Typical flow detection for glucose, based on the CNT/Nafion/ $\text{GO}_x$  modified gas chromatography (GC) electrode, can be seen in Fig. 3.10 (from the work by Wang's group) [61]. Figure 3.10 compares the amperometric responses for relevant physiological levels of glucose, ascorbic acid, acetaminophen, and uric acid at the CNT/Nafion/ $\text{GO}_x$  modified GC electrode (B) and Nafion/ $\text{GO}_x$  modified GC electrode (A). In Figure 3.10, the accelerated electron-transfer reaction of hydrogen peroxide at the CNT/Nafion/ $\text{GO}_x$  modified GC electrode allows for glucose measurements at very low potentials (i.e.,  $-0.05 \text{ V}$ ) where interfering reactions are minimized. As a result, a well-defined glucose signal (d) is observed, while the signals of acetaminophen (a), uric acid (b), and ascorbic acid (c) are negligible. No such discrimination is obtained at the Nafion/ $\text{GO}_x$  biosensor (without the CNT) (A) held at  $+0.80 \text{ V}$ , where large oxidation peaks are observed for all interferences, indicating that the permselective (charge exclusion) properties of Nafion are not adequate to

**Fig. 3.10.** Flow-injection signals for  $2 \times 10^{-4}$  M acetaminophen (a),  $2 \times 10^{-4}$  M ascorbic acid (b),  $2 \times 10^{-4}$  M uric acid (c), and  $1 \times 10^{-2}$  M glucose (d) at a Nafion/ $\text{GO}_x$ -modified GC electrode (A) at +0.8 V, and at a

MWCNT/Nafion/ $\text{GO}_x$ -modified GC electrode (B) at  $-0.05$  V, and flow rate of  $1.25 \text{ mL min}^{-1}$ . (Reprinted with permission from Ref. [61]. © 2003 American Chemical Society.)

fully eliminate anionic interferences. In short, the coupling of the permselective properties of Nafion with the electrocatalytic action of CNT allows for glucose detection with effective discrimination against both neutral and anionic redox constituents. Similarly, the CNT/Nafion-coated electrodes have also been demonstrated to dramatically improve the signal of dopamine in the presence of the common ascorbic acid interference [61].

Jin et al. used CNT-based sensors for LC detection [97, 98]. To overcome the aggregation of nanotubes in aqueous and common organic solution, nitric acid was used to treat CNTs to introduce carboxyl groups in the open ends of the MWCNTs. Such functionalized CNTs were cast onto the glassy carbon as the flow detector. Various biofluids containing neurotransmitters were tested using this protocol. The results from real samples such as plasma agreed with those from other methods.

In terms of the mechanism of the CNT-based flow sensor, Ghosh et al. recently found that the flow of a liquid on single-walled CNT bundles induces a voltage in the sample along the direction of the flow [98]. The magnitude of the voltage depended sensitively on the ionic conductivity and on the polar nature of the liquid. The nonlinear response of flow velocity and the voltage was attributed to a direct forcing of the free charge carriers in the nanotubes by the fluctuating Coulombic field of the liquid flowing past the nanotubes. Their work highlighted the potential of a CNT-based device as sensitive flow sensors and for energy conversion [98].

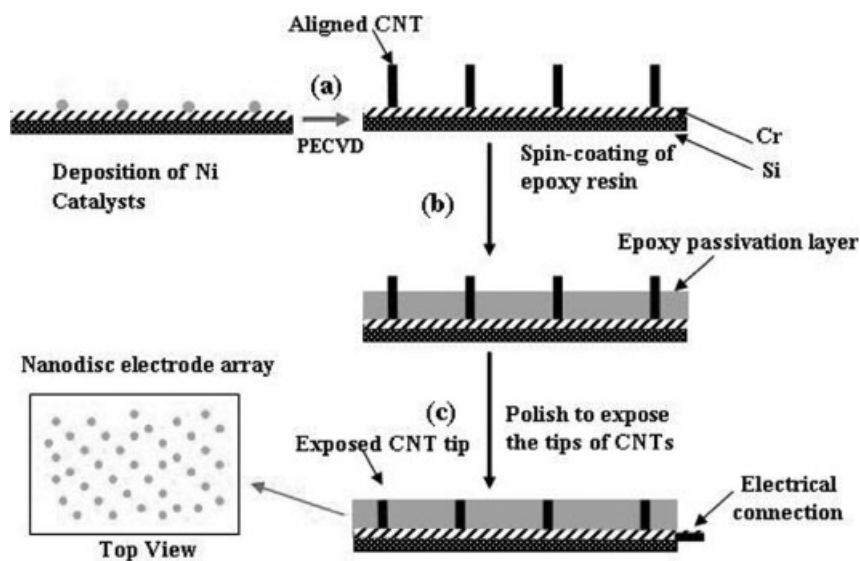

### 3.2.5

#### Carbon Nanotube Array-based Biosensors

Control over the orientation, distribution, and effective sensing sites of the nanotubes have been the subject of CNT-based biosensor research [56, 66]. Several ap-

proaches have been reported to achieve these controlled-density aligned CNTs and CNT arrays. The versatile approach is that of self-assembling aligned nanotube arrays by using oxidative acid treated single walled nanotubes [99]. These shortened tubes then react with DCC to introduce a carbodiimide leaving a group that allows reaction with thiols. Finally, these thiolated nanotubes are self-assembled on the gold surface to form aligned CNT arrays. Alternatively, aligned CNT arrays can be grown off a surface by using pyrolyzing CVD of relevant catalysts and carbon materials, followed by transferring the tubes onto a substrate support [73]. The third approach is to grow directly aligned CNTs onto an electrode surface by using CVDs or plasma, offering a controllable size and a given location for the catalyst spots that allows the growth of a given numbers of nanotubes [93].

Although vertically aligned CNTs have good material properties (e.g., good electrical conductivity, the capability to promote electron transfer reactions) and are of the right size (20 to 200 nm) for nanoelectrode arrays (NEAs), they lack the right spacing, having little support, and, therefore, the electrodes may lack robustness. To make each nanotube work as an individual nanoelectrode, the spacing needs to be sufficiently larger than the diameter of the nanotubes to prevent diffusion layer overlap from the neighboring electrodes [100]. Ren and co-authors recently developed a nonlithography method that allows the fabrication of low site density aligned CNT arrays with an interspacing of more than several micrometers [101]. Figure 3.11 demonstrates the manufacturing process of such aligned CNT arrays: Ni nanoparticles were randomly deposited on a 1-cm<sup>2</sup> Cr-coated silicon substrate

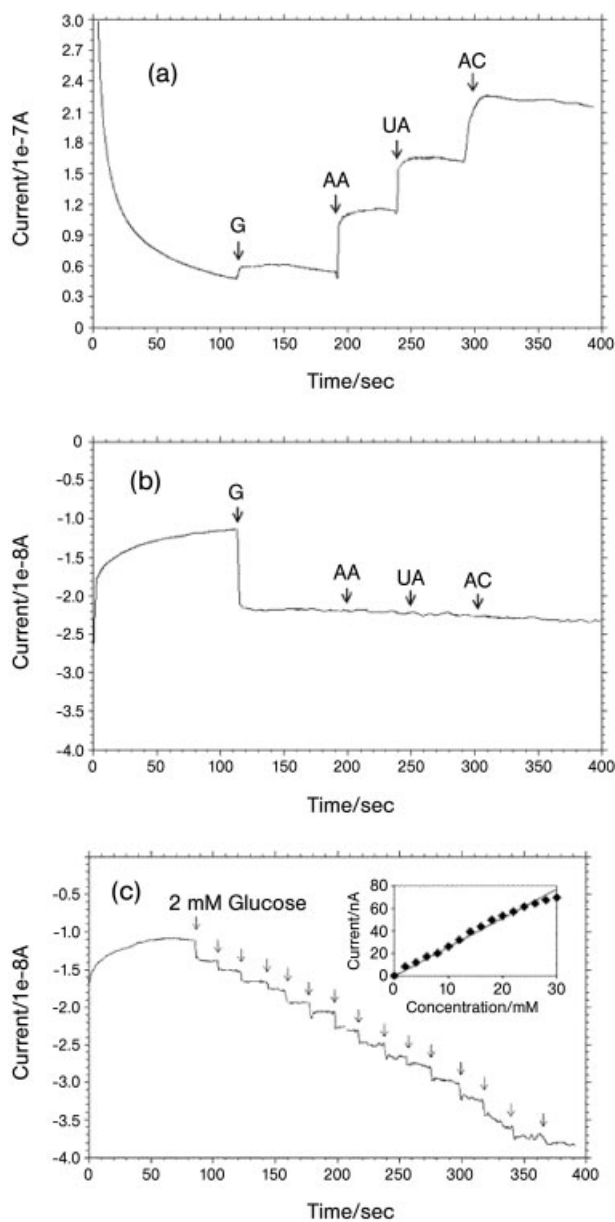

**Fig. 3.11.** Fabrication scheme of a low-site-density aligned CNT nanoelectrode array. (Reprinted with permission from Ref. [101]. © 2003 American Chemical Society.)

(Fig. 3.11a) by applying a pulse current to the substrate in a  $\text{NiSO}_4$  electrolyte solution. The size and the site density of the Ni nanoparticles were controlled by the amplitude and the duration of the pulse current. On these Ni particles, the CNTs were grown (Fig. 3.11b) in the plasma-enhanced chemical vapor deposition (PECVD) system at  $650^\circ\text{C}$  for 8 min with 160 sccm  $\text{NH}_3$  and 40 sccm  $\text{C}_2\text{H}_2$  gases with a total pressure of 15 Torr and a plasma intensity of 170 W. The aligned CNT arrays had a site density of  $1 \times 10^6$ – $3 \times 10^6 \text{ cm}^{-2}$ , a length of 10 to 12  $\mu\text{m}$ , and a diameter of 50–80 nm. A thin layer of Epon epoxy resin 828 (Miller-Stephenson Chemical Co., Inc., Sylmar, CA) was coated on the surface by magnetron sputtering to insulate the Cr layer. This was followed by applying m-phenylenediamine (MPDA) as a hardener. After these steps, the CNTs were half-embedded in the polymer resin, and the protruding part of the CNTs beyond the polymer resin was mechanically removed by polishing with a lens, followed by ultrasonication in water. Then the electronic connection was made on the CNT-Si substrate to make the CNT nanoelectrode arrays (Fig. 3.11c). Finally, the electrode arrays were pretreated by electrochemical etching in 1.0 M NaOH at 1.5 V for 90 s before electrochemical characterizations [101]. Results showed that, within these low site density CNTs, the NEAs consist of millions of nanoelectrodes, with each electrode being less than 100 nm in diameter. There is no degradation of these sensors for several weeks because of the excellent stability of the epoxy layer. Since the total current of the loosely packed electrode arrays is proportional to the total number of individual electrodes, having the number of the electrodes up to millions is highly desirable. The size reduction of each individual electrode and the increased total number of the electrodes result in improved signal-to-noise ratio (S/N) and detection limits.

Ng et al. have developed a soft lithography-mediated selective CVD template approach in preparing the multiwalled CNT membrane [102]. This membrane can be integrated with a flexible elastomeric polydimethylsiloxane framework to fabricate microsensing devices. The presented sensor design can be developed into a generic platform for electrochemical detection and gas sensing, as well as other general purpose sensory systems.

The unmodified and surface-confined aligned CNTs and CNT arrays by different preparation protocols discussed above have all been applied to the study of protein interaction [101, 103], DNA hybridization [104], and enzyme catalysis [66, 102]. Lin et al. have reported typical results for glucose biosensing using a CNT array (Fig. 3.12) [103]. The  $\text{GO}_x$  molecules were attached to the broken tips of the CNTs via carbodiimide chemistry by forming amide linkages between their amine residues and carboxylic acid groups on the CNT tips. Fig. 3.12(a) and (b) compare amperometric responses for 5 mM glucose (G), 0.5 mM ascorbic acid (AA), 0.5 mM acetaminophen (AC), and 0.5 mM uric acid (UA) at the  $\text{GO}_x$ -modified NEA and the potentials of +0.4 V (a) and -0.2 V (b). Well-defined cathodic and anodic glucose responses are obtained at this aligned CNT/ $\text{GO}_x$ -based biosensor at both potentials. However, the glucose detection at a lower operating potential (-0.2 V) is significantly less influenced by the interferences, indicating high selectivity towards the glucose substrate. Such a highly selective response to glucose is obtained

**Fig. 3.12.** (a, b) Amperometric responses for 5 mM glucose (G), 0.5 mM ascorbic acid (AA), 0.5 mM acetaminophen (AC), and 0.5 mM uric acid (UA) at a  $\text{GO}_x$ -modified, CNT-nanoelectrode array and potentials of +0.4 (a) and -0.2 V (b). Electrolyte: 0.1 M phosphate buffer/0.1 M NaCl (pH 7.4). (c) Amperometric

response at the  $\text{GO}_x$ -modified, CNT-nanoelectrode array for each successive addition of 2 mM glucose. Inset: the corresponding calibration curve. Potential: -0.2 V, other conditions are as in (a, b). (Reprinted with permission from Ref. [103]. © 2003 American Chemical Society.)

at this aligned CNT/GO<sub>x</sub>-based biosensor without the use of mediators and permselective membranes. The amperometric response at this sensor for each successive addition of  $2 \times 10^{-3}$  M glucose is presented in Fig. 3.12(c) with the corresponding calibration curve in the inset. The linear response to glucose is up to 30 mM, and steady state is reached within 20 to 30 s [103]. Because of this low potential detection, CNTs eliminate perspective interferences through the preferential detection of hydrogen peroxide at the CNT-based electrodes. Such development of interference-free transducers will significantly simplify the design and fabrication of biosensors. Biosensors based on low-site-density aligned CNTs are also suitable for the highly selective detection of glucose in various biological fluids (e.g., saliva, sweat, urine, and serum) [103].

Rusling et al. reported the first example of enzymes covalently attached onto the ends of vertically oriented SWCNT forest arrays [67]. These arrays were made from their unique methodology of assembling dense orthogonally oriented arrays of shortened SWCNTs. Quasi-reversible Fe<sup>III</sup>/Fe<sup>II</sup> voltammetry was obtained for the iron heme enzymes myoglobin and horseradish peroxidase coupled to the carboxylated ends of the nanotube forests by amide linkages. Their observation suggested that the “trees” in the nanotube forest behaved, electrically, similarly to a metal, conducting electrons from the external circuit to the enzymes. Accordingly, the electrochemically manifested peroxidase activity of myoglobin and horseradish peroxidase attached to the CNT array was demonstrated, showing analytical promise for hydrogen peroxide with a detection limit down to ~100 nM in buffer solutions. The covalently attached enzymes kept their activity for weeks in these prototype SWCNT-forest array biosensors [67]. Gooding and co-authors also observed the direct charge transfer between redox-active enzymes and the aligned CNTs’ surface [66]. Their mechanistic study revealed that the rate of electron transfer remains the same regardless of the lengths of the tubes. These findings enable electroactive molecules to be located several hundred nanometers from a macroscopic substrate electrode with no loss in performance. This might guide future modification of the CNT array for sensor applications.

While most of the array studies have focused on their electrochemical mode, because of the unique electronic properties of individual nanotubes and nanotube arrays, optical sensing based on CNT arrays has also been carried and has been reviewed by Xu [21].

### 3.2.6

#### Chemiluminescence

Miscellaneous CNT sensing applications have been reported recently by using different transducer techniques with various nanotube platforms. As a traditional technique, fluorescence spectroscopy has been widely employed in sensor and bioassay application because of its high sensitivity. However, there have been few reports regarding its study on CNTs, partly because of the limited aqueous solubility or dispersion of CNTs [105, 106]. By using amine-terminated oligonucleotide-functionalized CNTs, Hazani and co-authors were able to enhance nanotube solu-

Fig. 3.13. Reaction scheme of immobilization of streptavidin on nanotubes by covalent coupling. (Reprinted with permission from Ref. [105]. Copyright 2003 Wiley-VCH.)

bility to facilitate the confocal fluorescence imaging of the DNA hybridization from a fluorescence dye-tagged complementary sequence [107]. Baker et al. used thiol-terminated oligonucleotide-modified CNTs for the similar assay [108].

A more direct application of CNT based biosensors has been reported by Wohlstadter et al. in their electrogenerated chemiluminescence (ECL) study of immunoassays for  $\alpha$ -fetoprotein (AFP) [105]. Nanotubes possess several characteristics that make them attractive for ECL-based assays: First, they are conductive or semiconductive and hence can act as electrodes to generate ECL in aqueous solutions; second, nanotubes can be surface-functionalized as we discussed before; finally, their high surface area-to-volume ratio and  $sp^2$  network make them feasible for immobilizing biomolecules as well as their associated electrochemistry. Wohlstadter et al. first mixed nanotubes with poly(vinyl acetate) (EVA) to form a nanotube–EVA composite. This composite was then etched with strong acid to produce a densely packed nanotube sheet with available surface carboxylic acid groups. As can be seen in Fig. 3.13, streptavidin was then immobilized on the nanotube sheet by carbodiimide-activated coupling, followed by the attachment of a biotinylated mAb for AFP via the specific biotin–streptavidin interaction. Figure 3.14 shows the whole assay based on this sensor. The capture of AFP resulted in the binding of a  $Ru(bpy)_3^{3+}$  labeled antibody on to the EVA-MWCNTs composite electrode. As the  $Ru(bpy)_3^{3+}$  is chemiluminescent, binding is transduced by the release of light upon applying the electrode at potentials more positive than +1 V. This immunosensor with electrochemiluminescence detection was sensitive at AFP concentrations as low as 0.1 nM, with a linear range up to 30 nM [105].

By using chemiluminescent  $Ru(bpy)_3^{3+}$  as a marker, Dong et al. found that the CNT/Nafion composite possesses ECL sensitivity two orders of magnitude more than that at the silica/Nafion composite and three orders of magnitude more than that at pure Nafion films, again proving that the solubility enhancement for CNTs plays a key role in developing a CNT-based fluorescence sensor [106].

### 3.2.7

#### Field-effect Transistor and Bioelectronics

Advances in electronic detection based on 1D nanomaterials provide the ability for label-free and real time, yet sensitive and selective, sensing biomolecules. The development of CNTs with unique electronic properties has been spotlighted for future solid-state nanoelectronics. Therefore, CNT-based molecular electronics have

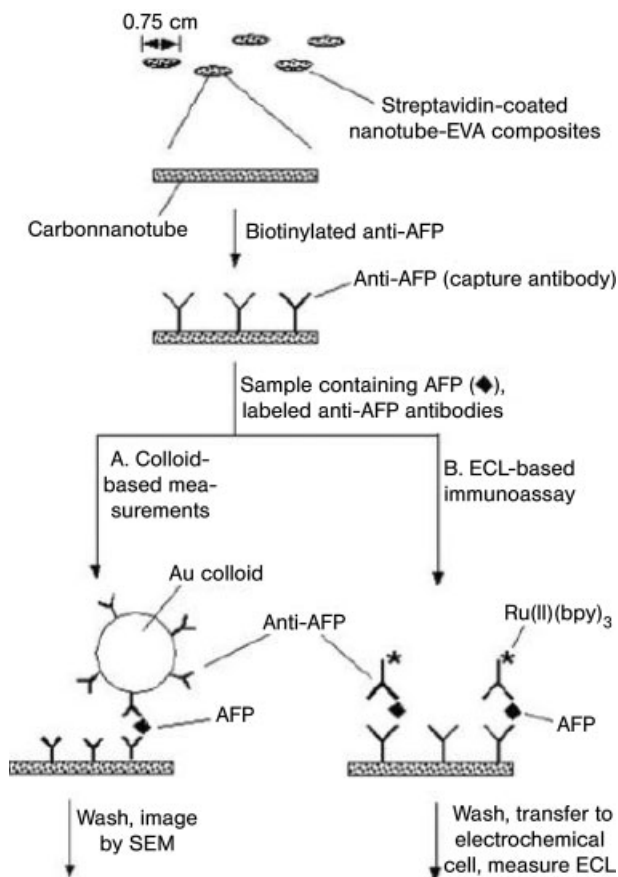

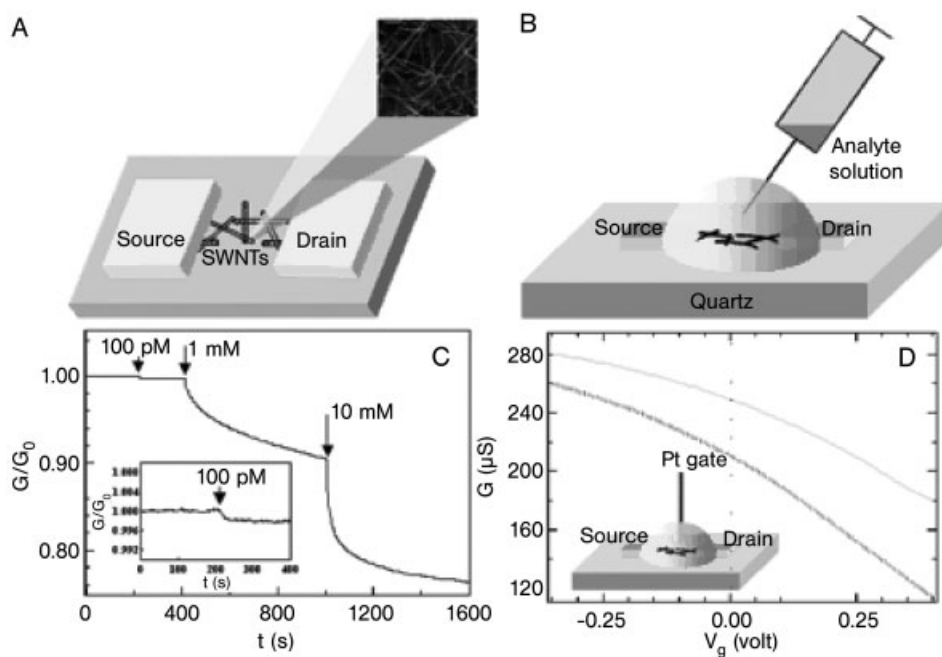

Fig. 3.14. Schematic of procedures for AFP assays based on the CNT-ECL sensor (not to scale). (Reprinted with permission from Ref. [105]. Copyright 2003 Wiley-VCH.)

received wide attention because of the semiconductor features of the nanotubes [109]. Among them, the study of CNT field-effect transistors (CNTFETs) is the core study to compare with the silicon-based transistors. The first CNTFETs were demonstrated by Tans et al. and Martel et al., respectively, in observing the CNTs' exploitable switching behavior [110, 133]. Since then, efforts have been made to improve the electrical characteristics of the CNTFETs. Presently, those explorable features of CNTFETs are the ballistic (scattering-free) and spin-conserving transport of electrons along the nanotubes, their ability to display metallic conducting as well as semiconducting behavior, and their access to the energy gap, which depends on the tube diameter and the rolling orientation of the tubes. CNTs also have extraordinarily high thermal conductivity. These unique properties make them behave similarly to conventional metal-oxide semiconductor field effect transistors

(MOSFETs) as well as differently, with a change from Schottky-barrier modulation at the contacts to bulk switching. These responding multiplicities, coupled with different CNT assembling approaches, offer various possible CNTFETs applications in biological diagnosis, e.g., proteins [5, 81] and cancer cell [111]. Chen and co-workers have demonstrated an exploration of SWCNT as a platform for investigating surface–protein and protein–protein binding and developing a highly specific electronic biosensor. They put SWCNT on a junction (drain and source) as shown in Fig. 3.15 [81]. The SWCNT was modified with polyethylene, which can reduce the non-specific interaction of proteins. A specific receptor was conjugated onto polyethylene-modified SWCNT. Therefore, the device can be highly specific in detecting proteins such as 10E3 m Ab (Fig. 3.4). The detection limit of this method was found to be about  $340 \text{ ng mL}^{-1}$  or 1.0 nM.

**Fig. 3.15.** Carbon nanotubes as electronic devices for sensing in aqueous solutions. (A) Schematic view of the electronic sensing device consisting of interconnected nanotubes bridging two metal electrode pads. An AFM image of a portion of the nanotube network ( $0.5 \mu\text{m}$  on a side) is shown. (B) Schematic setup for sensing in solution. Inset: Sensitivity to a 100-pM

protein solution. (D) Electrical conductance ( $G$ ) vs. gate voltage ( $V_g$ ) for a device in a 10-mM phosphate buffer solution. The gate voltage is applied through a Pt electrode immersed in the solution (inset). The upper (solid) and lower (broken) curves are the  $G$ – $V_g$  characteristics for the device before and after SA binding, respectively. The shift in the two curves suggests a change in the charge environment of the nanotubes. (Reprinted with permission from Ref. [81]. © 2003 NAS).

### 3.3

#### Nanowires in Biosensor Development

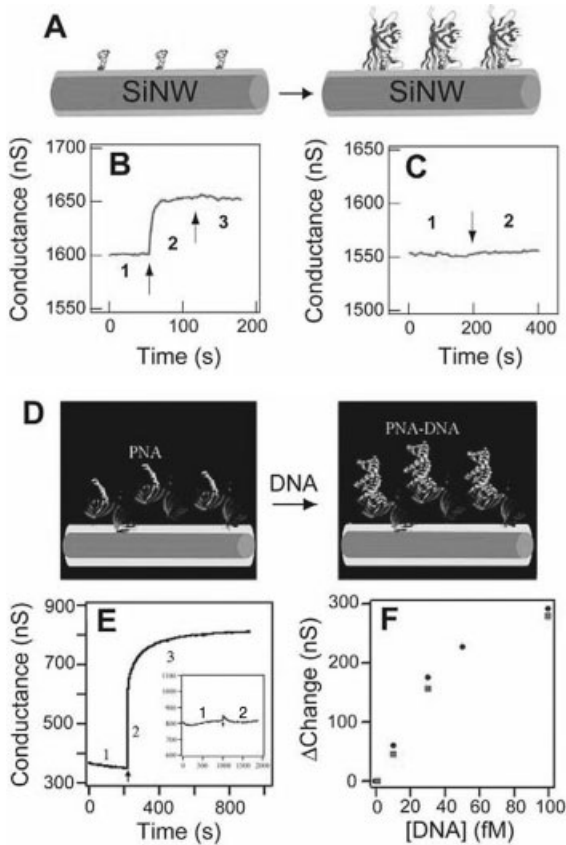

Recently, nanowires have been explored as building blocks to fabricate nanoscale electronic devices through self-assembly – a typical bottom-up approach for biosensing [4, 6, 9]. The underlying mechanism for a nanowire biosensor is a field effect that is transduced using a field-effect transistor [4]. This “bottom-up” approach to bionanoelectronics has several attractive features. First, the nanowires are extremely sensitive for detection of biointeractions on their surface because of their high aspect ratio. Second, the electronically switchable properties of semiconducting nanowires provide a sensing modality, a direct and label-free electrical readout, which is exceptionally attractive. Third, the size of the nanowires can be readily tuned to sub-100 nm and smaller, which can lead to a high density of a device on a chip. Therefore, it is feasible for the miniaturized devices to detect multiple samples real time *in vivo*. Fourth, the candidate materials for the nanowires are unlimited, which gives the researcher great flexibility in selecting the right materials for the functionality of the desired device. Presently, the most studied nanowires as a building block for biosensing are semiconducting nanowires, e.g., silicon nanowires [4, 6, 9], conducting polymer nanowires [17, 18], and oxide nanowires [112]. Some metal nanowires have also been developed for sensing. We will focus on semiconducting nanowires for biosensor development here.

