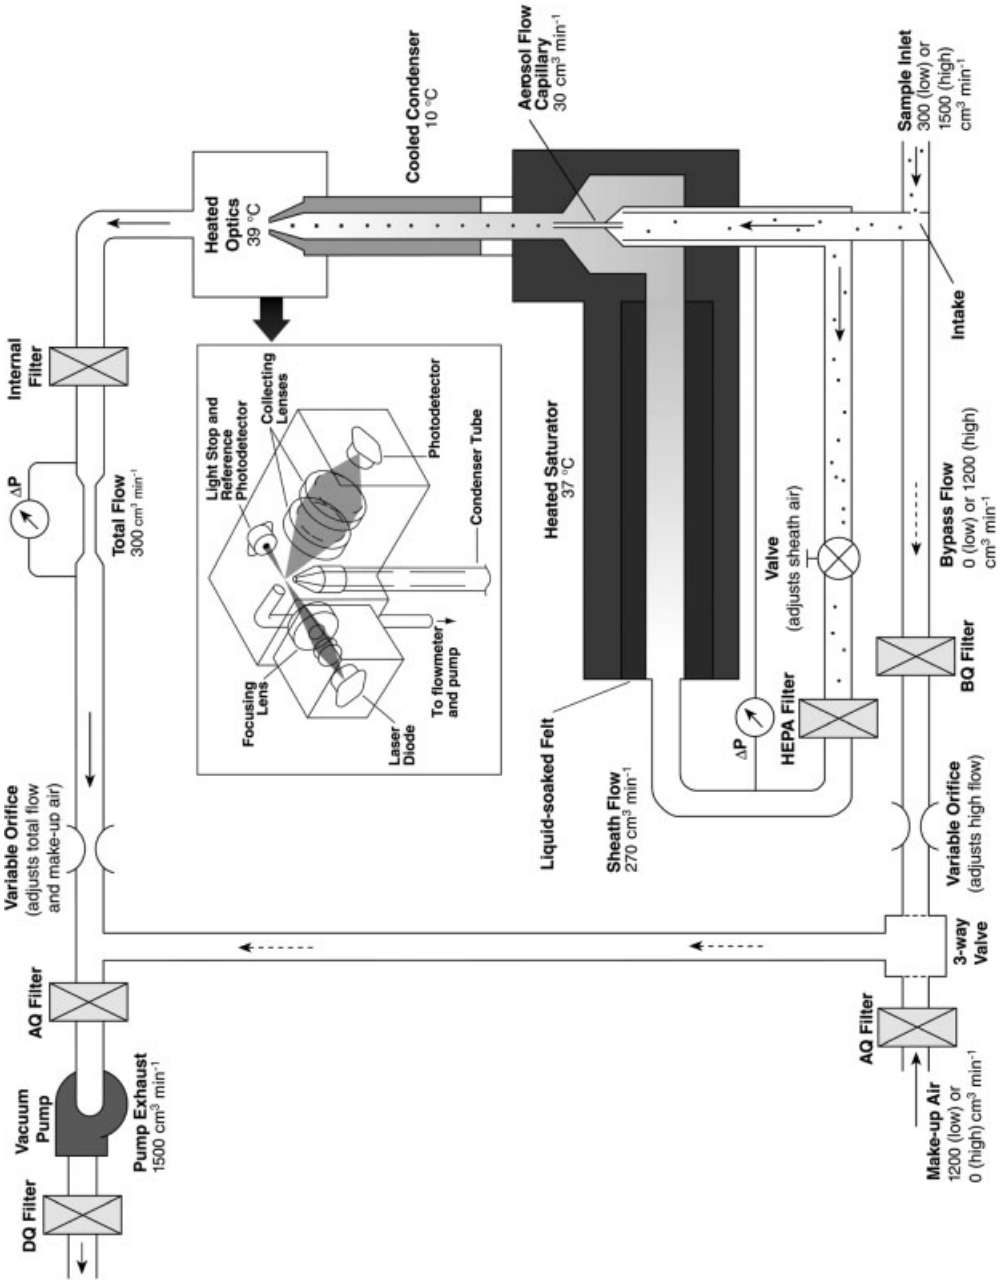

Figure 8.14 Schematic of a modern ultrafine condensation particle counter (TSI, Model 3025A).

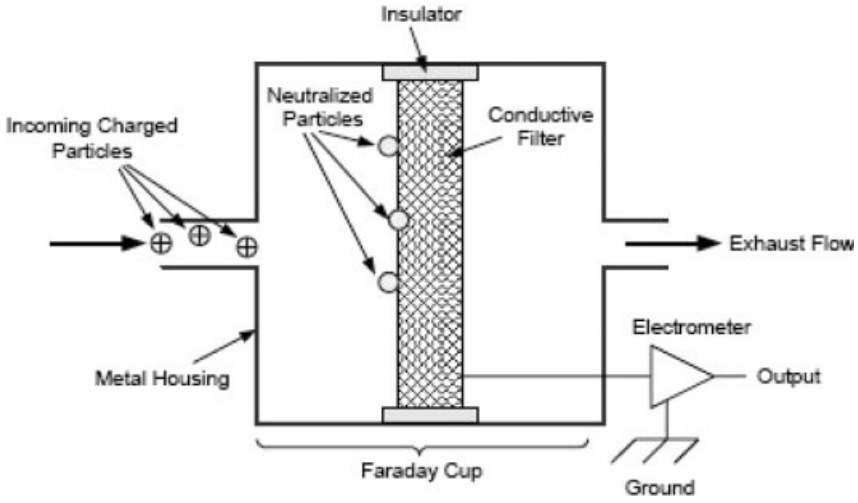

Figure 8.15 Schematic of an aerosol electrometer (TSI, Model 3068B).

is positively and negatively charged. In this case the electrometer current would be close to zero. If, however, the particles are freshly generated, they usually bear mainly unipolar charges with the polarity dependent on the generation process. The polarity of the measured current could therefore yield insight into the origin of the deposited particles. If the particles become intentionally charged prior to deposition in an electrometer and the relationship between particle size and charge is known, the integral current allows (limited) interpretation with respect to particle size and concentration. If the particles are monodisperse or mono-mobile, as for example delivered by an electrostatic classifier, the current can be directly related to the number concentration of particles in the aerosol. This fact is used in several applications, where condensation particle counters cannot be used, for example due to pressure or time resolution restrictions. Electrometers can detect arbitrarily small particles; however, they require a certain minimum current, caused by the deposited particles. Therefore, they require higher minimum particle concentrations than CPCs (Figure 8.15).

Overview of Aerosol Particle Sizing Instrumentation Various techniques for the determination and characterization of airborne particle size distributions (e.g. number, surface or size) exist. Three physically different basic principles for particle size determination can be differentiated: the electrical mobility, mechanical mobility and optical scattering. Figure 8.13 gives an overview of particle size ranges covered by the different techniques (abbreviations are explained in Table 8.2).

The optical scattering of light is dependent on the particle size in addition to the refractive index and hence is used directly for particle size classification and counting. The electrical and mechanical mobility are used for the fractionation of particle sizes with subsequent measurement of the number concentrations per size class by a separate particle counting device such as CPC or electrometer. Particle number size distributions are hence calculated based on the known investigated volume and the

counted particles per size class. Table 8.2 presents an overview of the available techniques and corresponding earliest references.

A very good overview of particle sizers based on optical and time-of-flight techniques can be found in a dissertation by Cole [34]. Further good overviews were given by Klaus and Baron [35], Chow [36] and McMurry [28].

The principles of the first two techniques (APS and OPS) will be briefly described in this section and the other techniques are presented in separate sections hereafter.

Particles are accelerated in an APS by passing the aerosol through a nozzle. Particles experience acceleration in that nozzle in accordance with their aerodynamic diameter and their speed after the nozzle is directly proportional to it. This speed is determined by a split laser beam after the nozzle, which simultaneously counts the particles. The main drawback of the APS is that it can only detect particles larger than about 500 nm aerodynamic diameter. Hence it can only be applied for the detection of large nanoparticle agglomerates and not for nanoparticles.

The OPC has a similar drawback since it normally is limited to particle sizes in the size range of the wavelength used. The detectable lower particle diameter is normally around 200 nm (Figure 8.16).

Differential and Scanning Mobility Particle Sizer To determine the number size distribution of submicron airborne particles, differential mobility particle sizers (DMPSs) and SMPSs are very commonly used. Depending on their configuration, they can cover a size range between 3 nm and 1 μm. The hardware of both instruments is substantially the same. The aerosol first passes through a size-selective inlet (impactor), before being neutralized in a neutralizer. The neutralized aerosol is then

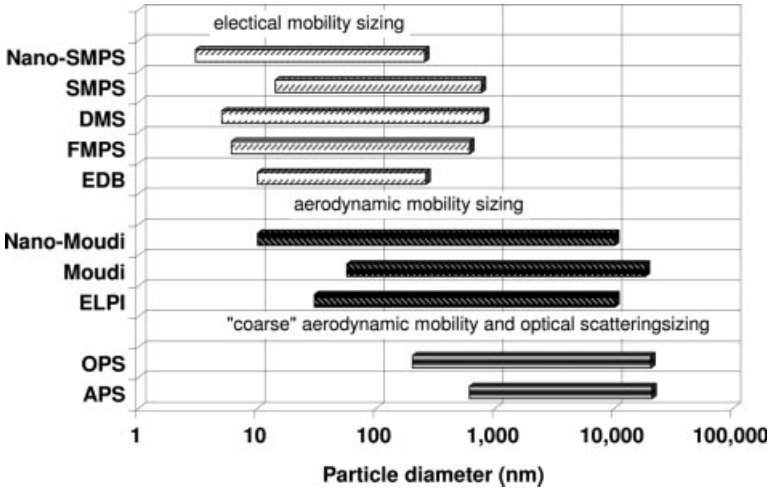

Figure 8.16 Size ranges of particle size distribution analyzers.

fractionated in a DMA, before the classified particles are counted in particle counting equipment (usually a CPC, sometimes an electrometer). Computer software is used to control the voltages applied to the DMA and to read the counts from the CPC. A schematic of a DMPS/SMPS is shown in Figure 8.17.

The general principle of a DMPS/SMPS is that a range of voltages is applied to the DMA. Each voltage corresponds to a certain electrical mobility. The concentration of mono-mobile particles is measured with the CPC and along with the known charge distribution evaluated to obtain the concentration of particles with this mobility diameter. In a DMPS, the voltages are applied sequentially and the number of particles counted after the concentrations have stabilized, before the next voltage is applied. In the more recently developed SMPS [37], the voltage is continuously ramped and an algorithm used to relate the measured concentrations to the applied voltages, that is to the according electrical mobility. While a DMPS still needed for ~15–20 min for a full scan, an SMPS can accomplish full scans within ~2 min.

The inversion of the measured mobility data into size distributions was described by Hoppel [39]. Since the particles were neutralized prior to classification in the DMA, the counted numbers not only contain singly but also larger, multiply charged particles, as sketched in Figure 8.18a. In order to determine the number size distribution from the mobility distribution, the concentration of multiply charged particles has to be subtracted for each channel (Figure 8.18b) and the resulting concentration of singly charged particles divided by the probability of singly charged particles for that particular size (Figure 8.18c), as for example given by Wiedensohler [40] (see Table 8.1). To understand the inversion technique, it is easiest to start with the channel of lowest electrical mobility, that is, with the largest particles. An appropriate size-selective inlet for a DMPS/SMPS is designed such that its cut-off diameter is below the diameter of doubly charged particles of the lowest detectable electrical mobility. Therefore, all particles in the lowest mobility channel are singly charged, because all particles bearing higher charge levels are captured in the

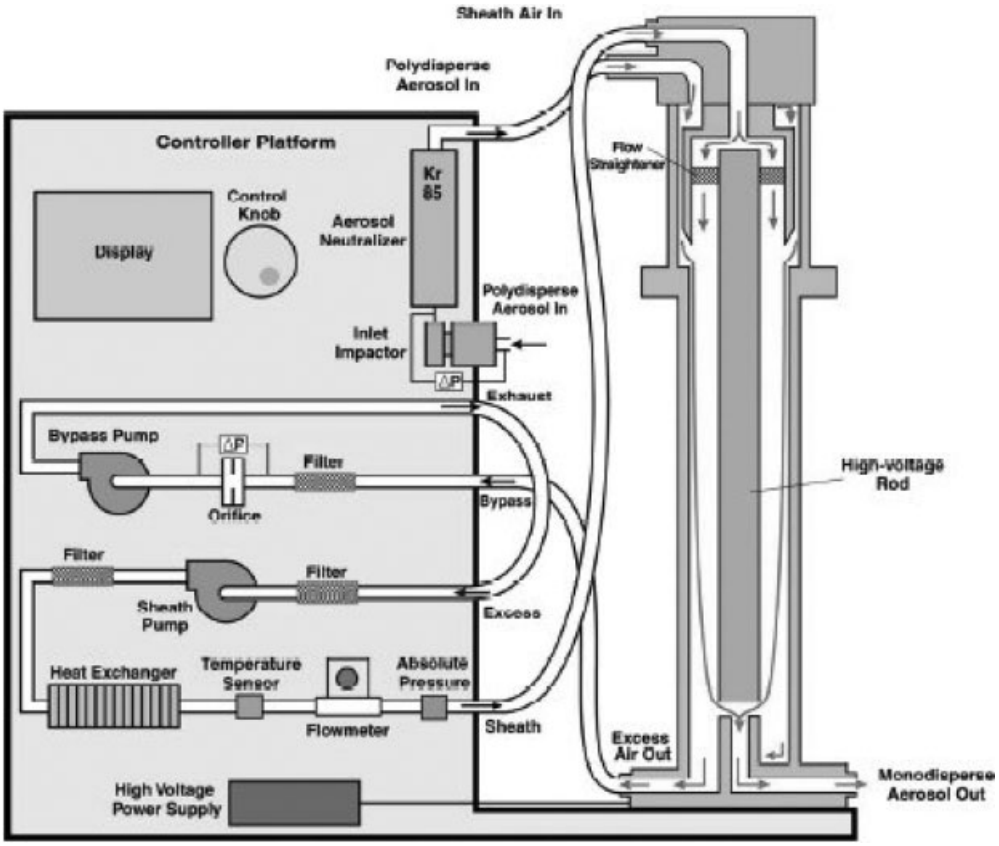

Figure 8.17 Schematic of a DMPS/SMPS (Courtesy of TSI Inc.).

pre-selector. The measured number concentration in the lowest mobility channel can thus without further correction be directly divided by the probability of singly charged particles in order to obtain the airborne number concentration. The same is true for all lower mobility channels, where the size of doubly charged particles is large enough to be captured in the pre-selector. In higher mobility channels, doubly (or higher) charged particles are present. Their size can be calculated by means of Equation 8.10 in the section on electrical mobility. Their concentration within the total measured concentration in the channel can be determined by multiplying the airborne concentration of particles of this (larger) size with the probability of doubly charged particles. The concentration of doubly charged particles is then subtracted from the measured concentration in order to obtain the concentration of only singly charged particles, which then needs to be divided by the probability of singly charged particles of that size in order to obtain the airborne concentration. Once the channels also contain triply or higher charged particles, they need to be subtracted from the measured data as described for the doubly charged particles and the result divided by the probability of singly charged particles.

After the correction described above (Figure 8.18a–c), the result is the number concentration for each channel where the channels now represent the average diameter of the singly charged particles. The magnitudes of the concentrations, however, might not necessarily represent the actual size distribution, as the width of the channels can vary with respect to the particle diameter. The number concentration for each channel (Figure 8.18c) therefore needs to be weighted with the channel width (Figure 8.18d). In SMPSs, the channel widths are based on either common or natural logarithms. Therefore, the number concentrations dN per channel are weighted with either the common logarithm [dN/d log(d_p)] or the natural logarithm [dN/d ln(d_p)].

All of the above-mentioned data inversion was based on the assumption that no particle losses occur in a DMPS/SMPS system. This is obviously not true. The data therefore need to be post-processed to be corrected for particle losses. Since the DMPS/SMPS systems are designed for submicron particles, losses can mainly be attributed to diffusion, whereas other loss mechanisms can be neglected. Corrections for diffusion losses are not generally covered in DMPS/SMPS evaluation software packages and therefore in some cases need to be done manually. If the size

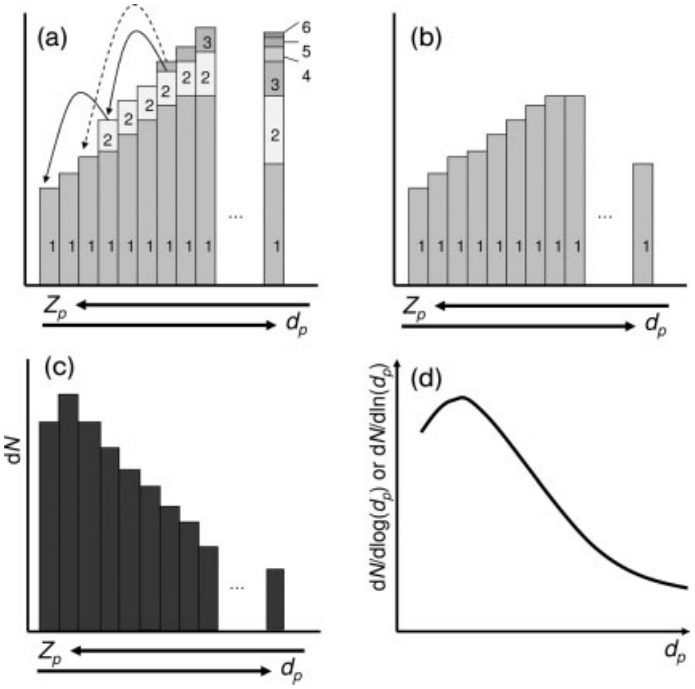

Figure 8.18 DMPS/SMPS data inversion: (a) measured mobility distribution, including multiply (1–6×) charged particles; arrows indicate the size of multiply charged particles; (b) multiply charged particles subtracted, only singly charged particles; (c) size distribution after division by probabilities of singly charged particles; (d) size distribution dN/d log(d_p) or dN/d ln(d_p), weighted with channel width.

distributions are not corrected, they tend to under-predict significantly the concentrations of particularly small particles with sizes mainly below 50 nm. In a DMPS/SMPS, diffusion losses occur in

- the size-selective inlet
- the neutralizer and internal plumbing
- the tubing to the DMA and CPC,
- the DMA
- the CPC.

If the DMPS/SMPS does not sample directly into the size-selective inlet, but with tubing connected to the inlet, losses inside this upstream tubing also need to be considered. Furthermore, the CPC counting efficiency needs to be taken into consideration. While the losses in the DMA require special treatment as described Reineking and Porstendörfer [67], the losses inside all tubing can be quantified as described by Gormley and Kennedy [40].

Based on the assumption that all sampled particles are spherical, the measured number size distribution can be converted into a surface or volume size distribution as illustrated in Figure 8.19. To compute the surface distribution, the number concentrations for each channel i need to be multiplied by the surface area of the particles in that channel:

$$\mathrm{d}S_i = \mathrm{d}N_i \pi \bar{d}_{\mathrm{p},i}^{\,2} \tag{8.12}$$

Similarly, the number concentration has to be multiplied by the particle volume to obtain the volume size distribution:

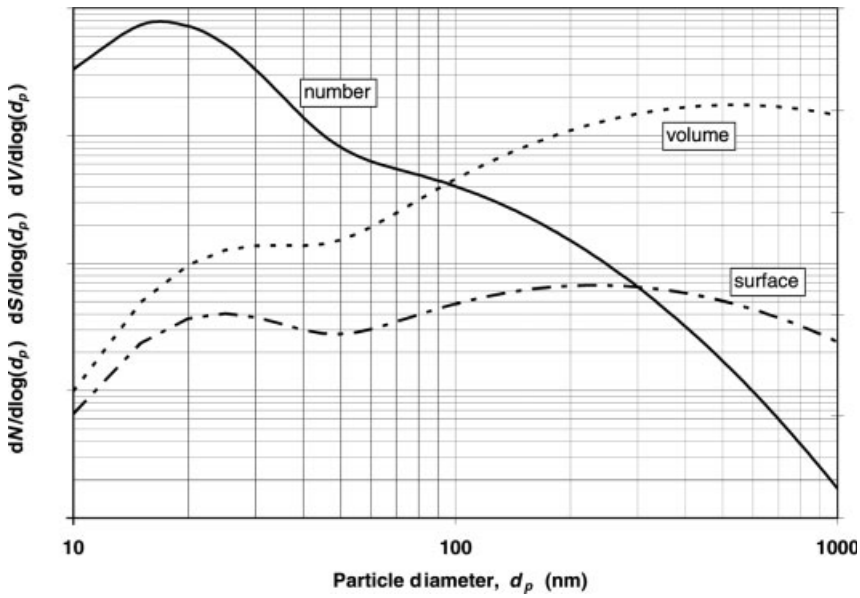

Figure 8.19 Number, surface and volume size distributions for spherical particles.

$$dV_i = dN_i \frac{\pi}{6} \bar{d}_p^3 \tag{8.13}$$

If the particles all have the same density, the volume distribution can also be transferred into a mass size distribution. If the particles are not spherical, the surface and volume distribution in Figure 8.19 can be understood as the surface and volume of electrically equivalent spheres.

Under certain assumptions, the surface area and volume distributions of chain-like ultrafine aggregates, such as soot particles, can be estimated, based on electrical mobility measurements as described by Lall and co-workers ([41, 42]). Their theory, however, is based on several assumptions:

- All aggregates are composed of primary particles, all of which have the same known diameter.
- The primary particles are much smaller than the mean free path of the surrounding gas molecules.
- The connections between the primary particles do not exhibit necks, that is, the surface area can be obtained by summing over the surface areas of the single primary particles.
- Fractal dimensions of the aggregates are smaller than two.

They take into account a different charging efficiency for aggregates compared with spheres, resulting in a shifted size distribution, and calculate the surface area of the particles based on the number and size of primary particles of which the agglomerates are composed.

Fast Mobility Particle Sizer SMPSs offer a time resolution of ~2 min. If the size distributions are quickly changing, such as due to the influence of a car driving by or accidental release of nanoparticles in workplaces, this time resolution may be too short. Tammet *et al.* [55], 1998 of Tartu University in Estonia developed an electrical aerosol spectrometer that measures number size distributions based on electrical mobility measurements. However, the different mobility channels are not measured sequentially as in an SMPS, but simultaneously, resulting in significantly higher time resolution. The instrument has been commercialized by TSI in two versions, the fast mobility particle sizer (FMPS) with a time resolution of 1 s and the engine exhaust particle sizer (EEPS) with a time resolution of 0.1 s. The two instruments are fundamentally the same. Whereas the FMPS is designed for ambient or workplace measurements, the EEPS is tailored for measuring engine exhausts and additionally includes means for the recording of engine data. It is only the higher particle concentration in engine exhaust that allows the EEPS to offer higher time resolution than the FMPS. Both instruments cover the same size range from 5.6 to 560 nm. The principle of the two instruments is shown in Figure 8.20.

The aerosol first passes a two-stage diffusion charger. The first stage puts a negative net charge on the particles in order to remove any potential high positive charge levels on the particles. The second stage puts a predictable net positive charge on the particles. The main instrument functions very similarly to a DMA, just that the

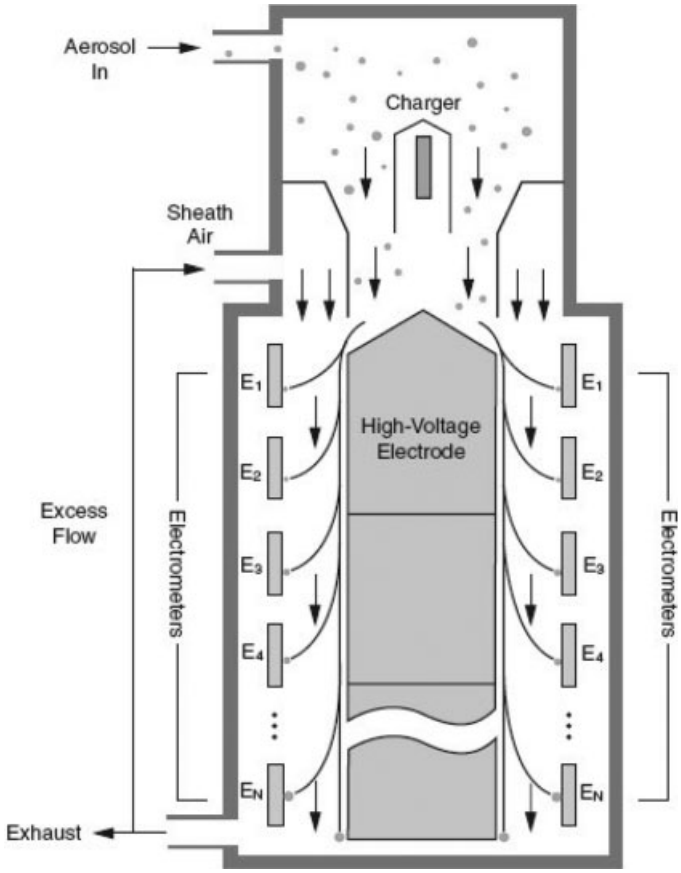

Figure 8.20 Schematic of the fast mobility particle sizer/engine exhaust particle sizer analyzer (Courtesy: TSI Inc.).

aerosol is introduced near the inner rod, with the sheath air surrounding the aerosol flow. The center rod is divided into three sections with different fixed voltages (increasing from top to bottom) applied to them. Since the voltages are fixed, the trajectories of the particles depend only on their electrical mobility. The outer cylinder contains a series of 22 electrodes, each separately connected to an electrometer. The current induced by deposited particles is continuously measured and used to determine the particle size distribution. The data inversion takes into account a number of parameters that affect the electrometer reading and the time resolution. The electrometer current can be affected by image charges that are induced if charged particles flow past a detection stage without being deposited. Additionally, there are time delays between the detection of small particles in an upper stage and larger particles in a lower stage.

A complex inversion algorithm is used to deconvolute the measured data and take into account image charges and time delays.

8.3.3.3 Online Physical–Chemical Characterization

Online, size dependent, single or bulk chemical analysis became practically available with the development of aerosol mass spectrometer only during recent years. They enable studies of e.g. particle composition, reaction, and source apportionment which were not possible before.

Aerosol Mass Spectrometers Two different aerosol mass spectrometers (AMSs) can be differentiated today – the real-time single-particle mass spectrometer (RTSPMS) and the thermal desorption chemical ionization mass spectrometer (TDCIMS).

The advantages of real-time, size-dependent determination of single particles were already seen in the 1970s. A schematic diagram of the first AMS is shown in Figure 8.21. The principle of this method is based on the ionization of particles directly in the mass spectrometer followed by ion mass and hence chemical analysis in the spectrometer. In the literature, a variety of general names have been applied to RTSPMS methods, including direct-inlet mass spectrometry, online laser microprobe mass spectrometry, particle-inlet mass spectrometry, particle beam mass spectrometry and rapid single-particle mass spectrometry [46].

The TDCIMS is a new instrument that can perform online measurements of the molecular composition of ultrafine aerosols at a time resolution of 5–10 min [47].

The TDCIMS will be outlined here with emphasis on recent major enhancements, while more details on the underlying measurement principle have been presented elsewhere [47]. Figure 8.22 shows a schematic of the instrument. The TDCIMS can be divided into three parts: the aerosol charger, the electrostatic precipitator and the

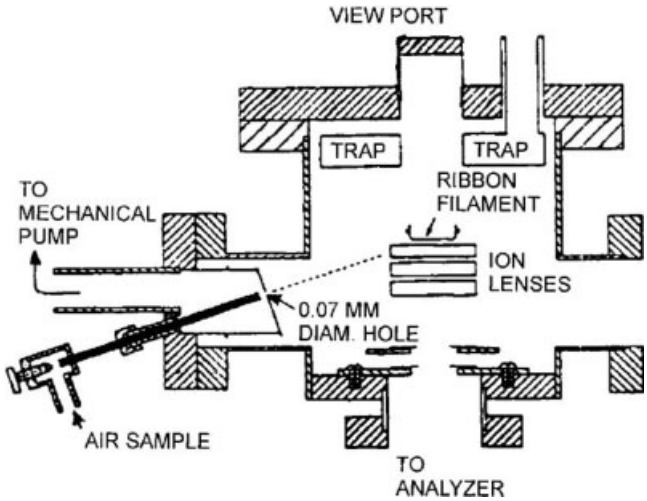

Figure 8.21 Schematic diagram of the original real-time single-particle mass spectrometer. The diagram shows the direct sample inlet directing an air flow to the filament for surface desorption/ionization of aerosol particles. Ions are mass analyzed in a magnetic sector mass analyzer (Adapted from [58] in [46]. Copyright 1977 American Chemical Society).

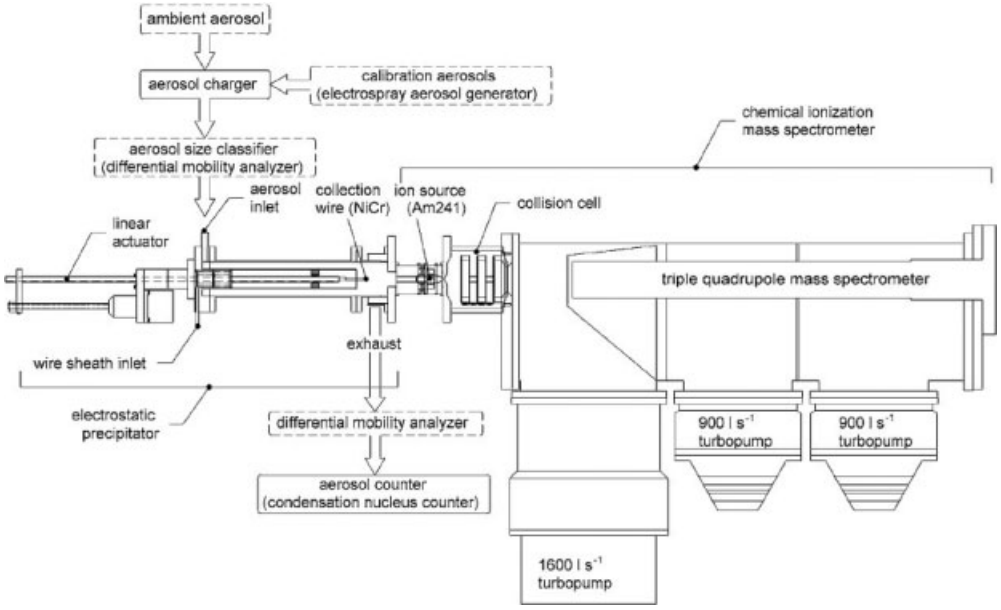

Figure 8.22 Schematic of an TDCIMS, with optional elements shown in dashed boxes (Adapted from [48]).

chemical ionization mass spectrometer. The aerosol charger generates singly charged aerosol from sampled ambient particles at flow rates of up to 6.6 (slpm). An optional differential mobility analyzer placed downstream of the charger can be used to achieve size selectivity of the aerosol. Charged particles are then introduced into the electrostatic precipitator, a cylindrical chamber that contains a collection wire mounted on a ceramic rod that is biased to a high voltage (usually 4200 V) and located on the center line of the chamber (see Figure 8.22). Prior to collection, the wire is cleaned by applying a current pulse to it, resistively heating it to 500 °C. After allowing the wire to cool to ambient temperature, a high voltage is applied so that these charged particles pass through a clean buffer gas that isolates the collection wire from contamination from the ambient gas and deposit on the tip of the wire. Once a sufficient number of particles have been collected, usually 1–10 pg over a period of 5–10 min, the wire is inserted into the ion source region of the chemical ionization mass spectrometer. A current is applied to the wire to thermally desorb the aerosol at a temperature of 300 °C. The third part of the instrument is the chemical ionization mass spectrometer and consists of the ion source region, a declustering collision cell and a mass spectrometer. The ion source consists of a ^{241}Am α-source that ionizes the reactant gas mixture at atmospheric pressure to form H_3O^+, O^{2-} and CO^{3-} and their higher clusters as the primary stable ions. The reactant gas is cryogenic nitrogen that has passed through a liquid nitrogen trap at slightly elevated pressure to remove some impurities, but which nonetheless is able to generate these ions in abundance. These regent ions react with the compounds evaporated from the aerosol to ionize them according to typical chemical ionization

mass spectrometry (CIMS) procedures [49] and electrostatic lenses direct these ions into the collision cell, where the ions are declustered from neutral compounds that may be present in the gas, most commonly water. The ions are detected using selected ion monitoring with a triple quadrupole mass spectrometer (paragraph adapted from [48]).

8.3.3.4 Offline Physical Characterization

Not all particle characteristics can be determined online, since either no online methods exist, as e.g. for particle morphology, or detection limit constrains. Therefore particles can be sampled on suitable substrates to overcome these limitations.

Electrostatic Precipitations and Impaction Electrostatic precipitators (ESPs) provide a simple mean for the collection of samples for offline analysis of, for example, chemical composition or morphology of airborne particles. Common applications of ESPs include samples for electron microscopy (SEM/TEM), for example coupled with EDX analysis, samples for atomic force microscopy (AFM), samples for total reflection X-ray fluorescence (TXRF) analysis, nanomaterial evaluation and atmospheric particle sampling.

Inside an ESP, the particles are exposed to an electric field, which directs particles of one polarity towards a sample electrode, whereas those particles of other polarity are deposited on the ESP wall. Uncharged particles are not affected by the electric field and therefore follow the gas streamlines. For effective particle sampling, unipolarly charged particles should be introduced into an ESP. Unipolar charging of particles can for example be achieved by a corona charger upstream of the ESP.

If connected directly to an outlet of a DMA, an ESP can be used to sample size selected particles without additional charging.

Figure 8.23 shows an ESP as developed by Dixkens and Fissan [50] which has been commercialized (TSI Model 3089). In this ESP, particles are homogenously distributed within a deposition spot. The spot size can be varied by controlling the flow aerosol flow rate and voltage applied to the electrode system.

Nanoparticles may also be sampled by using the impaction process. Commercially available cascade impactors separating and sampling particles even down to about 20 nm are the Nano-Moudi, the Berner low-pressure impactor and the electrical low-pressure impactor (ELPI) (Figures 8.24 and 8.25, see also [51]).

These cascade impactors are all based on the same principle, the inertia of particles. This principle is explained in Section 8.3.3.1. The main extension to the principle explained therein is the low-pressure conditions. Low pressure is necessary actually to use the principle of inertia to differentiate particles in the nanometer size range since gas–particle interactions otherwise interfere with the process and make a particle size separation for those size classes impossible.

Once the particles have been deposited on the substrates, either by ESP or by impaction, particles may be chemically analyzed in the bulk or as single particles. ESP is the better option for the latter chemical analysis.

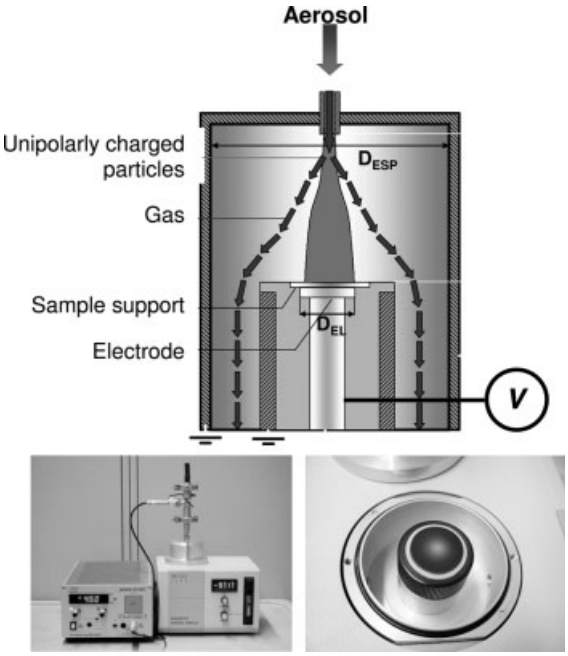

Figure 8.23 Schematic of an electrostatic precipitator (Dixkens and Fissan, 1999) and picture of commercial electrostatic precipitator with glassy carbon carrier.

8.4 Nanoparticle Detection and Measurement Strategies

No clear differentiation between natural and manmade ultrafine particles and nanoparticles can easily be done when measuring particles in the nanometer size range, as was shown in Section 8.3. Normally only a combination of methods will allow for a clear differentiation of nanoparticles from others. This will be explained in some detail for airborne nanoparticles.

The detection and measurement strategies to be pursued depend mainly on the nanoparticle characteristics and on the detection limits. Nanoparticle characteristics can be divided into physical–chemical and morphological characteristics. The physical–chemical characteristics determine, for example, which detection technique can be used for the identification of the nanoparticles. If, for example, TiO_2, Al_2O_3 or Fe nanoparticles are to be detected, a combination of TEM with EDX can be used. The microscopic techniques (TEM, SEM, ESEM (Environmental Scanning Electron Microscope)) also allow for the determination of the morphology/shape which can be of interest for the identification of nanoparticles of known shape and/or primary particles size. However, these techniques are less suitable for carbon nanoparticles since they cannot determine the chemical composition. Techniques such as single-particle AMS and/or particle size distribution measurement along with the online

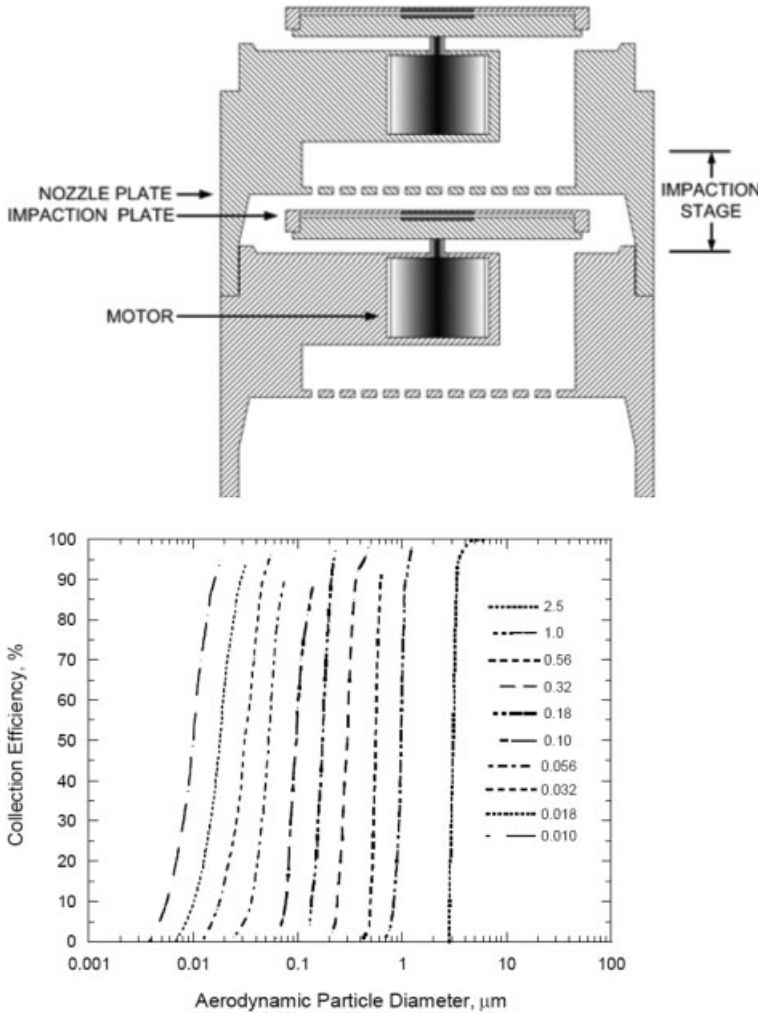

Figure 8.24 Schematic of Nano-Moudi II setup and particle separation curves (Courtesy of MSP Corporation).

detection of submicrometer elemental carbon (e.g. with an Aethalometer) may be more suitable. However, the microscopic methods are still an important tool actually to identify the source of carbon (e.g. diesel, nanotubes, carbon black).

Particle number concentrations, particle size distributions and surface area concentration may also be used for the measurements of nanoparticles. However, these methods are of more general character and do not differentiate between nanoparticles and other particles of diameter <100 nm.

The above-mentioned possible setups of measurement devices and techniques are important for the actual particle characterization. Nevertheless, these techniques are time consuming and expensive. Still, measurements as described above will be necessary if single nanoparticles in a complex matrix are to be detected and described

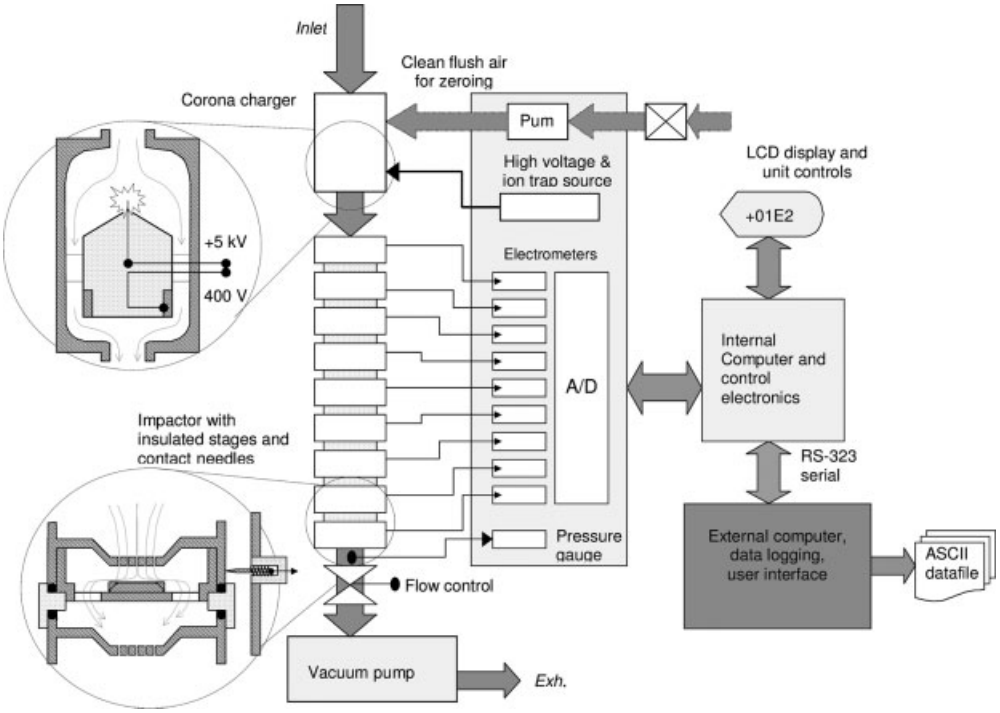

Figure 8.25 Schematic of an ELPI (Courtesy of Dekati Ltd.).

to be traceable to the product or are of such high toxicity that even single particles can cause health effects (e.g. asbestos).

The measurement techniques to be employed may be different if only larger quantities of nanoparticles have to be detected. Even here two different levels may be differentiated, exemplarily discussed here for number concentrations of particles of diameter <100 nm: nanoparticle contributions to airborne particles from 1000–100 000 cm^{-3} and contributions >100 000 cm^{-3}. Measurement techniques as used by Möhlmann [18] are applicable to identify source contributions >100 000 cm^{-3}. In his study, a single SMPS measuring particle number size distributions from 10 to 700 nm was used. This measurement allows for the calculation of the particle number concentration of particles of diameter <100 nm and for the determination of the mode (particle size with the highest number concentration). Still, since particle number concentrations of up to 100 000 cm^{-3} may occur naturally or by contributions from outside, this kind of measurement strategy is only applicable for higher number concentrations.

A different approach must be pursued if particle contributions by processes, leaks and work activities at levels down to about a few thousand particles per cubic meter are to be determined. Kuhlbusch *et al.* [17] and Kuhlbusch and Fissan [19] showed that particle contributions from sources outside the plant can be significant and have to be taken into account. By choosing a setup of instruments with simultaneous measurements inside the working area and at a comparison site in the direct vicinity of the work area but outside, they demonstrated the influence of outside

Table 8.3 Concentration-dependent measurement strategies.

Number concentration range (cm^{-3})	Strategy
>100 000	Determination of particle number concentrations and/or number size distributions only at the location of interest
1000–100 000	Determination of particle number concentrations and/or number size distributions simultaneously at the location of interest and a corresponding comparison location
<1000	Determination of particle number concentrations and/or number size distributions, along with particle samplers for single particle analysis for nanoparticle identification

Source: T. A. J. Kuhlbusch *et al.*, in preparation [54].

contributions to indoor measurements. By choosing this kind of setup they were able to differentiate (a) sources from outside of the work area, (b) continuous source contributions and (c) discontinuous source contributions. This possibility of differentiation of continuous and discontinuous source activities can be important when the continuous sources are active during the assessment of a discontinuous activity. The particles from the continuous source would have been attributed to the discontinuous source activity if no differentiation were to have been made.

Still, even when determining source activities by the methods describe above, single particle analysis may still be necessary to avoid data misinterpretation, such as attributing welding particles to nanoparticle bagging activity (Table 8.3).

Epidemiological Studies on Particulate Air Pollution

Irene Brüske-Hohlfeld and Annette Peters

9.1
Introduction

This chapter presents an overview of the main results stemming from epidemiological research on the health effects of exposure to particulate air pollution in the environment and at the workplace. Over the past two decades, evidence has accumulated that airborne particles are correlated with the incidence of respiratory and cardiovascular disease. Although remarkably consistent between numerous epidemiological studies in different geographic areas, these findings were at first received with some skepticism, as there appeared to be no plausible biological mechanism to explain the observed association between respiratory and cardiovascular mortality and the level of airborne particles. As epidemiology is an observational rather than an experimental science, it cannot establish causality on its own and is a rather blunt tool for elucidating biological mechanisms. However, in the meantime complementary information from controlled *in vivo* and *in vitro* experimental studies has supplied supporting evidence, which will be presented, for example, in Chapter 10.

9.1.1
Outline of the Chapter

We will start with a short definition of particle sizes, a brief comment on epidemiological study design and a description of what is known about the main potential entry routes for nanoparticles, focusing on the inhalation and metabolism of airborne particles. Thereafter, a summary of the observed adverse health effects of particulate air pollution from environmental epidemiological studies is given, with special emphasis on studies that have particularly investigated the effects of ultrafine particles. Then, looking – so to speak - backwards from the adverse health effects to particle exposure, we will bundle the evidence for diseases related to three organs: the

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

heart, the lungs and the central nervous system. Finally, we will summarize epidemiological studies that have looked into dusty workplace environments and have investigated the impact on health of exposed workers.

9.1.2 A Short Definition of Particle Sizes

Environmental air pollution consists of a complex mixture of compounds in gaseous, liquid and solid phases, the latter usually referred to as particulate matter (PM). Some particles are introduced from the source into the air in solid or liquid form, whereas others are formed in the air by gas to particle conversion. In general, ambient levels of particulate matter are characterized as particulate matter with an effective aerodynamic diameter of less than 10 µm (PM_{10}) or 2.5 µm ($PM_{2.5}$); see Figure 9.1.

These PM size cuts generally represent different sources and display different physical and chemical properties. They are generated by a large number of sources: motor vehicles, power plants, wind blown dust, photochemical processes, cigarette smoking, nearby quarry operation, etc. Ultrafine particles (UFP) as a component of ambient particulate air pollution are largely the result of combustion processes, such as automobile traffic and heating of homes, and composed of a core of elemental carbon covered by organic carbon compounds and secondary sulfates and nitrates. Although comparable in size (<100 nm) to technically produced nanoparticles, ambient ultrafine particles lack their potential specific toxicity. They have a high tendency to react chemically or coagulate. The number concentration of these very small particles exceeds by far that of larger particles in the urban area, but their contribution to the total

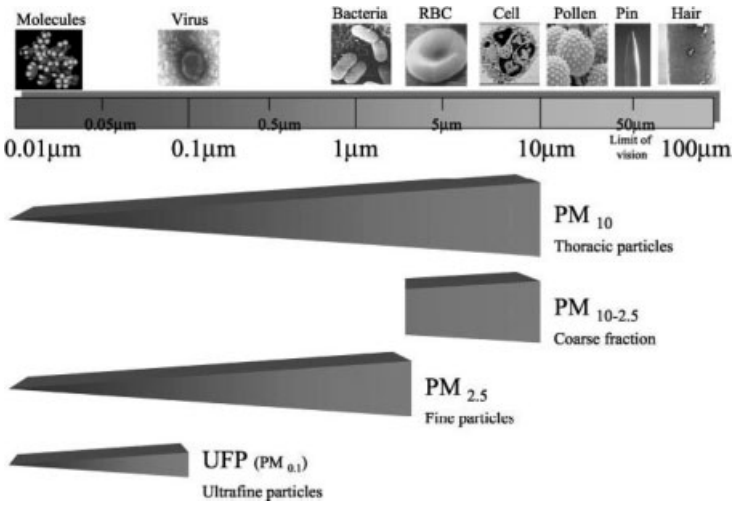

Figure 9.1 Particulate matter air pollution size distribution. (Reproduced with permission from [115]).

mass concentration is relatively low. With regard to ultrafine particles, the number concentration (n cm^{-3}) or surface area concentration ($\mu m^2\, m^{-3}$) or particle length concentration (mm cm^{-3}) is more relevant than particle mass. Such data on exposure are not routinely available by monitoring stations, but have to be collected independently. It has been proposed that the adverse health effect of airborne particles was mainly associated with the number concentrations of ultrafine particles [1–3] rather than the mass concentrations $PM_{2.5}$ or PM_{10}.

9.1.3
A Brief Comment on Epidemiological Study Design

As epidemiology often takes advantage of already existing data, most of the concurrent research relies on measurements of particle mass ($\mu g\, m^{-3}$) of PM_{10} or $PM_{2.5}$, which is typically recorded for regulatory purposes at central-site community-based monitoring stations. Although these studies do not specifically concentrate on nanosized particles, they contribute valuable information as it seems that it is the inherent fraction of combustion-derived ultrafine particles within PM_{10} that is actually responsible for the adverse health effects. There is sufficient reason to believe that ultrafine particles are important because compared with larger particles, they have a much larger surface area and higher concentrations of adsorbed or condensed toxic air pollutants (oxidant gases, organic compounds, transition metals) per unit mass.

The epidemiological approach to measuring associations between air pollution and health varies with the available data and the hypothesized health effects being investigated. Usually, air pollution epidemiological studies are classified as acute or chronic exposure studies. The acute exposure studies use short-term temporal changes in pollution as their source of exposure variability and evaluate short-term changes in health measures in a so called time-series analysis. The study design is that of a longitudinal panel study, in which a population is followed for a certain time and measurements are taken for the same person repeatedly. Thus, every person acts as his or her own control. Panel studies are free of confounding by personal characteristics and are most effective for studying short-term health effects (e.g. changes in lung function tests, inflammatory blood markers and immediate impact on mortality rate) of air pollution.

The development of lung cancer or other chronic diseases may be related to air pollution but will not correlate with short-term changes of exposure and a time series analysis will not be the appropriate form of statistical analysis. Instead, cohort studies offer the opportunity to compare the mortality of lung cancer, for example by using spatial or long-term temporal differences in pollution as a source of exposure variability. If confounding factors, such as smoking, can be measured in a cohort study, their influence can be removed in the statistical analyses.

Results in epidemiological research are usually presented as relative risk (RR) or odds ratio (OR). Without going into the underlying statistics and just to give the reader a rough idea, these numbers can be interpreted as the ratio of two probabilities for an event. The factor indicates the relative magnitude with which a risk is different

between two groups. The relative risk expresses the ratio of the probability of the event occurring in the exposed group versus the control (non-exposed) group. A 95% confidence interval (CI) is defined as the interval between two numbers with an associated probability p which is generated from a random sample of an underlying population, such that if the sampling was repeated numerous times and the CI recalculated from each sample according to the same method, a proportion p of the CIs would contain the population parameter in question. It must be noted that this is not equivalent to a (Bayesian) credible interval. We will cite OR and RR estimates from epidemiological studies along with their CIs to give the reader a perception of the magnitude of the measured association and the precision of this estimate mirrored by the width of the CI.

9.2 Potential Entry Routes for Nanoparticles into the Human Body

In principle, there are three main contact sites of the human organism with the environment: skin, lungs and intestinal tract. The skin provides a relatively thick (10 μm) first barrier against hazardous compounds that is difficult to pass, as opposed to the lungs, where in the gas exchange region the barrier between the alveolar wall and the capillaries is very thin. The air in the lumen of the alveoli is on average only 0.5 μm away from the blood. Epidemiological studies with their main focus on environmental air pollution can only contribute scientific findings to the effect of inhaling particles. The dermal or oral uptake of particles, although probably important in the context of manufactured nanomaterial, has so far not been the objective of epidemiology.

9.2.1 Inhalation and Metabolism of Airborne Particles

Particles can be inhaled when their aerodynamic diameter is less than 10 μm; larger ones will be trapped in the nose. In general, as particle size decreases, the access to the lower respiratory tract and the alveolar region increases [4]. This rule does not apply, however, for particles smaller than 100 nm, as the deposition of nanosized particles becomes governed by diffusional processes rather than gravity. For example, 20 nm UFP are predicted to be deposited in the alveolar region up to 50% and only about 10% each in the nasopharyngeal and tracheobronchial regions; in contrast, about 90% of inhaled UFP around 1 nm in size deposit in the nasopharyngeal region [5], whereas only about 10% of this size deposit in the tracheobronchial and essentially none in the alveolar region.

Inhaled particles will be cleared by various human defense mechanisms. The mucociliary escalator dominates clearance from the upper airways, where particles in the size range 2.5–10 μm deposit. The mucociliary escalator is an efficient transport system pushing the mucus, which covers the airways, together with trapped solid materials towards the mouth. Smaller particles ($PM_{2.5}$ and particles <100 nm)

reach the alveoli of the lung and can only be cleared by alveolar macrophages. The uptake of particles and fibers in the alveoli, not only results in activation of macrophages, but also stimulates the release of chemokines and pro-inflammatory cytokines into the circulation and the production of reactive oxygen species. Although the inflammatory response is a key component of host defense, it can also contribute to persistent inflammation and the pathogenesis of disease [6]. Independently of particle size, there are specific particle characteristics of manufactured nanoparticles such as shape (fibers versus crystals), surface (coated versus uncoated) and surface charges (hydrophilic versus hydrophobic properties), which affect deposition and clearance. Even physiological features of the host organism, such as blood circulation during strenuous physical activity [7, 8] or changed air flow due to pre-existing lung diseases [9], determine the extent and site of deposition of particles.

The impact of inhaled particles on extra pulmonary organs has only recently been recognized. Nemmar *et al.* found in five healthy volunteers that inhaled ultrafine ^{99m}Tc–carbon particles passed rapidly into the systemic blood circulation [10]. The literature on the translocation of very small particles from the lungs into the blood circulation is limited and still conflicting. In experimental animal studies, several authors have reported extra pulmonary translocation of ultrafine particles [11–13] after intratracheal installation or inhalation. However, the amount of ultrafine particles that translocate into blood and extra pulmonary organs differed among these studies.

The difference in deposition characteristics is very important to understand why nanoparticles can probably gain access into the human central nervous system (CNS) directly from deposits on the nasal mucosa via the olfactory epithelium and the olfactory nerves. This pathway has been well demonstrated for inhaled or nasally instilled compounds in animal experiments [14] and – if it also exists in humans – would be very important, as it circumvents the tight blood–brain barrier. Although the olfactory system of rodents requires 50% of the nasal mucosa as compared with only 5% in humans, Elder *et al.* suggest that the direct access of nanoparticles to the brain via the olfactory epithelium and the olfactory nerves is also relevant in humans [15].

9.3 Studies of Environmental Air Pollution in the USA and Europe

9.3.1 PM_{10} and $PM_{2.5}$

Based on health statistics and smog episodes in the past, a temporal correlation between high levels of air pollution and acute increases in morbidity and mortality was observed already in the 1950s (e.g. [16]). Since then, numerous epidemiological studies have shown that the association of daily deaths with daily air pollution is not confined to smog episodes, but exists at levels commonly observed in cities and rural areas.

9.3.1.1 Short-Term Studies

From 1988 to 1993, the averages of the annual mean PM_{10} concentrations at 799 sites monitored by the US EPA declined by 20%. Despite these improvements in air quality, Samet *et al.* [17] reported associations between particle concentrations and the number of deaths per day in 20 of the largest cities and metropolitan areas in the USA from 1987 to 1994 with mean 24-hour PM_{10} concentrations well below the standard. Analyses of the daily number of deaths occurring within an urban region have shown that 10 $\mu g\,m^{-3}$ PM_{10} were associated with an increase of 0.2%. The result is based on recent reanalyses of the National Mortality Morbidity Air Pollution Study (NMMAPS) that included 90 urban areas of the USA [18].

The APHEA (Air Pollution and Health: a European Approach) project was a large multicenter European study investigating the short-term effects of air pollution on health [19]. Twenty-nine European cities provided data on mortality from respiratory and cardiovascular diseases and data on daily ambient air pollution. An increase in PM_{10} by 10 $\mu g\,m^{-3}$ was associated with increases of 0.76% (95% CI: 0.47 to 1.05%) in cardiovascular deaths and 0.58% (95% CI: 0.35 to 0.90%) in respiratory deaths [20].

9.3.1.2 Long-Term Studies

In a prospective cohort study, Dockery *et al.* [21] estimated the effects of air pollution on mortality with data from a 14–16-year mortality follow-up of 8111 adults in six US cities, while controlling for individual risk factors. The adjusted mortality–rate ratio for the most polluted of the cities as compared with the least polluted was 1.26 (95% CI: 1.08 to 1.47). Air pollution was positively associated with death from lung cancer and cardiopulmonary disease but not with death from other causes considered together. A follow-up to the Six Cities Study shows that an overall reduction in $PM_{2.5}$ levels results in reduced long-term mortality risk [22]. Another study [23] dealt with the effect of air pollution control measures and compared for 72 months before and after the banning of coal sales in Dublin, Ireland, on age-standardized death rates. Average black smoke concentrations in Dublin declined by 35.6 $mg\,m^{-3}$ (70%) after the ban on coal sales. Adjusted non-trauma death rates decreased by 5.7% (95% CI: 4 to 7%, $p < 0.0001$), respiratory deaths by 15.5% (95% CI: 12 to 19%, $p < 0.0001$) and cardiovascular deaths by 10.3% (95% CI: 8 to 13%, $p < 0.0001$).

In 1982, the American Cancer Society enrolled approximately 1.2 million adults as part of the Cancer Prevention II study, a large cohort study. Participants completed a questionnaire detailing individual risk factor data (age, sex, race, weight, height, smoking history, education, marital status, diet, alcohol consumption and occupational exposures). These data were linked with air pollution data for metropolitan areas throughout the USA and combined with vital status and cause of death data through 31 December 1998. Fine particulate and sulfur oxide-related pollution were associated with all-cause, lung cancer and cardiopulmonary mortality. Each 10 $\mu g\,m^{-3}$ elevation in fine particulate air pollution was associated with approximately a 4, 6 and 8% increased risk of all-cause, cardiopulmonary and lung cancer mortality, respectively [24].

The impact of air pollution on potentially susceptible patients with pre-existing disease was evaluated by defining cohorts hospitalized for certain diseases: chronic

obstructive pulmonary disease [25], congestive heart disease [26, 27], myocardial infarction [28, 29] or diabetes [29, 30]. All of these studies showed an increased risk of experiencing acute exacerbation of their disease on days with a high concentration of air pollution or shortly afterwards. However, physiological responses with potentially negative effects such as an increase in plasma viscosity [31], in fibrinogen [32] and in C-reactive protein [4] were not restricted to frail populations, but were also observed in samples of randomly collected healthy subjects. Small increases in blood pressure may occur in association with elevated concentrations of ambient particles [33, 34].

9.3.2 Ultrafine Particles (UFP)

A study conducted in Erfurt, Germany, on daily mortality [35] showed comparable and independent increases in mortality associated with fine and ultrafine particles. All particles had a strong seasonality with maximum concentrations in winter. The ultrafine particle concentrations showed a pronounced day of the week effect with concentrations during the weekend 40% lower than during the week. This and a clear increase in the ultrafine particle concentrations during the rush hours suggested that the main source of ultrafine particles was automobile traffic. Associations between health effects and particle number and particle mass concentrations have been observed in different size classes and both immediate effects (lags 0 or 1 day) and delayed effects (lags 4 or 5 days) were found. The effects could be found for total mortality but also for respiratory and cardiovascular causes. There was a tendency for more immediate effects on respiratory causes and more delayed effects for cardiovascular causes. Mortality increased in association with ambient particles after adjustment for season, influenza epidemics, day of the week and meteorology and sensitivity analyses showed the results to be stable.

The first epidemiological evidence of effects of UFP on morbidity was collected in Erfurt on 27 adult asthmatics [36]. A stronger decrease in the peak expiratory flow was observed upon correlation with UFP number concentrations than with fine particle mass concentrations ($PM_{2.5}$). A decrease in respiratory functions, e.g. peak expiratory flow [37], and an increase in symptoms and medication use [38] were associated with elevated particle concentrations of ultrafine particles, independently of fine particles. Inflammatory events in the lungs took several days to develop. It was considered likely that a lag time existed between exposure to ultrafine particles and the acute respiratory health effects of the exposed population. Cumulative effects over 5 days seemed to be stronger than same-day effects. There was an indication that the acute effects of the number of ultrafine particles on respiratory health were stronger than that of the mass of the fine particles [39, 40].

To improve the knowledge on human exposure to particulate matter of different sizes and of different chemical composition in Europe and to develop standards for air quality in Europe, the ULTRA project was initiated. Specifically, the aims of the project were to improve exposure assessment to fine particles by assessing the size distributions, including ultrafine particles and elemental compositions of

fine particles in ambient air in three European cities with different sources of particulate air pollution. Three panel studies were carried out in Amsterdam, The Netherlands, Erfurt, Germany, and Helsinki, Finland, during winter and spring 1998–1999 [34, 41, 42]. In all three cities, about 50 elderly persons with coronary heart disease were followed up for 6 months with biweekly intensive examinations, which included measurements of the function of the heart and lungs, blood pressure and of biomarkers for lung damage from urine. The subjects also kept daily symptom diaries. These studies were limited to the investigation of the acute health effects of short-term exposure by evaluating the impact of day-to-day variation in ambient pollution on health through correlating mortality and morbidity with daily pollution levels. There was an association between exposure to ultrafine particles and cardiovascular morbidity in the population with chronic heart diseases. In Helsinki [43], independent associations between both fine and ultrafine particles and the risk of ST-segment depression in their ECG were observed among subjects with coronary heart disease. ST-segment depression is regarded as an indicator of myocardial ischemia. The study reports increased odds ratios for 45 subjects ranging from 1.03 to 3.29 with an estimated 2-day lag (95% CI: 0.54 to 6.32).

For the Erfurt Panel, the following ECG parameters reflecting myocardial substrate and vulnerability were measured: QT and QTc duration, T-wave amplitude, T-wave complexity and variability of T-wave complexity. Fixed-effect regression analysis was used, adjusting for subject, trend, weekday and meteorology. The analysis showed a significant increase in QT duration in response to exposure to organic carbon, a significant decrease in T-wave amplitude with exposure to ultrafine, accumulation mode and $PM_{2.5}$ particles (particles <2.5 μm in aerodynamic diameter) and a corresponding significant increase of T-wave complexity in association with $PM_{2.5}$ particles for the 24 h before ECG recordings. Variability of T-wave complexity showed a significant increase with organic and elemental carbon in the same time interval. The study provided evidence suggesting an immediate effect of air pollution on repolarization duration, morphology and variability representing myocardial substrate and vulnerability, key factors in the mechanisms of cardiac death [44].

In summary, both fine and ultrafine particles are associated with respiratory and cardiovascular morbidity and mortality and appear to do so independently of each other. There is also epidemiological evidence of similar responses to fine and ultrafine particles, although the size of the effects is often larger for ultrafine than for fine particles (at least on a per mass basis). In general, the relative effects of particulate air pollution are greater for respiratory than cardiovascular mortality. Nevertheless, due to the higher background rate of cardiovascular mortality, the absolute number of deaths attributable to particulate air pollution is much higher for cardiovascular than for respiratory deaths [45–47].

Studies on particles mass concentration indicate that there is linear relationship between PM_{10} and $PM_{2.5}$ and various health indicators (such as cough, symptom exacerbation, bronchodilator use, hospital admissions and mortality) [48] for concentration levels between 0 and 200 $\mu g\,m^{-3}$ and no threshold in particle concentrations below which health would not be jeopardized.

9.4
Cardiovascular Disease

Repeated exposures to elevated ambient air pollution concentrations might not only transiently deteriorate risk factor profiles. Several mechanisms have been hypothesized to contribute to deaths from cardiovascular diseases [49], as shown in Figure 9.2. The inhalation of particles provokes oxidative stress and triggers alveolar and systemic inflammation [2], the linchpin of further patho-physiological mechanisms leading to (1) altered blood rheology favoring coagulation [31, 50], (2) vascular dysfunction [43, 51] and (3) enhanced atherosclerosis, all increasing the risk of a subsequent myocardial infarction; and (4) the alteration of the autonomic nervous control of the heart increases the likelihood of ischemic events and cardiac arrhythmias [52]. Patients with implanted cardioverter defibrillators were more likely to receive interventions with high ambient air pollution 2 days before [53].

An association was found between exposure to traffic and the onset of a myocardial infarction within 1 h afterwards (OR 2.92; 95% CI: 2.22 to 3.83, $p < 0.001$). The time the subjects spent in cars, on public transportation or on motorcycles or bicycles was consistently linked with an increase in the risk of

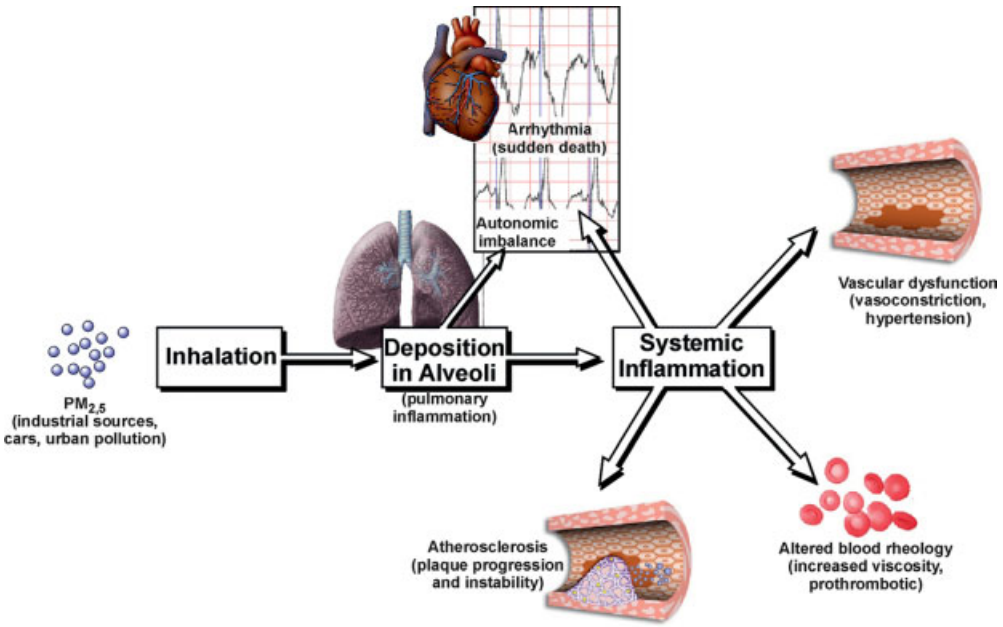

Figure 9.2 General mechanism of cardiovascular disease caused by particulate air pollution exposure. Inhalation of constituents of fine particulate matter ($PM_{2.5}$) can produce pulmonary inflammation. This can directly alter autonomic balance (cardiac rhythm) and lead to a systemic-wide inflammatory response capable of triggering acute and chronic cardiovascular disease. (Reproduced with permission from [49]).

myocardial infarction. Adjusting for the level of exercise on a bicycle or for getting up in the morning changed the estimated effect of exposure to traffic only slightly (OR for myocardial infarction, 2.73; 95% CI: 2.06 to 3.61, $p < 0.001$). The subject's use of a car was the most common source of exposure to traffic; nevertheless, there was also an association between time spent on public transportation and the onset of a myocardial infarction 1 h later [54].

Time-series studies have reported significant reductions in heart rate variability in association with higher ambient air pollution levels in elderly subjects [55, 56] and with occupational exposure concentrations in healthy young men [57]. Decreased heart rate variability reflects a disturbance of cardiac autonomic function and predicts an increased risk for sudden death. Peters [52] reviewed the association between particulate matter and heart disease and concluded that epidemiological studies have demonstrated coherent associations between daily changes in concentrations of ambient particles and cardiovascular disease mortality, hospital admission, disease exacerbation in patients with cardiovascular disease and early physiological responses in healthy individuals consistent with a risk factor profile deterioration.

9.5 Respiratory Disease

The APHEA 2 project investigated short-term health effects of particles in eight European cities and confirmed that particle concentrations were positively associated with increased numbers of hospital admissions for respiratory diseases [58]. Lung diseases attributed to environmental air pollution are (1) deterioration of lung function and respiratory symptoms, exacerbations of chronic obstructive lung disease (COPD) and chronic bronchitis, (2) asthma and allergies and (3) lung cancer.

9.5.1 Deterioration of Lung Function and Respiratory Symptoms

There are few sources of widespread urban air pollution that rival diesel exhaust. The combustion of diesel fuel leads to an emission aerosol that is nanoparticle in primary particle size, but rapidly forms aggregates of 80 nm nanoparticle (accumulation) mode with a solid carbon core. In Europe, exhaust from motor vehicle traffic is considered to contribute to more than 50% of ambient particulate matter (PM_{10}) [59]. For ultrafine particles, the contribution of automobile traffic is even higher. Traffic-related air pollution increases the risk of non-allergic respiratory symptoms and disease. This has been observed in so many epidemiological studies that only one review [60] and one study from The Netherlands are cited here as examples.

Diesel typically is emitted at ground level and ambient diesel levels are highest near highways and busy roads. Brunekreef *et al.* [61] studied children in six areas located near major motorways in The Netherlands and showed that lung function was associated with truck traffic density. The association was stronger in children living closest (<300 m) to the motorways. The results indicated that exposure to

traffic-related air pollution, in particular diesel exhaust particles, leads to reduced lung function in children living near major motorways.

The carbon content of particulate matter, which can be measured as elemental carbon (EC) or organic carbon (OC), served in several epidemiological studies as an exposure surrogate for traffic-related air pollution. It can be shown that alveolar macrophages are loaded with carbonaceous material. Bunn *et al.* [62] collected alveolar macrophages from 22 children aged from 3 months to 16 years with no respiratory symptoms by bronchoalveolar lavage prior to elective surgery. In each child, the size and composition of environmental particles within single sections from 100 separate alveolar macrophages were determined by electron microscopy and microanalysis. Particles consisted of a carbonaceous core and all were ultrafine (<0.1 μm). Other elements such as metals and silicon were not detected. The percentage of particle-containing AM did not change with age, but was increased in children whose parents lived on a main road compared with those living on a quiet residential road (median 10% vs. 3%, $p = 0.014$).

In a recent investigation, Kulkarni *et al.* [63] studied airway macrophages obtained by sputum induction from 64 healthy children in Leicestershire. The authors used the carbon content of airway macrophages as a marker of individual exposure to particulate matter derived from fossil fuel. Each increase in primary PM_{10} of 1.0 μg m^{-3} near each child's home address was associated with an increase of 0.10 μm^2 in the carbon content of airway macrophages and each increase of 1.0 μm^2 in carbon content of airway macrophages was associated with a reduction of 17% in forced expiratory volume in 1 s, of 12.9% in forced vital capacity and of 34.7% in the forced expiratory flow between 25 and 75% of the forced vital capacity. All these reductions were highly statistically significant. The data strengthened the evidence for a causal association between the inhalation of carbonaceous particles and impaired lung function in children.

9.5.2
Asthma and Allergies

Peterson and Saxon [64] reviewed the prevalence of allergic rhinitis and asthma and found an increase in frequency over the past two centuries. They suggested that certain pollutants such as those produced from the burning of fossil fuels, which have been shown to enhance *in vitro* and *in vivo* IgE production, may be partly responsible for the increased prevalence of allergic respiratory disease.

Laboratory studies in humans and animals have shown that particulate toxic pollutants, particularly diesel exhaust particulates, can enhance allergic inflammation and can induce allergic immune responses. Although road traffic pollution from automobile exhausts may be a risk factor for atopic sensitization, the evidence in support of this view remains contradictory [65, 66]. Some investigators have reported a clear association between the prevalence of allergy and road traffic-related air pollution, whereas such a difference was not observed in other studies.

Asthma is characterized by airway obstruction, with air trapping and increases in lung residual volume. Increases in alveolar volume would be expected to enhance diffusional deposition, the primary mechanism of deposition for UFPs, although

impaired alveolar ventilation would counter this increase. A panel study of subjects with asthma [36] found that peak flow varied more closely with the 5-day mean of UFP number than with fine particle mass concentration, suggesting that the UFP component of fine particle pollution contributes to airway effects in asthmatics. Penttinen *et al*. [40] noted that UFP number concentrations tended to be inversely but not significantly associated with measures of lung function. However, some epidemiological studies have not found associations between UFP exposure and health effects [41]. Inhaled UFPs have a high predicted deposition efficiency in the pulmonary region [67]. Thus, the expected number of particles retained in the lung with each breath is greater for UFPs than for larger particles. A study on 16 subjects with mild to moderate asthma demonstrated an efficient respiratory deposition of ultrafine particles especially in subjects with asthma [68]. Deposition was measured during spontaneous breathing at rest and exercise. The deposition fraction increased during exercise by particle number and mass concentration and reached a maximum for the smallest particles. When both the increased deposition fraction and minute ventilation were considered, the total number of particles retained in the lung was 74% greater in subjects with asthma than in healthy subjects. Thus, people with asthma have a higher total respiratory dose of UFPs for a given exposure, which may contribute to their increased susceptibility to the health effects of air pollution.

The association between particulate air pollution and asthma medication use and symptoms was assessed in a panel study of 53 adult asthmatics in Erfurt, Germany, in winter 1996–97. The results suggest that reported asthma medication use and symptoms increase in association with particulate air pollution (0.01–0.1 μm in diameter) and gaseous pollutants such as nitrogen dioxide [38].

9.5.3 Lung Cancer

Large cohort studies in the USA and Europe suggest that air pollution may increase lung cancer risk. For example, the Adventist Health Study found an increased risk of newly diagnosed lung cancers in a cohort study of 6338 non-smoking, white Californian adults, followed from 1977 to 1992, associated with elevated long-term ambient concentrations of PM_{10} [69]. In the Harvard Six Cities Study air pollution was positively associated with death from lung cancer [21]. Also, in the Cancer Prevention II study of the American Cancer Society it was quantitatively evaluated that for each $10\,\mu g\,m^{-3}$ elevation in fine particulate air pollution there is an increase of 8% in lung cancer mortality [24].

In Europe, the association between incidence of lung cancer and long-term air pollution exposure was investigated in a cohort of Oslo men followed from 1972–73 to 1998. During the follow-up period, 418 men developed lung cancer. For a $10\,\mu g\,m^{-3}$ increase in average home address exposure to nitrogen oxides NO_x – a traffic-related gas of urban air pollution – between 1974 and 1978, the risk of developing lung cancer increased by 8%, controlling for age, smoking habits and length of education [70]. To estimate the relationship between air pollution and lung cancer, a nested case–control study was set up within EPIC (European Prospective

Investigation on Cancer and Nutrition). There was a non-significant association between lung cancer and residence nearby heavy traffic roads as an indicator of exposure to air pollution [71].

Since epidemiological studies in railroad workers [72, 73] had suggested that diesel exhaust was a human lung carcinogen, public concern was aroused. Inhalation studies in rats exposed to high levels of diesel exhaust had also resulted in lung tumors [74, 75], although the results were not replicable in other species. Later studies in humans in motor exhaust-related occupations such as truck, forklift and other drivers of diesel vehicles, operators of heavy construction equipment, farm workers operating diesel equipment, bus maintenance garage workers and loading dock workers [76–81] supported the evidence that diesel exhaust might be a potential occupational carcinogen. Bhatia *et al.* [82] evaluated the relation between occupational exposure to diesel exhaust and cancer of the lung in a meta-analysis of 29 published cohort and case–control studies. Pooled effect measures weighted by study precision indicated a statistically significant increased relative risk of lung cancer from occupational exposure to diesel exhaust. This meta-analysis supported a causal association between increased risk of lung cancer and exposure to diesel exhaust. The International Agency for Research on Cancer (IARC) classified diesel exhaust as probably carcinogenic to humans (Group 2A) [83].

Numerous experimental studies *in vitro* and *in vivo* have provided unambiguous evidence for genotoxicity of air pollution. Several studies found an association between external measures of exposure to air pollution and increased levels of DNA adducts, with an apparent leveling off of the dose–response relationship. Due to the organic extracts of particulate matter, especially various polycyclic aromatic hydrocarbons (PAHs), particulate air pollution induces oxidative damage to DNA. Lung cancer develops through a series of progressive pathological changes occurring in the respiratory epithelium. Molecular alterations such as loss of heterozygosity, gene mutations and aberrant gene promoter methylation have emerged as potentially promising molecular biomarkers of lung carcinogenesis [84].

9.6 Diseases of the Central Nervous System

Transitional metals such as copper, manganese and iron have been associated with pathological lesions of the brain characteristic of a variety of neurodegenerative diseases such as Parkinson's disease, Alzheimer's disease and amyotrophic lateral sclerosis [85]. Metals are essential in the synthesis of DNA and RNA and are also cofactors of numerous enzymes, particularly those involved in respiration. In addition, several modifications indicative of oxidative stress have been described in association with neurons, neurofibrillary tangles and senile plaques in Alzheimer's disease.

These findings became even more important after inhalation experiments with rats by Oberdörster [14] suggested that ^{13}C-labeled nanoparticles with a size about 35 nm may migrate along the olfactory nerve into the olfactory bulb of the brain after

deposition on the olfactory mucosa in the nasal region. If this observation proves to be a route of entry of nanoparticles into the brain, it would circumvent the tight blood–brain barrier and might play a role in neurodegenerative disease.

In Mexico, neuropathological findings for 32 dogs from Southwest Metropolitan Mexico City, a highly polluted urban region, were compared with those for eight dogs from Tlaxcala, a less polluted, control city [86]. The report describes early and progressive alterations in the nasal respiratory and olfactory mucosa. Early changes included expression of nuclear neuronal NF-kappaB and iNOS in cortical endothelial cells occurring at ages 2 and 4 weeks; subsequent damage included alterations of the blood–brain barrier (BBB), degenerating cortical neurons, apoptotic glial white matter cells, deposition of apolipoprotein E (apoE)-positive lipid droplets in smooth muscle cells and pericytes, non-neuritic plaques and neurofibrillary tangles. The authors concluded that persistent pulmonary inflammation and deteriorating olfactory and respiratory barriers may play a role in the degenerative neuropathology observed in the brains of highly exposed dogs.

The greatest exposure to metals is likely to occur in occupational settings such as mining, alloy production and welding. Welding and laser operations are well known for their potential to produce large numbers of nanosized particles [87] (see Table 9.1), for example manual metal arc welding with covered electrodes releases particles in the size ranges 20–400 and 10–20 nm for gas-shielded metal arc welding.

A review by Tjälve and Henriksson [88] deals with the mechanism of uptake and transport of metals in the olfactory system. Metals discussed are mainly manganese, cadmium, nickel and mercury. Manganese was found to have a unique capacity to be taken up via the olfactory pathways and be passed transneuronally to other parts of the brain. It is considered that the occupational neurotoxicity of inhaled manganese may be related to an uptake of the metal into the brain via the olfactory pathways. Airborne manganese levels during welding practice were measured in a study on 97 welders engaged in electric arc welding in a vehicle manufacturer. Ambient manganese levels in welders' breathing zone were the highest inside the vehicle and the lowest in the center of the workshop. Serum levels of manganese in welders were about three-fold ($p < 0.01$) higher than those of controls [89].

The neurotoxicity of manganese has been known since the nineteenth century. In 1837, Couper described "manganism" characterized by extrapyramidal motor system dysfunction and in particular, Parkinson's disease and dystonia. Manganese is rapidly cleared from the blood by the liver, but elimination from the central nervous system takes a very long time. The neurological signs of manganism have received close attention because they resemble several clinical disorders collectively described as extrapyramidal motor system dysfunction and, in particular, Parkinson's disease and dystonia. Semchuk *et al.* [90], in a population-based case–control study in Calgary, Alberta, reported no significant increase in risk of Parkinson's disease associated with a history of rural exposure to manganese. In contrast, Gorell *et al.* [91], in a population-based case–control study at Henry Ford Health System (HFHS), Detroit, MI, found a significant association of Parkinson's disease with manganese with more than 20 years of occupational contact (OR 10.6, 95% CI: 1.06 to 105.83),

although only three cases and one control subject had such a lengthy exposure to manganese. The small number reporting such an exposure requires that the association be interpreted with caution.

Racette *et al*. performed a case–control study [92] that compared the clinical features of 15 career welders with two control groups with idiopathic Parkinson's disease. One control group was ascertained sequentially to compare the frequency of clinical features and the second control group was sex- and age-matched to compare the frequency of motor fluctuations. Welders were exposed to a mean of 47 144 welding hours. Welders had a younger age at onset (46 years) of Parkinson's disease compared with sequentially ascertained controls (63 years; $p < 0.0001$). There was no difference in frequency of tremor, bradykinesia, rigidity, asymmetric onset, postural instability, family history, clinical depression, dementia or drug-induced psychosis between the welders and the two control groups. Parkinsonism in welders was distinguished clinically only by age at onset, suggesting that welding may be a risk factor for Parkinson's disease.

9.7
Particulate Air Pollution at the Workplace

The inhalation of dust at work has historically always been and still remains one of the most important causes of ill-health related to work. Dust is responsible for serious and disabling diseases such as pneumoconiosis, interstitial lung disease and fibrosis, lung cancer and asthma. Research related to dust exposure at the workplace has historically always focused on the effects on the lung and only recently – probably triggered by environmental epidemiological studies – has started to look for implications regarding the cardiovascular system. For example, in a retrospective cohort study, an increased risk of mortality due to ischemic heart disease (OR 1.32, 95% CI: 1.13 to 1.55) was observed among heavy equipment operators [93] exposed to diesel motor emissions. The paragraphs below summarize the effects of particle inhalation on the lungs, as the impact of dust on the lungs has attracted most attention over the last 50 years in occupational medicine.

Pneumoconiosis, one of the civilization's oldest known occupational respiratory diseases, is caused by the inhalation of dust and is characterized by a reactive reparative process that leads to the formation of nodular fibrotic changes in the lungs. Gradually, the alveoli of the lungs become replaced by fibrotic tissue, causing an irreversible loss of the tissue's ability to transfer oxygen into the bloodstream. The fibrogenic potential of inorganic dusts varies considerably, with silica and asbestos having greater fibrogenic potential than coal dusts, iron and man-made mineral fibers. Silicosis, a condition of fibrosis of the lungs marked by shortness of breath and resulting from prolonged inhalation of crystalline silica dust, is also associated with lung cancer. The hypothesis that diffuse fibrotic disorders of the lung are associated with increased lung cancer risk stems from early observations at autopsy that lung cancer was often associated with fibrosis of the lung. This finding could be substantiated in a meta-analysis of lung cancer and silicosis [94].

The pooled RR estimate for the 23 studies that could be combined was 2.2, with a 95% CI of 2.1 to 2.4. The authors considered the association between silicosis and lung cancer as causal, either due to silicosis itself or due to a direct effect of the underlying exposure to silica. The IARC concluded that there is sufficient evidence for carcinogenicity of crystalline silica in humans [95].

In 2006, the IARC in Lyon, France, reassessed the carcinogenicity of carbon black and titanium dioxide and the results will be published as volume 93 of the IARC Monographs. Both substances are produced in the particulate form. Exposure to carbon black occurs mainly with aggregates with particle size 50–600 nm. The primary particles of titanium dioxide are typically 200–300 nm in diameter, but larger aggregates and agglomerates are readily formed. Ultrafine grades of titanium dioxide (10–50 nm) are used in sunscreens and plastics to block ultraviolet light. For carbon black and titanium dioxide, the Monograph Working Group of the IARC concluded that existing epidemiological studies provided inadequate evidence of carcinogenicity, but overall – taking also into account the sufficient evidence of carcinogenicity from toxicological experiments in laboratory animals – carbon black and titanium dioxide were classified as possibly carcinogenic to human beings (Group 2B).

Asbestos is the name given to a group of minerals that occur naturally as bundles of fibers which can be separated into thin threads. These fibers are not affected by heat or chemicals and do not conduct electricity. For these reasons, asbestos has been widely used in many industries. When asbestos fibers are set free and inhaled, exposed individuals are at risk of developing an asbestos-related disease such as asbestosis, lung cancer, mesothelioma of the pleura or peritoneum and other cancers, such as those of the larynx and oropharynx [96]. Asbestos remains the primary occupational carcinogenic substance affecting workers all over the world. Outside the workplace, asbestos is second only to tobacco as an environmental source of cancer.

Carbon nanotubes have attracted a great deal of attention due to their potential technological applications, but also – with their shape and physical appearance resembling those of asbestos fibers – have aroused considerable concern. Even though carbon nanotubes consist only of carbon, it does not seem adequate to classify them (and also fullerenes in general) as graphite. Varying physical shapes might well be associated with entirely different properties. Toxicity studies on nanomaterial will be extremely complex, as 10, 20 m, 50 and 500 nm titanium dioxide crystals, for example, will all be different. Despite the prominence of carbon nanotubes in nanotechnology, exploration of their interactions with biological materials remains sparse. In part, this reflects the challenge of observing nanotubes in biological environments. Single-walled carbon nanotubes in tissues evade detection by elemental analysis, as they contain only carbon, and often also by electron microscopy. One successful method described recently is near-infrared fluorescence microscopy [97].

Lam *et al.* [98] and Warheit *et al.* [99] have published the results of studies of the toxicity of single-walled carbon nanotubes in mice and rats, respectively. Using an intratracheal route of administration, they compared different means of nanotube production with effects of carbon black and quartz particles. In Lam *et al.*'s study,

the nanotubes were found to produce dose-dependent lung lesions. The effects of carbon black were distinctively different. The study by Warheit *et al.* was more comprehensive. It showed multifocal pulmonary granuloma but without evidence of ongoing pulmonary inflammation or cellular proliferation. These effects were different from those of quartz, carbon black and graphite. The conclusion from these two studies was that carbon nanotubes have different toxicological properties from other forms of carbon [100].

Another example of how the physical shape of nanoparticles will have an impact on cellular function was provided by Zhao *et al.* [101]. C_{60} fullerenes were found to bind to double-stranded DNA, either at the hydrophobic ends or at the minor groove of the nucleotide. They also bound to single-stranded DNA, deforming the nucleotides significantly. When the DNA molecule was damaged (specifically, a gap was created by removing a piece of the nucleotide from one helix), fullerenes could stably occupy the damaged site. The authors speculated that this strong association may negatively impact the self-repairing process of the double stranded DNA.

There have been two reports [102, 103] describing fibrotic lung disease that developed after exposure to indium tin oxide (ITO). ITO is a sintered alloy containing a large proportion of indium oxide and a small proportion of tin oxide and is used in the making of thin-film transistor liquid crystal displays (LCDs) for television screens, portable computer screens, cellphone displays and video monitors. One patient was engaged in wet surface grinding of ITO targets for 3 years and the other was exposed for 4 years to ITO as an aerosol while making transparent conductive films. Both patients came from the same factory and developed pulmonary fibrosis. One died of bilateral pneumothorax. The autopsy demonstrated interstitial pneumonia with numerous fine particles scattered throughout the lungs. Intrapulmonary deposition of indium and tin was shown by X-ray energy spectrometry in the fine particles. The level of serum indium was extremely high. According to Chonan and Taguchi [104], among 115 workers from the same metal plant, 14 revealed interstitial fibrosis on chest CT.

In experimental or occupational settings, exposure to airborne particles, fibers and fumes have long been recognized as causing fibrotic lung disease, with idiopathic pulmonary fibrosis (IPF) being the most distinct entity. IPF is a progressive and devastating lung disorder with a median survival of 2–4 years after diagnosis [105], yet the course of individual patients is highly variable. In various populations, the prevalence estimates for IPF have ranged from 6 to 32 per 100 000 persons. Approximately two-thirds do not have a known cause (idiopathic), whereas one-third result from known causes such as sarcoidosis, connective tissue disease, complication of certain drug exposures or radiation and occupational exposures.

In a meta-analysis of six case–control studies conducted in three countries, several exposures were significantly associated with IPF, including ever smoking (OR 1.58, 95% CI: 1.27 to 1.97), agriculture/farming (OR 1.65, 95% CI: 1.20 to 2.26), livestock (OR 2.17, 95% CI: 1.28 to 3.68), wood dust (OR 1.94, 95% CI: 1.34 to 2.81), metal dust (OR 2.44, 95% CI: 1.74 to 3.40) and stone/sand (OR 1.97, 95% CI: 1.09 to 3.55) [106]. Although multiple exogenous agents can initiate an inflammatory

alveolitis and result in interstitial lung disease, it is likely that the underlying pathogenetic mechanisms that mediate the development and progression of pulmonary fibrosis are similar. The natural history and the pathogenic mechanisms remain unknown; the long-prevailing hypothesis sustains the idea that chronic inflammation plays an essential role. According to this hypothesis, the alveolar epithelial alterations are caused by an unresolved inflammatory process. More recently, however, research emphasis changed from a focus on inflammation to alveolar epithelial injury, fibrogenesis in fibroblastic foci [107].

New cases of occupational asthma in France are collected by a national surveillance program, based on voluntary reporting, named Observatoire National des Asthmes Professionnels (ONAP) [108]. The most frequently incriminated agents were flour (20.3%), isocyanates (14.1%), latex (7.2%), aldehyde (5.9%), persulfate salts (5.8%) and wood dust (3.7%). The highest risks of occupational asthma were found in bakers and pastry makers, car painters, hairdressers and wood workers. Another voluntary surveillance scheme, SHIELD, for occupational asthma is located in the West Midlands, a highly industrialized region of the UK [109]. Spray painters represented the occupation at the highest risk of developing occupational asthma, followed by electroplaters, rubber and plastic workers, bakery workers and molders. Although the percentage of reported cases was low among healthcare workers, there was an increasing trend. Isocyanates still remained the most common causative agents, with 190 (17.3%) out of the total 1097 cases reported to the surveillance scheme in 7 years. There was a decrease in the reported cases due to colophony (from 9.5 to 4.6%) and flour and wheat (from 8.9 to 4.9%). There was an increase of reported cases due to latex (from 0.4 to 4.9%) and glutaraldehyde (from 1.3 to 5.6%).

The best evidence to support the hypothesis that it is the ultrafine fraction of PM_{10} that is responsible for the adverse health effects comes from toxicology [110]. Ultrafine particles have extra toxicity and inflammogenicity compared with fine, respirable particles of the same material when delivered at the same mass dose. This has been shown for a range of different materials of generally low toxicity, such as carbon black and titanium dioxide. Ultrafine particles cause inflammation in the lungs even when composed of relatively low toxicity materials. The mechanism of the induction of inflammation appears to be via oxidative stress and Ca^{2+} and signaling perturbations [111]. Particularly the large surface area of ultrafine particles provides a unique interface for catalytic reaction of surface-located agents with biological targets such as proteins and cells [112]. *In vivo* experiments showed that within hours after the respiratory system is exposed to nanoparticles, they may appear in many compartments of the body, including the liver, heart and nervous system. Inhalation experiments with rats resulted in ultrafine titanium dioxide particles being found on the luminal side of airways and alveoli, in all major lung tissue compartments and cells and within capillaries. Particles within cells were not membrane bound and hence had direct access to intracellular proteins, organelles and DNA, which may greatly enhance their toxic potential [113].

Current aerosol standards at the workplace are expressed in terms of mass concentration of particulate matter conforming to a particle size fraction.

Instruments able to measure particles below 100 nm were first introduced for environmental studies and are not in use for operational supervision due to a lack of regulations. This is surprising, as nanoparticles had been around the workplace for a long time before nanotechnology appeared on the scene. Aerosols in workplace environments may be derived from mechanical processes (e.g. the breaking or fracture of solid or liquid material) and may come from a variety of sources such as mining, chemical manufacture, textiles and agriculture. The size range can be anything from micrometer and submicrometer particles down to 100 nm and below. In a workplace study [114], nanoparticles occurring in different work processes were measured. Typical examples include welding fumes, metal fumes, soldering fumes, plasma cutting fumes, plasma spraying emissions, polymer fumes, vulcanization fumes, powder coating emissions, oil mists, aircraft engine emissions, bakery oven emissions, meat smokery fumes and particulate diesel motor emissions. The particles were for the most part the products of condensation in thermal and chemical reactions, the primary particles created having a size of only a few nanometers. The most frequently occurring particle size was between 160 and 300 nm. The total concentration of all particles in the measurement range 14–673 nm was between 500 000 and 2 500 000 particles per cm^3. A comparison of the occurrence of nanoparticles in different workplace atmospheres is given in Table 9.1 [87].

Most plasma and laser deposition and aerosol processes are performed in evacuated or at least closed reaction chambers. Therefore, exposure to nanoparticles is more likely to happen after the manufacturing process itself, except in those cases of failures during the processing. In processes involving high pressure (e.g. supercritical fluid techniques) or with high-energy mechanical forces, particle release could occur in the case of failure of sealing of the reactor or the mills. Furthermore, many particles, including metallic particles, are highly pyrophoric and there is a considerable risk of dust explosions [116].

Table 9.1 Comparison of nanoparticles in workplace air [87].

Workplace	Total concentration in measurement range 14–673 nm (particles cm^{-3})	Maximum of number concentration (nm range)
Outdoor, office	Up to 10 000	
Silicon melt	100 000	280–520
Metal grinding	Up to 130 000	17–170
Soldering	Up to 400 000	36–64
Plasma cutting	Up to 500 000	120–180
Bakery	Up to 640 000	32–109
Airport field	Up to 700 000	<45
Hard soldering	54 000–3 5000 000	33–126
Welding	100 000–40 000 000	40–600

10
Impact of Nanotechnological Developments on the Environment

Harald F. Krug and Petra Klug

10.1
Problem

Since Feynman's legendary statement, 'There's plenty of room at the bottom' [1], natural scientists in physics, chemistry, electronics and other fields have been occupied with newly combining the smallest units of matter. Using the resources of modern analysis, especially atomic force microscopy, not only can the properties of matter and atoms be examined, but even single atoms can be manipulated. Aside from the known results, this also gave rise to speculation that manipulation of matter at the single atom level was interpreted in such a way that the possibility exists of generating engines and machines that are able to replicate themselves and therefore possibly get out of control. Without wanting to evoke once again the discussion that has been going on for a long time between Eric Drexler, representative of the hazard hypothesism and Richard Smalley, representative of the safety hypothesis [2], the reactions to this nevertheless show that here (i) sensible communication is necessary in order to point out the real hazards and (ii) accompanying safety-relevant research is needed in order to identify the real hazards and to face them. What we have to count on in all probability in the near future is increased production of nanomaterials and nanoparticles and associated with that its possible release into the air, water and soil.

Bayer, as an example, has produced carbon nanotubes for over 2 years and the production capacity will increase over the next 5 years from

- 2005 3 tons

to

- 2006 30 tons
- 2007 60 tons
- 2009 200 tons
- 2012/13 3000 tons.

Within this book, several examples have been shown where nanomaterials can be used within the environment. The opportunities for applications are nearly endless;

Nanotechnology. Volume 2: Environmental Aspects. Edited by Harald Krug

ISBN: 978-3-527-31735-6

nevertheless, along with their use, numerous threats may arise when they are released into the environment and become distributed everywhere. Nanoparticles and nanomaterials are used in various applications from which they reach the water and the soil. Titanium dioxide and zinc oxide from sunscreens and surface coatings from textiles, glass or other surfaces may be washed off and contaminate natural water [3]. We are responsible for these products, their use and their disposal, hence we must be careful in distributing all these new materials before we know their exact behavior and fate within the environment. It is obvious that nanomaterials will reach the environment and exposure is therefore probable. If there is a biological effect within the organisms that are exposed to these products, then we can postulate a possible risk that has to be addressed:

$$\text{risk} = f(\text{exposure}, \text{hazard})$$

10.2 Risk Management

The first step in risk management is the identification of potential risks and their cause. A reasonable risk identification must include all areas of a technology, both the internal and the external factors (Figure 10.1). In order to achieve this, intensive research is necessary concerning both health-relevant and environment-relevant questions [4–6]:

- particle absorption by living organisms
- accumulation of nanoparticles in certain organs (e.g. lung, liver, spleen, brain, fetus)
- specific effects of nanoparticles in the respiratory tract (e.g. inflammation)
- fate and behavior of substances in the environment (e.g. mobilization of heavy metals, binding to and of toxic substances)

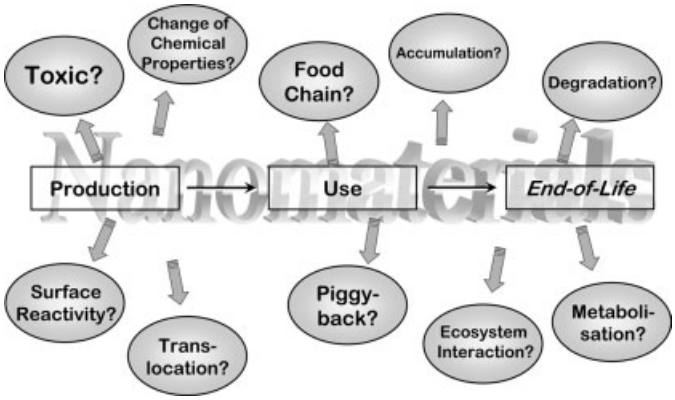

Figure 10.1 Questions of hazard identification of nanoparticles that can occur in the environment during the entire life cycle (Adapted from [5]).

- possible accumulation via the food chain
- desorption/adsorption
- unexpected effects.

A very important aspect in the judgment of possible risks from nanotechnological products lies in the differentiation of free and fixed nanoparticles, because there is obviously a large difference in their mobility. Furthermore, one must differentiate between particles and materials that are being manufactured as technical products and those that are created accidentally in technical processes and are released into the environment (e.g. diesel exhaust, fly ash, catalytic dust, candle soot). Humans are and have been exposed to such ultrafine particles (UFPs), which mainly result from combustion processes, since the beginning of their biological development. Whereas in former times forest fires, volcanoes and sand- and other storms occurred, since the industrial revolution and since the increase in motor traffic, a dramatic rise in UFPs in the air has taken place over the last century.

With the presumed and very fast development in the area of nanotechnological applications, it must now be taken into account that a further source of such minute particles will emerge that will reach humans via the environment: either from the environment to the people or vice versa.

The exposure that goes along with that to humans via the respiratory system, nutrition and skin and also the direct injection of nanoparticles in the medical sector could lead to adverse effects [7–10]. With the knowledge that newly synthesized nanomaterials possess completely new properties in view of chemical, physical and electronic applications, entirely new effects on living organisms can be postulated. For these reasons, the behavior of nanoparticles in the environment and in living organisms cannot simply be extrapolated; a significant prediction of the toxicity of nanoparticles on the basis of the knowledge concerning conventional materials cannot be made. The situation is, in addition to the above-mentioned new effects, not assessable, also for the following reasons:

- the large number of different materials
- the large number of different structures, surfaces, shapes and sizes.

Hence information about the safety and the possible hazards from nanomaterials is urgently needed. Toxicologists can, by all means, benefit from the previously performed studies on the effects of ultrafine particles on the environment, since this is where a multitude of findings already exist. Since the Middle Ages and earlier there have been well-documented cases on workplace-related exposure with effects on health. Especially workers in mines are subject to exposure to inhaled dust of any size for long periods of their lives, which can lead to pneumoconiosis and fibrosis of the lung. It has been shown that especially the fractions of ultrafine particles in the air lead to the greatest effects on health [11–17].

Present scientific knowledge about substances and devices produced using nanotechnologies precludes going further than identifying hazards – the first step in risk assessment – and providing some elements of hazard characterization – the

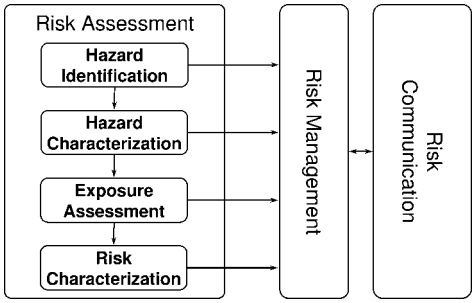

Figure 10.2 From risk assessment to risk communication.

second step in risk assessment. Research on the behavior of nanoparticles in different compartments of the environment and also research on the impacts of nanoparticles on animals and humans, depending on different ways of assimilation of nanoparticles (via the lung, via digestion or via the skin) is on the agenda. Together with assessments of the exposure of humans to nanoparticles at different locations (exposure at workplaces in industry or for consumers of nanoparticle-based products) – which would require prospective analyses of the production and distribution of nanoparticle-based products – the risk management chain (Figure 10.2) could be completed by scientific knowledge. Moreover, if there are some situations where risks could be assumed, we have to communicate these to politicians, the public and consumers. Affected people must have the chance to decide whether they want to accept such risks or not.

10.3 Sources of Nanoparticles: New Products

The results of these and many other studies could lead us to expect a cautionary and understandably biased view towards new sources of nanoparticles. Various products have already been on the market for a long time (Table 10.1).

Some of these products will sooner or later lead to a rise in the amount of particles in the environment, even if not all released particles will be in the ultrafine range under 100 nm. The use of nanotechnological products in all areas of life raises some important questions:

- Is the use immediately followed by an increased exposure towards nanoparticles and which exposure routes are involved?
- Where do the nanoparticles go after being released and where do they stay?
- Do the new materials pose an unacceptable risk?

The manufacture of nanomaterials and nanoparticles at present does not make a noteworthy contribution to the amount of particles in the environment. The public discussion and the voiced opinions in the daily media are currently based purely on speculation. On the other hand, it should also be made clear that the corresponding

Table 10.1 Use of nanoscale metal oxide and carbon modifications in various products of commercial interest (examples).

Type	Products (examples)
Metal oxides	
Silicon dioxide (SiO_2)	Additives in polymer composites
Titanium dioxide (TiO_2)	UV-A protection/photocatalysis
Aluminum oxide (Al_2O_3)	Solar cells
Iron oxide (Fe_3O_4, Fe_2O_3)	Pharmacology/medicine/catalysis
Zirconium oxide (ZrO_2)	Additives to scratch-resistant surfaces
Zinc oxide (ZnO)	UV-A protection/photonic
Carbon modifications	
Carbon black	Car tires, printers, copy machines
Fullerenes	
Buckminsterfullerenes (C_{60})	Mechanical and tri-biological applications/additives in lubrications/greases Additives to cosmetics
Carbon nanotubes	
Single-wall carbon nanotubes	Additives in polymer composites
Multi-wall carbon nanotubes	Electronic field emission Batteries Fuel cells
Carbon nanowires	
Various conformations	Mechanical and tri-biological applications Carrier material for catalysts Additives in polymer composites Elastic spumes

data for assessing an exposure and the hazards are still lacking and that the gaps in knowledge must definitely be closed. For this, a new research field has been established: nanotoxicology [18]. This specializes in analyzing the biological safety of technical nanostructures and nanomaterials. The same rules apply for this part of toxicological research as for the hazard assessment of other chemical impacts on the environment (Figure 10.3).

Within the assessment of relevant environmental problems of xenobiotics or chemicals, the predicted environmental concentration (PEC) and the predicted 'no-effect' concentration (PNEC) are of great importance. If the PEC value is low and the PNEC value is high (PEC/PNEC < 1), a low risk can be calculated and no measures for reduction are necessary, whereas in the opposite case, a high PEC value and a low PNEC value (PEC/PNEC > 1), further measures are indicated. On the one hand this can mean that a limited use will be the result, but it can be corrected by extended test procedures if it results in the relation between the two values being <1 again.

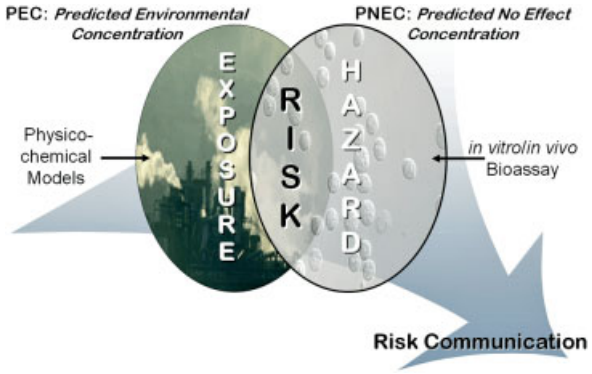

Figure 10.3 Conventional approach to ecotoxicological risk assessment.

10.4 Production and Use of Nanomaterials

As mentioned above, the production and use of nanomaterials will increase dramatically and all areas of daily life will be affected. Exposure to nanomaterials will become more probable, whereas an important differentiation will be whether these materials are coated or uncoated. Coatings change the properties of the material, which has a direct impact on the particle and its behavior in biological systems. Also of importance in view of possible far-reaching effects is the stability and along with that the survival time of the particles in the environment. Both the environmental-relevant and the health-relevant effects are largely dependent on whether the nanoparticles are persistent or not. As far as stable particles are concerned, basically the same is true as for long-lived chemicals: they could, if absorbed by living organisms, accumulate, concentrate in certain target organs and eventually develop a critical effect if the dosage reached is sufficiently high. Therefore, precautionary safety measures must be taken in good time, in order to recognize those stable materials with critical consequences and to prevent their release. It has been demanded by several researchers that the following points must be strictly observed:

- potential routes for human exposure
- possible industrial sources of occupational exposure
- level of exposure
- means of and effectiveness of control measures
- potential numbers exposed
- trends in the use of nanotechnological products
- timely recognition of effects that are caused by the change from the laboratory scale to the industrial scale.

These issues can be transferred in this or a similar fashion to the conditions in the environment; for example, nanoparticles in personal care products reach wastewater

and therefore also the environment, in small but continuous quantities, through body cleansing [3].

10.5 Workplace and the Environment: Effects and Aspects of Nanomaterials

The technical possibilities of nanotechnology to develop new types of miniature sensors, pollutant filters and fuel-cell catalysts can make a considerable contribution to the improvement of the environment. However, these developments are only at the beginning stage and the insecurity that is connected with the production of these new materials currently outweighs their possible advantages. To convey these advantages and to measure them against their possible disadvantages are a huge challenge for the developers of this technology. However, there are already a number of ideas for better 'end-of-pipe' technologies that could make a contribution to air pollution control, wastewater, soil and waste purification and energy production and storage. Some examples of uses in the environment that have been described in detail in the other chapters of this book are:

- Syntheses or fabrication processes can take place at room temperature and under normal pressure in order to save energy.
- The use of non-toxic catalysts leads to the minimal formation of pollutants and reduces material usage and emission.
- Water-based reactions can help save on solvents and reduce contaminants and an adapted 'just-in-time' production can reduce ecological environmental pollution and over-production.
- Nanoscale information technology will improve the tracking of products and product routes in order to control recycling, further use and 'end-of-life' disposal in an environmentally safe way.
- Nanoscale iron could be applied very efficiently for groundwater treatment along with further possibilities for improvement by using additional metals, such as palladium.
- Various nanomaterials can be used as semiconductor films for producing sensors or photocatalysts and these sensors could detect organic pollutants and degrade them by photocatalytic reactions.
- Single-molecule detection could help recognize pollutants early so that precautionary measures are possible.
- Nano-building blocks could analyze chemicals by specific reactions; biogenous toxins could be detected and food could be monitored more efficiently.

Already lead-off studies are being published where carbon nanotubes are used as sensors for gases [19], metal oxides show a sensitive reaction to moisture or hydrogen [20], silver polymer nanoparticles are used for the detection of aromatic hydrocarbons [21] and nanoparticles are used as sorbents of environmental contaminants [22].

Aside from these positive aspects of nanotechnological uses in the environment, we must not lose sight of the above-mentioned possible negative effects on the environment and on living organisms. In the meantime, recent studies have already been conducted which directly examine an exposure to nanoparticles and their effects on mortality. However, so far no significant increases in the standardized mortality rate for specific causes of death in rats that were subjected to high concentrations of nanoscale TiO_2 were found, or in manufacturing workers in a cohort study [23]. The existing data are anything but sufficient in order to serve as a basis for a scientific discussion. Even if the pure nanomaterials did not have a negative effect on living systems, according to the opinions of toxicologists and occupational physicians, they could still be able to bind other contaminants on their surface, enabling more facile transport into the air or water and subsequently leading to an increased burden of the organisms in the environment. Most nanomaterials and nanoproducts are currently only used in laboratories, so that environmental pollution so far low or negligible. However, with the increasing number of possible applications, the possible impact on the environment and the exposure of living organisms will increase [4, 24].

10.6 Distribution of Nanoparticles in Ambient Air

Depending on their production and use, nanoparticles can reach the water or air, from where they will eventually reach the groundwater or the soil. Furthermore, their use in disposable articles necessitates increased caution where recycling and waste management are concerned. Since nanoparticles in the air act more like gas molecules and hardly sediment at all, they could cover great distances. Currently, the long-term effects cannot be calculated by any means based on the poor data available. However, the air is one of the best-examined environmental compartments and its pollution has been recorded for many decades. The organisms that are exposed in ambient air are being examined intensively and many studies are examining the adverse effects of particular mass in the air (see Chapter 9 for detailed information). Nevertheless, the unreasonably hazardous effects especially of ultrafine particles in the air have been discovered during the past 10 years [16, 17, 25–27]. It could be assumed that the number of ultrafine particles in the air will increase in the coming years, first at the workplace and then in the environment. Especially due to the surface treatment of engineered nanoparticles, release of nanoscale particles could occur, while oxidic metal particles and carbon nanomaterials normally start to aggregate soon after their synthesis and form agglomerates, which frequently sediment faster than the primary particles. Immediately after their formation, the primary particles act more like a gas or a vapor phase where diffusion processes prevail (for details, see Chapter 7). The primary particles show high diffusion coefficients and blend in well in aerosol systems. This is an important aspect in the control of such minute particles in the air. In closed synthesis systems that show a leak, it is easier for nanoparticles to escape unnoticed, due to their much higher

Table 10.2 Coagulation half-life period of nano particles.

Particle diameter (nm)	Half-life at a concentration of			
	1 g m^{-3}	1 mg m^{-3}	1 μg m^{-3}	1 ng m^{-3}
1	2.20 μs	2.20 ms	2.20 s	36.67 min
2	12.00 μs	12.00 ms	12.00 s	3.34 h
5	0.12 ms	0.12 s	2.00 min	33.34 h
10	0.70 ms	0.70 s	11.67 min	8.10 d
20	3.80 ms	3.80 s	63.34 min	43.98 d

(Original values from [47]).

mobility, than it is for their larger counterparts. Due to the faster distribution, the measurable concentration directly at the leakage is rather low; in return, a larger number of individuals/workers could be exposed since the particles are distributed more extensively over a larger area. For this reason, gas detection systems must be used and not particle detectors, ultra-sensitive systems in any case. On the other hand, the higher speed of the smaller particles also leads to a larger number of collisions, which support the tendency for aggregation and agglomeration and facilitate particle growth. This growth process is directly dependent on the number of particles in the given volume and their mobility. Although this process runs very fast (Table 10.2), it must be considered that a newly formed nanoparticle resulting from these collisions, which is obviously larger than the primary particles, will nevertheless have at least one of its dimensions smaller than 100 nm.

One difficulty is, and also will be in future studies, that airborne particles do not display a uniform population, but rather result from very different sources. Hence, possibly emitted engineered particles can mix already at the workplace with, for example, diesel exhaust fumes during packing and loading of nanomaterials [28], so that assessment and distinct source definition are often difficult. Nevertheless, there are indications that during the processing of nanomaterials, the same ones are released into the air [29]. However, these are so far the only current studies that have dealt with the release of produced nanomaterials. Two further reports deal with the general aspects of the distribution of ultrafine particles in the atmosphere and at the workplace, but largely particles that are created unintentionally and not those produced technically [30, 31].

10.7 Distribution of Nanoparticles in Water

In all probability, and viewed over a longer period of time, distribution and exposure to the environment and to humans in the water and the soil will take place. If the growth in production in fact moves as fast as is predicted, increased concentrations of nanomaterials in the groundwater or in the soil could be an essential exposure route

that should be taken into consideration when assessing the risk for the environment [32]. Such products are already in use as titanium dioxide nanoparticles in sunscreens and paints, as carbon nanotubes in composite materials (car tires) or as aluminum particles in shampoos [3].

As mentioned above already, different metallic and polymeric nanoparticles can be used for groundwater remediation (for details, see Chapter 4) and are therefore a possible source of pollution [33–35].

In this context, two issues are of particular importance: on the one hand, the direct effects of nanomaterials in the environment must be examined, and on the other, the routes of the nanomaterials into the environment (and through it, e.g. through the porous soil matrix) must be clarified. Some studies have shown a large difference between the mobility of nanoparticles in porous media, depending on whether they are oxidic particles or carbon particles such as fullerenes [34, 36]. During their transport in the water or through the soil matrix, even harmless particles could react with other chemicals or adsorb them and therefore contribute to a possible hazard themselves [37–39]. Many substances have the capability of sticking to the surface of nanoparticles [21, 40]; these adsorbed chemicals could then cause a biological effect, the nanoparticles itself especially increase the uptake by organisms or directly lead to adverse effects (Figure 10.4). It is conceivable that the particles themselves or the bound pollutants after they have been taken up by living organisms cause, for instance, lysosomal damage, thereby increasing autophagy and in effect cell damage, as suggested by Moore [41].

Using the fullerenes as an example, it could be shown that the availability and the mobility of nanomaterials in the water and in the soil depend very strongly on the physico-chemical properties of the surface of these particles. At different ionic strengths and pH values, three fullerene preparations and four different oxidic materials behaved very differently with regard to their transport properties in the aquifer [34, 36]. Whereas the transport of mineral nanoparticles could be described by established models for the transport of particles in porous media, the same did not hold true for the fullerenes since they behaved in a totally unexpected way and showed unusual properties. Especially that particular form of fullerenes that has recently caused concern in biological tests [10] is the least mobile one in soil and water tests, so

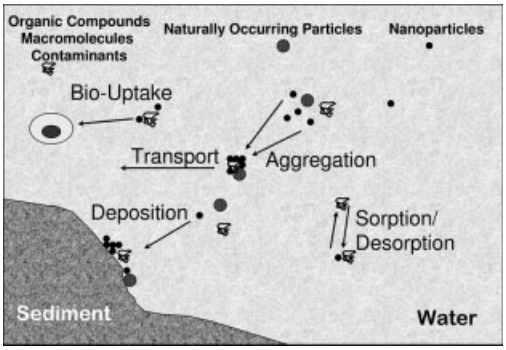

Figure 10.4 Distribution and possible reactions of nanoparticles in the aquatic system.

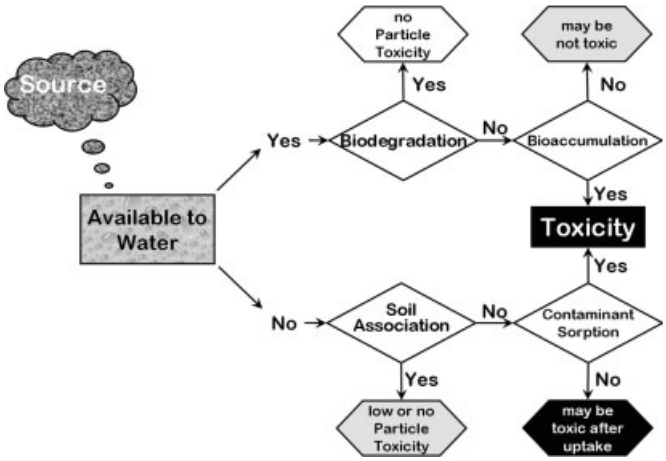

Figure 10.5 Decision scheme for an assessment of nanomaterials in environmental compartments.

that we can rather expect a reduced risk here. This example is intended to demonstrate that our knowledge about the behavior of nanomaterials in the environment is still totally insufficient and that the resulting debate about possible risks has not yet been professionally established. Hence a decision should be made for every single material, based on the knowledge about the availability and transport in water and/or soil (Figure 10.5).

The above-mentioned work by Oberdörster [10] showed, for the first time, a direct effect of fullerenes on fish. After exposure to 0.5 ppm of water-soluble buckyballs (C_{60}) for 48 h, the fish showed significantly increased levels of lipid peroxidation in the brain. Furthermore, the gene expression was checked, for example in the liver, where it was striking that there were genes that were turned on and others that were turned off. Also, there was evidence of a systemic effect of the fullerenes, despite the fact that the author herself judged the concentration to be very high and allocated the fullerenes only 'moderate toxicity'. Unanswered are the questions of how much of the material was really taken up by the fish and whether this material can really accumulate in the food chain or in specific organs, such as the brain. Such an accumulation would then suggest a hazard for other organisms. Therefore, it is necessary to increase the efforts in order to acquire more information about the bioaccumulation of nanomaterials, since many of them are not likely to be biodegradable and could therefore, under certain conditions, behave as persistent pollutants. Some follow-up studies by different authors resulted in controversial data as the high capacity for toxic effects of fullerenes could not documented by the same group when fullerenes were resuspended directly in water [42]. A solution of fullerenes in tetrahydrofuran (THF) has been shown to be highly toxic ([10]; [43]) and we could demonstrate that this is dependent on the peroxides formed in THF spontaneously. Hence it is not always the nanomaterials that are the toxic component band the solvents or contaminants often have a more dramatic effect on living organisms, as has been published elsewhere [44, 45].

10.8 Conclusions

On the basis of the displayed level of knowledge so far, five fundamental considerations can be taken into account about the eco-toxicological risk management of nanomaterials:

1. Research on the toxicology of nanomaterials has so far been more of a description of the symptoms, hence it is essential to find out more about the biological mechanisms on the cellular and molecular level.
2. The further development of models and model systems is necessary in order to understand cellular and physiological processes better and to be able to include the communication between the cells within the investigations.
3. It should be possible to establish a relationship between molecular, cellular and pathophysiological end-points with ecological consequences.
4. A more precise and preventive assessment of hazardous effects and risks of new developments in the sector of nanotechnology should be possible by strong improvement of the available data.
5. Of essential relevance is an increasing knowledge of the life-cycle of nanotechnological products, from production, through their use and until their disposal. This includes possible exposure scenarios in addition to the systemic effects in living organisms, to close knowledge gaps, where screening studies may be preferred instead of detailed analysis.

Only on the basis of improved knowledge about the potential dangers in the entire life cycle of the products will a risk assessment be possible and the corresponding measures can then be implemented in order to reduce a possible hazard.

This was also made clear at a workshop of the National Science Foundation (NSF) and the Environmental Protection Agency (EPA) in the USA, whose results were summarized by Dreher [46] as follows:

- valid exposure assessment for engineered nanoparticles.
- toxicity of nanoparticles
- extrapolation of their toxicity using existing data about particles and ambient fibers
- environmental and biological fate, transport, persistence and the possible transformation of nanoparticles
- recyclability and sustainability of nanotechnological products.

Hence the question remains unanswered of whether all nanomaterials are also simultaneously nanonoxes. The entire subject matter of environment and health is displayed very clearly in a recent review that deals with the possible routes of nanoparticles in the environment and the exposure routes by organisms [18]. At this point it is important to state that the currently available data are not sufficient for a realistic assessment of exposure, hazards and the associated risks. Moreover, nobody takes into account that there is a natural background exposure with several particle types

Table 10.3 Most frequent elements in the Earth's crust (italics: typically as oxides comparable to engineered nanoparticles).

Element	Concentration (%)
Oxygen	47
Silicon	*28*
Aluminum	*8*

Carbon	0.2
Others	<1

used in technical applications as well. Some elements produced as oxides at the nanoscale in very large amounts are equally distributed all over the Earth. Therefore, we cannot discriminate between synthetic materials and naturally occurring materials when the engineered nanoparticles have reached the environment (Table 10.3).

Therefore, specific regulatory measures are unnecessary at this point since it is completely unclear what they should actually be aimed at. Nevertheless, contact with nanomaterials should be given increased attention during development in the research laboratory and also during large-scale technical production since the unique properties of the new materials are able to show not only technical but also biological effects, and that the behavior of the nanoparticles towards bulk materials will certainly be changed. In the meantime, this has also been recognized by the funding organizations and both European and German governmental funding have initiated relevant projects. In these projects it is also taken into account that the field of nanotoxicology can only be approached in a multidisciplinary way, that is, in addition to industry and the agencies, also chemists, physicists, materials scientists, engineers, medical professionals, biologists, toxicologists, ecologists, statisticians and additional branches of study, who have to deal with all aspects of nanotechnology, including the ethical questions and the sustainability of this technology, are also challenged.

Phase-Coherent Transport

Thomas Schäpers

1.1
Introduction

From elementary quantum mechanics it is known that electrons possess wave properties in addition to their appearance as a particle. Often, these wave properties are difficult to observe directly, the main reason being that in many cases the electron wavelength is quite small – that is, in metals the wavelength of the electrons at the Fermi energy is only of the order of a few nanometers. Therefore, one possible approach to observing the phenomena related to the wave properties of the electrons is to reduce the sample size to dimensions close to the electron wavelength, as performed in a quantum point contact. Nevertheless, the wave nature of the electrons is sometimes revealed under much more relaxed conditions. An essential perquisite here is that the coherent wave propagation is maintained over sufficiently long distances, so that interference effects can occur. In most cases this condition is only fulfilled at low temperatures in the Kelvin range, where inelastic scattering is suppressed to a large extent.

In diffusive conductors, one possible way to achieve electron interference is if the diffusive motion allows electrons to propagate coherently in closed loops. This so-called "weak localization effect" can even be observed in macroscopic structures. The electron interference can be significantly modified if spin precession (i.e., due to spin-orbit coupling) comes into play. Well-controlled electron interference can be achieved if the wave propagation is guided by the shape of the conductor, and an excellent example in this respect is the Aharonov–Bohm effect, which is observed in ring-shaped conductors.

This discussion of phase-coherent transport in nanostructures begins by introducing the relevant length scales and the different transport regimes in Section 1.2. Subsequently, in Section 1.3 the Landauer–Büttiker formalism and ballistic transport through a split-gate point contact are discussed. Section 1.4 provides an explanation for the weak localization effect, which leads to an enhanced resistance, whilst in Section 1.5 it is shown that spin precession can result in the reversal of the weak localization effect. Phase-coherent transport in ring-shaped structures is discussed in Sections 1.4 and 1.5, while in Section 1.6 it is shown that the finite number of

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

scattering centers in very small structures can result in pronounced fluctuations in conductance. Although, within this chapter, transport phenomena in two- and one-dimensional structures are outlined, zero-dimensional structures – namely quantum dots – are discussed in detail in Chapter 2.

1.2 Characteristic Length Scales

Transport in nanoelectronic systems can be classified by relating its size to some specific characteristic length scales [1, 2] which determine how the carriers propagate through the sample. In the following sections, the elastic and inelastic mean free path are introduced, which quantify the degree of elastic and inelastic scattering occurring in the structure, respectively. A length scale, which provides information about loss of the phase memory is termed the phase-coherence length.

1.2.1 Elastic Mean Free Path

The elastic mean free path l_e is a measure of the distance between subsequent elastic scattering events. Such events occur due to the fact that the conductor is not ideal but rather contains irregularities in the lattice, such as impurities or dislocations. The scattering can be considered as *elastic*, which means that the electron energy is conserved. A typical example is the scattering of an electron at a charged impurity. If we assume a stationary scattering center, then effectively no energy is transferred during the scattering event, whereas the direction of the electron momentum can change greatly.

In order to determine the elastic mean free path l_e within the Drude model, one must first calculate the average time between elastic scattering events, τ_e. Its value can be extracted from the electron mobility μ_e, given by

$$\mu_e = \frac{e\tau_e}{m^*} \tag{1.1}$$

The quantities m^* and e are the effective electron mass and the elementary charge, respectively. The electron mobility is a measure of the increase of the drift velocity v_{drift} in a conductor with increasing electric field E: $v_{\text{drift}} = -\mu_e E$. In practice, the electron mobility is determined from the electron concentration n_e and the Drude conductivity σ_0 by

$$\mu_e = \frac{\sigma_0}{e n_e} \tag{1.2}$$

Experimentally, the electron concentration n_e is obtained from Hall measurements, while the conductivity σ_0 is deduced from resistance measurements at zero magnetic field.

Effectively, only electrons at the Fermi energy E_F contribute to the electron transport. Therefore, the elastic mean free path l_e is given by the length an electron

with the Fermi velocity v_F propagates until it is elastically scattered after the elastic scattering time τ_e:

$$l_e = \tau_e v_F \tag{1.3}$$

As an example, for a typical two-dimensional (2-D) electron gas in an AlGaAs/GaAs heterostructure (see Section 1.3), low-temperature mobilities of around $10^6\,\mathrm{cm}^2(\mathrm{Vs})^{-1}$ at $n_e = 3\times10^{11}\,\mathrm{cm}^{-2}$ are achieved. For a 2-D system the Fermi velocity is given by $v_F = \hbar\sqrt{2\pi n_e}/m^*$. With $m^* = 0.067m_e$ and using Equation 1.3, the length of the elastic mean free path is 9 µm.

1.2.2
Inelastic Mean Free Path

In addition to the elastic scattering discussed above, electron scattering can also be connected to an energy transfer. A typical example is the effect of lattice vibrations on electron transport. An electron moving within a crystal will be scattered by these lattice vibrations and either lose or gain energy, depending on whether it excites the lattice vibrations or is excited by them. As an energy transfer occurs, these scattering processes are considered to be *inelastic*. Similar to the previous discussion, one can define an inelastic scattering length l_{in} as a measure for the length between inelastic scattering events. Besides electron–phonon scattering, electron–electron scattering is another possible process, where a considerable amount of energy can be exchanged between both scattering partners [3].

1.2.3
Phase-Coherence Length

The phase-coherence length l_φ is the relevant length scale, which determines if phase-coherent transport can be observed in nanolectronic systems [2]. It is a measure of the distance that the electron propagates phase coherently before its phase is randomized. At low temperatures, the phase-coherence length can be larger than the elastic mean free path l_e. Thus, a number of elastic scattering events occur before the phase information is finally lost. During an elastic scattering event (i.e., at an impurity), the phase of an electron is not randomized; it is only shifted by well-defined amount. If the electron propagates along the identical path a second time, the phase accumulation will be exactly the same. This is in strong contrast to inelastic scattering events (e.g., electron–phonon scattering), where the scattering target changes with time. Consequently, the phase shift that the electron would acquire is different each time. However, care must be taken to identify l_φ right away with the inelastic mean free path l_{in}, as they are not identical in all cases; that is, spin-flip scattering is considered to be phase-breaking and thus contributing to l_φ whilst it may be elastic at the same time. In addition, small-energy-transfer electron–electron scattering, which is due to the fluctuation of the electric field produced by the electrons (Nyquist contribution), can contribute to a large extent to l_φ [4]. As mentioned above, at low temperatures a number of elastic scattering events occur

	Quantum	$\lambda_F,\ l_e \ll L,\ l_\varphi > l_e$
Ballistic	Classical	$\lambda_F \ll L < l_e,\ l_\varphi$
	Quantum	$\lambda_F \approx L < l_e,\ l_\varphi$

until the phase is broken, implying that the characteristic phase-breaking time τ_φ is larger than the elastic scattering time τ_e. Owing to the diffusive motion during the time τ_φ, the phase-coherence length l_φ must be expressed by

$$l_\varphi = \sqrt{D\tau_\varphi} \tag{1.4}$$

Here, D is the diffusion constant defined as

$$D = \frac{1}{d} v_F^2 \tau_e \tag{1.5}$$

with d the dimensionality of the system. Typical values for the phase-coherence length of an AlGaAs/GaAs 2-D electron gas below 1 K are of the order of several micrometers [5].

1.2.4 Transport Regimes

By comparing l_e and l_φ with the dimension L of the sample and the Fermi wavelength λ_F, different transport regimes can be classified, and these are summarized in Table 1.1. For the case where the elastic mean free path l_e is smaller than the dimensions of the sample, many elastic scattering events occur while the electrons propagate through the structure. The carriers are traveling randomly (*diffusive*) through the crystal, as illustrated in Figure 1.1a. If the phase-coherence

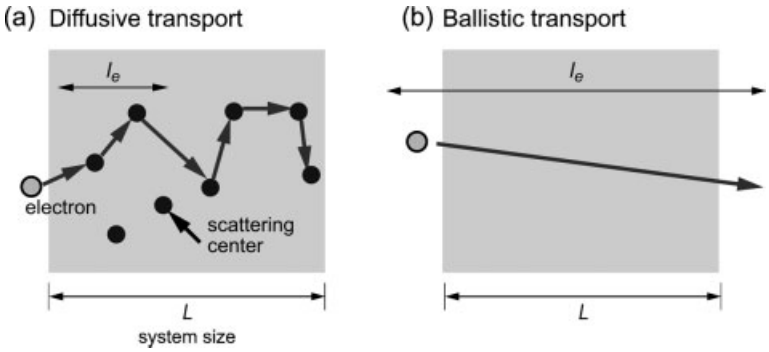

Figure 1.1 Illustration of (a) a diffusive conductor, and (b) a ballistic conductor. In the diffusive transport regime many elastic scattering events occur, while the electron crosses the sample. In the ballistic regime, the electron crosses the sample without any elastic scattering event.

length l_φ is shorter than the elastic mean free path l_e, the transport is considered as classical. In contrast, if $l_\varphi > l_e$, then quantum effects owing to the wave nature of the electrons can be expected. This diffusive regime is thus called the *quantum* regime. As illustrated in Figure 1.1b, in the case that l_e is larger than the dimensions of the sample, the electrons can transverse the system without any scattering; this regime is called *ballistic*. Depending on the magnitude of the Fermi wavelength λ_F in comparison to the dimension of the sample, the transport can either be regarded as classical ballistic or quantum ballistic. In the following section, ballistic transport will first be discussed, and later the transport phenomena in the diffusive regime.