#### 3.3.1

##### Silicon Nanowire-based Biosensors

Silicon nanowires are generally fabricated by CVD [14, 15] and template etching [113, 114]. For the purpose of biosensing, the modification of silicon nanowires is through a silanization reaction on the silicon surface, which introduces the active groups, e.g., amino, carboxyl, or biotin, on the surface of the nanowires. Then the receptor, which can specifically recognize the interested analyte, will be immobilized on the surface through those active groups, the interaction between biomolecules and their counterparts on the silicon surface will introduce the conductance change caused by the field effect, and the conductance change can be electronically transduced. Thus far, silicon nanowire-based biosensors have been developed for detection DNA [4, 8, 115, 116], proteins [4, 9], and viruses [6].

Lieber’s group is pioneering the development of silicon nanowire-based biosensors [4, 8]. Biological macromolecules, such as proteins and nucleic acids, are typically charged in aqueous solutions and, as such, can be detected readily by nanowire sensors when appropriate receptors are linked to the nanowire active surface. Figure 3.16 shows the real time detection of proteins and DNA based on silicon nanowires. They modified silicon nanowires with biotin, which has a strong affinity to protein streptavidin on the oxide surface of nanowires [4]. When a solution of streptavidin is delivered to a nanowire sensor device modified with a biotin receptor, they found that the conductance of nanowires increases rapidly to a constant value, and this conductance value is maintained after the addition of pure buffer

**Fig. 3.16.** Real-time detection of proteins and DNA. (A) Schematic of a biotin-modified Si nanowire and subsequent binding of streptavidin to the modified surface. (B) Conductance versus time for a biotin-modified Si nanowire, where Region 1 corresponds to the buffer solution, Region 2 corresponds to the addition of 250 nm streptavidin, and Region 3 corresponds to pure buffer solution. (C) Conductance versus time for an unmodified Si nanowire; Regions 1 and 2 are the same as in (B). (D) Schematic of a Si

nanowire sensor surface modified with a PNA receptor before and after duplex formation with target DNA. (E) Si nanowire DNA sensing; the arrow corresponds to the addition of a 60-fM complementary DNA sample, and the inset shows the device conductance following addition of 100-fM mutant DNA. (F) Conductance versus DNA concentration; data points indicated by ■ and ● are obtained from two independent devices. (Reprinted with permission from Ref. [4], [8]. (A)–(C) 2001 © AAAS and (D)–(F) 2004 © ACS.)

(Fig. 3.16B). However, adding a streptavidin solution to unmodified silicon nanowires does not produce a change in conductance (Fig. 3.16C). The conductance change is caused by the specific interaction between biotin and streptavidin, and these results are further proved by an experiment in which blocking the streptavidin binding sites leads to an absence of response from biotin-modified silicon nanowires. They also studied the detection limit and found that the electrical detec-

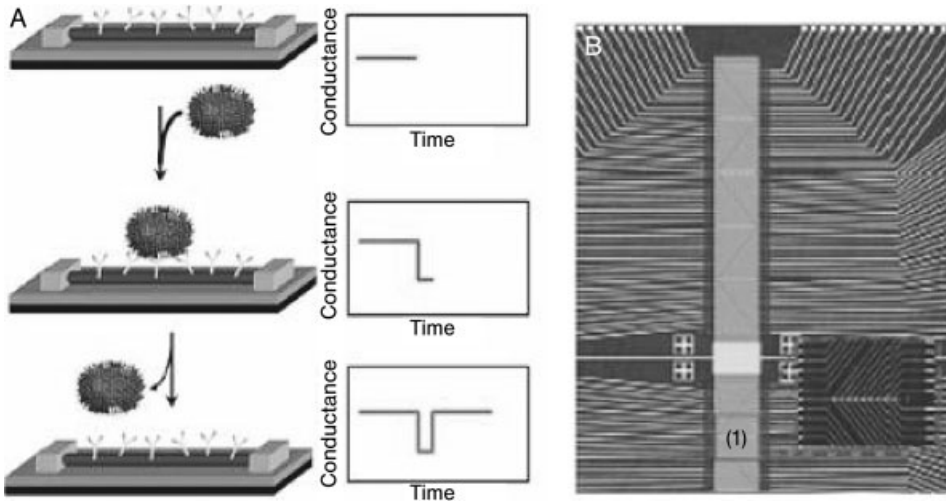

tion could be carried out to 10 pM, which is below the detection level required for a number of disease marker proteins. More recently, a silicon nanowire field effect device has been investigated as a biosensor to detect the sequence of DNA [8]. First, a PNA was immobilized on the surface of the p-type Si nanowires (Fig. 3.16D). When a complementary DNA target was introduced to the device, the hybridization of DNA (Fig. 3.16D) caused the conductance of the nanowires to increase (Fig. 3.16E). PNA was used as a receptor for DNA detection because the uncharged PNA molecules have a greater affinity and stability than the corresponding DNA recognition sequence. They have used this device to detect the wild type versus the DF508 mutation site in the cystic fibrosis transmembrane receptor gene and showed that the conductance increases when adding a 60-fM wild-type DNA sample solution (Fig. 3.16E). The increase in conductance of the Si nanowire device is consistent with the increase in the negative charge density associated with the binding of negatively charged DNA at the surface, and moreover, careful control experiments show that the binding response is specific to the wild-type sequence. Further study shows that the direct electrical detection for DNA is possible down to at least the 10-fM level, and the method is reproducible (Fig. 3.16F).

The same group have also studied the use of the Si nanowire for detecting a single virus and demonstrated that the Si nanowires could be assembled to form arrays for multiplexed detection of samples [6]. Addressable arrays are fabricated by a process that uses a fluid-based assembly, such as microfluidic or Langmuir–Blodgett methods, to align and set the average spacing of nanowires over large areas for photolithography to define interconnections (Fig. 3.17A). They also fabricated a state-of-the art array containing more than 100 addressable elements (Fig. 3.17B). All the of the active nanowire sensor devices are confined to a central rectangular area on the device chip that overlaps with the microfluidic sample delivery channels, as illustrated in the figure. They further demonstrated the use of this nanowire array for detecting two types of virus at the same time. An antibody receptor that is specific either for influenza or for adenovirus was modified on p-type Si nanowires. Simultaneous conductance measurements were obtained when adenovirus, influenza, and a mixture of both viruses were delivered to the device. Other groups have also studied the use of silicon nanowires for DNA and protein analysis [115, 116].

### 3.3.2

#### **Conducting Polymer Nanowire-based Biosensors**

In recent years, conducting polymer-based nanostructured materials have been used extensively in resistive sensors [17]. Because of their promising properties, which include high surface areas, chemical specificities, tunable conductivities, material flexibilities, and easy processing, various methods have been developed to fabricate conducting polymer nanowires. For example, (a) polyaniline nanowires have been obtained through a facile synthesis [117] or by electrospinning methods [118]; (b) template-directed electrochemical processes have been employed to fabricate nanowire junctions that feature robust polymer electrode contacts [119]; and (c) mechanical stretching [120] and magnetic field-assisted assembly [121] pro-

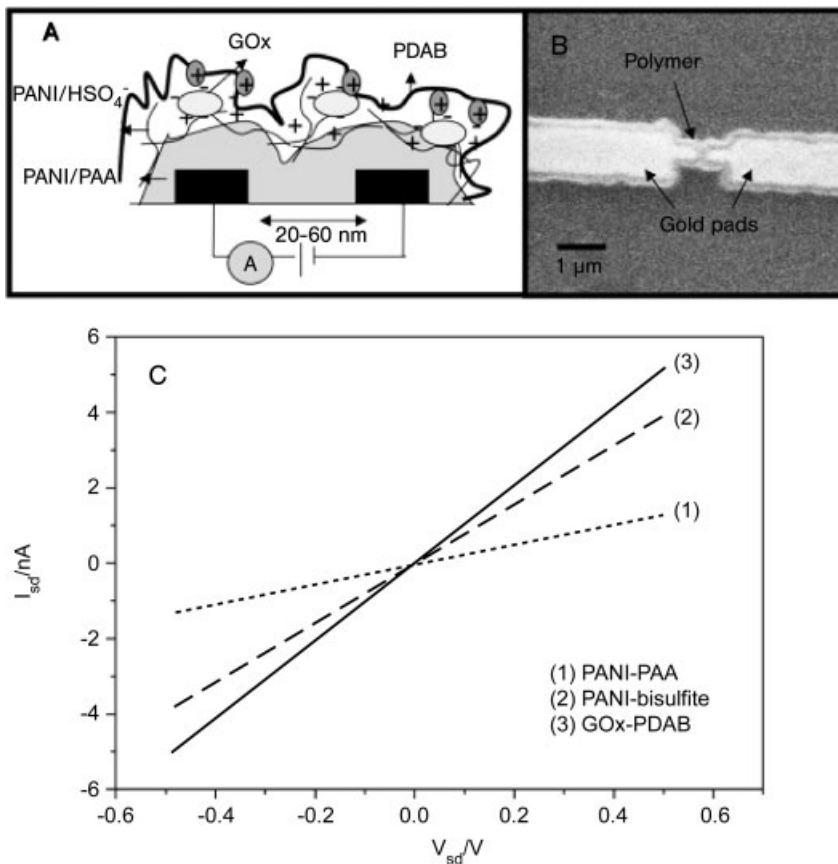

**Fig. 3.17.** (A) Schematic of a single virus binding and unbinding to the surface of a Si nanowire device modified with antibody receptors and the corresponding time-dependent change in conductance. (B) Optical image of the upper portion of a sensor device array, where the inset shows one row of

individually addressable nanowire elements. The rectangle labeled (1) highlights the position of the microfluidic channel used to deliver samples and overlap the active elements. (Reprinted with permission from Ref. [6]. © 2004 NAS).

cesses have produced miniaturized polymer-electrode junctions. A templateless electrochemical assembly of conducting polymer nanowires has also been developed recently [17, 18]. The development of biosensors based on conducting polymer nanowires is still in its infancy. Some examples are introduced as follows.

Tao's group have demonstrated a glucose biosensor using conducting polymer/enzyme junctions and found that a unique feature can arise when shrinking a sensor to a nanometer [122]. Figure 3.18(A) shows the structure of the polymer/enzyme nanojunction sensor. The thickness of the polyaniline in the junction is 20–60 nm. The polyaniline/enzyme nanojunction was prepared by co-polymerization of monomer aniline and GOx in an aqueous solution. The signal transduction mechanism of the sensor is based on the changes in nanojunction conductance as a result of glucose oxidation induced change in the polymer redox state. Because of the small size of the nanojunction, they found that the response to glucose is fast and less than 1.0 s. However, the response time for glucose with a 10  $\mu\text{m}$  gap is up to 10 min. The detection of limit for this method is at the  $\mu\text{M}$  level.

Myung's group has developed a facile technique for synthesizing conducting polymer nanowires by electrodeposition within channels between two electrodes on the surface of silicon wafers. They demonstrated that this technique can fabricate multiple individually addressable conducting polymer nanowires between two junctions. They also demonstrated the capability to create a scalable and high-density array by site-specific positioning of conducting polymer nanowires of the same and different composition on the same chip. Furthermore, the same group

**Fig. 3.18.** (A) Structure of the polymer nanojunction sensor. (B) SEM image of PANI-PAA/PANI-bisulfite/GOx-PDAB films deposited on gold pads with gaps of 20–60 nm. (C)  $I$ – $V$  curves obtained in air after each nanogap modification step: (1) polymerization of PANI-PAA carried out in 0.4 M aniline + 150 mg mL<sup>-1</sup> PAA (MW: 2000) solution with 0.5 M Na<sub>2</sub>SO<sub>4</sub> and 0.5 M H<sub>2</sub>SO<sub>4</sub> by a potential sweep between –0.2 and 0.9 V vs. SCE during the first cycle and between –0.2 and 0.78 V vs. SCE during the following cycles at 0.05 V s<sup>-1</sup>;

(2) polymerization of PANI bisulfite in a 0.4 M aniline + 0.5 M NaHSO<sub>4</sub> solution acidified to pH 0 with H<sub>2</sub>SO<sub>4</sub> by a single potential sweep from –0.2 to 0.9 V vs. SCE; (3) immobilization of GOx-PDAB by exposing the polymer nanojunction to 0.5 M Na<sub>2</sub>SO<sub>4</sub> + 25 mM 1,2-diaminobenzene + 167 μM glucose oxidase in a pH 5 citric acid/Na<sub>2</sub>HPO<sub>4</sub> (McIlvaine) buffer solution for 15 min, followed by electro-deposition of PDAB at +0.4 V vs. SCE for 4 min. (Reprinted with permission from Ref. [122]. © 2004 ACS).

reported bio-affinity sensing using biological functionalized conducting polymer nanowire. The device incorporated with polypyrrole nanowires made by the facile technique can be used for studying protein–protein interaction [123].

Wang et al. demonstrated template-free fabrication of polyaniline nanowire on electrode junctions by electrodeposition, and this method can be extended to syn-

thesize other conducting polymer nanowires, e.g., polypyrrole and poly(Edot). They systematically studied the electron transport properties of these conducting polymer nanowires with an electrolyte gate [124].

### 3.3.3

#### Metal Oxide Nanowire-based Biosensors

Metal oxide nanowires (MONWs) have been used to develop biosensors [112, 125]. They can work as a valid alternative to CNTs or Si NWs. Curreli and co-workers have reported a selective functionalization of  $\text{In}_2\text{O}_3$  nanowires for biosensor applications. They first generated a self-assembled monolayer (SAM) of 4-(1,4-dihydroxybenzene) butyl phosphonic acid (HQ-PA) on the  $\text{In}_2\text{O}_3$  NW surface. Oxidized HQ-PA can react with a range of functional groups, which can be easily incorporated in biomolecules. They have successfully attached DNA on the  $\text{In}_2\text{O}_3$ , and this study opens an avenue for using such metal oxide nanowires for biosensing [112].

## 3.4

### Nanocantilevers for Biosensors

Recently, microfabricated cantilevers have successfully been used for biosensors [126–132]. The adsorption of biomolecules on the surface will induce surface stress, which can be measured with micro/nanocantilevers. Adsorption of two proteins, immunoglobulin (IgG) and albumin (BSA), on a gold surface has been studied in a buffer solution in terms of surface stress measurements. Fritz and coworkers have reported the specific transduction, via surface stress changes, of DNA hybridization and receptor–ligand binding into a direct nanomechanic response of microfabricated cantilevers [126]. Cantilevers were fabricated in arrays and functionalized with a selection of biomolecules. The differential deflections of the cantilever were responses of individual cantilevers. Figure 3.19 illustrates the DNA hybridization on nanocantilevers in solution. First, a different sequence of DNA probe was modified on the surface of cantilevers (Fig. 3.19A), and then target DNA was injected. Only the cantilever that provides the matching sequence was found to have surface stress. It has been demonstrated that a single mismatch between 12-mer oligonucleotide is detectable. This method shows important advantages in that it does not require labeling, optical excitation, or external probes. In addition, the transduction process is repeatable and enables cyclic operation. At the same time, Hansen et al. have reported a cantilever-based optical deflection assay for discrimination of DNA single-nucleotide mismatches [127].

Furthermore, Wu and coworkers have extended this research to a real biological system, disease-related proteins. They reported that microcantilevers of different geometries have been used to detect two forms of prostate-specific antigens (PSAs) over a wide range of concentration range  $0.2 \text{ ng mL}^{-1}$  to  $60 \text{ } \mu\text{g mL}^{-1}$  in a background of human serum albumin and human plasminogen at  $1.0 \text{ mg mL}^{-1}$

**Fig. 3.19.** Scheme illustrating the hybridization experiment. Each cantilever is functionalized on one side with a different oligonucleotide base sequence (red or blue). (A) The differential signal is set to zero. (B) After injection of the first complementary oligonucleotide (green), hybridization occurs

on the cantilever that provides the matching sequence (red), increasing the differential signal  $\Delta x$ . (C) Injection of the second complementary oligonucleotide (yellow) causes the cantilever functionalized with the second oligonucleotide (blue) to bend.

[129]. This study makes this technique a clinically relevant diagnostic technique for prostate cancer.

### 3.5

#### Summary

One-dimensional nanomaterials, such as CNTs, semiconducting nanowires, and Si-based nanocantilevers have shown promise as new detection platforms that are equal or superior to many other sensing materials. This is mainly attributed to their unique electronic, mechanic, thermal, and chemical properties. The preparation, purification, and dispersion of single-walled and multiwalled nanotubes have, especially, been reviewed. Various sensor fabrication protocols based on those 1D nanomaterials have been discussed in detail. A typical application for DNA and proteins, including enzymes and antibodies, has been described, and the respective responding mechanisms have been addressed in this comprehensive review. Various 1D nanomaterial-based biosensors have found broad application from their

respective designs, including unmodified and surface-confined nanomaterials. Accordingly, biosensing based on amperometric amplification, field-effect transistors, signal-enhanced immunoassay, and non-enzymatic monitoring, and surface stress has been described for various biosensor designs. This research field is experiencing explosive growth, and new reports appear on a daily basis. We anticipate that the high order array design, combined with multiple biorecognition, will be the hotspot for the next stage of the 1D nanomaterial-based sensor studies.

### Acknowledgments

The work performed at Pacific Northwest National Laboratory (PNNL) was supported by the Laboratory Directed Research and Development program, DOE-EMSP, SERDP (Project ID 1297), and NIH/1R01 ES010976-01A2. The authors' research described in this chapter was performed in part at the Environmental Molecular Sciences Laboratory, a national scientific user facility sponsored by the DOE Office of Biological and Environmental Research and located at PNNL. PNNL is operated for DOE by Battelle under Contract DE-AC05-76RL01830.

### Glossary

**Amperometry** An electrochemical technique that measures electrical current at a fixed potential upon adding analyte or titrant into the measuring cell.

**Biosensor** Any probe designed to measure biological molecules' concentration or structures, monitor biological processes, or translate biochemical signals into quantifiable physical signals.

**Carbon nanotube (CNT)** A 1D fullerene with a cylindrical shape that consists of a seamless structure with hexagonal honeycomb lattices, being several nanometers in diameter and up to hundreds of microns long. CNTs can be divided into two major groups, i.e., single-wall carbon nanotubes (SWCNTs) and multiwall carbon nanotubes (MWCNTs). SWCNTs represent a single graphite sheet rolled flawlessly, demonstrating a tube diameter of 1 to 2 nm, whereas MWCNTs show concentric and closed graphite tubules with diameters ranging from 2 to 50 nm and an inter-layer distance of approximately 0.34 nm.

**Catalysis** The acceleration of a chemical reaction by a catalyst.

**Chemiluminescence** A luminescence phenomenon produced by the direct transformation of chemical energy into light energy.

**DNA** Deoxyribonucleic acid. A naturally occurring polymer consisting of a phosphate backbone, sugar rings, and various bases. Usually it is found as single- or double-stranded deoxynucleotides.

**Field effect transistor (FET)** A semiconductor transistor with a region of donor material with two terminals designated as the "source" and the "drain," respectively, and an adjoining region of acceptor material in between, called the "gate."

The voltage between the gate and the substrate controls the current flow between the source and the drain by depleting the donor region of its charge carriers to a greater or lesser extent.

**Enzyme electrode** A type of biosensor that uses an enzyme-anchored electrode setup.

**Hybridization** The process of forming double stranded DNA molecules by combining two complementary single-stranded oligonucleotides.

**Nafion** A brand from a DuPont produced polymer that was synthesized by modifying a Teflon polymer. Like Teflon, Nafion is extremely chemically inert. However, unlike Teflon, Nafion is very ion-conductive because it contains sulfonic acid groups. These unique properties make Nafion useful in ion-exchange membranes, humidity sensors, fuel cells, etc.

**Lithography** A technique that creates chemical patterns on a metal or ceramic surface. It is currently used in making integrated electronic circuits, computer chips, etc.

**Organophosphorus compounds** Organic molecules that contain the element phosphorus. Organophosphorus (OP) compounds are very toxic and are thus widely used as pesticides and chemical-warfare agents (CWAs).

**Polymer** A macromolecule consisting of repeated chemical units.

**Screen printing** A traditional printing method that is used to print everything from T-shirts to coffee mugs and decals. It uses a squeegee to force ink through a stencil created on a mesh fabric onto some type of substrate such as a silk, metal, or stone. It is a mass production method. It has been used for fabricating sensors, such as single-use glucose strips.

**Sol-gel technique** A sol is a homogeneous dispersion of the solid particles (~100 to 1000 nm) in a liquid where only the Brownian motions suspend the particles. A gel is a state where both liquid and solid are dispersed in each other, which presents a solid network containing liquid components. The sol-gel technique is a low-temperature method using chemical precursors that can produce ceramics and glasses with better purity and homogeneity than high-temperature conventional processes. This technique currently has wide application in preparing electronic, optical, and electro-optic devices.

### Abbreviations

1D	One-dimensional
AFM	Atomic-force microscopy
AFP	$\alpha$ -Fetoprotein
ALP	Alkaline phosphatase
BSA	Bovine serum albumin
CE	Capillary electrophoresis
CNT	Carbon nanotube
CNTFET	Carbon nanotube field-effect transistor
CVD	Catalytic vapor deposition

CWA	Chemical-warfare agent
DCC	Dicyclohexylcarbodiimide
DMF	<i>N,N</i> -Dimethylformamide
DNA	Deoxyribonucleic acid
DOE	U.S. Department of Energy
EAD	Electric arc discharge
ECL	Electrogenerated chemiluminescence
EVA	Poly(vinyl acetate)
FET	Field-effect transistor
GC	Gas chromatography
GOx	Glucose oxidase
HQ-PA	4-(1,4-Dihydroxybenzene) butyl phosphonic acid
HRP	Horseradish peroxidase
IgG	Immunoglobulin G
LA	Laser ablation
LC	Liquid chromatography
MONW	Metal oxide nanowire
MOSFET	Metal-oxide-semiconductor field effect transistor
MPDA	<i>m</i> -Phenylenediamine
mRNA	Message ribonucleic acid
MWCNT	Multiwall carbon nanotube
NADH	$\beta$ -Nicotinamide adenine dinucleotide
NEA	Nanoelectrode array
PECVD	Plasma-enhanced chemical vapor deposition
PEG	Poly(ethylene glycol)
PNA	Peptide nucleic acid
PNNL	Pacific Northwest National Laboratory
Ppy	Polypyrrole
PSA	Prostate-specific antigen
RNA	Ribonucleic acid
SAM	Self-assembled monolayer
SpA	Staphylococcal protein A
SWCNT	Single-wall carbon nanotube
TEM	Transmission electron microscopy

# Fullerene-based Electrochemical Detection Methods for Biosensing

*Nikos Chaniotakis*

### 4.1

#### Introduction

The football-like structure of fullerenes was discovered by Harold Kroto, James Heath, Sean O'Brien, Robert Curl, and Richard Smalley in 1985 [1]. These large nanostructures are made up of only carbon atoms, and are called Fullerenes after the American architect Richard Buckminster Fuller [2]. Buckminster Fuller designed large dome-shaped structures, such as the famous geodesic dome in Montreal Canada, built in 1967 for the Expo '67. Geodesic domes have no internal supports; they are light, and rigid, made up of specific geometrical prefabricated panels that can be assembled and taken apart quickly. Similarly, fullerenes have only carbon atoms, in a football like shell, made of five- and six-membered rings that are fused together.

The diameter of  $C_{60}$  Fullerene is so small, approximately  $10 \text{ \AA}$  ( $10^{-10} \text{ m}$ ) [3], that even the state of the art high resolution electron microscope cannot give us a clear image of it. The molecular model and the simulated HRTEM images of  $C_{60}$  fullerene [4] shown in Fig. 4.1 can help us visualize what this material actually looks like, while Fig. 4.2 can help us visualize how small it actually is. The size ratios between the earth ( $d = 1.275 \times 10^{-7} \text{ m}$ ) and the football ( $d = 0.22 \text{ m}$ ) is approximately the same as that between the football and the  $C_{60}$  fullerene.

### 4.2

#### Aims of the Chapter

This chapter addresses the use of the nanostructured fullerenes in the area of electrochemical biosensing, and its implementation to the development of electrochemical biosensors. Therefore, the basic concepts of both the idea of biosensing and the electrochemical properties of fullerenes must be well understood. This knowledge will allow for the understanding of the usefulness of the fullerenes in biosensing, as well as the possibilities provided for future applications. Fullerenes

**Fig. 4.1.** Left: Molecular model drawing of  $C_{60}$ . Right: simulated HRTEM images focused at different planes of  $C_{60}$ . (Adopted from Ref. [4].)

are structures, or molecules, that have been at the forefront of research and public interest for more than 20 years now. Despite this, their applications are quite limited, mainly because their physicochemical characteristics are still not very well understood. The use of the fullerenes and their derivatives can provide multi-dimensional advances in the area of chemical sensors and biosensors in particular. Their electrochemical characteristics, combined with their unique physicochemical properties, provide the grounds for such claims, even though the current range of applications in this specific scientific area is rather limited.

This chapter provides a complete overview of fullerene-based electrochemical detection methods with specific emphasis on biosensing. Initially, it provides the background on the development of fullerenes as well as their electrochemical characteristics. This information is followed by a detailed description of the evolution and design characteristics of sensing systems based on biomolecules, the so-called biosensing. This combination provides the reader with well-rounded information on the exact role of the fullerenes in biosensing. Finally, it gives direction on the future role of these and similar nanostructures for possible applications in chemistry and biochemistry, both *in vitro*, and *in vivo*.

**Fig. 4.2.** The relative size of  $C_{60}$  to a football is approximately the same as that of a football to the earth.

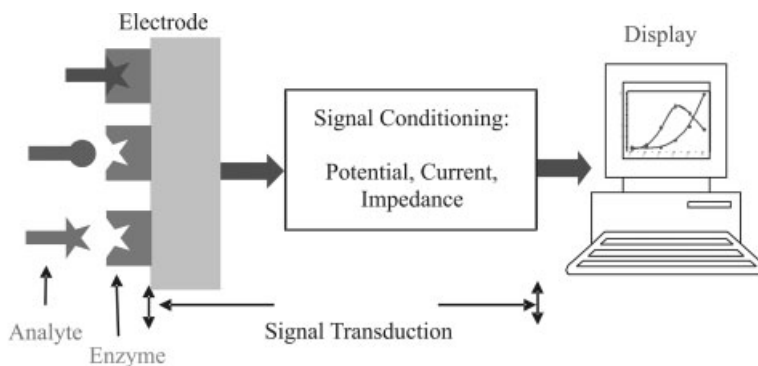

### 4.3

#### Electrochemical Biosensing

The monitoring of the chemical and biochemical substances involved in the biological world is one of the important biological functions that make life possible. This is because the detection of substrates, signals and other external stimuli allow for direct interaction of a living system with the environment, and thus make life viable. Such information can also be very useful in many everyday human activities. Health issues, environmental problems, food quality and safety are some of the human activity areas that need direct and selective quantitative biochemical information. For this reason researchers for more than 50 years, and since the introduction of the oxygen electrode [5], have been using biosensing principles for the development of analytical instruments. These efforts have led to the development of a series of analytical devices called “biosensors” [6].