1.3 Ballistic Transport

In this section transport in the ballistic transport regime will be discussed; that is, where the elastic mean free path exceeds the dimensions of the sample. First, the Landauer–Büttiker formalism is explained, where the resistance of a sample is described in terms of transmission and reflection probabilities, which is a very convenient scheme to analyze the transport in the ballistic regime. Subsequently, the quantized conductance of a split-gate point contact will be discussed, making use of the Landauer–Büttiker formalism.

1.3.1 Landauer–Büttiker Formalism

In order to analyze the electronic transport properties of a sample, usually a current is allowed to flow between two contacts while the response of the system is measured by two voltage probes. The latter are not necessarily different from the current contacts. The ratio between the voltage drop U and the current I can be defined as a *macroscopic resistance*. (The expression *macroscopic* is used here as only the global properties of the sample are measured.)

A very intuitive interpretation of the macroscopic resistance, R, of a sample can be obtained if the so-called Landauer–Büttiker formalism is used [6–9]. In this model, the resistance

$$\mathcal{R}_{mn,kl} = \frac{U_{kl}}{I_{mn}} \tag{1.6}$$

is defined by the voltage measured between contacts k and l and the current flowing between contacts n and m.

In order to keep things simple, the discussion is restricted to a conductor connected via ideal one-dimensional (1-D) ballistic leads to four corresponding reservoirs. The geometry of the sample is depicted in Figure 1.2. The ballistic wires should consist of only a single 1-D. The reservoirs with the corresponding chemical potentials μ_i ($i = 1, \ldots, 4$) serve as source and drain for carriers flowing in and out of

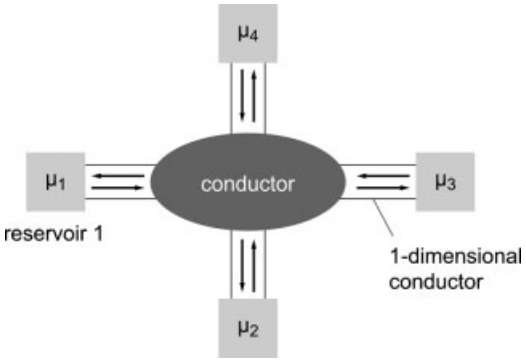

Figure 1.2 Schematic illustration of a four-terminal resistance measurement set-up. The conductor is connected by ideal one-dimensional leads to four corresponding reservoirs.

the conductor. At zero temperature, the i-th reservoir can supply electrons to the conductor up to a maximum energy of μ_i. Each carrier from the lead, which reaches the reservoir is absorbed by the reservoir, irrespective of the phase and energy of the carriers. As discussed above, inelastic scattering is forbidden within the leads, so that electrons once injected into the conductor maintain their energy until they reach one of the reservoirs.

As an example, we will study the current contributions in the 1-D lead 1, which results in the net current I_1. The current injected from reservoir 1 is given by:

$$I_{inj} = e \int_0^{\mu_1} D_{1D}(E) v(E) dE \tag{1.7}$$

where $v(E)$ is the velocity of the electrons. As the wire is 1-D, the density of states of a 1-D system must be inserted, which is given by

$$D_{1D}(E) = \frac{2}{hv(E)} \tag{1.8}$$

So far, only the states propagating from reservoir 1 are considered, and the density of states used here is half of the commonly known value because there is only one direction of propagation [1]. It can be seen directly that the product of the 1-D density of states $D_{1D}(E)$ and the velocity $v(E)$ is constant, and therefore the current leaving reservoir 1 has the following simple form:

$$I_{inj} = \frac{2e}{h} \mu_1 \tag{1.9}$$

Part of the current supplied by reservoir 1 will be reflected back into the conductor. If R_{ii} is defined as the reflection probability for a reflection of carriers from lead i back into lead i, then the current reflected into lead 1 can be written as

$$I_R = -\frac{2e}{h} R_{ii} \mu_i \tag{1.10}$$

In addition, electrons are transmitted from the other three leads into lead 1. By defining the transmission probability from lead j into lead i ($i \leftarrow j$) as T_{ij}, we arrive at the following expression for the current transmitted into lead 1:

$$I_T = -\frac{2e}{h}\sum_{j=2}^{4} T_{1j}\mu_j \tag{1.11}$$

By summing all of these contributions it can be seen that the net current flowing in lead 1 is finally given by:

$$\begin{aligned} I_1 &= I_{inj} + I_R + I_T \\ &= \frac{2e}{h}\left[(1-R_{11})\mu_1 - \sum_{j=2}^{4} T_{1j}\mu_j\right], \end{aligned} \tag{1.12}$$

or, more generally, the current in lead i is given by

$$I_i = \frac{2e}{h}\left[(1-R_{ii})\mu_i - \sum_{j\neq i} T_{ij}\mu_j\right] \tag{1.13}$$

By using Equation 1.13, the above-defined resistance $\mathcal{R}_{mn,kl}$ can be determined for given reflection and transmission probabilities of the sample. According to the initial definition of $\mathcal{R}_{mn,kl}$, as given in Equation 1.6, the net current I_{mn} flows between contacts n and m. The leads k and l do not carry a net current in case of an ideal voltage measurement. The voltage drop U_{kl} is given by the difference of the electrochemical potentials divided by e: $(\mu_k - \mu_l)/e$. In the following section, Equation 1.13 will serve as a basis to describe the transport properties of a split-gate quantum point contact.

1.3.2
Split-Gate Point Contact

In split-gate quantum point contacts the transport is limited to only one dimension. This is obtained by first restricting the propagation of the electrons to a plane. In these so-called "two-dimensional electron gases" (2DEGs), the carriers are confined at an interface of two different semiconductor layers. A typical example of a 2DEG realized in an AlGaAs/GaAs layer system is depicted in Figure 1.3. Here, the carriers are located at the AlGaAs/GaAs interface and, owing to the conduction band offset between AlGaAs and GaAs, a triangular quantum well is formed at the interface. The electrons in the quantum well are supplied by an n-type δ-doped (very thin) layer. In order to prevent ionized impurity scattering, the electrons in the quantum well are separated from the δ-doped layer by an undoped AlGaAs spacer layer. Using this scheme, very large electron mobilities and thus very long elastic mean free paths of the order of several micrometers can be achieved.

A further restriction of the electron propagation to only one dimension can be realized by using split-gate point contacts [10, 11]. As illustrated in Figure 1.4, two opposite gate fingers are separated by a distance of a few hundreds of nanometers. Split-gate electrodes are usually prepared by using electron beam lithography. Since

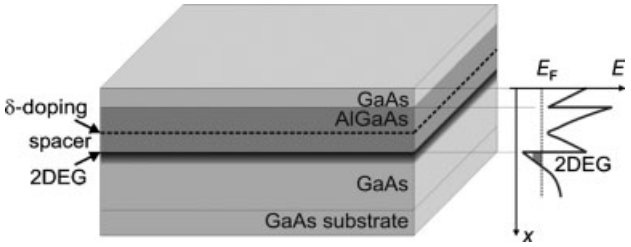

Figure 1.3 Layer sequence of an AlGaAs/GaAs heterostructure containing a two-dimensional electron gas at the AlGaAs/GaAs interface. A schematic illustration of the conduction band profile is shown on the right-hand side.

the Fermi wavelength λ_F of a 2-D electron gas is typically a few tenths of a nanometer, the separation of the split-gates is comparable with λ_F. The length of the channel formed by the gate electrodes is usually smaller than 1 μm, and thus smaller than the elastic mean free path l_e. According to the classification introduced in Section 1.2, the transport can be considered as ballistic.

By applying a sufficiently large negative voltage to the gate fingers, the underlying 2-D electron gas is depleted underneath the gate fingers (see Figure 1.4a). Only a small opening between the gate fingers remains for the electrons to propagate from one side to the opposite side; however, by varying the gate voltage it is possible to control the effective width of the opening. An increase of the negative bias voltage enlarges the depletion area and thus reduces the opening width. At sufficiently large negative bias voltages the opening can even be closed completely (pinch-off).

Owing to the depletion area underneath the split-gate electrodes, it can be assumed that the electrons in the 2DEG are confined in a potential well along the y-axis, while the free propagation takes place along the x-axis. If the potential profile in the plane of the 2DEG induced by the split-gate electrodes is expressed by $V(x, y)$, the Hamilton

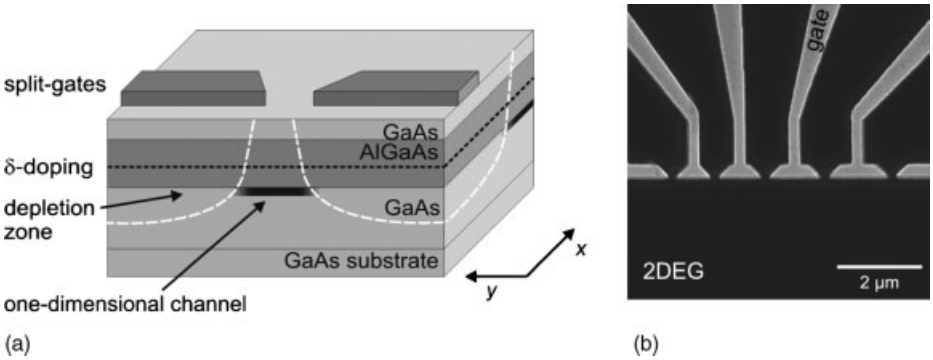

Figure 1.4 (a) Schematic illustration of a split-gate point contact on an AlGaAs/GaAs heterostructures. By applying a negative gate voltage to the split-gate electrodes, the electron gas underneath is depleted. The electrons can only pass the small opening. (b) An electron beam micrograph of split-gate point contacts.

operator has the following form:

$$H = \frac{\hbar^2}{2m^*}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) + V(x, y) \tag{1.14}$$

In order to determine the precise shape of the potential $V(x, y)$ as a function of the gate voltage, elaborated self-consistent simulations are required [12]. However, for most applications it is sufficient to assume an approximated potential profile. For low gate voltages an appropriate approximation is a rectangular potential profile, while for higher negative gate voltages the potential well can be approximated by a parabolic potential. As an example, we will consider here the latter potential shape. Due to the short length of the channel formed by the split-gates, the 2-D potential profile will be saddle-shaped. However, if the potential shaped along the constriction is smooth (adiabatic limit), it is sufficient to consider only the narrowest point of the channel, which can be expressed by

$$V(y) = \frac{1}{2} m^* \omega_0^2 y^2 + V_0 \tag{1.15}$$

Here, ω_0 is the characteristic frequency of the parabolic potential, while V_0 represents the height of the inflection point of the saddle-shaped potential. For the energy dispersion of the 1-D subbands in the point contact, we obtain

$$E_n(k_x) = E_n^0 + V_0 + \frac{\hbar^2 k_x^2}{2m^*}, \quad n = 1, 2, 3, \ldots, \tag{1.16}$$

with

$$E_n^0 = (n - 1/2)\hbar\omega_0, \tag{1.17}$$

the energy eigenvalues of the harmonic oscillator. By changing the gate voltage at the split-gate electrodes, the effective width of the opening can be adjusted. In the parabolic approximation ω_0 is increased if a more negative gate voltage is applied, and this leads to an increased separation of the energy eigenvalues. As a consequence, lesser levels are occupied up to the Fermi energy (see Figure 1.5a and b).

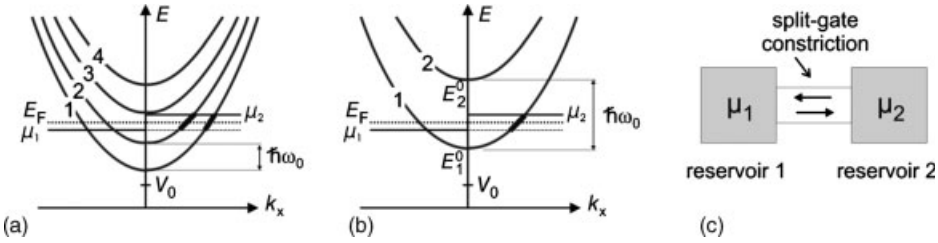

Figure 1.5 (a) Energy dispersion of a one-dimensional channel with the two lowest levels lying below the Fermi energy E_F. (b) Corresponding situation with only one subband occupied. The energy separation between the levels given by $\hbar\omega_0$ is larger compared to the situation shown in (b). (c) A one-dimensional conductor; that is, the channel formed by the split-gate electrodes, connected by two reservoirs with the electrochemical potential μ_1 and μ_2, respectively.

Before examining the experimental outcome of measurement of the split-gate point contact resistance, the conduction of a 1-D conductor by using the Landauer–Büttiker formalism will be briefly discussed. It must first be assumed that the conductor is connected on both terminals to reservoirs with the electrochemical potentials μ_1 and μ_2, respectively (i.e., the 2DEG on both sides of the split-gates), as shown in Figure 1.5c.

For a set-up with only two reservoirs, and where only the lowest subband is occupied, the following expression is obtained according to the Landauer–Büttiker formalism [cf. Equation 1.13]:

$$(h/2e)I = (1 - R_{11})\mu_1 - T_{12}\mu_2 \tag{1.18}$$

$$-(h/2e)I = (1 - R_{22})\mu_2 - T_{21}\mu_1 \tag{1.19}$$

At zero magnetic field ($B = 0$), the transport is time-inversion invariant so that the following relationships hold:

$$T_{12} = T_{21} = T = 1 - R_{11} = 1 - R_{22} \tag{1.20}$$

Thus, finally we arrive at the expression for the conductance of the constriction:

$$G = \frac{I}{U} = \frac{Ie}{\mu_1 - \mu_2} = \frac{2e^2}{h}T \tag{1.21}$$

As illustrated in Figure 1.5b, only carriers with energy between μ_1 and μ_2 contribute to the conductance. If backscattering is neglected ($T = 1$), the conduction through a constriction is simply given by:

$$G = \frac{2e^2}{h}. \tag{1.22}$$

It should be stressed that the constant conductance is a result of the cancellation of the energy dependence of the density of states and the velocity for the 1-D case [cf. Equation 1.7], which is not the case for 2-D or three-dimensional (3-D) systems. In analogy, the conductance can be calculated if N subbands are occupied. The occupied subbands taking part in the transport are usually called channels; the situation for two channels ($N = 2$) is illustrated in Figure 1.5a. If N one-dimensional channels are assumed, then the total transmission probability from reservoir j to reservoir i ($i \leftarrow j$) can be expressed as

$$T_{ij} = \sum_{mn}^{N} T_{ij,mn} \tag{1.23}$$

where $T_{ij,mn}$ denotes the transmission probability from the n-th subband of lead j into the m-th subband of lead i. If ideal transmission and no intersubband scattering is assumed, then the total transmission probability of a 1-D channel with N subbands is given by $T = N$. Thus, each subband contributes with $2e^2/h$ to the conductance so that the total conductance of a constriction with N subbands occupied is given by

$$G = \frac{2e^2}{h}N \tag{1.24}$$

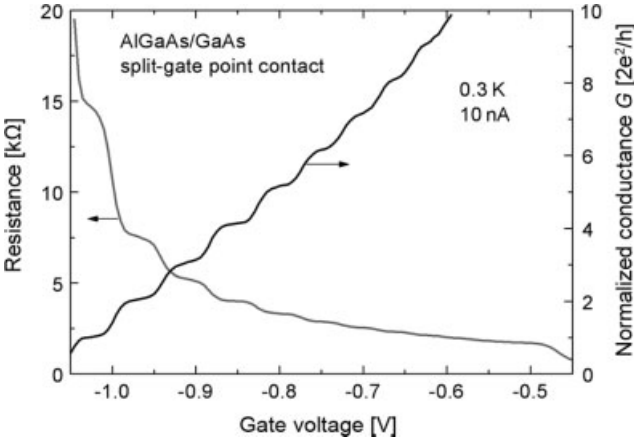

Figure 1.6 Resistance and conductance of an AlGaAs/GaAs split-gate point contact as a function of the gate voltage. The conductance is plotted in units of $2e^2/h$.

This remarkable result indicates that the conductance of a 1-D constriction changes in steps equal to $2e^2/h$, if the number of channels is altered by adjusting the widths of the constriction. The latter can be achieved by applying an appropriate voltage to the split-gate electrodes.

An experimental result of the resistance and conductance of quantum point contact based on a 2DEG in an AlGaAs/GaAs heterostructure is shown in Figure 1.6. With a more negative gate voltage, the resistance of the point contact increases, as the width of the constriction becomes increasingly narrower. As can be seen in Figure 1.6, if the conductance G is plotted, it can clearly be seen that G decreases stepwise by multiples of $2e^2/h$ with increasing negative gate voltage.

The experimentally observed curves can deviate in many aspects from the ideal curves. The calculations given above were restricted to zero temperature, but at finite temperatures the broadening of the Fermi distribution function results in a broadening of the steps owing to the partial occupation and emptying of the 1-D channels. The geometrical shape of the point contact opening also affects the transmission through the point contact. For example, sharp edges of the point contact opening can result in reflections of the incoming and transmitted electrons waves at the inlet and outlet of the 1-D channel. As a result, oscillations are expected in the plateaus of the steps [13, 14].

1.4 Weak Localization

Interference effects of electron waves due to phase coherent transport can be seen even in large samples, where the phase coherence length is much smaller than the dimensions of the sample. This effect, called weak localization, results in an increased resistance compared to the classically expected value [15, 16]. Weak localization is observed if the temperature is sufficiently low so that the phase coherence length l_φ is

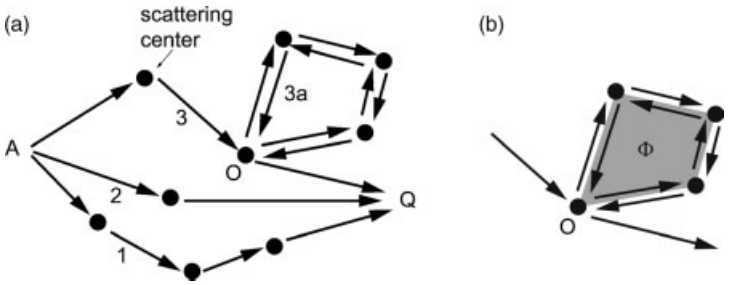

Figure 1.7 (a) Possible trajectories of electrons propagating from point *A* to *Q*. The trajectory 3a represents a closed loop. (b) Detail of a closed loop with a magnetic flux Φ penetrating this loop.

larger than the elastic scattering length l_e. As we will see below, the effect of weak localization depends strongly on the dimensionality of the system. The lower the dimension of the system is, the stronger the effect of weak localization is, that is in quasi one-dimensional wire structures weak localization is most pronounced. In order to illustrate the general mechanisms leading to weak localization, we will first introduce a simple model. Later on more quantitative expressions for the conductivity corrections will be given.

1.4.1 Basic Principles

Let us consider a diffusive conductor, in which an electrons starting at point *A* propagate to point *Q*. Some typical trajectories of an electron are sketched in Figure 1.7, illustrating that there are many possibilities for an electron to propagate from *A* to *Q*.

It is assumed that the elastic mean free path l_e is smaller than the distance between *A* and *Q*. Thus, an electron undergoes many elastic scattering events on its way. However, during elastic scattering the electron does not lose its phase memory. If it is assumed that the phase coherence length is longer than the distance between *A* and *Q*, the phase information is not lost. By following Feynman, each path *j* can be described from the initial state *A* to the final state *Q* by a complex probability amplitude C_j given by [17, 18]:

$$C_j = c_j \exp(i\varphi_j) \tag{1.25}$$

Here, φ_j is the phase shift that the electron acquires on its way from *A* to *Q* while propagating along path *j*. Often, there are many possible paths for an electron to propagate between *A* and *Q*. For example, for free electron propagation the phase accumulation along the path *j* can be calculated from the action S_j by

$$\varphi_j = \frac{S_j}{\hbar} \tag{1.26}$$

The non-relativistic action S_j is defined by

$$S_j = \int_{t_A}^{t_Q} dt \mathrm{L}(\boldsymbol{r}, \dot{\boldsymbol{r}}, t) \tag{1.27}$$

with

$$\mathrm{L}(\boldsymbol{r}, \dot{\boldsymbol{r}}, t) = \frac{m}{2}\dot{r}^2 \tag{1.28}$$

the Lagrangian function of a free propagating electron. Here, t_A is the time when the electron starts at A, and t_Q the time when it arrives at Q. The quantities $\boldsymbol{r}$ and $\dot{\boldsymbol{r}}$ are the position and velocity of the particle, respectively. However, the electron acquires not only a phase shift during free propagation but also well-defined phase shifts by the elastic scattering events, so that the total phase accumulated along the path is the sum of both contributions. The total amplitude for the propagation from A to Q is given by the sum of the amplitudes C_j of all undistinguished paths. Finally, the total probability P_{AQ} for an electron to be transported from A to Q is determined by the square of the total amplitude

$$P_{AQ} = \left| \sum_j c_j e^{i\varphi_j} \right|^2 \tag{1.29}$$

In systems with a large number of possible paths, the phases φ_j are usually randomly distributed, and therefore the wave nature should have no effect on the electron transport due to averaging. Nevertheless, the fact that an increase of the resistance is observed, compared to the classical transport, is a result of closed loops (see Figure 1.7a, trajectory 3a). Along these loops, an electron can propagate in two opposite orientations with the corresponding complex amplitudes $C_{1,2} = c_{1,2}\exp(i\varphi_{1,2})$. The current contribution of the current returning to the starting point of the loop (O) is given by

$$P_{OO} = |C_1 + C_2|^2 = |C_1|^2 + |C_1|^2 + 2\mathrm{Re}(C_1^* C_2) \tag{1.30}$$

Since, for time-reversed paths $c_1 = c_2$ and $\varphi_1 = \varphi_2$, we obtain

$$|C_1 + C_2|^2 = 4|C_1|^2 \tag{1.31}$$

For classical non-phase-coherent transport, the probability would simply be $|C_1|^2 + |C_2|^2$, which is a factor of 2 smaller than for the phase-coherent case. A larger probability to return to the origin implies that the net current through the sample is reduced. Hence, the carriers are *localized* within the loop. Such localization does not depend on the size of the loop as long as its length is smaller than the phase-coherence length. It is important to note here that constructive interference occurs for *all* possible closed loops in the conductor, and is therefore not averaged out. As a result, the total resistance is increased compared to the classical case.

1.4.2
Weak Localization in One and Two Dimensions

In the following section, it is briefly sketched how a value for the correction of the conductance due to weak localization can be obtained quantitatively [18]. For the weak localization effect we are interested only in those processes where the electrons return to their starting points. The discussion will first be restricted to a 2-D system, for example a 2-D electron gas in an AlGaAs/GaAs heterostructure. A larger number

of scattering centers increase the probability for backscattering of the electrons. The larger the number of scattering centers is, the smaller is the diffusion constant; as a consequence one obtains for the return probability due to diffusive motion: $1/(4\pi Dt)$. For the total return probability, it must be ensured that the phase of the electrons is preserved up to time τ_φ, which provides a pre-factor $\exp(-t/\tau_\varphi)$. Furthermore, it is required that the electron is at least once elastically scattered; thus, a pre-factor $[1-\exp(-t/\tau_e)]$ must be included. In total, the correction to the conductance can be expressed as [19, 20]:

$$\begin{aligned}\Delta\sigma_{2D} &= -\frac{2\hbar}{m^*}\sigma_0\int_0^\infty dt\frac{1}{4\pi Dt}(1-e^{-t/\tau_e})e^{-t/\tau_\varphi} \\ &= -\frac{e^2}{2\pi^2\hbar}\ln\left(1+\frac{\tau_\varphi}{\tau_e}\right)\end{aligned} \tag{1.32}$$

Here, σ_0 is the classical Drude conductivity of a 2-D system. The localization vanishes, if the phase-breaking time τ_ϕ is much smaller than τ_e, since then the logarithmic factor tends towards zero. The ratio of the correction due to weak localization to the Drude conductivity $\Delta\sigma_{2D}/\sigma_0$ is usually small and of the order of $1/k_F l_e$. Here, $k_F = m^* V_F/\hbar$ is the Fermi wavenumber. For a typical 2-D electron gas with $\mu_e = 10^6\,\mathrm{cm^2\,V\,s^{-1}}$ at $n_e = 3\times10^{11}\,\mathrm{cm^{-2}}$, a correction of less than 0.1% would be expected.

For a quasi 1-D structure of width W with $l_\varphi \gg W$, the diffusion is effectively reduced to one dimension, so that the return probability can now be expressed by $W^{-1}(4\pi Dt)^{-1/2}$. The conductivity correction in this case is given by [20]:

$$\Delta\sigma_{1D} = -\frac{e^2}{\pi\hbar}\frac{l_\varphi}{W}\left[1-\left(1+\frac{\tau_\varphi}{\tau_e}\right)^{-1/2}\right] \tag{1.33}$$

A comparison of the 1-D and 2-D cases reveals that the weak localization correction to the conductivity is much larger for the 1-D case. In the latter case, the ratio $\Delta\sigma_{1D}/\sigma_0$ is of the order $(l_\varphi/W)(1/k_F l_e)$. If a phase-breaking time of $\tau_\phi = 10^{-10}$ s and a width of $W = 200$ nm are assumed, the result is a ratio $\Delta\sigma_{1D}/\sigma_0$ of 6%, for a wire based on the 2-D electron gas as specified above. Clearly, this value is much larger than the corresponding value for a 2-D system.

1.4.3 Weak Localization in a Magnetic Field

If the sample is penetrated by a magnetic field $\boldsymbol{B}$, the phase accumulation along a certain trajectory is modified, since the Lagrangian function L [cf. Equation 1.28] of an electron with charge $-e$ contains an additional term

$$\mathrm{L}(\boldsymbol{r},\dot{\boldsymbol{r}},t) = \frac{m}{2}\dot{\boldsymbol{r}}^2 - e[\dot{\boldsymbol{r}}\boldsymbol{A}(r,t)] \tag{1.34}$$

Here, $\boldsymbol{A}$ is the vector potential defined by $\boldsymbol{B} = rot\ \boldsymbol{A}$. In the presence of a vector potential, the probability amplitude C_1 of a closed loop propagated in clockwise

orientation acquires an additional phase factor

$$C_1 \rightarrow C_1 \exp\left(-i\frac{e}{\hbar}\oint \boldsymbol{A}d\boldsymbol{l}\right) = C_1 \exp\left(i\frac{2\pi\Phi}{\Phi_0}\right) \tag{1.35}$$

Here, $\Phi = BS$ is the magnetic flux penetrating the enclosed area S of the loop, with $\Phi_0 = h/e$ the magnetic flux quantum. For the propagation in the opposite orientation one obtains

$$C_2 \rightarrow C_2 \exp\left(-i\frac{2\pi\Phi}{\Phi_0}\right) \tag{1.36}$$

The phase difference accumulated between both time-reversed paths is therefore

$$\Delta\varphi = 4\pi\frac{\Phi}{\Phi_0} \tag{1.37}$$

Thus, if a magnetic field is applied, the property that constructive interference occurs for *all* loops in case of $B = 0$ is lost. Generally, many loops enclosing different areas are found in a diffusive conductor and, depending on the size of the loops, different phase shifts $\Delta\varphi$ develop. Thus, for a particular magnetic field the localization is lifted to a different extent depending on the loop size. If the magnetic field is increased starting from zero, the constructive interference is destroyed first for the largest loops. Finally, if the magnetic field is sufficiently large, the phase difference will be randomly distributed between the ensemble of loops. On average, the degree of localization decreases with increasing magnetic field, resulting in a continuous decrease of the resistance.

For a quantitative approach one must take into account that, in addition to the usual phase breaking at zero magnetic field, the phase is also broken effectively by a magnetic field. Similar to l_φ a length l_m is defined, which is characterized by the condition that the area l_m^2 corresponds to the case that the penetrating flux is equal to Φ_0. Thus, l_m is defined by $\sqrt{\hbar/eB}$. As outlined above, for a flux Φ_0 the phase difference between time-reversed paths is already significant. The characteristic magnetic relaxation time τ_B related to l_m can be estimated from the relationship $l_m \sim \sqrt{D\tau_B}$, in analogy to Equation 1.4 defining l_φ. The expression that quantitatively describes the increase of the conductivity with increasing magnetic field is given by [21, 22]:

$$\Delta\sigma_{2D}(B) - \Delta\sigma_{2D}(0) = \frac{e^2}{2\pi^2\hbar}\left[\Psi\left(\frac{1}{2}+\frac{\tau_B}{2\tau_\varphi}\right) - \Psi\left(\frac{1}{2}+\frac{\tau_B}{2\tau_e}\right) + \ln\left(\frac{\tau_\varphi}{\tau_e}\right)\right] \tag{1.38}$$

where $\Psi(x)$ is the digamma function. The exact expression for τ_B, which must be inserted into Equation 1.38, is given by $\tau_B = l_m^2/2D$. At zero magnetic fields the relevant maximum size of the loops at which the phase coherence is broken is given by l_φ^2. In a finite magnetic field, weak localization is suppressed if a noticeable phase shift between time-reversed loops is accumulated. This is the case for loops with the area of about l_m^2. By comparing both relationships, it is clear that the magnetic field has a significant effect on the conductance for $l_\varphi^2 \approx l_m^2$. This relationship defines a critical

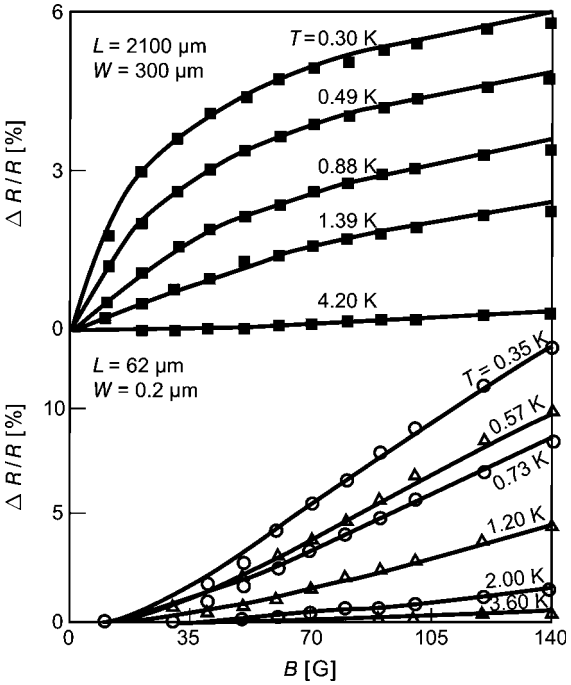

Figure 1.8 Comparison of the weak localization effect in a two-dimensional (upper graph) and a one-dimensional electron gas (lower graph) in AlGaAs/GaAs. For the one-dimensional structures a much higher magnetic field is required to suppress the weak localization effect. (Reprinted with permission from [23]. Copyright (1987) by the American Physical Society.)

magnetic field B_c, which is given by

$$B_c = \frac{\hbar}{2el_\varphi^2} \tag{1.39}$$

Thus, at the characteristic field of B_c one expects a suppression of weak localization. For semiconductor structures, l_φ may be of the order of 1 μm, and result in a critical field of about 1 mT. In the case of a 2-D electron gas, weak localization is suppressed at relatively low magnetic fields (see Figure 1.8).

In 1-D systems in the dirty metal limit, defined as $l_e \ll W \ll l_\varphi$, the closed trajectories contributing to weak localization are quenched in one direction, with a typical enclosed area of the loop given by $W\sqrt{D\tau_B}$ (see Figure 1.9a). For a unit phase shift this area corresponds to l_m^2, resulting in a magnetic relaxation time of $\tau_B \sim l_m^4/DW^2$ and a critical field of $B_c \sim \hbar/eWl_\varphi$. The full expression for the weak localization correction of one-dimensional systems in the dirty limit is given by [24]

$$\Delta\sigma_{1D}(B) = \frac{e^2}{\pi\hbar}\frac{\sqrt{D}}{W}\left[\left(\frac{1}{\tau_\varphi}+\frac{1}{\tau_B}\right)^{-1/2} - \left(\frac{1}{\tau_\varphi}+\frac{1}{\tau_e}+\frac{1}{\tau_B}\right)^{-1/2}\right] \tag{1.40}$$

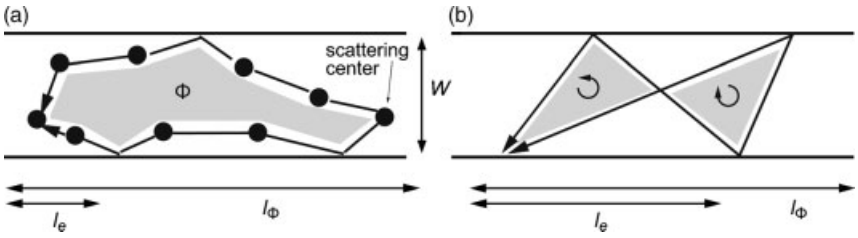

Figure 1.9 (a) Typical closed trajectory in a dirty metal one-dimensional conductor ($l_e \ll W \ll l_\phi$). (b) Typical closed trajectory in a narrow one-dimensional structure with $W \ll l_e$. Here, diffusive boundary scattering results in loops which self-interact. The net flux is cancelled in this configuration.

with magnetic relaxation time in this case given by $\tau_B = 3l_m^4/WD$. It should be noted that, at zero magnetic fields, Equation 1.32 is recovered. Furthermore, a closer inspection of B_c reveals, that if the width of the wire is reduced, the critical field is increased, ensuring that the weak localization effect is preserved up to much higher magnetic fields compared to the 2-D case. This is confirmed by the measurements shown in Figure 1.8, where the magnetoresistance peak is wider in the 1-D case. In wire structures based on high-mobility, 2-D electron gases, the elastic mean free path l_e may be larger than the width of the wire: $W \ll l_e$. In this ballistic regime, the electrons propagate without any scattering between the wire boundaries. As illustrated in Figure 1.9b, owing to diffusive boundary scattering the typical closed loops will self-interact. As both parts of the loop area are traversed in opposite orientation, the net flux is basically cancelled [20]. Clearly, the flux cancellation results in a further increase of the critical field.

1.5 Spin-Effects: Weak Antilocalization

So far, the effect of spin on the electron interference has been neglected, and this approach is valid as long as the spin orientation is conserved. However, in many materials the spin changes its orientation while the electron propagates along the closed loops, resulting in the weak localization effect.

It can be assumed that $|s\rangle$ is the initial spin state, this generally being a superposition of the spin up $|\uparrow\rangle$ and spin down $|\downarrow\rangle$ states. In principle, there are two possibilities of how the spin orientation can be changed:

- The Elliot–Yafet mechanism. Here, the potential profile of the scattering centers can lead to spin-orbit coupling; this results in a spin rotation, while the electron is scattered at the impurities (see Figure 1.10a).
- The so-called D'yakonov–Perel mechanism, where the spin precesses while the electron propagates *between* the scattering centers (see Figure 1.10b). The origin of the spin precession may either be a lack of inversion symmetry (i.e., in zinc blende

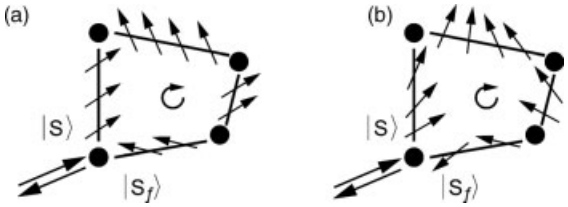

Figure 1.10 (a) Typical closed trajectory in forward direction with spin scattering at the impurities. The initial spin state $|s\rangle$ is transformed to the final spin state $|s_f\rangle$. The spin orientation is preserved while propagation between the scattering centers. (b) The situation where a spin precession occurs while the electron propagates between the scattering centers.

crystals; the Dresselhaus effect [25]), or an asymmetric potential shape of the quantum well forming a 2-D electron gas (the Rashba effect) [26].

Further details on spin precession are provided in Chapter 3 of this volume and Chapter 5 of volume 4 of this series (Bandyopadhyay, S., Monolithic and Hybrid Spintronics. In: Schmid, G. (ed), Nanotechnology, Vol 4, Chapter 5).

Regardless of the underlying mechanism, if an electron propagates along a closed loop, its spin orientation is changed. The modification of the spin orientation can be expressed by a rotation matrix $\mathbf{U}$ [27]. For the propagation along the loop in forward (f) direction the final state $|s_f\rangle$ can be expressed by

$$|s_f\rangle = \mathbf{U}|s\rangle \tag{1.41}$$

where $\mathbf{U}$ is the corresponding rotation matrix. For propagation along the loop in a backwards directions (b), the final spin state is given by

$$|s_b\rangle = \mathbf{U}^{-1}|s\rangle \tag{1.42}$$

Here, use is made of the fact that the rotation matrix of the counter-clockwise propagation is simply the inverse of $\mathbf{U}$. For interference between the clockwise and counter-clockwise electron waves, not only the spatial component is relevant but also the interference of the spin component:

$$\begin{aligned}\langle s_b|s_f\rangle &= \langle \mathbf{U}^{-1}s|\mathbf{U}s\rangle \\ &= \langle s|\mathbf{U}^{\dagger}\mathbf{U}|s\rangle \\ &= \langle s|\mathbf{U}^2|s\rangle.\end{aligned} \tag{1.43}$$

The final expression was obtained by making use of the fact that $\mathbf{U}$ is a unitary matrix: $\mathbf{U}^{-1} = \mathbf{U}^{\dagger}$, with $\mathbf{U}^{\dagger}$ the adjoint (complex conjugated and transposed) matrix of $\mathbf{U}$. Weak localization – and thus constructive interference – is recovered if the spin orientation is conserved in the case that $\mathbf{U}$ is the unit matrix $\mathbf{1}$.

However, if the spin is rotated during electron propagation along a loop, in general no constructive interference can be expected. Moreover, for each loop a different interference will be expected. Interestingly, averaging over all possible trajectories even leads to a reversal of the weak localization effect such that, instead of an increase

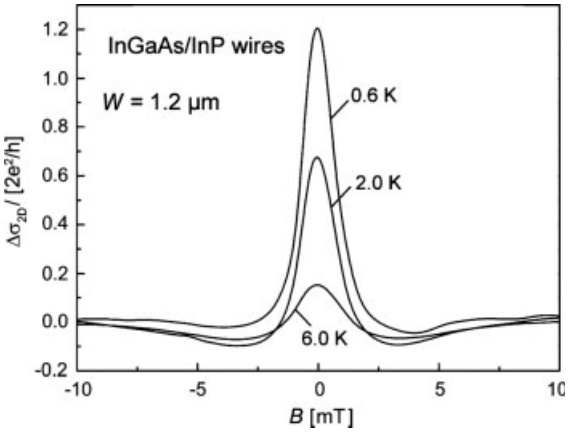

Figure 1.11 Magneto-conductivity measured on a set of 160 InGaAs/InP wires at various temperatures [29]. The Rashba spin-orbit coupling, present in this type of quantum well, results in weak antilocalization, an enhanced conductivity at zero magnetic field. The wires had a geometrical width of 1.2 µm.

in the resistance, a decrease occurs [22, 27, 28]. As the sign of the quantum mechanical correction to the conductivity is reversed, this effect is referred to as "weak antilocalization".

The weak antilocalization measurements of a set of InGaAs/InP wires are shown in Figure 1.11. In contrast to the weak localization effect, an enhanced conductivity is found at $B = 0$. However, if a magnetic field is applied then the weak antilocalization effect is gradually suppressed. Notably, important parameters characterizing the spin scattering and spin precession can be extracted from weak antilocalization measurements. In fact, detailed information of the Rashba and Dresselhaus contributions in a particular material can be obtained by fitting the experimental curves to the appropriate theoretical model. It should be noted that both contributions are important for the spin field effect transistor, as introduced in Chapter 3 of this volume and Chapter 5 of volume 4 of this series (Bandyopadhyay, S., Monolithic and Hybrid Spintronics. In: Schmid, G. (ed), Nanotechnology, Vol 4, Chapter 5).

1.6 Al'tshuler–Aronov–Spivak Oscillations

The fact that, in a metallic conductor, closed loops are responsible for the reduction of the resistance if a magnetic field is applied raises the question: Is it possible to observe resistance oscillations due to interference if the shape of the closed loops are restricted by a fixed, well-defined geometry? In the following sections, it will be shown that indeed these oscillations – the so-called Al'tshuler–Aronov–Spivak oscillations – can be observed in ring-shaped conductors, if the rings are penetrated by a magnetic flux. A series of interconnected ring-shaped conductors is shown schematically in

Figure 1.12 A series of interconnected ring-shaped conductors. Each ring is penetrated by a magnetic flux Φ. The interference of the time-reversed trajectories leads to the Al'tshuler–Aronov–Spivak oscillations as a function of a magnetic field.

Figure 1.12, where the enclosed magnetic flux Φ is the same for each ring. Thus, the phase shift $\Delta\varphi$ between time-reversed paths, as given by Equation 1.37, is approximately the same in all rings. By using Equation 1.30, the total amplitude in a loop is given by [30, 31]:

$$\begin{aligned} P &= \left| C_1 \exp\left(i2\pi \frac{\Phi}{\Phi_0} \right) + C_2 \exp\left(-i2\pi \frac{\Phi}{\Phi_0} \right) \right|^2 \\ &= 2|C_1|^2 [1 + \cos(4\pi\Phi/\Phi_0)]. \end{aligned} \tag{1.44}$$

From the equation given above it can be concluded that the resistance in this type of structure should oscillate with a period of $\Phi_0/2$.

The first demonstration of this type of weak localization resistance oscillations was provided by Sharvin and Sharvin [31], who evaporated a thin Mg film onto the surface of a quartz filament. The magnetic field was applied in axial orientation with respect to the filament while the current was flowing through the Mg film along the filament. A comparison with the cross-section of the filament confirmed, that the resistance oscillations indeed had a period of $\Phi_0/2$.

Beside cylindrical samples, Al'tshuler–Aronov–Spivak oscillations can also be observed in planar quantum wire networks, similar to the structure shown in Figure 1.12 [33]. The closed trajectories are realized by squares connected to a chain or to a mesh, as shown in Figure 1.13 (inset).

The relative resistance difference $\Delta R/R_0$ as a function of a perpendicular magnetic field is shown in Figure 1.13. Pronounced oscillations are found in the chain as well as in the mesh structure. For smaller square elements, the oscillation period is larger as a larger magnetic field is required to generate a magnetic flux of $\Phi_0/2$. In order to observe Al'tshuler–Aronov–Spivak oscillations, the phase-coherence length must be larger than the circumference of the squares. For the chain structure, the total resistance is given by adding the contribution of each single square. Depending on the type of material, each ring produces either a maximum or minimum at $B = 0$, depending on the absence or presence of spin scattering. This ensures that, after summation of the contribution of each element of the chain, the Al'tshuler–Aronov–Spivak oscillations are not averaged out.

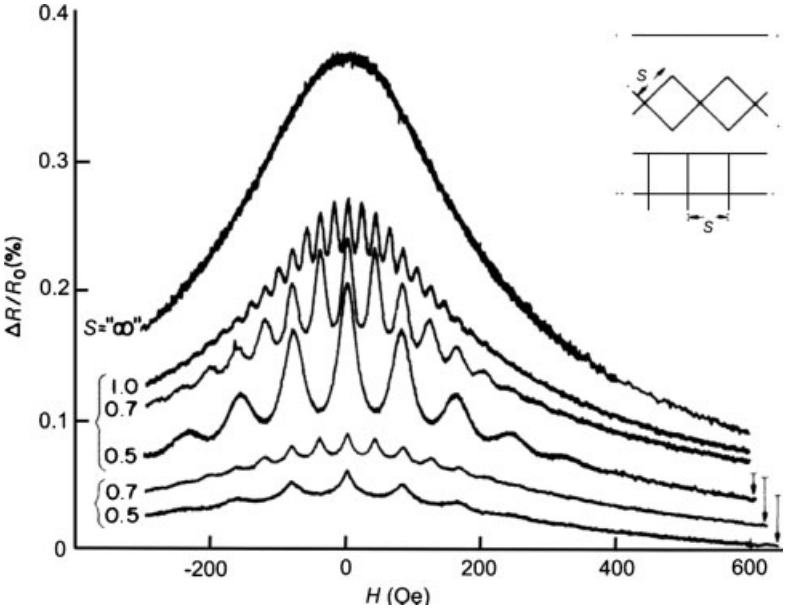

Figure 1.13 Magnetoresistance of 21 nm-thick and 55 nm-wide lithium wires of different geometry measured at 0.13 K. The upper curve shows the measurement of a single wire. Here, a resistance maximum at $B = 0$ due to weak localization is found. The following three curves show the resistance for a chain of squares. The size of the elements decreases for lower curves, respectively. The lowest two curves show the measurement on a mesh structures. The size S of the unit cell (in micrometers) is indicated next to each curve. (Reprinted with permission from [33]. Copyright (1986) by the American Physical Society.)

1.7 The Aharonov–Bohm Effect

In contrast to the Al'tshuler–Aronov–Spivak oscillations, which originate from the interference of electrons propagating along time-reversed paths interfering at the point of departure, the Aharonov–Bohm effect is based on electron waves propagating along two different branches of a ring structure and interfering at the opposite side of the ring. This situation is illustrated schematically in Figure 1.14a.

The Aharonov–Bohm effect was predicted, from a theoretical point of view, in 1959 [34]. The essence of this effect is that the vector potential $\boldsymbol{A}$ affects the interference of the electron waves, even in the case when the magnetic field $\boldsymbol{B}$ in the conductor is zero. In order to clarify this point, the experimental set-up shown in Figure 1.14a will be discussed. Here, the magnetic field $\boldsymbol{B}$ is restricted to an area within the ring structure (the gray-shaded area in Figure 1.14a), and is zero in the ring-shaped conductor. Classically no effect is expected since, at the location of the electrons, no magnetic field is present. However, as seen in Section 1.6, the vector potential $\boldsymbol{A}$, which is non-zero in the conductor, will induce a phase shift of the electron wave and thus affect the electron transport.

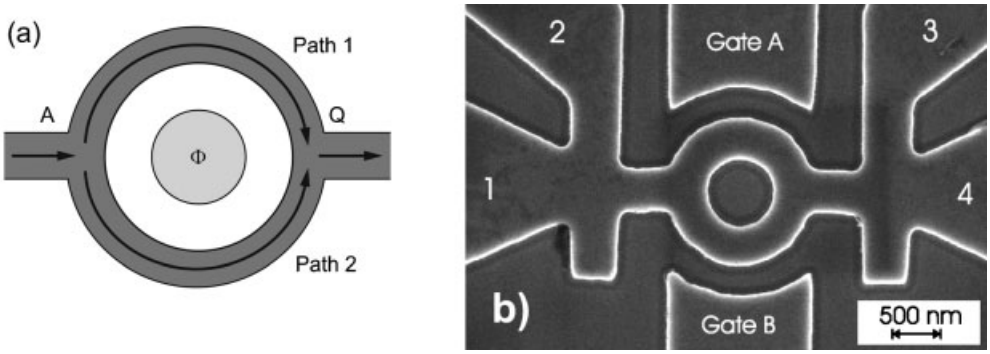

Figure 1.14 (a) Electron trajectories in a ring-shaped conductor. For the Aharonov–Bohm effect the ring is penetrated by a magnetic field within the inner diameter of the conductor. No magnetic field is applied within the conductor. The magnetic flux within the ring is Φ. (b) Electron beam micrograph of an AlGaAs/GaAs ring structure with two in-plane gates (A and B).

The phase difference $\Delta\varphi$ of two electron waves propagating along the upper and the lower branches of the ring (paths 1 and 2 in Figure 1.14a) and interfering at the end point Q of the ring is given by

$$\begin{aligned}\Delta\varphi &= \chi_1 - \chi_2 - \frac{e}{\hbar}\int\limits_{path1} \boldsymbol{A}d\boldsymbol{l} + \frac{e}{\hbar}\int\limits_{path2} \boldsymbol{A}d\boldsymbol{l} \\ &= \Delta\chi + \frac{e}{\hbar}\oint \boldsymbol{A}d\boldsymbol{l}.\end{aligned} \tag{1.45}$$

Here, χ_1 and χ_2 are the phases that the electron waves acquire during their propagation along path 1 and path 2 at zero magnetic field in the interior of the ring. In contrast to weak localization, the paths are different and therefore not time-reversed. Since the impurity configurations on both branches usually differ, the accumulated phases are different in both branches.

We will now return to the Aharonov–Bohm effect itself. By making use of $rot\,\boldsymbol{A} = \boldsymbol{B}$, Equation 1.45 results in

$$\begin{aligned}\Delta\varphi &= \Delta\chi + \frac{e}{\hbar}\int \boldsymbol{B}d\boldsymbol{f} \\ &= \Delta\chi + 2\pi\frac{\Phi}{\Phi_0}.\end{aligned} \tag{1.46}$$

The surface integral over $\boldsymbol{B}$ corresponds to the magnetic flux Φ penetrating the ring. As illustrated in Figure 1.14a, the area penetrated by the magnetic field does not need to be as large as the opening of the ring. As can be inferred from Equation 1.46, a phase shift of 2π is acquired if the magnetic flux is changed by a magnetic flux quantum Φ_0. Thus, the period is twice as large as the period of the Al'tshuler–Aronov–Spivak oscillations discussed above.

For the first experiments demonstrating the Aharonov–Bohm effect, a set-up was used where the electrons were not exposed to a magnetic field [36, 37]. These experiments were performed with an electron beam in a vacuum and a shielded magnet coil. In solid-state the Aharonov–Bohm effect was first demonstrated in Au rings, with the diameter of the ring structure being less than 1 μm and a wire width of a few tens of nanometers [38]. In metallic ring structures, the magnetic field cannot usually be prevented from penetrating the wire itself. Nevertheless, the vector potential $\boldsymbol{A}$ is still responsible for the effect on the electron interference pattern. A typical ring structure defined in an AlGaAs/GaAs semiconductor heterostructures is shown in Figure 1.14b [35]. One important difference between the Aharonov–Bohm experiments on nanoscaled rings and experiments using electron beams in vacuum, is that in the former case the electrons are usually scattered many times within the conductor before reaching the opposite side of ring. Thus, the elastic mean free path is most often smaller than the ring size. In addition, in metallic or semiconducting ring structures the phase-coherence length is in the order of the ring diameter at low temperatures, and consequently many electrons lose their phase memory while propagating through the ring. This is the reason why the oscillation amplitude is considerably smaller than the total resistance of the structure. As can be seen in Figure 1.15, pronounced Aharonov–Bohm oscillations were observed in ring structures based on 2-D electron gases in an $In_{0.77}Ga_{0.23}As/InP$ heterostructure [39]. A comparison of the enclosed area of the ring confirmed that the oscillation period corresponded to a magnetic flux quantum Φ_0. Owing to the low effective electron mass and to the high mobility in these heterostructures, the phase-coherence length can exceed 1 μm at temperatures below 1 K, and consequently large oscillation amplitudes are achieved. Previously, resistance modulations of up to 12% have been observed in this type of structure.

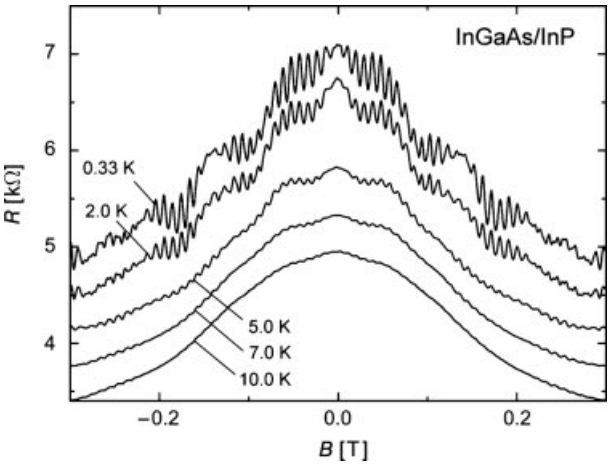

Figure 1.15 Magnetoresistance of an $In_{0.77}Ga_{0.23}As/InP$ ring structure measured at 0.3 K. The ring had a diameter of 820 nm, with a width of the wires forming the ring of about 85 nm. (Reprinted with permission from [39]. Copyright (1995) by the American Physical Society.)

When the Al'tshuler–Aronov–Spivak oscillations were discussed, it was found that at $B = 0$ a maximum is observed in the resistance, owing to the constructive interference between time-reversed loops (see Figure 1.13). For the Aharonov–Bohm effect, the interference at the branching point is determined by the two different paths 1 and 2 along the two branches of the ring, as illustrated in Figure 1.14a. The phase difference $\Delta\chi$ at $B = 0$ between the two paths depends to a large extent on the distribution of scattering centers in the ring; that is, for different rings – regardless of whether they have the same geometry – a different phase shift $\Delta\chi$ is accumulated. As a result, no clear maximum or minimum, as for the Al'tshuler–Aronov–Spivak oscillations, is expected at $B = 0$. In fact, it could be shown that the amplitude of the Aharonov–Bohm oscillations is decreased if the signal of many rings is averaged [40]. This is due to the fact that the contributions of interferences of the different rings with the same oscillation period but with statistically distributed phase shifts $\Delta\chi$ are averaged out.

Besides the magnetic control of the interference pattern of an Aharonov–Bohm ring structure, the oscillation pattern can also be changed electrostatically by means of a gate electrode. A typical AlGaAs/GaAs sample with two in-plane gates is shown in Figure 1.14b. By applying a voltage to one of the gates, the electron concentration in the corresponding branch of the ring is altered. A change of the carrier concentration goes along with a change of the Fermi wavelength and, as a result, the phase accumulated in this branch of the ring is changed. Clearly this will immediately affect the interference pattern, as can be seen in Figure 1.16.

It is interesting to observe that the oscillation pattern of the sample is symmetric with respect to the magnetic field. This can be seen in Figure 1.16, where the resistance oscillations are shown as a grayscale plot as a function of magnetic field

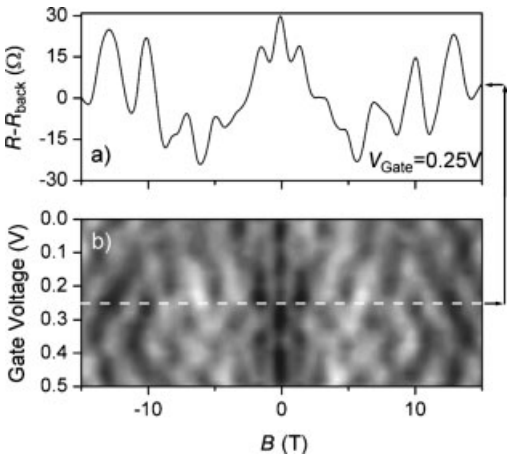

Figure 1.16 (a) Magnetoresistance of the AlGaAs/GaAs ring structure shown in Figure 1.14b for 0.25 V applied to gate B. The voltage at gate A was set to zero. The background resistance R_{back} was subtracted from the total resistance. (b) Grayscale plot of the magnetoresistance $R\text{-}R_{back}$ for different voltages applied to gate A and B. The dark and light regions correspond to large and low resistance values, respectively. The dashed line indicated the measurement shown in (a).

and gate voltage. The symmetric pattern is due to the fact that, although four terminals are used during the measurement, the measurement is effectively a two-terminal measurement. For such a measurement it can be shown in general that the resistance is symmetric under reversal of the magnetic field: $R(-B) = R(B)$ [9]. The reason for the two-terminal nature of the measurement is the coupling of the two contacts on each side, although these are not independent, as would be required for a pure four-terminal measurement.

1.8 Universal Conductance Fluctuations

A closer inspection of the Aharonov–Bohm effect measurements reveals that irregular fluctuations are often superimposed on the regular oscillations. This can be seen clearly in the measurements shown in Figure 1.15 where a long-wavelength underground is observed superimposed on the oscillations. The fluctuations are reproducible if the measurements are repeated for the same sample [42, 43]; however, if different samples with the same geometry and fabricated using the same material are compared, it is found that a different fluctuation pattern belongs to each sample. This is the reason, why the individual fluctuation pattern of a sample is sometimes referred to as a *fingerprint*. Conductance fluctuations are observed in semiconducting structures as well as in metallic samples [44, 45]. However, as the size of semiconductor devices becomes smaller, the statistical distribution of the remaining few dopant atoms will result in a spread of the device characteristics. Thus, resistance fluctuations are not only important in the phase-coherent regime but are also becoming much more of an issue in device applications.

1.8.1 Basic Principles

The reason, why each sample shows a different conductance fluctuation pattern becomes clear when it is realized that very few scattering centers (i.e., impurities) are present in very small structures. In fact, if the sample possesses very few impurities then it is the impurity configuration that governs the transport properties. Moreover, if only a finite number of scattering centers is present, an ensemble average cannot be applied for the theoretical description, as this does not take into consideration the particular spatial distribution of the scattering centers. Of course fluctuations may be observed not only in ring structures but also in a single quantum wire, as they originate from the spatial configuration of the scattering centers in the wire. The conductance fluctuations of a single Au wire are shown in Figure 1.17.

The fluctuations shown in Figure 1.17 cover an interval of approximately $\pm e^2/h$, the fluctuation amplitude of which, as proven by a detailed theoretical analysis, is universal [47, 48]. For a qualitative explanation of the physical origin of the conductance fluctuations, the reader is referred to the above-mentioned Aharonov–Bohm effect. As illustrated in Figure 1.18a, the electron is able to propagate along a certain number of paths in order to cross the wire.

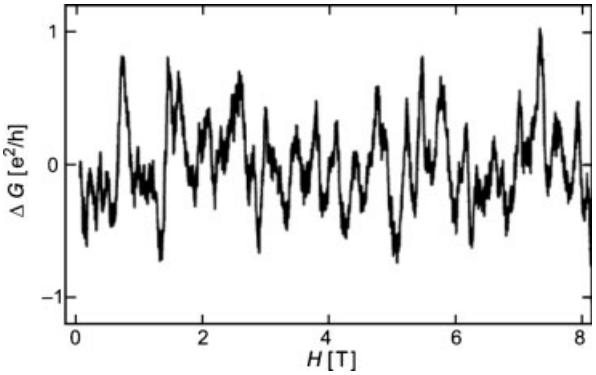

Figure 1.17 Conductance fluctuations as a function of magnetic field of a 310 nm-long and 25 nm-wide Au wire measured at a temperature of 10 mK [46]. (© Taylor &Francis Ltd.).

The total transmission probability results from the squared amplitude of all possible trajectories. Among these trajectories, a limited number of paths may be found which meet again after a certain distance. If a magnetic field is applied, the paths become penetrated by a magnetic flux Φ; subsequently, if the magnetic field is varied, superpositioning of the electron waves of two paths (which cross twice) leads to a variation in the transmission probability due to the Aharonov–Bohm effect. Then, in contrast to a well-defined ring structure, the encircled areas differ among the various locations of the wire, such that a different Aharonov–Bohm period is developed for each area. Superposition of the different quasi Aharonov–Bohm rings then produces an irregular conductance pattern [43]. It is important that only a limited number of trajectories exists, so that an effective averaging out of the

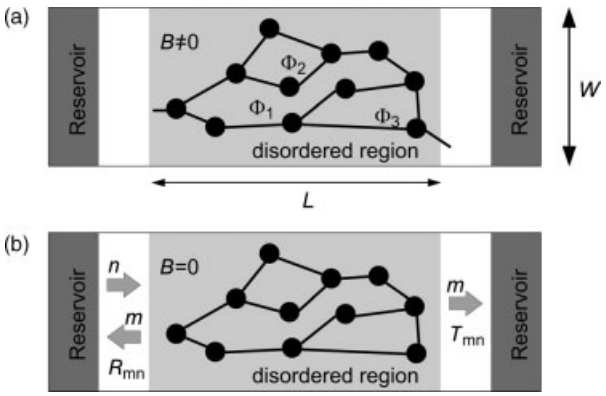

Figure 1.18 (a) Electron trajectories in a quantum wire. If a magnetic field is applied, loops are penetrated by a magnetic flux Φ_1, Φ_2, Φ_3, ... (b) Sample configuration considered for the calculation of the conductance fluctuations using the Landauer–Büttiker formalism. The wire consists of a disordered region connected by ballistic areas to the phase-randomizing reservoirs. Here, *n* denotes the incoming channel, while *m* is the outgoing channel (transmitted or reflected).

oscillations is prevented. In addition to varying the magnetic field, it is also possible to observe conductance fluctuations by increasing the applied voltage, but this will lead to a change in the Fermi wavelength of the electrons.

1.8.2 Detailed Analysis

A detailed theoretical description of conductance fluctuations is based on the particular scattering center configuration [47, 48]. Hence, by using this theoretical approach it was possible to calculate the average oscillation amplitude of sample-specific conductance fluctuations. One important point of the theoretical model is that a variation in the magnetic field or the Fermi energy induces the same type of fluctuation as would an ensemble average (quasi-ergodic hypothesis). This allows the measurement of only a single sample rather than measuring numerous different wires at zero magnetic field and constant Fermi energy.

In the following section it will first be shown that the magnitude of the conductance fluctuations at zero temperature is of the order e^2/h, independent of the sample size. The only requirement is that the transport takes place within the diffusive regime. For the derivation, an ensemble of different wires with different impurity configurations at zero magnetic field is considered. An explanation of the universality of conductance fluctuations follows the approach of Lee [49], although for the following considerations use will be made of the Landauer–Büttiker formalism (see Section 1.3.1), where conductance is expressed by the transmission probabilities of the different quantum channels. A scheme of the conductor is shown in Figure 1.18b, where the current is flowing from the left to the right reservoir. The disordered region of the wire is connected by ballistic areas to the phase-randomizing reservoirs.

The first step of the process is to express the Drude conductance of a diffusive conductor by the Landauer–Büttiker formula. Hence, the Drude conductance for a single spin direction can be written as

$$G = \frac{e^2}{h}\sum_{m,n}^{N} T_{mn} = \frac{e^2}{h}\left(N - \sum_{m,n}^{N} R_{mn}\right) \tag{1.47}$$

where $N = k_F W/\pi$ is the number of quantum channels of a 1-D conductor of width W, and k_F is the Fermi wavenumber. The quantities T_{mn} and R_{mn} denote the transmission and reflection probabilities from channel n into channel m, respectively [cf. Equation 1.23 and 1.20, the indices i, j for the channels are omitted, here]. Interest has been shown in the variations of the conductance for different impurity configurations, and the quantity related to this is the variance of the conductance, which is defined by:

$$\mathrm{var}(G) = \langle \Delta G^2 \rangle = \langle (G - \langle G \rangle)^2 \rangle \tag{1.48}$$

Here, $\langle \cdots \rangle$ denotes the average over different impurity configurations. The square root of the variance, $\delta G \equiv \sqrt{\mathrm{var}(G)}$, is a measure of the magnitude of the conductance

fluctuations, the quantity, which is determined experimentally. With the expression for the conductance, given by Equation 1.47, one obtains for the variance:

$$\begin{aligned} \mathrm{var}(G) &= \left(\frac{e^2}{h}\right)^2 \mathrm{var}\left(N - \sum_{m,n}^{N} R_{mn}\right) \\ &= \left(\frac{e^2}{h}\right)^2 \mathrm{var}\left(\sum_{m,n}^{N} R_{mn}\right) \\ &= \left(\frac{e^2}{h}\right)^2 N^2 \mathrm{var}(R_{mn}), \end{aligned} \tag{1.49}$$

and it is assumed that $\mathrm{var}(R_{mn})$ is independent of m and n. The question might be asked as to why the variance is not calculated directly by using the transmission probabilities T_{mn}. Following Lee [49], this causes a problem, since for transmission processes in the diffusive transport regime with many impurity collisions a sequence of scattering events is shared by different channels of the conductor. As a consequence, the different channels are not completely uncorrelated, so that problems are encountered in the proceeding averaging procedure. The situation is different, however, if reflection processes are considered, where it may be assumed that only a few scattering events are responsible for the back-reflection. This is also the reason, why it can be assumed that the reflections in different channels are uncorrelated.

In order to calculate the variance of R_{mn}, use is made of the concept of Feynman paths. By analogy to the probability to propagate between to points A and Q, as expressed by Equation 1.29, the probability for a reflection from channel n into m by the square of the total amplitude of all possible paths j which propagate from the incoming channel n into the outgoing channel m can be expressed as:

$$R_{mn} = \left|\sum_j C_j\right|^2 \tag{1.50}$$

According to Equation 1.49, the variance of R_{mn} must first be calculated in order to obtain the variance of G. The variance of R_{mn} is given by

$$\mathrm{var}(R_{mn}) = \langle R_{mn}^2 \rangle - \langle R_{mn} \rangle^2 \tag{1.51}$$

The last term is the square of the average reflection probability $\langle R_{mn} \rangle$, which can be expressed by

$$\langle R_{mn} \rangle = \sum_{ij} \langle C_i C_j^* \rangle \tag{1.52}$$

If uncorrelated paths are assumed, as discussed above, so that

$$\langle C_i C_j^* \rangle = 0 \tag{1.53}$$

one finally obtains

$$\langle R_{mn} \rangle = \sum_i \langle C_i C_i^* \rangle = \sum_i \langle |C_i|^2 \rangle \tag{1.54}$$

For the first term in Equation 1.51, the following can be written:

$$\begin{aligned}\langle R_{mn}^2\rangle &= \sum_{ijkl}\langle C_i C_j C_k^* C_l^*\rangle \\ &= \sum_{ijkl}\{\langle|C_i|^2\rangle\langle|C_j|^2\rangle\delta_{ik}\delta_{jl} + \langle|C_i|^2\rangle\langle|C_j|^2\rangle\delta_{il}\delta_{jk}\} \\ &= 2\sum_{ij}\langle|C_i|^2\rangle\langle|C_j|^2\rangle = 2\langle R_{mn}\rangle^2.\end{aligned} \tag{1.55}$$

Thus, the variance of R_{mn} is given simply by $\langle R_{mn}\rangle^2$.

For small transmission probabilities $T_{mn} \to 0$, which is the case for a sufficient number of scattering centers in the wire ($l_e \ll L$), the average reflection probability may be approximated by [49]

$$\langle R_{mn}\rangle \approx \frac{1}{N} \tag{1.56}$$

so that finally one obtains

$$\mathrm{var}(G) = \left(\frac{e^2}{h}\right)^2 N^2 \mathrm{var}(R_{mn}) \approx \left(\frac{e^2}{h}\right)^2 \tag{1.57}$$

for the variance of the conductance in the diffusive limit. As can be seen here, the conductance fluctuations are of the order of e^2/h. The universal magnitude of the conductance fluctuations is found for example in the measurement shown in Figure 1.17.

1.8.3 Fluctuations in Long Wires

Until now, it has been assumed that the wire length is smaller than the phase-coherence length, but the question must also be addressed as to what happens if the length L of the wire exceeds the phase-coherence length l_φ. In this situation, the wire may be cut into $N = L/l_\varphi$ phase-coherent pieces connected in series (see Figure 1.19).

Each of these segments produces resistance fluctuations, δR_0, so that the total resistance fluctuations are given by

$$\delta R = \sqrt{N}\delta R_0 \tag{1.58}$$

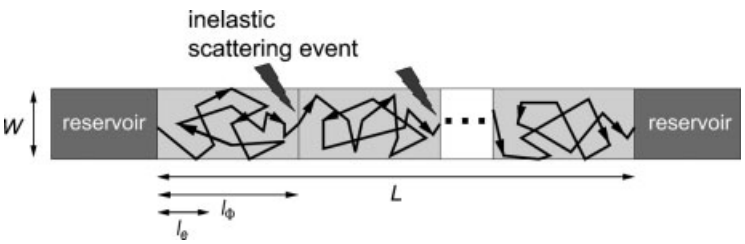

Figure 1.19 The conductance fluctuations are determined by cutting the wire into $N = L/l_\varphi$ coherent pieces.

By using the total resistance $R = NR_0$, where R_0 is the resistance of a single segment, the total conductance fluctuations can be calculated:

$$\delta G = \left| -\frac{\delta R}{R^2} \right| = \frac{e^2}{h}\frac{\sqrt{N}}{N^2} = \frac{e^2}{h} N^{-3/2} \tag{1.59}$$

If N is substituted by the ratio between total length and phase coherence length, the following is finally obtained:

$$\delta G = \frac{e^2}{h}\left(\frac{l_\varphi}{L}\right)^{3/2} \tag{1.60}$$

It is important to note that no exponential decrease of the fluctuations with respect to length is expected. In contrast, only a relatively weak decrease of δG with increasing length is predicted, and this was indeed confirmed experimentally [50].

1.8.4 Energy and Temperature Dependence

In semiconductor structures the electron concentration – and thus the Fermi energy – can be controlled by means of a gate electrode. An impression of how the Fermi energy affects the conductance fluctuations can be gained by comparing the change of E_F with the characteristic correlation energy E_{Th} (Thouless energy).

First, an insight must be obtained into the nature of the correlation energy E_{Th}. For the sake of simplicity, an ideal system can be assumed where any scattering is neglected. Along the length L, the phase develops as

$$\varphi = kL \tag{1.61}$$

If a state is now considered with a slightly different wavevector $k \to k' = k + \Delta k$, the phase difference between both waves is

$$\Delta\varphi = \Delta k L \tag{1.62}$$

The energy difference between both states can be quantified as

$$\Delta E = \frac{dE}{dk}\Delta k = \hbar v_F \frac{\Delta\varphi}{L} = \hbar\Delta\varphi\frac{1}{\tau_{Th}} \tag{1.63}$$

Here, τ_{Th} is the time that the wave requires to propagate along length L. The Thouless energy, E_{Th}, is defined as the energy difference where both states are uncorrelated, at which point if the phase difference $\Delta\varphi$ is equal to 1, the following is obtained:

$$E_{Th} = \frac{\hbar v_F}{L} = \frac{\hbar}{\tau_{Th}} \tag{1.64}$$

Thus, the Thouless energy is connected to the time $\tau_L = L/v_F$ that an electron wave requires to cover the dimension L of the system. Up to now, only a ballistic system has been considered, but in the diffusive regime the corresponding characteristic time is given by $\tau_{Th} = L^2/D$. Only if the Fermi energy is changed by a value comparable to E_{Th} is the next energy level reached and the conductance changed to a value uncorrelated

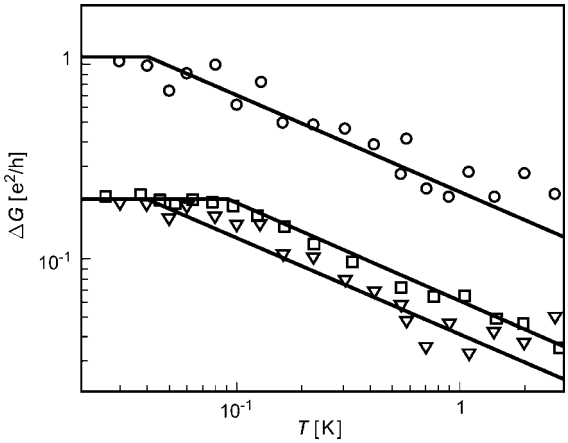

Figure 1.20 Decrease in conductance fluctuations with temperature for a ring structure with a diameter of 820 nm (○). In addition, the temperature dependence of the Aharonov–Bohm oscillations of a 820 nm-wide ring (▽) and for a 325 nm-wide ring (□) are shown [46]. (© Taylor &Francis Ltd.).

to the conductance value of the previous energy value. The correlation energy for small quantum wires has a relative large value, which would not be expected if a large number of uncorrelated trajectories were to be averaged.

If the temperature is increased, then the Fermi distribution becomes smeared out. However, while the temperature remains sufficiently low that the width of the Fermi distribution is smaller than E_{Th}, the maximum fluctuation amplitude is maintained. When the smearing of the Fermi distribution exceeds E_{Th}, a number of approximately $N = (k_B T)/E_{Th}$ segments contribute. As these N segments are uncorrelated, the fluctuation amplitude decreases with $1/\sqrt{N}$, thus $1/\sqrt{T}$. This behavior was confirmed experimentally, as shown in Figure 1.20 [46]. At low temperature the fluctuation amplitude is found initially to be constant, but if the temperature is increased above a critical value a continuous decrease following $1/\sqrt{T}$ is observed. From the starting point of the decrease at $T = 0.1$ K, the correlation energy can be estimated. Typically, a value for E_{Th} of the order of 10 μeV would be obtained for this sample.

1.9 Concluding Remarks

It is clear that many interesting phenomena related to phase-coherence transport can be observed in semiconducting or metallic nanostructures. Although, many of these effects are quite well understood and the theoretical models well established, in other cases open questions remain. For example, does the phase coherence time always saturate if the temperature is sufficiently low [2]? Very recently, the issue of phase

coherence in nanostructures has attracted much attention in connection with solid-state quantum computation, where the maintenance of phase coherence is a critical issue. Furthermore, spin-related phenomena are a subject of current interest, as phase-coherent spin manipulation is regarded as an interesting option for future electronic devices.

Clearly, this chapter can provide only a brief overview of the most important phenomena connected with phase-coherent transport in nanostructures. However, for further information, the reader is referred to various textbooks [1, 51, 52] and reviews [2, 18, 46].

Charge Transport and Single-Electron Effects in Nanoscale Systems

Joseph M. Thijssen and Herre S.J. van der Zant

2.1
Introduction: Three-Terminal Devices and Quantization

In electronics, charges are manipulated by sending them through devices which have a few terminals: a *source* which injects the charge; and a *drain* which removes the charge from the device. Occasionally, a third terminal, called a *gate*, is present, and this is used to manipulate the charge flow through the device. The gate does neither inject charge into, nor removes it from the device. Three-terminal devices are standard elements of electronic circuits, where they act as switches or as amplifying elements. Semiconductor-based three-terminal switches are responsible for the tremendous increase in computer speed achieved over the past few decades.

Feynman, in his famous lecture [1], pointed out that the possible scale reduction from the standards of that period was still enormous, and he also suggested that quantum mechanical behavior may result in a different way of operation of the devices, which may open new horizons for applications. Indeed, as we now know, two aspects become important when the size of the device is reduced. The first aspect is indeed the quantum mechanical behavior, and the second is the quantization of the charges flowing into and out of the devices. It is interesting to analyze how the energy scales at which the two effects become noticeable, depend on the device size.

The charge quantization is subtle in view of quantum mechanics: in principle, the charge carried by an electron is distributed in space. In quantum mechanics, a single charge may be distributed according to $|\psi(r)|^2$, where $\psi(r)$ is the quantum mechanical wave function, and this leaves open the possibility of having a fractional charge inside the device. Therefore, the discrete nature of charge does not seem to play a role in the charge transport. However, if the device were to be uncoupled from its surroundings, we would only find integer charges residing on it. This puzzle is solved by realizing that the expectation value of the electrostatic energy, which must be included into the Hamiltonian governing the electron behavior, is dominated by the charge distribution which occurs most of the time. It can be shown that the charge within a device that is *weakly* coupled to its surroundings, is always very close to an integer. Therefore,

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

in order to observe Coulomb effects resulting from the discreteness of the electron charge, it is necessary to consider devices that are weakly coupled to the surroundings.

For the charge quantization, the energy scale associated with the discreteness of the electron charge is given by

$$E_C = \frac{e^2}{2C},$$

where C is the capacitance of the device. This is the energy needed to add a unit charge to the device – it is called the "charging energy". Taking as an estimate the capacitance of a sphere with radius R, we have

$$E_C = \frac{e^2}{8\pi\varepsilon_0 R} = \frac{1}{2R} E_H, \tag{2.1}$$

where, in the rightmost expression, R is given in atomic units (Bohr radii), as is the energy (E_H is the atomic unit of energy – it is called the Hartree and it is given by 27.212 eV). In Section 2.4, we shall present a more detailed analysis for the case where the device is (weakly) coupled to a source, drain and gate.

The energy scale for quantum effects is given by the distance between the energy levels of an isolated device. As a rough estimate, we consider the particle in the (cubic) box problem with energy levels separated by a level splitting Δ given by

$$\Delta = \text{const} \times \frac{\hbar^2}{mL^2} = \text{const} \times \frac{1}{L^2} E_H, \tag{2.2}$$

where m is the electron mass and L is the box size (which must be given in atomic units in the rightmost expression). The first multiplicative constant is of order 1; it depends on the geometry and on the details of the potential.

In the case of carbon nanotubes, the device is much smaller in the lateral direction than along the tube axis. In such cases it is useful to distinguish between the two sizes. The lateral size leads to a large energy splitting and the longitudinal splitting may become vanishingly small. For a metallic nanotube, the level spacing associated with the tube length L is

$$\Delta = \frac{\hbar v_F}{2L},$$

where v_F is the Fermi velocity $v_F = \hbar k_F/m$ with $\nu_F \approx 8 \times 10^5\,\mathrm{m\,s^{-1}}$.

Equations 2.1 and 2.2 tell us how the typical Coulomb and quantum energies scale with the device size (R or L). In Figure 2.1, several experimental realizations are shown of small gated devices that may be weakly coupled to source, drain. Most of these devices have the layout shown in Figure 2.2. An order of magnitude estimate for the charging energy and level splitting for some typical three-terminal devices is provided in Table 2.1. Semiconducting and nanotube quantum dots have been studied in great detail, and their behavior is fairly well understood; however, at the time of writing, the properties of molecular quantum dots are still much less established mainly because it is difficult to fabricate them in a reliable manner.

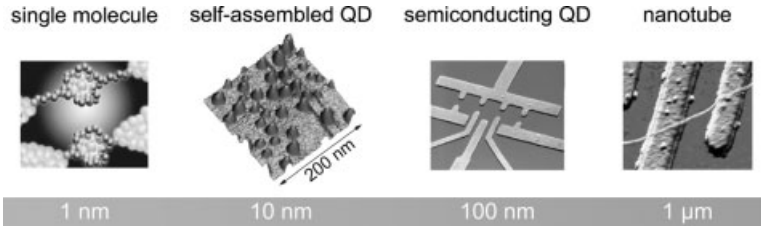

Figure 2.1 Different quantum dot systems.

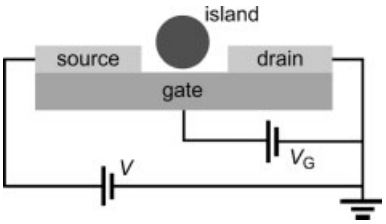

Figure 2.2 A schematic diagram of the three-terminal device layout.

When studying transport through a small island, weakly coupled to a source and a drain, information can be obtained about the quantum level splitting Δ and the charging energy E_C if the energy of the particles flowing through the device can be controlled with precision high enough to resolve these energy splittings. Pauli's principle states that electrons can only flow from an occupied state in the source to an empty state in the drain. The separation between empty and occupied states in the leads is only sharp enough when the temperature is sufficiently low. It can be seen that a low operation temperature is essential for observing the quantum and charge quantization effects. The energy scale associated with the temperature is given by k_BT, so we must have

$$k_BT \leq \Delta, E_C.$$

Note that for molecular devices, with their relatively large values of Δ and E_C, quantum and charge quantization effects should still be observable at room temperature. In a typical metallic island, $\Delta \ll k_BT$, and the Coulomb blockade dominates the level separation. In this case we speak of a *classical dot* (see also Chapter 21 of this volume).

In the present chapter we explain the different aspects of charge transport, with emphasis on those devices in which the level spacing and the charging energy plays an essential role in the transport properties. This is the case in quantum dots and in many molecular devices.

Table 2.1 Typical charging energies and level spacings for various three-terminal devices.

	Ga As quantum dot	Carbon nanotube[a]	Molecular transistor
E_C	0.2–2 meV	3 meV	>0.1 eV
Δ	0.02–0.2 meV	3 meV	>0.1 eV

[a]Metallic nanotube, 500 nm in length.

2.2 Description of Transport

In this section, we present a qualitative discussion of the different transport mechanisms, after which attention will be focused on the weak-coupling case.

The major question here is what picture should be used to describe transport through small devices. In solids, electrons are usually thought of in terms of the independent particle model, in which the wave function of the many-electron system is written in the form of a Slater determinant built from one-electron orbitals. This is an exact solution for a Hamiltonian, which is a sum of one-electron Hamiltonians:

$$H = \sum_i h_i. \tag{2.3}$$

The electrostatic repulsion between the electrons:

$$V_{ES} = \frac{1}{4}\pi\varepsilon_0 \frac{e^2}{|\vec{r_i} - \vec{r_j}|}.$$

does not satisfy this requirement. Also, the electrons couple electrostatically to the motion of the nuclei, which interact among themselves via a similar Coulomb interaction. Several schemes exist for building a Hamiltonian, such as Equation 2.3, in which the interaction between the electrons is somehow moved into a (possibly non-local) average electrostatic potential. The best known such schemes are the Hartree–Fock (HF) and the density functional theory (DFT). The question is now whether the independent electron picture can survive in the study of transport through small devices. The answer is that single-electron orbitals still form a useful basis for understanding this transport, but that the Coulomb and electron–nucleus interaction must be included quite explicitly into the description in order to understand single-electron effects.

2.2.1 Structure of Nanoscale Devices

Although it often cannot be used in the transport itself, the single particle picture is still suitable for the bulk-like systems to which the device is coupled, and for the narrow leads which may be present between the island and the bulk reservoirs. These elements are described in Chapter 1, and their properties will be recalled only briefly here, with emphasis on the issues needed in the context of the present chapter.

2.2.1.1 The Reservoirs

The reservoirs are bulk-like regions where the electrons are in equilibrium. These regions are maintained at a specified temperature, and the number of electrons is variable as they are connected to the voltage source and the leads to the device (see below). The electrons in these reservoirs are therefore distributed according to Fermi functions with a given temperature T and a chemical potential μ:

$$f_{FD}(E) = \frac{1}{\exp[(E-\mu)/k_BT]+1}.$$

This function falls off from 1 at low energy to 0 at high energy. For $(\mu - E_0) \ll k_BT$, where E_0 is the ground state energy, this reduces to a sharp step down from 1 to 0 at $E = \mu$, and μ can in that case be identified with the Fermi energy (the highest occupied single-particle energy level).

In order to have a current running through the device and the leads, the source and drain reservoirs are connected to a voltage source. A bias voltage causes the two leads to have different chemical potentials.

2.2.1.2 The Leads

Sometimes it is useful to consider the leads as a separate part of the system, in particular for convenience of the theoretical analysis. The leads are channels, which may be considered to be homogeneous. They form the connection between the reservoirs and the island (see below). They are quite narrow and relatively long. Electrons in the leads can still be described by single-particle orbitals. If the leads have a discrete or continuous translational symmetry, the states inside them are Bloch waves. By separation of variables, we can write the states as

$$e^{ik_z z} u_T(x, y)$$

with energy

$$E = E_T + \frac{\hbar^2 k_z^2}{2m}.$$

It is seen that the states can be written as a transverse state $u_T(x, y)$ which contributes an amount E_T to the total energy, times a plane wave along z. The quantum numbers of the transverse wave function $u_T(x, y)$ are used to identify a channel.

In this chapter, usually no distinction is made between reservoirs and leads: rather, they are both simply described as baths in equilibrium with a particular temperature and chemical potential (which may be different for the source and drain lead). However, for a theoretical description of transport, it is often convenient to study the scattering of the incoming states into outgoing states – in that case, the simple and well-defined states of the leads facilitate the description.

2.2.1.3 The Island

This is the part of the system which is small in all directions (although in a nanotube, the transverse dimensions are much smaller than the longitudinal); hence, this is the part where the Coulomb interaction plays an important role. To understand the device, it is useful to take as a reference the isolated island. In that case we have a set of quantum states with discrete energies (levels). The density of states of the device consists of a series of delta-functions corresponding to the bound state energies.

Now imagine there is a knob by which we can tune the coupling to the leads. This is given in terms of the rate $\Gamma/\hbar$ at which electrons cross the tunnel barriers separating the island from the leads. The transport through the barriers is a tunneling process which is fast and, in most cases, it can be considered as elastic: the energy is conserved in the tunneling process. Generally speaking, when the island is coupled to the leads (or directly to the reservoirs), the level broadens as a result of the continuous density of states in the leads (or reservoirs), and it may shift due to charge transfer from the leads to the island. Two limits can be considered. For weak coupling, $\Gamma \ll E_C$, Δ, the density of states should be close to that of the isolated device: it consists of a series of peaks, the width of which is proportional to Γ. Sometimes, we wish to distinguish between the coupling to the source and drain lead, and use Γ_S and Γ_D, respectively. For strong coupling, that is, $\Gamma \gg E_C$, Δ, the density of states is strongly influenced by that of the leads, and the structure of the spectrum of the island device is much more difficult to recognize in the density of states of the coupled island.

If we keep the number of electrons within the island fixed, we still have the freedom of distributing the electrons over the energy spectrum. The only constraint is the fact that not more than one electron can occupy a quantum state as a consequence of Pauli's principle. The change in total energy of the device is then mainly determined by the level splitting which is characterized by the energy scale, Δ. If we wish to *add* or *remove* an electron to or from the device, we must pay or we gain in addition a charging energy respectively.

It should be noted that, in principle, Γ may depend on the particular charge state on the island. This is expected to be the case in molecules: the charge distribution usually strongly differs for the different orbitals and this will certainly influence the degree in which that orbital couples to the lead states.

At this stage, an important point should be emphasized. From statistical mechanics, it is known that a particle current is driven by a chemical potential difference. Therefore, the chemical potential of the island is the relevant quantity driving the current to and from the leads. However, in an independent particle picture, a single particle energy is identical to the chemical potential (which is defined as the difference in *total* energy between a system with $N+1$ and N particles). Therefore, if we speak of a single-particle energy of the island, this should often be read as "chemical potential".

2.2.2 Transport

For an extensive discussion of the issues discussed in this paragraph, the reader is referred to the monograph by Datta [2].

As seen above, in the device we can often distinguish discrete states as (Lorentzian) peaks with finite width in the density of states. A convenient representation of transport is then given in Figure 2.3, which shows that the effect of the gate is to shift the levels of the device up and down, while leaving the chemical potentials μ_S and μ_D of the leads unchanged (for small devices, the gate field is inhomogeneous due to the

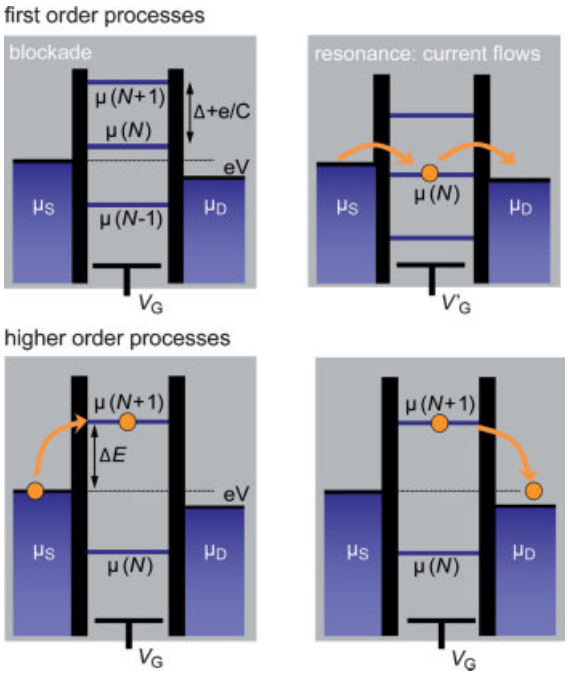

Figure 2.3 Schematic representation of the electrochemical potentials of an island connected to two reservoirs, across which a small (negative) bias voltage V is applied. A voltage on the gate electrode can be used to shift the electrostatic potential of the energy level. Top: Resonant transport becomes possible when the gate voltage pushes one of the levels within the bias window eV. The $\mu(N)$ level is aligned with μ_S and the number of electrons on the dot alternates between N and $N-1$ (sequential tunneling). Bottom: The levels are not aligned. The Coulomb blockade fixes the number of electrons on the dot to N. Transport, however, is possible through a virtual co-tunnel process in which an unoccupied level is briefly occupied. A similar process exists for the occupied level, $\mu(N)$, which may be briefly unoccupied. In contrast to resonant transport, the level is empty (full) most of the time. For all panels it should be noted that, in reality, the levels are not sharp lines but rather have a finite width, Γ. Similarly, the edge between the occupied (blue) and unoccupied states is blurred by temperature via the Fermi–Dirac function.

effect of the leads; moreover, the electrostatic potential in the surface region of the leads will be slightly affected by the gate voltage).

The transport through the device can take place in many different ways. A few classifications will now be provided which may help in understanding the transport characteristics of a particular transport process.

2.2.2.1 Coherent-Incoherent Transport

First, the transport may be either *coherent* or *incoherent*, a notion which pertains to an independent particle description of the electrons where the electrons occupy one-particle orbitals. In the case of coherent transport, the phase of the orbitals evolves deterministically. In the case of incoherent processes, the phase changes in an unpredictable manner due to interactions which are not contained in the indepen-

dent particle Hamiltonian. Such interactions can be either electron–electron or electron–phonon interactions, or between the electrons and an electromagnetic field.

If the electrons spend a long time on the island – which occurs when the couplings to the leads are weak – then the decoherence will be complete. Only for short traversal times the phase will be well preserved.

2.2.2.2 Elastic–Inelastic Transport

Another distinction is that between elastic and inelastic transport. In the latter case, interactions may cause energy loss or gain of the electrons flowing through the device. This energy change may be caused by the same interactions as those causing decoherence (electron–electron, electron–phonon, electron–photon). It should be noted, however, that decoherent transport can still be elastic.

2.2.2.3 Resonant–Off-Resonant Transport

This classification is relevant for elastic tunneling in combination with weak coupling to the leads. In resonant transport, electrons are injected at an energy corresponding to a resonance of the island. Such a resonance corresponds to a discrete energy level of the isolated device. The transport resonance energy corresponds to the center of the shifted peak; this is seen as a peak in the transport current for that energy or, more specifically, an increase of the current as soon as a resonance enters the bias window. The fact that the coupling to the leads is weak causes the time that an electron resides in the device to be rather long. If this time is longer than the time taken for the electron orbital to lose its coherence, we speak of *sequential tunneling*, as the transport process may then be viewed as electrons hopping from the lead to the island where they stay a while before hopping off to the drain. In off-resonant transport, the electrons are injected at energies (far) off the resonance.

2.2.2.4 First-Order versus Higher-Order Processes

The standard technique for calculating the current arising from coherent processes is time-dependent perturbation theory. In this theory, the transition from one particular state to another is calculated in terms of transitions between the initial, intermediate and final states. The first-order process (Figure 2.3, top) corresponds to a direct transition from the initial to the final state and, for this process, the current is proportional to the couplings Γ between device and leads. In off-resonant first-order processes, the current decays rapidly with the energy difference between the closest discrete level on the island and the Fermi energies of the leads (ΔE in Figure 2.3).

Second-order transport processes, often called *co-tunneling*, take place via an intermediate state, as illustrated in the lower panel of Figure 2.3. In these processes, the current is proportional to higher powers of the couplings, but they are less strongly suppressed with increasing distance (in energy) between the states in the leads and on the island. Therefore, they may sometimes compete with – or even supersede – first-order processes, provided that the intermediate state is sufficiently far in energy (chemical potential) from those in the leads. Currents due to second-order processes vary quadratically with the coupling strengths.

Molecules can often be viewed as chains of weakly coupled sites. If the Fermi energy of the source lead (i.e., the injection energy) is at some distance below the on-site energies of the molecule, the dominant transport mechanism is through higher order processes, which in electron transfer theory are known as *superexchange* processes. This term also includes hole transport through levels below the Fermi energy of the leads.

2.2.2.5 **Direct Tunneling**

It should be noted that if the device is very small (e.g., a molecule), there is a possibility of having direct tunneling from the source to the drain, in which the resonant states of the device are not used for the transport.

2.3 Resonant Transport

We start this section by studying resonant transport qualitatively [2]. Suppose we have one or more sharp resonant levels which can be used in the transport process from source to drain. We neglect inelastic processes inside the device during tunneling from the leads to the device, or vice versa. In order to send an electron into the device at the resonant energy, we need occupied states in the source lead. This means that the density of states in that lead must be non-zero for the resonant energy (otherwise there is no lead state at that energy), and that the Fermi–Dirac distribution must allow for that energy level to be occupied. Furthermore, for the electron to end up in the drain, the states in the drain at the resonant energy should be empty according to Pauli's principle. We conclude that for the transport to be possible, the resonance should be *inside the bias-window*. This window is defined as the range of energies between the Fermi energies of the source and the drain.

The process is depicted in Figure 2.3 (top), and from this picture we can infer the behavior of the current as a function of the bias voltage. It can be seen that no current is possible (left panel) for a small bias voltage as a result of a finite difference in energy ΔE between the energy of the resonant state on the island and the nearest of the two chemical potentials of the leads. The current sets off as soon as the bias window encloses the resonance energy (right panel). Any further increase of the bias voltage does not change the current, until another resonance is included. The mechanism described here gives rise to current–voltage characteristics shown in Figure 2.4.

At this point, two remarks are in order. First, the image sketched here supposes weak coupling and a low temperature. Increasing the temperature blurs the sharp edge in the spectrum between the occupied and empty states, and this will cause the sharp steps seen in the I/V curve to become rounded. Second, the differential conductance, dI/dV as a function of the bias voltage V shows a peak at the positions where the current steps up.

In the previous section it was noted that the coupling $\Gamma = \Gamma_S + \Gamma_D$ between leads and device can be given in terms of the rate at which electrons hop from the lead onto the device. From this, an heuristic argument leads via the time–energy uncertainty

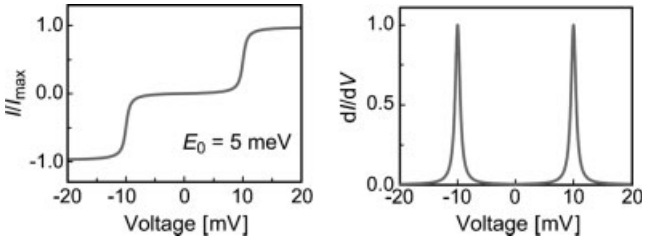

Figure 2.4 Left: Current–voltage characteristic calculated with Equation 2.6 for a level that is located 5 meV from the nearest Fermi energy of one of the electrodes. A symmetric coupling to the leads is assumed with a total broadening of 0.5 meV. Right: Corresponding differential conductance with a peak height equal to the conductance quantum. Note that the peak width is of the order of the total broadening.

relation to the conclusion that Γ gives us the extent to which an energy level[1)] E_0 on the island is broadened. Simple models for leads and device yield a Lorentzian density of states on the device [2]:

$$D(E) = \frac{1}{2\pi}\frac{\Gamma}{(E-E_0)^2 + (\Gamma/2)^2}.$$

Further analysis, which is based on a balance between ingoing and outgoing electrons [2] gives the following expression for the current:

$$I(E) = -\int \frac{e}{\hbar} D(E) \frac{\Gamma_S \Gamma_D}{\Gamma_S + \Gamma_D} \left[f_{FD}(E-\mu_S) - f_{FD}(E-\mu_D) \right] dE. \tag{2.4}$$

It must be remembered that the bias voltage (the potential difference between source and drain) is related to the chemical potentials μ_D and μ_S as

$$-eV = \mu_S - \mu_D;$$

where $e > 0$ is unit charge. A positive bias voltage drives the electrons from right to left, such that the current is then from left to right; this is defined as the positive direction of the current.

If the density of states has a single sharp peak, then current is only possible when this peak lies inside the bias window. Indeed, replacing $D(E)$ by a delta-function centered at E_0 directly gives

$$I = \frac{-e}{\hbar}\frac{\Gamma_S \Gamma_D}{\Gamma_S + \Gamma_D}\left[f_{FD}(E_0-\mu_S) - f_{FD}(E_0-\mu_D) \right].$$

At low temperature, the factor in square brackets is 1 when E_0 lies inside the bias window and 0 otherwise. It can be seen that the maximum value of the current is found as

1) Note that the energy should be identified with the chemical potential of the island; see the comment in the previous section.

$$|I_{\max}| = \frac{e}{\hbar}\frac{\Gamma_S\Gamma_D}{\Gamma_S+\Gamma_D}. \tag{2.5}$$

For low temperature, the Fermi functions in Equation 2.4 become sharp steps, and the integral of the Lorentzian can be carried out analytically, yielding

$$I = \frac{e}{\pi\hbar}\frac{\Gamma_S\Gamma_D}{\Gamma_S+\Gamma_D}\left[\arctan\left(2\frac{\mu_S-E_0}{\Gamma}\right)-\arctan\left(2\frac{\mu_D-E_0}{\Gamma}\right)\right]. \tag{2.6}$$

Equation 2.4 is valid in the limit where we can describe the transport in terms of the independent particle model. It has the form of the Landauer formula:

$$I = \frac{e}{\hbar}\int T(E)[f_{FD}(E-\mu_D)-f_{FD}(E-\mu_S)]dE,$$

which is discussed extensively in Chapter 1 of this volume. In that chapter it is shown that the transmission per channel (which corresponds to the eigenvalues of the matrix $T(E)$) has a maximum value of 1, so that the current assumes for low temperatures a maximum value of

$$I_{\max} = \frac{e^2}{\hbar}nV, \tag{2.7}$$

where n is the number of channels inside the bias window. It should be noted that this maximum occurs only for *reflectionless* contacts, for which a wave incident from the leads onto the device, is completely transmitted. This usually occurs when the device and the leads are made from the same material. The strong-coupling result in Equation 2.7 has been given in order to emphasize that the two Equations 2.5 and 2.7 hold in quite opposite regimes.

Often, in experiments the differential conductance dI/dV is measured, and this can be calculated from the expression in Equation 2.4:

$$\frac{dI}{dV} = -\frac{e^2}{\hbar}\frac{\Gamma_S\Gamma_D}{\Gamma_S+\Gamma_D} \int dE D(E)\{\eta f'_{FD}(E-\bar{\mu}+\eta eV)-(1-\eta)f'_{FD}[E-\bar{\mu}-(1-\eta)eV]\}, \tag{2.8}$$

where f'_{FD} denotes the first derivative of the Fermi–Dirac distribution with respect to its argument, and $\bar{\mu} = (\mu_S+\mu_D)/2$. The parameter η specifies how the bias voltage is distributed over the source and drain contact; for $\eta = 1/2$, this distribution is symmetric. For $T = 0$, the Fermi–Dirac distribution function reduces to a step function, and its derivative is then a delta-function. For low bias ($V \approx 0$), the integral picks up a contribution from both delta functions occurring in the integral in Equation 2.8. The result is

$$\frac{dI}{dV} = 4\frac{e^2}{\hbar}\frac{\Gamma_S\Gamma_D}{\Gamma_S+\Gamma_D}D(\mu),$$

where the energy E in Equation 2.8 is taken at the Fermi energy of either the source or the drain. As the maximum value of $D(E)$ is given as

$$D(E)_{\max} = \frac{2}{\pi}\frac{1}{\Gamma_S+\Gamma_D},$$

it follows that the maximum of the differential conductance occurs when $\Gamma_S = \Gamma_D$ and is then given by e^2/h. Note that this holds even when the current is much smaller than the quantum conductance limit [see Equation 2.7] which follows from the Landauer formula.

At *finite* temperature, for $k_BT \gg \Gamma$ and zero bias, working out the derivative with respect to bias of Equation 2.8 gives:

$$\frac{dI}{dV} = \frac{e^2\Gamma_S\Gamma_D}{4k_BT(\Gamma_S+\Gamma_D)}\left[\cosh\frac{e\alpha(V_G - V_0)}{2k_BT}\right]^{-2}. \tag{2.9}$$

This line shape (see Figure 2.5) is characterized by a maximum value $e^2\Gamma_S\Gamma_D/4k_BT(\Gamma_S+\Gamma_D)$, attained when the gate voltage reaches the resonance $V_0 = E_0/e$. The full-width half maximum (FWHM) of this peak is $3.525k_BT/e\alpha$. The parameter α is the gate coupling parameter: the potential on the island varies linearly with the gate voltage, $\Delta V_I = \alpha\Delta V_G$. These features are often used as a signature for true quantum resonant behavior as opposed to classical dots, where the small value of Δ renders the spectrum of levels accessible to an electron continuous. For a classical dot, the peak height is independent of temperature and the FWHM is predicted to increase by a factor 1.25 [3,4]. It should be noted that, in a quantum dot, Γ sets a lower bound for the temperature dependence of the peak shape: for $\Gamma > k_BT$ the peak height and shape are independent of temperature (not visible in Figure 2.5 due to the small value for Γ chosen there).

Interestingly, the finite width of the density of states, which is given by $\Gamma_S + \Gamma_D$, can in principle be measured experimentally from the resonance line widths at low temperature. It should be noted that the expressions for the current and differential conductance depend only on the combinations $\Gamma_S + \Gamma_D$ and $\Gamma_S\Gamma_D/(\Gamma_S + \Gamma_D)$. If both are extracted from experimental data, the values of Γ_S and Γ_D can be determined (although the symmetry between exchange of source and drain prevents us from identifying which value belongs to the source).

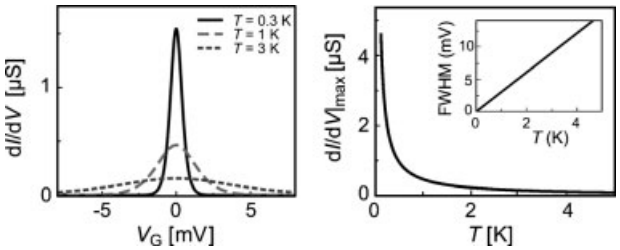

Figure 2.5 Left: Temperature-dependence of the Coulomb peak height [Equation 2.9] in the resonant transport model, showing the characteristic increase as the temperature is lowered. Right: Peak height as a function of temperature. The inset shows the full-width half maximum (FWHM) of the Coulomb peak as a function of temperature (see text). Calculations are performed with $\Gamma = 10^9\,s^{-1}$ and a gate coupling of 0.1 in the regime $\Gamma < k_BT$.

2.4
Constant Interaction Model

In Section 2.1.1 it was seen that in the weak-coupling regime, energy levels can be discrete for two reasons: quantum confinement (the fact that the state must "fit" into a small island), and charge quantization effects. The scale for the second type of splitting is the charging or Coulomb energy, E_C. It is important to realize that this energy will only be noticeable when the coupling to the leads is small in comparison with E_C; this situation is referred to as the *Coulomb blockade* regime. In this situation, a clear distinction should be made a between one or two electrons occupying a level, as their Coulomb interaction contributes significantly to the total energy. The transport process may be analyzed using the so-called *constant interaction model* [3], which is based on the set-up shown in Figure 2.6. Elementary electrostatics provides the following relation between the different potentials and the charge Q on the island:

$$CV_I - C_S V_S - C_D V_D - C_G V_G = Q,$$

where $C = C_S + C_D + C_G$. Note that this equation can be written in the form:

$$V_I = V_{ext} + \frac{Q}{C},$$

with

$$V_{ext} = (C_S V_S + C_D V_D + C_G V_G)/C.$$

It is seen that the potential on the dot is determined by the charge residing on it and by the induced potential V_{ext} of the source, drain and gate.

We take as a reference configuration the one for which all voltages and the charge are zero. For total energies, U rather than E is used in order to avoid confusion with the single-particle energies E_n resulting from solving the single-particle Schrödinger equation. The electrostatic energy $U_{ES}(N)$ with respect to this reference configuration after changing the source, drain and gate potentials and putting N electrons (of charge $-e$) on the island is then identified as the work needed to place this extra charge on the island, and the energy cost involved in changing the external potential when a charge Q is present:

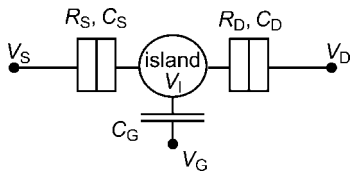

Figure 2.6 The capacitance model. A schematic drawing of an island connected to source and drain electrodes with tunnel junctions; the gate electrode shifts the electrostatic potential of the island.

$$U_{ES}(N) = \int_{Q=0,V_{ext}=0}^{-Ne,V_{ext}} (V_I dQ + Q dV_{ext}) = \frac{(Ne)^2}{2C} - NeV_{ext}.$$

The integral is over a path in Q, V_{ext} space; it is independent of the path – that is, of how the charge and external potential are changed in time.

The result for the total energy, including the "quantum energy" due to the orbital energies is

$$U(N) = \frac{(Ne)^2}{2C} - NeV_{ext} + \sum_{n=1}^{N} E_n.$$

The energy levels E_n correspond to states which can be occupied by the electrons in the device, provided that their total number does not change, as changing this number would change the Coulomb energy, which is accounted for by the first term. This expression for the total energy is essentially the constant interaction model.

From non-equilibrium thermodynamics, it is known that a current is driven by a chemical potential difference; hence, we should compare the chemical potential on the device,

$$\mu(N) = U(N) - U(N-1) = (N - 1/2)\frac{e^2}{C} - eV_{ext} + E_N, \tag{2.10}$$

with that of the source and drain in order to see whether a current is flowing through the device. From the definition of V_{ext} we see that the effective change in the chemical potential due to a change of the gate voltage (while keeping source and drain voltage constant), carries a factor C_G/C; this is precisely the gate coupling, which is called the α factor (this was referred to at the end of Section 2.3).

It is important to be aware of the conditions for which the constant interaction model provides a reliable description of the device. The first condition is weak coupling to the leads; the second condition is that the size of the device should be sufficiently large to make a description with single values for the capacitances possible. Finally, the single-particle levels E_n must be independent of the charge N. The constant-interaction model works well for weakly coupled quantum dots, for which it is very often used. However, for molecular devices the presence of a source and drain both of which are large chunks of conducting material separated by very narrow gaps, reduces the gate field to be barely noticeable close to the leads and far from the gate. This inhomogeneity of the gate field may lead to a dependence of the gate capacitance C_G with N due to the difference in structure of subsequent molecular orbitals, and the chemical potential on the molecule will vary non-linearly with the gate potential.

As will be seen below, the distance between the different chemical potential levels can be inferred from three-terminal measurements of the (differential) conductance. From Equation 2.10, this distance is given by

$$\mu(N+1) - \mu(N) = \frac{e^2}{C} + E_{N+1} - E_N.$$

It should be noted that the difference in energy levels occurring in this expression ($E_{N+1} - \mathrm{E}_N$) is nothing but the splitting Δ mentioned at the very start of this chapter. However, for typical metallic and semiconductor quantum dots, this splitting is usually significantly smaller than the charging energy, so that this quantity determines the distance between the energy levels:

$$\mu(N+1) - \mu(N) = \frac{e^2}{C}.$$

Note that this *addition energy* is twice the energy of a charge on the dot (as the addition energy is the second derivative of the energy with respect to the charge).

Now, the current can be studied as a function of bias and gate voltage. In Section 2.2.2 it was seen that, in the weak coupling regime and at low temperature, the current is suppressed when all chemical potential levels lie outside of the bias window. As the location of these levels can be tuned by using the gate voltage, it is interesting to study the current and differential conductance of the device as a function of the bias *and* of the gate voltage.

We can calculate the line in the V, V_G plane which separates a region of suppressed current from a region with finite current; this line is determined by the condition that the chemical potential of the source (or drain) is aligned with that of a level on the island. Again, it is assumed that the drain is grounded (as in Figure 2.2). From the expression in Equation 2.10 for the chemical potential, and using the definition for V_{ext}, we find the following condition for the chemical potential to be aligned to the source (keeping the dot's charge constant):

$$V = \beta(V_G - V_C),$$

where $\beta = C_G/(C_G + C_D)$ and $V_C = (N - 1/2)\frac{e}{C_G} + \frac{C}{C_G}\frac{E_N}{e}$; that is, the voltage corresponding to the chemical potential on the dot in the absence of an external potential. If the chemical potential is aligned with the drain, we have

$$V = \gamma(V_C - V_G)$$

with $\gamma = C_G/C_S$. The expressions given here are specific for a grounded drain electrode. It is easily verified that, irrespective of the grounding, it holds that

$$\frac{C}{C_G} = \frac{1}{\alpha} = \frac{1}{\beta} + \frac{1}{\gamma}.$$

Each resonance generates two straight lines separating regions of suppressed current from those with finite current. For a sequence of resonances, the arrangement shown in Figure 2.7a is obtained. The diamond-shaped regions are traditionally called "Coulomb diamonds", as they were very often studied in the context of metallic dots, where the chemical potential difference of the levels is mainly made up of the Coulomb energy. The name is also used in molecular transport, although this is – strictly speaking – not justified there as Δ may be of the same order as the Coulomb interaction.

From the Coulomb diamond picture we can infer the values of some important quantities. First, we consider two successive states on the molecule with chemical potentials $\Delta\mu_{(N)}$ and $\Delta\mu_{(N+1)}$. If we suppose that both states have the

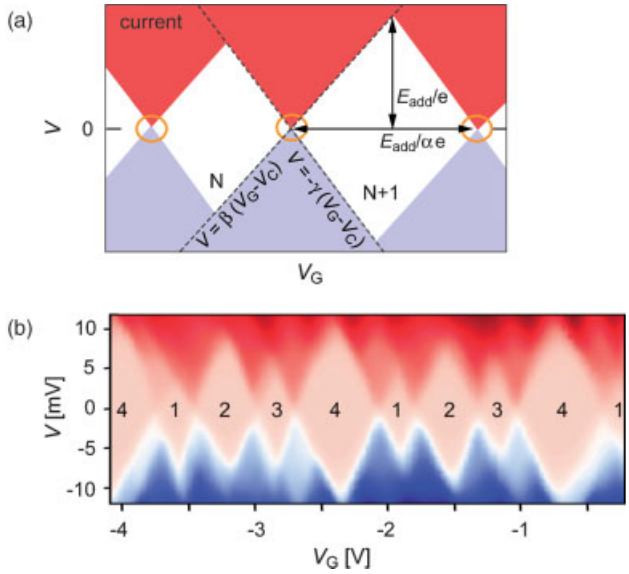

Figure 2.7 Linear transport. (a) Two-dimensional plot of the current as a function of bias and gate voltage (stability diagram). For a small bias, current flows only in the three points corresponding to the situation shown in Figure 2.3 (top right). These points are known as the "degeneracy points". Red = positive currents; blue = negative currents; white = blockade, no current. (b) Measured stability diagram of a metallic, single-walled carbon nanotube, showing the expected fourfold shell filling. The blockade regime is shown in pink. (Data from Ref. [5].).

same gate-coupling parameter α, it can be seen that the upper and lower vertices of the diamond are both at a distance

$$\Delta V = \frac{|\mu(N) - \mu(N+1)|}{e} = \frac{E_{add}}{e}$$

from the zero-bias line. This difference in chemical potentials is the electron addition energy, E_{add}. If the addition energy is dominated by the charging energy, then the total capacitance can be determined. Combining this with the slopes of the sides of the diamond, which provide the relative values of C_G, C_S and C_D, all of these capacitances we can be determined explicitly.

One interesting consequence of the previous analysis is that, if the capacitances do not depend on the particular state being examined, then the height of successive Coulomb diamonds is constant. If, in addition to the Coulomb energy, a level splitting is present, this homogeneity will be destroyed, as can be seen in Figure 2.7b, which shows the diamonds for a carbon nanotube (CNT) [5]. The alternation of a large diamond with three smaller ones can be nicely explained with a model Hamiltonian [6]. In the case of transport through molecules there is no obvious underlying structure in the diamonds.

The electron addition energy is sometimes connected to the so-called HOMO–LUMO gap. [These acronyms represent the Highest Occupied (Lowest Unoccupied)

Molecular Orbital, and denote orbitals within an independent particle scheme.] If the Coulomb interaction is significant, the HOMO–LUMO gap can be related to the excitation energy for an optical absorption process in which an electron is promoted from the ground state to the first excited state, without leaving the system. In that case, the change in Coulomb energy is modest, and the energy difference is mostly made up of the quantum splitting Δ. It should be noted, however, that the HOMO and LUMO are usually calculated using a computational scheme whereby the orbitals are calculated for the ground-state configuration – that is, without explicitly taking into account the fact that all orbitals change when, for example, an electron is excited to a higher level.

The addition energies are partly determined by quantum confinement effects and partly by Coulomb effects. A difficulty here is that these energies will be different for a molecular junction, in which a molecule is either physisorbed or chemisorbed to conducting leads, than for a molecule in the gas phase. There are several effects responsible for this difference. First, if there is a chemical bond present, then the electronic orbitals extend over a larger space, which reduces the confinement splitting. Second, a chemical bond may cause a charge transfer from lead to molecule, which in turn causes the potential on the molecule to change. Third, the charge distribution on the molecule will polarize the surface charge on the leads, which can be represented as an *image charge*. Such charges have the effect of reducing the Coulomb part of the addition energy. In experiments with molecular junctions, much smaller addition energies are often observed than in gas-phase molecules. At the time of writing, there is no quantitative understanding of the addition energy in molecular three-terminal junctions, although the effects mentioned here are commonly held responsible for the observed gaps.

2.5
Charge Transport Measurements as a Spectroscopic Tool

A stability diagram can be used not only for finding addition energies, but also to form a spectroscopic tool for revealing subtle excitations that arise on top of the ground state configurations of an island with a particular number of electrons on it. These excitations appear as lines running parallel to the Coulomb diamond edges. An example taken from Ref. [7] is shown in Figure 2.8a, where the white arrows indicate the excitation lines. At such a line, a new state (electronic or vibrational) enters the bias window, thus creating an additional transport channel. The result is a stepwise increase in the current, and a corresponding peak in the differential conductance. The energy of an excitation can be determined by reading off the bias voltage of the intersection point between the excitation line and the Coulomb diamond edge through the same argument used for finding addition energies. The excitations correspond to the charge state of the Coulomb diamond at which they ultimately end (see Figure 2.8c). The width of the lines in the dI/dV plot (or, equivalently, the voltage range over which the stepwise increase in current occurs) is determined by the larger of the energies k_BT and Γ. In practice, this means that sharp lines – and thus accurate information on spectroscopic features – are obtained at low temperatures and

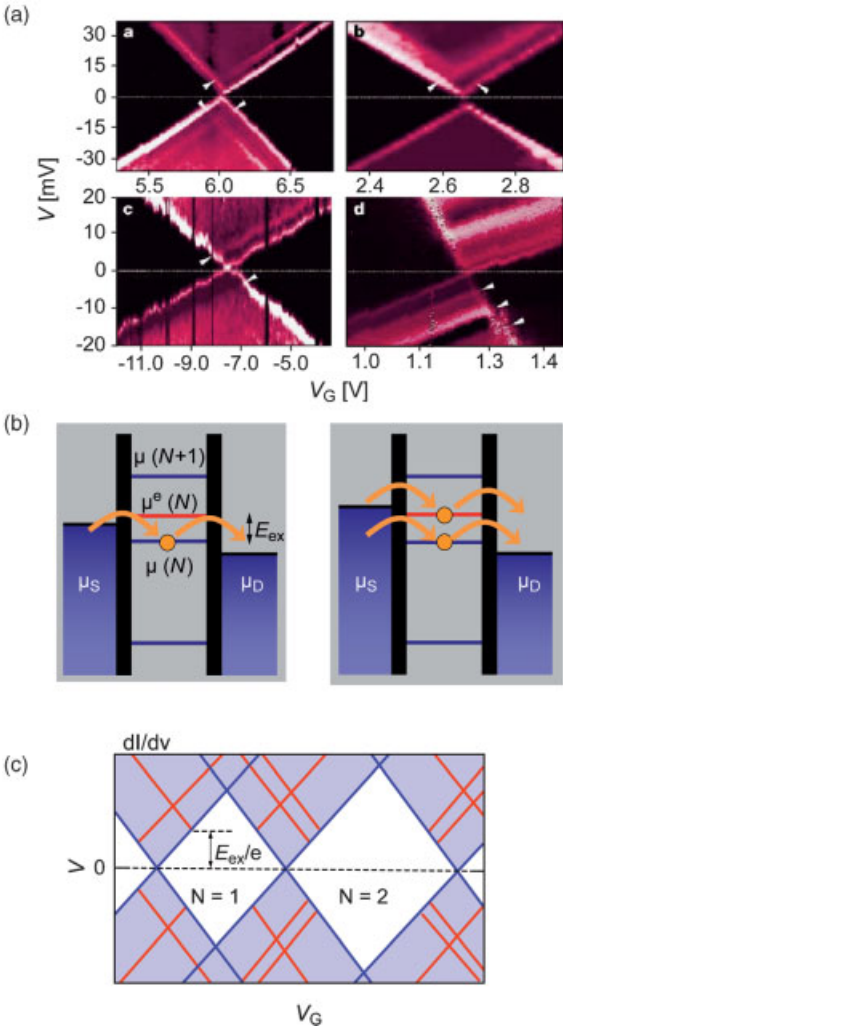

Figure 2.8 Non-linear transport and excited states. (a) Four different conductance maps (stability diagrams) of C_{60} molecules trapped between two electrodes [7]. Excitations lines are indicated by arrowheads. These run parallel to the diamond edges, and are due to vibrational modes of the C_{60} molecule. (b) Electrochemical potential plot of a dot with three electronic energy levels and one excited state (red). Transport through an excited level becomes possible as soon as the red level enters the bias window. (c) Schematic representation of a differential conductance map. The red lines show the positions at which excited states enter the bias window. The associated stepwise increases in current appear as lines running parallel to the edges of the diamond-shaped regions. Blue: dI/dV is zero but the current is not (sequential-tunneling regime). White: current blockade.

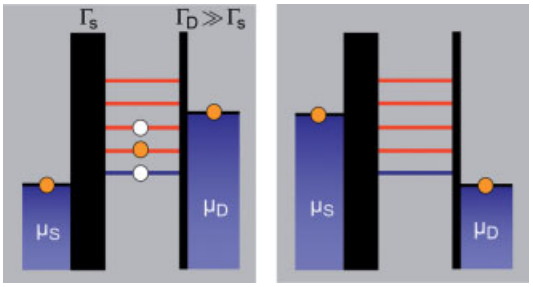

Figure 2.9 Asymmetric coupling to the electrodes leads to an almost full occupancy if tunneling out of the level is limited by the thick barrier (left: low tunnel rate) and almost zero occupancy of the level if tunneling out is determined by the thin barrier (right: high tunnel rate). Note, that of the three levels in the bias window, only one of them can be occupied at the same time. An increase of the bias voltage such that another excited level enters the bias window yields a very small current increase in the case (as depicted on the left-hand side) because the thick barrier remains the limiting factor for the current. In contrast, on the right-hand side a new transport channel becomes available and the current shows a clear stepwise increase.

for weak coupling to the leads. However, it should be noted that the current is proportional to Γ [Equations 2.4 and 2.5], so that Γ should not be too small; in fact, a Γ-value in the order of 0.1–1 meV seems typical in experiments that allow for spectroscopy.

An important experimental issue here is that, for a particular charge state, the lines are often visible on only one side of the Coulomb diamond (see Figure 2.8a, lower right panel). This is due to an asymmetry in the coupling – that is, for $\Gamma_D \gg \Gamma_S$ (or $\Gamma_S \gg \Gamma_D$). The situation at the two "main" diamond edges is illustrated in Figure 2.9. A thick and a thin barrier between the island and the source/drain represent these anti-symmetric couplings. It is clear that if the chemical potential in the lead connected through the thin barrier is the higher one, then the island will have one of its transport channels filled. The limiting step for transport is the thick barrier, and only the occupied orbital will contribute to the current. When an extra transport orbital becomes available, this will have only a minor effect on the total current, but if the chemical potential of the lead beyond the thick barrier is high, then the transport levels on the island will all be empty. The lead electrons which must tunnel through the thick barrier have as many possible channels at their disposal as there are possible empty states: the more orbitals, the more channels there are, and therefore a stepwise increase occurs each time a new excitation becomes available.

2.5.1
Electronic Excitations

In order to study how detailed information on the electronic structure of the island can be obtained from conduction measurements, we consider a system consisting of levels that are separated in energy by the Δ_i (see Figure 2.10). It should be noted that this level splitting does not include a charging energy: the levels can be occupied in charge-neutral excitations. For one extra electron on the island, $N = 1$, the ground

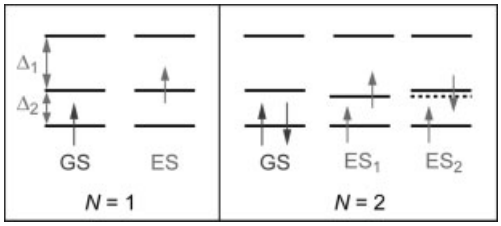

Figure 2.10 Schematic drawing of the ground state (GS) filling and the excited states (ES). Left: The island contains one electron and the first excited state involves a transition to the nearest unoccupied level. (In a zero magnetic field there is an equal probability to find a down spin on the dot.) Right: Two electrons with opposite spin occupy the lowest level. The first excited state involves the promotion of one of the spins to the nearest unoccupied level. A ferromagnetic interaction favors a spin flip. The antiparallel configuration (ES_2) has a higher energy (see text).

state is the one in which it occupies the lowest level. As discussed above, as soon as this level is inside the bias window, the current begins to flow, thereby defining the edges of the Coulomb diamonds. When the bias increases further, transport through the excited level becomes possible. This leads to a step-wise increase of the current as there are now two states available for resonant transport, and this increases the probability for electrons to pass through the island. It should be noted that both levels cannot be occupied at the same time, as this requires a charging energy in addition to the level splitting. The resulting peak in the dI/dV forms a line (red) inside the conducting region (blue), ending up at the "$N=1$" diamond (white), as shown in Figure 2.8c. ($E_{ex}=\Delta_1$ in this case). A second excitation is found at $\Delta_1+\Delta_2$; subsequent excitations intersect the diamond edge at bias voltages $\sum_i \Delta_i$, but they are only visible if $\sum_i \Delta_i < e^2/C$.

Now, we consider the case where two electrons are added to the neutral island ($N=2$). When two electrons occupy the lower orbital, the Fermi principle requires their spin to be opposite. The first excited state is the one in which one of the electrons is transferred to the higher orbital, which costs an energy of Δ_1. A ferromagnetic exchange coupling favors a triplet state with a parallel alignment. If we take only exchange interactions between different orbitals into account, this results in an energy gain of J with respect to the situation with opposite spins. Thus, the first excitation is expected to be at $\Delta_1 - J$, and the second one (corresponding to opposite spins) at Δ_1. The energy difference between the two excitations in Figure 2.8c provides a direct measure of J. In some systems, J may be negative (antiferromagnetic case) and the antiparallel configuration has a lower energy.

The simple analysis presented here captures some of the basic features of few-electron semiconducting quantum dots [8] in which the charge states to which the levels belong, can be identified. The complete electron spectrum has also been determined in metallic CNT quantum dots [5,9]. Although, for a nanotube, many densely spaced excitations occur, level spectroscopy is possible as the regularly spaced levels are well separated from each other with $E_C \approx \Delta$. Careful inspection of the excitation and addition spectra of CNTs shows that the exchange coupling J is ferromagnetic and that it is small, of the order of a few meV, or less. Further

identification of the states can be performed in a magnetic field, using the Zeeman effect as a diagnostic tool. Douplet states are expected to split into two levels, and triplet states into three.

One final remark concerns the $N = 0$ diamond. In systems such as semiconducting quantum dots, where there is a gap separating the ground state from the first excited state, Δ_1 may be of the order of hundreds of meV, and in that case no electronic excitations are expected to end up in this diamond.

2.5.2 Including Vibrational States

An interesting phenomenon in molecular transport occurs when the molecular vibrations couple to the electrons, giving rise to excitations available for transport (as mentioned above). This phenomenon has been studied quite extensively in recent years, and the basics will briefly be discussed at this point (for further details, see Refs. [10,11]).

Molecules are rather "floppy" in nature, and from classical mechanics it is known that small deformations of a molecule with respect to its lowest energy conformation can be described in terms of *normal modes*. These are excitations in which all nuclei oscillate with the *same* frequency ω (although some nuclei may stand still). In particular, these excitations have the form

$$R_{i,\alpha}^{(l)}(t) = X_{i,\alpha}^{(l)} \exp(i\omega^{(l)} t),$$

where $R_{i\alpha}^{(l)}$ is the Cartesian coordinate $\alpha = x, y, z$ of nucleus i; l labels the normal mode; $X_{i,\alpha}^{(l)}$ is a fixed vector which determines the amplitudes of the oscillation for the degree of freedom labeled by i,α. The vibrations are described by a harmonic oscillator, which has a spectrum with energy levels separated by an amount $\hbar\omega^{(l)}$:

$$E_v^{(l)} = \hbar\omega^{(l)}(v + 1/2), \quad v = 0, 1, 2, \ldots.$$

For molecular systems, the normal modes are often referred to as *vibrons* (in analogy with phonons in a periodic solid). These modes couple with the electrons as the electrons feel a change in the electrostatic potential when the nuclei move in a normal mode. The coupling is determined by the electron–vibron coupling constant, called λ.

The presence of vibrational excitations can be detected in transport measurements. However, it should be noted that for this to happen, the vibrational modes must be excited, which can occur for two reasons: (i) the thermal fluctuations excite these modes; or (ii) they can be excited through the electron–vibron coupling.

In order to study the effect of electron–vibron coupling on transport, for simplicity the discussion is restricted to a single vibrational mode and a single electronic level. The nuclear part of the Hamiltonian is

$$H = \frac{P^2}{2M} + \frac{1}{2} M\omega^2 X^2$$

where P, X and M represent the momentum, position and mass of the oscillator.

It twins out [11] that the electron-vibron coupling has the form:

$$H_{e-v} = \lambda\hbar\omega\hat{n}X/u_0,$$

where $\hat{n}$ is the number operator, which takes on the values 0 or 1 depending on whether there is an electron in the orbital under consideration; $u_0 = \sqrt{\hbar/(2M\omega)}$ is the zero-point fluctuation associated with the ground state of the harmonic oscillator. The electron–vibron coupling λ is given as (φ is the electronic orbital):

$$\lambda = \frac{1}{\hbar\omega}\sqrt{\frac{\hbar}{2\omega}}\frac{1}{\sqrt{M}}\left\langle \varphi \left| \frac{\partial H_{el}}{\partial X} \right| \varphi \right\rangle.$$

When the charge in the state φ increases from 0 to 1, the equilibrium position of the harmonic oscillator (i.e., the minimum of the potential energy) is shifted over a distance $-2\lambda u_0$ along X, and it is also shifted down in energy (see Figure 2.11a). Fermi's "golden rule" states that the transition rate for going from the neutral island in the conformational ground state to a charged island in some

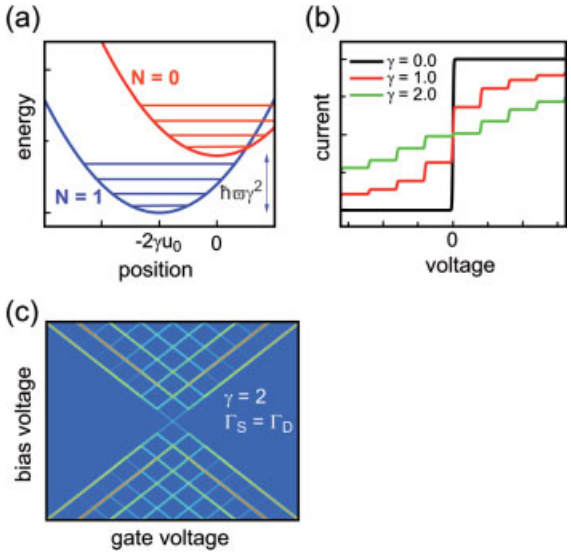

Figure 2.11 (a) Potential of the harmonic oscillator for the empty (red) and occupied state (blue). When an electron tunnels onto the island, the position of the potential minimum is shifted in space and energy. (b) Current–voltage characteristics calculated for three different values of the electron–phonon coupling constant. For non-zero coupling steps appear, which are equally spaced in the voltage (harmonic spectrum). (c) Differential conductance plotted in a stability diagram for an island coupled to a single vibrational mode. Lines running parallel to the diamond edges correspond to the steps, forming a lozenge pattern of excitation lines in (b). Around zero bias the current is suppressed for this rather large electron–phonon coupling (phonon blockade).

excited vibrational state is proportional to the square of the overlap between the initial and final states. Hence, this rate is proportional to the overlap of the ground state of the harmonic oscillator corresponding to the higher parabola and the excited state of the oscillator corresponding to the shifted parabola (to be multiplied by the coupling between lead and island). This overlap is known as the Frank–Condon factor. It is clear that for large displacements, this overlap may be larger for passing to a vibrationally excited state than for passing to the vibrational ground state of the shifted oscillator. The Franck–Condon factors may be calculated analytically (see for example Ref. [10]).

The sequential tunneling regime, which corresponds to weak coupling, can be described in terms of a rate equation: the *master equation*. This describes the time evolution of the probability densities for the possible states on the molecular island. The master equation can be used for any sequential tunneling process and is particularly convenient when vibrational excitations play a role. The details of formulating and solving master equations are beyond the scope of this chapter, but the interested reader is referred to Refs. [11,12] for further details.