According to IUPAC [7], a biosensor is “A device that uses specific biochemical reactions mediated by isolated enzymes, immunosystems, tissues, organelles or whole cells to detect chemical compounds usually by electrical, thermal or optical signals.” Based on this definition, electrochemical biosensing is the recognition process that is based on the use of a specific biochemical reaction or mediated by isolated enzymes, immunosystems, tissues, organelles or whole cells, and the signal of the processes involved is relayed (transduced) to the analysts using current, potential, or impedance. The transduction is based on the interaction of the activity of electrochemically active species that are in a close contact and adjacent to the working electrode, the transducer. These species are then reduced or oxidized, depending on the experimental conditions, and the resulting signal is monitored. The signal that is obtained is related to the analyte of interest, and thus the analytical information sought is obtained. While the transduction mechanism has to do with the electrode and electronics employed, the difficult task of analyte recognition is undertaken by the biosensing element. The biosensing element is usually a membrane, or a layer of material into which the enzymes, immunosystems, tissues, organelles or whole cells are immobilized.

Electrochemical biosensing methods are characterized by the fact that they can provide continuous, on-line information on the activity of an analyte. Analytes that are usually detected using biosensors are substances that can either take part in an enzyme-catalyzed reaction (catalytic biosensors), or inhibit an enzyme-catalyzed reaction (inhibition biosensors). Electrochemical biosensors can thus provide on-line and continuous quantitative biochemical information on the activity of the analyte, either within a biological system or in the environment surrounding these biological systems. This information is based on the electrochemical signals that result from a biological recognition event, and it is manifested through the electrode, the so-called transducer. The transducer can be any surface or matrix that can interact with the biological recognizing element, relaying the electrochemical recognizing process to the display and the analyst. Figure 4.3 shows a schematic diagram of all the components of a biosensor.

**Fig. 4.3.** Schematic diagram showing the main components of a biosensor. The analyte interacts with the biological recognition element (biocatalyst) and it is converted into product(s). This reaction is monitored by the

signal transduction system, converting it into an electrical signal. The output from the transducer is amplified, processed, and displayed to the analyst.

The role of chemistry and biochemistry is to optimize the biological recognition element, as well as the transducer surface that is in contact with this biosensing element. The biosensing process is usually based on the what is called the lock and key concept [8] or, in a more modern term, the host–guest interaction. The host is the biological molecule or the system that is responsible for the recognition, while the guest is the analyte or the species that we are interested in recognizing and quantitatively measuring its concentration or activity in the sample.

In the electrochemical biosensors the signal transduction takes place using the electrochemical properties of the species involved in the recognition process. Current, potential and resistance are the main parameters that can be utilized for decoding the effect a stimulus has (the analyte) on a recognition element. Clearly, there are various processes involved within a biosensor, which will transform a biochemical information into analytically useful data. For this reason the proper interaction and communication between the biological part, the biochemical processes, the transducers and other materials used is very important. To this, one must add the understanding and control of the electrochemical processes involved throughout the system. Only under these conditions can a biosensor device be designed that will provide analytically useful information on the presence of a specific analyte. At the same time, the proper interaction of these disciplines and materials involved will in the long run determine the stability of the device, the selectivity over other interfering substances, the detection limit that can be achieved, as well as the size of the device and its possible applications. As shown in Fig. 4.3, the sensor element is responsible for recognition of the analyte, while the transducer translates this information into the appropriate signal for recording. These two processes should be spatially very close, especially when electrochemical detection is utilized, without any inverse effects. Electrochemical processes are those involving

the three basic ohms law parameters, that is current ( $I$ ), potential ( $V$ ), and resistance ( $R$ ). Based on these parameters, electrochemical biosensors are categorized as amperometric, potentiometric, or impedometric. The simplicity and the sensitivity of the measurement of these parameters is the basis for the wide range of application of these methods. Electrochemical biosensing has an additional advantage, namely its ability to monitor localized events taking place at the interface between the biosensing element and the system under investigation. For all these reasons, electrochemical biosensors have found a very wide range of applications, while scientists all over the world are still working on improving their characteristics, as well as on finding new applications.

#### 4.3.1

##### **Making a Biosensor**

As an example, an outline of how a biosensor can be made in simple steps is provided here. Even though some technical terms are omitted for simplicity, the system described can be used for the measurement of an analyte such as glucose with very good analytical characteristics.

Making a biosensor has become by now a relatively simple procedure. The main components as described in Fig. 4.3 are:

- 1 The enzyme for the biorecognition.
- 2 The membrane(s) to hold the enzyme and to complete the biosensor element.
- 3 The transducer electrode, which includes the working and the counter electrode and, if possible, a reference electrode.
- 4 The electronic signal processing and display unit.

All these materials and tools are available, at a relatively low cost. A very good detailed description of the procedure can be found in the book *Biosensors. A Practical Approach* [9].

#### 4.4

##### **Evolution of Biosensors**

Electrochemical biosensors have been in continuous development and improvement since their first appearance in 1969 [6]. The development of electrochemical biosensors are concomitant with the three “biosensor generations” that have appeared in the literature. The major factor that determines the successful development of biosensors is the communication between the biosensing element or biomolecule and the transducer. The first-generation electronic coupling between redox enzymes and electrodes achieved this communication with the native enzyme co-factor [10] (Fig. 4.4A). The second-generation replaces this native redox couple with an electrochemically active compound, the mediator [11]. The mediator can be either free in solution or immobilized with the biomolecule (Fig. 4.4B).

Fig. 4.4. Schematic diagram of (A) first-, (B) second-, and (C) third-generation biosensors.

Third-generation biosensors aim at direct electron transfer between the native enzyme co-factor and the electrode surface [12, 13] (Fig. 4.4C).

A mediator is a substance that acts as the “middle man” in transferring the generated signal from the active site to the transducer. For electrochemical biosensors, a mediator is a redox species (a species that can be easily reduced or oxidized) that is spatially close to both the active center and the transducer, without harmful effects to the biosensing element.

Evidently, from these schematic diagrams of the biosensors, the interaction between the analyte, the catalytic site of the biological element and transducer plays a decisive role in the performance and quality characteristics of the biosensing system. Several processes are involved. Initially, there is a diffusion process of the substrates to the active center and then another diffusion of the products from the active center to the transducer. Alternatively, the product of the reaction can provide the signal to the transducer using either a mediator, or the biomolecule itself. This is one of the main roles that fullerenes are asked to play in biosensing.

#### 4.5

##### Mediation Process in Biosensors

Electrochemical detection in biosensing provides a convenient, efficient means of amplification. For such a process to occur within the closed system of a biosensor, the signal must flow to the transducer regardless of the activity of substances other than either the analyte or the product of the catalytic reaction. This task is usually undertaken by the natural coenzymes and co-factors found in the enzymes. The electrochemical reactions of the redox enzymes are known to have slow electron-transfer kinetics to and from a transducer or electrode. There are three main parameters that determine the kinetics of this electron-transfer mechanism. The first has to do with the physicochemical properties of the active site, such as charge, hydrophobicity and surface active groups. The second is related to the distance of the active site from the outer surface of the protein, while the distance of the protein from the electrode surface is the third determining parameter. For these reasons,

and in order that these biocatalytic reactions can proceed at analytically useful rates, the potential used on the transducer is much larger than that required to actually oxidize or reduce the natural biomolecule mediator. Lowering the redox potential of the substrates involved in these processes will not only increase the reaction rates but, at the same time, it will improve the sensitivity and most importantly the selectivity of the biosensor [14]. Lowering the operating potential will aid in increasing the enzyme stabilization, prolonging its activity, and decreasing the rate of denaturation. To achieve this, artificial mediators or electron relays are employed that can efficiently interact with both the enzyme catalytic site and the electrode surface. Such successful mediators should have lower redox potential than that of the natural enzyme mediator so that they can act as electron acceptors during the enzymatic reaction. Also, they should be compatible with both the transducer surface as well as the biomolecule. Finally, they should be stable, while providing sites for chemical functionalization. Molecules or nanostructures that are good candidates for such electron mediation should also have fast and reversible redox states, they should be stable both in the oxidized and in the reduced form, their redox potentials should be close to those of the enzyme's active site, and they should not react with any of the reactants or products of the enzymatic reaction. The reduced form of the mediator can then transfer the electron to the electrode surface, and after they are oxidized back to its initial state are ready to proceed to the next cycle.

#### 4.5.1

##### Case A: Non-mediated Biosensor

Under normal conditions the electron transfer in enzyme-catalyzed redox reactions takes place with the mediation of natural cofactors such as  $O_2$  and NADH. Figure 4.5 shows this process for the glucose biosensor.

The electron-transfer process is carried out by the natural coenzymes found in the biosystem, and the electrons are transferred to the transducer for the signal

Fig. 4.5. Flowchart of the processes involved in a non-mediated electrochemical biosensor. The operating potential in the case of glucose is +800 mV.

generation. In this case, the mediation is carried out using FAD–FADH and  $\text{H}_2\text{O}_2$ – $\text{O}_2$  electrochemical couples. Since the system is sensitive to the activity of both peroxide and oxygen, oxygen electrodes have been extensively used as transducers in electrochemical biosensors. Evidently, close contact between the enzymes with the transducer surface is mandatory. Such heterogeneous electron-transfer reactions are energetically demanding since the catalytic site of the enzyme is deeply buried within the protein structure and protected by the hydrophobic core of the protein. This is evident by the rather large potential polarization potential of the transducer (+800 mV) required to operate the glucose biosensor (Fig. 4.5). Such large potentials have very detrimental effects on the lifetime and selectivity of the biosensor. This is why, under these potentials, the stability of the enzymes to denaturation and deactivation is drastically decreased, while at the same time all substances that can be oxidized at that potential will seriously interfere during the measurement. Based on these facts a decrease in the operating potential is a very important experimental requirement, and it can be achieved with the use of mediators.

#### 4.5.2

##### Case B: Mediated Biosensor

As mentioned above, the use of mediators in the development of biosensors can provide specific solutions to operational problems of biosensors. Mediators can aid in improving the stability, the reproducibility, the selectivity and thus the range of applications of biosensors. Figure 4.6 shows the flowchart of a mediated biosensor. Numerous compounds have been proposed as mediators in biosensors. Most of them are different ferrocene derivatives or osmium complexes [15, 16]. Figure 4.7 shows two voltammograms of a glucose biosensor without (a) and with (b) the use of mediator. Note that at the operation potential of 400 mV, the signal obtained, and thus the sensitivity of the biosensor, is more than  $5\times$  higher.

**Fig. 4.6.** Flowchart of the processes involved in a mediated electrochemical biosensor. Note that the operating potential has dropped to +400 mV.

Fig. 4.7. Response of a non-mediated (a) and a mediated (b) glucose biosensor.

## 4.6

### Fullerenes

#### 4.6.1

##### Synthesis of Fullerenes

Fullerenes were discovered by Kroto and Smalley in 1985 in vaporized graphite under inert gas. Since then, several methods for the synthesis of fullerene have been reported. Many of them are based on laser ablation of carbon. Alternatively, graphite can be heated using either high power current source or, instead, an AC or DC arc discharge, to generate a “soot” of various carbon structures. Simple chromatographic separation of the soot provides high purity fullerenes [17, 18]. Based on this technology fullerenes can now be synthesized in large quantities (Fig. 4.8) [19, 20].

After the successful synthesis of  $C_{60}$  by thermal methods, fullerenes have also been synthesized using wet chemistry lab technology. A step-by-step synthesis based on polyne is now also possible [21–23] based on the precursor shown in Fig. 4.9. The synthesis of fullerenes in a step by step procedure provides the capability to control the surface functionalization of the  $C_{60}$ . Such functionalization can add new physicochemical characteristics to these molecules, rendering them, for example, more water soluble, adding sites for covalent bonding with biomolecules, or making them more susceptible to redox reactions.

#### 4.6.2

##### Biofunctionalization of Fullerenes

Fullerenes are very robust, very lipophilic and relatively unreactive nanostructures. There are a lot of instances where the physicochemical characteristics of these structures need to be altered to make them more hydrophilic, to link them to other

Fig. 4.8. Schematic of apparatus used to synthesize large quantities of fullerenes.

biomolecules, or immobilize them to a protein or other substrates, so that they are more suitable for a specific application. Initially, the functionalization of the fullerenes with organic and organometallic ligands has enabled them to be extensively studied in many fields. Different organic and organometallic ligands have been added by adsorption or covalent immobilization to the shell of the fullerenes, in-

Fig. 4.9. Precursor for the chemical synthesis of  $C_{60}$ . Upon heating, chlorine is liberated, and the molecule folds up to generate  $C_{60}$ .

creasing their hydrophilicity, or altering their optical and electrochemical properties [24–31]. In addition, the ability of the fullerenes to accept and donate electrons to the species surrounding them can also be drastically influenced and elegantly controlled using these functionalization methods [32, 33]. These functionalized nanostructures have already found applications in medicine, electronics and optoelectronics [34] and, recently, biosensing applications.

One of the advantages of grafting the biomolecule onto the surface of the fullerene is the fact that these two units will be spatially very close. Such a close arrangement will allow for direct and efficient interaction of the nanostructure with the biomaterial, and thus increase the efficiency of the processes involved [35].

Various substituted  $C_{60}$  derivatives have been derived to probe DNA reactions [36] or their radical scavenging properties. Unique structures, such as that illustrated in Fig. 4.10, have proved to be very interesting both for their interaction with radicals as well as with cell walls and DNA. Similarly, very interesting water-soluble fullerene derivatives such as the one shown in Fig. 4.11 [37] have appeared in the literature. However, their application in biosensing has not been extensively evaluated. It is, for example, envisioned that such positively charged species will both protect and stabilize proteins and enzymes [38], while at the same time pro-

vide an efficient way for signal transduction and mediation. Finally, the discovery of  $C_{60}$  antibodies [39] (Fig. 4.12) has already paved the way for the application of such systems in piezoelectric crystal immunosensors [40].

#### 4.6.3

#### Electrochemistry of Fullerenes

From the early stages of the discovery of fullerenes their electrochemical characteristics were considered to be very interesting and unique [41]. For this reason the electrochemistry of fullerenes in both solutions and films has been under intensive scientific investigation for many years [42]. Fullerene  $C_{60}$  behaves as an n-type semiconductor with a bandgap in the range of 1.6 eV, and its electron affinity is of the order of 2.7 eV [43]. Fullerenes in general have an expanded network of  $sp^2$  hybridized bonds that allows them to undergo up to six, one-electron reversible reduction reactions between  $-0.61$  and  $1.00$  V vs. SHE. Molecular orbital calculations predict very low lying triply degenerate LUMOs [44, 45]. The electron affinity of  $C_{60}$  can be explained qualitatively by considering its numerous perylene units, which upon receiving two electrons could go from an unstable  $4n$ -system to a stable aromatic  $4n + 2$  system. Moreover, the formation of  $sp^3$ -like anionic centers may lower the energy of the somewhat strained fullerene surface of bent  $sp^2$  carbons [46, 47, 48, 49].

Evidently, these early results show that the fullerene anions are stable due to the large separation between the distinct redox states and are, therefore, attractive oxidizing agents. Since then, there has been a considerable effort to clarify their electrochemical behavior in different solutions and matrices [50]. The bottom line of all these studies is that fullerenes indeed have unique electrochemical characteristics, as shown by the variety of redox couples. As carbonaceous materials, fullerenes are expected to have very unique electrochemical behavior within biological systems.

## 4.7

**Fullerene-mediated Biosensing**

As shown above,  $C_{60}$  fullerenes are nanomaterials with very unique redox characteristics. They are ideal substances for absorbing energy, taking up electrons (reduction), and releasing them (oxidation) with ease to a transducer. They are not harmful to biological materials and proteins, while they are small enough to come at least close to the active site of catalytic enzymes. At the same time they can be chemically modified, so that they can be functionalized to meet the needs of various applications.

For these reasons fullerenes were recognized very early on as materials that can play a decisive role in biocatalysis. Indeed, fullerenes have found applications in the area of biocatalysis and sensors from their early days of existence [51–54]. The idea of introducing a  $C_{60}$  chemically modified electrode to electrochemical research was first presented by Compton and coworkers in 1992 [55]. The sensor was prepared by immobilizing  $C_{60}$  films by drop coating onto surfaces of the noble metal electrodes, which were then coated with the Nafion protecting films. In this way, the amount of  $C_{60}$  required for performing electrochemical experiments was reduced and the signal enhanced compared with using  $C_{60}$  dissolved in solution. Subsequently, the electrochemical behavior of the  $C_{60}$  chemically modified electrodes (CMEs), has been widely investigated, providing the possibility of their electroanalytical applications [56]. Soon after,  $C_{60}$  fullerene film modified electrodes were investigated for the electrochemical reactions of cytochrome *c* using  $C_{60}$  fullerene deposited on glassy carbon (Fig. 4.13) [57, 58]. It was established then that the response of cytochrome *c* was quite independent of the underlying substrate (gold or glassy carbon), indicating that the fullerene film indeed acted as a promoter. Moreover, the molecular sieve type character and the possible effect of negative charges or polar groups on the surface of the films were suggested to be the reasons for the enhanced stability of the electrochemical response observed com-

**Fig. 4.13.** AFM picture of a  $C_{60}$  fullerene on glassy carbon. (Adopted from Ref. [57].)

pared with bare electrodes. The rate of electron transfer to cytochrome *c* was drastically improved with the use of fullerenes as electron shuttles between the cytochrome and the carbon electrode.

These very promising initial results in biocatalysis suggested that, indeed, fullerenes can be ideal substances for electron mediation also in biosensors, since they are small, robust, biocompatible and have a wide range of oxidation/reduction potentials. In addition fullerenes are very lipophilic, while at the same time they can be chemically modified by functionalized matrix, and also with the hydrophilic proteins and the active site of the enzymes. All these characteristics make them ideal for use as mediators in electrochemical biosensing. In 1998 [59] carboxylic derivatives of  $C_{60}$  were covalently attached to a cystamine-monolayer-functionalized Au-electrode for the monitoring of biocatalysis transformations. It was then shown that the  $C_{60}$  monolayer can provide electrical communication between the electrode and a soluble glucose oxidase, GOx, with sufficiently high electron-transfer rates. The use of  $C_{60}$  as an electron mediator for electrocatalyzed biotransformations presented in this work set the stage for the direct application of  $C_{60}$  in biosensors. This was followed by reports in which fullerenes were used as mediating agents capable of charge transfer between redox enzymes and electrodes. Fullerene molecules can be used without functionalization, or after immobilization in gold electrodes with good success [60, 61].

Fullerenes has also been suggested as mediators in supported bilayer lipid membrane (s-BLM) biosensors [62–65]. s-BLMs are self-assembled systems that can be used for the design of electrochemical sensors and biosensors. S-BLMs are very thin membranes formed onto a transducer (platinum, gold, etc.) that can come in contact with the system to be analyzed. The introduction of biomolecules into these BLMs makes them suitable for the monitoring of chemical and biological species in systems such as that shown in Fig. 4.14.

Based on this idea, fullerenes have been used for the development of highly sensitive s-BLM-based chemical sensors for  $I^-$  [66]. The increase in sensitivity is because fullerenes change the electrical parameters of s-BLMs and facilitate the electron transfer of  $I^-$  at the metal surface, according to reaction scheme (1):

Fig. 4.14. s-BLM incorporating fullerene and enzyme for the construction of a BLM biosensor.

**Fig. 4.15.** Scheme of electrochemical sensor based on C<sub>60</sub>-modified s-BLM for the detection of volatile organic compounds (odorants). (Adopted from Ref. [67].)

The same idea has been applied for the electrochemical detection of volatile organic compounds using a sensor setup such as the one shown in Fig. 4.15 [67].

In these molecular devices fullerenes can also act as light-sensitive dipoles, capable of photoinduced charge separation, which undergo redox reactions across the substrate–hydrophobic lipid bilayer–aqueous solution junctions. Based on this, light addressable devices can be developed. Indeed, recent results [68] have also indicated that the photoinduced activation or switching of electron transfer of the enzyme glucose oxidase to the transducer is possible (Fig. 4.16).

Using fullerenes as an optical nanostructure switch, the biosensor is active only under light illumination, at potentials very close to zero versus Ag/AgCl reference electrode.

The functionalized fullerenes grafted onto polyelectrolytes were shown to be significant tools in biosensor design. Polyelectrolytes are very efficient enzyme stabilization systems.

The controlled interaction with enzymes allows for the protection and stabilization of the protein from denaturation, unfolding and, thus, deactivation [69–73].

**Fig. 4.16.** Flowchart of the processes involved in a light-induced fullerene-mediated electrochemical biosensor. Note that the operating potential has dropped to +100 mV.

**Fig. 4.17.** Structure of fullerene-functionalized polyethylenimine (PEI-C<sub>60</sub>). Such structures provide both stabilization and signal mediation.

Systems such as polyethylenimine functionalized with fullerenes (Fig. 4.17) via covalent bonding allow for the simultaneous stabilization of the protein, and mediation of the signal [74].

Controlled modification of the fullerene surface with biomolecules is the state of the art method to improve the catalytic redox properties of proteins (Fig. 4.18). Covalent bonding of fullerene onto proteins has significant advantages over direct

**Fig. 4.18.** Schematic illustration of protein conjugated to *N*-(3-maleimidopropionyl)-3,4-fullerolridine used for the development of subtilisin-based biosensor. (Adopted from Ref. [75].)

immobilization on nonporous silica or similar matrices [75]. The small size of the C<sub>60</sub> molecule makes the active site of the enzyme accessible to the substrate, and thus there is no diffusional limitation for the substrate to reach the active site imposed by the C<sub>60</sub> surface. The enzyme retains its activity and behaves in a similar manner as its free solution form.

#### 4.8

#### Conclusions

Even though the basic physicochemical characteristics of Fullerenes have only recently been realized, they have already contributed significantly in the area of biosensing and nanobiotechnology. In addition, the use of fullerenes and their derivatives have already provided multidimensional advances in the area of electrochemical sensors and biosensors in particular. The electrochemical characteristics of fullerenes, combined with their unique physicochemical properties lend its use in the design of novel biosensor systems, even though the current range of applications in this specific scientific area is still rather limited. Given their signal mediation, protein and enzyme functionalization and light induced switching; fullerenes can potentially provide new and powerful tools in the fabrication of electrochemical biosensors in the future.

# Optical Biosensing Based on Metal and Semiconductor Colloidal Nanocrystals

*Roberto Comparelli, Maria Lucia Curri, Pantaleo Davide Cozzoli, and Marinella Striccoli*

### 5.1

#### Overview

Nanomaterial-based optical sensors are among the most advanced class of sensing devices produced in the recent past for the continuous, real-time monitoring of diverse analytes. Following the tremendous impact of the unusual properties of nanoscale matter on present technology, scientific publications dealing with sensing applications have concomitantly proliferated. Research on these topics embraces wide and interdisciplinary fields under intense evolution, making it difficult to provide a comprehensive scenario of the current status of their development. This chapter is specifically intended to offer a critical view on the specific potential of colloidal nanocrystals as a distinguishable class of nanosized materials for biosensing. Especially, it will emphasize how the size-dependent optical properties of nanocrystals can be flexibly tailored by the synthetic tools accessible by modern material chemistry, specifically addressing optical techniques and methods for well-defined sensing purposes.

The review of this subject will therefore be organized as follows: (a) the introduction will focus on the chemical-physical properties that justify the choice of nanocrystals as advantageous in various diagnostic approaches; (b) several optical techniques that can be used as transduction methods for biosensing will then be described in detail; (c) selected examples of specific applications and biochemical studies will be presented; and (d) in the conclusions, a few key issues regarding the commercial development of the presented techniques will be discussed.

### 5.2

#### Introduction

Current interest in both fundamental and practical scientific research is oriented towards the design and engineering of new generations of devices based on nanosized inorganic objects coupled with assembled molecules [1–3]. The tremendous

**Fig. 5.1.** (a) Schematic representation of single colloidal nanocrystal coated with organic molecules. (b) High-resolution transmission electron microscope picture of CdS nanocrystal.

efforts in this direction have been motivated by the recognition of size-, shape-, and composition-dependence of the optoelectronic, magnetic, and catalytic properties of matter at the nanoscale [4].

Recent advances in both physical and chemical synthetic approaches have made various nanostructured materials available for novel technological applications (Fig. 5.1).

The unique and intriguing optoelectronic properties of such nanostructured objects can find applications in the fabrication of new and original nanosensors in the wide field of biochemistry. In particular, this chapter emphasizes the impact of semiconductor and noble metal colloidal nanocrystals on the development of optically driven detection methodologies for biosensing purposes.

A “biosensor” can be broadly defined as a sensing device able to measure any property with biological significance or connected with bioactivity by means of biomolecules and/or biologically related structures. More appropriately, a biosensor is a small device that, as the result of a chemical interaction or process occurring between the analyte and the sensing element, transforms quantitative or qualitative chemical or biochemical information into an analytically useful signal. Biosensors are usually considered a subset of chemical sensors because of the peculiar transduction methods associated with them, sometimes referred to as the sensor “platforms”. The fundamental understanding of the physics and chemistry of nanosized metal and semiconductors has stimulated intense efforts to the development of innovative strategies for biosensing devices. Although various sensing mechanisms, based on the changes of magnetic, electrochemical, piezoelectric, and resistivity properties of matter, have been exploited so far, optical transduction has largely been the most preferred tool in many biosensing applications because of its superior advantages and versatility. Especially, optical platforms are technologically appealing, as they offer high detection limits, little sensitivity to electro-

Fig. 5.2. Colloidal nanocrystals are commensurate with biomacromolecules.

magnetic noise, the possibility of remote control and information transfer through optical fibers, long lifetime, and amenability to multiplexing. Such interest is further motivated by the expectation that nanomaterial-based optical biosensors will not only replace conventional sensors, but also enable the fabrication of unprecedented sensing devices. Finally, the recent advantages in photonic technologies and the low cost availability of commercial optical fibers and lasers will certainly encourage access to new frontiers of biosensing.

Inorganic objects on the nanometer scale promise easy integration with many bio-related domains. The fact that nanoparticles share the same size regime (<50 nm) as that of many biomolecules opens access to the fabrication of novel composite nanostructures with the biological and the inorganic components suitably coupled (Fig. 5.2).

Including nanomaterials in a sensing device can be beneficial in that unprecedented transduction modes, relying on their special properties, can be, in principle, developed for any event of biological relevance.

The emerging disciplines of nanoengineering, nanoelectronics, and nanobioelectronics, require suitably sized and functionalized nanosized particles as the “building blocks” with which to construct their architectures and active elements. Especially, colloidal nanocrystals represent attractive precursors for creating various electronic and sensor components due to the ease of their fabrication and to their intrinsic robustness, allowing for further processing. Such objects are composed of a crystalline inorganic core and a protective shell of surface anchored molecules provided by a solution-phase synthesis. Nanocrystals are grown directly in a liquid solution by chemical methods that facilitate their medium-scale production in a reaction flask.

Colloidal nanoparticles differ significantly from other classes of nanostructured materials in that their surface chemistry can be conveniently manipulated to enhance compatibility with biological environments, to achieve nanocrystal immobilization onto substrates, conjugation with selected biomolecules, and/or incorporation into different matrixes (Fig. 5.3).