Figure 2.11b and c were prepared using such a master equation analysis. For sufficient electron–phonon coupling, steps appear in the current–voltage characteristics (Figure 2.11b), which for $\Gamma_D = \Gamma_S$ leads to the lozenge pattern in a stability diagram, as illustrated in Figure 2.11c. It should be noted that, if the vibrational modes are excited, they may in turn lose their energy through coupling to the leads or other parts of the device. This can be represented by an effective damping term for the nuclear degrees of freedom. For actual molecules, solving the master equations by using Frank–Condon factors obtained from quantum chemical calculations may be used to compare theory with experiment. This is especially useful because the observed vibrational frequencies can be used as a "fingerprint" of the molecule under study [7,13–15] (see also Figure 2.8a).

2.6 Second-Order Processes

In the analysis presented so far, sequential tunneling events do not contribute to the current inside Coulomb diamonds as they are blocked in these regions. However, it should be realized that elastic co-tunneling processes (as depicted in the upper part of Figure 2.3) always take place, albeit that the current levels are generally very small. For second-order processes, the current is proportional to $\Gamma_S\Gamma_D$ instead of showing a linear dependence (on $\Gamma_S\Gamma_D/(\Gamma_S + \Gamma_D)$) as for first-order processes. Consequently, co-tunneling becomes more important for larger Γ-values. In some cases, higher order coherent processes involving virtual states give rise to observable features inside Coulomb diamonds. In the following section, two examples are discussed; namely, the Kondo effect in quantum dots, which is an elastic co-tunneling process conserving the dot energy, and inelastic co-tunneling, which leaves the dot in an excited state.

2.6.1
The Kondo Effect in a Quantum Dot with an Unpaired Electron

The Kondo effect has long been known to cause a resistance increase at low temperatures in metals with magnetic impurities [16]. However, in recent years Kondo physics has also been observed in semiconducting [17], nanotube [18] and single-molecule quantum dots [19]. It arises when a localized unpaired spin interacts by antiferromagnetic exchange with the spin of the surrounding electrons in the leads (see Figure 2.12a). The Heisenberg uncertainty principle allows the electron to tunnel out for only a short time of about $\hbar/\Delta E$, where ΔE is the energy of the electron relative to the Fermi energy and is taken as positive. During this time, another electron from the Fermi level at the opposite lead can tunnel onto the dot, thus conserving the total energy of the system (elastic co-tunneling). The exchange interaction causes the majority spin in the leads to be opposite to the original spin of the dot. Therefore, the new electron entering from these leads is more likely to have the opposite spin. This higher-order process gives rise to a so-called *Kondo resonance* centered around the Fermi level. The width of this resonance is proportional to the characteristic energy scale for Kondo physics, T_K. For $\Delta E \gg \Gamma$, T_K is given by:

$$k_B T_K = \frac{\sqrt{\Gamma U}}{2} \exp\left[\frac{\pi \Delta E(\Delta E + U)}{\Gamma U}\right]. \tag{2.11}$$

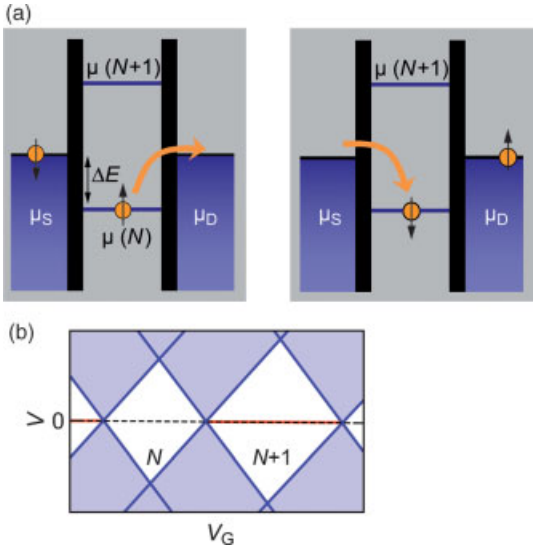

Figure 2.12 (a) A schematic drawing of the two-step Kondo process which occurs for odd occupancy of the island. (b) The Kondo effect leads to a zero bias conductance peak (red lines) in the differential conductance plots. *N* is even in this case.

Typical values for T_K are 1 K for semiconducting quantum dots, 10 K for CNTs, and 50 K for molecular junctions. This increase of T_K with decreasing dot size can be understood from the prefactor, which contains the charging energy ($U = e^2/C$).

In contrast to bulk systems, the Kondo effect in quantum dots leads to an *increase* of the conductance, as exchange makes it easier for the spin states belonging to the two electrodes to mix with the state (of opposite spin) on the dot, thereby facilitating transport through the dot. The conductance increase occurs only for small bias voltages, and the characteristic feature is a peak in the trace of the differential conductance versus bias voltage (see Figure 2.10b, red lines). The peak occurs at zero bias inside the diamond corresponding to an odd number of electrons. (For zero spin, no Kondo is expected; for $S = 1$ a Kondo resonance may be possible, but the Kondo temperature is expected to be much smaller.) The full width at half maximum (FWHM) of this peak is proportional to T_K: FWHM $\approx 2k_B T_K/e$. Equation 2.11 indicates that T_K is gate-dependent because ΔE can be tuned by the gate voltage. Consequently, the width of the resonance is the smallest in the middle of the Coulomb blockade valley and increases towards the degeneracy point on either side.

Another characteristic feature of the Kondo resonance is the logarithmic decrease in peak height with temperature. In experiments, this logarithmic dependence of the conductance maximum is often used for diagnostic means, and in the middle of the Coulomb blockade valley it is given by:

$$G(T) = \frac{G_C}{[1 + (2^{1/S} - 1)(T/T_K)^2]^S}, \tag{2.12}$$

where $S = 0.22$ for spin-1/2 impurities and $G_C = 2e^2/h$ for symmetric barriers. For asymmetric barriers, G_C is lower than the conductance quantum. Equation 2.12 shows that for low temperatures, the maximum conductance of the Kondo peak saturates at G_C while at the Kondo temperature it reaches a value of $G_C/2$.

2.6.2 Inelastic Co-Tunneling

The inelastic co-tunneling mechanism becomes active above a certain bias voltage, which is independent of the gate voltage. At this point, the current increases stepwise because an additional transport channel opens up. In the stability diagram, this results in a horizontal line inside the Coulomb-blockaded regime. This conductance feature appears symmetrically around zero at a source-drain bias of $\pm\Delta/e$ for an excited level that lies at an energy Δ above the ground state. Co-tunneling spectroscopy therefore offers a sensitive measure of excited-state energies, which may be either electronic or vibrational. Often, in combination with Kondo peaks, inelastic co-tunneling lines are commonly observed in semiconducting, nanotube and molecular quantum dots. An example of inelastic co-tunnel lines (dashed horizontal lines) for a metallic nanotube quantum dot is shown in Figure 2.13a.

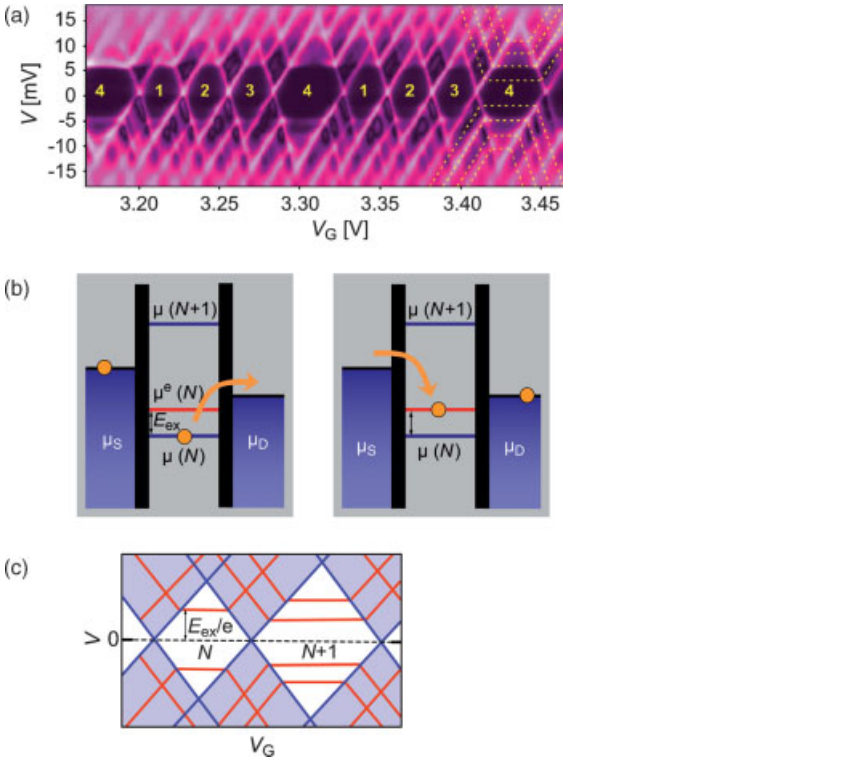

Figure 2.13 Inelastic co-tunneling. (a) A measured stability diagram of a metallic, single-walled carbon nanotube (from Ref. [5]). The dashed horizontal lines indicate the presence of inelastic co-tunnel lines. (b) Schematic drawing of this two-step tunneling process, leaving the dot in an excited state. (c) Inelastic co-tunneling gives rise to horizontal lines in the blocked current region. The energy of the excitation can directly be determined from these plots, as indicated in the figure.

Figure 2.13b shows the mechanism of inelastic co-tunneling. An occupied state lies below the Fermi level, and this can only virtually escape for a small time, as governed by the Heisenberg uncertainty relation. If, in the meantime, an electron from the left lead tunnels onto the dot in the excited level (red), then effectively one electron has been transported from left to right. The dot is left in an excited level, and the energy difference E_{ex} must be paid by the bias voltage; hence, this two-step process is only possible for $|V| > E_{ex}/e$. Relaxation inside the dot may then lead to the dot to decay into the ground state.

Acknowledgments

The authors thank Menno Poot for his critical reading of the manuscript.

3
Spin Injection–Extraction Processes in Metallic and Semiconductor Heterostructures

Alexander M. Bratkovsky

3.1
Introduction

Spin transport in metal-, metal-insulator, and semiconductor nanostructures holds promise for the next generation of high-speed, low-power electronic devices [1–10]. Amongst important spintronic effects already used in practice are included a giant magnetoresistance (MR) in magnetic multilayers [11] and tunnel MR (TMR) in ferromagnet-insulator-ferromagnet (FM-I-FM) structures [12–19]. The injection of spin-polarized electrons into semiconductors is of particular interest because of relatively large spin relaxation time ($\sim$1 ns in semiconductors, $\sim$1 ms in organics) [2] during which the electron can travel over macroscopic distances without losing polarization, or stay in a quantum dot/well. This also opens up possibilities, albeit speculative ones, for quantum information processing using spins in semiconductors.

The potential of spintronic devices is illustrated most easily with a simple spin-dependent transport process, which is a tunneling magnetoresistance in FM-I-FM structure (see the next section). The effect is a simple consequence of the golden rule that dictates a dependence of the tunnel current on the density of initial and final states for tunneling electron. Most of the results for tunnel spin junctions may be reused later in describing the spin injection from ferromagnets into semiconductors (or vice versa) in the later sections.

It is worth noting from the outset that there are two major characteristics of the spin transport processes that will define the outcome of a particular measurement, namely *spin polarization* and *spin injection efficiency*. These may be very different from each other, and this may lead (and frequently does) to a confusion among researchers. The spin polarization measures the imbalance in the *density* of electrons with opposite spins (spin accumulation/depletion),

$$P = \frac{n_\uparrow - n_\downarrow}{n_\uparrow + n_\downarrow}, \tag{3.1}$$

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

while the injection *efficiency* is the *polarization* of injected *current J*

$$\Gamma = \frac{J_\uparrow - J_\downarrow}{J_\uparrow + J_\downarrow}, \tag{3.2}$$

where $\uparrow(\downarrow)$ refers to the electron spin projection on a quantization axis. In case of ferromagnetic materials, the axis is antiparallel to the magnetization moment $\vec{M}$. Generally, $P \neq \Gamma$, but in some cases they can be close. Since in the ferromagnets the spin density is constant, a reasonable assumption can be made that the current is carried independently by two electron fluids with opposite spins (Mott's two-fluid model [20]). Then, in the FM bulk the injection efficiency parameter is

$$\Gamma = \Gamma_F = \frac{(\sigma_\uparrow - \sigma_\downarrow)}{\sigma}, \tag{3.3}$$

where $\sigma_{\uparrow(\downarrow)}$ are the conductivities of up-, (down)spin electrons in ferromagnet, $\sigma = \sigma_\uparrow + \sigma_\downarrow$.

In the case of spin tunneling, it is found that Γ characterizes the value of MR in magnetic *tunnel* junctions, which is quite obvious as there one measures the difference between *currents* in two configurations: with parallel (P) and antiparallel (AP) moments on electrodes. The tunnel current is small; hence the injected spin density is minute compared to metallic carrier densities. At the same time, in experiments where one injects spin (creates a non-equilibrium spin population) in a quantum well, this results in the emission of polarized light (spinLED), the measured intensity of which is, obviously, proportional to the spin polarization *P* (see below).

We will outline the major spin-transport effects here in the Introduction, starting with an analysis of tunnel magnetoresistance (TMR), followed by giant magnetoresistance (GMR) and spin-torque (ST) switching in magnetic nanopillars. We will then outline the spin-orbit effects in three-dimensional (3-D) and two-dimensional (2-D) semiconductor systems (Dresselhaus and Vasko-Rashba effects) and use this for further discussion of Datta–Das interference device and the Spin-Hall effect. A brief assessment will then be made of spin logic devices, showing why they are impractical because of difficulty in precise manipulation of individual spins, in addition to practically gapless excitation of the spin waves that easily destroy a particular spin configuration of the multispin system. Spin ensemble-based quantum computing – that is, coherent manipulation of spin ensembles over a number of steps – is, even less likely than using classical spin logic.

We then turn to spin injection/extraction effects in ferromagnetic metal-semiconductor heterojunctions. It is shown that efficient spin injection is possible with modified Schottky junctions, and is a strongly non-linear effect. A brief discussion is then provided of a few possible spin-injection effects and devices, some of which are likely to be demonstrated in the near future. The final section is devoted to a complementary topic of spin injection in degenerate semiconductors. These processes are significantly different from the case of non-degenerate semiconductors so as to warant a separate discussion.

3.2
Main Spintronic Effects and Devices

3.2.1
TMR

Tunnel magnetoresistance is observed in metal–insulator–metal magnetic tunnel junctions (MTJ), usually with Ni–Fe, Co–Fe electrodes and (amorphous) Al_2O_3 tunnel barrier where one routinely observes upward of 40–50% change in conductance as a result of the changing relative orientation of magnetic moments on electrodes. A considerably larger effect, about 200% TMR, is found in Fe/MgO/Fe junctions with an epitaxial barrier, that may be related to surface states and/or peculiarities of the band structure of the materials. As will be seen shortly, TMR is basically a simple effect of an asymmetry between densities of spin-up and -down (initial and final tunneling) states. TMR is intimately related to giant magnetoresistance [11]; that is, a giant change in conductance of magnetic multilayers with relative orientation of magnetic moments in the stack.

We can estimate the TMR using the golden rule which states that the tunnel current at small bias voltage V is $J_\sigma = G_\sigma V$, $G_\sigma \propto |M|^2 g_{i\sigma}\, g_{f\sigma}$, where $g_{i(f)\sigma}$ is the density of initial (final) tunneling states with a spin projection σ, and M is the tunneling matrix element. Consider the case of electrodes made from the same material. It is clear from the band schematic shown in Figure 3.1 that the total rates of tunneling in parallel (a) and antiparallel (b) configurations of moments on electrodes are different.

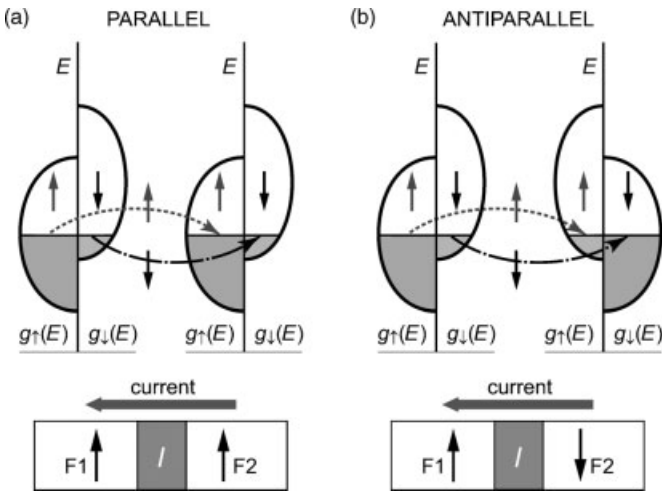

Figure 3.1 Schematic illustration of spin tunneling in FM-I-FM junction for (a) parallel (P) and (b) antiparallel (AP) configuration of moments on ferromagnetic electrodes. Top panels: band diagram; bottom panels: schematic of the corresponding magnetic configuration in the junction with regards to current direction.

Indeed, denoting $D = g_\uparrow$ and $d = g_\downarrow$ as the partial densities of states (DOS), we can write down the following golden rule expression for parallel and antiparallel moments on the electrodes:

$$G_P \propto D^2 + d^2, \quad G_{AP} \propto 2Dd, \tag{3.4}$$

and arrive at the expression for TMR first derived by Jullieres [12]

$$\mathrm{TMR} \equiv \frac{G_P - G_{AP}}{G_{AP}} = \frac{(D-d)^2}{2Dd} = \frac{2P^2}{1-P^2}, \tag{3.5}$$

where we have introduced a polarization P, which fairly approximates the polarization introduced in Equation 3.1, at least for narrow interval of energies:

$$P = \frac{D-d}{D+d} \equiv \frac{g_\uparrow - g_\downarrow}{g_\uparrow + g_\downarrow}. \tag{3.6}$$

Below, we shall see that the "polarization" entering expression for a particular process, depends on particular physics and also on the nature of the electronic states involved. It should be noted that, for instance, the DOS entering the above expression for TMR, is not the *total* DOS but rather the one for states that contribute to tunneling current. Thus, Equation 3.6 may lead one to believe that the *tunnel* polarization in elemental Ni should be negative, as there is a sharp peak in the minority carrier density of states at the Fermi level. The data, however, suggest unambiguously that the tunnel polarization in Ni is positive [14], $P > 0$. This finds a simple explanation in a model by M.B. Stearns, who highlighted the presence in elemental 3d metals parts of Fermi surface with almost 100% d-character and a small effective mass close to one of a free electron [21]. A detailed discussion of TMR effects is provided below.

3.2.2 GMR

There are important differences between TMR and GMR processes. Indeed, GMR is most reminiscent of TMR for current-perpendicular-to-planes (CPP) geometry in FM-N-FM-... stacks, where N stands for normal metal spacer (Figure 3.2a). In the CPP geometry, the spins cross the nanometer-thin normal spacer layer (N) without spin flip, similarly to tunneling through the oxide barrier, but the elastic mean free path is comparable or smaller than the N thickness, so that a drift-diffusive electrons transport takes place in metallic GMR stacks. In commonly used current-in-plane geometry (CIP), the electrons bounce between different ferromagnetic layers, (Figure 3.2b) effectively showing the same motif in transport across the layers as in the CPP geometry. Comparing with TMR, the latter (and spin injection efficiency) depends on the difference between the densities of states g_σ, spin $\sigma = \uparrow(\downarrow)$ at the Fermi level, while GMR depends on relative conductivity

$$\sigma_\sigma = e^2 \langle g_\sigma v_\sigma^2 \tau_\sigma \rangle_F,$$

where the angular brackets indicate an average over the Fermi surface that involves the Fermi velocity v_σ and the momentum relaxation time τ_σ One can still use the

Mott's two independent spin fluid picture, but as one is dealing with metallic heterostructure, the continuity (or Boltzmann) equations must be solved for a periodic FM-N-FM-... stack to find the ramp of an electrochemical potential that defines the total current. Neglecting any slight imbalance of electrochemical potentials for two spins in the N regions (spin accumulation), one may construct an equivalent circuit model for CPP stack in the spirit of Mott's model, and thus qualitatively explain the GMR. The parallel "spin" layer resistances would be $R_{\uparrow(\downarrow)}$ $\sigma_{\uparrow(\downarrow)}L_F$ for the FM layers, and $r = \sigma_N^{-1}L_N$ in the normal N regions with thicknesses $L_F(L_N)$, respectively. For conductances in two configurations of the moments, we then obtain (Figure 3.2c):

$$G_{\mathrm{P}} = \frac{1}{R_{\mathrm{P}}} = \frac{1}{2R_{\uparrow} + r} + \frac{1}{2R_{\downarrow} + r}, \tag{3.7}$$

$$G_{\mathrm{AP}} = \frac{1}{R_{\mathrm{AP}}} = \frac{2}{R_{\uparrow} + R_{\downarrow} + r}, \tag{3.8}$$

and the GMR simply becomes

$$\mathrm{GMR} = \frac{G_{\mathrm{P}} - G_{\mathrm{AP}}}{G_{\mathrm{AP}}} = \frac{(R_{\downarrow} - R_{\uparrow})^2}{(2R_{\uparrow} + r)(2R_{\downarrow} + r)} \tag{3.9}$$

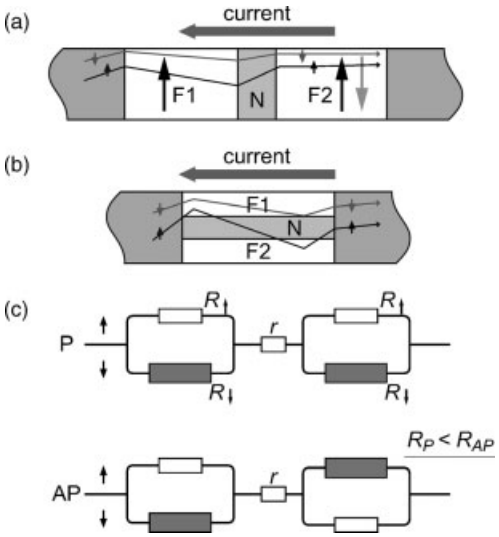

Figure 3.2 Schematic of giant magnetoresistance (GMR) in (a) current perpendicular to plane (CPP) and (b) current in-plane (CIP) geometries. Electron scattering in the GMR valve depends on the configuration of moments and spin of traversing electrons in both configurations. (c) Equivalent circuit model for GMR. Two-fluid spin model that is valid in the absence of spin relaxation, leads to higher resistivity for antiparallel arrangement of magnetic moments in the spin valve, $R_{AP} > R_P$.

which we can rewrite as

$$\mathrm{GMR} = \frac{\Gamma_F^2}{(1 + r/R)^2 - \Gamma_F^2} \approx \frac{\Gamma_F^2}{1 - \Gamma_F^2}, \tag{3.10}$$

where $R = R_\uparrow + R_\downarrow$. The latter is very similar to the expression TMR [Equation 3.5], but there is an absence of a factor two in the numerator. It can be seen that the polarization entering GMR is different from that entering TMR. Even in more common CIP geometry, the electrons certainly do scatter across the interfaces; hence, this equation can also be used for semi-quantitative estimates of the GMR effect in CIP geometry (Figure 3.2c). Obviously, the effective circuit model [Equations 3.7 and 3.8] remains exactly the same because it simply reflects the two-fluid approximation for contributions of both spins. However, all effective resistances depend in rather nontrivial manner on the geometry (CPP or CIP) and electronic structure of the metals involved that is particularly complicated in magnetic transition metals.

In terms of applications, the TMR effect is used in non-volatile magnetic random access memory (MRAM) devices and as a field sensor, while GMR is widely used in magnetic read heads as field sensors. The MRAM devices are in a tight competition with semiconductor memory cards (FLASH), since MRAM is technologically more involved (and hence more expensive) than standard silicon technology. It is problematic to use those effects in building three-terminal devices with gain that would show any advantage over standard CMOS transistors.

3.2.3
(Pseudo)Spin-Torque Domain Wall Switching in Nanomagnets

Magnetic memory based on TMR is non-volatile, may be rather fast (~1 ns), and can be scaled down considerably toward paramagnetic limits observed in nanomagnets. Switching, however, requires the MTJ to be placed at a crosspoint of the bit and word wires carrying current that produces a sufficient magnetic field for switching the domain orientation in "free" (unpinned) MTJ ferromagnetic electrodes. The undesirable side effect is a crosstalk between cells, a rather complex layout, and a power budget. Alternatively, one may take a GMR multilayer in a nanopillar form with antiparallel orientation of magnetic moments and run a current through it (this would obviously correspond to a CPP geometry) (Figure 3.3). In this case, there will be a spin accumulation in the drain layer; that is, the accumulation of *minority* spins in the drain electrode for *antiparallel* configuration of moments on electrodes (for the electrodes made out the same material. This formally means a transfer of spin (angular) moment across the space layer. Injection of angular momentum means that there is a change in the spin momentum on the drain electrode, the spin projection on the quantization axis then evolves with time simply because of an influx of electrons with a different projection of polarization on the (drain electrode) quantization axis, $d\mathcal{P}_{\mathrm{Rz}}/dt \neq 0$, $\mathcal{P}_{\mathrm{Rz}} = n_+ - n_-$, where $\pm$ marks along (against) the quantization axis on the right electrode with $n_{+(-)}$ the densities of majority (minority) electrons. One may call this a (pseudo) torque effectively acting on a moment in the

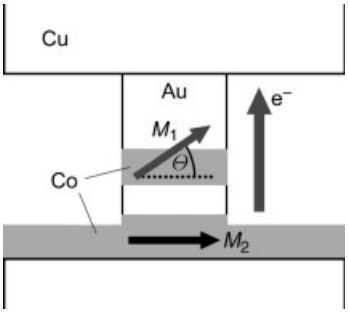

Figure 3.3 Schematic of a nanopillar device for spin-torque measurements. Current through the device results in change in angle θ between magnetic moments in the free layer in the middle and the bottom ferromagnetic electrode.

drain electrode, although this is obviously not a good term. This simple effect was predicted in Refs. [22, 23], and observed experimentally in nanopillars multilayer stacks by Tsoi *et al.* [24], and also in other studies.

The spin *accumulation* is proportional to density J of the spin-polarized current through the drain magnet or magnetic particle, that carries $(-\hbar J/2q)$ spin moment with it per second. The change in the longitudinal component of spin polarization $\mathcal{P}_{\mathrm{Rz}}$ in the right electrode next to the interface is then simply

$$\begin{aligned} d\mathcal{P}_{\mathrm{Rz}} &= -\frac{\hbar(J_+ - J_-)}{2q} = -\frac{\hbar V(\mathcal{G}_+ - \mathcal{G}_-)}{2q} \\ &= -\frac{qV(T_+ - T_-)}{4} \\ &= -\frac{\hbar V}{4q}(G_{+\uparrow} + G_{+\downarrow} - G_{-\uparrow} - G_{-\downarrow}), \end{aligned} \tag{3.11}$$

in a linear regime, where $\mathcal{G}_\pm = (q^2/\hbar)T_\pm$ are the conductances for spin-up and -down channels, expressed through the transmission probabilities $T_\pm$ and partial spin conductances G. There is an angle θ between the quantization axes on the source and drain electrode, $\cos\theta = \vec{\mathcal{P}}_{\mathrm{L}} \cdot \vec{\mathcal{P}}_{\mathrm{R}}/(\mathcal{P}_{\mathrm{L}}\mathcal{P}_{\mathrm{R}})$. The partial spin conductances G are in turn given by the standard Landauer expression through the transmission coefficients $t_{\sigma\sigma'}$ as $T_{\sigma=\pm} = \sum_{\sigma'=\uparrow,\downarrow}|t_{\sigma\sigma'}|^2$. The above expression can be expressed through the partial conductances for arbitrary configuration of spins on the electrodes $G_{+\uparrow} = (q^2/\hbar)|t_{+\uparrow}|^2$, $G_{-\uparrow} = (q^2/\hbar)|t_{-\uparrow}|^2, \ldots$, where the orientation along (against) the spin on the right electrode, $\mathcal{P}_{\mathrm{R}}$, is marked by the subscript $+(-)$. Assuming that there is no spin-flip in the oxide (non-magnetic metal) spacer, we can express the transmission amplitudes through those calculated for parallel/antiparallel configuration of spins on the electrodes with the use of a standard rule for spin wave function in a rotated frame.

Finally, the rate of change in polarization on the drain electrode due to influx of polarized current is simply

$$\frac{d\mathcal{P}_{Rz}}{dt} = -\frac{\hbar V}{4q}\left[(G_{\uparrow\uparrow} - G_{\downarrow\downarrow})\cos^2\frac{\theta}{2} + (G_{\uparrow\downarrow} - G_{\downarrow\uparrow})\sin^2\frac{\theta}{2}\right], \tag{3.12}$$

and the term on the right-hand side should be added to the driving force in the Landau–Lifshitz (LL) equation on the right-hand side. This expression should be better suited for MTJs, as in metallic spin valves one must consider spin accumulation in a metallic spacer. Note that Slonczewski obtains $d\mathcal{P}_{Rz}/dt \propto \sin\theta$ for MTJs [25], which may be inaccurate. Indeed, consider the antiparallel configuration ($\theta = \pi$) of *unlike* electrodes. Then, $d\mathcal{P}_{Rz}/dt \propto G_{\uparrow\downarrow} - G_{\downarrow\uparrow} \neq 0$, since for the unlike electrodes $G_{\uparrow\downarrow} \neq G_{\downarrow\uparrow}$, and there obviously will be a change in the spin density in the right electrode because the influx of spins into majority states would not be equal to the influx into minority states. To handle the resulting spin dynamics properly, one needs to write down the continuity equation for the spin, similar to Equation 3.23 below, with Equation 3.12 as the boundary condition at the interface.

Time-resolved measurements of current-induced reversal of a free magnetic layer in permalloy/Cu/permalloy elliptical nanopillars at temperatures from 4.2 to 160 K can be found in Ref. [26]. There is considerable device-to-device variation in the ST attributed to presence of an antiferromagnetic oxide layer around the perimeter of the Permalloy free layer (and some ambiguity in an expression used for the torque itself). Obviously, controlling this layer would be very important for the viability of the whole approach for memory applications, and so on. There are reports about the activation character of switching that may be related to pinning of the domain walls at the side walls of the pillar. The injected DC polarized current may also induce a magnetic vortex oscillation, when vortex may be formed in a magnetic island in, for example, a pillar-like spin valve. These induced oscillations have recently been found [27]. It is worth noting that the agreement between theory and experiment may be fortuitous: thus, in permalloy nanowires the speed of domain wall has substantially exceeded the rate of spin angular momentum transfer rate [28].

3.3
Spin-Orbital Coupling and Electron Interference Semiconductor Devices

In most cases of interest, such as direct band semiconductors near high-symmetry points, and a two-dimensional electron gas [29, 30], the spin-orbital (SO) coupling effects can be treated fairly well within the Kane's or Luttinger–Kohn's models in so-called *kp* method (see e.g. Refs. [31, 32]). The SO interaction is given by the term in electron Hamiltonian

$$H_{SO} = \frac{\hbar}{4m_0^2c^2}\left[\vec{\nabla}\ U \times\ \vec{p}\right]\ \vec{\sigma}\,, \tag{3.13}$$

where $\vec{p} = -i\hbar\nabla$ the electron momentum operator.

SO interactions lead in some cases, as for semiconductor 2-D channels, to various effects that can be used to build electron interference devices, at least as a matter of principle. As an interesting (yet unrealized at the time of writing) example of such a

three-terminal spintronic device, it is worth describing Datta–Das ballistic spintronic modulator/switch [3]. This is a quantum interference device with FET-like layout where a 2-D electron gas (2DEG) has a ferromagnetic source and drain. The asymmetric confinement potential induces precession of spins injected into the 2DEG channel due to specific low-symmetry SO effect (Vasko–Rashba spin splitting) [29, 30]. The resulting angle may become large, $\sim\pi$ in channels $\gtrsim \mu$m long and made of narrow-gap semiconductors with strong so coupling. Since the ferromagnetic drain works as a spin filter, one hopes that changing the gate voltage would change the shape of the confinement potential and the Vasko–Rashba coupling constant α. As a result, one may be able to change the precession angle of ballistic electrons and the current through the structure (yet to be observed). To appreciate the situation, we need to describe the SO effects in a simple *kp*-model for semiconductors. As we shall see, the SO effects are expectedly weak, being of relativistic nature, and so in general are the effects. It is difficult to expect that SO-based devices can outperform any of the conventional electronics devices in standard applications.

In MOSFET structures the confining potential is asymmetric, so there appears an inversion asymmetry term derived by Vasko [28] (Vasko–Rashba or simply Rashba term, see also Ref. [29]). The only contribution coming from the confinement field in SO Hamiltonian is $\propto\langle\nabla_z V\rangle$ giving the Vasko–Rashba term,

$$H_{\mathrm{R}} = \alpha(k_y\sigma_x - k_x\sigma_y). \tag{3.14}$$

The magnitude of the coupling constant α depends on the confining potential, and this can in principle be modified by gating. It also defines the spin-precession wave vector $k_\alpha = \alpha m/\hbar^2$. Such a term, H_{R}, is also present in cubic systems with strain [35]. The Vasko–Rashba Hamiltonian for heavy holes is cubic in k, and, generally, very small.

Electric fields due to impurities (and external field) lead to extrinsic contributions of the spin-orbit coupling in the standard form

$$H_{\mathrm{ext}} = \lambda[\,\vec{k}\times\nabla U]\,\vec{\sigma}\,, \tag{3.15}$$

where U is the potential due to impurities and an externally applied field, with the coupling constant λ derived from 8×8 Kane Hamiltonian in third-order perturbation theory [33, 34]

$$\lambda = \frac{P^2}{3}\left[\frac{1}{E_g^2} - \frac{1}{(E_g+\Delta)^2}\right], \tag{3.16}$$

where P is the matrix element of momentum found from $\langle S|p_x|X\rangle = \langle S|p_y|Y\rangle = \langle S|p_z|Z\rangle = iPm_0/\hbar$. This is the same analytical form as the vacuum spin-orbit coupling but, for $\Delta>0$ the coupling has the *opposite sign*. Numerically, $\lambda = 5.3$ Å^2 for GaAs and 120 Å^2 for InAs, that is, spin-orbit coupling in *n*-GaAs is by *six orders* of magnitude larger than in vacuum [31]. This helps to generate the relatively large extrinsic spin currents observed in the spin-Hall effect (see below). In 2-D, $H_{\mathrm{ext}} = \lambda(\vec{k}\times\nabla U)_z\cdot\sigma_z$.

Now, we can analyze the behavior of polarized electrons injected into the 2DED channel. A free-electron VR Hamiltonian H_{VR} has two eigenstates with the momenta $k_{\pm}(\epsilon)$ for opposite spins for each energy ϵ, with $k_- - k_+ = 2m\alpha/\hbar^2$. Datta and Das [3] have noted that the conductivity of the device depends on the phase difference $\Delta\theta = (k_- - k_+)L = 2m\alpha L/\hbar^2$ between electron carriers after crossing a ballistic channel of a length L and oscillates with a period defined by the interference condition $(k_- - k_+)L = 2\pi n$, with n as integer. An equivalent description of the same phenomenon is the precession of an electron spin in an effective magnetic field $\vec{B}_{\mathrm{so}} = (2\alpha/g\mu_B)(\vec{k}\times\hat{\mathbf{z}})$, with μ_B the Bohr magneton, g the gyromagnetic ratio. The device is supposed to be controlled by the gate voltage V_g that modulates the SO coupling constant α, $\alpha = \alpha(V)_g$. This pioneering report generated much attention, yet to date the device appears not to have been demonstrated. Using typical parameters from Refs. [36, 37], $\hbar\alpha \approx 1 \times 10^{-11}\,\mathrm{eV}\cdot\mathrm{m}$ and $m = 0.1\,m_0$ for the effective carrier mass, current modulation would be observable in channels with relatively large length $L \gtrsim 1\,\mu\mathrm{m}$. Given the above, the observation of the effect would need: (i) efficient spin injection into channel from the FM source, which is tricky and requires a modified Schottky barrier (see below); (ii) the splitting should well exceed the bulk inversion asymmetry effect; (iii) the inhomogeneous broadening of α due to impurities, that mask the Vasko–Rashba splitting, should be small; and (iv) one should be able to gate control α. All these represent great challenges for building a room-temperature interference device, where one needs to use narrow-gap semiconductors and structures with *ballistic* channels. The device is not efficient is a diffusive regime. The gate control of α has been demonstrated (see Refs. [36, 38] and references therein).

3.3.1
Spin-Hall Effect (SHE) and Magnetoresistance due to Edge Spin Accumulation

Recently, there has been a resurgence of interest in the spin-Hall effect (SHE), which is another general consequence of the spin-orbital interaction, predicted by Dyakonov and Perel in 1971 [40]. These authors found that because of the spin-orbital interaction the electric and spin currents are intertwined: an electrical current produces a transverse spin current, and *vice versa*. In the case when impurity scattering dominates, which is quite often, the transverse is caused by the Mott skew scattering of spin-polarized carriers due to the SO interaction, [see Eq. (3.13)]. Since the current drags along the polarization of the carriers, the *spin accumulation at the edges* occurs, a so-called spin-Hall effect (SHE). In ferromagnets, the appearing Hall current is termed *anomalous*, and is always accompanied by the SHE. Importantly, the edge spin accumulation results in a slight *decrease* in sample resistance. External magnetic field would destroy the spin accumulation (Hanle effect) and lead to a *positive magnetoresistance*, recently identified by Dyakonov [41].

We present here a simple phenomenological description of spin-Hall effects (direct and inverse) and Dyakonov's magnetoresistance [42]. To this end, we introduce the electron charge flux $\vec{f}$ related to the current density as $\vec{J} = -q\vec{f}$, where q is

the elementary charge. For parts not related to the SO interaction, we have the usual drift-diffusion expression:

$$\vec{f}^{(0)} = -\mu n \vec{E} - D\vec{\nabla} n, \tag{3.17}$$

where μ and D are the usual electron mobility and diffusion coefficient, connected by the Einstein relation, $\vec{E}$ the electric field, and n is the electron density. The spin polarization flux t_{ij} is a tensor characterizing the flow of the jth component of the polarization *density* $\mathcal{P}_j = n_{j\uparrow} - n_{j\downarrow}$ in the direction i (spin density is $s_j(\mathbf{r}) = \frac{1}{2}\mathcal{P}_j$). It is non-zero even in the absence of spin–orbit interaction, simply because the spins are carried by electron flux, and we mark the corresponding quantity $t_{ij}^{(0)}$. Then, we have

$$t_{ij}^{(0)} = -\mu E_i \mathcal{P}_j - D\partial_i \mathcal{P}_j, \tag{3.18}$$

where $\partial_i = \partial/\partial x_i$, and one can add other sources of current, such as temperature gradient, in Equations 3.17 and 3.18. Spin–orbit interaction couples the charge and spin currents. For a material with an inversion symmetry, we have [42]:

$$f_i = f_i^{(0)} + \gamma \varepsilon_{ijk} t_{jk}^{(0)}, \tag{3.19}$$

$$t_{ij} = t_{jk}^{(0)} - \gamma \varepsilon_{ijk} f_k^{(0)}, \tag{3.20}$$

where ϵ_{ijk} is the unit antisymmetric tensor and $\gamma \ll 1$ is a dimensionless coupling constant proportional to the spin–orbit interaction λ [Equation 3.16] (typically, $\gamma \sim 10^{-2} - 10^{-3}$). The difference in signs in Equations 3.19 and 3.20 is consistent with the Onsager relations, and is due to the different properties of $\vec{f}$ and t_{ij} with respect to time inversion. Explicit phenomenological expressions for the two currents follow from Equations 3.17–3.20 [40, 41]:

$$\vec{J}/q = \mu n \vec{E} + D\vec{\nabla} n + \beta \vec{E} \times \vec{P} + \delta \vec{\nabla} \times \vec{\mathcal{P}}, \tag{3.21}$$

$$t_{ij} = -\mu E_i \mathcal{P}_j - D\partial_i \mathcal{P}_j + \varepsilon_{ijk}(\beta n E_k + \delta \partial_k n), \tag{3.22}$$

where the parameters $\beta = \gamma\mu$, $\delta = \gamma D$, satisfy the same Einstein relation, as do μ and D. The spin polarization vector evolves with time in accordance with the continuity equation [41, 42]:

$$\partial_t \mathcal{P}_j + \partial_i t_{ij} + |\vec{\Omega} \times \vec{\mathcal{P}}|_j + \mathcal{P}_j/\tau_s = 0, \tag{3.23}$$

where the vector $\Omega = g\mu_B H/\hbar$ is the spin precession frequency in the applied magnetic field $\vec{H}$, and τ_s the spin relaxation time. The term $\beta \vec{E} \times \vec{P}$ describes the *anomalous Hall effect*, where the spin polarization plays the role of the magnetic field. We ignore the action of magnetic field on the particle dynamics, which is justified if $\omega_c \tau \ll 1$, where ω_c is the cyclotron frequency and τ is the momentum relaxation time. Since normally $\tau_s \gg \tau$, it is possible to have both $\Omega\tau_s \gg 1$ and $\omega_c\tau \ll 1$ in a certain range of magnetic fields. It is also assumed that the equilibrium spin polarization in the applied magnetic field is negligible. The fluxes [Equations 3.21 and 3.22] need to be modified for an inhomogeneous magnetic field by adding a counter-term

proportional to $\partial B_j/\partial x_i$, which takes care of the force acting on the electron with a given spin in an inhomogeneous magnetic field $\vec{H}(r)$.

Equations 3.21–3.23 derived in Ref. [41] fully describe all physical consequences of spin–charge current coupling. For instance, the term $\delta\,\vec{\nabla}\times\vec{\mathcal{P}}$ describes an electrical current induced by an inhomogeneous spin density (so-called Inverse spin-Hall Effect) found experimentally for the first time by Bakun *et al.* [42] under the conditions of optical spin orientation. The term $\beta n\epsilon_{ijk}E_k$ (and its diffusive counterpart $\delta\epsilon_{ijk}\partial n/\partial x_k$) in Equation 3.22, describes what is now called the spin-Hall effect: an electrical current induces a transverse spin current, resulting in spin accumulation near the sample boundaries [41]. Recently, a spin-Hall effect was detected optically in thin films of n-doped GaAs and In GaAs [44] (with bulk electrons) and 2-D holes [45]. All of these phenomena are closely related and have their common origin in the coupling between spin and charge currents given by Equations 3.21 and 3.22. Any mechanism that produces the anomalous Hall effect will also lead to the spin-Hall effect, and vice versa. Remarkably, there is a single dimensionless parameter, γ, that governs the resulting physics.

It was found recently by Dyakonov that the spin-Hall effect is accompanied by a *positive* magnetoresistance due to spin accumulation near the sample boundaries [41]. The spin accumulation occurs over the spin diffusion length $L_s = \sqrt{D\tau_s}$. Therefore, it depends on the ratio L_s to the sample width L and vanishes in wide samples with $L_s/L \ll 1$. In a stripe sample with the width L (in xy plane), the z-component of $\mathcal{P}$ varies across the stripe (y-axis), $\vec{\nabla}\times\vec{\mathcal{P}} \neq 0$, this creates a positive correction to a current compared to a hypothetical case of an absent spin–orbit coupling, and the sample resistivity goes down. By applying the magnetic field in xy plane, one may destroy the spin polarization (the Hanle effect) and observe the *positive* (Dyakonov's) magnetoresistance in magnetic fields at the scale $\Omega\tau_s \sim 1$.

The data for 3-D [44] and 2-D [46] GaAs suggest the estimate $\gamma \sim 10^{-2}$, for platinum at room temperature [48] one finds $\gamma = 3.7\times10^{-3}$, so in these cases a magnetoresistance due to spin accumulation is on the order of 10^{-4} and 10^{-5}, respectively. It should be possible to find this MR due to its characteristic dependence on the field and the width of the sample, when it becomes comparable to the spin diffusion length. Because of the high sensitivity of electrical measurements, magnetoresistance might provide a useful tool for studying the spin–charge interplay in semiconductors and metals.

3.3.2
Interacting Spin Logic Circuits

There are various suggestions of more exoteric devices based on, for example, arrays of spin-polarized quantum dots with exchange coupled single spins with typical exchange coupling energy $\delta \sim 1$ meV [47], or magnetic quantum cellular automata [48]. It is assumed that one can apply a local field or short magnetic π-pulse to flip the "input" spin that would result in nearest-neighbor spins to flip in accordance with the new ground state (of the antiferromagnetically coupled circuit of quantum dots). The idea is that those spin arrays (no quantum coherence is required) can be used to

perform classical logic on bits represented by spins pointing along or against the quantizations axis, $|+z\rangle \to 1$, $|-z\rangle \to 0$. However, there are problems with using those schemes. Indeed, the standard Zeeman splitting for electron in the field of 1 T is only 0.5 K *in vacuo*, so that one needs the field of *at least* ∼150 T to flip the spin (or use materials with unusually large gyromagnetic factors), or one can apply ∼1 T transversal *B*-field for some 30 ps to do the same. The practicalities of building such a control system at a nanoscale is a major challenge, and would require a steep power budget. The other challenge is that instead of *nearest-neighbor* spins falling into a new shallow ground state with the directions of all other spins fixed, the initial flip would trigger spin wave(s) in the circuit, thus destroying the initial set-up. Indeed, the spin wave spectrum in large coupled arrays of N spins is almost gapless, with the excited state just $\sim\delta/N$ above the ground state (see e.g., Ref. [49]). Additionally, the spins are subject to a fluctuating external (effective) magnetic field that tends to excite the spin waves and destroy the direction of the spins along set quantization axis $\pm z$. For the same reason, keeping the spins in a *coherent* superposition state is unlikely, so quantum computing with coupled spins is even less practical [50].

It is clear from the above discussion, however, that it is unlikely that the Datta–Das or any other interference devices can offer any advantages over standard MOSFETs, especially as they do not have any *gain*, should operate in a ballistic regime (i.e., at low temperatures in clean systems), and require new fabrication technology.

3.4 Tunnel Magnetoresistance

Here, we describe some important aspects of TMR on the basis of simple microscopic model for elastic, impurity-assisted, surface state-assisted and inelastic contributions. Most of these results are generic, and some will be useful later to analyze room-temperature spin injection into semiconductor through a modified Schottky barrier. A model for spin tunneling has been formulated by Julliere [12], and further developed in Refs. [17, 18, 21]. It is expected to work rather well for iron-, cobalt-, and nickel-based metals, according to theoretical analysis [21] and experiments [15]. However, it disregards important points such as an impurity scattering and a reduced effective mass of carriers inside the barrier. Both issues have important implications for magnetoresistance and will be considered here, along with proposed novel half-metallic systems which should, in principle, show the ultimate performance. Enhanced performance is also found in MTJ with MgO epitaxial oxide barrier, which may be a combination of band-structure and surface effects [16, 51]. In particular, Zhang and Butler [51] predicted a very large TMR in Fe/MgO/Fe, bcc Co/MgO/Co, and FeCo/MgO/FeCo tunnel junctions, having to do with peculiar band matching for majority spin states in a metal with that in MgO tunnel barrier.

We shall describe electrons in ferromagnet-insulating barrier-ferromagnet (FM–I-FM) systems by the Schrödinger equation [17] $[-(\hbar^2/2m_i)\nabla^2 + U_i - \frac{1}{2}\vec{\Delta}_{xc}\vec{\sigma}]\psi = E\psi$ with $U(\mathbf{r})$ the potential (barrier) energy, $\vec{\Delta}_{xc}(\mathbf{r})$ the exchange splitting of, for example,

d-states in 3d ferromagnets (=0 inside the barrier), $\vec{\sigma}$ stands for the Pauli matrices; index $i = 1(3)$ for left (right) ferromagnetic electrode FM1(2) and $i = 2$ for tunneling barrier (quantities for the tunnel barrier also marked t), respectively.

We start with the expression for a direct tunnel current density of spin σ from FM1 to FM2 [52]

$$J_{\sigma 0} = \frac{q}{h}\int dE[f(E - F_{\sigma 0}^{\mathrm{FM2}}) - f(E - F_{\sigma 0}^{\mathrm{FM1}})]\int \frac{d^2 k_{\parallel}}{(2\pi)^2} T_{\sigma}(E,\ \vec{k}_{\parallel}), \tag{3.24}$$

where $f(x)$ is the Fermi–Dirac distribution function with local Fermi level $F_{\sigma 0}^{\mathrm{FM1(2)}}$ for ferromagnetic electrode FM1(2), $T_{\sigma} = \sum_{\sigma'} T_{\sigma\sigma'}$ the transmission probability from majority (minority) spin subband in FM1 $\sigma = \uparrow$ or $\downarrow$ into majority (minority) spin subband in FM2, $\sigma' = \uparrow (\downarrow)$. It has a particularly simple form for a square barrier and *collinear* [parallel (P) or antiparallel (AP)] moments on electrodes:

$$T_{\sigma\sigma'} = \frac{16 m_1 m_3 m_2^2 k_1 k_3 \kappa^2}{(m_2^2 k_1^2 + m_1^2\kappa^2)(m_2^2 k_3^2 + m_3^2\kappa^2)} e^{-2\kappa w}, \tag{3.25}$$

where κ is the attenuation constant for the wavefunction in the barrier $k_1 \equiv k_{1\sigma}$, $k_2 = i\kappa$, $k_3 \equiv k_{3\sigma'}$ are the momenta normal to the barrier for the corresponding spin subbands, w is the barrier width, and we have used a limit of T at $\kappa w \gg 1$ [18]. With the use of Equations 3.17 and 3.18, and accounting for the misalignment of magnetic moments in ferromagnetic terminals (given by the mutual angle θ), we obtain following expression for the junction conductance per unit area, assuming $m_1 = m_3$,

$$G = G_0(1 + P_1 P_2 \cos\theta), \tag{3.26}$$

$$\begin{aligned} P_{1(2)} &= \frac{k_{\uparrow} - k_{\downarrow}}{k_{\uparrow} + k_{\downarrow}} \frac{\kappa^2 - m_2^2 k_{\uparrow} k_{\downarrow}}{\kappa^2 + m_2^2 k_{\uparrow} k_{\downarrow}} \\ &= \frac{(v_{\uparrow} - v_{\downarrow})(v_t^2 - v_{\uparrow} v_{\downarrow})}{(v_{\uparrow} + v_{\downarrow})(v_t^2 + v_{\uparrow} v_{\downarrow})}, \end{aligned} \tag{3.27}$$

where $P_{1(2)}$ is the effective polarization of the FM1(2) electrode, $\kappa = [2m_2(U_0 - E)/\hbar^2]^{1/2}$, and U_0 is the top of the barrier. Equation 3.26 correct an expression derived earlier [17] for the effective mass of the carriers in the barrier. To obtain the last simple expression for tunnel current polarization Equation 3.27, which has exactly the same form also for FM-semiconductor modified Schottky junctions (below), we have introduced the carrier band velocities $v_{\uparrow(\downarrow)} = \hbar k_{\uparrow(\downarrow)}/m$, that are generally different for FM1(2), and "tunneling" velocity $v_t = \hbar\kappa/m_2$. These relations between the velocity an momentum are equivalent to an *effective mass* approximation.

By taking a typical value of $G_0 = 4$–$5\ \Omega^{-1}\,\mathrm{cm}^{-2}$ (Ref. [15] $k_{\uparrow} = 1.09\ \text{Å}^{-1}$, $k_{\downarrow} = 0.42\ \text{Å}^{-1}$, $m_1 \approx 1$ (for itinerant d electrons in Fe) [21] and a typical barrier height for Al_2O_3 (measured from the Fermi level μ) $\phi = U_0 - \mu \approx 3$ eV, and the thickness $w \approx 20$ Å, one arrives at the following estimate for the effective mass in the barrier: $m_2 \approx 0.4$ [53]. These values give $P_{\mathrm{Fe}} = 0.28$, which is noticeably smaller than the experimental value of 0.4–0.5 (note that neglect of the mass correction, $m_2 < 1$, as in Ref. [17], would give a negative value of the effective polarization). Below, we shall see that tunneling

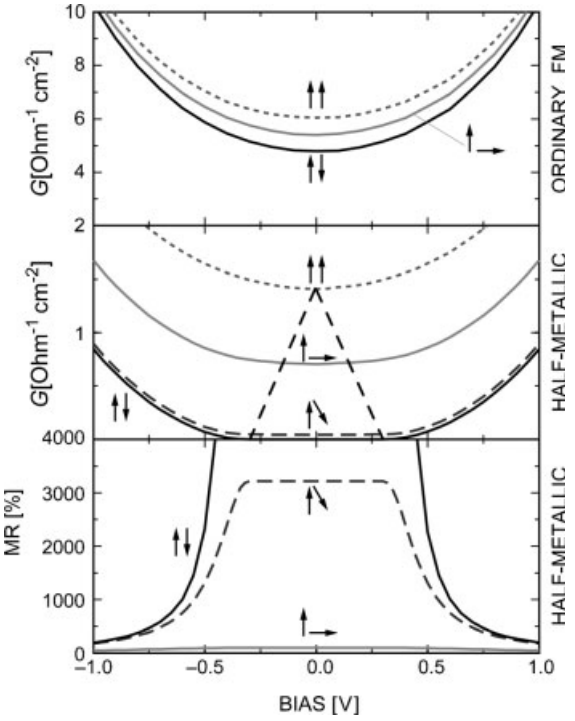

Figure 3.4 Conductance and magnetoresistance of tunnel junctions versus bias. Top panel: conventional (Fe-based) tunnel junction (for parameters, see text). Middle panel: half-metallic electrodes. Bottom panel: magnetoresistance for the half-metallic electrodes. The dashed line shows schematically a region where a gap in the minority spin states is controlling the transport. Even for imperfect antiparallel alignment ($\theta = 160^\circ$, marked $\uparrow\searrow$), the magnetoresistance for half-metallics (bottom panel) exceeds 3000% at biases below the threshold V_c. All calculations have been performed at 300 K, with inclusion of multiple image potential and exact transmission coefficients. Parameters are described in the text.

assisted by polarized surface states may lead to much larger TMR, this may relevant to observed large values of TMR [19].

The most striking feature of Equation 3.26 is that MR tends to infinity for vanishing $k_\downarrow$; that is when the electrodes are made of a 100% spin-polarized material ($P = P' = 1$) because of a gap in the density of states (DOS) for minority carriers up to their conduction band minimum $E_{\mathrm{CB}\downarrow}$. Then G^{AP} vanishes together with the transmission probability Equation 3.25, as there is a zero DOS at $E = \mu$ for both spin directions. Such a half-metallic behavior is rare, but some materials possess this amazing property, most interestingly the oxides CrO_2 and Fe_3O_4 (e.g., see recent discussion in Ref. [2]). These oxides are very interesting for future applications in combination with matching materials, as will be seen below.

Remarkably, for $|V| < V_c$ in the AP geometry one has $MR = \infty$. From the middle and the bottom panels in Figure 3.4 we see that even at 20° deviation from the AP configuration, the value of MR exceeds 3000% in the interval $|V| < V_c$, and this is indeed a very large value.

3.4.1
Impurity Suppression of TMR

An important aspect of spin-tunneling is the effect of tunneling through the defect states in the (amorphous) oxide barrier. Dangling bonds and random trap states may play the role of defects in an amorphous barrier. Since the contacts under consideration are typically short, their current–voltage (I–V) curve and MR should be very sensitive to defect resonant states in the barrier with energies close to the Fermi level, forming "channels" with the nearly periodic positions of impurities. Generally, channels with one impurity (most likely to dominate in thin barriers) would result in a monotonous behavior of the I–V curve, whereas channels with two or more impurities would produce intervals with negative differential conductance. Impurity-assisted spin tunneling at zero temperature [the general case of non-zero temperature would require integration with the Fermi factors as in Equation 3.24] can be written in the standard form [54]:

$$G_\sigma = \frac{2e^2}{\pi\hbar}\sum_i \frac{\Gamma_{L\sigma}\Gamma_{R\sigma}}{(E_i-\mu)^2+\Gamma^2}, \tag{3.28}$$

where $\Gamma_\sigma = \Gamma_{L\sigma} + \Gamma_{R\sigma}$ is the total width of a resonance given by a sum of the partial widths $\Gamma_{L(R)}$ corresponding to electron tunneling from the impurity state at the energy E_i to the left (right) terminal. It is easiest to analyze the case of parallel (P) and antiparallel (AP) mutual orientation of magnetic moments M_1 and M_2 on electrodes with the angle θ between them. In this case, one looks at tunneling of majority (maj) and minority (min) carriers from the left electrode $L_\sigma = (L_{maj}, L_{min})$ into states $R_\sigma = (R_{maj}, R_{min})$ for parallel orientation ($\theta = 0$) or $R_\sigma = (R_{min}, R_{maj})$ in antiparallel orientation ($\theta = \pi$), respectively. The general case is then easily obtained from standard spinor algebra for spin projections. The tunnel widths can be evaluated analytically for a rectangular barrier, $\Gamma_{L\sigma} \sim g_{L\sigma}\Omega\exp[-\kappa(w+2z_i)]$, where z_i is the coordinate of the impurity with respect to the center of the barrier, $g_{L\sigma}$ the density of states in the (left) electode, Ω [18].

The resonant conductance Equation 3.28 has a sharp maximum [$= e^2/(2\pi\hbar)$] when $\mu = E_i$ and $\Gamma_L = \Gamma_R$, that is for the symmetric position of the impurity in the barrier for parallel configuration. For antiparallel configuration, most effective impurities will be positioned somewhat off-center since the DOS for the majority and minority spins may be quite different. An asymmetric position of effective impurities in the AP orientation immediately suggests smaller conductance G_{AP} than G_P and *positive* ("normal") impurity TMR > 0. This result is confirmed by direct calculation. Indeed, if we assume that we have ν defect/localized levels in a unit volume and unit energy interval in a barrier, then, replacing the sum by an integral in Equation 3.28, and considering a general configuration of the magnetic moments on terminals, we obtain the following formula for impurity-assisted conductance per unit area in leading order in $\exp(-\kappa w)$:

$$G_1 = g_1(1 + \Pi_L\Pi_R\cos\theta), \tag{3.29}$$

where we have introduced the quantities

$$g_1 = \frac{e^2}{\pi\hbar} N_1, \quad N_1 = \pi^2 \nu \Gamma_1/\kappa,$$

$$\Pi_{L(R)} = \frac{(r_\uparrow - r_\downarrow)}{(r_\uparrow + r_\downarrow)}, \tag{3.30}$$

N_1 being the effective number of one-impurity channels per unit area, and one may call Π_F a "polarization" of the impurity channels, defined by the factor $r_\sigma = [m_2 \kappa k_\sigma/(\kappa^2 + m_2^2 k_\sigma^2)]^{1/2}$ with momenta k_σ for left (right) [L (R)] electrode.

Comparing direct and impurity-assisted contributions to conductance, we see that the latter dominates when the density of localized states $\nu \gtrsim (\kappa/\pi)^3 \epsilon_i^{-1} \exp(-\kappa w)$, and in our example a crossover takes place at the density of localized states $\nu \gtrsim 10^{17}\,\mathrm{eV}^{-1}\,\mathrm{cm}^{-3}$. When resonant transmission dominates, the magnetoresistance will be given by

$$MR_1 = \frac{2\Pi_L \Pi_R}{(1 - \Pi\Pi')}, \tag{3.31}$$

which is only 4% in the case of Fe. We see that indeed MR_1 is suppressed yet remains positive (unless the polarization of tunnel carriers is opposite to the magnetization direction on one of the electrodes, in this case MR is obviously inverted for trivial reasons). There are speculations about a possibility of negative MR_1, which is analyzed below in the following subsection.

We have estimated the above critical DOS for localized states for the case of Al_2O_3 barrier, in systems such as amorphous Si the density of localized states is higher because of considerably smaller band gap, and estimated as $8 \times 10^{18}\,\mathrm{eV}^{-1}\,\mathrm{cm}^{-3}$, mainly due to dangling bonds and band edge smearing because of disorder [55]. One can appreciate that in junctions with thin Al_2O_3 amorphous barriers (<20–25 Å) of practical interest the impurity-assisted tunneling is not the major effect, so the above consideration of elastic tunneling applies. In this seminal work, Beasley have studied a-Si barriers with wide variety of thicknesses $w = 30$–1000 Å and obtained detailed data on crossover from direct tunneling to directed inelastic hopping along statistically rare, yet highly conductive, chains of localized states. The crossover thicknesses depend heavily on the materials parameters of the barrier. The above-described suppression of TMR by impurities was confirmed experimentally for magnetic tunnel junctions in Ref. [56].

3.4.2 Negative Resonant TMR?

It should be noted that the MR becomes suppressed yet remains positive. Indeed, the conductance is dominated, but can it change sign, or become *inverted* in the case of impurity assisted tunneling? It was shown above that the asymetry of polarized DOS in contacts gives *positive* resonant tunneling TMR. Negative (inverse MR_1) can only appear if the dominating impurity levels were lined up with the Fermi level [Equation 3.28] and positioned in asymmetric positions in the barrier, with for

example, the "right" width of the resonance much larger than the "left" width, $\Gamma_{R\sigma} \equiv \Gamma_\sigma \gg \Gamma_{L\sigma} \equiv \gamma_\sigma$

$$G_\sigma \approx \frac{e^2}{\pi\hbar}\frac{\gamma_\sigma}{\Gamma_\sigma},$$

$$\text{TMR} \sim -P_1 P_2, \ (?) \tag{3.32}$$

the latter was noted in Ref. [57]. However, the required coincidence is statistically very unlikely in tunnel junctions, where the number of impurity states involved is $\gg 1$, as in all usual situations with a possible exception of very small area tunnel junctions. Indeed, the data in Ref. [57] suggest that, in a tiny percentage of small area junctions, the TMR is negative. The attempts to simulate the amorphous barrier that may produce such a result in resonant tunneling regime showed, however, that one needs an unphysically large amount of disorder in the barrier to obtain traces of negative TMR. Indeed, for the barrier with height $U = 1.5$ eV, an unphysical amount of onsite disorder $\gamma = 4U = 6$ eV should be assumed. It must be concluded that the speculations about negative resonant TMR in Ref. [57] have nothing to do with most observations of inverse TMR. Averaging over disorder suppresses TMR, as predicted in Ref. [18] and observed in for example Ref. [56]. It is noted, however, that is the case when the impurity states are located at a particular interface in the barrier, perhaps as in tunnel junctions with composite barriers MgO/NiO [58], there may be a suppression and a slight inversion of TMR in a certain window of bias voltages, given by the energy interval occupied by the interfacial states, as described elsewhere [59].

3.4.3
Tunneling in Half-Metallic Ferromagnetic Junctions

Now we shall discuss a couple of systems with half-metallic behavior, CrO_2/TiO_2 and CrO_2/RuO_2 (Figure 3.5). These are based on half-metallic CrO_2, and all species have the rutile structure type with almost perfect lattice matching, which should yield a good interface and should help in keeping the system at the desired stoichiometry. TiO_2 and RuO_2 are used as the barrier/spacer oxides. The electronic structure of CrO_2/TiO_2 is truly stunning in that it has a half-metallic gap which is 2.6 eV wide and extends on both sides of the Fermi level, where there is a gap either in the minority *or* majority spin band. Thus, a huge magnetoresistance should, in principle, be seen not only for electrons at the Fermi level biased up to 0.5 eV, but also for *hot* electrons starting at about 0.5 eV above the Fermi level. We note that states at the Fermi level are a mixture of Cr(d) and O($2p$) states, so that p–d interaction within the first coordination shell produces a strong hybridization gap, and the Stoner spin-splitting moves the Fermi level right into the gap for minority carriers (Figure 3.5). It is worth noting that CrO_2 and RuO_2 are very similar in terms of a paramagnetic band structure, but the difference in the number of conduction electrons and exchange splitting results in a usual metallic behavior of RuO_2 as compared to the half-metallic ferromagnet CrO_2.

An important difference between two spacer oxides is that TiO_2 is an insulator whereas RuO_2 is a good metallic conductor. Thus, the former system can be used in a

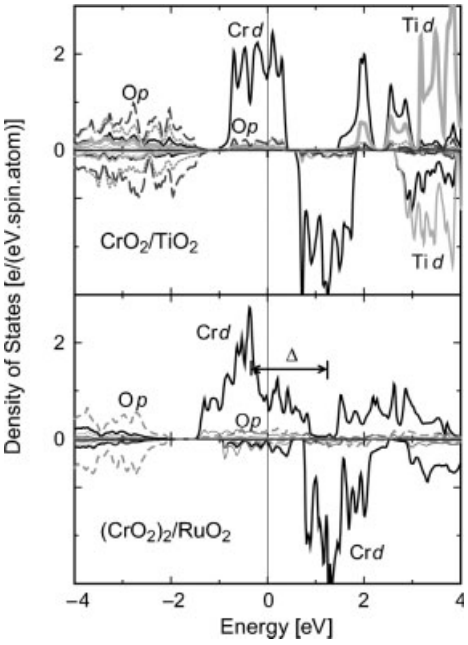

Figure 3.5 Density of states of CrO_2/TiO_2 (top panel) and $(CrO_2)_2/RuO_2$ (bottom panel) half-metallic multilayers calculated with the use of the LMTO method. The partial contributions are indicated by letters. The zero of energy corresponds to the Fermi level. Δ indicates a spin-splitting of the Cr *d* band near E_F (schematic). Note a strong hybridization of Cr *d* with O 2*p* states at E_F and below the hybridization gap. Growth direction is [001].

tunnel junction, whereas the latter will form a metallic multilayer. In the latter case the physics of conduction is different from tunnelling, but the effect of vanishing phase volume for transmitted states still works when current is passed through such a system *perpendicular to planes*. One interesting possibility is to form three-terminal devices with these systems, like a spin-valve transistor [60], and check the effect in a hot-electron region. CrO_2/TiO_2 seems to a be a natural candidate to check the present predictions about half-metallic behavior and for a possible record tunnel magnetoresistance. One important advantage of these systems is an almost perfect lattice match at the oxide interfaces. The absence of such a match of the conventional Al_2O_3 barrier with Heussler half-metallics (NiMnSb and PtMnSb) may have been among other reasons for their unimpressive performance [2]. The main concerns for achieving a very large value of magnetoresistance will be spin-flip centers, magnon-assisted events, and imperfect alignment of moments. As for conventional tunnel junctions, the present results show that presence of defect states in the barrier, or a resonant state, as in a resonant tunnel diode-type of structure, reduces their magnetoresistance several fold but may dramatically increase the current through the structure.

3.4.4
Surface States Assisted TMR

Direct tunneling, as we have seen, gives a TMR of about 30%, whereas in recent experiments TMR is well above this value, approaching 40–50% in systems with Al_2O_3 amorphous barrier, and 200% in systems with epitaxial MgO barriers [16, 52]. It will become clear below, that this enhancement is unlikely to come from the inelastic processes. Until now, we have disregarded the possibility of localized states at metal–oxide interfaces. Bearing in mind that the usual barrier AlO_x is amorphous, the density of such surface states may be high, and we must take into account tunneling into/from those states. The results for Tamm states that may exist at clean interfaces, are similar. The corresponding tunneling conductance per unit area is [19]:

$$G_s(\theta) = \frac{e^2}{\pi\hbar} B\bar{D}_s(1 + P_F P_s \cos\theta),$$

$$P_s = \frac{D_{s\uparrow} - D_{s\downarrow}}{D_{s\uparrow} + D_{s\downarrow}}, \quad \bar{D}_s = \frac{1}{2}(D_{s\uparrow} + D_{s\downarrow}), \tag{3.33}$$

where P_s is the polarization and $\bar{D}s$ is the average density of surface states, and θ is the mutual angle between moments on electrodes. The parameter $B \sim [2\pi\hbar^2 m\kappa/(m_2^2 w)]\exp(-2\kappa w)$, where w is the barrier width, κ is the absolute value of electron momentum under the barrier, m and m_2 are the free electron mass and the effective mass in the barrier, respectively. The corresponding magnetoresistance would be $MR_s = 2P_F P_s/(1 - P_F P_s)$. It is easy to show that the bulk-to-surface conductance exceeds the bulk-to-bulk one at densities of surface states $D_s > D_{sc} \sim 10^{13}\,\mathrm{cm}^{-2}\,\mathrm{eV}^{-1}$ per spin, comparable to those found at some metal–semiconductor interfaces. Since this result was obtained, various groups confirmed this with *ab-initio* calculations, usually without mentioning the original result obtained in Ref. [19].

If on both sides of the barrier the density of surface states is above the critical value D_{sc}, the magnetoresistance would be due to surface-to-surface tunneling with a value given by $MR_{ss} = 2P_{s1}P_{s2}/(1 - P_{s1}P_{s2})$. If the polarization of surface states is larger than that of the bulk, as is often the case even for imperfect surfaces [61], then it would result in enhanced TMR.

3.4.5
Inelastic Effects in TMR

Inelastic processes with excitation of magnon or phonon modes introduce new energy scales into the problem (30–100 meV) which correspond to a region where unusual I–V tunnel characteristics are seen (Figure 3.6). One can describe their effect on TMR fairly well within the tunnel Hamiltonian approach [19]. We obtain for magnon-assisted inelastic tunneling current at $T = 0$ with the use of tunnel Hamiltonian formalism [62]:

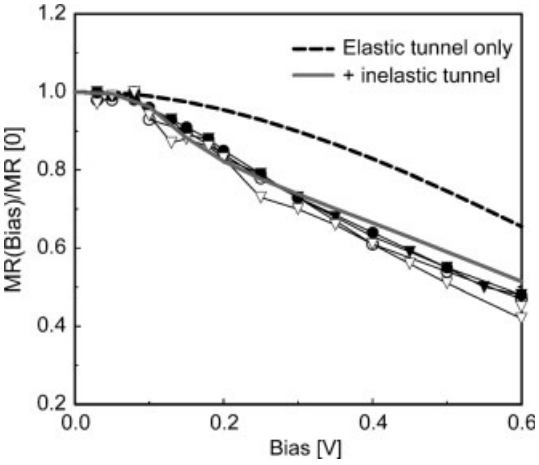

Figure 3.6 Fit to experimental data for the magnetoresistance of $CoFe/Al_2O_3/NiFe$ tunnel junctions [9] with inclusion of elastic and inelastic (magnons and phonons) tunneling. The fit gives for magnon DOS $\propto \omega^{0.65}$, which is close to a standard bulk spectrum $\propto \omega^{1/2}$.

$$
\begin{aligned}
I^x_{\mathrm{P}} &= \frac{2\pi e}{\hbar}\sum_{\alpha} X^{\alpha} g^L_{\downarrow} g^R_{\uparrow} \int d\omega \rho^{\mathrm{mag}}_{\alpha}(\omega)(eV-\omega)\theta(eV-\omega),\\
I^x_{\mathrm{AP}} &= \frac{2\pi e}{\hbar}\left[X^R g^L_{\uparrow} g^R_{\uparrow} \int d\omega \rho^{\mathrm{mag}}_{\mathrm{R}}(\omega)(eV-\omega)\theta(eV-\omega)\right.\\
&\quad \left. + X^L g^L_{\downarrow} g^R_{\downarrow} \int d\omega \rho^{\mathrm{mag}}_{\mathrm{L}}(\omega)(eV-\omega)\theta(eV-\omega)\right],
\end{aligned}
\tag{3.34}
$$

where X is the incoherent tunnel exchange vertex, $\rho^{\mathrm{mag}}_{\alpha}(\omega)$ is the magnon density of states that has a general form $\rho^{\mathrm{mag}}_{\alpha}(\omega) = (\nu+1)\omega^{\nu}/\omega_0^{\nu+1}$, the exponent ν depends on a type of spectrum, ω_0 is the maximum magnon frequency, $g_{\mathrm{L\ (R)}}$ marks the corresponding electron density of states on left (right) electrode, $\theta(x)$ is the step function, $\alpha = L,R$. The analogous expressions can be written down for phonon contribution with the important distinction that electron–phonon interaction does *not* affect spin (if one ignores any small magnetoelastic contribution). The elastic and inelastic contributions together will define the total junction conductance $G = G(V,T)$ as a function of the bias V and temperature T. We find that the inelastic contributions from magnons Equation 3.34 and phonons grow as $G^x(V,0) \propto (|eV|/\omega_0)^{\nu+1}$ and $G^{ph}(V,0) \propto (eV/\omega_D)^4$ at low biases. These contributions saturate at higher biases: $G^x(V,0) \propto 1 - \frac{i+1}{\nu+2}\frac{\omega_0}{|eV|}$ at $|eV| > \omega_0$; $G^{ph}(V,0) \propto 1 - \frac{4}{5}\frac{\omega_D}{|eV|}$ at $|eV| > \omega_D$. This behavior would lead to sharp features in the I–V curves on a scale of 30–100 mV (Figure 3.6).

It is important to highlight the opposite effects of phonons and magnons on the TMR. If we take the case of the same electrode materials and denote $D = g_{\uparrow}$ and $d = g_{\downarrow}$,

then we see that $G^{x}_{\mathrm{P}}(V,0) - G^{x}_{\mathrm{AP}}(V,0) \propto -(D-d)^2(|eV|/\omega_0)^{\nu+1} < 0$, whereas $G^{ph}_{\mathrm{P}}(V,0) - G^{ph}_{\mathrm{AP}}(V,0) \propto +(D-d)^2(eV/\omega_D)^4 > 0$; that is, spin-mixing due to magnons *kills* the TMR, whereas the phonons tend to reduce the negative effect of magnon emission [63]. Different bias and temperature dependence can make possible a separation of these two contributions, which are of opposite sign. At finite temperatures we obtain the contributions of the same respective sign as above. For magnons: $G^{x}_{\mathrm{P}}(0,T) - G^{x}_{\mathrm{AP}}(0,T) \propto -(D-d)^2(-TdM/dT) < 0$, where $M = M(T)$ is the magnetic moment of the electrode at a given temperature T. The phonon contribution is given by a standard Debye integral with the following results: $G^{ph}_{\mathrm{P}}(0,T) - G^{ph}_{\mathrm{AP}}(0,T) \propto +(D-d)^2(T/\omega_D)^4 > 0$ at $T \ll \omega_D$, and $G^{ph}_{\mathrm{P}}(0,T) - G^{ph}_{\mathrm{AP}}(0,T) \propto +(D-d)^2(T/\omega_D)$ at $T \gtrsim \omega_D$. It is worth mentioning that the magnon excitations are usually cut off, for example, by the anisotropy energy K_{an} at some ω_c. Therefore, at low temperatures the conductance at small biases will be almost constant. We conclude that the inelastic processes are responsible for TMR diminishing with bias voltage, the unusual shape of the I–V curves at low biases, and their temperature behavior, which is also affected by impurity-assisted tunneling. The surface states-assisted tunneling may lead to enhanced TMR, if their polarization is higher than that of the bulk. This could open up ways to improving performance of ferromagnetic tunnel junctions.

3.5
Spin Injection/Extraction into (from) Semiconductors

Much attention has been devoted recently to exploring the possibility of a three-terminal spin injection device where spin is injected into semiconductor from either metallic ferromagnetic electrode [67, 68], or from magnetic semiconductor electrode, as demonstrated in Ref. [64]. However, the magnetization in FMS usually vanishes or is too small at room temperature. Relatively high spin injection from ferromagnets (FM) into non-magnetic semiconductors (S) has recently been demonstrated at low temperatures [65], and the attempts to achieve an efficient room-temperature spin injection have faced substantial difficulties [66]. Theoretical studies of the spin injection from ferromagnetic metals, as initiated in Refs. [68, 69], have been subject of extensive research in Refs. [5–10, 69–77] that has gained much insight into the problem of spin injection/accumulation in semiconductors. As a consequence, some suggestions for *spin transistors* and other spintronic devices have appeared that are experimentally realizable, can work at room temperatures, and exceed the parameters of standard semiconductor analogues [5, 6].

As an important distinction with spin transport in magnetic tunnel junctions, one would like to create non-equilibrium spin polarization and manipulate it with external fields in semiconductors, with a possible advantage of long spin relaxation time in comparison with mean collision time. In order to be interesting for applications, there should be a straightforward method of creating substantial non-equilibrium spin polarization *density* in semiconductor. This is different from

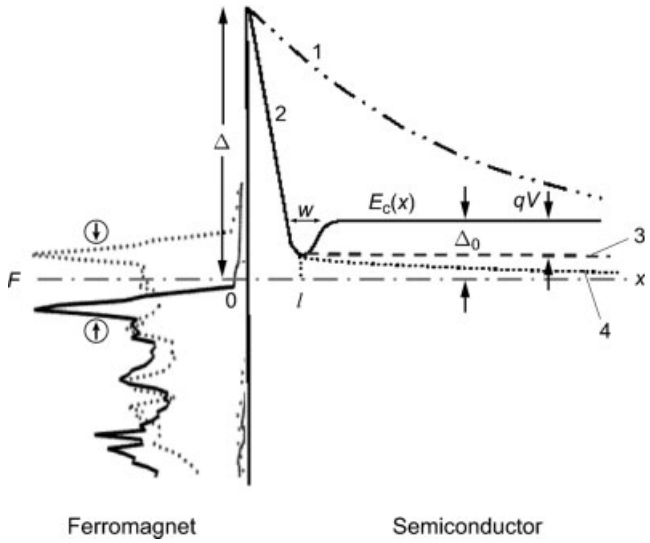

Figure 3.7 Energy diagrams of ferromagnet-semiconductor heterostructure with δ-doped layer (F is the Fermi level; Δ the height and l the thickness of an interface potential barrier; Δ_0 the height of the thermionic barrier in n-semiconductor). The standard Schottky barrier (curve 1); $E_c(x)$ the bottom of conduction band in n-semiconductor in equilibrium (curve 2), under small (curve 3), and large (curve 4) bias voltage. The spin-polarized density of states in Ni is shown at $x < 0$.

tunnel junctions, where one is interested in large spin injection efficiency; that is, in large resistance change with respect to magnetic configuration of the electrodes. Obviously, a spin imbalance in the drain ferromagnetic electrode is created in MTJ, proportional to the current density, but relatively minute, given a huge density of carriers in a metal. The principal difficulty of *spin injection* in semiconductor from ferromagnet is that the materials in the FM-S junctions usually have very different electron affinity and, therefore, high Schottky barrier forms at the interface [78] (Figure 3.7, curve 1). Thus, in GaAs and Si the barrier height $\Delta \simeq 0.5$–0.8 eV with practically all metals, including Fe, Ni, and Co [65, 78], and the barrier width is large, $l \gtrsim 100$ nm for doping concentration $N_d \lesssim 10^{17}\,\mathrm{cm}^{-3}$. The spin-injection corresponds to a reverse current in the Schottky contact, which is saturated and usually negligible due to such large l and Δ [78]. Therefore, a thin heavily doped $n^+ - \mathrm{S}$ layer between FM metal and S is used to increase the reverse current [78] determining the spin-injection [6, 8, 65, 72]. This layer sharply reduces the thickness of the barrier, and increases its tunneling transparency [6, 78]. Thus, a substantial spin injection has been observed in FM-S junctions with a thin n^+–layer [65].

One usually overlooked formal paradox of spin injection is that a current through Schottky junctions (as derived in textbooks) depends solely on parameters of a semiconductor [78], and cannot formally be spin-polarized. Some authors even

emphasize that in Schottky junctions "spin-dependent effects do not occur" [70]. In earlier reports [67–76], spin transport through FM-S junction, its spin-selective properties, and non-linear I–V characteristics have not been actually calculated. They were described by various, often contradictory, boundary conditions at the FM-S interface. For example, Aronov and Pikus assumed that *spin injection efficiency* of a FM-S interface is a constant equal to that in the ferromagnet FM, $\Gamma = \Gamma_F$, [Equation 3.3], and then studied non-linear spin accumulation in S considering spin diffusion and drift in an electric field [67]. The authors of Refs. [68–72] assumed a continuity of both the currents and the electrochemical potentials for both spins, and found that a spin polarization of injected electrons depends on a ratio of conductivities of a FM and S (the so-called "conductivity mismatch" problem). At the same time, it has been asserted in Refs. [73–76] that the spin injection becomes appreciable when the electrochemical potentials have a substantial discontinuity (produced e.g., by a tunnel barrier [74]). The effect, however, was described by the unknown spin-selective interface conductances $G_{i\sigma}$, which cannot be found within those theories.

We have developed a microscopic theory of the spin transport through ferromagnet-semiconductor junctions, which include an ultrathin heavily doped semiconductor layer (δ-doped layer) between FM and S [6, 8]. We have studied the non-linear effects of spin accumulation in S near reverse-biased modified FM-S junctions with the δ-doped layer [6] and spin extraction from S near the modified forward-biased FM-S junctions [8]. We found conditions for the most efficient spin injection, which are *opposite* to the results of previous phenomenological theories. We show, in particular, that: (i) the current of the FM-S junction does depend on spin parameters of the ferromagnetic metal but *not* its conductivity, so, contrary to the results [68–72, 74–76], the "conductivity mismatch" problem *does not exist* for the Schottky FM-S junctions. We find also that: (ii) a spin injection efficiency Γ of the FM-S junction depends strongly on the current, contrary to the assumptions in [67–72, 74–76]; and (iii) the highest spin polarization of both the injected electrons P and spin injection efficiency can be realized at room temperatures and relatively small currents in *high-resistance* semiconductors, *contrary* to claims in Ref. [71], which are of most interest for spin injection devices [3, 4, 6]. We also show that: (iv) tunneling resistance of the FM-S junction must be relatively small, which is *opposite* to the condition obtained in linear approximation in Ref. [74]; and that (v) the spin-selective interface conductances $G_{i\sigma}$ are not constants, as was assumed in Ref. [73–76], but vary with a current J in a strongly non-linear fashion. We have suggested a new class of spin devices on the basis of the present theory.

Below, we describe a general theory of spin current, spin injection and extraction in Section 3.5.1, followed by the discussion of the conditions of an efficient spin injection and extraction in Section 3.5.2. Further, we turn to the discussion of high-frequency spin valve effect in a system with two δ-doped Schottky junctions in Section 3.5.3 A new class of spin devices is detailed in Section 3.5.3 field detector, spin transistor, and square-law detector. The efficient spin injection and extraction may be a basis for efficient sources of (modulated) polarized radiation, as mentioned in Section 3.5.4.

3.5.1
Spin Tunneling through Modified (Delta-Doped) Schottky Barrier

The modified FM-S junction with transparent Schottky barrier is produced by δ-doping the interface by sequential donor and acceptor doping. The Schottky barrier is made very thin by using large donor doping N_d^+ in a thin layer of thickness l. For reasons which will become clear shortly, we would like to have a narrow spike followed by the narrow potential well with in the width w and the depth $\sim rT$, where T is the temperature in units of $k_B = 1$ and $r \sim 2$–3, produced by an acceptor doping N_a^+ of the layer w (Figure 3.7). Here $l \lesssim l_0$, where $l_0 = \sqrt{\hbar^2/[2m_*(\Delta - \Delta_0)]}$ ($l_0 \lesssim 2$ nm), the remaining low (and wide) barrier will have the height $\Delta_0 = (E_{c0} - F) > 0$, where E_{c0} is the bottom of the conduction band in S in equilibrium, q the elementary charge, and ϵ (ϵ_0) the dielectric permittivity of S (vacuum). A value of Δ_0 can be set by choosing a donor concentration in S,

$$N_d = N_c \exp\left[\frac{(F^S - E_{c0})}{T}\right] = N_c \exp\left(\frac{-\Delta_0}{T}\right) = n, \tag{3.35}$$

where F^S is the Fermi level in the semiconductor bulk, $N_c = 2M_c(2\pi m_* T)^{3/2}h^{-3}$ the effective density of states and M_c the number of effective minima of the semiconductor conduction band; n and m_* the concentration and effective mass of electrons in S [79]. Owing to small barrier thickness l, the electrons can rather easily tunnel through the δ-spike, but only those with an energy $E \geq E_c$ can overcome the wide barrier Δ_0 due to thermionic emission, where $E_c = E_{c0} + qV$. We assume here the standard convention that the bias voltage $V < 0$ and current $J < 0$ in the reverse-biased FM-S junction and $V > 0$ ($J > 0$) in the forward-biased FM-S junction [78]. At positive bias voltage $V > 0$, we assume that the bottom of conduction band shifts upwards to $E_c = E_{c0} + qV$ with respect to the Fermi level of the metal. Presence of the mini-well allows to keep the thickness of the δ-spike barrier equal to $l \lesssim l_0$ and its transparency high at voltages $qV \lesssim rT$ (see below).

The calculation of current through the modified barrier is rather similar to what has been done in the case of tunnel junctions above, with a distinction that in the present case the barrier is triangular, (Figure 3.7). We again assume elastic coherent tunneling, so that the energy E, spin σ, and $\vec{k}_{||}$ (the component of the wave vector $\vec{k}$ parallel to the interface) are conserved. The exact current density of electrons with spin $\sigma = \uparrow, \downarrow$ through the FM-S junction containing the δ-doped layer (at the point $x = l$; Figure 3.7) is written similarly to Equaion 3.24 as:

$$J_{\sigma 0} = \frac{q}{h}\int dE[f(E - F^S_{\sigma 0}) - f(E - F^{FM}_{\sigma 0})] \int \frac{d^2 k_{\|}}{(2\pi)^2} T_\sigma, \tag{3.36}$$

where $F^S_{\sigma 0}(F^{\mathrm{FM}}_{\sigma 0})$ are the spin quasi-Fermi levels in the semiconductor (ferromagnet) near the FM-S interface, and the integration includes a summation with respect to a band index. Note that here we study a strong *spin accumulation* in the semiconductor. Therefore, we use *nonequilibrium* Fermi levels, $F^{\mathrm{FM}}_{\sigma 0}$ and $F^S_{\sigma 0}$, describing distributions

of electrons with spin $\sigma = \uparrow,\downarrow$ in the FM and the S, respectively, which is especially important for the semiconductor. In reality, due to very high electron density in FM metal in comparison with electron density in S, $F_{\sigma 0}^{FM}$ differs negligibly from the equilibrium Fermi level F for currents under consideration; therefore, we can assume that $F_{\sigma 0}^{FM} = F$, as in Refs. [18, 52] (see discussion below).

The current Equation 3.36 should generally be evaluated numerically for a complex band structure $E_{k\sigma}$ [79]. The analytical expressions for $T_\sigma(E, k_{||})$ can be obtained in an effective mass approximation, $\hbar k_\sigma = m_\sigma v_\sigma$, where $v_\sigma = |\nabla E_{k\sigma}|/\hbar$ is the band velocity in the metal. The present Schottky barrier has a "pedestal" with a height $(E_c - F) = \Delta_0 + qV$, which is opaque at energies $E < E_c$. For $E > E_c$ we approximate the δ-barrier by a triangular shape and one can use an analytical expression for $T_\sigma(E, k_{||})$ [5] and find the spin current at the bias $0 < -qV \lesssim rT$, including at room temperature,

$$J_{\sigma 0} = j_0 d_\sigma \left[\frac{2n_{\sigma 0}(V)}{n} - \exp\left(-\frac{qV}{T} \right) \right], \tag{3.37}$$

$$j_0 = \alpha_0 n q v_T \exp(-\eta \kappa_0 l). \tag{3.38}$$

with the most important spin factor

$$d_\sigma = \frac{v_T v_{\sigma 0}}{v_{t0}^2 + v_{\sigma 0}^2}. \tag{3.39}$$

Here $\alpha_0 = 1.2(\kappa_0 l)^{1/3}$, $\kappa_0 \equiv 1/l_0 = (2m_*/\hbar^2)^{1/2}(\Delta - \Delta_0 - qV)^{1/2}$, $v_{t0} = \sqrt{2(\Delta - \Delta_0 - qV)/m_*}$ is the characteristic "tunnel" velocity, $v_\sigma = v_\sigma(E_c)$ the velocity of polarized electrons in FM with energy $E = E_c$, $v_T = \sqrt{3T/m_*}$ the thermal velocity. At larger reverse bias the miniwell on the right from the spike in Figure 3.7 disappears and the current practically saturates. Quite clearly, the tunneling electrons incident almost normally at the interface and contribute most of the current (a more careful sampling can be done numerically [79]).

One can see from Equation 3.30 that the total current $J = J_{\uparrow 0} + J_{\downarrow 0}$ and its spin components $J_{\sigma 0}$ depend on a conductivity of a semiconductor but *not* a ferromagnet, as in usual Schottky junction theories [79]. On the other hand, $J_{\sigma 0}$ is proportional to the spin factor d_σ and the coefficient $j_0 d_\sigma \propto v_T^2 \propto T$, but not the usual Richardson's factor T^2 [78]. Equation 3.37, for current in the FM-S structure, is valid for any sign of the bias voltage V. Note that at $V > 0$ (forward bias) it determines the spin current from S into FM. Hence, it describes *spin extraction* from S [8].

Following the pioneering studies of Aronov and Pikus [67], one customarily assumes a boundary condition $J_{\uparrow 0} = (1 + \Gamma_F)J/2$. Since there is a spin accumulation in S near the FM-S boundary, the density of electrons with spin σ in the semiconductor is $n_{\sigma 0} = n/2 + \delta n_{\sigma 0}$, where $\delta n_{\sigma 0}$ is a non-linear function of the current J, and $\delta n_{\sigma 0} \propto J$ at small current [67] (see also below). Therefore, the larger J the higher the $\delta n_{\sigma 0}$ and the smaller the current $J_{\sigma 0}$ [see Equation 3.37]. In other words, a type of negative feedback is realized, which decreases the spin injection efficiency Γ and

makes it a non-linear function of J (see below). We show that the spin injection efficiency, Γ_0, and the polarization, $P_0 = [n_\uparrow(0) - n_\downarrow(0)]/n$ in the semiconductor near FM-S junctions essentially differ, and that both are small at small bias voltage V (and current J) but *increase* with the current up to P_F. Moreover, P_F can essentially differs from Γ_F, and may ideally approach 100%.

The current in a spin channel σ is given by the standard drift-diffusion approximation [67, 76]:

$$J_\sigma = q\mu n_\sigma E + qD\nabla n_\sigma, \tag{3.40}$$

where E is the electric field; and D and μ are the diffusion constant and mobility of the electrons respectively. D and μ do not depend on the electron spin σ in the non-degenerate semiconductors. From current continuity and electroneutrality conditions

$$J(x) = \sum_\sigma J_\sigma = \text{const}, \quad n(x) = \sum_\sigma n_\sigma = \text{const}, \tag{3.41}$$

we find

$$E(x) = J/q\mu n = \text{const}, \quad \delta n_\downarrow(x) = -\delta n_\uparrow(x). \tag{3.42}$$

Since the *injection* of spin-polarized electrons from FM into S corresponds to a reverse current in the Schottky FM-S junction, one has $J < 0$, and $E < 0$ Figure 3.7. The spatial distribution of density of electrons with spin σ in the semiconductor is determined by the continuity equation [67, 71]

$$\nabla J_\sigma = \frac{q\delta n_\sigma}{\tau_s}, \tag{3.43}$$

where in the present one-dimensional case $\nabla = d/dx$. With the use of Equations 3.40 and 3.42, we obtain the equation for $\delta n_\uparrow(x) = -\delta n_\downarrow(x)$ [67, 76]. Its solution satisfying a boundary condition $\delta n_\uparrow \to 0$ at $x \to \infty$, is

$$\delta n_\uparrow(x) = C\frac{n}{2}\exp\left(-\frac{x}{L}\right) \equiv P_{n0}\exp\left(-\frac{x}{L}\right), \tag{3.44}$$

$$L_{\text{inject (extract)}} = \frac{1}{2}\left[\sqrt{L_E^2 + 4L_s^2} + (-)L_E\right] = \frac{L_s}{2}\left(\sqrt{\frac{J^2}{J_S^2} + 4} - \frac{J}{J_S}\right), \tag{3.45}$$

where the plus (minus) sign refers to forward (reverse) bias on the junction, $L_s = \sqrt{D\tau_s}$ is the usual spin-diffusion length, $L_E = \mu|E|\tau_s = L_s|J|/J_s$ the spin-drift length. Here we have introduced the characteristic current density

$$J_S \equiv qDn/L_s, \tag{3.46}$$

and the plus and minus signs in the expression for the spin penetration depth L Equation 3.45 refer to the spin *injection* at a reverse bias voltage, $J < 0$, and spin *extraction* at a forward bias voltage, $J > 0$, respectively. Note that $L_{\text{inject}} > L_{\text{extract}}$, and the spin penetration depth for injection increases with current, at large currents, $|J| \gg J_S$, $L_{\text{inject}} = L_s|J|/J_s \gg L_s$, whereas $L_{\text{extract}} = L_sJ_s/J \ll L_s$.

The degree of spin polarization of non-equilibrium electrons (i.e., a spin *accumulation* in the semiconductor near the interface) is given simply by the parameter C in Equation 3.37:

$$C = \frac{n_\uparrow(0) - n_\downarrow(0)}{n} = P(0) \equiv P_0. \tag{3.47}$$

By substituting Equation 3.44 into Equations 3.40 and 3.37, we find

$$J_{\uparrow 0} = \frac{J}{2}\left(1 + P_0 \frac{L}{L_E}\right) = \frac{J}{2}\frac{(1+P_F)(\gamma - P_0)}{\gamma - P_0 P_F}, \tag{3.48}$$

where $\gamma = \exp(-qV/T) - 1$. From Equation 3.41, one obtains a quadratic equation for $P_n(0)$ with a physical solution that can be written fairly accurately as

$$P_0 = \frac{P_F \gamma L_E}{\gamma L + L_E}. \tag{3.49}$$

By substituting Equation 3.49 into Equation 3.37, we find for the total current $J = J_{\uparrow 0} + J_{\downarrow 0}$:

$$J = -J_m \gamma = -J_m(e^{-qV/T} - 1), \tag{3.50}$$

$$J_m = \alpha_0 n q v_T (1 - P_F^2)(d_{\uparrow 0} + d_{\downarrow 0}) e^{-\eta \kappa_0 l}, \tag{3.51}$$

for the bias range $|qV| \lesssim rT$. The sign of the Boltzmann exponent is unusual because we consider the tunneling thermoemission current in a modified barrier. Obviously, we have $J > 0$ (<0) when $V > 0$ (<0) for forward (reverse) bias.

We notice that at a reverse bias voltage $-qV \simeq rT$ the shallow potential mini-well vanishes, and $E_c(x)$ takes the shape shown in Figure 3.7 (curve 3). For $-qV > rT$, a wide potential barrier at $x > l$ (in S behind the spike) remains flat (characteristic length scale $\gtrsim 100\,\text{nm}$ at $N_d \lesssim 10^{17}\,\text{cm}^{-3}$), as in usual Schottky contacts [78]. Therefore, the current becomes weakly dependent on V, since the barrier is opaque for electrons with energies $E < E_c - rT$ (curve 4). Thus, Equation 3.50 is valid only at $-qV \lesssim rT$ and the reverse current at $-qV \gtrsim rT$ practically saturates at the value

$$J_{\text{sat}} = qn\alpha_0 v_T (d_{\uparrow 0} + d_{\downarrow 0})(1 - P_F^2)\exp(r - \eta\kappa_0 l). \tag{3.52}$$

With the use of Equations 3.50 and 3.45, we obtain from Equation 3.42 the spin polarization of electrons near FM-S interface,

$$P_0 = -P_F \frac{2J}{2J_m + \sqrt{J^2 + 4J_S^2} - J}. \tag{3.53}$$

The spin injection efficiency at FM-S interface is, using Equations 3.30, 3.41, 3.38 and 3.46,

$$\Gamma_0 \equiv \frac{J_{\uparrow 0} - J_{\downarrow 0}}{J_{\uparrow 0} + J_{\downarrow 0}} = P_0 \frac{L}{L_E} = -P_F \frac{\sqrt{4J_S^2 + J^2} - J}{2J_m + \sqrt{J^2 + 4J_S^2} - J}. \tag{3.54}$$

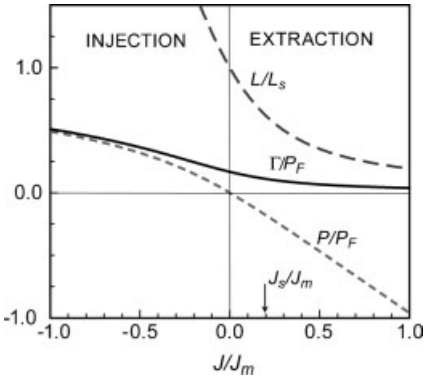

Figure 3.8 The spin accumulation $P = (n_\uparrow - n_\downarrow)/n$, the spin polarization of a current $\Gamma = (J_\uparrow - J_\downarrow)/J$, and the relative spin penetration depth L/L_s (broken line) in the semiconductor as the functions of the relative current density J/J_s for spin injection ($J < 0$) and spin extraction ($J > 0$) regimes. P_F is the spin polarization in the ferromagnet, the ratio $J_s/J_m = 0.2$, L_s is the usual spin diffusion depth. The spin penetration depth considerably exceeds L_s for the injection and smaller than L_s for the extraction.

One can see that Γ_0 strongly differs from P_0 at small currents. As expected, $P_n \approx P_F|J|/J_m \to 0$ vanishes with the current (Figure 3.8), and the prefactor differs from those obtained in Refs. [67, 71, 73, 75, 76].

These expressions should be compared with the results for the case of a degenerate semiconductor, Ref. [10], for the polarization

$$P_0 = -\frac{6P_F J}{3\left(\sqrt{J^2 + 4J_S^2} - J\right) + 10J_m}, \tag{3.55}$$

and the spin injection efficiency

$$\Gamma_0 = -P_F \frac{\sqrt{4J_S^2 + J^2} - J}{2J_m + \sqrt{J^2 + 4J_S^2} - J}. \tag{3.56}$$

In spite of very different statistics of carriers in a degenerate and non-degenerate semiconductor, the accumulated polarization as a function of current behaves similarly in both cases. The important difference comes from an obvious fact that the efficient spin accumulation in degenerate semiconductors may proceed at and below room temperature, whereas in present design an efficient spin accumulation in FM-S junctions with non-degenerate S can be achieved at around room temperature only.

In the reverse-biased FM-S junctions the current $J < 0$ and, according to Equations 3.46 and 3.47, sign $(\delta n_{\uparrow 0}) = \text{sign}\ (P_F)$. In some realistic situations, like elemental Ni, the polarization at energies $E \approx F + \Delta_0$ would be negative, $P_F < 0$ and, therefore, electrons with spin $\sigma = \downarrow$ will be accumulated near the interface. For large currents $|J| \gg J_S$, the spin penetration depth L in Equation 3.45 increases with

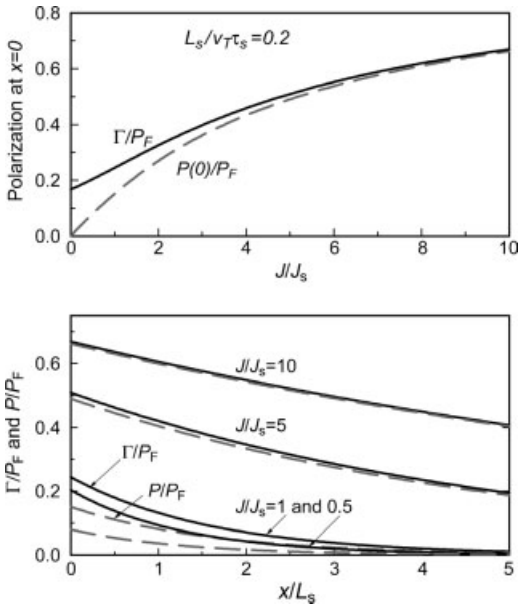

Figure 3.9 Spin polarization of a current $\Gamma = (J_\uparrow - J_\downarrow)/J$ (solid line) and spin accumulation $P = (n_\uparrow - n_\downarrow)/n$ (broken line) in the semiconductor as the functions of the relative current density J/J_s (top panel) and their spatial distribution for different densities of total current J/J_s (bottom panel) at $L_s/v_T\tau_s = 0.2$ where $J_s = qnL_s/\tau_s$, P_F is the spin polarization in the ferromagnet (see text).

current J and the spin polarization (of electron density) approaches the maximum value P_F. Unlike the spin accumulation P_0, the spin injection efficiency (polarization of current) Γ_0 does not vanish at small currents, but approaches the value $\Gamma_0^0 = P_F J_S/(J_S + J_m) \ll P_F$ in the present system with transparent tunnel δ-barrier. There is an important difference with the magnetic tunnel junctions, where the tunnel barrier is relatively opaque and the injection efficiency (polarization of current) is high, $\Gamma \approx P_F$ [18]. However, the polarization of carriers P_0, measured in, for example, spin-LED devices [66], would be minute (see below). Both P_0 and Γ_0 approach the maximum P_F only when $|J| \gg J_S$, (Figure 3.9). The condition $|J| \gg J_S$ is fulfilled at $qV \simeq rT \gtrsim 2T$, when $J_m \gtrsim J_S$.

Another situation is realized *in the forward-biased FM-S junctions* when $J > 0$. Indeed, according to Equations 3.53 and 3.54 at $J > 0$ the electron density distribution is such that sign $(\delta n_{\uparrow 0}) = -$sign (P_F). If a system like elemental Ni is considered (Figure 3.7), then $P_F(F + \Delta_0) < 0$ and $\delta n_{\uparrow 0} > 0$; that is, the electrons with spin $\sigma = \uparrow$ would be accumulated in a non-magnetic semiconductor (NS), whereas electrons with spin $\sigma = \downarrow$ would be extracted from NS (the opposite situation would take place for P_F $(F + \Delta_0) > 0$). One can see from Equation 3.46 that $|P_0|$ one can reach a

maximum P_F only when $J \gg J_s$. According to Equation 3.50, the condition $J \gg J_s$ can only be fulfilled when $J_m \gg J_s$. In this case Equation 3.46 reduces to

$$P_0 = \frac{-P_F J}{J_m} = -P_F(1 - e^{-qV/T}). \tag{3.57}$$

Therefore, the absolute magnitude of a spin polarization approaches its maximal value $|P_0| \simeq P_F$ at $qV \gtrsim 2T$ linearly with current (Figure 3.8). The maximum is reached when J approaches the value J_m, which depends weakly on bias V (see below). In this case $\delta n_{\uparrow(\downarrow)}(0) \approx \mp P_F n/2$ at $P_F > (d_\uparrow > d_\downarrow)$, so that the electrons with spin $\sigma = \uparrow$ are *extracted*, $n_\uparrow(0) \approx (1 - P_F)n/2$, from a semiconductor, while the electrons with spin $\sigma = \downarrow$ are *accumulated* in a semiconductor, $n_\uparrow(0) \approx (1 + P_F)n/2$, near the FM-S interface. The penetration length of the accumulated spin Equation 3.45 at $J \gg J_s$ is

$$L = \frac{L_s^2}{L_E} = \frac{L_s J_S}{J \ll L_s} \ll L_s \quad \text{at} \quad J \gg J_S, \tag{3.58}$$

that is, it decreases as $L \propto 1/J$ (Figure 3.8). We see from Equation 3.54 that at $J \gg J_s$

$$\Gamma_0 = \frac{P_F J_S^2}{J_m J} \to 0. \tag{3.59}$$

Hence, the behavior of the spin injection efficiency at forward bias (extraction) is very different from a spin injection regime, which occurs at a reverse bias voltage: here, the spin injection efficiency Γ_0 remains $\ll P_F$ and vanishes at large currents as $\Gamma_0 \propto J_s/J$. Therefore, we come to an unexpected conclusion that *the spin polarization of electrons,* accumulated in a non-magnetic semiconductor near forward biased FM-S junction can be relatively large for the parameters of the structure when the spin injection efficiency is actually very *small* [8]. Similar, albeit much weaker phenomena are possible in systems with *wide opaque* Schottky barriers [80] and have been probably observed [81]. Spin extraction may also be observed at low temperature in FMS-S contacts [82]. A proximity effect leading to polarization accumulation in FM-S contacts [83] may be related to the same mechanism.

3.5.2
Conditions for Efficient Spin Injection and Extraction

According to Equations 3.51 and 3.46, the condition for maximal polarization of electrons P_n can be written as

$$J_m \gtrsim J_s, \tag{3.60}$$

or, equivalently, as a condition

$$\beta \equiv \frac{\alpha_0 \upsilon_T (d_{\uparrow 0} + d_{\downarrow 0})(1 - P_F^2) e^{-\eta l/l_0} \tau_s}{L_s} \gtrsim 1. \tag{3.61}$$

Note that when $l \lesssim l_0$, the spin injection efficiency at small current is small $\Gamma_0^0 = P_F/(1+\beta) \gg P_F$, since in this case the value $\beta \simeq (d_{\uparrow 0} + d_{\downarrow 0})\alpha_0 \nu_T \tau_s / L_s \gg 1$ for

real semiconductor parameters. The condition $\beta \gg 1$ can be simplified and rewritten as a requirement for the spin-relaxation time

$$\tau_s \gg D\left(\frac{\Delta - \Delta_0}{2\alpha_0 \nu_{\sigma 0}^2 T}\right)^2 \exp\frac{2\eta l}{l_0}. \tag{3.62}$$

It can be met only when the δ-doped layer is very thin, $l \lesssim l_0 \equiv \kappa_0^{-1}$. With typical semiconductor parameters at $T \simeq 300\,\mathrm{K}$ ($D \approx 25\,\mathrm{cm}^2\ \mathrm{s}^{-1}$, $(\Delta - \Delta_0) \simeq 0.5\,\mathrm{eV}$, $\upsilon_{\sigma 0}$ $10^8 \mathrm{cm}^2\ \mathrm{s}^{-1}$ [78]) the condition in Equation 3.62 is satisfied at $l \lesssim l_0$ when the spin-coherence time $\tau_s \gg 10^{-12}\,\mathrm{s}$. It is worth noting that it can certainly be met: for instance, τ_s can be as large as ~1 ns even at $T \simeq 300\,\mathrm{K}$ (e.g., in ZnSe [84]).

Note that the higher the semiconductor conductivity, $\sigma_s = q\mu n \propto n$, the larger the threshold current $J > J_m \propto n$ [Equation 3.51]for achieving the maximal spin injection. In other words, the polarization P_0 reaches the maximum value P_F at *smaller* current in *high-resistance* lightly doped semiconductors compared to heavily doped semiconductors. Therefore, the "conductivity mismatch" [70, 74, 75] is actually irrelevant for achieving an efficient spin injection.

The necessary condition $|J| \gg J_s$ can be rewritten at small voltages, $|qV| \ll T$, as

$$r_c \ll \frac{L_s}{\sigma_s}, \tag{3.63}$$

where $r_c = (dJ/\mathrm{d}V)^{-1}$ is the tunneling contact resistance. Here, we have used the Einstein relation $D/\mu = T/q$ for non-degenerate semiconductors. We emphasize that Equation 3.63 is *opposite* to the condition found by Rashba in Ref. [74] for small currents.

We also emphasize that the spin injection in structures considered in the literature [4, 65–76] has been dominated by electrons at the Fermi level and, according to calculation [85], $g_\downarrow(F)$ and $g_\uparrow(F)$ are such that $P_F \lesssim 40\%$. We also notice that the condition in Equation 3.61 for parameters of the Fe/AlGaAs heterostructure studied in Refs. [65] ($l \simeq 3\,\mathrm{nm}$, $l_0 \simeq 1\,\mathrm{nm}$ and $\Delta_0 = 0.46\,\mathrm{eV}$) is satisfied when $\tau_s \gtrsim 5 \times 10^{-10}\,\mathrm{s}$ and can be fulfilled only at low temperatures. Moreover, for the concentration $n = 10^{19}\,\mathrm{cm}^{-3}$ E_c lies below F, so that the electrons with energies $E \simeq F$ are involved in tunneling, but for these states the polarization is $P_F \lesssim 40\%$. Therefore, the authors of Ref. [65] were indeed able to estimate the observed spin polarization as being ≈32% at low temperatures.

Better control of the injection can be realized in heterostructures where a δ-layer between the ferromagnet and the *n*-semiconductor layer is made of very thin heavily doped n^+-semiconductor with larger electron affinity than the *n*-semiconductor. For instance, FM–n^+-GaAs–*n*-$Ga_{1-x}Al_xAs$, FM–n^+-Ge_xSi_{1-x}–*n*-Si or FM–n^+-Zn_{1-x} Cd_x Se–*n*-ZnSe heterostructures can be used for this purpose. The GaAs, Ge_xSi_{1-x} or $Zn_{1-x}Cd_xSe$$n^+$–layer must have the width $l < 1\,\mathrm{nm}$ and the donor concentration $N_d^+ > 10^{20}\mathrm{cm}^{-3}$. In this case, the ultrathin barrier forming near the ferromagnet-semiconductor interface is transparent for electron tunneling. The barrier height Δ_0 at Ge_xSi_{1-x}–Si, GaAs–$Ga_{1-x}Al_xAs$ or $Zn_{1-x}Cd_xSe$–ZnSe interface is controlled by the composition x, and can be selected as $\Delta_0 = 0.05$–$0.15\,\mathrm{eV}$. When the donor concentration in Si, $Ga_{1-x}Al_xAs$, or ZnSe layer is $N_d < 10^{17}\,\mathrm{cm}^{-3}$, the injected electrons cannot penetrate relatively low and wide barrier Δ_0 when its width $l_0 > 10\,\mathrm{nm}$.

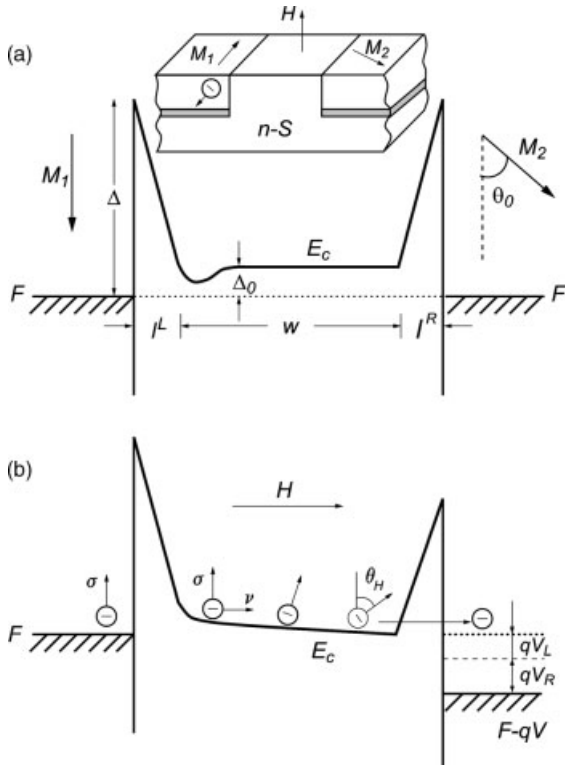

Figure 3.10 Energy diagram of a the FM-S-FM heterostructure with δ-doped layers in equilibrium (a) and at a bias voltage V (b), with V_L (V_R) the fraction of the total drop across the left (right) δ-layer. F marks the Fermi level, Δ the height, $l^{L(R)}$ the thickness of the left (right) δ-doped layer, Δ_0 the height of the barrier in the n-type semiconductor (n-S), E_c the bottom of conduction band in the n-S, w the width of the n-S part. The magnetic moments on the FM electrodes $\vec{M}_1$ and $\vec{M}_2$ are at some angle θ_0 with respect to each other. The spins, injected from the left, drift in the semiconductor layer and rotate by the angle θ_H in the external magnetic field H. Inset: schematic of the device, with an oxide layer separating the ferromagnetic films from the bottom semiconductor layer.

3.5.3
High-Frequency Spin-Valve Effect

Here we describe a new high-frequency spin valve effect that can be observed in a FM-S-FM device with two back-to-back modified Schottky contacts (Figure 3.10). We find the dependence of current on a magnetic configuration in FM electrodes and an external magnetic field. The spatial distribution of spin-polarized electrons is determined by the continuity [Equation 3.43] and the current in spin channel σ is given by Equation 3.40. Note that $J < 0$, thus $E < 0$ in a spin injection regime. With the use of the kinetic equation and Equation 3.40, we obtain the equation for $\delta n_\uparrow$, Equation 3.43 [68]. Its general solution is

$$\delta n_{\uparrow}(x) = \frac{n}{2}(c_1 e^{-x/L_1} + c_2 e^{-(w-x)/L_2}), \tag{3.64}$$

where $L_{1(2)} = (1/2)[\sqrt{L_E^2 + 4L_s^2} + (-)L_E]$ is the same as found earlier in Equation 3.45. Consider the case when $w \ll L_1$ and the transit time $t_{tr} \simeq w^2/(D + \mu|E|w)$ of the electrons through the *n*-semiconductor layer is shorter than τ_s. In this case, a spin ballistic transport takes place; that is, the spin of the electrons injected from the FM_1 layer is conserved in the semiconductor layer, $\sigma' = \sigma$. Probabilities of the electron spin $\sigma = \uparrow$ to have the projections along $\pm\vec{M}_2$ are $\cos^2(\theta/2)$ and $\sin^2(\theta/2)$, respectively, where θ is the angle between vectors $\sigma = \uparrow$ and $\vec{M}_2$. Accounting for this, we find that the resulting current through the structure saturates at bias voltage $-qV > T$ at the value

$$J = J_0 \frac{1 - P_R^2 \cos^2\theta}{1 - P_L P_R \cos\theta}, \tag{3.65}$$

where J_0 is the prefactor similar to Equation 3.38. For the *opposite* bias the total current J is given by Equation 3.65 with the replacement $P_L \leftrightarrow P_R$. The current J is minimal

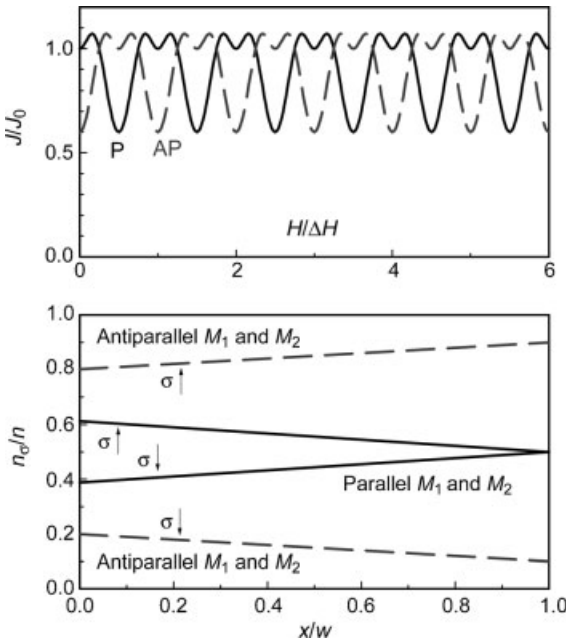

Figure 3.11 Oscillatory dependence of the current J through the structure on the magnetic field H (top panel) for parallel (P) and antiparallel (AP) moments M_1 and M_2 on the electrodes, Figure 3.10, and $P_L = P_R = 0.5$. Spatial distribution of the spin polarized electrons $n_{\uparrow(\downarrow)}/n$ in the structure for different configurations of the magnetic moments M_1 and M_2 in the limit of saturated current density J, $w = 60$ nm, $L_2 = 100$nm (bottom panel).

for antiparallel (AP) moments $\vec{M}_1$ and $\vec{M}_2$ in the electrodes when $\theta = \pi$ and near maximal for parallel (P) magnetic moments $\vec{M}_1$ and $\vec{M}_2$.

The present heterostructure has an additional degree of freedom, compared to tunneling FM-I-FM structures that can be used for *magnetic sensing*. Indeed, spins of the injected electrons can precess in an external magnetic field H during the transit time t_{tr} of the electrons through the semiconductor layer ($t_{tr} < \tau_s$). The angle between the electron spin and the magnetization $\vec{M}_2$ in the FM_2 layer in Equation 3.65 is in general $\theta = \theta_0 + \theta_H$ where θ_0 is the angle between the magnetizations M_1 and M_2, and $\theta_H = \gamma_0 g H t_{tr}(m_0/m_*)$ is the spin rotation angle. Here, H is the magnetic field normal to the spin direction, $\gamma = qg/(m_* c)$ is the gyromagnetic ratio, g is the g-factor. According to Equation 3.65, with increasing H the current *oscillates* with an amplitude $(1 + P_L P_R)/(1 - P_L P_R)$ and period $\Delta H = (2\pi m_*)(\gamma_0 g m_0 t_{tr})^{-1}$ (Figure 3.11, top panel). The maximum operating speed of the field sensor is very high, since redistribution of nonequilibrium-injected electrons in the semiconductor layer occurs over the transit time $t_{tr} = w/\mu|E| = J_s w \tau_s/(J L_s)$, $t_{tr} \lesssim 10^{-11}$ s for $w \lesssim 200_*$ nm, $\tau_s \sim 3 \times 10^{-10}$ s, and $J/J_s \gtrsim 10$ ($D \approx 25\ \mathrm{cm^2\ s^{-1}}$) at $T \simeq 300$ K [78]). Therefore, the operating frequency $f = 1/t_{tr} \gtrsim 100$ GHz may be achievable at room temperature. We see that: (i) the present heterostructure can be used as a sensor for an ultrafast nanoscale reading of an inhomogeneous magnetic field profile; (ii) it includes two FM-S junctions and can be used for measuring the spin polarizations of these junctions; and (iii) it is a *multifunctional* device where current depends on the mutual orientation of the magnetizations in the ferromagnetic layers, an external magnetic field, and a (small) bias voltage. Thus, it can be used as a logic element, a magnetic memory cell, or an ultrafast read head.

3.5.4
Spin-Injection Devices

The high-frequency spin-valve effect, described above, can be used for designing a new class of ultrafast spin-injection devices such as an amplifier, a frequency multiplier, and a square-law detector [6]. Their operation is based on the injection of spin-polarized electrons from one ferromagnet to another through a semiconductor layer, and spin precession of the electrons in the semiconductor layer in a magnetic field induced by a (base) current in an adjacent nanowire. The base current can control the emitter current between the magnetic layers with frequencies up to several 100 GHz. Here, we shall describe a spintronic mechanism of ultrafast amplification and frequency conversion, which can be realized in heterostructures comprising a metallic ferromagnetic nanowire surrounded by a semiconductor (S) and a ferromagnetic (FM) thin shells (Figure 3.12a). Practical devices may have various layouts, with two examples shown in Figure 3.12b and c.

Let us consider the principle of operation of the spintronic devices shown in Figure 3.12a. When the thickness w of the n-type semiconductor layer is not very small ($w \gtrsim 30$ nm), tunneling through this layer would be negligible. The base voltage V_b is applied between the ends of the nanowire. The base current J_b, flowing through the nanowire, induces a cylindrically symmetric magnetic field $H_b = J_b/2\pi\rho$ in the S layer, where ρ is the distance from the center of nanowire. When the emitter

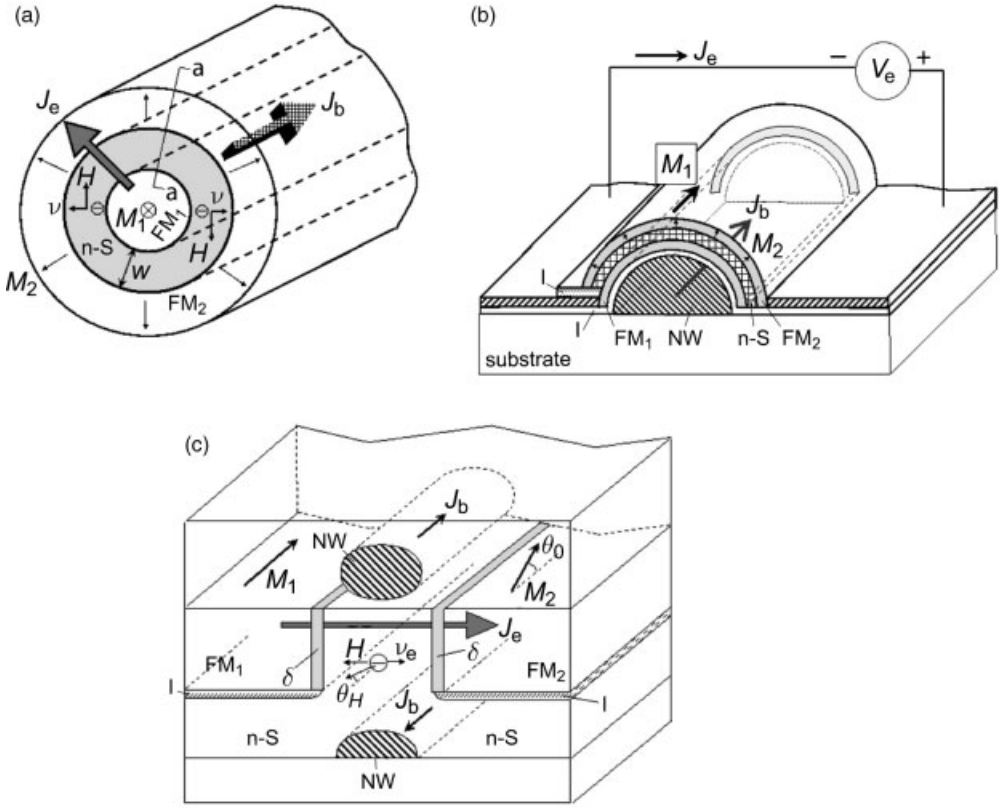

Figure 3.12 Schematic of the spin injection-precession devices having (a) cylindrical, (b) semi-cylindrical, and (c) planar shape. Here, FM_1 and FM_2 are the ferromagnetic layers; *n*-S the *n*-type semiconductors layer; *w* the thickness of the *n*-S layer; δ the δ-doped layers; NW the highly conductive nanowires; I the insulating layers. The directions of the magnetizations $\vec{M}_1$ and $\vec{M}_2$ in the FM_1 and FM_2 layers, as well as the electron spin σ, the magnetic field H_b, and the angle of spin rotation θ in S are also shown.

voltage V_e is applied between FM layers, the spin-polarized electrons are injected from the first layer (nanowire FM_1) through the semiconductor layer into the second (exterior) ferromagnetic shell, FM_2. The FM_1-S and FM_2-S junctions are characterized by the spin injection efficiencies P_1 and P_2, respectively. We assume that the transit time t_{tr} of the electrons through the S layer is less than the spin relaxation time, τ_s (i.e., we consider the case of a spin ballistic transport). The exact calculation gives a current J_e, through the structure as a function of the angle θ between the magnetization vectors $\vec{M}_1$ and $\vec{M}_2$ in the ferromagnetic layers. At small angles θ or $P_1 = P_{\mathrm{L}}$ or $P_2 = P_{\mathrm{R}}$

$$J_e = J_{0e}(1 + P_L P_R \cos\theta), \tag{3.66}$$

where $\theta = \theta_0 + \theta_{\mathrm{H}}$, θ_0 is the angle between $\vec{M}_1$ and $\vec{M}_2$, and θ_H is the angle of the spin precesses with the frequency $\Omega = \gamma H_\perp$, where $H_\perp$ is the magnetic field component

normal to the spin and γ is the gyromagnetic ratio. One can see from Figure 3.12a that $H_\perp = H_b = J_b/(2\pi\rho)$. Thus, the angle of the spin rotation is equal to $\theta_H = \gamma H_b t_{tr} = t_{tr} J_b/2\pi\rho_s$, where ρ_s is the characteristic radius of the S layer. Then, according to Equation 3.57,

$$J_e = J_{e0}[1 + P_1 P_2 \cos(\theta_0 + k_j J_b)], \tag{3.67}$$

where $k_j = \gamma t_{tr}/2\pi\rho_s = \gamma/\omega\rho_s$ and $\omega = 2\pi/t_{tr}$ is the frequency of a variation of the base current, $J_b = J_s \cos(\omega t)$.

Equation 3.67 shows that, when the magnetization M_1 is perpendicular to M_2, $\theta_0 = \pi/2$, and $\theta_H \ll \pi$,

$$J_e = J_{e0}(1 + k_j P_1 P_2 J_b),\ G = dJ_e/dJ_b = J_{e0} k_j P_1 P_2. \tag{3.68}$$

Hence, the *amplification* of the base current occurs with the gain G, which can be relatively high even for $\omega \gtrsim 100$ GHz. Indeed, $\gamma = q/(m_* c) \approx 2.2(m_0/m_*)10^5\ m/(\text{A}\cdot\text{s})$, where m_0 is the free electron mass, m_* the effective mass of electrons in the semiconductor, and c the velocity of light. Thus, the factor $k_j \simeq 10^3\,\text{A}^{-1}$ when $\rho_s \simeq 30$ nm, $m_0/m_* = 14$ (GaAs) and $\omega = 100$ GHz, so that $G > 1$ at $J_{e0} > 0.1$ mA/$(P_1 P_2)$.

When M_1 is collinear with M_2 ($\theta_0 = 0,\pi$) and $\theta_H \ll \pi$, then, according to Equation 3.67, the emitter current is

$$J_e = J_{e0}(1 \pm P_1 P_2) \mp \frac{1}{2} J_{e0} P_1 P_2 k_j^2 J_b^2. \tag{3.69}$$

Therefore, the time-dependent component of the emitter current $\delta J_e(t) \propto J_b^2(t)$, and the device operates as a square-law detector. When $J_b(t) = J_{b0}\cos(\omega_0 t)$, the emitter current has a component $\delta J_e(t) \propto \cos(2\omega_0 t)$, and the device operates as a *frequency multiplier*. When $J_b(t) = J_h \cos(\omega_h t) + J_s \cos(\omega_s t)$, the emitter current has the components proportional to $\cos(\omega_h \pm \omega_s)t$; that is, the device can operate as a high-frequency *heterodyne detector* with the conversion coefficient $K = J_{e0} J_h P_1 P_2 k_j^2/4$. For $k_j = 10^3\text{A}^{-1}$, one obtains $K > 1$ when $J_{e0} J_h > 4\ (\text{mA})^2/(P_1 P_2)$.

3.5.5
Spin Source of Polarized Radiation

The spin extraction effect can be used for making an efficient source of (modulated) polarized radiation. Consider a structure containing a FM-S junction with the δ-doped layer and a double p–n'–n heterostructure where the n'-region is made from narrower gap semiconductor (Figure 3.13). We show that the following effects can be realized in the structure when both FM-S junction and the heterostructure are biased in the forward direction, and the electrons are injected from n-semiconductor region into FM and p-region. Due to a spin selection property of FM-S junction [7], spin-polarized electrons appear in n-region with a spatial extent $L \lesssim L_s$ near the FM-S interface, where L_s is the spin diffusion length in NS. When the thickness of the n-region w is smaller than L, the spin-polarized electron from the n-region and

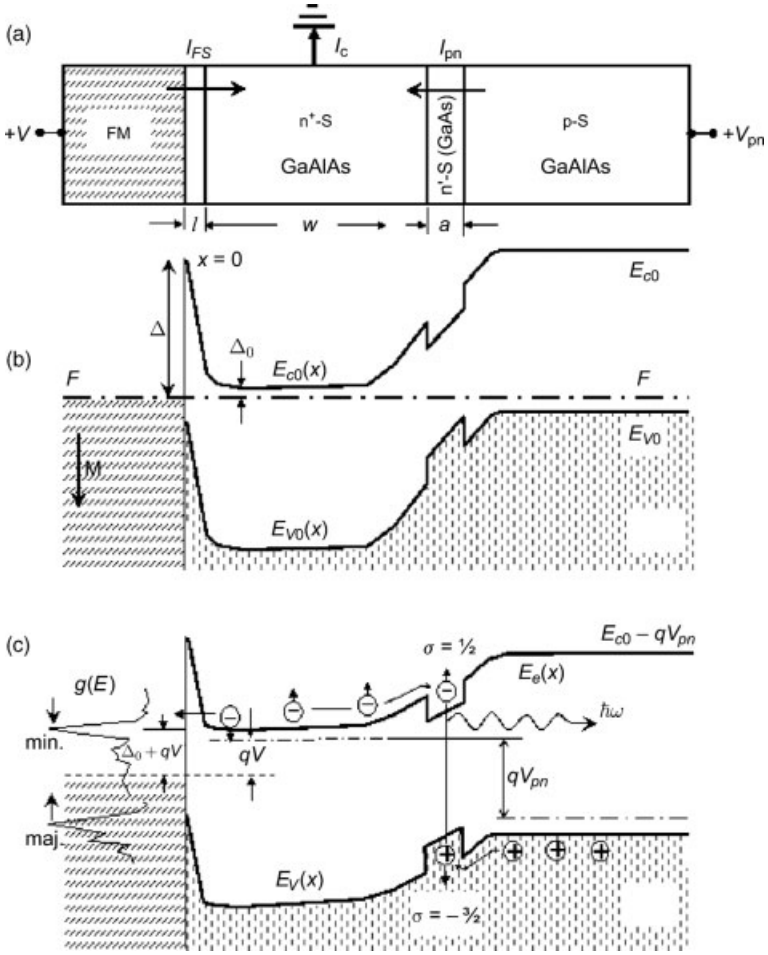

Figure 3.13 Schematic (a) of structure and the band diagram of polarized photon source containing FM-S junction with δ-doped layer and a double n^+–n'–p heterostructure without (b) and under the bias voltage V. Minority spin electrons are extracted from n^+–S semiconductor layer and the remaining (majority) electrons are recombined in n'–S quantum well. F is the Fermi level, Δ the height and l the thickness of the δ-doped layer, Δ_0 the height of a barrier in the n-type semiconductor, $E_c(x)$ the bottom of conduction band in the semiconductor. The spin density of states is shown at $x < 0$ with a high peak in minority states at $E = F + \Delta_0$, typical of elemental Ni, as an example.

holes from p-region are injected and accumulated in a thin narrow-gap n'-region (quantum well) where they recombine and emit polarized photons.