**Fig. 5.3.** Colloidal nanocrystals can be surface functionalized for (a) guided assembly, (b) biomolecular recognition, (c) sensing devices, and (d) solution-based receptors.

Nanoparticles have been used in biosensors for the last two decades. The fabrication and characterization methods for nanomaterials have been progressively refined to the point that deliberate modulation of their size, shape, and composition can be now obtained, thereby permitting a fine control of their properties. Colloidal techniques have long been known, but only recently has a great body of work been devoted to the synthesis of nanocrystals specifically intended for the construction of devices and complex composite nanostructures.

Today, the key goal in nanocrystal-based technology is to reproducibly synthesize nanoparticles having several properties, such as specific size, tailored shapes, crystal phase and crystallographic orientation, well-defined surface chemistry, solubility in any desired solvent, and multifunctional performances. These latter can be achieved by combining different materials in a single hybrid nanostructure, due to novel structural and electronic properties arising from interactions of the single components. A new concept of “purpose-built” nanomaterials has thus emerged, whose basic idea is to model and design materials with the proper morphology, size, shape and surface status to probe, tune and optimize the material’s physical-chemical properties. The ability in tailoring all these characteristics is an essential condition to extend NCs to large-scale technological and industrial applications.

Now, the structure of nanosized noble metals and semiconductors can be systematically engineered to produce materials with specific emissive, absorptive, and light-scattering properties, which make these materials ideal for multiplexed analyte detection. The control of composition and shape can allow for the variation of additional parameters useful in the detection of target analytes.

Furthermore, techniques for surface modification and patterning have advanced to such a great extent that the binding affinity of materials for various biomolecules

can be modulated by suitable chemical tools as much as desired, leading to novel generations of nanoscale arrays of biomacromolecules and small molecules together on surfaces [2a]. The overall ensemble of these capabilities has allowed the design of functional materials that can be implemented into new optical assays in biosensors based on improved modes of signal transduction.

## 5.3

### Colloidal Nanocrystals

#### 5.3.1

##### Size-dependent Optical Properties

Most nanocrystal physical properties evolve as a function of the size and/or shape, approximately following some “scaling laws” [5]. Two major reasons account for this special dependence in nanocrystals: the confinement of charge carrier motion in a small material volume, and the significant fraction of atoms residing at the surface, as compared with that in the corresponding bulk counterpart.

Now, in any material, there will be a size below which a substantial change of fundamental electrical and optical properties occurs with size: these variations will be seen when the energy spacing  $\delta$  of successive quantum levels ( $\delta = 4E_F/3n$ , where  $E_F$  is the Fermi level of the bulk material and  $n$  is the total number of valence electrons in the nanocrystal) exceeds the thermal energy ( $\sim 25$  meV at room temperature). For a given temperature, this occurs at a very large size in semiconductors, as compared with metals, insulators, van der Waals, or molecular crystals.

In semiconductors, the quantum-sized effects result in a widening of the band gap and in the development of well-defined energy levels at the band edges [7]. These facts can be clearly observed in the optical absorption spectra of “quantum dots”: the threshold energy for absorption is shifted to shorter wavelengths with decreasing the particle size and discrete spectral features develop in the spectrum, which correspond to the allowed optical transitions (Fig. 5.4). The positions of the lowest energy absorption peak (which is usually the most defined) as well as that of the luminescence peak are strictly correlated to the average particles size, while their widths reflect, in part, the remaining size distribution. In anisotropic nanocrystals, such as nanorods and tetrapods, the shift behavior of the exciton peak is characteristically dependent on the shortest confined dimension [8] (Fig. 5.5). Furthermore, the size-dependence of semiconductor nanocrystal band-gap provides a tool for tuning the redox potentials of photogenerated holes and electrons, allowing redox process that would be forbidden for extended solids.

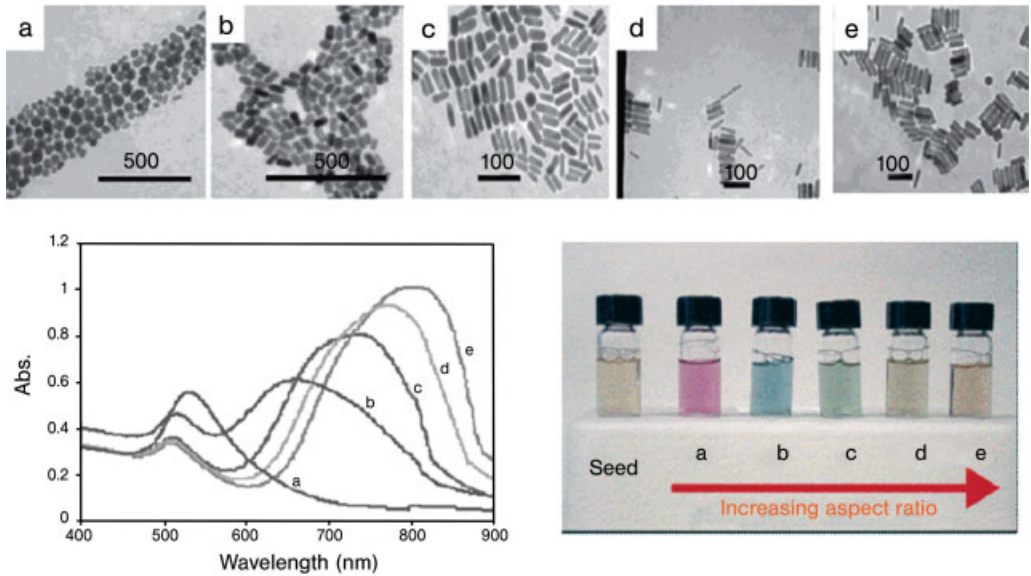

In noble metals, the decrease in size below the electron mean free path gives rise to intense absorption in the visible–near-UV region [9]. The optical absorption spectra exhibit absorption peaks that do not derive from quantum confinement effects but result from the collective oscillations of the itinerant free electron gas on the particle surface, that are induced by the incident electromagnetic wave. Such resonances, referred to as surface plasmons (SPs), are seen when the wavelength

**Fig. 5.6.** TEM images (top), absorption spectra (left), and photographs (right) of aqueous solutions of gold nanorods of various aspect ratios. Seed sample: aspect ratio 1; sample a, aspect ratio 1.35 (0.32); sample b, aspect ratio 1.95 (0.34); sample c, aspect ratio

3.06 (0.28); sample d, aspect ratio 3.50 (0.29); sample e, aspect ratio 4.42 (0.23). Scale bars: 500 nm for a and b, 100 nm for (c–e). The value in parenthesis represents the error in the determination of the aspect ratio. (From Ref. [10].)

of incident light far exceeds the particle diameter. In the “intrinsic size” regime ( $<5$  nm), noble metal nanoparticles do not show any plasmon absorption, while the absorption of particles larger than 50–60 nm (in the “extrinsic size” region) is broad and covers most of the visible region.

The spectrum of anisotropic particles can exhibit several bands (Fig. 5.6) corresponding to multipole SP resonances and becomes further modified by charge accumulation, molecular adsorption, solvent nature, and aggregation status of the particles (Fig. 5.7) [10, 11].

Interestingly, in the nanosized regime noble metals exhibit a considerable shift of their redox potential toward negative values, which makes them work as efficient electron-transfer mediators [12, 13] (Fig. 5.8).

In nanocrystals the number of atoms residing at the surface is a large fraction of the total and the density of bulk defects is rather low [14]. To minimize surface energy, substantial reconstructions in the atomic positions can occur, so that nanocrystal surfaces can be largely disordered, yielding spherical or ellipsoidal shapes, or can expose regular facets, as are present in extended crystals. Surface rearrangement can be more easily visible in extremely small clusters (in the 3–50 atoms range), where, as there is no clearly identifiable interior, unique bonding geometries, distinct from those of the bulk solid, are assumed.

**Fig. 5.7.** The surface plasmon resonance of Au nanoparticles can be modified by their aggregation status. The left-hand side of the figure shows the temporal evolution of the absorption spectrum of gold upon UV-photocatalytic reduction of  $10^{-3}$  M  $\text{HAuCl}_4$  in

the presence of  $5 \times 10^{-2}$  M  $\text{TiO}_2$  nanorods in  $\text{CHCl}_3$ -EtOH. The corresponding TEM images (right-hand side) show the progress of Au nanoparticle assembly after irradiation for (a) 20, (b) 60, (c)–(e) 120, and (d)–(h) 240 min. (From Ref. [11].)

**Fig. 5.8.** An example of electron transfer mediated by nanosized metal nanoparticles, showing the absorption changes occurring to UV pre-irradiated  $\text{TiO}_2$ -stabilized Au NPs (a) upon successive additions (5  $\mu\text{m}$  each) of Uniblue A (UBA), an organic dye, under  $\text{O}_2$ -free conditions (b–m). When all stored electrons are consumed, the absorption

features of unreduced UBA can be observed (spectrum n). Conditions:  $[\text{TiO}_2] = 0.1$  M, nanorods:  $3 \times 25$  nm;  $[\text{Au}] = 5 \times 10^{-7}$  M, metal size:  $15 \pm 3$  nm; pre-irradiation time: 30 min. Spectra were taken using the respective photocatalyst solution as the reference. (From Ref. [12], some spectra have been removed for clarity.)

In nanocrystals having applications in opto-electronic devices, surface states invariably result in energy levels within the forbidden energy gap. They act as traps for electrons or holes, ultimately leading to the degradation of the electrical and optical properties of the material. In contrast, lower coordination surface atoms in metal and semiconductor oxides are usually beneficial toward catalysis and sensing of various chemical reactions [15]. The coordination numbers of surface atoms may vary over wide ranges because different crystallographic faces, edges, steps, point defects, and dislocations may be exposed, resulting in a substantial energetic heterogeneity. Unsaturated valences may be, therefore, completed by adsorbed target molecules, the latter affecting the overall electronic distribution of the nano-sized object. More importantly, the qualitative change in the electronic structure of nanocrystals coupled with chemisorption of suitable substrates can bestow unusual optoelectronic behavior for both the inorganic and organic component.

### 5.3.2

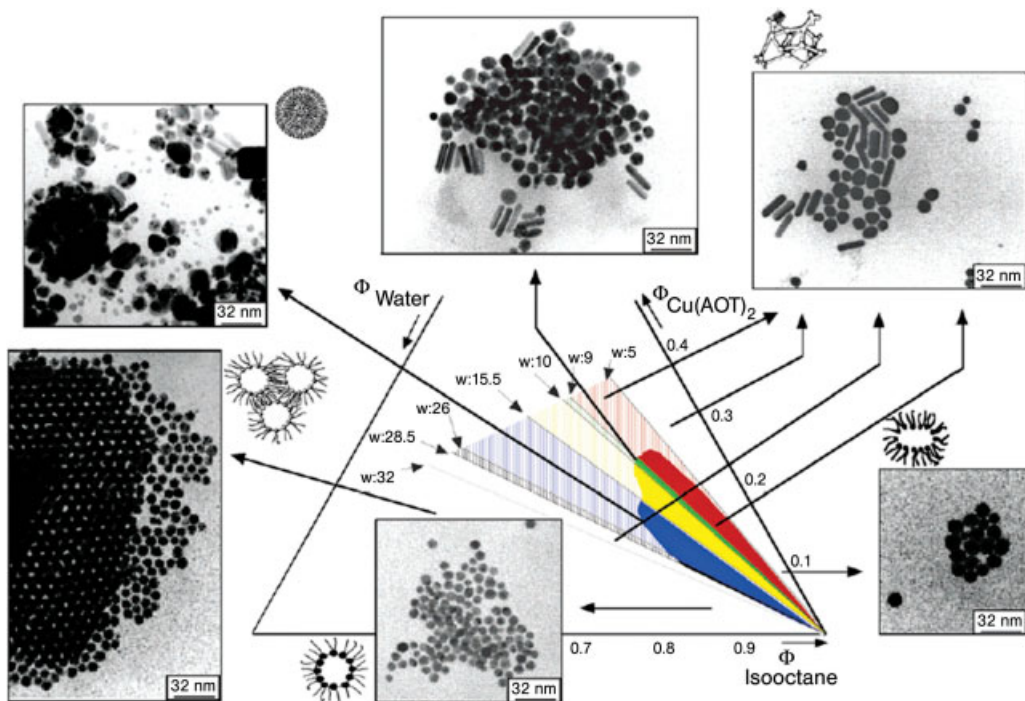

#### Chemical Synthesis

In colloidal approaches, a fine modulation over the NC size and shape is possible by adjusting the balance between the nucleation and the growth stage. To achieve this, in general the key ingredient is the presence of one or more organic molecules in the reactor, broadly termed as “surfactants”. Surfactants are amphiphilic compounds, i.e., molecules composed by one hydrophilic part (a polar or a charged functional group) and one hydrophobic part (in the simplest case, one or several hydrocarbon chains). They can act in two main different ways, described below.

(a) *Organic Templates*: Depending on physical-chemical parameters, such as surfactant concentration, temperature, solvent polarity, additives, ionic strength, amphiphilic compounds tend to assemble into soluble aggregates [16]. These assemblies can have spherical shapes or evolve into rod-like or cylindrical aggregates, flexible bilayers, and planar bilayers. Therefore, the liquid phase can contain hydrophilic or hydrophobic compartments of nanometer size prior to the synthesis, which serve as NC templates. The addition of monomers to the growing cluster is naturally terminated once a NC fills the compartment volume, which predetermines a specified distribution of the NC population close to that of nanocompartments [17] (Fig. 5.9).

In bulk colloidal dispersions, the role of compartments is generally played by direct or reverse micelles, microemulsion droplets, or by the pores (cavities) in any bicontinuous cubic phase of a lipid. A self-assembled amphiphile layer on the interface is also capable of compartmentalizing the accepted reagents, to introduce nanocrystalline structures (so-called membrane mimetic chemistry), and to orient the nanocrystal domains in the nanoreactors [18].

(b) *Terminating agents*: The growth of NCs can be properly controlled in many cases by use of special molecules that behave as “terminating” agents. Such molecules direct the growth of nanostructures by dynamically coordinating their surface under the reaction conditions. Some examples of suitable surfactants include molecules carrying functional groups with electron-donor atoms, such as alkyl thiols,

**Fig. 5.9.** Example of nanoparticle shape control achieved by combining the strategy of surfactant-based templating and the capping of salts or molecules. Various shapes of copper nanocrystals are obtained in the various parts of the phase diagram of  $\text{Cu}(\text{AOT})_2$ -water-isoctane in the oil-rich region. (From Ref. [17].)

phosphines, phosphine oxides, phosphates, phosphonates, amides or amines, carboxylic acids, and nitrogen-containing aromatics [17–19].

The choice of surfactants varies from case to case: a molecule that binds too strongly to the surface of the quantum dot is not useful, as it would not allow the nanocrystal to grow. A weakly coordinating molecule, however, would yield large particles, or aggregates. The surfactant molecules must be chemically stable at the reaction temperature to be suitable candidates for controlling growth. At lower temperatures, or more generally, when the growth is stopped, the surfactants are more strongly bound to the surface of the NCs and provide their solubility in a wide range of solvents. More importantly, surface defects (unsaturated valences) that act as traps for electron and holes, in turn degrading their optoelectronic properties, can be effectively passivated through coordination bonds with the surface ligands.

By controlling the mixture of surfactant molecules that are present during the generation and the time growth of the nanocrystals, excellent control of their size and shape is possible for many materials (Fig. 5.10) [20]. Under appropriate conditions, the choice of suitable surfactants can indeed modulate the reactivity of the

**Fig. 5.10.** Shape control of colloidal nanocrystals. (a) Kinetic shape control at high growth rate. High-energy facets grow more quickly than low energy facets in a kinetic regime, using one type of metal coordinating group. (b) Kinetic shape control through selective adhesion. The introduction of an organic molecule that selectively adheres to a particular crystal facet can be used to slow the growth of that side relative to others, i.e., metal coordinating groups with different affinities to nanocrystal facets are used, leading to the formation of rod- or disk-shaped nanocrystals. (c) More intricate shapes result from sequential elimination of a high-energy

facet. The persistent growth of an intermediate-energy facet eventually eliminates the initial high-energy facet, forming complex structures such as an arrow- or zigzag-shaped nanocrystals. (d) Controlled branching of nanocrystals. The existence of two or more crystal structures in different domains of the same crystal, coupled with the manipulation of surface energy at the nanoscale, can be exploited to produce branched inorganic nanostructures such as tetrapods. Inorganic dendrimers can be further prepared by creating subsequent branch points at defined locations on the existing nanostructures. (From Ref. [20].)

molecular precursors and direct shape changes by adhering selectively to the various facets of the growing crystallites. Delicate control of parameters, such as strain, surface reactivity, interfacial energy, and crystal solubility at the nanoscale [8–21], opens access to various complex NC morphologies and even hybrid architectures, ranging from simple core/shell systems to individual nanostructures with linear and/or branched topology [21], with site-specific deposits of a different material [22], and hetero-groups made of magnetic, metal or fluorescent spherical NCs [21d, 23].

The surfactant coating on the NC surface provides great synthetic flexibility in that it can be exchanged with another coating of organic molecules having different functional groups or polarity.

After the synthesis, colloidal nanocrystals can be further processed (e.g., functionalized with selected biomolecules or coupled with other nanosized objects) and/or transferred to any desired substrate or object.

Many applications of the quantum-mechanical aspects of quantum dots can be found in optics. As the more general case of atoms and molecules, quantum dots

can be excited either optically or electrically. Regardless of the nature of excitation, quantum dots may emit photons when they relax from the excited state to the ground state. Based on these properties, quantum dots may be used as lasing media, as single-photon sources, as optically addressable charge storage devices, or as fluorescent labels.

Colloidal quantum dots have also been used for the development of light-emitting diodes [24] and in the fabrication of photovoltaic devices [25]. In these devices, the nanocrystals are incorporated into a thin film of conducting polymer.

Chemically synthesized quantum dots fluoresce in the visible range with a wavelength tunable by the size of the colloids. The possibility of controlling the onset of absorption and the color of fluorescence by tailoring the size of the nanocrystals makes them interesting objects for the labeling of biological structures [26] as a new class of fluorescent markers. The tunability combined with extremely reduced photobleaching makes colloidal quantum dots an interesting alternative to conventional fluorescent molecules.

#### 5.4 Nanocrystal Functionalization for Biosensing

In general, practical applications can take advantage of some unique properties of NCs, such as that of being conjugable, connectable or anyway joinable with biomaterials, thus enabling biolabeling [29], biosensing [30] and use for biomedical purposes [28c–31].

Sensing processes operated by biomaterials bound to surfaces are commonly practiced in analytical biochemistry. Actually, many recent sensing applications are the result of a natural evolution of the bioconjugation chemistry, which is based on the idea of merging biological and non-biological molecular species and/or systems, to realize novel markers for cellular biology, labeling, and biosensing.

In this perspective, the use of NC-biomaterial conjugates has been demonstrated to provide a general route for the development of optical biosensors, which exploit the newly designed nanomaterial based hybrids.

The synthesis of noble metal NCs (which possess a naturally higher bioaffinity) in the presence of biomolecules has been proposed to provide nanoparticles directly connected to biologically relevant molecules [32]. However, semiconductor nanocrystals, which are typically prepared by non-aqueous routes in organic media, require several post-synthetic treatments to enhance their compatibility with biological environments. Such processing is delicate in that it should preserve the NC optical properties over the desired spectral range.

Therefore, in the last decade several studies have provided the means to obtain water-soluble and biocompatible NCs, while keeping intact their original optical characteristics.

The plethora of nanocrystal functionalization methods reported can be mainly divided into three classes: (a) surface capping exchange (typically with bi-functional agents), (b) coating with siloxane and (c) modification of the pristine capping layer

of NCs via hydrophobic interactions. Figure 5.11 gives a schematic representation describing different surface functionalization methods.

#### 5.4.1

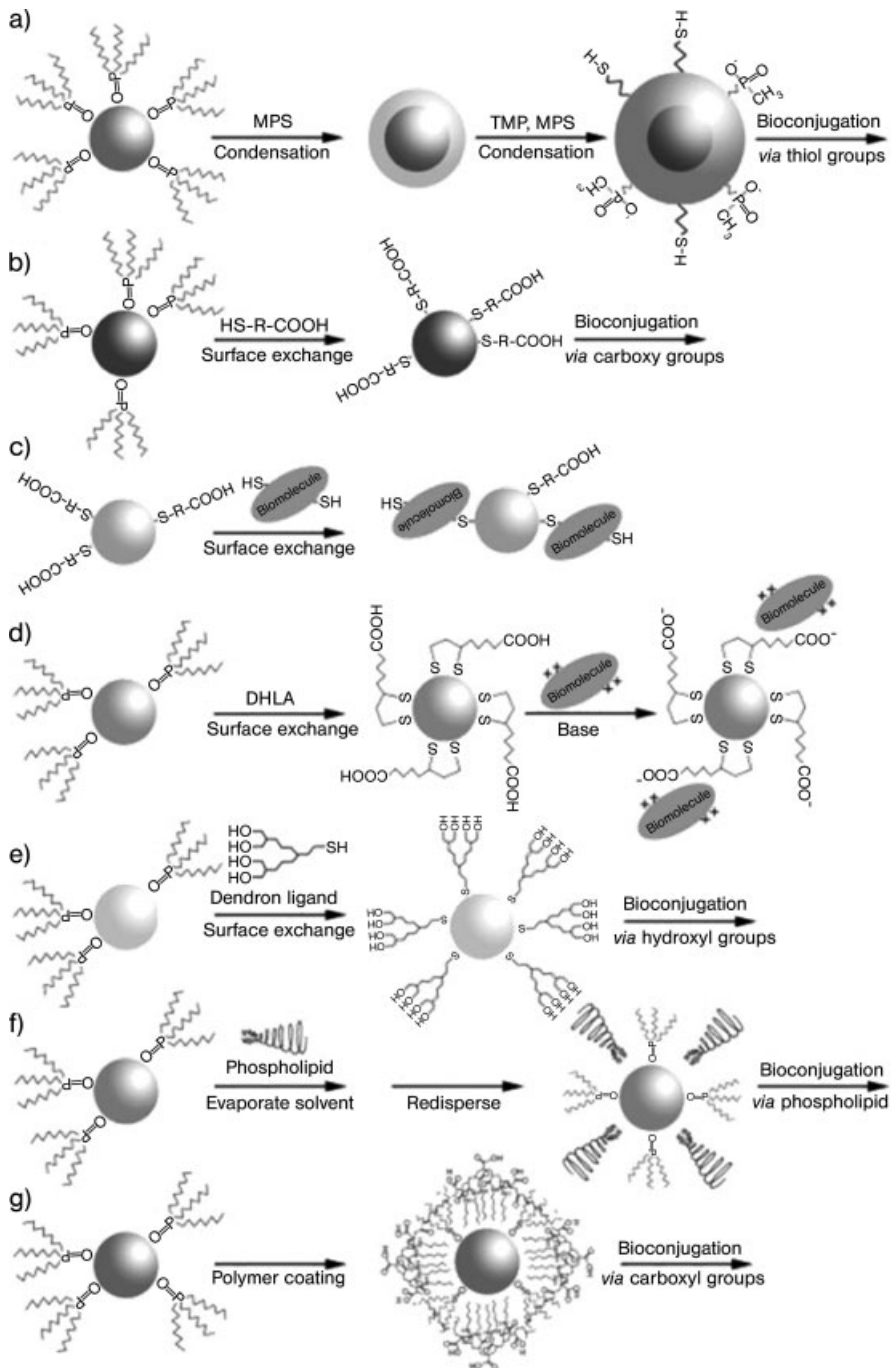

##### Surface Capping Exchange

This approach has been proposed for the functionalization of cadmium and zinc chalcogenide NCs (e.g., CdSe, CdS, ZnS, ZnSe) and of their related core-shell derivatives (CdSe@ZnS, CdSe@ZnSe, CdS@ZnS). The basic idea is the substitution of the pristine organic capping layer with bifunctional ligands. Mercapto-acids (mercapto-acetic, mercapto-succinic, mercapto-propionic, mercapto-benzoic, and so on) have been the most commonly used molecules to this purpose [34]. They interact with the NC surface by means of the thiol group while water solubility is ensured by the outermost exposed carboxylic moiety. A major limitation is that mercaptoacid-capped NCs are highly soluble in water only when the carboxylic group is deprotonated, so that the stability of the particles at acid pHs is poor. More importantly, in comparison with the original NC emission, a reduction in photoluminescence (PL) quantum yield is usually observed, the extent of which depends on the nature of the linker exchanged and on the medium. Also, progressive detachment of thiol ligands from the NC surface due to the established dynamic adsorption-desorption equilibrium can usually result in NC aggregation and precipitation over periods longer than one week [29a–35]. Despite these drawbacks, this simple procedure allows for the preparation of fresh batches in gram scale on an “as-needed” basis. Moreover, if further bioconjugation of such thiol-modified NCs is accomplished, their stability in water can be enhanced [29a].

Bifunctional agents, such as dithiothreitol (DTT) [34] and dihydrolipoic acid (DHLA) [30–36] carrying two thiol moieties per molecule, provide stronger interactions with the NC surface, thus prolonging their stability in water (up to 2 months in the case of DTT and up to 1–2 years with DHLA) [37]. This evidence suggests that polydentate thiolated ligands could be even more effective [35b]. DHLA-capped NCs are stable at pH > 7, while at slightly acid pHs aggregation can occur.

Mercapto-capped NCs can be bioconjugated either by replacing the capping layer with thiol-modified biomolecules (e.g., DNA [30a] or proteins [38, 39]) or by carboxylic group activation. The hydroxyl groups in DTT can be exploited to achieve bioconjugation by just making them react with nucleophilic agents, such as amines. This approach, suitable to different types of NCs [28c], does not require specific coupling agents and allows one to employ commercially available nucleotides. If NCs are stabilized by negatively charged ligands (for instance DHLA or citrate), bioconjugation can be obtained by electrostatic interactions [36a–40].

The surface capping exchange can also be performed directly with biomolecules. For instance, small biomolecules, like serotonin, can replace tri-*n*-octylphosphine oxide (TOPO) on CdSe@ZnS NC [41]. Analogously, these NCs have been functionalized with synthetic phytochelatin-related peptides, providing them with a coating of biotinylated peptides, which efficiently bind to streptavidin [42]. Lysine and biotin have been used to modify Au NPs and to bind them to various proteins [43],

**Fig. 5.11.** Example strategies for nanocrystal surface modification: (a) coating with silica shell; capping exchange with (b) bifunctional linkers, (c) thiolated molecules, (d) bivalent

linkers, (e) and organic dendrons. (f) and (g) Nanocrystal modification via hydrophobic interaction. (From Ref. [33].)

immunoglobulin (IgG), and BSA. This approach is particularly successful for metal particles capped by loosely bound molecules, such as citrate, as demonstrated in the case of Au [44] and Ag [45]. Conversely, in the case of CdS NCs [46] weaker interactions have been observed as well as a luminescence quenching.

Finally, organic dendrons can also replace the native ligand capping on core-shell NCs, leaving the exposed hydroxyl moieties available for bioconjugation in aqueous environment, as reported for TOPO-capped CdSe NCs and Au NPs [47].