The conditions for maximal polarization are obtained as follows. When the thickness of n-region is $w < L$, we can assume that $\delta n_\uparrow(x) \simeq \delta n_{\uparrow 0}$ and $P_n \simeq P_0$. In this case, integrating Equation 3.43 over the volume of the n-semiconductor region (with area S and thickness w), we obtain

$$I_{\uparrow FS} + I_{\uparrow pn} - I_{c\uparrow} = q\delta n_{\uparrow 0} wS/\tau_s = P_0 I_S w/2L_s. \tag{3.70}$$

Here, $I_s = J_s S$; $I_{\uparrow FS} = J_{\uparrow 0} S$ and $I_{\uparrow pn}$ are the electron currents with spin $\sigma = \uparrow$ flowing into the n-region from FM and the p-region, respectively; $I_{\uparrow c}$ is the spin current out of the n-region in a contact (Figure 3.13a). The current $I_{\uparrow pn}$ is determined by injection of electrons with $\sigma = \uparrow$ from the n-region into the p-region through the crossectional area S, equal to $I_{\uparrow pn} = I_{pn} n_{\uparrow 0}/n = I_{pn}(1 + P_0)/2$, where I_{pn} is the total current in the p–n junction. The current of metal contact I_c is not spin-polarized; hence $I_{c\uparrow} = (I_{pn} + I_{FS})/2$, where I_{FS} is the total current in the FM-S junction. The current in the FM-S junction I_{FS} approaches a maximal value $I_m = J_m S$ at rather small bias, $qV_{FS} > 2T$. When $I_{pn} \ll I_{FS} \simeq I_m$ and $I_m \gg I_S w/L_s$, we get $P_0 \simeq -P_F$. The way to maximize polarization is by adjusting V_{FS}. The maximal $|P_0|$ can be achieved for the process of electron tunneling through the δ-doped layer when the bottom of conduction band in a semiconductor $E_c = F + \Delta_0 + qV_{FS}$ is close to a peak in the density of states of minority carriers in the elemental ferromagnet (Figure 3.13c, curve g).

The rate of polarized radiation recombination is $R_\sigma = qn'_\sigma d/\tau_R$ and the polarization of radiation is $p = (R_\uparrow - R_\downarrow)/(R_\uparrow + R_\downarrow) = 2\delta n'_\uparrow/n'$. Since $I_{pn} = qn'd/\tau n$, we find $2\delta n'_\uparrow/n' = P_0 \tau'_s (\tau'_s + \tau_n)^{-1}$, so that $p = P_0 \tau'_s (\tau'_s + \tau_n)^{-1}$. Thus, the radiation polarization p can approach maximum $p \simeq |P_F|$ at large current $I \simeq I_m$ when $\tau < \tau'_s$. The latter condition can be met at high concentration n' when the time of radiation recombination $\tau_R \simeq \tau_n < \tau'_s$. For example, in GaAs $\tau_R \simeq 3 \times 10^{-10}$ s at $n \gtrsim 5 \times 10^{17}\,\mathrm{cm}^{-3}$ [86] and τ'_s can be larger than τ_R [84]. We emphasize that spin injection efficiency near a forward-biased FM-S junction is very small.

Practical structures may have various layouts, with one example shown in Figure 3.14. It is clear that the distribution of $\delta n_\uparrow(r\rightharpoonup)$ in such a 2-D structure is characterized by the length $L \lesssim L_s$ in the direction x where the electrical field E can be strong, and by the diffusion length L_s in the (y, z) plane where the field is weak. Therefore, the spin density near FM and p–n junctions will be close to $\delta n_{\uparrow 0}$ when the size of the p-region is $d < L_s$. Thus, the above results for one-dimensional structure

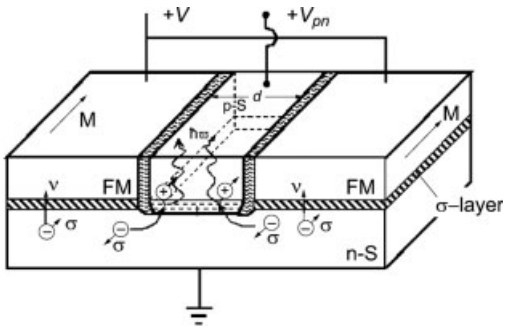

Figure 3.14 Layout of a structure from Figure 3.13, including FM layers and semiconductor n- and p-regions. Here, n' made from narrower gap semiconductor, δ-doped layers are between the FM layers and the n-semiconductor. FM layers are separated by thin dielectric layers from the p-region.

(Figure 3.13) are also valid for more complex geometry shown in Figure 3.14. The predicted effect should also exist for a reverse-biased FM-S junction where the radiation polarization p can approach $+P_F$.

3.6 Conclusions

In this chapter we have described a variety of heterostructures where the spin degree of freedom can be used to efficiently control the current: magnetic tunnel junctions, metallic magnetic multilayers exhibiting giant magnetoresistance, spin-torque effects in magnetic nanopillars. We also described a method of facilitating an efficient spin injection/accumulation in semiconductors from standard ferromagnetic metals at room temperature. The main idea is to engineer the band structure near the ferromagnet-semiconductor interface by fabricating a delta-doped layer there, thus making the Schottky barrier very thin and transparent for tunneling. A long spin lifetime in a semiconductor allows the suggestion of some interesting new devices such as field detectors, spin transistors, square-law detectors, and sources of the polarized light described in the present text. This development opens up new opportunities in potentially important novel spin injection devices. We also discussed a body of various spin-orbit effects and systems of interacting spins. In particular, Spin Hall effects result is positive magnetoresitance due to spin accumulation that may be used to extract the coeefficints for spin-orbit transport. We notice, however, that Datta–Das spinFET would have inferior characteristics compared to MOSFET. We also discussed the severe challenges facing *single-spin logic and, especially, spin-based quantum computers*.

4.1
The Binary Switch as a Basic Information-Processing Element

4.1.1
Information and Information Processing

Information can be defined as a technically quantitative measure of distinguishability of a physical subsystem from its environment [1]. One way to create distinguishable states is by the *presence* or *absence* of material particles (information carrier) in a given location. For example, one can envision the representation of information as an arrangement of particles at specified physical locations as for instance, the depiction of the acronym "IBM" by atoms placed at discrete locations on the material surface (Figure 4.1).

Information of an arbitrary type and amount – such as letters, numbers, colors, or graphics specific sequences and patterns – can be represented by a combination of just two distinguishable states [1–3]. The two states – which are known as binary states – are usually marked as state 0 and state 1. The maximum amount of information, which can be conveyed by a system with just two states is used as a unit of information known as 1 bit (abbreviated from "binary digit"). A system with two distinguishable states forms a basis for *binary switch*.

The binary switch is a fundamental computational element in information-processing systems (Figure 4.2) which, in its most fundamental form, consists of:

- two states 0 and 1, which are equally attainable and distinguishable
- a means to control the change of the state (a gate)
- a means to read the state
- a means to communicate with other binary switches.

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

4.1.2 Properties of an Abstract Binary Information-Processing System

An elementary binary information-processing system consists of N binary switches connected in a certain fashion to implement a function. Each binary switch is characterized by a dimension L and a switching time t_{sw}. A related dimensional characteristic is the packing density (the number of binary switches per unit area). In order to increase the packing density, n_{bit}, the characteristic dimension, L, of the binary switch must decrease:

$$n_{bit} \sim \frac{1}{L^2} \tag{4.1}$$

Another fundamental characteristic of a binary switch is the *switching energy*, E_{sw}.

One indicator of the ultimate performance of an information processor, realized as an interconnected system of binary switches, is the *maximum binary throughput* (BIT); that is, the number of binary transitions per unit time per unit area.

$$\text{BIT} = \frac{n_{bit}}{t_{sw}} \tag{4.2}$$

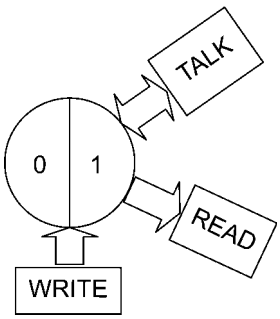

Figure 4.2 The constituents of an abstract binary switch.

One can increase the binary throughput by increasing the number of binary switches per unit area, n_{bit}, and/or decreasing the switching time – that is, the time to transition from one state to the other, $t_{sw.}$

It should be noted that, as each binary switching transition requires energy E_{sw}, the total power dissipation growth is in proportion to the information throughput:

$$P = \frac{n_{bit}}{t_{sw}} \cdot E_{sw} = \mathrm{BIT} \cdot E_{sw} \tag{4.3}$$

The above analysis does not make any assumptions on the material system or the physics of switch operation. In the following sections we investigate the fundamental relations for n_{bit}, t_{sw}, E_{sw} and the corresponding implications for the computing systems.

4.2
Binary State Variables

4.2.1
Essential Operations of an Abstract Binary Switch

The three essential properties of a binary switch are *Distinguishability*, *Controllability* and *Communicativity*. It is said that a binary switch is *Distinguishable* if – and only if – the binary state (0 or 1) can be determined with an acceptable degree of certainty by a measurement (READ operation). The binary switch is *Controllable* if an external stimulus can reliably change the state of the system from 0 to 1 or from 1 to 0 (WRITE operation). The binary switch is *communicative* if it is capable of transferring its state to other binary switches (TALK operation).

4.2.2
The Use of Particles to Represent Binary Information

Information-processing systems represent system states in terms of physical variables. One way to create physically distinguishable states is by the *presence* or *absence* of material particles or fields in a given location. Figure 4.3a illustrates an abstract model for a binary switch the state of which is represented by different positions of a material particle. In principle, the particle can possess arbitrary mass, charge, and so on. The only two requirements for the implementation of a particle-based binary switch are the ability to detect the presence/absence of the particle in, for example the location x_1, and the ability to move the particle from x_0 to x_1 and from x_1 to x_0.

$\Pi_{correct}$ is defined as the probability that the binary switch is in the correct state at an arbitrary time after the command to achieve that state is given. (Alternatively, one can use the probability of error $\Pi_{err} = 1 - \Pi_{correct}$). A necessary condition for the distinguishability of a binary switch is

$$\Pi_{correct} > \Pi_{err} \tag{4.4}$$

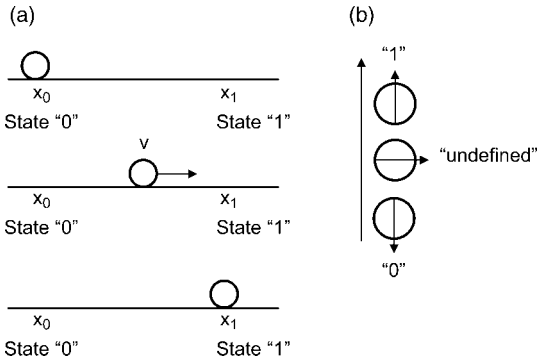

Figure 4.3 An abstract model for the operation of a binary switch formed (a) by different locations of material particles and (b) by opposite direction of the electron spin magnetic moment.

Or equivalently:

$$\Pi_{\text{err}} < 0.5 \tag{4.5}$$

As will be discussed below, in the physical realizations of binary switches, there always is some error probability ($\Pi_{\text{err}} > 0$) in the operation of the switch. As the error probability cannot exceed 0.5, in the following analysis we will use the condition in Equation 2.5 to estimate the parameters of a binary switch in the limiting case.

An elementary switching operation of a binary switch consists of three distinct steps. For example, consider the switch in Figure 4.3a switching from "0" to "1". The three steps are: (i) the initial STORE "0" mode; (ii) the transition CHANGE "0–1" mode; and (iii) the final STORE "1" mode. All three modes have characteristic times and can be described by the coordinate and velocity of the information carrier/material particle.

In STORE "0" the particle must be located in position $x = x_0$ and remain there for the time T_{state}. In CHANGE "0–1" mode, the state is *undefined*, as the particle is in the transition from x_0 to x_1 with a velocity $v_{01} > 0$ (for simplicity, velocity can be taken as the linear dimension of the switch divided by transition time). In STORE "1" ("0") the particle must be located in position $x = x_1$ (x_0) and have lifetime T_{state}. The switching time t_{sw} in this case is given by $t_{\text{sw}} = L/v_{01}$, where $L = x_1 - x_0$ is the linear size of the binary switch.

The question is, what are the requirements for T_{state} and t_{sw} in a binary switch for information processing? As binary logic operates with *two* logic states "0" and "1", while the binary switch has *three* physical states "0", "1" and UNDEFINED (i.e., CHANGE), if the READ operation of binary switch occurs in the UNDEFINED state, an error will result.

The conditions for maximum distinguishability of an ideal binary switch are:

- Unlimited lifetime of each state in the absence of control signal: $T_{\text{state}}^{\max} \to \infty$ in STORE mode. More specifically, for example, synchronous circuits with clock, $T_{\text{state}} \in [T_{\text{clock}}, \infty[$, where T_{clock} is the clock period.

- Fast transition between binary states at the presence of control signal: $t_{sw} \to 0$ in CHANGE mode (say a negligible fraction of the clock period).

As $T_{state}^{max} \to \infty$ in STORE mode, the particle velocity in both 0 and 1 states must be zero, as the particle must be at rest, that is, $v_0 = v_1 = 0$; that is, the kinetic energy $E = \frac{mv^2}{2}$ of the particle should ideally be zero in both STORE modes. In the CHANGE mode, the average particle velocity is $\langle v_{01} \rangle > 0$, and $E > 0$. The switching time can then be estimated as

$$t_{sw} = \frac{L}{\langle v_{01} \rangle} = L\sqrt{\frac{m}{2E}} \tag{4.6}$$

Equation 2.6 sets a limit for the switching speed in the non-zero distance case (non-relativistic approximation). Note that in binary switch operation, an amount of energy E must be supplied to the particle before the CHANGE operation begins, and taken out of the particle after the CHANGE.

If energy remains in the system, the information-bearing particle will oscillate between the two states with the period $2t_{sw.}$ In an oscillating system, if friction is neglected, then energy is preserved (no dissipation) but the information state is not: the lifetime of each binary state $T_{state} \to 0$. The conditions (i) and (ii) of maximum distinguishability will be violated and such a system cannot act as a binary switch.

Alternatively, if one wishes to preserve the binary state (i.e., $T_{state} > 0$), the energy must be rapidly taken out from the system. The time of energy removal t_{out} must be less then half of the switching time: $t_{out} < \frac{t_{sw}}{2}$, otherwise an unintended transition to another state may occur. One rapid way to remove energy is by *thermal dissipation to the environment*. If instead, the aim is to remove the energy in a controllable manner, for example for a possible re-use, a faster switch will be needed which, according to Equation 4.6 will require a greater energy for its operation. It is concluded that non-zero energy dissipation is a necessary attribute of binary switch operations.

The above analysis considers binary switches, with states represented by the *presence* or *absence* of material particles (the information-defining particle or information carrier) in a given locations, for example the utilization of electrons as information carriers. As mentioned above, the electromagnetic field also can, in principle, be used to represent information. For example, a popular candidate is a binary switch that uses the electron spin magnetic moment, when the two opposing directions of the magnetic field represent "0" and "1" (Figure 4.3b).

4.3
Energy Barriers in Binary Switches

4.3.1
Operation of Binary Switches in the Presence of Thermal Noise

Consider again, a binary switch where the binary state is represented by particle location (see Figure 4.3a). Until now, it has been assumed that the information-

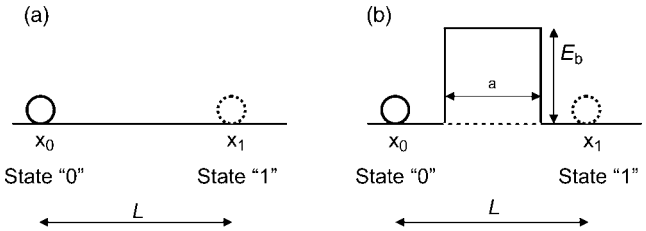

Figure 4.4 Illustration of an energy barrier to preserve the binary states in the presence of noise.

defining particle in the binary switch has zero velocity/kinetic energy, prior to a WRITE command. However, each material particle *at equilibrium* with the environment possesses kinetic energy of $1/2\ k_B T$ per degree of freedom due to thermal interactions, where k_B is Boltzmann's constant and T is temperature. The permanent supply of thermal energy to the system occurs via the mechanical vibrations of atoms (phonons), and via the thermal electromagnetic field of photons (background radiation).

The existence of random mechanical and electromagnetic stimuli means that the information carrier/material particle located in x_0 (Figure 4.4a) has a non-zero velocity in a non-zero-T environment, and that it will spontaneously move from its intended location. According to Equation 4.6, the state lifetime in this case will be

$$T_{\text{state}} \sim L\sqrt{\frac{m}{k_B T}} \tag{4.7}$$

For an electron-based switch ($m = m_e = 9.11 \times 10^{-31}$ kg) of length $L = 1\,\mu$m at $T = 300$ K. Equation 4.8 gives T_{state} as ~15 ps, and hence the time before the system would lose distinguishability would be very small.

In order to prevent the state from changing randomly, it is possible to construct energy barriers that limit particle movements. The energy barrier, separating the two states in a binary switch is characterized by its height E_b and width a (Figure 4.4b).

The barrier height, E_b, must be large enough to prevent spontaneous transitions (errors). Two types of unintended transition can occur: "classical" and "quantum". The "classical" error occurs when the particle jumps over barrier, and this can happen if the kinetic energy of the particle E is larger than E_b. The corresponding "classic" error probability, Π_C, is obtained from the Boltzmann distribution as:

$$\Pi_C = \exp\left(-\frac{E_b}{k_B T}\right) \tag{4.8}$$

The presence of energy barrier of width a sets the minimum device size to be $L_{\min} \geq a$.

4.3.2 Quantum Errors

Another class of errors, termed "quantum errors", occur due to quantum mechanical tunneling through the barrier of finite width a. If the barrier is too narrow, then

spontaneous tunneling through the barrier will destroy the binary information. The conditions for significant tunneling can be estimated using the Heisenberg uncertainty principle, as is often carried out in texts on the theory of tunneling [4]:

$$\Delta x \Delta p \geq \frac{\hbar}{2} \tag{4.9}$$

The uncertainty relationship of Equation 4.9 can be used to estimate the limits of distinguishability. Consider again a "two-well" bit in Figure 4.4b. As is known from quantum mechanics, a particle can pass (tunnel) through a barrier of finite width, even if the particle energy is less than the barrier height, E_b. An estimate of how thin the barrier must be to observe tunneling can be made from Equation 4.9; for a particle at the bottom of the well, the uncertainty in momentum is $\sqrt{2mE_b}$, which gives:

$$\sqrt{2mE_b}\Delta x \approx \frac{\hbar}{2} \tag{4.10}$$

Equation 4.10 states that by initially setting the particle on one side of the barrier, it is possible to locate the particle on either side, with high probability, if Δx is of the order of the barrier width a. That is, the condition for losing distinguishability is $\Delta x \lesssim a$, and the minimum barrier width is:

$$a_{\min} = a_H \approx \frac{\hbar}{2\sqrt{2mE_b}}, \tag{4.11}$$

where a_H is the *Heisenberg distinguishability length* for "classic to quantum transition".

For $a < a_H$, the tunneling probability is significant, and therefore particle localization is not possible. In order to estimate the probability of tunneling, Equation 4.10 can be re-written, taking into account the tunneling condition $a \leq \Delta x$:

$$\sqrt{2m}(a\sqrt{E_b}) \leq \frac{\hbar}{2} \tag{4.12}$$

From Equation 4.12, the "tunneling condition" can also be written in the form

$$1 - \frac{2\sqrt{2m}}{\hbar} a\sqrt{E_b} \geq 0, \tag{4.13}$$

Since for small x, $e^{-x} \sim 1 - x$, the tunneling condition then becomes

$$\exp\left(- \frac{2\sqrt{2m}}{\hbar} \cdot a \cdot \sqrt{E_b} \right) \geq 0 \tag{4.14}$$

The left-hand side of Equation 4.14 has the properties of probability. Indeed, it represents the tunneling probability through a rectangular barrier given by the Wentzel–Kramers–Brillouin (WKB) approximation [5]:

$$\Pi_{WKB} \sim \exp\left(- \frac{2\sqrt{2m}}{\hbar} \cdot a \cdot \sqrt{E_b} \right) \tag{4.15a}$$

This equation also emphasizes the parameters controlling the tunneling process, which include the barrier height E_b and barrier width a, as well as the mass m of the

information-bearing particle. If separation between two wells is less than a, the structure of Figure 4.4b would allow significant tunneling. In fact, it is instructive to examine the physical meaning of Equation 4.11, which we marked as the condition of significant tunneling or "classic to quantum transition". Substituting Equation 4.11 into Equation 4.15a provides an estimate for tunneling probability through a rectangular barrier of width a_H:

$$\Pi_{WKB} \sim \exp\left(- \frac{2\sqrt{2m}}{\hbar} \cdot a_H \cdot \sqrt{E_b} \right) = \exp(-1) \approx 0.37 \tag{4.15b}$$

Thus, the Heisenberg distinguishability length a_H from Equation 4.11 corresponds to a tunneling probability of approximately 37%.

4.3.3
A Combined Effect of Classical and Quantum Errors

As discussed in the previous sections, there are two mechanisms of spontaneous transitions (errors) in binary switching: the over-barrier transition ("classic" error); and through-barrier tunneling ("quantum" error). The probabilities of the classic and quantum errors are given by Equations 4.8 and 4.15a, respectively. The joint error probability of the two mechanisms is [3]:

$$\Pi_{err} = \Pi_C + \Pi_Q - \Pi_C \cdot \Pi_Q \tag{4.16}$$

Or, from Equations 4.8 and 4.15a, we obtain:

$$\Pi_{err} = \exp\left(- \frac{E_b}{k_B T} \right) + \exp\left(\frac{2\sqrt{2m}}{\hbar} \cdot a\sqrt{E_b} \right) - \exp\left(- \frac{\hbar E_b + 2ak_B T\sqrt{2mE_b}}{\hbar k_B T} \right) \tag{4.17}$$

4.4
Energy Barrier Framework for the Operating Limits of Binary Switches

4.4.1
Limits on Energy

The minimum energy of binary transition is determined by the energy barrier. The work required to suppress the barrier is equal or larger than E_b; thus, the minimum energy of binary transition is given by the minimum barrier height in binary switch. The minimum barrier height can be found from the distinguishability condition [Equation 4.5], which requires that the probability of errors $\Pi_{err} < 0.5$. First, the case is considered when only "classic" (i.e., thermal) errors can occur. In this case, according to Equation 4.8:

$$\Pi_{err} = \Pi_C = \exp\left(- \frac{E_b}{k_B T} \right) \tag{4.18}$$

These classic transitions represent the thermal (Nyquist–Johnson) noise. By solving Equation 4.18 for $\Pi_{\text{err}} = 0.5$, we obtain the Boltzmann's limit for the minimum barrier height, E_{bB}

$$E_{\text{bB}} = k_{\text{B}} T \ln 2 \approx 0.7 k_{\text{B}} T \tag{4.19}$$

Equation 4.19 corresponds to the minimum barrier height, the point at which distinguishability of states is completely lost due to thermal over-barrier transitions. In deriving Equation 4.19, tunneling was ignored – that is, the barrier width is assumed to be very large, $a \gg a_{\text{H}}$.

Next, we consider the case where only quantum (i.e., tunneling) errors can occur. In this case, according to Equation 4.15a

$$\Pi_{\text{err}} = \Pi_{\text{Q}} \sim \exp\left(- \frac{2\sqrt{2m}}{\hbar} \cdot a \cdot \sqrt{E_{\text{b}}} \right) \tag{4.20}$$

By solving Equation 4.20 for $\Pi_{\text{err}} = 0.5$, we obtain the Heisenberg's limit for the minimum barrier height, E_{bH}

$$E_{\text{bH}} = \frac{\hbar^2}{8ma^2} (\ln 2)^2 \tag{4.21}$$

Equation 4.21 corresponds to a narrow barrier, $a \sim a_{\text{H}}$, the point at which distinguishability of states is lost due to tunneling transitions. In deriving Equation 4.21, over-barrier thermal transitions were ignored – that is, the temperature was assumed to be close to absolute zero, $T \to 0$.

Now, we consider the case when both thermal and tunneling transitions contribute to the errors in a binary switch. In this case, the total error probability is given by Equation 4.17. An approximate solution of Equation 4.17 for $\Pi_{\text{err}} = 0.5$ is

$$E_{\text{b min}} = k_B T \ln 2 + \frac{\hbar^2}{8ma^2} (\ln 2)^2 \tag{4.22}$$

Equation 4.22 provides a generalized value for minimum energy per switch operation at the limits of distinguishability, that takes into account both classic and quantum transport phenomena. The graph in Figure 4.5 shows the numerical solution of Equation 4.17 and its approximate analytical solution given by Equation 4.22 for $\Pi_{\text{err}} = 0.5$. Is it clearly seen that for $a > 5$ nm, the Boltzmann's limit, $E_{\text{bB}} = k_{\text{B}} T \ln 2$, is a valid representation of minimum energy per switch operation, while for $a < 5$ nm, the minimum switching energy can be considerably larger.

4.4.2 Limits on Size

The minimum size of a binary switch L cannot be smaller then the distinguishability length a_{H}. From both Equations 4.11 and 4.19, one can estimate the Heisenberg's length for the binary switch operation at the Boltzmann's limit of energy:

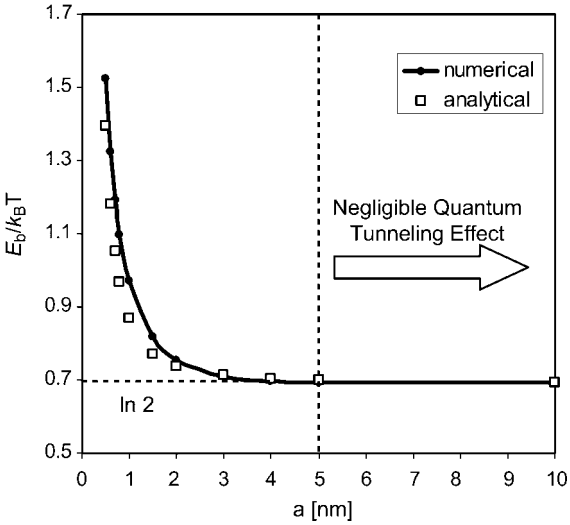

Figure 4.5 Minimum energy per switch operation as a function of minimum switch size.

$$a_{\mathrm{HB}} = \frac{\hbar}{2\sqrt{2mk_{\mathrm{B}}T\ln 2}} \tag{4.23}$$

For electrons ($m = m_{\mathrm{e}}$) at $T = 300\,\mathrm{K}$, we obtain $a_{\mathrm{HB}} \sim 1\,\mathrm{nm}$.

The distinguishability length a_{HB} defines both the minimum size of the switch and the separation between the two neighboring switches. Thus, the maximum density of binary switches is:

$$n_{\max} \leq \frac{1}{(2a_{\mathrm{HB}})^2} \tag{4.24}$$

For electron-based binary switches at 300 K ($a_{\mathrm{HB}} \sim 1\,\mathrm{nm}$) and $n_{\max} \sim 10^{13}\,\mathrm{cm}^{-2}$.

4.4.3 Limits on Speed

The next pertinent question is the minimum switching time, $\tau_{\min}$, which can be derived from the Heisenberg relationship for time and energy:

$$\Delta E \Delta t \geq \frac{\hbar}{2} \tag{4.25a}$$

or

$$\tau_{\min} \cong \frac{\hbar}{2\Delta E} \tag{4.25b}$$

Equation 4.25b is an estimate for the maximum speed of dynamic evolution [6] or the maximum passage time [7]. It represents the zero-length approximation for the

switching speed, in contrast with Equation 4.6, which is distance-dependent. If $L \sim a_H$, then Equation 4.6 converges to Equation 4.25b.

For the Boltzmann's limit, $E = E_{bB}$ [Equation 4.19], we obtain

$$\tau_{min\,B} \cong \frac{\hbar}{2k_B T \ln 2} \approx 2 \cdot 10^{-14}\ \mathrm{s} \tag{4.26}$$

It should be noted that Equation 4.26 is applicable to all types of device, and no specific assumptions were made about any physical device structure.

4.4.4
Energy Dissipation by Computation

Using Equations 4.1–4.3 allows one to estimate power dissipation by a chip containing the smallest binary switches, $L \sim a_{HB}$ [Equation 4.23], packed to maximum density [Equation 4.24] and operating at the lowest possible energy per bit [Equation 4.19].

The power dissipation per unit area of this limit technology is given by:

$$P = \frac{n_{max} E_{min\,B}}{\tau_{min\,B}} \sim \frac{10^{13}\ \mathrm{cm}^{-2} \cdot 3 \cdot 10^{-21}\ \mathrm{J}}{2 \cdot 10^{-14}\ \mathrm{s}} \sim 2 \cdot 10^{6}\ \frac{\mathrm{W}}{\mathrm{cm}^2} \tag{4.27}$$

The energy density bound in the range of $\mathrm{MW\,cm^{-2}}$ obtained by invoking $k_B T \ln 2$ as the lower bound for the device energy barrier height is an astronomic number. If known cooling methods are employed, it appears that that heat-removal capacity of several hundred $\mathrm{W\,cm^{-2}}$ represents a practically achievable limit. The practical usefulness of alternative electron-transport devices may be derived from lower fabrication costs or from specific functional behavior; however, the heat removal challenge will remain.

4.5
Physics of Energy Barriers

The first requirement for the physical realization of any arbitrary switch is the creation of distinguishable states within a system of such material particles. The second requirement is the capability for a conditional change of state. The properties of distinguishability and conditional change of state are two fundamental and essential properties of a material subsystem that represents binary information. These properties are obtained by creating and control energy barriers in a material system.

The physical implementation of an energy barrier depends on the choice of the state variable used by the information processing system. The energy barrier creates a local change of the potential energy of a particle from a value U_1 at the generalized coordinate q_1 to a larger value U_2 at the generalized coordinate q_2. The difference $\Delta U = U_2 - U_1$ is the barrier height. In a system with an energy barrier, the force exerted on a particle by the barrier is of the form $F = \frac{\partial U}{\partial q}$. A simple illustration of a one dimensional barrier in linear spatial coordinates, x, is shown in Figure 4.6a. It should

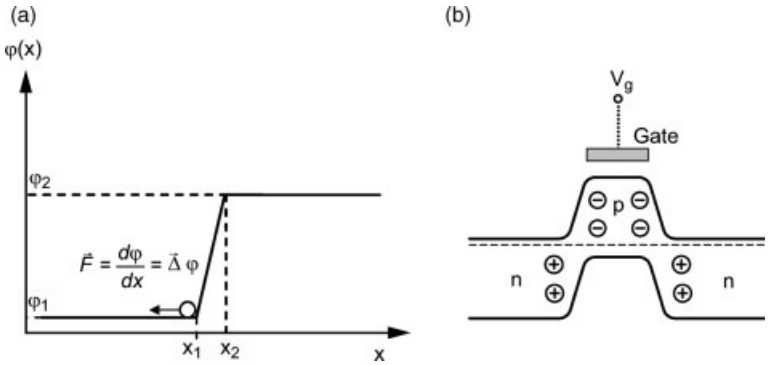

Figure 4.6 An illustration to the energy barrier in a material system. (a) Abstraction; (b) physical implementation by doping of a semiconductor.

be noted, that the spatial energy changes in potential energy require a finite spatial extension ($\Delta x = x_2 - x_1$) of the barrier (Figure 4.6a and b). This spatial extension defines a minimum dimension of energy barrier, $a_{\min}$: $a_{\min} > 2\Delta x$. In this section, we consider the physics of barriers for electron charge, electron spin, and optical binary switches.

4.5.1 Energy Barrier in Charge-Based Binary Switch

For electrons, the basic equation for potential energy is the Poisson equation

$$\nabla^2 \varphi = -\frac{\rho}{\varepsilon_0}, \tag{4.28}$$

where ρ is the charge density, $\varepsilon_0 = 8.85 \times 10^{-12}\,\mathrm{F\,m^{-1}}$ is the permittivity of free space, and φ is the potential: $\varphi = U/e$. According to Equation 4.28, the presence of an energy barrier is associated with changes in charge density in the barrier region. The barrier-forming charge is introduced in a material, for example by the doping of semiconductors. This is illustrated in Figure 4.6b, for a silicon n-p-n structure where the barrier is formed by ionized impurity atoms such as P^+ in the n-region and B^- in the p-region. The barrier height E_{b0} depends on the concentration of the ionized impurity atoms [8]:

$$E_{b0} \approx k_B T \ln \frac{N_A^- N_B^+}{n_i}, \tag{4.29}$$

where, N_A^-, N_B^+, and n_i are the concentration of negatively charged impurities (acceptors), positively charged impurities (donors), and the intrinsic carrier concentration in a semiconductor, respectively.

The minimum barrier extension is given by the Debye length [8]:

$$L_D \approx \sqrt{\frac{\varepsilon_0 \varepsilon k_B T}{e^2 N_D}}, \tag{4.30}$$

where ε is the relative dielectric permittivity of a semiconductor, and $N_D = N_A^- = N_B^+$ (abrupt p-n junction approximation). The maximum concentration of electrically active dopants N_{max} is close to the density of states in the conduction, N_c, and valence bands, N_v of the semiconductor. For silicon, $N_{max} \sim 10^{19}\,cm^{-3}$ [8], and it follows that $L_{Dmin} \sim 1.3\,nm$. The minimum barrier length therefore is $a_{min} = 2L_{Dmin} \sim 2.6\,nm$.

The energy diagram of Figure 4.6b is typical of many semiconductor devices, for example, field effect transistors (FET). The barrier region corresponds to the FET channel, while the wells correspond to the source and drain. In order to enable electron movement between the source and drain, the barrier height must be decreased (ideally suppressed to zero). To do this, the amount of charge in the barrier region needs to be changed, according to Equation 4.28. A well-known relationship connects the electrical potential difference $\Delta\varphi = V$ and charge, Δq, through capacitance

$$C = \frac{\Delta q}{\Delta\varphi} \tag{4.31}$$

In field-effect devices, in order to change the charge distribution in the barrier region – and hence lower the barrier – a voltage is applied to an external electrode (gate), which forms a capacitor with the barrier region (in bipolar devices, external charge is injected in the barrier region to control the barrier height). When voltage V_g is applied to the barrier region, the barrier will change from it initial height E_{b0} (determined by impurity concentration):

$$E_b = E_{b0} - eV_g \tag{4.32}$$

The voltage needed to suppress the barrier from E_{b0} to zero (the threshold voltage) is:

$$V_t = \frac{E_{b0}}{e} \tag{4.33}$$

Thus, the operation of all charge transport devices involves charging and discharging capacitances to change barrier height, thereby controlling charge transport in the device. When a capacitor C is charged from a constant voltage power supply V_g, the energy E_{dis} is dissipated, that is, it is converted into heat [9]:

$$E_{dis} = \frac{CV_g^2}{2} \tag{4.34}$$

The minimum energy needed to suppress the barrier (by charging the gate capacitor) is equal to the barrier height E_b. Restoration of the barrier (by discharging gate capacitance) also requires a minimum energy expenditure of E_b. Thus, the minimum energy required for a full switching cycle is at least $2E_b$.

It should be noted that in the solid-state implementation of binary switch, the number of electrons in both wells is large. This is different from an abstract system having only one electron (see above). In a multi-electron system, the electrons strike the barrier from both sides, and the binary transitions are determined by the net electron flow, as shown in Figure 4.7.

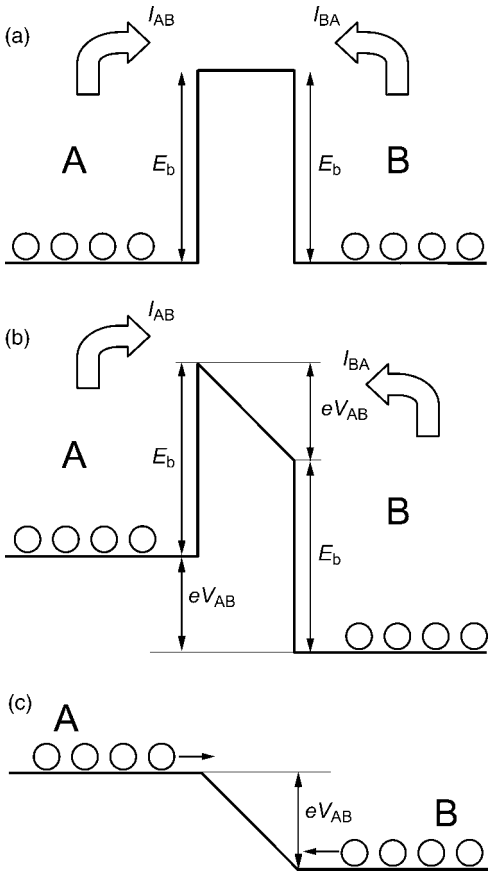

Figure 4.7 The fundamental operation of multi-electron binary switch. (a) No energy difference between wells **A** and **B**, resulting in a symmetric energy diagram. (b) Energy asymmetry is created due to energy difference eV_{AB} between the wells **A** and **B**. (c) State CHANGE operation: the barrier height E_b is suppressed by applying gate potential V_g, while energy difference eV_{AB} between the wells **A** and **B**.

Let N_0 be the number of electrons that strike the barrier per unit time. Thus, the number of electrons N_A that transition over the barrier from well **A** per unit time is

$$N_A = N_0 \exp\left(-\frac{E_b}{k_B T}\right) \tag{4.35}$$

The corresponding current I_{AB} is

$$I_{AB} = e \cdot N_A = eN_0 \exp\left(-\frac{E_b}{k_B T}\right) \tag{4.36}$$

Electrons in well **B** also can strike the barrier and therefore contribute to the over-barrier transitions with current I_{BA}. Thus, the net over-barrier current is

$$I = I_{AB} - I_{BA} \tag{4.37}$$

The energy diagram of Figure 4.7a is symmetric, hence $I_{AB} = I_{BA}$, and $I = 0$. Therefore, no binary transitions occur in the case of symmetric barrier. In order to enable the rapid and reliable transition of an electron from well **A** to well **B**, an energy asymmetry between two wells must be created. This is achieved by energy difference eV_{AB} between the wells **A** and **B** (Figure 4.7b).

For such an asymmetric diagram, the barrier height for electrons in the well **A** is E_b, and for electrons in the well **B** is $(E_b + eV_{AB})$. Correspondingly, from Equations 4.36 and 4.37 the net current is

$$\begin{aligned} I &= eN_0 \exp\left(-\frac{E_b}{k_B T}\right) - eN_0 \exp\left(-\frac{E_b - eV_{AB}}{k_B T}\right) \\ &= eN_0 \exp\left(-\frac{E_b}{k_B T}\right)\left[1 - \exp\left(-\frac{eV_{AB}}{k_B T}\right)\right] \end{aligned} \tag{4.38a}$$

By substituting Equation 4.32 for E_b, we obtain:

$$I = eN_0 \exp\left(-\frac{E_{b_0} - eV_g}{k_B T}\right)\left[1 - \exp\left(-\frac{eV_{AB}}{k_B T}\right)\right] \tag{4.38b}$$

By expressing E_{b0} as eV_t from Equation 4.33 and using the conventional notations $I = I_{ds}$ (source-drain current) and $V_{AB} = V_{ds}$ (source-drain voltage), we obtain the equation for the subthreshold I–V characteristics of FET [10]:

$$I_{ds} = I_0 \exp\left(\frac{e(V_g - V_t)}{k_B T}\right)\left[1 - \exp\left(-\frac{eV_{ds}}{k_B T}\right)\right] \tag{4.38c}$$

An example plot of Equation 4.38c is shown in Figure 4.8.

The minimum energy difference between the wells, eV_{ABmin}, can be estimated based on the distinguishability arguments for CHANGE operation, when is E_b is

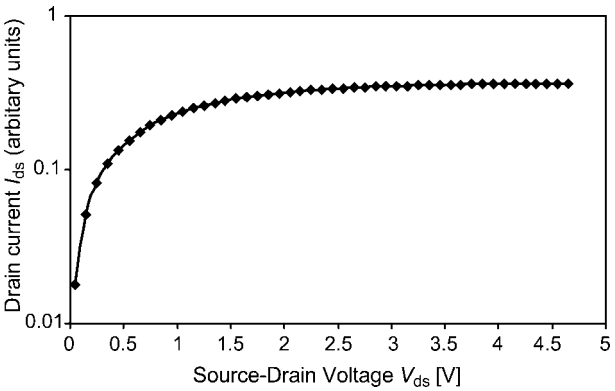

Figure 4.8 A source-drain *I-V* characteristic derived from the energy barrier model for a charge-based binary switch.

suppressed by applying the gate voltage, for example $E_b = 0$ (Figure 4.7c). For a successful change operation, the probability that each electron flowing from well **A** to well **B** is not counterbalanced by another electron moving from well **B** to well **A** should be less than 0.5 in the limiting case. The energy difference eV_{AB} forms a barrier for electrons in well **B**, but not for electrons in well **A**, and therefore, from Equation 4.18 we obtain

$$eV_{ABmin} = E_{b_{min}} = k_B T \ln 2 \tag{4.39}$$

If N is the number of electrons involved in the switching transition between two wells, the total minimum switching energy is

$$E_{SWmin} = 2E_b + NeV_{AB} = (N+2)k_B T n2 \tag{4.40a}$$

If $N = 1$, then

$$E_{SW_{min}} = 3k_B T \ln 2 \approx 10^{-20}\,\text{J} \tag{4.40b}$$

4.5.2 Energy Barrier in Spin-Based Binary Switch

In addition to charge, e, electrons possess intrinsic angular momentum (spin). As result, they also possess a permanent magnetic moment [11]:

$$\mu_s = \pm\frac{1}{2} g \cdot \mu_B \tag{4.41}$$

where μ_B is the Bohr magneton, $\mu_B = \frac{e\hbar}{2m_e}$, and g is the coupling constant known as the Landé gyromagnetic factor or g-factor. For free electrons and electrons in isolated atoms $g_0 = 2.00$. In solids, consisting of a large number of atoms, the effective g-factor can differ from g_0.

The energy of interaction, $E_{\mu-B}$, between a magnetic moment $\vec{\mu}$ and a magnetic field $\vec{B}$ is:

$$E_{\mu-B} = -\vec{\mu} \cdot \vec{B} \tag{4.42}$$

For the electron spin magnetic moment in a magnetic field applied in the z direction, the energy of interaction takes two values, depending on whether the electron spin magnetic moment is aligned or anti-aligned with the magnetic field. From Equations 4.41 and 4.42 one can write, assuming $g = 2$

$$\begin{aligned} E_{\uparrow\uparrow} &= -\frac{e\hbar}{2m_e} \cdot B_z \\ E_{\uparrow\downarrow} &= +\frac{e\hbar}{2m_e} \cdot B_z \end{aligned} \tag{4.43}$$

The energy difference between the aligned and anti-aligned states represents the energy barrier in the spin binary switch and is

$$E_b = E_{\uparrow\downarrow} - E_{\uparrow\uparrow} = 2\mu_B B_z \tag{4.44}$$

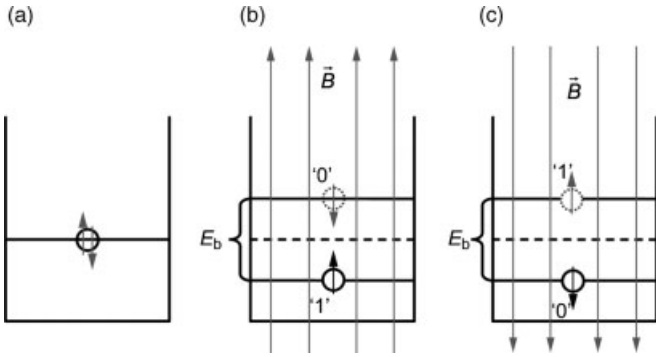

Figure 4.9 An abstract model of a single spin binary switch. (a) $B = 0$, the two states are indistinguishable. (b, c) $B \neq 0$, the two binary states are separated by the energy gap E_b.

Equations 4.43 and 4.44 represent a physical phenomenon known as Zeeman splitting [11]. The operation of a single spin binary switch is illustrated in Figure 4.9. In the absence of an external magnetic field, there is equal probability that the electron has magnetic moment $+\mu_B$ or $-\mu_B$; that is, the two states are indistinguishable (Figure 4.9a). When an external magnetic field is applied (Figure 4.9b and c), the two states are separated in energy. The lower energy state has higher probability of population and this represents the binary state "1" (Figure 4.9b) or "0" (Figure 4.9c) in this system. Binary switching occurs when the external magnetic field changes direction, as shown in Figure 4.9b and c.

This abstraction, while very simple, applies to all types of spin devices, at equilibrium with the thermal environment, including for example proposed spin transport devices [12–14] and coupled spin-polarized quantum dots [15].

The barrier-forming magnetic field B can be either a built-in field formed by a material layer with a permanent magnetization, or created by an external source (e.g., an electromagnet). In both cases, the change in the direction of the external magnetic field required for binary switching is produced by an electric current pulse in one of two opposite directions. The need for two opposite directions of electrical current flow requires additional electrical binary switches to control current flow in the electromagnet.

Some generic electrical circuits to manipulate the barrier height are a spintronic binary switch are shown in Figure 4.10. These require four electrical binary switches in the case of single power supply (Figure 4.10a), or two binary switches in the case of two power supplies (Figure 4.10b).

Thus, each spin-based binary switch requires two or four "servant" charge-based binary switches. This will result in larger area per device and also a larger energy consumption per operation, as compared to the charge-based switches. As the minimum switching energy of one charge-based device is $\sim 3k_BT$ [according to Equation 4.40b], the minimum switching energy of a spin device E_{spin} for single power supply scheme is

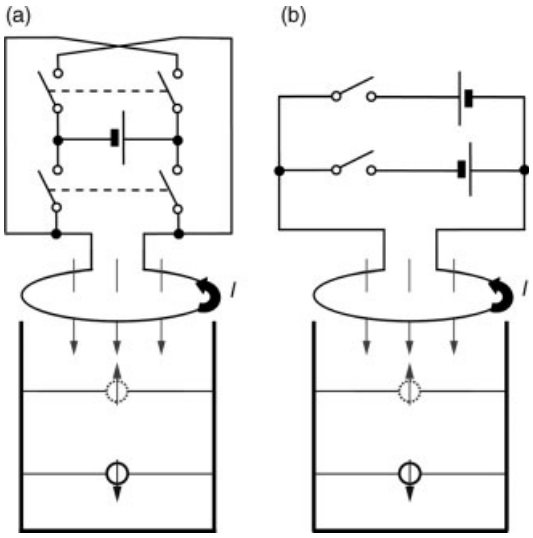

Figure 4.10 A generic electrical circuit to control spin binary switch. (a) Single power supply scheme; (b) double power supply scheme.

$$E_{\text{spin}} = E_{\text{M}} + 12k_{\text{B}}T \tag{4.45}$$

where E_{M} is the energy required to generate the magnetic field to change the spin state.

One possible way to address the "electrical" challenge for spin devices is to change the spin control paradigm. The paradigm described above uses a system of binary switches, each of which can be controlled independently by an external stimulus, and each switch can, in principle control any other switch in the system. However, it is not clear whether a spin state-based device can be used to control the state of subsequent spin devices without going through an electrical switching mechanism as discussed above. Although it is possible that local interactions may be used to advantage for this purpose [15, 16], feasibility assessments of these proposals in general information processing applications are clearly required.

Let us now consider a hypothetical single spin binary switch that, ideally, might have atom-scale dimensions. At thermal equilibrium there is a probability of spontaneous transition between spin states "1" and "0" in accordance with Equation 4.18. Correspondingly, for $\Pi_{\text{err}} < 0.5$, according to Equation 4.19 the energy separation between to state should be larger than $k_{\text{B}}T \ln 2$

$$2\mu_{\text{B}}B_{\text{min}} = k_{\text{B}}T \ln 2 \tag{4.46}$$

From Equations 4.19 and 4.44 we can obtain the minimum value of B for a switch operation

$$B_{\text{min}} = \frac{k_{\text{B}}T \ln 2}{2\mu_{\text{B}}} = \frac{m_{\text{e}}}{e\hbar} k_{\text{B}}T \ln 2 \tag{4.47}$$

Table 4.1 Maximum magnetic fields and limiting factors (from Ref. [17]).

Magnet	B_{max} [T]	Limiting factor
Conventional magnetic-core electromagnet	~2	Permeability saturation of the of magnetic core
Steady-field air-core NbTi and Nb_3Sn superconducting electromagnet	~20	Critical magnetic field
Steady-field air-core water-cooled electromagnet	~30	Joule heating
Pulsed-field hybrid electromagnet	~50	Maxwell stress

At $T = 300$ K, Equation 4.47 results in $B_{min} \approx 155$ Tesla (T), which is much larger than can be practically achieved (a summary of the technologies used to generate high magnetic fields is provided in Table 4.1).

One of the most difficult problems of very high magnetic field is the excessive power consumption and Joule heating in electromagnets. The relationship between power consumption, P, and magnetic field B, in an electromagnet is [17]:

$$P \sim B^2 \tag{4.48}$$

Moreover, as the production of magnetic fields with $B > 10$ T requires many megawatts of power, these magnetic field-production systems have large dimensions and a mass of many tons (see Table 4.2).

Thus, it is concluded that single electron spin devices operating at room temperature would require local magnetic fields greater than have been achieved to date with large-volume apparatus.

In multi-spin systems, it is possible to increase the magnetic moment μ and therefore, to decrease the magnitude of the external magnetic field B required for binary switch operation. The increase of μ may be due to an increase in number of co-aligned spins, which results in collective effects such as paramagnetism and ferromagnetism.

Table 4.2 Examples of practical implementations of the sources of magnetism.

Magnet	B [T]	P	Mass	Comments
Small bar magnet	~0.01	—	~g	—
Small neodymium–iron–boron magnet	~0.2	—	~g	—
Big Magnetic-core electromagnet	~2	~100 W	~kg	—
Steady-field superconducting electromagnet [19]	~16	~MW	~tons	Cryogenic temperatures
Current status of Pulse Magnet Program at National High Magnetic Field Laboratory [18]	60–65	~MW	~tons	Cryogenic temperatures; a 30-min cooling time between shots Lifetime ~400 cycles

4.5.3 Energy Barriers for Multiple-Spin Systems

In a system of N spins in an external magnetic field, there are $N_{\uparrow\uparrow}$ spin magnetic moments parallel to the external magnetic field, and the resulting magnetic moment is

$$\mu = \mu_B \cdot N_{\uparrow\uparrow} = \mu_B N(1 - \Pi_{\text{err}}) = \mu_B N\left(1 - \exp\left(-\frac{\mu_B B}{k_B T}\right)\right) \tag{4.49}$$

As seen above, for all practical cases $\mu_B B \ll k_B T$, and since $(1 - e^x) \approx x$, for $x \to 0$, there results

$$\mu \approx \frac{N\mu_B^2 B}{k_B T} \tag{4.50}$$

Equation 4.50 is known as the Curie law for paramagnetism [11]. From Equations 4.50 and 4.44 one can calculate the minimum number of electron spins required for spin binary switch operating at realistic magnitudes of the magnetic field:

$$N_{\min} \approx \frac{\ln 2}{2}\left(\frac{k_B T}{\mu_B B}\right) \tag{4.51}$$

For example, for $B = 0.1$ T (a small neodymium–iron–boron magnet; see Table 4.1), $N_{\min} \sim 7 \times 10^6$. If the number of electrons with unpaired spins per atom is f (f varies between 1 and 7 for different atoms), then the number of atoms needed is $N_{\min}/f$. Correspondingly, one can estimate the minimum critical dimension $a_{\min}$ of the binary switch as:

$$a_{\min} \sim \left(\frac{N_{\min}}{f \cdot n_V}\right)^{\frac{1}{3}}, \tag{4.52}$$

where n_V is the density of atoms in the material structure. Assuming an atomic density close to the largest known in solids, $n_V = 1.76 \times 10^{23}\ \text{cm}^{-3}$ (the atomic density of diamond) and $B \sim 0.1$ T, we obtain $a_{\min} \sim 41$ nm for $f = 1$ and $a_{\min} \sim 22$ nm for $f = 7$. Thus, it is concluded that for reliable operation at moderate magnetic fields, the physical size of a multi-spin-based binary switch is larger than the ultimate charge-based devices. The effect of collective spin behavior is currently used, for example, in magnetic random access memory (MRAM) [14] and in electron spin resonance (ESR) technologies.

As an example, it is estimated that the energy needed to operate a spin-based binary switch for the case when the magnetic field is produced by electrical current I in a circular loop of wire surrounding the switch, as shown in Figure 4.10. The magnetic field in the center of the loop is [20]:

$$B = \frac{\mu_0 I}{2r}, \tag{4.53}$$

where μ_0 is the magnetic permeability of free space.

In order to switch the external magnetic field, for example from zero to $+\vec{B}$ or from $+\vec{B}$ to $-\vec{B}$, work must be done. If the magnetic field is formed by electrical current I produced by an external voltage source, then the energy dissipated by one half of switching cycle (e.g., the rise from zero to $+\vec{B}$):

$$E_{\text{dis}} = \frac{LI^2}{2} \tag{4.54}$$

where L is electrical inductance. Equation 4.54 is analogous to the energy of $CV^2/2$ dissipated in charge-based devices [Equation 4.34].

If magnetic field needs to be sustained for the time period t, then additional energy will be dissipated due to resistance R, and thus the total energy dissipation is:

$$E_{\text{dis}} = \frac{LI^2}{2} + I^2 R \cdot t \tag{4.55}$$

If the magnetic field does not need to be sustained (e.g., in ferromagnetic devices), after switching the current must be reduced to zero, in which case another amount of energy of Equation 4.54 is dissipated. Thus, the energy expenditure needed to generate the magnetic field E_{M} [see Equation 4.55] in a full switching cycle is

$$E_{\text{M}} = LI^2 \tag{4.56}$$

By definition, electrical inductance L is a proportionality factor connecting magnetic flux Φ and the electric current I that produces the magnetic field [20]:

$$\Phi = L \cdot I \tag{4.57}$$

The magnetic flux in turn is defined as

$$\Phi = B \cdot A \tag{4.58}$$

where A is the area, $\text{A} = \pi r^2$, for the case of circular loop.

From Equations 4.53,4.57 and 4.58, the inductance of a circular loop of radius r is approximately:

$$L \approx \frac{\pi \mu_0 r}{2} \tag{4.59}$$

Equation 4.64 is an approximation assuming constant magnetic field inside the loop and ignoring the effects of wire thickness.[1)]

By combining Equations 4.53,4.56 and 4.59, we obtain:

$$E_M = \frac{2\pi}{\mu_0} r^3 B^2 \tag{4.60}$$

For the minimum device size given by Equation 4.52, and noting that $r \geq a_{\min}$ as obtained from Equations 4.19 and 4.60:

1) An accurate result for the inductance of the circular loop is $L = \mu_0 r[\ln(8r/b) - 7/4]$, where b is the radius of the wire [21]. This differs from Equation 4.59 by a factor of 1.6–3 for a realistic range of r/b ratios of 10–100.

$$E_{\mathrm{M\,min}} = \frac{\pi \ln 2}{\mu_0 n_V}\left(\frac{k_\mathrm{B}T}{\mu_\mathrm{B}}\right)^2 \tag{4.61}$$

For the largest atomic density of solids, $n_\mathrm{V} = 1.76\times10^{-23}\,\mathrm{cm}^{-3}$ (diamond), we obtain:

$$E_{\mathrm{M\,min}} \approx 2\cdot10^{-18}\,\mathrm{J} \approx 480 k_\mathrm{B}T \tag{4.62}$$

4.5.4
Energy Barriers for the Optical Binary Switch

Optical digital computing was – and still is – considered by some as a viable option for massive information processing [22]. Sometimes, it is referred to as "computing at speed of light" [23] and, indeed, photons do move at the speed of light. At the same time, a photon cannot have a speed other then the speed of light, c, and therefore it cannot be confined within a binary switch of finite spatial dimensions.

The minimum dimension of optical switch is given by the wavelength of light, λ. If $a_{\min} < \lambda$, there is high probability that the light will not "sense" the state – that is, the error probability will increase. For visible light, $a_{\min} \sim 400\,\mathrm{nm}$.

Binary state control in the optical switch is accomplished by local changes in optical properties of the medium, such as the refraction index, reflectivity or absorption, while photons are used to read the state. In many cases, the changes in optical properties are related to a rearrangement of atoms under the influence of electrical, optical, or thermal energy. The energy barrier in this case is therefore related to either inter-atomic or inter-molecular bonds. Examples of such optical switches are liquid crystal spatial light modulators [22] and non-linear interference filters [22]. Another example is a change in refractive index as the result of a crystalline-to amorphous phase change, which is used for example in the rewritable CD. The minimum switching energy of this class of optical switches is related to the number of atoms, N, and therefore to the size L. In the limiting case, $L \sim a_{\min} \sim \lambda$. In order for the atoms of an optical switch to have a distinguishable change of their position, the energy supply to each atom should be larger than $k_\mathrm{B}T$. The total switching energy is therefore:

$$E \sim N \cdot k_\mathrm{B}T \tag{4.63}$$

For a minimum energy estimate, we must consider the smallest possible N, which corresponds to an single-atom plane of size λ. If optical switch materials have an atomic density n, then one obtains:

$$E \sim n^{\frac{2}{3}} \cdot \lambda^2 \cdot k_\mathrm{B}T \tag{4.64}$$

For most solids, $n = 10^{22}$–$10^{23}\,\mathrm{cm}^{-3}$. Taking $n = 5\times10^{22}\,\mathrm{cm}^{-3}$, $T = 300\,\mathrm{K}$, and $a_{\min} \sim 400\,\mathrm{nm}$, we obtain $E \sim 10^{14}\,\mathrm{J}$, which is in agreement with estimates of the physical limit of switching energy of optical digital switches, as reported in the literature [22].

Optical switches may also be based on electroabsorption. In these devices, the absorption changes by the application of an external electric field that deforms the

energy band structure. One example that has attracted considerable interest for practical application is the Quantum-Confined Stark Effect [24]. If an electrical field is applied to a semiconductor quantum well, the shape of the well is changed, perhaps from rectangular to triangular. As result, the position of energy levels also changes, and this affects the optical absorption. As the formation of an electric field requires changes in charge distribution [Equation 4.28], the analysis of electroabsorption optical switch is analogous to a charge-based switch, where the energetics is determined by charging and discharging of a capacitor [Equations 4.31 and 4.32]. It should be noted that the capacitance of an optical switch is considerably larger then the capacitance of electron switch, because of larger capacitance area of the optical switch ($\sim\lambda^2$). By using the estimated minimum size of an electron switch $a_{e\min} \sim 1$ nm (as estimated in Section 4.4.2), and taking into account Equation 4.40b, we obtain an estimate for the switching energy of an electroabsorption device:

$$E \sim 3k_B T \frac{\lambda^2}{a_{e\,\min}^2} \approx 1.2 \cdot 10^{-20}\,\mathrm{J} \cdot \frac{(400\,\mathrm{nm})}{(1\,\mathrm{nm})} \approx 10^{-15}\,\mathrm{J} \tag{4.65}$$

The result from Equation 4.65 is in an agreement with estimates of physical limit of electro-absorption optical switch, as detailed in the literature [22, 25].

This energy barrier – and therefore the switching energy for an optical binary switch – is relatively high, with estimates for the theoretical limit for optical device switching energy varying between 10^{-14} and 10^{-15} J, for different types of optical switch [22]. It should be noted that the switching speed is the speed of re-arrangement for atoms or for charge in the material, and is not related to the speed of light.

4.6 Conclusions

Based on the idea that information is represented by the state of a physical system – for example, the location of a particle – we have shown that energy barriers play a fundamental role in evaluating the operating limits of information-processing systems. In order for the barrier to be useful in information-processing applications, it must prevent changes in the state of the processing element with high probability, and it also must support rapid changes of state when an external CHANGE command is given. If one examines the limit of tolerable operation – that is, the point at which the state of the information-processing element loses its ability to sustain a given state – it is possible to advance estimates of the limits of performance for various types of information-processing element. In these limit analyses, the Heisenberg uncertainty relationship can serve as a basis for estimating performance using algebraic manipulations only.

It was shown that charge-based devices in the limit could offer extraordinary performance and scaling into the range of a few nanometers, albeit at the cost of enormous and unsustainable power densities. Nonetheless, it appears that there is considerable room for technological advances in charge-based technologies. One could consider using electron spin as a basis for computation, as the binary system

state can be defined in terms of spin orientation. However, an energy barrier analysis, based on the equilibrium room-temperature operation of a digital spin-flipping switch, has revealed that extraordinarily large external magnetic fields are required to sustain the system state, and hence that a high energy consumption would result. (Although it has been proposed that if devices can be operated out-of-equilibrium with the thermal environment, then perhaps computational state variables can be chosen to improve on the switching energy characteristic of spin-based devices [26].) The need for very large magnetic fields can be eased by utilizing multiple electron spins to represent the state of the processing element. Unfortunately, the number of electrons that must be utilized is such that the size of the processing elements would be about an order of magnitude larger than that of a charge-based device. Finally, we briefly examined the different physical realizations for optical binary elements, and found that the inability to localize a photon, although an advantage for communication systems, works against the implementation of binary optical switches. As a general rule, optical binary switches are significantly larger than charge-based switches.

Although it appears that it will be difficult to supplant charge as a mainstream information-processing state variable, there may be important application areas where the use of spin or optics could be used to advantage. While the present chapter has focused on the properties of the processing elements themselves, information-processing systems are clearly comprised of interconnected systems of these elements, and it is the system consideration that must remain paramount in any application. Nonetheless charge-based systems, by using the movement of charge to effect element-to-element communication, avoid changing any state variable to communicate, and this is a decided advantage.

Charged-Particle Lithography

Lothar Berger, Johannes Kretz, Dirk Beyer, and Anatol Schwersenz

5.1
Survey

The extensive functional range of modern microelectronics is being driven by the ability to pack large numbers of transistors into a small piece of silicon as an integrated circuit. Today, the method used to pattern almost all integrated circuits is *photolithography* (also referred to as *optical lithography*), where circuit patterns from master images, the transmission photomasks, are transferred to silicon wafers by projection optics. In more detail, the wafer is coated with a photoresist, which is exposed with the desired circuit pattern (see Figure 5.1). The resulting resist pattern is transferred to the wafer by subsequent process steps. A detailed introduction to photolithography can be found in Ref. [1], while a comprehensive study is presented in Ref. [2].

The pivotal device of the integrated circuits of today is the metal oxide semiconductor field effect transistor (MOSFET), for which a sample photolithographic process, producing the electrical connections, is shown in Figure 5.2. Here, the bulk transistor has already been fabricated on the wafer, and consists of the doped areas of source, drain, and gate. The wafer is then coated with a positive photoresist, and exposed to form the contact areas for the transistor (Figure 5.2a). The exposed areas of the photoresist are removed by a developer chemical (b), after which the insulating layer, now open at source, drain, and gate, is etched away (c). After metallization, the remaining unexposed photoresist is removed by a stripping chemical (d).

In 2006, the gate length of the MOSFET in the most advanced integrated circuits is typically 65 nm. The gate length, being the smallest feature required, is also known as the *critical dimension* (CD) of the pattern. A CD of 65 nm is close to the resolution limit of the current photolithography. The smallest feature is determined by:

$$\mathrm{CD} = k_1 \frac{\lambda}{\mathrm{NA}} \tag{5.1}$$

where k_1 is a factor determined by the projection optics and process flow, λ is the wavelength of the photons, and NA is the numerical aperture between the objective optical lens and the resist plane.

Nanotechnology. Volume 3: Information Technology I. Edited by Rainer Waser

ISBN: 978-3-527-31738-7

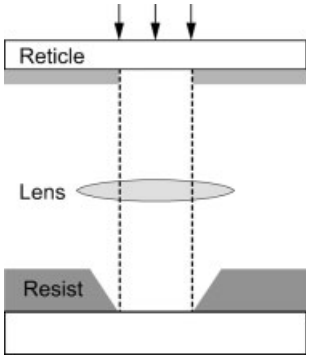

Figure 5.1 The principle of photolithography.

While a number of techniques have been developed to increase the resolution by reducing k_1 (referred to as *resolution enhancement techniques*; RET), the smallest feature that can be prepared by photolithography is ultimately dependent on the wavelength λ of the photons. Therefore, there is a history of reducing the wavelength, which is 193 nm for the current state-of-the-art *deep ultraviolet lithography* (DUVL). With $k_1 \approx 0.3$ for current projection optics and process flow, and NA ≈ 0.95 for a technically feasible projection in air, CD ≈ 61 nm represents the smallest feature.