#### 5.4.2

##### Coating with a Silica Shell

*Surface silanization* is the procedure through which a hydrophilic silica shell is grown on NCs after displacing the original hydrophobic capping layer, ultimately providing NCs with solubility in water [26a]. In the general approach, the first step accomplishes ligand exchange with mercaptosilanes, usually mercaptopropyltrimethoxysilane (MPS). The mercapto groups ( $-SH$ ) are bound to the NC surface, whereas methoxy groups ( $-OCH_3$ ) are exposed to the solvent. Subsequently, siloxane bonds ( $-Si-O-Si-$ ) can be formed by reacting the methoxysilane moieties with each other under basic conditions. The final result is a highly cross-linked silica shell possessing improved resistance against dissolution [48, 49]. To provide hydrophilicity, in a further step, molecules bearing mercaptosilane groups at one end and hydrophilic groups at the other one are attached to the shell via the formation of siloxane bonds, leading to a multilayered shell. By properly selecting the hydrophilic functional groups in the latter step, it is possible to tailor the NC surface functionality [26a–48a]. Interestingly, negatively charged particles are obtained by providing the surface with phosphonate groups (for instance, by using trihydroxysilylpropylmethylphosphonate, TMP), which prevent the NCs from agglomerating and/or precipitating by means of electrostatic repulsions. Alternatively, by replacing TMP with poly(ethylene glycol) (PEG)–silane, stable neutral NCs can be prepared that repel each other by steric hindrance [50]. Finally, trimethoxysilylpropyl trimethylammonium chloride can be suitably manipulated to confer a small positive charge to the particles [32]. Bioconjugation can occur via conversion of residual MPS thiol groups into amine or carboxyl groups and via reaction with suitable bifunctional linkers, as established in the pertinent literature [28c–31a].

Silanized NCs also do not undergo to aggregation phenomena in electrolytic solutions, while retaining their original optical properties. Unfortunately, the silica shell often suffers for being inhomogeneous [29–32]. More importantly, the chemical complexity and the delicateness of the steps involved in the silanization process render the preparation of silanized NCs extremely difficult to scale up beyond the milligram quantities per batch.

#### 5.4.3

##### Surface Modification through Hydrophobic Interactions

A class of modification techniques allows one to obtain water-soluble NCs without removing the pristine capping layer. Such procedures ensure retention of the orig-

inal optical properties of NCs, as the inorganic core always remains shielded from the external environment. The general strategy relies on exploiting hydrophobic interactions between the pristine NC capping layer and suitable amphiphilic molecules. These latter can intercalate and/or interdigitate with the native capping layer alkyl chains, exposing their hydrophilic head out to the solution. A successful example is represented by phospholipid micelles encapsulating CdSe@ZnS NCs [28c–31a]. The polar head of phospholipids can be used for bioconjugation by reaction with bifunctional agents, like EDC, 1-ethyl-3-(3-(dimethylamino)propyl)-carbodiimide hydrochloride. As drawbacks, aggregation can be induced to some extent by EDC [36a], and the technique is laborious and provides only milligrams quantities per batch. Despite this, the NC optical properties are fully retained after phase transfer [31b–51].

Commercially available amphiphilic polymers bearing hydrophobic alkyl side chains and hydrophilic groups, such as PEG or multiple carboxylate groups, have also been used [52]. Several polymers have been employed: octylamine-modified polyacrylic acid [52a], block copolymers [52b], and polyanhydrides [52c]. Bioconjugation is accomplished by linking biocompatible ligands to polymer-coated NCs by reaction with the hydrophilic heads. PEG-derivatized polymers can also improve biocompatibility and reduce non-specific binding. Carboxylate-functionalized polymers strongly interact with primary amines via condensation, which can be applied to most common proteins in their native form without further modification or activation. In this regard, a high reactivity of polyanhydrides toward primary amines has been observed [52c]. Notably, NCs functionalized with high molecular weight triblock polymers [as those composed of a hydrophobic poly(butyl acrylate) segment, a hydrophobic poly(methacrylate) segment, of a hydrophilic poly(methacrylic acid) segment, and of and a hydrophobic hydrocarbon chain] are so well protected that their optical properties do not change under a broad range of pH (1–14) and salt conditions (0.01 to 1 M), or even upon harsh treatments with concentrated acid [52b]. Nonetheless, both phospholipid micelles and polymer coating can not prevent the NC size from increasing to a great extent, which can limit the intracellular mobility and may preclude fluorescence resonance energy transfer studies [35b].

More recently, host–guest chemistry has been exploited to induce the phase transfer of organic capped metal and semiconductor NCs into water by means of cyclodextrins [53]. Due to their peculiar characteristics [54], cyclodextrin-modified NCs can be very appealing for biological studies. This method deals with the formation of a host–guest complex between the hydrophobic cyclodextrin cavity and the alkyl chains of the surfactants anchored on an NC surface. Among the various classes of cyclodextrins tested,  $\alpha$ -cyclodextrins appear the most suitable for this purpose, since no aggregation or precipitation phenomena have been observed. In an alternative approach, metal NCs have also been synthesized [55] in the presence of modified cyclodextrins behaving as the capping ligands for the particles, while leaving their cavity available to perform host–guest chemistry. In this case, only a broadening of the NC size distribution has been observed during the synthesis.

## 5.5 Optical Techniques

Recent advances have been reported in the development of sensors based on optical detection methods, with remarkable improvements in terms of sensitivity and selectivity. This progress has been triggered by the access to new technical instrumentation and techniques, as well as by the availability of unprecedented materials. The discovery and the fundamental understanding of the peculiar optical properties of nanocrystals have led to a re-evaluation of the potential of well-assessed optical methods (colorimetric assays and fluorescence-based recognition) and, at the same time, have extended the technological opportunities.

Depending on the nature of the optical transduction signals, nanocrystal-based biosensors may be roughly divided into luminescence-based sensors and absorption-based sensors, relying on the changes of the emission and absorbance intensity, respectively [56]. Another possible classification can be made with reference to the chemical composition (metal or semiconductor) of the material used in the sensing process. Such diverse categorization can sometimes merge with each other, resulting in a lack of clarity in the definition. In this section we adopt a more schematic approach by classifying the methods according to the specific optical process that is exploited for the detection process.

### 5.5.1

#### Colorimetric Tests

The simplest method for detecting analytes is by measuring the absorption changes that occur because of some analyte–NC interactions modifying the optical properties of the nanocrystals [57]. Especially, metal nanoparticles are convenient for this purpose, as their surface plasmons are characterized by high extinction coefficients, many orders of magnitude larger than those of organic dyes [58]. The absorption spectrum, primarily reflecting the particle size, shape, composition [59], as well as the dielectric constant of the surrounding medium, can be sensitively affected by any process that alters the surface charge density, like direct adsorption of molecules, or variation in the mean interparticle distance induced by molecular recognition events (e.g., DNA hybridization, antigen–antibody interactions). The resulting shift in the plasmon maximum, and changes in band width and intensity, can be explained qualitatively in terms of particle electromagnetic interactions through simple quasi-static limit scattering models [60].

### 5.5.2

#### Fluorescence

Fluorescence is the optical phenomenon for which a molecule or a material (fluorophore), after gaining excitation by some means, can return to its minimum energy state by emitting light. Excitation and emission processes in a typical mole-

**Fig. 5.12.** Jablonski diagram describing the fluorescence process in a molecule. Upon absorption of a photon of energy ( $h\nu_a = E_{S_1} - E_{S_0}$ ), a molecule in the ground singlet state ( $S_0$ ) is promoted to a vibronic sublevel of the lowest excited singlet state ( $S_1$ ). Nonradiative, fast relaxation brings the molecule down to the lowest  $S_1$  sublevel. Emission of a photon of energy  $h\nu_e < h\nu_a$  with radiative rate  $k_r$  can take place, bringing back

the molecule to one of the vibronic sublevels of the ground state. Alternatively, the molecule can undergo collisional quenching, returning to its ground state without photon emission (nonradiative rate  $k_{nr}$ ). A third type of process is intersystem crossing to the first excited triplet state  $T_1$  (rate  $k_{ISC}$ ). Relaxation to the ground state takes place either by photon emission (phosphorescence) or nonradiative relaxation (rate  $k_{nr}$ ).

cule are represented by a Jablonski diagram, depicting the initial, final, and intermediate electronic and vibrational states of the molecule (Fig. 5.12).

In general, the molecule can be excited, by a one- or multiphoton process, from its electronic ground state  $S_0$  to the first excited state  $S_1$ . Its return to the ground state can be accompanied by the emission of a fluorescence photon. The  $S_1 \pm S_0$  transition competes with another photophysical process, called intersystem crossing, that is responsible for converting the  $S_1$  state into the first excited triplet state  $T_1$ . An irreversible photobleaching can follow the latter event, ultimately preventing a fraction of molecules from contributing to the overall fluorescence signal.

In general, fast intramolecular vibrational relaxations are responsible for the lower energy of the emitted photons with respect to that associated with the incident light. The difference in energy between absorption and emission is named the Stokes shift – it accounts for the wavelength separation of the emitted fluorescence from the excitation light. This phenomenon renders fluorescence a powerful analytical tool. The delay (lifetime) between the absorption step and the detected fluorescence depends on the nature of the fluorophore and on its local environment.

The efficiency of photon absorption is proportional to the local electric field and to the dipole moment of the fluorophore. For an immobilized fluorophore, the spatial orientation of the absorbing molecule dipole can be determined by recording the emitted fluorescence as a function of the direction of the linear polarization of the excitation light. For a mobile molecule, more information is needed, because the emission dipole may change orientation significantly in a short time. Fluctua-

tions that are faster than the fluorescence lifetime lead to a depolarized emission, while fluctuations covering timescales longer than the lifetime but shorter than the instrumental integration time lead to anticorrelation of the two orthogonal emission polarizations. Fluorescence polarization measurements have been used in analytical and clinical chemistry and as a biophysical research tool for studying the mobility of membrane lipids, domain motions in proteins, and interactions at the molecular level. Also, fluorescence polarization-based immunoassays are also extensively utilized for clinical diagnostics.

Measurement of fluorescence intensity is a widely applied technique in biological applications, as it is related to the number of photons emitted by a fluorescing sample upon excitation. Based on fluorescence wavelength and intensity level determination, various molecular or cellular targets can be easily tagged. The fluorescence intensity may be influenced by several factors, such as the excitation intensity thermal fluctuations, self-absorption, self-fluorescence, and fading due to photobleaching of the probe. However, organic fluorophores usually have emission bands with long tails extending to the red part of the visible spectrum. This issue could limit multiplexing and would require the use of interference filters in the optical readout, reducing the dynamic range of intensity levels. In contrast, the emission spectrum of semiconductor nanocrystals is narrow and Gaussian; their absorption spectrum is continuous and extended in the UV, so that a single wavelength can excite nanocrystals of different sizes, yielding several emission colors at once. Therefore, multicolor NC probes can be used to track multiple molecular targets simultaneously.

### 5.5.3

#### Fluorescence Resonance Energy Transfer

Among the most promising optical biodetection techniques, Fluorescence Resonance Energy Transfer (FRET) has been used to carry out analyte recognition and binding, while simultaneously producing useful output signals through an integrated signal transduction system [61]. FRET has been used in carefully designed sensing systems for proteins, peptides, nucleic acids and small molecules.

FRET is one of the few tools available for measuring nanometer scale distances and/or changes in distances, both *in vitro* and *in vivo*. This technique indeed relies on the distance-dependent transfer of energy from a donor fluorophore to an acceptor fluorophore. Recent advances have led to both qualitative and quantitative improvements, including increased spatial resolution, distance range, and sensitivity [62]. This progress has been facilitated by the use of new fluorescent dyes and by novel optical methods and instrumentation.

In FRET, a donor fluorophore is excited by incident light, and if an acceptor is in its close proximity, the excited state energy from the donor can be transferred to the acceptor. This event leads to a reduction in the fluorescence intensity and in the excited state lifetime of the donor, and to a concomitant increase in the emission intensity of the acceptor. The efficiency of the process depends on the inverse sixth-distance between the donor and the acceptor [Eq. (1)], where  $R_0$  is the dis-

tance at which half of the energy is transferred, and depends on the spectral characteristics of the dyes and their relative orientation.

$$\text{efficiency} = 1/\{1 + (R/R_0)^6\} \quad (1)$$

This would allow one to measure: (a) interactions between molecules, e.g., between proteins, between a protein and a ligand or (b) distances between two sites in a macromolecule.

A crucial aspect of FRET biosensor development involves optimizing the relative positions of energy levels of the donor and acceptor dyes to make them operate in concert with the desired recognition elements. Although organic dyes are available to accomplish this, many of them have functional limitations, such as pH dependence, susceptibility to photobleaching, and narrow excitation bands coupled with broad emission peaks, which can compromise sensor performance. The photo-physical properties of nanocrystals, such as size-tunable photoluminescence spectra, broad absorption, narrow emission lines, and high quantum yields, make them good candidates as energy donors able to overcome some of the problems associated with conventional molecular-based FRET systems. Indeed, it has been recently demonstrated [63] that the use of single-NC-incorporated nanosensors for DNA detection can reduce significantly, or even eliminate, the complication of background fluorescence encountered by conventional molecular FRET probes (Fig. 5.13). Further, the target signal is amplified through enhanced energy-transfer efficiency by increasing the number of acceptors linked to a donor. These features allow NC-incorporated nanosensors to generate a very distinct target signal that is easily distinguishable from the background in the presence of low target abundance and a large excess of the probe.

#### 5.5.4

##### Fluorescence Lifetime

The Fluorescence Lifetime (FLT) is a measure of the time a fluorophore spends in the excited state before returning to the ground state by emitting a photon. If a fluorophore population is excited, the lifetime  $\tau$  is the time it takes for the excited molecules to decay to  $1/e$  or 36.8% of the original population. The decay of the intensity as a function of time is given by Eq. (2).

$$I_t = \alpha e^{-t/\tau} \quad (2)$$

where  $I_t$  is the intensity at time  $t$ ,  $\alpha$  is a normalization term (pre-exponential factor) and  $\tau$  is the lifetime of the excited state. Knowledge of the excited state lifetime of a fluorophore is crucial for quantitative interpretations of fluorescence measurements, such as quenching, polarization, and FRET. Excited state lifetimes are measured in the time domain by illuminating the sample with a short pulse of light and recording the temporal behavior of the emission intensity. In pioneering work, these short light pulses having widths on the order of several nanoseconds were

**Fig. 5.13.** Operative principle of single-NC-based DNA nanosensors. (a) Conceptual scheme showing the formation of a nanosensor assembly in the presence of

targets. (b) Fluorescence emission from Cy5 caused by FRET between Cy5 acceptors and a NC donor in a nanosensor assembly. (c) Experimental setup. (From Ref. [63].)

generated using flash lamps. Modern laser sources can now routinely provide pulses with widths on the order of picoseconds or shorter. If the decay is a single exponential and the lifetime is long compared with the exciting light, then the lifetime can be determined directly from the slope of the curve. If the lifetime and the excitation pulse width are comparable, deconvolution methods taking in account the effect of the exciting pulse shape must be used to extract the lifetime.

Fluorescence lifetime is a parameter that is mostly unaffected by inner filter effects, static quenching and variations in the fluorophore concentration. For this reason, FLT can be considered as one of the most robust fluorescence parameters. Therefore, FLT measurements are advantageous in clinical and high-throughput screening applications, where it is necessary to discriminate against the high background fluorescence from biological samples. Also, the decay studies offer a route to multiplexing. The ability to distinguish two fluorophores with similar spectra but different lifetimes is another way to allow an increased number of parameters to be measured (Fig. 5.14).

Several approaches have been used for the development of FLT-based biosensors. For example, in simple binding assays, the binding of two components (one being fluorescently labeled) is accompanied by a change in the fluorescence lifetime. In quench-release type assays, a quenched species, exhibiting low but detectable fluo-

**Fig. 5.14.** Normalized ensemble fluorescence decay of CdSe@ZnS nanocrystals (1.8-nm radius, 575-nm peak emission). The solid curve is a triple exponential fit to the data with components at 3.4, 16.1, and 35.6 ns. The measured fluorescence decay of Rhodamine molecules in water is also displayed (dashed curve) and is well described by a single exponential decay with time constant 4.3 ns. (From Ref. [65].)

rescence, is initially present in large excess. If a fluorescence compound is released (e.g., by binding to a complementary DNA strand or by an enzymatic reaction) the FLT of the system increases. Finally, the study of lifetime is a powerful tool to measure the energy transfer efficiency in FRET assays by using a non-fluorescent acceptor, which helps to circumvent the problem of spectral cross talk between the donor and the acceptor.

FLT measurements offer additional opportunities in fluorescence microscopy, where the local probe concentration can not be controlled. Lifetime microscopy allows image contrast to be created from the fluorescence lifetime of a probe at each point of the image. Typical examples are the mapping of cell parameters, such as pH, ion concentrations or oxygen saturation. To enhance contrast in cellular imaging and analysis by FLT imaging, labeling agents with long lifetime fluorescence are required. Usually, organic dyes undergo radiative emission from allowed singlet–singlet electronic transitions, with typical decay rates of few nanoseconds. Unfortunately, such rapid emission merges with the time scale of short-lived self-fluorescence background from many naturally occurring species in biological specimens. In fact, self-fluorescence of several proteins often precludes observation of small details, unless the target is heavily loaded with dyes (which, in turn, results in phototoxicity problems). Lanthanide chelates with lifetimes in the sub-microsecond to millisecond range have also been successfully used [62]. However, because their FLT is too long, these probes have a limited photon turnover rate and, therefore, low sensitivity. In contrast, nanocrystals are more advantageous, in that they emit light slowly enough to avoid serious interference by self-fluorescence background, but also fast enough to maintain a high photon turnover rate. Indeed, ensemble measurements show a multi-exponential decay after pulsed excitation, which yields decay times between 10 and 40 ns. Benefiting from the long lifetime

of NCs and using fast pulsed laser excitation, it is possible to reject all photons emitted within the first few ns after the pulse, while revealing only those arriving after the decay of fluorescence from all dyes or self-fluorescent proteins (time-gated imaging). Also, the allowed repetition rate of a few megahertz is compatible with rapid cell imaging.

### 5.5.5

#### **Multiphoton Techniques**

Another class of widely used optical methods for biological detection makes use of multiphoton-based approaches [65]. Such nonlinear optical techniques are based on the fact that two or more photons of low energy can be simultaneously absorbed by a fluorophore, producing the emission of a photon with a shorter wavelength. Since multiphoton absorption is a nonlinear effect, it strictly requires a high source intensity and a tightly focused incident beam. To illuminate the sample with the necessary intensity, while preserving it from thermal damage, a femtosecond pulsed laser source is commonly used. The laser beam is then focused through an objective onto a sample treated with a fluorescent dye. Although single photons do not possess enough energy to induce an absorption transition, the photon density is sufficiently high in the centre of the tightly focused laser beam to cause direct absorption of two photons, so that an up-converted emission can result in. The fluorescence signal can be thus only detected in the focus of the laser beam. The focus can be also rasterized through the sample to create a 2D mapping. A typical advantage of this technique is that it suffers little from photobleaching effects. Indeed, irradiation in the far-red and near-infrared (NIR) spectral regions is characterized by low scattering and absorption by the biological environment [66]. More recently, NIR radiation has been used to excite visible CdSe@ZnS core-shell NCs in mouse capillaries using multiphoton fluorescence imaging [67].

### 5.5.6

#### **Metal-enhanced Fluorescence**

The use of metallic materials to favorably alter the intrinsic photo-physical characteristics of fluorophores in a controllable manner is a fairly new concept that has received much attention only in the past few years.

Although fluorescence is a highly sensitive technique, allowing for the detection of single molecules, it exhibits intrinsic detection limits. These latter are typically related to the fact that the detection of a fluorophore is usually limited by its quantum yield, self-fluorescence of the sample, and/or by its photostability. In typical fluorescence measurements, the experimental set-up is such that the sampled area is large relative to the size of the fluorophores and relative to the absorption and emission wavelengths. In this arrangement, the fluorophores irradiate freely in space. Interestingly, for fluorophores close to metallic surfaces or nanoparticles the free-space condition is altered, resulting in dramatic spectral changes. The so-called Metal Enhanced Fluorescence (MEF) [68] arises from the interaction of the

dipole moment of the fluorophore and the surface plasmon field of the metal, resulting in an increase in the radiative decay rate and in stronger fluorescence emission. Indeed, the quantum yield ( $Q_0$ ) and lifetime of the fluorophore ( $\tau_0$ ) in the free-space condition are given by Eqs. (3) and (4), respectively.

$$Q_0 = \Gamma / (\Gamma + k_{nr}) \quad (3)$$

$$\tau_0 = 1 / (\Gamma + k_{nr}) \quad (4)$$

where  $\Gamma$  and  $k_{nr}$  are the radiative and non-radiative decay rate, respectively. Due to the close proximity to a metal surface, the radiative decay rate increases by a term  $\Gamma_m$ . In this case, the quantum yield ( $Q_m$ ) and lifetime of the fluorophore ( $\tau_m$ ) near the metal surface are given by Eqs. (5) and (6) [69]:

$$Q_m = (\Gamma + \Gamma_m) / (\Gamma + \Gamma_m + k_{nr}) \quad (5)$$

$$\tau_m = 1 / (\Gamma + \Gamma_m + k_{nr}) \quad (6)$$

These equations allow the prediction of unusual behavior of a fluorophore near to a metallic surface. Notably, from Eqs. (3)–(6), as  $\Gamma_m$  increases, the quantum yield increases, while the lifetime decreases. These effects have also been justified theoretically [70], being analogous to the increase in Raman signals observed in surface-enhanced Raman scattering. However, a remarkable difference is that fluorescence enhancement is activated by interactions through space and does not require direct contact between the fluorophores and the metal surface.

Remarkably, metal surfaces can affect the radiative decay rates of fluorophores and can also be beneficial to resonance energy transfer. In practice, this means that weakly emitting materials (dyes, proteins, or DNA) with low quantum yields can be transformed into more efficient fluorophores with shorter fluorescence lifetimes. The reduction in fluorescence lifetime associated to MEF implies that molecules spend less time in the excited state, thus reducing photobleaching effects. The dramatic increase in the fluorescence emission occurs for fluorophores located at well-defined distances (50–200 Å) above metal surfaces with nanoscale roughness. This enables the use of photosensitive fluorophores that can hardly be employed in conventional fluorescence studies because of their high susceptibility to photobleaching. Another interesting effect is observed when fluorescence originates from nanomaterials with periodic patterns. In this case, the fluorescence emission can be spatially directed over a small viewing angle [71], which leads to emission sufficiently intense to be revealed by detectors without extensive optics. Such high directional emission combined with the increase in quantum yield offers the potential for efficient MEF-based sensors and microarrays [72].

### 5.5.7

#### Surface Plasmon Resonance

In the past decade, sensing by Surface Plasmon Resonance (SPR) has been demonstrated to be a powerful tool to probe of protein–ligand, protein–protein, and

protein–DNA interactions. More interestingly, this technique provides a means not only to quantify the equilibrium and kinetic constants related to such events, but also for setting up very sensitive, label-free biochemical assays.

This optical technique is based on the detection of change in reflectivity of a laser beam, incident to a metallic thin layer, due to the interaction with surface plasmons propagating on metallic surface. A surface plasmon is a collective surface excitation of conduction electrons in a metal that can be excited by means of photon irradiation [73]. This concept originates in the plasma approach of Maxwell's theory, in which the free electrons of a metal are treated as an electron liquid of high density (plasma) and density fluctuations occurring on the surface of such a liquid are called plasmons, surface plasmons (SP), or surface polaritons. According to Maxwell's theory, surface plasmons can propagate along a metallic surface and are characterized by a spectrum of eigenfrequencies related to the wave-vector by a dispersion relation. Since the dispersion relation of SPs never intersects the dispersion relation of light in air, which can be represented by a straight line, the resonances cannot be excited directly by a freely propagating beam of light incident upon a metal surface. However, if the exciting beam travels through an optically denser medium (e.g., glass) of high dielectric constant, it is possible to decrease the slope of the straight line corresponding to the photon dispersion. If this is the case, plasmons can be excited by p-polarized light undergoing total internal reflection on the glass surface. More precisely, the plasmons are excited by the evanescent wave associated with the internal reflection, which can penetrate deeply even to the metal/air interface (Fig. 5.15). The fields associated with the surface plasmon (SP) extend into the media adjacent to the interface and decay exponentially away from it. Consequently, the SP is sensitive to changes in the environment near the interface and therefore is a sensing probe.

Whenever the momentum of the incoming photon matches with that of the plasmon, surface plasmon resonance is excited. This phenomenon can be inferred

Fig. 5.15. Kretschmann configuration for surface plasmon resonance.

from the drop in intensity of reflected light when a suitable angle for resonance is approached at which an energy transfer between evanescent wave and surface plasmon occurs [74]. The value of the resonant angle is a sensitive function of the dielectric constants of the two contacting media.

The resonance conditions are influenced by the material adsorbed onto the thin metal film. Owing to this property, the surface plasmon resonance can be used to monitor surface reactions, as any organic or inorganic layer deposited on the metal surface causes changes in dielectric function of the medium, determining the new conditions for resonance (i.e., at a different resonance angle). The shape of the whole resonance curve, i.e., its depth and width depends on optical absorption within the metal and on radiation losses resulting from surface roughness. Therefore, optical systems based on SPR can provide a safe, remote, non-destructive means of sensing. SPR has already been used for gas sensing, biosensing, immunosensing and electrochemical studies. A satisfactory linear relationship is found between the resonance energy and the concentration of biochemically relevant molecules, such as proteins, sugars, and DNA [75]. The SPR signal, which is expressed in resonance units, therefore represents a measure of mass concentration at the sensor chip surface. This means that the analyte and ligand association and dissociation can be revealed, while rate constants as well as equilibrium constants can be then calculated.

A fraction of the light energy incident at a sharply defined angle can interact with the delocalized electrons in the metal film (plasmon), thus reducing the reflected light intensity. The precise value of incidence angle at which this occurs is determined by several factors, among which the most relevant is the refractive index of the backside layer of the metal film into which the evanescent wave propagates. This layer is the non-illuminated side of the metal film on which target molecules are immobilized and addressed by ligands in a mobile phase running along a flow cell. When a binding event occurs, the local refractive index is modified, leading to a change in SPR angle, which can be monitored in real-time by detecting changes in the intensity of the reflected light (Fig. 5.16).

The change rates for the SPR signal can be analyzed to extract apparent rate constants for the association and dissociation steps of the monitored reaction. The ratio of these values gives the apparent equilibrium constant (affinity). The magnitude of the change in the SPR signal is directly proportional to the immobilized mass, and can thus be roughly interpreted in terms of the reaction stoichiometry. Signals are easily obtained from sub-microgram quantities of material.

Since the SPR signal depends only on binding to the immobilized template, it is also possible to study binding events from molecules in extracts, i.e., in the presence of poorly purified components. The light source for SPR is a near-infrared light emitting diode that has a fixed range of incident angles. The SPR response is monitored by an array of light sensitive diodes covering the whole wedge of the reflected light. The angle at which minimum reflection occurs is detected and converted into resonance units.

Many biomolecular binding events cause changes in the refractive index at the surface layer, which are detected as changes in the SPR signal. In general, the re-

**Fig. 5.16.** Typical SPR curves of surfaces modified with Au-MIP/MIP gel (1), with Au-MIP/MIP of lower nanoparticle density (2), with MIP/MIP (3), and with 11-mercaptoundecanoic acid (4) in water at 30 °C. (From Ref. [76].)

fractive index change for a given change of mass concentration at the surface layer is practically of comparable magnitude for all proteins and peptides, and is similar for glycoproteins, lipids and nucleic acids.

#### 5.5.8

#### Surface-enhanced Resonance Spectroscopy

Raman spectroscopy provides highly resolved vibrational spectra at room temperature without suffering from rapid photobleaching of the investigated molecule. However, Raman scattering is an intrinsically inefficient process with scattering cross sections ( $\sim 10^{-30}$  cm<sup>2</sup> per molecule) approximately 14 orders of magnitude smaller than the absorption cross sections ( $\sim 10^{-16}$  cm<sup>2</sup> per molecule) of fluorescent dye molecules. Therefore, to achieve sensitivity at the single molecule level, the normal Raman scattering efficiency must be enhanced  $10^{14}$ -fold or more. Surface-enhanced Raman Spectroscopy (SERS) is a Raman Spectroscopic technique that provides a greatly enhanced Raman signal from Raman-active molecules that are adsorbed onto suitably prepared metal surfaces. An increase in the intensity of Raman signal of the order of  $10^4$ – $10^6$  has been routinely observed, and can be as high as  $10^8$ – $10^{14}$  for some systems [77]. SERS was first discovered for analytes adsorbed onto Au, Ag, Cu or alkali (Li, Na, K) metal surfaces, with useful excitation wavelength near or in the visible region. Interestingly, a giant signal enhancement has been found using silver and gold faceted nanocrystals, allowing both detection and identification of single, non-fluorescent molecules. Therefore SERS is not only highly sensitive, but it is also selective as a result of enhancement mechanisms operating only at surfaces.

The importance of SERS is that the surface selectivity and sensitivity is extended to various molecular systems that are inaccessible by conventional Raman scatter-

ing, such as to *in situ* and ambient analyses of electrochemical, catalytic, biological, and organic systems. SERS measurements can be carried out under ambient conditions in a broad spectral range. Both electromagnetic-field and chemical-based models have been used to explain the SERS phenomenon. Electromagnetic effects dominate over the chemical effects, which in fact contribute to enhancement by one–two orders of magnitude [78]. Chemical enhancement (CE) involves changes in the electronic states of the analyte following its surface chemisorption [79], while electromagnetic enhancement (EME) is related to the metal surface roughness. The latter can be developed in several ways, such as, for example, by means of (a) oxidation–reduction cycles on electrode surfaces; (b) vapor deposition of metal particles onto substrates; (c) lithographically produced metal spheroid assemblies; (d) metal deposition over a mask of polystyrene nanospheres; (e) metal colloids [80]. All of these methods basically aim to provide rough metal surface for which roughness is actually due to metal nanoparticles or aggregates.

The intensity of the Raman scattered radiation is proportional to the square of the magnitude of the electromagnetic field incident to the analyte [Eq. (7)]:

$$I_R = E^2 \quad (7)$$

where  $I_R$  is the intensity of the Raman field, and  $E$  is the total electromagnetic field associated with the analyte. Moreover,  $E$  is given by Eq. (8):

$$E = E_a + E_p \quad (8)$$

where  $E_a$  is the electromagnetic field on the analyte in the absence of any roughness features and  $E_p$  is the electromagnetic field emitted from the particulate metal roughness feature [81]. Of course, the electromagnetic field of the excitation radiation is incident to the analyte. In normal Raman scattering ( $E_p = 0$ ),  $E_a$  is relatively small since the source of the electromagnetic radiation (the laser) is relatively far away. However, in SERS the roughness features provide an additional field,  $E_p$ , in close proximity to the adsorbate, that is associated with the metal particles. Because of this proximity, any electromagnetic field from the particle will strongly contribute to  $E$ . Thus, the magnitude of the particle field is of crucial importance in determining the overall intensity of the Raman signal. Since the plasmon excitation is also confined in a small material volume (related to the characteristic features of the surface roughness), the field  $E_p$  associated with it is also very intense. The large electromagnetic energy density on the particle effects the scattering  $I_R$ , as described by Eqs. (7) and (8). It follows that analyte molecules adsorbed between two SERS-active particles will yield a higher signal than those molecules being close to only one particle.

Since the surface roughness features are so relevant to SERS, much attention has been devoted to their study. Normal roughening procedures produce heterogeneous surfaces where the particles have various sizes, shapes, and orientations [82]. The frequency of incident light that is most effective in producing an intense field on the particle severely depends on the degree of surface roughness as well as on the nature of metal used. The specific region on the particle where analyte ad-

sorption occurs affects the magnitude of the SERS enhancement, as the EME is strongest where the particle has the highest curvature.

The CE mechanism is less understood than the EME enhancement, but brings about some interesting considerations. The molecule adsorbed onto the surface has necessarily to interact with the surface. CE exists because of this interaction, which has been described in several ways. The proximity of metal adsorbate may allow pathways of electronic coupling from which novel charge-transfer intermediates are formed that have a higher Raman scattering cross-section than that of a non-adsorbed analyte. This fact resembles a resonance Raman effect. Another explanation is that the molecular orbitals of the adsorbate overlap with the conduction band of the metal, thus modifying the analyte chemical properties [83]. Interestingly, the CE effect results in an alteration in the scattering cross-section, whereas the EME effect generally leads to change in the scattering intensity without affecting the scattering cross-section.

The distance dependence of SERS is used in the overlayer technique. An ultrathin solid or liquid film is adsorbed onto the SERS-active substrate, with the analyte within the film taking advantage of the EME of the substrate. It follows that the Raman spectrum of the analyte is greatly enhanced. This makes SERS applicable to various targets, such as organic films, semiconductors, insulators, etc. Spacer layers can be adsorbed onto the substrate, and can alter the chemistry of either the substrate or that of the overlayer, extending the utility of SERS even further. An advantage to the overlayer technique is that it suffers less from the inhibitory effect of metal surface defects, such as pinholes in silver [84].

As most of signal enhancement is due to electromagnetic fields whose intensities decrease with increasing distance from the point source, it follows that an analyte would benefit from SERS substrates even if it were located at some distance away from the active surface. Theoretical calculations have been performed, and the SERS enhancement,  $G$ , has been found to scale with distance according to Eq. (9):

$$G = [r/(r + d)] \quad (9)$$

where  $r$  is the radius of the spherical metal roughness feature, and  $d$  is the distance of the analyte from that feature. Experimentally,  $G$  decreases by a factor of ten at a distance of 2–3 nm, or equivalent to one–two monolayers.

Traditionally, SERS-based sensing has employed roughened metal surfaces or colloidal particles immobilized on a substrate to create relatively large active areas for sensing [85]. More recently, efforts have been focused on the potential of using individual nanoparticles or small clusters of nanoparticles as the sensing elements [86]. This approach has paved the way to a wide range of applications that so far have been difficult to address with conventional chemical sensors. A remarkable example is the possibility of using these probes inside single living cells. The small size of the nanoparticles (50–100 nm in diameter) combined with the highly localized probe volume makes these particles work as localized sensors suitable for monitoring biological processes in living cells.

### Advantages and Disadvantages of Nanocrystals in Optical Detection

Colloidal nanocrystals have several peculiar advantages over organic dyes that are conventionally used in optical bio-detection [29d–87]. Indeed, their wide absorption spectrum, coupled with their extinction cross-section, makes it possible to excite different luminescent nanoparticles with different sizes by one single excitation wavelength. Organic fluorophores, however, exhibit discrete and well-spaced absorption bands with cross-sections nearly an order of magnitude smaller. In addition, most semiconductor nanocrystals have narrow (few tenths of nanometers) symmetric emission peaks that can be finely tuned from blue to red up to the near-infrared region [88]. The high color purity achievable by precise size control represents the main advantage offered by colloidal nanocrystals, especially in multiplexing applications. In contrast, organic dyes are often characterized by asymmetric spectra with distinct phonon progression towards the longer wavelength, which leads to undesirable spectral overlap among different channels in a detecting system for the measurements. Moreover, the typical fluorescence quantum yields of NCs, defined as the ratio of the number of photon emitted in radiative channel to the number of photon absorbed, can be as high as that of organic dyes, approaching values close to 30%. As a further advantage, semiconductor NCs are much less susceptible to photobleaching than organic dyes, which are rapidly and irreversibly photodegraded [52a].

The sensitivity of luminescence of NCs to their surface status (defects and/or dangling bonds) and to the local environment has typically represented the major limitation to technological applications. Now, core–shell heterostructures, where the nanocrystal is coated with a thin inorganic shell of a wider band gap semiconductor, provide increased fluorescence quantum efficiencies (>50%) and greatly improved photochemical stability (Fig. 5.17).

The sensitive detection in thick specimen requires wavelengths such that excitation light can penetrate up to the desired depth, and the emitted light must be able to travel back to a photodetector. Several semiconductor materials have been used to generate bright nanocrystals that emit between 650 and 2000 nm [89]. NCs with emission maxima between 750 and 860 nm have been employed to image the coronary vasculature in a rat model, while NCs emitting in the 840–860 nm region have been used to sentinel lymph-node mapping in cancer [90, 31c]. This use of near-IR emitting NCs can be thus profitably extended for “*in vivo*” biosensing applications, as NCs have been demonstrated to retain their emission in tissues *in vivo* for months.

Colloidal semiconductor nanocrystals represent, therefore, a valid alternative to organic fluorophores and their superior fluorescence properties account for the large success illustrated by several applications as biosensors.

Historical inconveniences of colloidal nanocrystals, such as the loss of emission in aqueous environment or the poor biocompatibility and bioconjugability, have been effectively overcome in recent years by suitable functionalization methods that have been reported in the Section 5.3. A serious difficulty with the large-scale

**Fig. 5.17.** Schematic diagram of core–shell nanocrystals of CdSe@ZnS. The growth of a thin layer of ZnS on CdSe nanocrystal cores causes an increased optical confinement.

use of colloidal nanocrystals, especially those subjected to bioconjugation treatments, lies in the still expensive fabrication costs. However, it is expected that commercial expansion of chemical manufacturers will lead to a more competitive environment and, possibly, to lower production costs.

## 5.7 Applications

The impact of nanotechnology on biosensing has been tremendous owing to the availability of the more robust, versatile and efficient materials for sensing. The following subsections review several successful examples of the use of colloidal nanoparticles in optical biosensing.

### 5.7.1

#### Biosensing with Semiconductor Nanocrystals

The broad spectrum of “colors”, which can be obtained by exciting semiconductor NCs of different size with a single excitation laser wavelength, poses the basis for the simultaneous detection of several markers in biosensing and assay applications. NCs can be used as fluorescent labels for immunosensing and DNA sensing, providing tunable wavelength, narrow emission peaks, and 100-fold higher stability than molecular fluorescent dyes [91].

The novel applications of NCs have highlighted their wide potential in present technology. Several examples can be found on the use of luminescent CdSe@ZnS core–shell nanocrystal bioconjugates in quantum dot-based sensors. Biomolecules can be labeled with luminescent NCs. They have been also demonstrated to be in-

volved in efficient fluorescence resonance energy transfer between neighboring NCs of different sizes, while their emission is readily quenched by bound fluorescent dyes. Sensor assemblies have been reported that employ NCs linked to dye-labeled biological receptors to exploit donor–acceptor energy transfer between the NCs and the receptors for detection purposes based on molecular recognition events. The effect of variation in concentration of the energy acceptors bound to a nanocrystal surface on the luminescence quenching of either in soluble and solid phase conditions has been investigated. The obtained results suggest the occurrence of fluorescence quenching between NCs and surface anchored dye–biological receptor [36b].

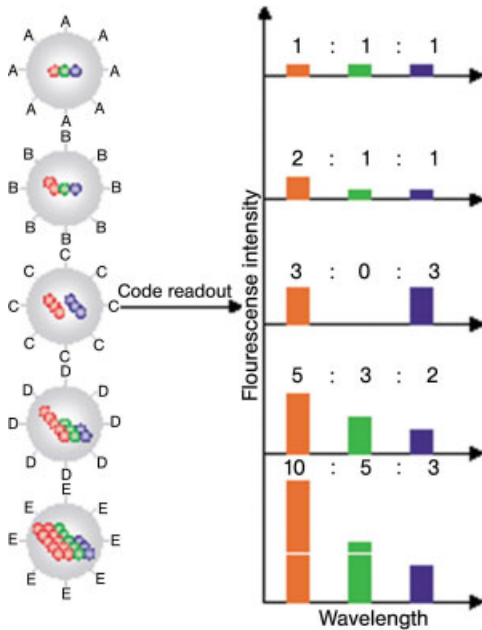

An application of quantum dots is the multiplexed optical encoding and the high-throughput analysis of genes and proteins. This is a very important issue, because most complex human diseases (such as cancer) involve many genes and proteins. Tracking a panel of molecular markers at the same time will allow scientists to understand, classify and to differentiate such complex human diseases.

The advantageous core–shell nanocrystals have also been exploited in combination with polymers [29c] (Fig. 5.18).

First, polystyrene microspheres doped with single-size CdSe@ZnS nanocrystals in known amounts are prepared and analyzed. Fluorescence intensity analysis of the beads clearly discriminates ten different intensity levels and indicates a high degree of bead uniformity and bead identification accuracy. Next, the beads with three colors of quantum dots are prepared. Significantly, fluorescent resonant energy transfer from the small nanocrystals to the large nanocrystals is not observed. The triple-coded bead is then used to demonstrate a DNA hybridization assay. Overall, these results indicate that a new spectral coding technology with potentially wide application to various biological assays that can be developed using fluorescent nanocrystals, embedded in microspheres. In this regard, NC probes are particularly attractive, because of the simultaneous excitation and continuous tuning by variation of particle size and chemical composition. The use of six colors and ten intensity levels can, theoretically, encode one million protein or nucleic acid sequences. Specific capturing molecules, such as peptides, proteins, and oligonucleotides can be covalently linked to the beads, which encode a specific spectroscopic signature. To determine whether an unknown analyte is captured or not, conventional assay methodologies (similar to direct or sandwich immunoassay) can be applied.

Bioconjugated NCs have also been used successfully in time-gated fluorescence detection of tissue sections. This optical technique is based on lifetime fluorescence microscopy employed for the selective and sensitive characterization of fluorescence species and in biophysical studies of proteins. Silanized nanocrystals were added to a 3T3 mouse fibroblasts cells grown on fibronectin treated coverslips, without signs of toxic response to the presence of NCs in the medium being observed [64].

The use of luminescent colloidal semiconductor nanocrystals as fluorophores have expanded to the range in FRET-based sensing applications [92]. If fully exploited, the unique NC properties should allow development of FRET-based nano-

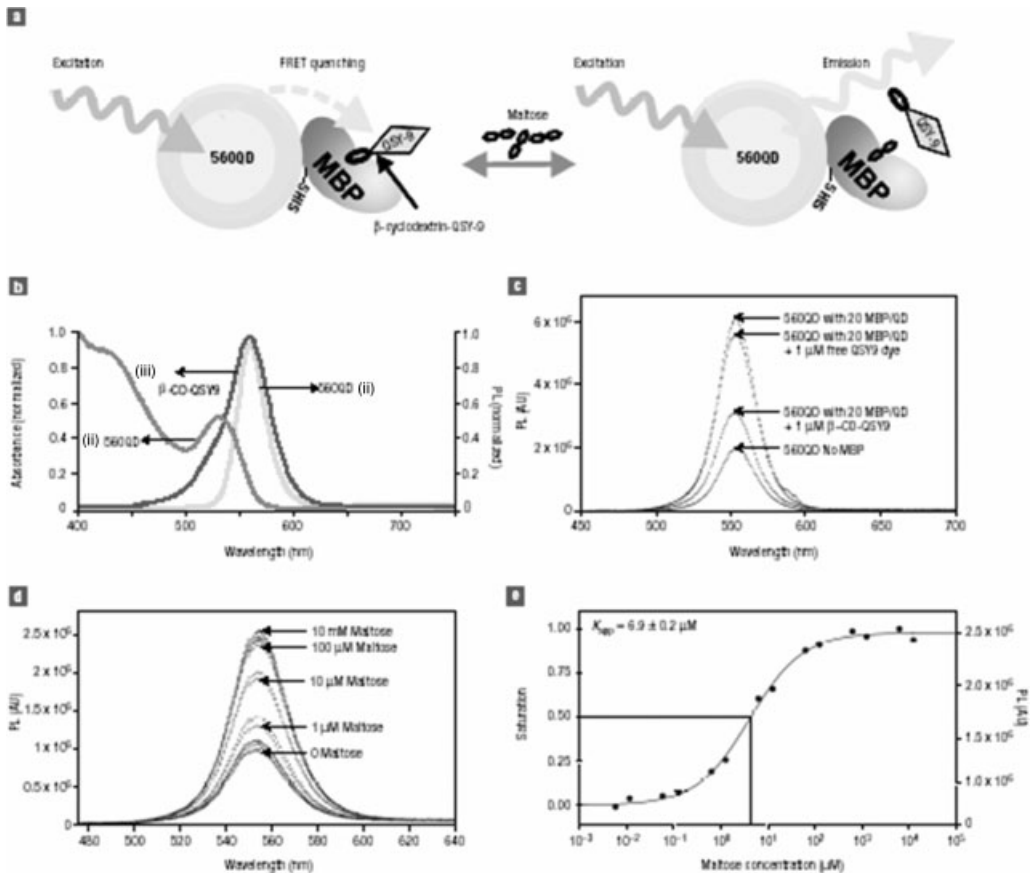

**Fig. 5.18.** Schematic illustration of optical coding based on wavelength and intensity multiplexing. Large spheres represent polymer microbeads, in which small colored spheres (multicolor quantum dots) are embedded according to predetermined intensity ratios. Molecular probes (A–E) are attached to the bead surface for biological binding and recognition, such as DNA–DNA hybridization and antibody–antigen/ligand–receptor interactions. The numbers of colored spheres

(red, green, and blue) do not represent individual NCs, but are used to illustrate the fluorescence intensity levels. Optical readout is accomplished by measuring the fluorescence spectra of single beads. Both absolute intensities and relative intensity ratios at different wavelengths are used for coding purposes; for example, (1:1:1) (2:2:2), and (2:1:1) are distinguishable codes. (From Ref. [29c].)

scale assemblies capable of continuously monitoring target (bio)chemical species in diverse environments [93].

It has been confirmed that semiconductor nanocrystals can be FRET donors, quenchable with efficiencies up to 99%, when using organic fluorophores, non-emissive dyes, gold nanoparticles, or other nanocrystals as acceptors (Fig. 5.19) [94].

NCs conjugated to maltose binding proteins have been used as *in situ* biosensors for carbohydrate detection. A fluorescence quenching is observed by adding a maltose derivative covalently bound to a FRET acceptor dye, while PL emission is recovered upon addition of native maltose, as the sugar–dye compound is displaced. In this work, the recovery of nanocrystal fluorescence upon maltose addition can be directly related to maltose concentration, because of both the physical orientation and stoichiometry of the maltose receptors on the nanocrystals are considered as

**Fig. 5.19.** Function and properties of a maltose nanosensor. (a) Nanocrystal-MBP nanosensor operation principle. Each NC is surrounded by MBP. The formation of complex NC-MBP with CD-QSY9 (maximum absorption  $\sim 565$  nm) results in quenching of NC emission. Added maltose displaces CD-QSY9 from the sensor assembly, resulting in an increase in direct NC emission. (b) Spectral properties of the nanosensor. Absorption (i) and emission spectra (ii) of MBP-conjugated NC are displayed along with the absorption spectra (iii) of CD-QSY9. (c) Demonstration

of NC-MBP FRET quenching. PL spectra (AU = arbitrary units) were collected from NCs and NCs mixed with an average of 20 MBP/NC, obtaining an increase in PL ( $\sim 300\%$ ). The same NC-MBP conjugates were then mixed with either free QSY9 dye or CD-QSY9. (d) NC-10MBP maltose sensing. Titration of a NC-10MBP/NC conjugate (quantum yield  $\sim 39\%$ ) preassembled with CD-QSY9 with increasing concentrations of maltose. (e) Transformation of titration data. The right-hand axis shows PL at 560 nm, and fractional saturation is shown on the left-hand axis. (From Ref. [94].)

parameters. Although the FRET quenching efficiency was low, this work demonstrates the potential of NC-based *in situ* biosensing.

Other important applications of fluorescent nanocrystals as FRET-based biosensors have been very recently developed for ultrahigh sensitive detection of DNA [63]. The DNA nanosensor can consist of two target-specific oligonucleotide

probes, which include a reporter probe labeled with a fluorophore and a capture probe labeled with biotin, in addition to a NC conjugated with several streptavidins. The nanocrystal works as both a FRET energy donor and a target concentrator, producing an extremely low level of background fluorescence that is difficult to achieve with conventional organic fluorophores. When a target DNA is present in solution, it is sandwiched by the two probes. Several sandwiched hybrids are then captured by a single NC through biotin–streptavidin binding, resulting in a local concentration of targets in a nanoscale domain. The resulting assembly brings the fluorophore acceptors and the nanocrystal donor into close proximity, leading to fluorescence emission by the acceptors by means of FRET upon illumination of the donor, indicating the presence of targets.

### 5.7.2

#### **Biosensing with Metallic Nanoparticles**

The use of gold colloids in biodetection dates back to the early 1970s when the immunogold staining procedure was invented. Since that time, the labeling of targeting molecules, such as antibodies, with gold NCs has deeply modified the approach to detection of biologically relevant components.

The optical transduction of receptor–ligand interactions at the surface of noble metal NCs via changes in their extinction spectrum is attractive for the development of biosensors, because a colorimetric transduction scheme is considerably simpler to implement than conventional, planar SPR.

It has been shown [95] that, for oligonucleotide-functionalized 30-nm Au NCs, the amount of optical absorbance recorded for an array surface of bound particles is directly related to the number of bound particles and to the concentration of hybridizable targets in solution. This study also demonstrates that, using microstructured substrates, DNA-modified areas with dimensions in the micrometer range specifically recognize complementary NC-bound DNA strands, with the signal background from unfunctionalized areas of the chip remaining rather low.

The environmental sensitivity of the color of nanosized gold has been exploited in a first prototype of biosensor in [96]. This study demonstrated the possibility of colorimetrically monitoring the binding of antibody to the surface of Au NCs functionalized with protein antigens.

Highly selective, colorimetric detection methods based on polynucleotide-modified gold particle probes have been also proposed (Fig. 5.20) [97]. Specifically, in the presence of 13-nm Au NCs, the color of the solution changes from red to blue, as a consequence of analyte-induced formation of Au NC aggregates in which the individual surface plasmon resonances are coupled. This simple phenomenon points to the use of metal NCs as DNA detection agents for nucleic acid targets. Actually, it has been found that spotting the solution onto a white support amplifies the colorimetric change and provides a permanent record for each test. Such system can detect about 10 fmol of oligonucleotides.

This type of colorimetric biosensor based on Au NCs has been extensively used in the analysis of biomolecules.

**Fig. 5.20.** Temporal changes in the UV/Vis spectra of nanoparticle aggregates grown from DNA linkers 1–3 (defined in parts A–C, respectively). The y-axes are labeled “extinction” since the larger aggregate structures will contain scattering as well as absorbance components. (From Ref. [97d].)

Gold NCs have been modified with an aptamer, which is specific to a defined growth factor, to allow monitoring of the change in color and extinction coefficient due to NC aggregation [44c]. The color of the aptamer-modified Au NCs significantly changes at low concentrations ( $<400$  nM), while only minor changes are detected at higher concentrations ( $>400$  nM). In addition, the ionic strength of the medium and the NC surface status surface are also important parameters in determining the ultimate sensitivity and specificity of the aptamer–nanoparticle-based probes. Efforts are now focused on the development of aptamer modified Au nanorods, to achieve further sensitivity enhancement. Special precautions must, however, be taken to prevent aspecific adsorption of biomolecules.

The performances of a label-free optical biosensor [98] have been tested in the real-time quantification of biomolecular interactions on a surface in a commercially available UV–visible spectrophotometer and in colorimetric end-point assays with an optical scanner. Such a sensor shows a concentration-dependent binding and a detection limit of 16 nM for streptavidin.

In this perspective, coupling the optical properties of noble metal colloids with improved bioconjugation protocols has the potential to provide excellent detection

capabilities. SPR has been widely used to monitor a broad range of analyte–surface binding reactions, including the adsorption of small molecules, ligand–receptor binding, protein adsorption on self-assembled monolayers, antibody–antigen binding, DNA and RNA hybridization, and protein–DNA interactions [99]. The SPR sensing mechanism relies on the measurement of small changes in refractive index that occur in response to analyte binding at or near the surface of a noble metal (Au, Ag, Cu) thin film. Chemosensors and biosensors based on SPR spectroscopy possess many desirable characteristics: (a) a refractive index sensitivity of the order of  $10^{-1}$  pg mm $^{-2}$ ; (b) a large sensing length scale ( $\sim 200$  nm) dictated by the exponential decay of the evanescent electromagnetic field; (c) multiple instrumental modes of detection (viz., angle shift, wavelength shift, and imaging); (d) real-time detection on the  $10^{-1}$ – $10^{-3}$  s time scale for measurement of binding kinetics; and (e) lateral spatial resolution of the order of  $10$   $\mu$ m allows for multiplexing and miniaturization, especially using the SPR imaging mode of detection [100]. Although SPR spectroscopy is an intrinsically nonselective sensor platform, a high degree of analyte selectivity can be conferred by means of attaching high specificity ligands to the surface and then passivating the sensor surface with non-specific binding molecules. Other practical advantages of SPR can be recognized, such as that of being label-free [101] useful for probing unpurified complex mixtures, such as clinical samples, easy to integrate with the available commercial instrumentation and with advanced microfluidic sample handling [100]. The development of large-scale biosensor arrays composed of highly miniaturized signal transducer elements that enable the real-time, parallel monitoring of multiple species is an important driving force in biosensor research.

Au NCs linked to bioreceptors provide labeled conjugates that can be used to follow the biorecognition event at a biosensor surface. Resonance enhancement of the absorption properties of nanosized metals binding to a surface by biorecognition interactions has also been used as an effective approach for biosensor devices [102]. Au nanoparticles have been extensively applied in bioaffinity binding events based on enhanced SPR. SPR biosensing has been improved dramatically in DNA immunosensing in the presence of Au NCs [103]. A sensor interface has been modified with antibody units, with the surface being functionalized with the complementary antigen component, and, finally, making this affinity assembly react with a secondary antibody labeled with Au NCs. The association of an antigen with its antibody-functionalized surface can be detected by SPR. However, the change in the SPR spectrum is larger if the secondary antibody is bound to the surface. The secondary antibody is, notably, not able to associate with the modified surface, unless the antigen is already bound there, thus providing an amplification route for the primary recognition event. Amplification is dramatically increased when the secondary antibody is labeled with gold. The binding of the Au NCs to the immunosensing interface leads to a large shift in plasmon angle, to a broadening of the plasmon resonance, and to an increase in the minimum reflectance, thereby allowing for picomolar detection of the antigen. Similarly, an enhancement in sensitivity by about 3 orders of magnitude has been obtained in DNA analysis when Au NC-functionalized DNA molecules have been used as probes [76].