Attempts to reduce the wavelength further have been investigated extensively, but encountered problems. For example, at $\lambda = 157$ nm no fully suitable material has been found to fabricate the transmission photomask and the lenses of the projection optics. Therefore, the current 193-nm photolithography is now scheduled to be extended into 193 nm immersion photolithography, which increases the NA by

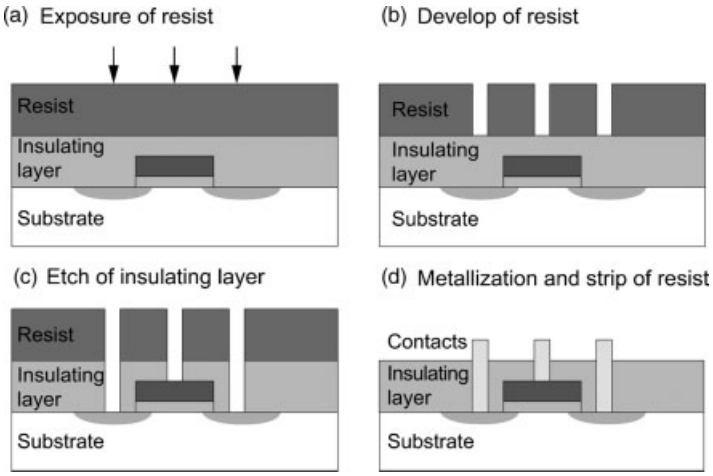

Figure 5.2 The photolithographic process for making electrical connections to a transistor.

conducting the exposure not in air, but in a liquid. With NA ≈ 1.4 for a technically feasible projection in water, CD ≈ 42 nm can be achieved. Much progress has been made with immersion photolithography, and the technique is currently at the stage of pilot production.

Another means of reducing the wavelength is to forego the use of transmission photomasks and projection optics with lenses, and to utilize reflective masks and mirror projection optics. Lithography involving reflection is no longer considered as classical photolithography. The wavelength of the photons where mirrors can be applied most effectively is 13.5 nm, and lithography of 13.5 nm involving masks with multilayer Bragg reflectors is referred to as *extended ultraviolet lithography* (EUVL), for which considerable research effort is currently being expended. At this point, it should be mentioned that EUVL differs greatly from DUVL in that it requires the redevelopment of almost all the exposure equipment and lithography processes currently in use. A comprehensive study of the process is presented in Ref. [3].

An alternative to any lithography involving photons is *charged-particle lithography*, where charged particles (electrons, ions) are used for patterning. While certain charged particle lithography techniques are already used for special applications, such as fabricating masks for photolithography, or prototyping, promising new charged-particle lithography techniques for preparing integrated circuits are currently under development, and may in time complement or even replace photolithography.

In order to illustrate the relationship between charged-particle lithography and photolithography, it is of help to examine the International Technology Roadmap for Semiconductors (ITRS), which demonstrates the status of lithographic techniques currently in use and under development within the microelectronics industry. The ITRS for the year 2006 is shown in Figure 5.3 [4]. According to the current ITRS, in 2007 the most likely successors of DUVL include EUVL, a multiple-electron-beam lithography technique called *maskless lithography* (ML2), and *nanoimprint lithography* (NIL). Charged-particle lithography techniques known as electron projection lithography (EPL) and ion projection lithography (IPL), both of which use a transmission mask and projection optics with electromagnetic lenses to direct electrons and ions, were removed from the ITRS in 2004. Proximity electron lithography (PEL), which uses a 1 : 1 transmission mask, was removed in 2005, although its re-emergence cannot be ruled out completely.

In this chapter we discuss the physical concepts and the principal advantages and limitations of charged-particle lithography techniques. A brief insight is also provided into the charged-particle lithography techniques currently in use and under development, while a strong focus is placed on ML2 techniques. The chapter comprises four sections: Section 5.1 includes a survey of the field, while Section 5.2 incorporates discussions of electron beam lithography and electron resists, and their major applications:

- the fabrication of transmission masks for DUVL and reflective masks for EUVL

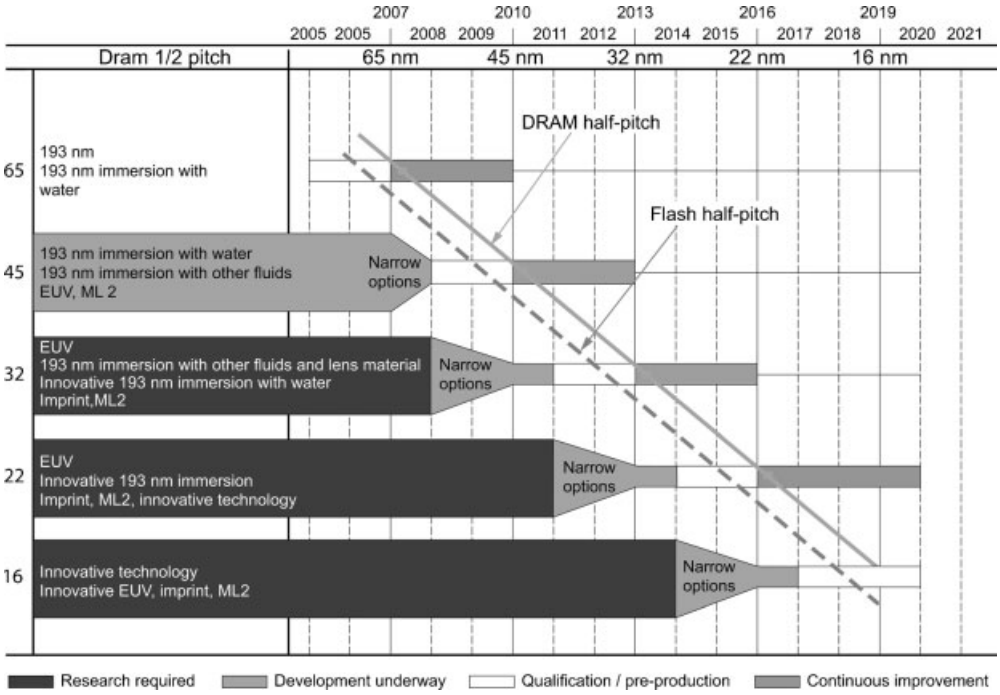

Figure 5.3 The lithography roadmap of 2006 [4].

- the direct-writing of patterns onto wafers with single beams for prototyping, low-volume production, and mix-and-match with photolithography
- the direct-writing of patterns on wafers with multiple beams for volume production: ML2
- the fabrication of imprint templates for NIL.

Section 5.2 concludes with a discussion of the special requirements for mix-and-match, namely the integration of electron beam lithography (EBL) with photolithography. Section 5.3 presents details of ion beam lithography (IBL), for which the major applications include:

- the direct-structuring of patterns on wafers without resist processing, for prototyping, low-volume production, and special applications
- the fabrication of imprint templates for NIL, with direct-structuring of patterns without resist processing.

A graphical overview of the charged-particle lithography techniques discussed in this chapter is provided in Figure 5.4. Finally, Section 5.4 provides a conclusion and outlook on charged-particle lithography techniques.

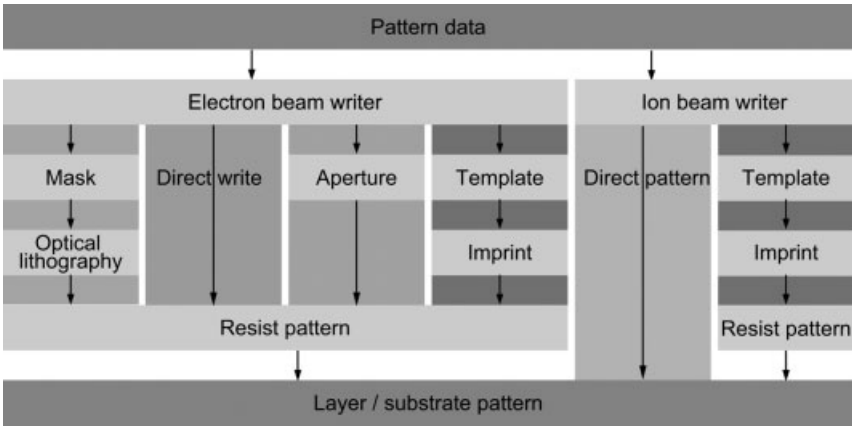

Figure 5.4 Charged-particle lithography techniques: an overview.

5.2 Electron Beam Lithography

5.2.1 Introduction

Electron beam lithography involves the use of electrons to induce a chemical reaction in an electron resist for pattern formation (the properties of electron resists are discussed in detail in Section 5.2.2). Because of the extremely short wavelength of accelerated electrons, EBL is capable of very high resolution, as $\lambda = h/(mv)$, $E_{kin} = (mv^2)/2$, and $E = eU$ gives:

$$\lambda = \frac{h}{\sqrt{2meU}} \tag{5.2}$$

Therefore, the typical acceleration voltage of $U = 100\,\text{kV}$ results in $\lambda = 0.004\,\text{nm}$, which is well below the atomic scale. Even with simple EBL systems, 10-nm patterns have been demonstrated [5], which is well beyond any other lithographic technique. Further, EBL is unaffected by the major issues of optical lithography – diffraction and reflection – and much less affected by the depth-of-focus (DOF) limit [1, 2].

The first EBL tools where based on the scanning electron microscope, and first developed during the 1960s [6]. A schematic representation of a simple EBL system is shown in Figure 5.5. The column consists of an electron source, and the electron optics. The substrate is mounted on a precision stage below the column, where its position is controlled by a laser interferometer. As the electron source and electron optics require a high vacuum, a load–unload system with an air-lock is also fitted.

5.2.1.1 Electron Sources

While early EBL systems based on scanning electron microscopy (SEM) used field emission sources, where the electrons are extracted out of a sharp-tip cathode, modern

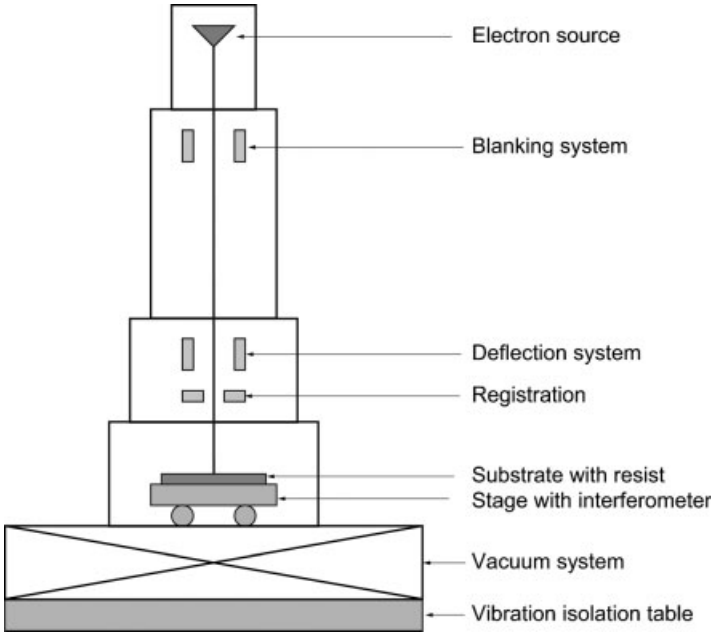

Figure 5.5 Schematic representation of a simple electron beam lithography system.

systems employ thermal sources. Such a thermal source consists of an emission region, where the cathode is heated, and an extraction region, where an electric field extracts the electrons and accelerates them to form a beam. The maximum current density j which can be obtained from this type of source for an acceleration voltage V and an acceleration distance d is limited by space-charge effects [6]:

$$j = \frac{1}{9\pi d^2}\sqrt{\frac{2q}{m}}\,V^{\frac{3}{2}} \tag{5.3}$$

The properties of common field emission and thermal sources are listed in Table 5.1 [6]. Because of its lower operating temperature and energy spread, LaB_6 is the source of choice for most current tools.

5.2.1.2 Electron Optics

Electron optics is based on the fact that electrons can be deflected by electromagnetic fields. The electric field between two grid electrodes, which causes bending of the trajectory of an electron, is shown in Figure 5.6.

Table 5.1 A comparison of the properties of common field emission and thermal sources [6].

Parameter	Field emission: tungsten	Thermal: tungsten	Thermal: LaB_6
Operating temperature T [K]	300	2700	1700
Energy spread [eV]	0.3	3	1.5

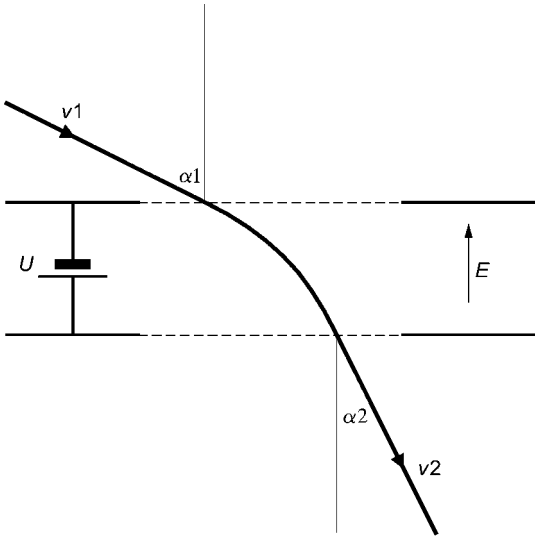

Figure 5.6 Electron–optical refraction.

For this configuration, the conservation of energy for an electron yields:

$$E_{kin,1} + eU = E_{kin,2} \tag{5.4}$$

where $E_{kin,1} = (mv_1^2)/2 = eU_0$ and $E_{kin,2} = (mv_2^2)/2$, and Equation 5.4 can be expressed as an electron–optical refraction law:

$$\frac{\sin\alpha_1}{\sin\alpha_2} = \frac{v_2}{v_1} = \sqrt{1 + \frac{U}{U_0}} \tag{5.5}$$

Electron Lenses A simple electrostatic lens (Einzel lens) consists of three rings, where the outlying rings have the same electrostatic potential (Figure 5.7).

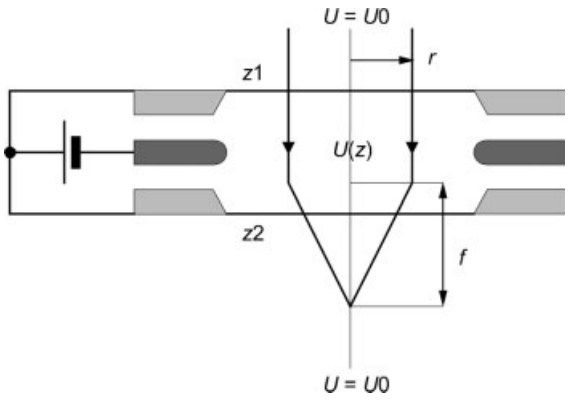

Figure 5.7 Electrostatic lens.

For this configuration, if the charge effects are negligible, then a simple equation for the paraxial trajectories of electrons can be obtained [6]:

$$\frac{d^2r}{dz^2} + \frac{1}{2U}\frac{dU}{dz}\frac{dr}{dz} + \frac{1}{4U}\frac{d^2U}{dz^2}r = 0 \tag{5.6}$$

It should be noted that as Equation 5.6 is invariant towards the scaling of the voltage U, voltage instabilities in general do not cause a jitter of trajectories through electrostatic lenses. With the geometrical relation of the trajectory r and the focal length f, $dr(z_1)/dz = -r_1/f$, and $r \approx r_1$, Equation 5.6 yields [6]:

$$\frac{1}{f} \approx \frac{1}{8\sqrt{U_0}} \int_{z_1}^{z_2} \left(\frac{dU}{dz}\right)^2 U^{-\frac{3}{2}}\, dz \tag{5.7}$$

Magnetic lenses utilize the force on an electron in a magnetic field:

$$\vec{F} = e\,\vec{v} \times \vec{B} \tag{5.8}$$

A simple magnetic lens is a solenoid ring (Figure 5.8).

For this configuration, if the radial field components are negligible, then a simple equation for the paraxial trajectories of electrons can be obtained [6]:

$$\frac{d^2r}{dz^2} = -\frac{e}{m}\frac{B_z^2}{8U_0}r \tag{5.9}$$

With the geometrical relation of the trajectory r and the focal length f, $dr(z_2)/dz = -r_1/f$, and $r \approx r_1$, Equation 5.9 yields [6]:

$$\frac{1}{f} \approx \frac{e}{8mU_0} \int_{z_1}^{z_2} B_z^2\, dz \tag{5.10}$$

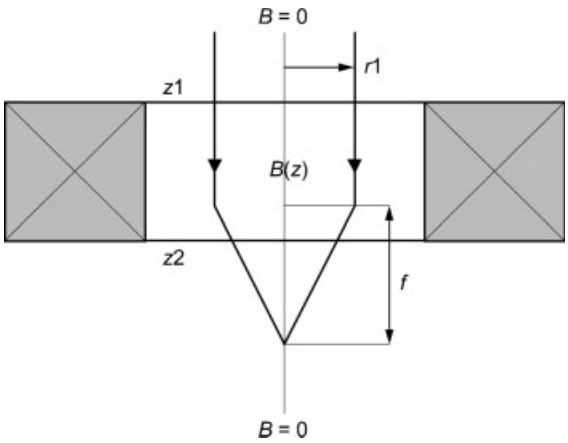

Figure 5.8 Magnetic lens.

Electron Optical Columns For the design of electron optical columns, the previous simple considerations are not adequate. It is required to derive the trajectories of electrons in a general form, which is valid also for non-rotational-symmetric lenses. A straightforward calculation can be based on the general equation of motion of electrons in an electron optical column:

$$\frac{d}{dt}(m\vec{v}) = e\left[\vec{E}(\vec{r},t) + \vec{v} \times \vec{B}(\vec{r},t)\right] \tag{5.11}$$

It is convenient to substitute with the arc element of the trajectory, $ds = |d\vec{r}| = vdt$:

$$m\frac{d\vec{v}}{ds} = e\left[\frac{\vec{E}}{v} + \frac{d\vec{v}}{ds} \times \vec{B}\right] \tag{5.12}$$

The trajectory equation can be derived in Cartesian coordinates, and with the introduction of the abbreviations $\eta = \sqrt{\frac{e}{2m_0}}$, $\varepsilon = \frac{e}{2m_0c^2}$, $\Phi_0 = \frac{E_0}{e}$, $\hat{\Phi} = (\Phi_0 + \Phi)[1 + \varepsilon(\Phi_0 + \Phi)]$, $\rho = |\vec{r}\,'| = \sqrt{1 + (x')^2 + (y')^2}$, where E_0 is the initial kinetic energy of an electron at the source, the trajectory equation results as follows [7]:

$$\begin{aligned} x'' &= \frac{\rho^2}{2\hat{\Phi}}\left(\frac{\partial\hat{\Phi}}{\partial x} - x'\frac{\partial\hat{\Phi}}{\partial z}\right) + \frac{\eta\rho^2}{\sqrt{\hat{\Phi}}}\left(\rho B_y - y' B_t\right) \\ y'' &= \frac{\rho^2}{2\hat{\Phi}}\left(\frac{\partial\hat{\Phi}}{\partial y} - y'\frac{\partial\hat{\Phi}}{\partial z}\right) + \frac{\eta\rho^2}{\sqrt{\hat{\Phi}}}\left(-\rho B_x + x' B_t\right) \end{aligned} \tag{5.13}$$

It should be noted that this trajectory equation is valid only if all the trajectories are continuous – that is, if $x'(z)$, $y'(z)$ are finite. This is not the case with electron mirrors, although these are not used in current electron optical columns.

Aside of the trajectory representation of Equation 5.13, more elaborate mathematical methods have been applied to the analytic investigation of electron optical columns concepts and designs, focusing on the prediction of projection imperfections, called *aberrations*. These methods include the classical mechanics approach of Lagrange or Hamilton formalism [7], with the latter leading towards the Hamilton–Jacobi theory of electron optics, which is capable of treating whole sets of trajectories, and therefore is a standard tool for the design of electron optical columns with minimal aberrations [8].

Recently, with the support of computer algebra tools, a Lie algebraic electron optical aberration theory has been derived, which makes accessible high-order canonical aberration formulas, and therefore may open up new possibilities in the design of high-performance electron beam projection systems [9].

Electron Optical Aberrations Electron optical columns suffer from projection deviations termed aberrations, which are caused either by non-ideal electron optical

elements, or by the physical limits of electron optics. An ideal electron optical lens should project an electron beam crossing the entrance plane at the point (x_0, y_0) onto the exit plane at the point $(x_1, y_1) = m(x_0, y_0)$, where m is a scalar called the *magnification*. Unfortunately, however, a real lens suffers from imperfections. For example, a real lens has the same focal length only for paraxial electron beams, while off-axis beams are slightly deflected. This is called *spherical aberration*, and is expressed by a coefficient C_s, relative to the beam position in the aperture plane (x_a, y_a):

$$(x_0, y_0) \rightarrow m\left(x_0 + C_s x_a\left(x_a^2 + y_a^2\right), y_0 + C_s y_a\left(x_a^2 + y_a^2\right)\right) \tag{5.14}$$

With $C_s > 0$, an electron beam is blurred into a finite disk. Electron optical aberration theory shows that C_s cannot be made to vanish completely for rotational symmetric lenses [7], which in turn led to the introduction of non-rotational symmetric elements such as quadrupoles or octopoles. An overview of lens aberrations occurring in an electron optical column is provided in Ref. [7]. Additionally, the non-ideality of the electron source must be considered: a real electron source has a small spread in electron energy and, as the focal length of electron lenses depends on the electron energy, a non-monochromatic electron beam is blurred into a finite disk. This is referred to as *chromatic aberration*. In addition to these lens aberrations, other electron optical elements, such as beam deflectors, also introduce aberrations.

For a high-resolution EBL system, optimal projection is crucial, and therefore the aberrations discussed above must either be minimized by the design of the electron optical column, or compensated by additional electron optical elements. For example, since it is not possible to prepare a column with perfect rotational symmetry, an electron beam always suffers from astigmatism and misalignment. In order to compensate for astigmatism, a non-rotational symmetric element is required, a *stigmator*. This may be an electrostatic quadrupole, which is a circular arrangement of four electrodes. However, stigmators are usually designed as electrostatic octopoles which, in addition to quadrupole fields, can also generate dipole fields at any angle to correct beam misalignment [10].

While major efforts have been made to apply aberration theory to the design of an electron column with minimal aberrations, only powerful numerical optimization tools can be utilized for any systematic approach [11]. Such a tool generally consists of the following packages:

- an electromagnetic field computation package
- an electron beam ray tracing package
- an electron exposure spot plotting package
- an optimizer for minimizing aberrations.

An aberrations optimizer typically implements the damped least squares (DLS) method for iteratively minimizing overall aberrations. The individual aberrations $f_i(x_1, \ldots, x_n)$, depending on the column parameters x_j, (lens positions, sizes,

strengths), are weighted and summed into a deviation function:

$$\Psi = \sum_i (w_i f_i)^2 \tag{5.15}$$

which is then minimized. With this method, existing electron column designs can be improved, and new designs optimized automatically.

In addition to the design of electron optical columns with minimal aberrations, it has been proposed to implement adaptive aberration correction by introducing novel electron optical elements: for example, an electrostatic dodecapole, with time-dependent voltage control for the poles [12]. The learning process could be based on exposure pattern images.

5.2.1.3 Gaussian Beam Lithography

Patterning in EBL can be accomplished by focusing the electrons into beams with very narrow diameters. Because the electrons are created by a thermal source, they have a spread in energy. The trajectories of the electrons therefore vary slightly, resulting in electron beams with near-Gaussian intensity distribution after traversing the electron optics [13].

The basic principle of Gaussian electron beam exposure is *raster scanning*. Similar to a television picture tube, the electron beam is moved in two dimensions across the scanning area on the electron resist, which typically is about 1 mm^2. Within that area, which is termed the *deflection field*, the electron beam can be moved very rapidly by the electron optics. In order to change the position of this area on the substrate, a mechanical movement of the precision stage is required. Patterns which stretch over more than 1 mm^2 must be stitched together from separate deflection fields; in order to avoid discontinuities in the patterns at the boundaries of the deflection fields (these are known as *butting errors*, and potentially are caused by mechanical movement of the stage), the positions of these boundaries are calibrated and corrected in sophisticated manner.

In order to create the pattern shown in Figure 5.9a, the electron beam is moved across the area where the desired pattern is located, and is blanked on spots not intended for exposure. Raster scanning certainly has the major problem that the electron beam must target the whole scanning area, which takes a considerable time. Therefore, a great improvement is to target only the area of the desired pattern; this is termed *vector scanning* (Figure 5.9b). However, another major limitation remains in that, if a pattern consists of large and small features, the diameter of the electron

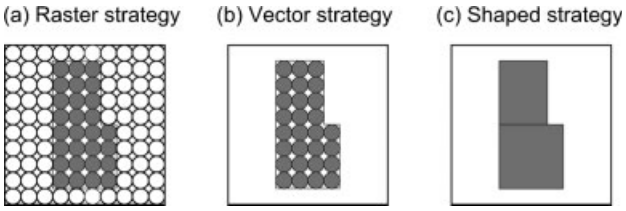

Figure 5.9 Writing a pattern with: (a) raster-, (b) vector-, and (c) vector shaped & beam strategies.

beam must be adapted to the smallest feature, thereby greatly increasing the exposure time of the large features.

5.2.1.4 Shaped Beam Lithography

In order to overcome the limitations of both raster and vector scanning, EBL tools have been developed which can shape electron beams. A shaped electron beam is created by special aperture plates and, in contrast to the near-Gaussian intensity distribution of standard EBL tools, shaped electron beam tools can apply rectangular, or even triangular, intensity distributions [14]. At present the fastest technique available is vector scanning using shaped electron beams; when using this technique the pattern shown in Figure 5.9c requires only two exposures.

The principal function of a variable-shaped beam (VSB) column is illustrated in Figure 5.10. The electron source illuminates a first shaping aperture, after which a first condenser lens projects the shaped beam onto a second shaping aperture. The beam position on the second aperture is controlled by an electrostatic deflector. A second condenser lens projects the shaped beam onto the demagnification system, consisting of two lenses, and the final aperture in between. After demagnification, the

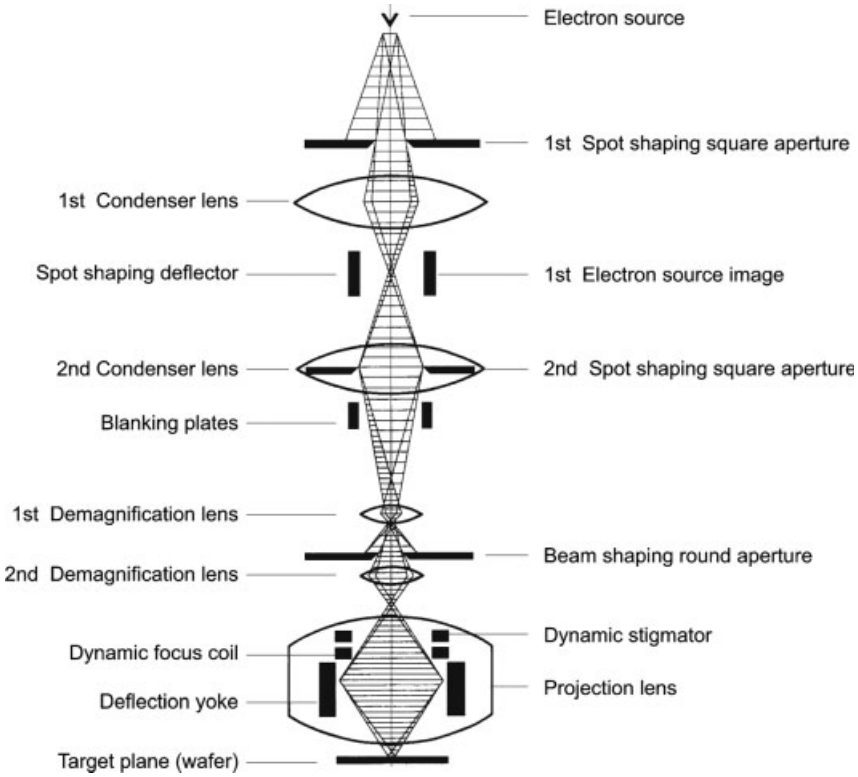

Figure 5.10 Variable beam-shaping column [15]. (© 1979, IEEE.)

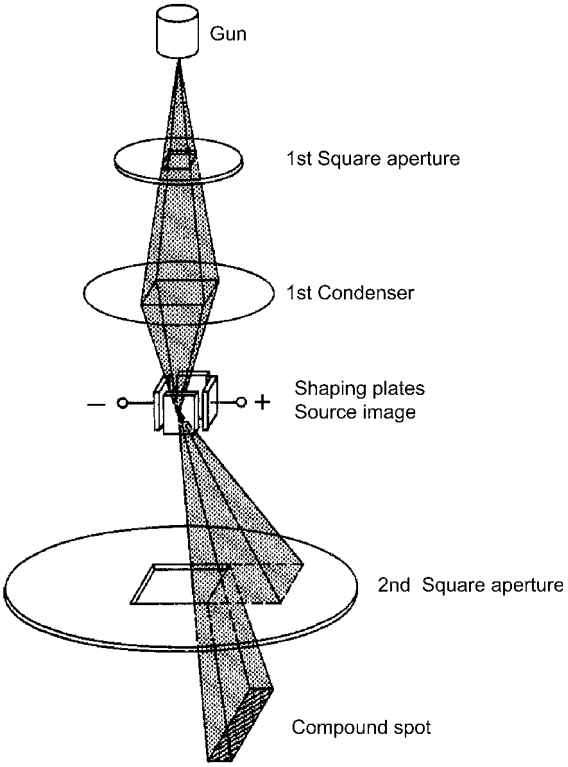

Figure 5.11 Variable beam-shaping method [15]. (© 1979, IEEE.)

shaped beam is projected onto the substrate by the final projection system, which consists of a stigmator and a projection lens with an integrated deflector.

The formation of shaped beams is illustrated for the example of rectangular spots in Figure 5.11. Two square apertures shape the spot; the image of a first square aperture, which appears in the plane of a second square aperture, can be shifted laterally with respect to the second aperture. This results in a rectangular spot which then is demagnified and projected onto the substrate.

Modern shaped electron beam tools can apply both rectangular and triangular spots. For example, the Vistec SB3050 [16] employs a LaB_6 thermal source, and utilizes a vector scan exposure strategy, a continuously moving stage, and the variable-shaped beam principle. The maximum shot area is $1.6 \times 1.6\,\mu m$, and rectangular shapes with 0° and 45° orientation, as well as triangles, can be exposed in a single shot. A detailed view of the two shaping aperture plates is shown in Figure 5.12.

The architecture and motion principle of the stage is decisive for pattern placement accuracy, so as to avoid butting errors. Position control by interferometer with a resolution $<1\,nm$, and the use of a beam tracking system, allow write-on-the-fly exposures with stage speeds of up to $75\,mm\,s^{-1}$. The driving range of the stage is

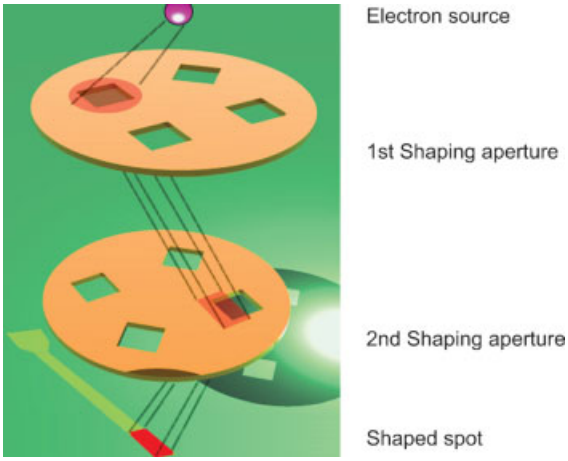

Figure 5.12 Schematic of electron beam shaping by double-aperture for rectangular and triangular spots [16].

310 × 310 mm, thus enabling the exposure of 6 in and 9 in masks, as well as 300 mm wafers (see Figure 5.13).

However, even such a precision stage cannot eliminate butting errors completely, and therefore the vector-shaped beam strategy involves overlapping exposure shapes, resulting in features being exposed at least twice, a process known as *multi-pass writing*.

A production-worthy EBL system is highly automated, with no human intervention required for operation, except for an operator issuing a command for the system to start loading the substrate and writing the pattern. The pattern is encoded in a digital data file, and stored in a computer memory or a mass storage device. Prior to writing, the original design data must be converted to a format which is usable by the writing tool. This data fracturing is accomplished using separate computer hardware, usually

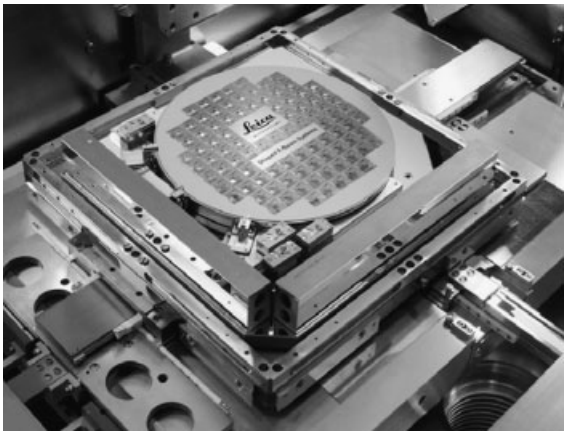

Figure 5.13 Electron beam lithography precision stage [16].

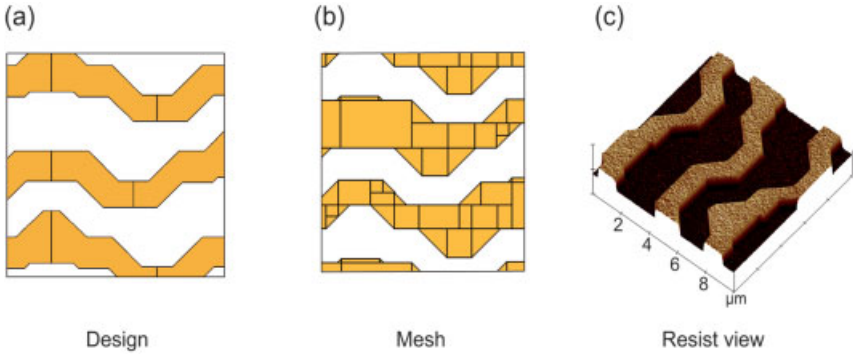

Figure 5.14 Writing a complex pattern with a vector-shaped beam strategy. (a) Design; (b) data fracturing into shapes; (c) the final atomic force microscopy resist picture.

a high-performance cluster, operating a real-time multi-threaded operating system, and data preparation software. An example of the writing of a complex pattern with vector shaped-beam strategy is shown in Figure 5.14.

EBL tools are usually tailored specifically for either photomask or wafer applications (this is also referred to as *direct-write lithography*), and the principal advantages and limitations of these processes are presented in more detail in Sections 5.2.3.1 and 5.2.3.2. Evaluations of the current leading-edge electron beam writing systems are available in Refs. [16–18].

5.2.1.5 **Patterning**

As highlighted at the start of Section 5.1, EBL – unlike optical lithography – is unaffected by major issues of optical lithography, such as diffraction and reflection, and much less affected by the DOF limit. However, it also encounters specific patterning issues, which must be addressed.

The most critical issue results from the scattering of the electrons passing through matter. While this scattering in part is indeed required for transferring energy to the electron resist for exposure, many electrons scatter into different directions from their original trajectories. In Figure 5.15, the shaded areas of the resist are intended for exposure. However, the electrons show two scattering modes, from resist intended for exposure into resist not intended for exposure – this is *forward scattering* (a); and through resist intended for exposure into the substrate and back into resist

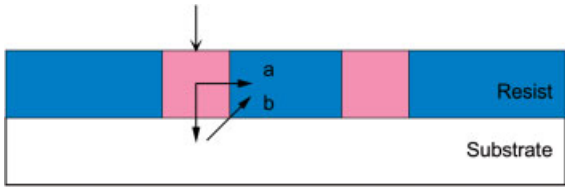

Figure 5.15 Electron-scattering modes. (a) Forward scattering; (b) back-scattering.

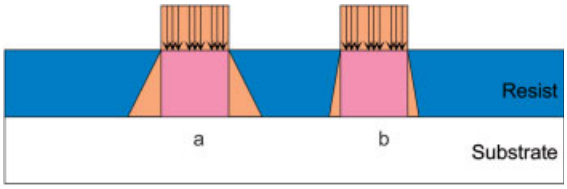

Figure 5.16 Forward scattering at: (a) low electron energy and (b) high electron energy.

not intended for exposure – this is *back-scattering* (b). Both scattering modes lead to unintended exposure, and therefore to degraded resolution and distortion of patterns. This issue is known as the *proximity effect* [19], and should be minimized as much as possible.

Forward scattering into the resist is addressed by increasing the acceleration voltage of the electrons, as shown in Figure 5.16. Although the first electron lithography tools used $U = 10\,\text{kV}$, and current tools employ 50 kV, more recently 100 kV tools have been introduced. This increase in acceleration voltage leads also to an improved projection performance, because the imperfections in the electron optics are less pronounced.

However, back-scattering intensifies with greater electron energy. With the currently required feature size being less than the range of back-scattered electrons, the features are broadened by back-scattering, thus offsetting the resolution improvement by reduced forward scattering.

For optimal resolution and minimal distortion, correction methods are therefore applied to overcome the proximity effect. A simple compensation technique, which accounts for back-scattering only, is to use a second exposure equaling the background exposure of the first one, with a reverse additional energy distribution [20]. However, as a second exposure is undesirable due to the additional writing time, a proximity correction by dose variation is introduced during data processing for converting the circuit designs [21]. Such a correction must be based on suitable models for proximity effect predictions. Here, a useful tool is the Monte-Carlo-based simulation of scattering from electron impact. Simulated trajectories for 100 electrons impacting into one point are shown in Figure 5.17, where both forward scattering and back-scattering appear distinctively.

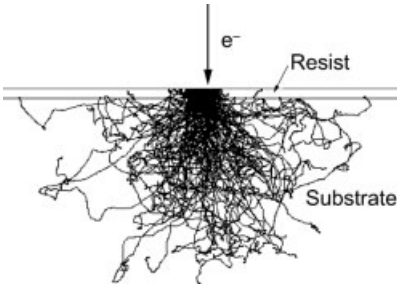

Figure 5.17 Simulated trajectories for 100 electrons impacting into one point.

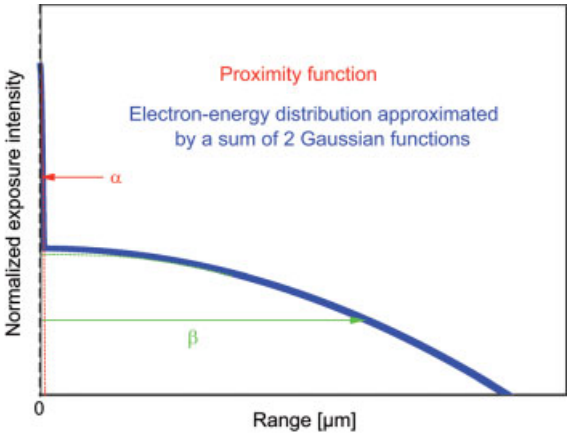

Figure 5.18 Proximity function (point exposure distribution fitted within two Gaussian functions).

In addition to model-based analysis, interpretations of generic pattern distortions of non-corrected patterns, as well as successive back-simulations, are utilized for the reconstruction of proximity effects [22], therefore enabling the best possible correction.

Current compensation techniques rely on either shot-by-shot modulation of the exposure dose, modification of the pattern geometry, or a combination of both methods. The proximity function $f(r)$ is usually described as a sum of two or more normalized two-dimensional Gaussian functions:

$$f(r) = \frac{1}{\pi(1+\eta)}\left[\frac{1}{\alpha^2}e^{-\frac{r^2}{\alpha^2}} + \frac{\eta}{\beta^2}e^{-\frac{r^2}{\beta^2}}\right] \tag{5.16}$$

The term α characterizes the forward scattering, and the term β the back-scattering, of the electrons. The parameter η is the deposited energy ratio of the back-scattering component towards the forward-scattering component, and r is the distance from the point of electron impact. The behavior of this function is shown by the diagram in Figure 5.18.

The concept of proximity correction by shot-to-shot dose modulation is illustrated in Figure 5.19: two features in close distance should be exposed. When applying a uniform exposure dose (Figure 5.19a) the intended resist exposure by forward scattering is compromised by back-scattering, leading to a distorted overall exposure, and to broadened features. When applying a suitably modulated exposure dose (Figure 5.19b), the resulting resist exposure by forward scattering complements the back-scattering, leading to the intended resist exposure.

5.2.2 Resists

Electron beam patterning requires specially designed electron-sensitive resists. As with photoresists, electron resists are available either as positive resists (which are insoluble in the developer chemical and become soluble when exposed), or as

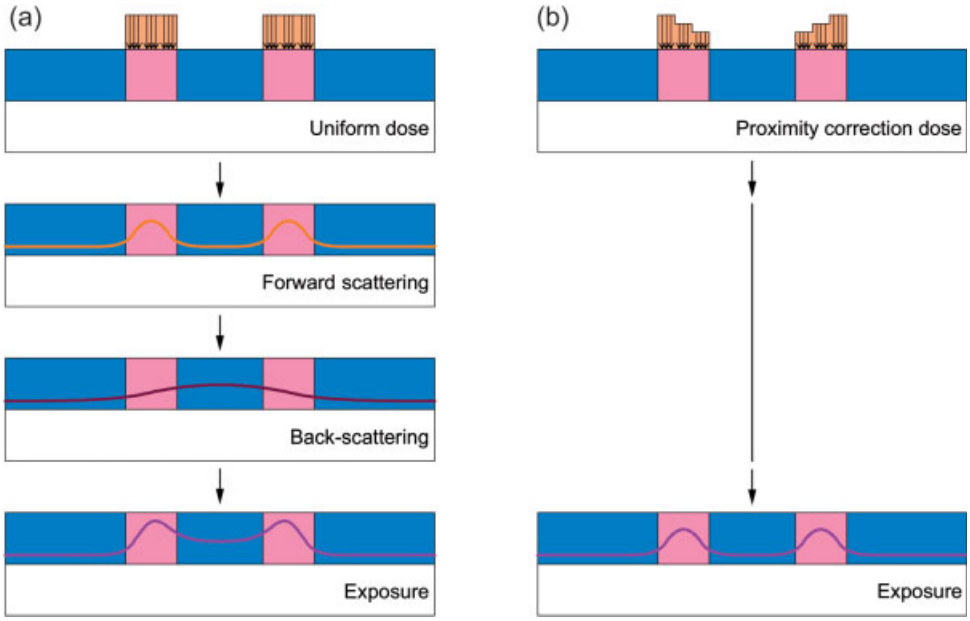

Figure 5.19 Proximity correction by shot-to-shot dose modulation.

negative resists (which are soluble from the start, and become insoluble when exposed). While the chemistry of electron resists is usually considerably different from that of photoresists, a parameter termed *contrast* can be defined to characterize the resolution of the resists.

In order to determine the contrast of an electron resist, the developing rate depending on the exposure dose is plotted; this is also called the characteristics of the electron resist. For a low-exposure dose, the resist still behaves like an unexposed resist, whereas for a high dose it is fully activated. The idealized characteristics of positive and negative electron resists are shown in Figure 5.20.

Linearization yields two parameters that define the characteristics: the resist sensitivity D_0, where the resist activation starts, and the resist activation D_v, after which the resist is fully activated. The contrast is then defined as:

$$\gamma = \frac{1}{\log \frac{D_V}{D_0}} \tag{5.17}$$

A high steepness of the transition in the characteristics therefore results in a high contrast.

Early electron resists employed just a single component for obtaining the latent image. In a positive resist, the image was created by electron-induced chain scission, with high-molecular-weight polymers with long chains being fragmented into smaller chains. The contrast of the resist was engineered by maximizing the difference in molecular weight before and after exposure. In a negative resist, the fragmentation into smaller chains generates radicals, which induce a crosslinking.

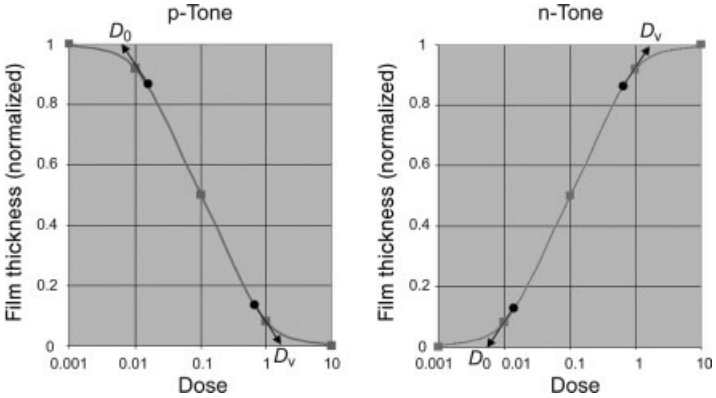

Figure 5.20 Idealized characteristics of positive and negative electron resists.

One of the first resists to be developed for EBL was polymethyl methacrylate (PMMA) [23]. Electron beam exposure breaks the polymer into fragments that are dissolved by a solvent-based developer (see Figure 5.21). Because of its very high resolution capability of <10 nm, PMMA is still used for certain R&D applications and electron beam writer resolution tests. However, it is not suitable for commercial lithography, mainly because of its poor resistance to dry etching.

Another group of early electron resists is based on a copolymer of chloromethacrylate and methylstyrene. One commercial resist for direct-write applications is ZEP-520 [24], which has considerable advantages compared to PMMA. While providing a comparable resolution of <10 nm, the sensitivity towards electrons is 10-fold higher, and the resistance to dry etching is 2.5-fold higher. Although these resists are still used for R&D applications, they have fallen out of favor for commercial lithography, because they require solvent-based developers that, because of their rapid evaporation rate in air, introduce temperature gradients on wafers, and therefore uniformity problems. A 45 nm 1 : 1 dense-lines pattern of a ZEP-520 resist is shown in Figure 5.22 [25].

For some time, UV photoresists have been used as electron resists. This group of resists is based on diazonaphthoquinone (DNQ), and has the advantage of using an aqueous developer. Their resistance to dry etching is also threefold higher. However, with resolutions <250 nm, and despite still being used extensively in optical lithography for micro-electromechanical systems (MEMS) fabrication, their time in

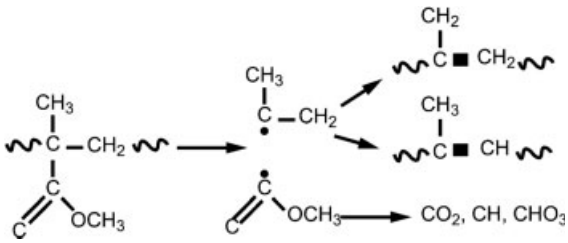

Figure 5.21 The reaction chemistry of polymethyl methacrylate (PMMA).

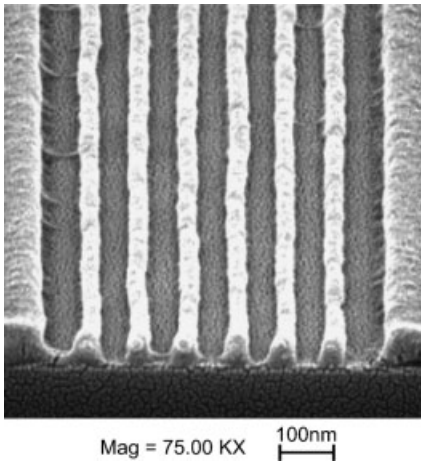

Figure 5.22 ZEP-520 : 45 nm 1 : 1 dense-lines test pattern [25].

EBL has passed. A detailed presentation of the chemistry of DNQ photoresists can be found in Ref. [26].

The impetus for the development of the electron resists used today was derived from the need for a new type of photoresist required for the introduction of DUV optical lithography. Because of the limitations of DNQ-based resists in resolution and sensitivity, *chemically amplified* (CA) resists have been introduced [27]. These are based on a multi-component scheme, where a sensitizer chemical causes dissolution modification within the exposed areas of the polymer matrix. The latent image is obtained from energy transfer to the sensitizer chemical molecules, causing a degradation into their ionic pairs or neutral species, which can catalyze the reaction events needed for solubility distinction. Commonly, photo acid generators (PAG) or photo base generators (PBG) are utilized as sensitizers in CA resists.

In a positive CA resist the PAG, upon exposure, releases an acid. During heating of the substrate after exposure (the post-exposure bake; PEB), this acid reacts with the resin, which in turn becomes soluble towards an aqueous developer. In addition, further acid is produced. With this multiplication reaction an exposed PAG molecule can trigger up to 1000 reactions. It is also acknowledged that a CA resist shows a high quantum yield compared to a DNQ-based resist.

Following the establishment of CA photoresists, specialized electron CA resists have now been developed. The reaction mechanism of a positive electron CA resist is shown in Figure 5.23. The CA electron resists that are used mainly in current commercial EBL are the positive-tone FEP-171 [28], and the negative-tone NEB-22 [29]. These resists both have resolutions $<$100 nm and show excellent process performance, especially in photomask fabrication [30, 31].

However, with the need for $<$50 nm resolution – especially for direct-write applications – the development and evaluation of more advanced positive and negative CA resists is currently the subject of intense investigation [32]. For example, the 50 nm dense lines and 70 nm dots with high contrast, obtained with a recently developed and evaluated positive CA resist [33], are shown in Figure 5.24.

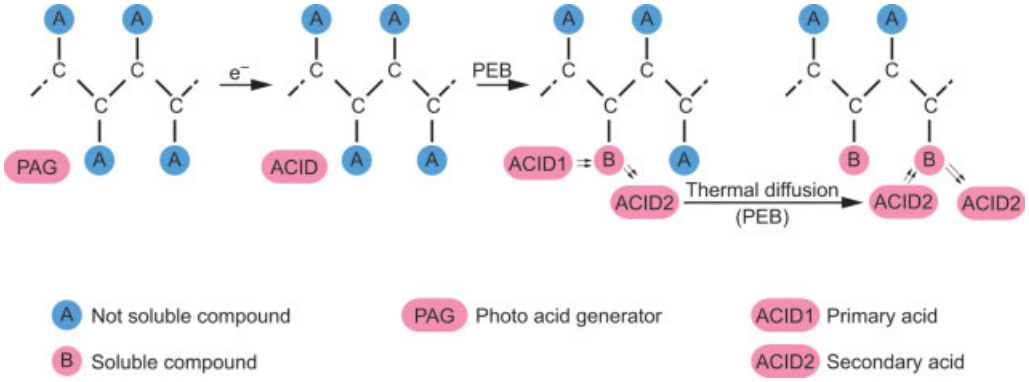

Figure 5.23 Reaction chemistry of a positive electron chemically amplified resist.

The major challenges in the development of CA resists for <50 nm resolution are to: (i) reduce the diffusion length during PEB; (ii) improve etch stability; and (iii) reduce the line edge roughness. For very small features, the molecular structure of the resist contributes to the roughness of the lines, which can be a significant fraction of the linewidth. A measure of line edge roughness is the standard deviation σ of the actual line edge relative to the average line edge. The reduction of line edge roughness is pursued by the application of resins with shorter molecules.

All of the electron resists discussed so far have been based on organic polymers. Although, in principle, it has been shown that such resists can achieve a resolution close to 10 nm, before applicable in manufacturing additional points must be taken into consideration, including the above-mentioned line edge roughness. As polymers are relatively large molecules, they cannot easily form smooth edges close to the atomic scale. Hence, in parallel to the improvement of CA resists, inorganic electron beam resists, such as hydrogen silsesquioxane (HSQ), are being pursued [34]. Initially, HSQ was used as a low-dielectric (low-*k*) material, with a *k*-factor of 2.5–3.0. In addition, HSQ demonstrates good spin-coating properties, such as good gap-fill, global planarization, and crack-free adhesion. It also shows excellent proces-

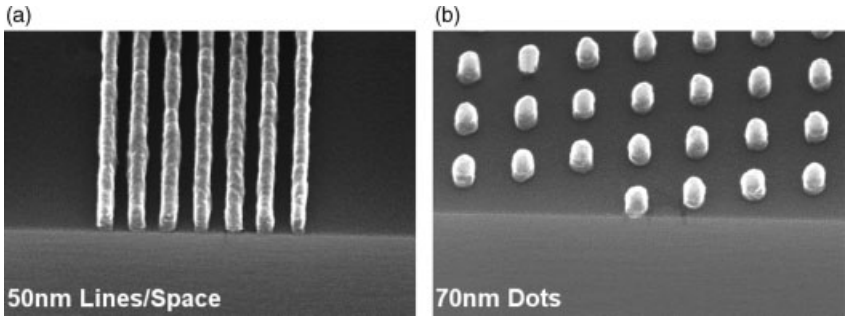

Figure 5.24 An advanced positive chemically amplified resist. (a) The 50 nm dense lines test pattern; (b) the 70 nm dots test pattern [33].

sing properties, notably a high thermal stability. HSQ is an oligomer composed of caged silsesquioxane within a linear Si−O network. A thermal curing is carried out to convert the caged species into a highly crosslinked network through the hydrolysis and condensation of the reactive Si−H functionalities.

Following the discovery that electron beam irradiation also initiates this curing reaction, HSQ was proposed as an inorganic electron resist. Our current understanding is that the Si−H bonds are broken during electron beam irradiation and are, in the presence of absorbed moisture, converted into silanol (Si−OH) groups. These silanol groups are unstable, and therefore condense, causing the caged molecule to break into a linear network. This transition drastically decreases the dissolution rate of the matrix within an aqueous base, thus enabling the use of HSQ as negative-tone electron resist. Furthermore, due to its high etch resistance HSQ can be utilized in a bi-layer resist process (BLR), where the patterns are transferred through a planarizing layer using reactive ion etching (RIE). As, with the rise in popularity of maskless lithography, BLR may become much more important, it is described in more detail in Section 5.2.3.3. With the implementation of a sensitizer chemical into the functional matrix (similar to the PAG in a polymeric CA resist), HSQ can, at least potentially, be made production-applicable.

5.2.3 Applications

Although EBL has a wide range of applications, the major focus is currently on the fabrication of transmission masks for DUVL and reflective masks for EUVL. Another important application is the direct-writing of patterns on wafers with single beams (which is also referred to as direct-write EBL; EBDWL). EBDWL is mainly used for fabricating device prototypes, and with recent improvements in shaped electron beam lithography tools, is also suitable for the low-volume production of application-specific integrated circuits (ASIC) and other specialized devices, for example hard disk heads. Multiple EBL such as maskless lithography (ML2), where a single electron beam is split into multiple beams to enable massively parallel EBDWL, shows the potential to complement or even replace optical lithography. The fabrication of imprint templates for NIL by using EBL techniques similar to photomask making is steadily gaining in importance. Finally, EBL is also combined with optical lithography in volume production, where it is used to fabricate critical structures such as gates. This approach – termed *mix-and-match lithography* production, or *hybrid lithography* if a single resist is utilized as both electron resist and photoresist – has special requirements.

5.2.3.1 Photolithography Masks

In optical lithography, the patterns on wafers are reproductions of those on a photomask. As the photomask is used for thousands of chip exposures, the quality of photomasks is critical for optical lithography. Photomasks are fabricated with techniques similar to those used in wafer processing (see Section 5.1). A photomask blank, a glass substrate with a deposited opaque film (usually chromium) is coated

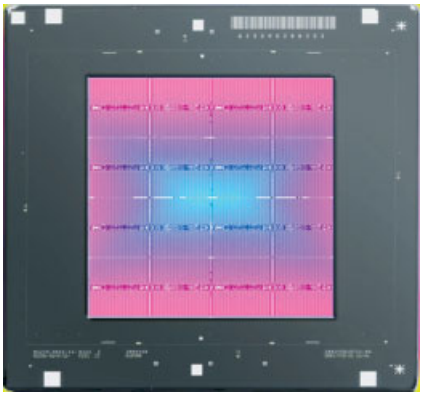

Figure 5.25 Photomask for deep ultraviolet optical lithography [35].

with a resist, and the latter is exposed with the pattern, developed, and the opaque film is etched. A processed photomask for DUV optical lithography is shown in Figure 5.25 [35].

Three types of photomask are currently in use. The simplest type is the binary mask (Figure 5.26a) [36], which employs only clear areas in the opaque chromium film to project the pattern to the wafer. Unfortunately, binary masks have the problem that, because of diffraction, the edges of the resist lines do not become straight. To rectify this problem, masks with molybdenum silicide films, which function as phase shifters, are used in phase-shift masks (PSM) (Figure 5.26b) [36]. Recently, so-called chromeless phase lithography (CPL) masks have been introduced for a resolution-enhancement technique (RET) called *off-axis illumination*, as shown in Figure 5.26c [36].

The pattern of a CPL mask featuring 125 nm lines applicable for 32 nm optical lithography is shown in Figure 5.27 [37]. An introduction to the functional principles of the different photomask types and their application in optical lithography is provided in Ref. [1].

Typically, photomask patterning is carried out with beam writers. Whilst for low- and medium-resolution masks, optical beam writers can be used, high-resolution masks are prepared using electron beam writers [38]. The general EBL techniques were described in Section 5.2.1; today, raster scanning has been replaced by vector scanning, and both Gaussian-beam and shaped-beam writers are currently employed for mask-making.

Gaussian-beam lithography is usually applied in a different way for photomasks than as described in Section 5.2.1.3. In addition to the IC patterns, photomasks also contain smaller features than the CD for optical proximity correction (OPC). When using Gaussian-beam writing, creation of the pattern in Figure 5.28 requires a beam size equivalent to the smallest feature (here, the right upper edge), but this leads to long writing times. However, it is possible to expose this pattern with a beam-size which is twice the size of the smallest feature. Because of the Gaussian intensity distribution, the 2σ circle touches the edges of the writing grid, whereupon the outline of the pattern can be made by multiple exposures of the spots; this is referred

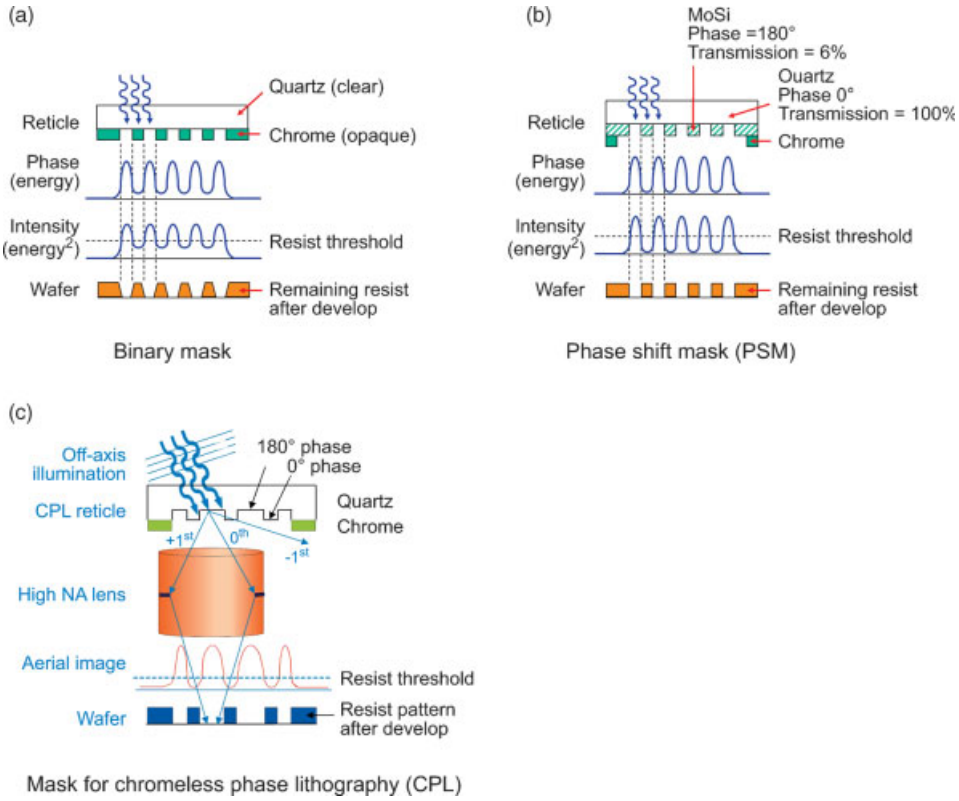

Figure 5.26 Mask types for deep ultraviolet optical lithography. (a) Binary; (b) phase-shift masks (PSM); (c) chromeless phase lithography (CPL) [36].

to as *multi-pass gray writing* [39]. The straight outlines are exposed four times, while the outlines of the pattern can be moved locally by exposing spots only three, two, or one times. Because of the overlap between spots and the multiple passes, this method has the additional effect of smoothing the exposure.

Although Gaussian-beam strategy is still used today, high-end mask-making has become a domain of 50 kV variable-shaped beam writers, which have a significantly higher throughput than Gaussian-beam writers. The shaped-beam strategy is applied as discussed in Section 5.2.1; however, mask-making encounters several specific issues, each of which must be addressed.

In addition to the proximity effect (see Section 5.2.1.5), which is a short-range phenomenon, long-range effects also appear which may stretch over large portions of the masks. The re-scattering of incident electrons at the objective electron lens can lead to a long-range background exposure, called a *fogging effect*. Further, an optimal exposure result may be compromised by succeeding processing steps, such as developing or etching. During developing, the concentration of the developer chemical decreases faster in areas with dense patterns, than in areas with sparse patterns. Similar effects appear in both wet and dry etching, and this may lead to long-

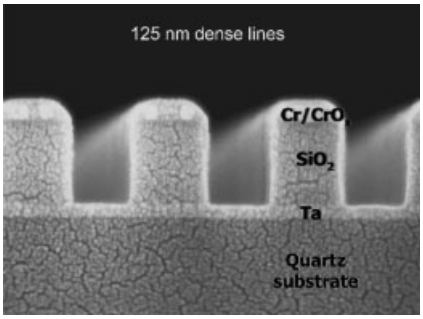

Figure 5.27 Photomask for deep ultraviolet optical lithography: 125 nm lines on mask result in 32 nm lines on the wafer [37].

range distortions of the final patterns, known as the *loading effect*. Whilst both fogging and loading effects can, in principle, be corrected within post-exposure process steps such as the PEB, the proximity effect correction methods of electron beam writers have been successfully augmented for handling both fogging and loading effects.

As shown in Section 5.2.1.5, forward scattering into the resist can be reduced by increasing the acceleration voltage of the electrons. However, this approach causes a significant increase in scattering within the substrate, and as a result the substrate is heated up. For silicon wafers, this problem is less pronounced, because silicon has a high thermal conductivity, and distortions of the wafer can be rectified by electrostatic chucks with wafer backside cooling. However, photomasks have a low thermal conductivity, and because of their large thermal capacity, the local temperature increases significantly during exposure. Therefore, mask writing tools currently do not exceed 50 kV acceleration voltage, and there is a reluctance to employ 100 kV tools.

The fabrication of high-end photomasks with EBL requires specialized post-exposure processing equipment. The PEB is a critical process step for CA resists, requiring a temperature uniformity of <0.1 K within the resist plane of the mask. Because of the large thermal capacity of photomasks, and their non-radial shape, such temperature uniformity is difficult to achieve. The PEB equipment is preferably connected directly to the electron beam writer, thus enabling the PEB and development to be conducted immediately after exposure. With such a direct connection, a

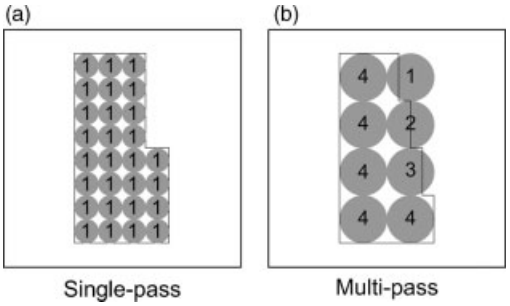

Figure 5.28 Writing a pattern with: (a) vector single-pass; and (b) with vector multi-pass strategies.

specially tailored post-exposure processing is applicable to compensate writing errors such as fogging and loading, and to improve overall pattern uniformity. The PEB is especially suitable for such compensation [40].

Besides photomask making, electron beam techniques have recently been introduced for the repair of photomasks [41] which, to date, has been the domain of ion beam structuring (see Section 5.3.2.1). If, due to a problem in the manufacturing process, a part of the opaque film is stuck when it should have been removed, it can be selectively removed by an electron beam-induced etching process; moreover, if part of the opaque film is damaged, it can be partially redeposited.

5.2.3.2 **Direct-Write Lithography**

Electron beam writers may also be used to create patterns on wafers directly, a process referred to as EBDWL. As shown in Section 5.2.1, EBDWL has the potential for fabricating features close to the atomic scale, and also provides very large depth-of-focus compared with optical lithography. As an example, a transistor demonstrator employing a gate with linewidth of 13 nm, and which has been fabricated by EBDWL utilizing vector Gaussian beam strategy [33], is shown in Figure 5.29.

EBDWL is especially suitable for fabricating device prototypes, as the device and the driving integrated circuit can be made directly from the computer-aided design (CAD) file. The production of device prototypes by optical lithography is not feasible, as a high-end photomask would first have to be made. Even if this effort were to be undertaken, it would not be possible to make any quick design changes. Notable applications of EBDWL in prototyping currently include research into nanoscale planar transistors (Figure 5.30) [42], and the next-generation transistor designs such as FinFET (Figure 5.31) [43, 44], or carbon nanotube FETs (CNTFET) [45].