**Fig. 5.21.** Schematic representation of Au-MIP/MIP-coated SPR sensor chip for detection of an analyte, dopamine. (From Ref. [76].)

An SPR sensing device sensitive to a low molecular weight analyte has been fabricated starting from molecularly imprinted polymer gel with embedded Au NCs onto a gold substrate of a chip sensor. The sensing mechanism is based on swelling of the imprinted polymer gel that is triggered by an analyte binding event within the polymer gel (Fig. 5.21). The swelling increases the distance between the Au NCs and substrate, shifting the SPR resonance angle to higher values.

The modified sensor chip shows changes in the SPR angle in response to dopamine concentration, which agrees with the supposed sensing mechanism. The presence of Au NCs has been proven to be essential for enhancing the signal intensity. The analyte-binding process and the consequent swelling appears to be reversible, thus allowing re-use of the sensor chip.

There has been a recent explosion in the use of metallic nanostructures to favorably modify the spectral properties of fluorophores and to alleviate some of the photophysical constraints associated with these fluorophores. The use of fluorophore-metal interactions can lead to ultrabright over-labeled proteins, generating a new class of probes based on MEF proteins covalently labeled with fluorophores to be used as reagents, e.g., in immunoassays or for the immunostaining of biological specimens with specific antibodies. For these applications, the commonly used fluorescein is unfortunately self-quenching, thus resulting in a homo-

transfer process [68]. Self-quenching can be largely avoided by the close proximity to Ag islands [68]. Such a decrease in self-quenching has been ascribed to an increase in the rate of radiative decay. These results suggest the possibility of exploiting ultrabright labeled proteins based on high labeling ratios, and the release of self-quenching through metal enhanced fluorescence.

An approach has also been reported that should provide a readily measurable change in fluorescence intensity in DNA hybridization assays [104] due to the presence of Ag particles. This approach should ensure an intensity enhancement relative to the background with an increase in the number of detected photons per fluorophore molecule by a factor of ten or more. In the presence of thiolated oligonucleotide single-stranded DNA as the capturing sequence bound to Ag particles, an increase in the emission intensity has been observed upon addition of a single strand fluorescein-labeled DNA. This effect can be attributed to the localization of the fluorescein labeled DNA near to the particles by hybridization with the capturing DNA.

A metal-enhanced multiphoton excitation has also been studied. For multiphoton excitation of fluorescence, most of excitation occurs at the focal point of the excitation beam, where the local intensity is the highest. For a two-photon absorption process, the rate of excitation is proportional to the square of the incident intensity. This suggests that two-photon excitation can be greatly enhanced [69–105]. Such an enhancement in the excitation rate is expected to provide selective excitation of fluorophores near to metal islands of colloids, even if the solution contains a considerable concentration of other fluorophores that could undergo two-photon excitation at the same wavelength, but which are more distant from the metal surface. Recently, the enhanced and localized multiphoton excitation of fluorophores adjacent to metallic silver islands has been observed to be accompanied by a reduction in lifetime, as compared with that detected using one-photon excitation. At present, following the widespread use of multiphoton excitation in microscopy and medical imaging, the use of metallic nanostructures appears promising to both enhance and localize fluorescence.

Recent works have demonstrated the effectiveness of MEF in solution-based biosensing applications. Silica-coated Ag colloids can represent enhanced-fluorescence sensing platform as a three- to fivefold enhancement has been observed [106]. It has also been found that oligonucleotide-modified Ag particles and fluorophore-labeled complementary oligonucleotides can yield an increased emission from the fluorophore-labeled complementary oligonucleotide after hybridization, which could allow access to DNA detection based on the aggregation of metallic NCs binding to the fluorophore label [3b].

The unusual optical properties of noble metal NCs have been also used to design a label-free biosensor in a chip format. The NC size affects the sensitivity of the biosensor significantly. The sensor has been fabricated by making Au NCs chemisorbed nanoparticles on amine-functionalized glass. In the investigated size range (12–48 nm), sensors fabricated from 39-nm-diameter Au NCs exhibited the highest sensitivity to the change in the bulk refractive index as well as the largest “analyti-

cal volume”, defined as the region around the nanocrystal within which a change in refractive index induces a change in the optical properties of the immobilized NCs. The detection limit for streptavidin–biotin binding of a sensor fabricated from 39-nm diameter nanoparticles is 20× better than that of a sensor fabricated from 13-nm-diameter gold nanoparticles by another method [101].

Surface-enhanced Raman scattering (SERS) of substrates bound to nanoparticles allows molecular vibrational spectra to be amplified by a factor of  $10^5$  [107]. Although this technique has not been widely applied for detecting biorecognition events on surfaces, a cytochrome *c*–Au NC conjugate associated with silver surface has been revealed by a SERS spectrum [108].

The use of a versatile format based on gold nanoparticles-based microarray demonstrated high selectivity and sensitivity for protein binding and kinase functionality, indicating that the method is based on the fact that specific antibody–protein binding or peptide phosphorylation events can be marked by attaching gold nanoparticles and then depositing silver to enhance the signal. The detection principle is based on the resonance light scattering. The attachment of gold nanoparticles is achieved by standard avidin–biotin chemistry. The obtained results show that a low detection limit for protein binding has been achieved together with a large dynamic range. Similarly, for kinase functionality a high sensitivity has been reached [109]. Recently the SERS response of individual nanoscale pH sensors based on functionalized silver nanoparticles has been tested *in vitro* [110].

The 4-MBA-capped nanoparticles (4-MBA, 4-mercaptobenzoic acid, is a non-resonant molecule) have shown a pH-dependent response in a pH range relevant to biological systems, showing promise for application in intracellular chemical measurements (Fig. 5.22). The nanoparticle sensors can be incorporated into living cells while retaining their functionality and robust signal.

## 5.8

### Towards Marketing

Generally, the term “technological applications” strictly refers to scientific products that can be potentially put on the road towards markets. The combination of biology, material science, and modern optical techniques has certainly great potential in offering a new generation of devices able to solve biosensing problems in a sensitive, selective, fast and high-performance way. Nevertheless, present applications of nanocrystals in the biosensing field are still far from being recognized as commercializable.

Presently, in detection devices relying on chip-based biosensing, the capturing molecules on the chip surfaces are patterned on the microscale. A large parallel screening of diverse analytes can be thus achieved in a small area, which greatly facilitates simultaneous sensing. Further miniaturization in the form of nanoarrays would allow for orders of magnitude larger multiplexed detection, eventually improving detection limits due to the smaller analyte capture area. Several estab-

**Fig. 5.22.** Raman spectrum of solid 4-mercaptobenzoic acid (4-MBA) (a) and the SERS spectra of 4-MBA attached to silver nanoparticles at pH 12.3 (b) and at pH 5.0 (c). Insets to the left of each spectra illustrate the dominant state of the molecule under the conditions described. (From Ref. [110].)

lished techniques, as well as emerging technologies, such as dip-pen nanolithography, nanografting, and focused ion beam lithography are possible candidate tools to fabricate nanoscale patterns of biomolecules or hybrid systems.

Lithographic techniques can also be used to fabricate nanoscopic patterns or containers on surfaces that should significantly reduce the sample volume required and, possibly, lower detection limits even more. The development of such nanopatterning techniques can be expected to represent the next step that has to be made towards achieving further miniaturization [3b]. The commercial exploration of nanomaterials for biosensing deals also with the development, the production and the commercialization of nanocrystals suitably engineered. In this regard,

a large progress has been realized, as authenticated by the first related patents [111].

Industrial interest in this direction is indicated by the number of companies that have worked in synergy with academic institutions, where the seed ideas have been generated. Quantum size effects in semiconductor NCs for tagging biomolecules or the use of bio-conjugated noble metal nanoparticles to label and sense biomolecules or bio-related analytes are among the most explored application fields.

Other key issues for the progress of nanomaterial based biosensing are related to material toxicity and safety issues. The properties of colloidal NCs should be better exploited in *in vivo* biosensing devices. In this perspective, the issue of toxicity of the used nanosized material became crucial. The toxicity suspects of many semiconductor nanocrystals have recently alerted the scientific community, becoming also a societal topic of considerable importance and discussion. Indeed, *in vivo* toxicity is likely to be a key factor in determining whether nanoparticles would be approved by regulatory agencies as biosensing probes for clinical use on human beings. For example, a recent study [31c] indicates that CdSe NCs are highly toxic to cultured cells under UV illumination for extended periods of time. This is not surprising because the UV irradiation can break covalent chemical bonds and induce NC photodissolution, ultimately releasing toxic cadmium ions into the culture medium. In the dark, however, NCs protected by a polymer coating have been found to be essentially non-toxic to cells and animals, as no effects on cell division or ATP production have been ascertained. For polymer-encapsulated NCs, chemical or enzymatic degradation of the inorganic cores is unlikely.

Finally, possible toxicity problems associated with long-term exposure of technical human staff devoted to routine production, manipulation, and “*in vitro*” use of NCs for fundamental research purposes must be carefully considered [112].

## 5.9

### Conclusions

The potential of nanomaterial-based optical biosensing has been assessed by recent research developments and implemented into various novel and/or improved optical techniques, competing strongly with traditional methods. The merits of nanocrystals can be recognized in the breakthrough, compared with conventional assays, in terms of both selectivity and sensitivity. Optimization of the physical, chemical and fabrication parameters is necessary to ensure extension of these devices from experimental prototypes to large-scale industrial production.

Future design and engineering of biosensing devices able to detect analytes in complex matrices and environments will, essentially, need close interdisciplinary exchange and stimulating collaborations among material scientists, engineers, analytical, (bio)chemical and biomedical researchers. This can, hopefully, be expected to guarantee the realization of efficient sensors at relatively low cost for easy commercialization.

# Quantum Dot-based Nanobiohybrids for Fluorescent Detection of Molecular and Cellular Biological Targets

Rumiana Bakalova, Zhivko Zhelev, Hideki Ohba,  
and Yoshinobu Baba

### 6.1 Introduction

Over the last several years, semiconductor quantum dots (QDs) have won recognition as a new generation of fluorophores in bioimaging and biosensing, because of their unique spectral properties compared with traditional organic dyes: high quantum yield (>50% versus 15–50% for classical organic dyes); high molar extinction coefficients ( $\sim 10\text{--}100\times$  that of traditional organic dyes); broad absorption spectra with narrow, symmetric fluorescence spectra (full-width at half-maximum  $\sim 25\text{--}40$  nm) spanning the ultraviolet to near-infrared; large effective excitation/emission Stokes shifts; high resistance to photobleaching and exceptional resistance to photo- and chemical degradation. All these characteristics make QDs brighter fluorescent probes ( $10\text{--}20\times$  brighter than classical organic dyes) under photon-limited *in vivo* and *in situ* conditions, where the light intensities are severely attenuated by scattering and absorption. These novel optical properties can be used to optimize the signal-to-noise (signal-to-background) ratio and to improve the sensitivity of the fluorescence detection devices, as well as to increase the quality of fluorescent cellular and molecular labeling, and deep-tissue *in situ* and *in vivo* fluorescent imaging. Moreover, the size-tunable fluorescent emission (as a function of core size for binary semiconductor materials) and the broad excitation spectra (which allow excitation of mixed QD populations at a single wavelength) give possibilities for application of QDs in multiplexed fluorescent analyses.

The present chapter overviews the current status and future trends of QD-based nanobiohybrids for ultrasensitive fluorescent detection of molecular and cellular biological targets. Section 6.2 outlines the basic principles of design and synthesis of highly fluorescent QDs, appropriate for life science research, with their advantages and drawbacks over classical fluorophores. Section 6.3 summarizes currently data on applications of QD-based nanobioprobes in cellular and deep-tissue imaging *in situ* and *in vivo*, using the following fluorescent detection methods: fluorescent confocal microscopy, two-photon microscopy, fluorescence correlation spectroscopy, single-molecule microscopy. It describes the potential of multifunctional

QDs for positron emission tomography and functional magnetic resonance imaging. Sections 6.4 and 6.5 focus on the application of QDs in several basic fluorescent biotechnologies *in vitro* (e.g., FRET analyses, time-resolved photoluminescence spectroscopy, immunoblotting). These sections describe, for the first time, the great capacity of QDs for improvement and quantification of immunoblot analysis of protein expression, using a fluorescent detection, as well as for development of new generation optical recognition-based biosensors. A new type of QDs possessing a long fluorescence life-time (approximately 90 ns) is also reported. Finally, Section 6.6 briefly describes future trends for QD-based composite materials as novel fluorescent standards for thin calibration of fluorescent instrumentation.

## 6.2

### Quantum Dots – Basic Principles of Design and Synthesis, Optical Properties, and Advantages over Classical Fluorophores

#### 6.2.1

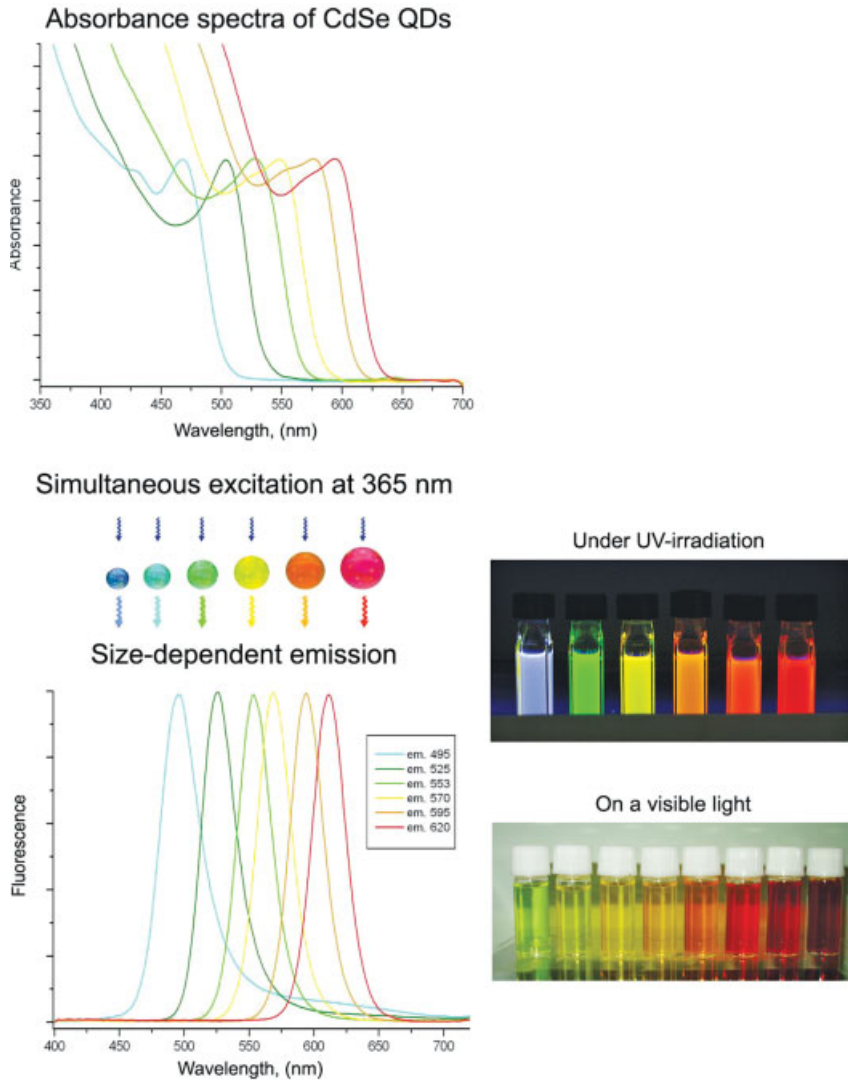

##### Basic Principles of Design and Synthesis of Quantum Dots

QDs are made from inorganic colloidal semiconductors. They are single crystals a few nanometers in diameter whose size and shape can be precisely controlled by the duration, temperature, and ligand molecules used in the synthesis [1]. This process yields QDs that have unique composition- and size-dependent absorption and emission (Fig. 6.1).

Absorption of a photon with energy above the semiconductor band gap energy results in the creation of an exciton. The absorption has an increased probability at higher energies (i.e., shorter wavelengths) and results in a broadband absorption spectrum, in marked contrast to standard fluorophores. For nanocrystals smaller than the so-called Bohr exciton radius (a few nanometers), energy levels are quantized, with values directly related to the QD size – an effect called quantum confinement that gives the name “quantum dots”. The relative recombination of an exciton (characterized by a long life-time, >10 ns) [2] leads to the emission of a photon in a narrow, symmetric energy band.

Surface defects in the QD crystal structure act as temporary “traps” for the electron or hole, preventing their radiative recombination. The alternation of trapping and untrapping events results in intermittent fluorescence (blinking) visible at the single-molecule level [3–5]. This reduces the overall quantum yield (the ratio of emitted to absorbed photons). The way to overcome these problems and to protect surface atoms from oxidation and other chemical reactions is to grow a shell of a few atomic layers of a material with a large band gap on top of the nanocrystal core. The shell can be designed carefully to obtain quantum yields close to 90%. This step also enhances QD’s photostability by several orders of magnitude in comparison with conventional dyes.

For application of QDs in life science experiments, it is necessary to dissolve the core-shell nanocrystals in aqueous solutions at physiological conditions (pH  $\sim$  7–7.4 and physiologically normal ion strength), avoiding aggregation completely.

**Fig. 6.1.** Size-dependent absorption and emission of CdSe quantum dots (from  $\sim 2$  to  $\sim 6$  nm in diameter, starting from the blue color).

Presently, the best available QDs for biological applications are made of CdSe cores overcoated with a layer of ZnS. The size of CdSe/ZnS QDs varies from 3 to 10 nm. Their quantum yield is very high in organic solvents ( $\sim 85\%$ ); however, the direct phase-transfer to aqueous solutions using appropriate surface-modifying agents results in a significant decrease or complete loss of their fluorescent proper-

ties (as a result of direct contact between the metal surface and the polar environment). Thus, additional organic coating of CdSe/ZnS QDs is necessary to preserve (at least partially) their high quantum yield in aqueous solutions. The organic (usually polymer) coating is required not only to preserve the quantum yield but, mostly, for isolation of the metal surface, which is sensitive to oxidation. For example, QDs that are covered only with water-soluble surface ligand can be easily oxidized by the oxygen dissolved in aqueous solution. As a result, QDs aggregate, form about 100–500 nm clusters, and lose completely their unique properties. The polymer coat forms a box around single QDs and thus avoids the aggregation and preserves the unique properties of the semiconductor core–shell nanocrystal.

Several excellent reviews summarize the advantages and drawbacks of the synthetic strategies for water-soluble QDs [6–11]. QDs have been synthesized using both two-element systems (binary dots) and three-element systems (ternary alloy dots). The most successful strategy for additional coating of CdSe/ZnS QDs before their subsequent water-solubilization is an organic coating using “diblock” or “triblock” copolymers [8, 12], amine box dendrimers [13], dihydrolipoic acid derivatives [14, 15], modified acrylic acid polymer [16–18]. However, current organic coats have one important shortcoming – the obtained QD particles have a non-defined heterogeneous size after the organic coating. Moreover, the total size of the organic-coated CdSe/ZnS QDs usually varies in the range 15–50 nm – a size that is commensurable with or larger than that of biomolecules (proteins, oligonucleotides, etc.) that the particles have to be conjugated with. Despite their relatively large size, recent life science experiments have shown that bioconjugated QD probes behave like fluorescent proteins and do not suffer from serious binding kinetic or steric hindrance problems and can be used in fluorescent imaging of molecular and cellular targets [8, 9, 12, 19–32]. In this “mesoscopic” size range, QDs also have a greater surface area and a lot of functionalities to develop multifunctional nanoparticles that can be used for linking to multiple diagnostic and therapeutic agents. However, the comparatively large sizes of water-soluble QDs make them inappropriate for several approaches, e.g., FRET-based biosensing technologies (the Forster-radius for effective FRET is calculated as 5–10 nm). Since the organic coating is necessary to avoid aggregation of the metal nanoparticles and to preserve their high quantum yield in aqueous solutions, future expectations have been directed to the development of methods for overcoating of QDs with a maximal size of organic coat of ~8 nm.

### 6.2.2

#### **Optical and Chemical Properties – Advantages Compared with Classical Fluorophores**

Semiconductor QDs have attracted much interest for bioimaging and biosensing, because of their unique spectral properties over traditional organic fluorophores. Briefly, the following characteristics distinguish QDs from the commonly used fluorophores: high quantum yield (more 50% versus 15–50% for standard organic dyes); high molar extinction coefficients (in the order of  $0.5\text{--}5 \times 10^6 \text{ M}^{-1} \text{ cm}^{-1}$ , which is  $\sim 10\text{--}100\times$  larger than those of traditional organic dyes –  $5\text{--}10 \times 10^4$

$M^{-1} \text{ cm}^{-1}$ ) [7, 33]; broad absorption spectra with narrow, symmetric photoluminescence spectra (full-width at half-maximum  $\sim 25\text{--}40 \text{ nm}$ ) spanning the UV to near-infrared; low life-time-limited emission rates for single QDs ( $\sim 5\text{--}10\times$  lower than those of single organic dyes), because of their longer excited state life-times ( $20\text{--}50 \text{ ns}$ ); large effective Stokes shifts; high resistance to photobleaching (several thousand times more stable than organic dyes) and exceptional resistance to photo- and chemical degradation [34–36], which makes them well-suited for continuous tracking studies over a long period of time. All these characteristics make QDs brighter fluorescent probes ( $10\text{--}20\times$  brighter than organic dyes) [37, 38] under photon-limited *in vivo* and *in situ* conditions, where light intensities are severely attenuated by scattering and absorption. These novel optical properties can be used to optimize the signal-to-background (signal-to-noise) ratio. For example, the comparatively long fluorescence life-time of QDs enables the use of time-gated detection to separate their signal from that of shorter lived species, such as background autofluorescence encountered in viable cells and animals. Moreover, the longer excited state life-times of QDs provide a means to separate the QD fluorescence from background fluorescence using a time-domain imaging technique [39, 40]. Figure 6.2 shows a comparison of the excited state decay curves of QDs and organic dyes.

Assuming that the initial fluorescence intensities of QDs and dyes after a pulse excitation are the same and that the fluorescence life-time of QDs is one order of magnitude longer, one can estimate that the QD and dye intensity ratio ( $I_{\text{QD}}/I_{\text{dye}}$ ) will increase rapidly from 1 at time  $t = 0$  to  $\sim 100$  in only  $10 \text{ ns}$  ( $t = 10 \text{ ns}$ ). Thus,

**Fig. 6.2.** Comparison of the excited state decay curves (monoexponential model) of QDs and classical organic dyes. The longer excited state life-time of QDs allows the use of time-domain imaging to discriminate against the background fluorescence (short life-times);

$\tau_{(\text{dye})}$  and  $\tau_{(\text{QD})}$  are the delay times for the fluorescence signals to decrease to  $1/e$  of their original values, where  $e$  is the natural log constant ( $= 2.718$ ). (Kindly provided from X. Gao [8]).

**Fig. 6.3.** Comparison of excitation/emission Stokes shifts between QDs and classical organic dyes – an important issue for optimization of the signal-to-noise (signal-to-background) ratio.

the image contrast (measured by signal-to-noise or signal-to-background ratio) can be markedly improved by time-delayed data acquisition.

The large Stokes shifts of QDs (measured by the distance between the excitation and emission peaks) can be used to further improve detection sensitivity (Fig. 6.3). As shown in Fig. 6.3, the Stokes shifts of QDs can be as large as 300–400 nm, depending on the wavelength of the excitation light. Organic dye signals with a small Stokes shift are often mimicked by strong tissue and cell autofluorescence. In contrast, QD signals with a large Stokes shift are clearly recognizable above the background. This “color contrast” is only available to QD probes, as the signals and background can be separated by wavelength-resolved or spectral imaging [12].

The most attractive features for life science research are the size- and composition-tunable emission of QDs from visible to infrared wavelengths, which give a possibility for their use to image and track multiple molecular targets simultaneously, e.g., combinatorial optical encoding, in which multiple colors and intensities are combined to encode thousands of genes, proteins or small-molecule compounds (a), and simultaneous sensing and imaging of several molecular and more complex targets (b) [17, 41–48].

Single QDs can be observed and tracked over an extended period of time (up to a few hours) with fluorescent confocal microscopy [49], total internal reflection microscopy [50, 51], or basic wide-field epifluorescence microscopy [19, 52]. Single-molecule microscopy is possibly one of the most exciting new capabilities offered to biologists. A related technique, fluorescence correlation spectroscopy, has allowed determination of the brightness per particle and also provides measurement of the average QD size [53]. QDs are also excellent probes for two-photon confocal microscopy [51, 54, 55] because they are characterized by a large absorption cross section. They can be used simultaneously with standard dyes. In particular, QDs

have a largely untapped potential as novel tracers in PET and MRI imaging [9], as customizable donors of a fluorescence resonance energy transfer (FRET) pair [23, 24, 28, 56–61], and as photosensitizers [31, 32, 62]. In the next several subsections we discuss the application of QD-based probes in most usable imaging and sensing methodologies in life science experiments.

### 6.3 Quantum Dots for Fluorescent Labeling and Imaging

The unique optical properties of QDs make them very attractive as novel fluorophores in various life science investigations, in which traditional fluorescent organic dyes fall short of providing long-term stability and simultaneous detection of multiple fluorescent signals. The ability to make QDs water soluble and target them to specific biomolecules has led to promising applications in cellular labeling, deep-tissue imaging, *in vitro* fluorescent assays, and FRET-based techniques.

#### 6.3.1

##### Structure of Quantum Dot Nanobiohybrids for Fluorescent Microscopic Imaging

Since water-soluble QDs have many functional groups ( $\text{NH}_2^-$ ,  $\text{COOH}^-$ ,  $\text{SH}^-$ , etc.) on their surface, they are easily conjugated with different biomolecules (proteins, DNAs, RNAs, small ligands, etc.), as well as with appropriate chemical substances (e.g., drugs). The resulting conjugates combine the properties of both materials, i.e., the spectroscopic characteristics of the nanocrystal and the biomolecular function of the surface-attached entities.

There are two types of conjugates, depending on the QD size. Using QDs with size commensurable with or slightly larger than that of many biomolecules, it is possible to obtain QD-based nanobiohybrids that consist of a single QD with several biomolecules attached on its surface. Thus, the large number (10 to 100) of potential surface attachment groups can be used to “graft” different functionalities to individual QDs, resulting in multifunctional probes. For instance, in addition to a recognition moiety, QDs can be equipped with a membrane-crossing or cell-internalization capability, and/or and enzymatic function.

In contrast, using small QDs (approximately 2–3 nm in diameter) it is possible to obtain nanobiohybrids that consist of several QD particles attached to a single biomolecule (usually protein) [26]. In this case, QDs have an important privilege for fluorescence detection methods in comparison with classical organic dyes – the attachment of several small size QDs on the surface of one protein molecule does not result in fluorescence self-quenching, in contrast to classical dyes (e.g., cyanines, fluorescein, etc.) where the conjugation of several dye molecules with one protein molecule results in a strong fluorescence self-quenching. This assumption is based on our comparative study of the fluorescence intensity of multifunctional PMAM dendrimers conjugated with different numbers of QD particles (~2 nm in diameter) or cyanine 3/cyanine 5 molecules (unpublished data).

Several strategies can be used to manipulate the molecular orientation of the ligands attached on the QD surface as well as their molar ratios with respect to QDs. However, QD probes with precisely controlled ligand orientations and molar ratios are still not available.

Two problems associated with fluorescence microscopy – cell and tissue autofluorescence in the visible spectrum (which can mask the signals from labeled molecules) and the requirement of long observation times – have created a need for new QD probes that emit in the near-infrared (NIR) region (wavelength > 700 nm) and are more photostable than current organic fluorophores [29].

### 6.3.2

#### Quantum Dots for Fluorescent Cell Imaging

QDs have made the most progress and attracted the greatest interest in cellular labeling and imaging. Within the last two-three years, numerous reports have described the ability of one or more “color/size” of biofunctionalized QDs to label cells [20–22, 26, 30, 32, 37, 50, 63–68]. Many of these reports show that QD labeling permits extended visualization of cells under continuous laser illumination as well as multicolor imaging, highlighting the advantages offered by these fluorophores (Fig. 6.4) [20, 22, 26, 65–68].

A clear differentiation can be made between labeling of live and fixed cells (dead with crosslinked components to maintain cellular architecture). Fixed cells can be treated “harshly” to facilitate entry of the QDs by chemically creating pores. To label live cells, the process must be handled softly to maintain cellular viability. Live-cell experiments introduce a few extra levels of complexity, depending on the application: whole-cell QD labeling, labeling of membrane-bound proteins, and cytoplasmic, subcellular or nuclear target labeling. The major impediment is the entry of the relatively large QDs into the cell across the cellular membrane lipid bilayers. For small size water-soluble QDs, the positive charge on the surface can facilitate this process, but for negatively charged QDs this is usually extremely difficult. Such QDs can be delivered into the cells only through some specific (receptor-mediated) transport based on the functional molecules conjugated on the QD surface. The results indicate that large amounts of QDs can be delivered into live mammalian cells via three different mechanisms: non-specific pinocytosis, microinjection, and peptide-induced transport [16, 17, 22, 69–71]. For example, transferrin has been used to facilitate endocytosis of QDs by mammalian cells and to label pathogenic bacteria and yeast cells [38], whereas lectin-conjugated QDs were used to detect specifically Gram-negative bacteria [61, 72]. Different types of QD functionalization have also been explored as a way to target QDs to cell surface proteins. Some examples include streptavidin, secondary or primary antibodies, receptor ligands such as epidermal growth factor or serotonin, recognition peptides, and affinity pairs such as biotin–avidin after engineering of the target protein [19–22, 25, 70, 73, 74]. To reduce the size of QD probes, researchers have used ligands of cell surface receptors bound to QDs via a biotin–streptavidin link or by direct crosslinking [21, 25, 70]. Some cell surface proteins can be recognized by small

**Fig. 6.4.** Stability of QD fluorescence during continuous laser scanning on a confocal fluorescent microscope. (A) Top row: Nuclear antigens labeled with QD630-streptavidin (red), and microtubules labeled with Alexa-488 conjugated with anti-mouse IgG (green) simultaneously in 3T3 cells. Bottom row: Microtubules labeled with QD630-streptavidin (red), and nuclear antigens stained with Alexa-488 conjugated with anti-human IgG (green). Specimens were continuously illuminated for 1 min with light from a 100 W mercury lamp under a  $100\times 1.30$  oil-immersion objective. An

excitation filter ( $\lambda_{\text{ex}} = 485$  nm) was used to excite both Alexa-488 and QD630. Emission filters at  $\lambda_{\text{em}} = 535$  nm and  $\lambda_{\text{em}} = 635$  nm were used to collect Alexa-488 and QD630 signals, respectively. Images were captured with a CCD camera at 10 s intervals for each color automatically. (According to Wu et al. [20]). (B) Fluorescent microscopic imaging of interaction of QD-lectin conjugates with leukemia cells (green): dynamic of the signal during 30 min scanning. (According to Zhelev et al. [26]).

peptides (screened by phage-display technology) [74], so it is attractive to use peptides for QD functionalization. The same concepts could also be used to label sub-cellular or nuclear targets. However, QDs need to enter the cell cytoplasm and to reach their target without being trapped in the endocytosis. A surprising finding is that two billion QDs could be delivered into the nucleus of a single cell, without compromising its viability, proliferation or migration [8, 16, 71, 75]. The ability to image single-cell migration and differentiation in real time is expected to be important to several research areas such as embryogenesis, cancer metastasis, stem-cell therapeutics and lymphocyte immunology.

The main advantage of QDs in cellular imaging resides in their resistance to photobleaching over long periods of time (minutes to hours), allowing the acquisition of images that are crisp and well contrasted. The increased photostability of QDs is especially useful for acquisition of many consecutive focal-plane images and their reconstruction into a high-resolution three-dimensional (3D) projection,

e.g., for 3D optical sectioning, where a major issue is bleaching of fluorophores during acquisition of successive z-sections. This compromises the correct reconstruction of 3D structures [76]. The very small number of QDs is necessary to produce a fluorescent signal. In addition, QDs are available in a virtually unlimited number of well-separated colors, all excitable by a single wavelength. This property could be used in fluorescent confocal microscopy to perform nanometer-resolution colocalization of multiple-color individual QDs.

### 6.3.3

#### Quantum Dots for Fluorescent Deep-tissue Imaging *In Vivo*

The long-term stability and brightness of QDs make them ideal candidates for *in vivo* fluorescent targeting and imaging. At present, such imaging uses two groups of organic fluorophores: the fluorescent proteins expressed by the cells themselves and fluorescent dyes that are exogenously loaded into the cells. Organic fluorophores have numerous limitations, restricting their usefulness for *in vivo* fluorescent microscopy. A first limitation is the difficulty in simultaneous imaging of multiple independent organic fluorophores, based on two characteristics of these fluorophores. First, they require distinct excitation wavelengths and have a very small Stokes shift between excitation and emission wavelengths (Fig. 6.3). Thus, multiple excitation lines are needed for imaging multiple organic fluorophores and each additional excitation line limits the spectra available for emission collection. Second, they emit over a broad region of the visible spectra. Thus the emission of different fluorophores overlaps with each other and with much of the tissue autofluorescence. A second limitation is the susceptibility of organic fluorophores to photodamage and metabolic degradation, which restricts their use in long-term *in vivo* imaging [53]. Moreover, some organic fluorophores (e.g., fluorescein) have a limited response to multiphoton excitation, which is a particular liability when trying to image into tissues.

QDs completely overcome these limitations. They can be excited by a wide spectrum of single and multiphoton excitation light, which is well separated from their emission spectra. The large Stokes shifts allow the possibility to overcome, or at least to minimize, tissue autofluorescence that appears near the excitation region (Fig. 6.5). Thus, only one excitation wavelength is needed to simultaneously excite several different QD probes. QDs also have narrow emission spectra, which are tunable to any desired wavelength from blue to infrared. Thus from their emission spectra several different QD probes can be easily distinguished. QDs are also virtually resistant to photobleaching and are as bright as the best-known organic fluorophores. Further, they have a good multiphoton absorption between 700 and 1000 nm. These features make QDs desirable for long-term multicolor *in vivo* imaging.

Theoretical modeling studies have indicated that two spectral windows are available for *in vivo* QD imaging – one at 700–900 nm and other at 1200–1600 nm [77–

Fig. 6.5. Comparison of mouse skin autofluorescence and QD emission spectra, obtained under excitation at 350 nm. The results demonstrate that QD signals can be shifted to a spectral region where autofluorescence is reduced. (This figure was kindly provided from X. Gao [8].)

79]. There are great expectations for QDs emitting in the near-IR region that are ideal for *in vivo* imaging. In this region of the electromagnetic spectrum there is low tissue scattering and absorption, yielding the greatest tissue penetration depth and optical signal. In this case, QDs offer an excellent alternative to organic fluorophores for *in vivo* animal imaging. However, biocompatible near-IR-emitting organic fluorophores suffer from low QY (quantum yield), broad emission spectra, and an inability to multiplex. Near-IR QDs can, potentially, be designed to have high QYs and molar absorption coefficients, leading to a highly luminescent and useful *in vivo* contrast agent. In fact, high QY near-IR organic soluble QDs have already been designed [29, 80–82] – a major hurdle is the preservation of the optical properties of organic-soluble near-IR QDs after surface modification with biocompatible coatings and water solubilization. The highest reported QY for biocompatible near-IR-emitting QDs made from CdSe/CdTe alloy is 17%.

Another important issue for application of QDs *in vivo* is their overcoating with high molecular weight poly(ethylene glycol) (PEG) molecules that gives a possibility to reduce their accumulation in the liver and bone marrow, and to ensure effective targeting and imaging of the desired tissue *in vivo* (e.g., blood vessels, solid tumors, tumor metastases, lymph nodes, etc.) [12, 16, 18]. In contrast to small organic dyes, which are eliminated from the circulation within minutes after injection, PEG-coated QDs remained in the blood circulation for an extended period of time (half-life more than 3 h) (Fig. 6.6A) [18, 29]. This long-circulating feature can be explained by the unique structural properties of QD nanoparticles. PEG-coated QDs fall within an intermediate size range: they are small enough and sufficiently

**Fig. 6.6.** (A) Noninvasive imaging of 645 nm-emitting mPEG-750 QDs (A, C, E) and 655 nm-emitting mPEG-5000 QDs (B, D, F, G). Nude mice are imaged at different post-injection times. Significant liver uptake is detected using mPEG-750 QDs even at 10 min, while using mPEG-5000 QDs such uptake is visible after 1 h. The same QDs are very stable and can be also detected after 3 h. (Reprinted from Ref. [18] with the permission of ACS Publications).

hydrophilic to slow down opsonization and reticuloendothelial uptake, but are large enough to avoid renal filtration. In this context, near-IR QDs also have great potential to be used in diagnostic blood vessel (e.g., stenosis, aneurism, stroke, etc.).

To guarantee high binding affinities of QD probes to the respective cellular or molecular target *in vivo*, the nanocrystals are usually conjugated with antibodies or small peptides [12, 63]. Antibodies offer higher binding affinity of QDs than peptides, but they add size to the nanoparticles (~5–30 nm). Furthermore, antibodies could limit the co-coating of other molecules (e.g., polymers) onto the surface of QDs. By contrast, peptides are smaller than antibodies – large libraries of targeting peptides for specific diseases can be identified using screening tech-

**Fig. 6.6.** (B1) In vivo imaging of vasculature labeled by a tail vein injection of water-soluble QDs (fluorescence wavelength, 550 nm). Fluorescent capillaries, containing  $\sim 1 \mu\text{M}$  QDs, were clearly visible through the skin at the base of the dermis ( $\sim 100 \mu\text{m}$  deep). Blue pseudocolor is collagen imaged via its second

harmonic signal at 450 nm. (B2) Comparison image at the same depth as in (B1), acquired by injecting FITC-dextran at its solubility limit. Scale bars in (B1) and (B2):  $20 \mu\text{m}$ . Excitation is at 880 nm for (B1) and 780 nm for (B2). (Reprinted from ref. [84] with the permission of Science Publishing Group.)

niques, such as phage-display – and provide greater flexibility in QD surface engineering.

Currently, there are several excellent examples for application of QDs in *in vivo* cellular targeting and imaging, including fluorescent deep-tissue imaging. Two-photon laser exciton confocal microscopy has been used to visualize blood vessels in mice after intravenous injection of QDs, showing that higher contrast and imaging depth can be obtained at a lower excitation power than with organic dyes [53]. Larson and coworkers found that the two-photon absorption cross-sections of QDs are two to three orders of magnitude larger than those of traditional organic fluorophores (Fig. 6.6.(B)) [81].

**Fig. 6.7.** *In vivo* fluorescence imaging of QD-PSMA antibody conjugates in mouse bearing C4-2 human prostate tumor. Orange-red fluorescence signals indicate a prostate tumor growing in a live mouse (right-hand mouse). Control studies using a healthy mouse (without tumor) and the same amount of QD

injected showed no localized fluorescence signals (left-hand mouse). (a) Original image; (b) unmixed autofluorescence image; (c) unmixed QD image; (d) super-imposed image. (This figure was kindly provided from X. Gao [12].)

QD-peptide conjugates have been also used to target tissue-specific vascular markers (lung blood vessels and cancer cells) by intravenous injection in mice [18]. Histological sections of different organs after 5 or 20 min of circulation showed that QD-peptide conjugates reach their targets and are internalized by endocytosis in target cells but not in surrounding tissues, probably because of their large size relative to dye molecules (which stain surrounding tissues). *In vivo* imaging of targeted QD delivery has recently been achieved in mice by Gao et al., who intravenously injected PEG-coated QDs functionalized with antibodies to prostate-specific membrane antigen (PSMA) (Fig. 6.7) [12]. However, since their QDs emit in the visible spectrum, the authors use a spectral demixing algorithm to separate tissue autofluorescence from QD signal in grafted tumors.

This problem has been eliminated by Kim et al. [29], who have injected near-IR-emitting QDs intradermally into mice and pigs and demonstrated the visualization of sentinel lymph nodes in these animals via optical imaging (Fig. 6.8).

To improve tissue penetration, Kim et al. have prepared a novel core-shell nanostructure called type II QDs with fairly broad emission at 850 nm and a moderate QY of  $\sim 13\%$  [29]. In contrast to conventional QDs (type I), the shell materials in

type II QDs have valence and coordination band energies both lower than those of the core materials. As a result, the electrons and holes are physically separated and the nanoparticles emit light at reduced energies (longer wavelengths). Injection of only picomolar amounts of the QDs enables visualization of sentinel lymph nodes 1 cm below the skin using excitation rates of only  $5 \text{ mW cm}^{-2}$ . QDs rapidly migrate to nearby lymph nodes and can be imaged virtually background-free, allowing image-guided resection of a lymph node in a pig. The sentinel nodes have been confirmed by a second intradermal injection of blue dye (the current “gold standard”), which also flowed to the same nodes. The advantage of QD over blue dye is the ability to “see” through several centimeters of tissue so that there would be real-time visual guidance of the surgery, with resolution being limited only by the visual acuity of the surgeon. Visual inspection would also allow the surgeon to confirm that all sentinel nodes had been removed from the node field. There is also exciting potential for histopathologists to focus exactly on the part of the sentinel node containing the QDs by using a fluorescent microscope.

Sentinel lymph node biopsy is elegantly simple in concept but quite often very difficult to perform accurately in individual patients. The sentinel nodes can be very deep, up to 10 cm from the skin, and sometimes the nodes are inside the body cavities; situations such as these are considered as problematic for optical imaging using near-IR fluorescence. Therefore, anything that potentially improves the technique is welcome. The work of Kim et al. [29] points to the possibility that QD probes could be used for real-time intra-operative optical imaging, providing an *in situ* visual guide so that a surgeon could locate and remove small lesions (e.g., metastatic tumors) quickly and accurately. At present, however, appropriate high-quality QDs with near-IR-emitting properties are not yet available. Most materials (e.g., PdS, PdSe, CdHgTe and CdSeTe) are either not bright enough or not stable enough for biomedical imaging applications. There is an urgent need to develop bright and stable near-IR-emitting QDs that are broadly tunable in the far-red and IR spectral regions.

**Fig. 6.8.** Near-IR QD sentinel lymph node mapping in mouse and pig. (a) Images of mouse injected intradermally with 10 pmol of near-IR QDs in the left paw. Left-hand side – pre-injected near-IR autofluorescence image; middle – 5 min post-injection white light color video image; right – 5 min post-injection near-IR fluorescence image. An arrow indicates the putative axillary sentinel lymph node. Fluorescence images have identical exposure times and normalization. (b) Images of the mouse obtained 5 min after re-injection with 1% isosulfan blue (standard) and exposure of the actual sentinel lymph node. Left-hand side

– color video; right – near-IR fluorescence images. Isosulfan blue and near-IR QDs are localized in the same lymph node (arrows). (c) Images of the surgical field in a pig injected intradermally with 400 pmol of near-IR QDs in the right groin. Four time points are shown from top to bottom: before injection (autofluorescence), 30 s after injection, 4 min after injection, and during image-guided resection. For each time-point: Left – color video; middle – near-IR fluorescence; and right – color-near-IR merge images. (This figure was kindly provided from J. Frangioni [29].)

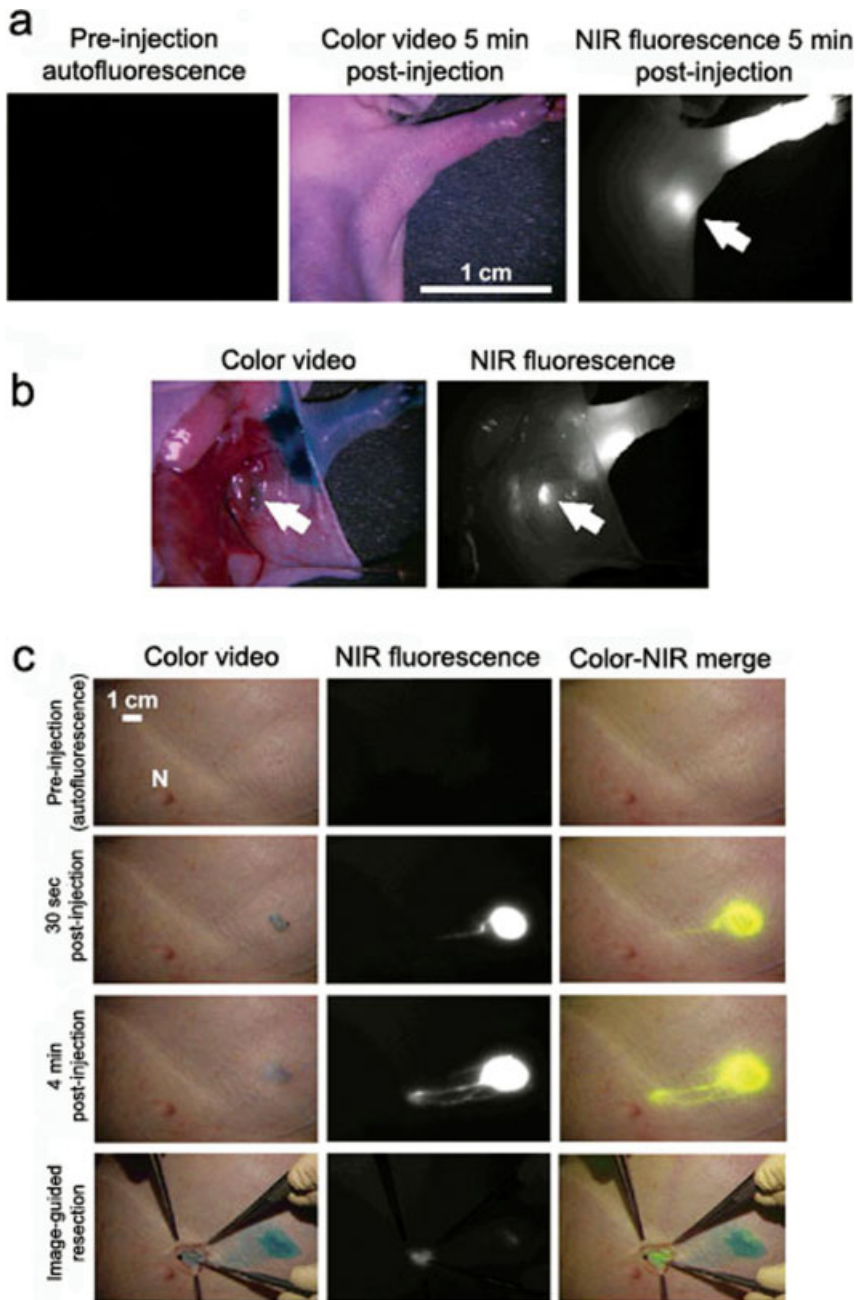

Fig. 6.8

Fig. 6.9. Multifunctional QD-based probes for simultaneous application in different imaging techniques (e.g., fluorescent imaging, MRI, PET).

#### 6.3.4

#### Potential of Quantum Dots for Positron Emission Tomography (PET) and functional Magnetic Resonance Imaging (fMRI)

The ability to design a wide variety of QDs and targeting molecules provides a new set of tools for engineering novel contrast probes for non-invasive imaging techniques such as PET, MRI, and CT. As a research tool, these probes could have many uses, from monitoring tissue implants to studying the real-time dynamics of tumor metastasis.

Despite their relatively large hydrodynamic radii (10–15 nm), bioconjugated QD probes do not suffer from serious binding kinetic or steric-hindrance problems. In this “mesoscopic” size range, QDs also have more surface areas and functionalities that can be used for linking to multiple diagnostic (e.g., radioisotopic or magnetic) and therapeutic (e.g., anticancer) agents. Multimodality imaging probes could be created by integrating QDs with paramagnetic or superparamagnetic agents, as well as with chelators for radioactive isotopes (Figs. 6.9 and 6.10).

Fig. 6.10. MicroPET imaging of QD uptake in live animals. QDs having DOTA (a chelator for radiolabeling) and PEG on their surface were radiolabeled with  $^{64}\text{Cu}$  (positron-emitted isotope with a half-life of 12.7 h). These QDs were then injected via the tail vein into nude mice ( $\sim 80 \mu\text{Ci}$  per animal) and imaged in a

small animal PET-scanner. Rapid and marked accumulation of QDs in the liver was detected. This could be avoided by functionalizing QDs with higher molecular weight PEG chains. (Reprinted from Ref. [9] with the permission of Science Publishing Group.)

Researchers have recently attached QDs to Fe<sub>2</sub>O<sub>3</sub> and FePt nanoparticles and even to paramagnetic gadolinium chelators [83, 84]. By correlating the deep imaging capabilities of MRI with ultrasensitive optical imaging, a clinician could visually identify tiny tumors or other small lesions during an operation and remove the diseased cells and tissue completely. Medical imaging modalities such as MRI and PET can identify diseases non-invasively, but they do not provide a visual guide during surgery. The development of magnetic or radioactive QD probes has the potential to solve this problem.

## 6.4

### Quantum Dots for Immunoblot Analysis with Fluorescent Detection

#### 6.4.1

##### Basic Principles of Classical and QD-based Immunoblot Analyses

Although immunoblotting technology is about 20 years old it is still a major analytical approach for detection of protein expression in cells and tissues, used in molecular and cellular biology and molecular medicine. Currently, it is one of the basic methodologies (together with northern blot analysis and Light Cycler technology) for microarray data validation and verification in functional genomics and proteomics projects.

Figure 6.11(A) shows the basic principle of classical immunoblot analysis (Western blot).

The protein fractions are separated from cell lysate using gel-electrophoresis and are subsequently transferred to a PVDF membrane. The protein of interest is detected using two-step immunoblotting procedure: incubation of PVDF membrane with primary monoclonal antibody that interacts specifically with the target protein and does not interact with other protein fractions (a); washing of membrane and incubation with secondary antibody, conjugated with enzyme (usually horse radish peroxidase, HRP) (b). The blotted antigen is detected by the chemiluminescence of the HRP-catalyzed reaction of appropriate substrate, exposed to X-ray or Polaroid films.

Notably, despite its widespread and long-standing use, immunoblotting has not been much improved from its initial state 20 years ago. The standard immunoblot analysis suffers from several shortcomings: a semi-quantitative nature; a long duration (usually more 24 h); a poor reproducibility of the obtained data; a risk to reach saturation of the enzyme reaction and to mimic the concentration-dependent difference of the blotted antigens; a low sensitivity for detection of “tracer” proteins – including the impossibility of using directly cell lysates for protein separation and immunoblotting, as well as a necessity to use preliminary procedures for immunoprecipitation and concentration of these proteins (each step holds a risk for accumulation of analytical errors). Every researcher in the genomics/proteomics field has been faced with the difficulties in obtaining reproducible and high quality immunoblot images.

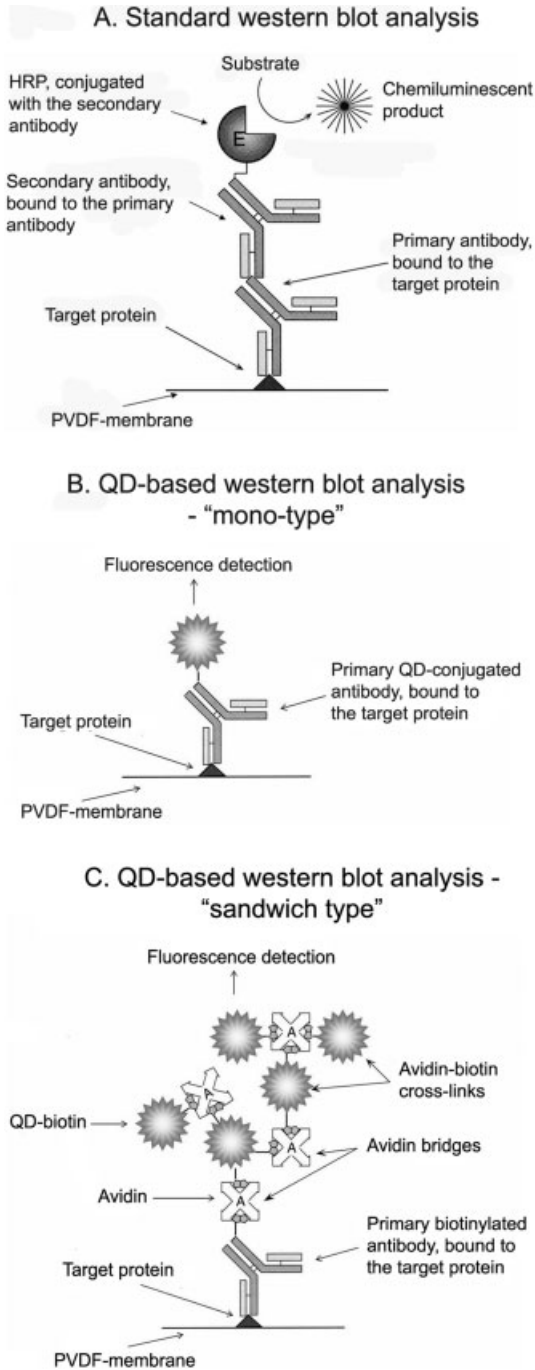

Fig. 6.11. Principle schemes of classical and QD-based immunoblot analyses.

In the middle of August 2004 the Quantum Dot Corporation (USA) offered on the market two western blotting kits, and in the January 2005 issue of *Nature Methods* [85] they undoubtedly demonstrated the potential of QD-based immunoblotting technology in multiplex fluorescent detection of proteins or protein states from a single immunoblot. Their protocol is similar to the classical one; however, the secondary antibody is conjugated with QD instead of enzyme, and the fluorescence of blot images instead of chemiluminescence is detected. The described procedure takes the same time as standard western blot analysis with chemiluminescent detection. However, the narrow emission of QD-labeled protein blots enables simplified image acquisition and quantification that gave a possibility to overcome the semiquantitative nature of western blot analysis. It is possible to store QD-labeled blots in a buffer at 4–8 °C with minimal loss of the fluorescent signal for imaging at a later date.

We have tried to improve QD-based western blotting technology, to simplify and to make it quantitative and applicable for detection of “tracer” proteins directly in cell lysates [27, 86].

Below, we present two immunoblotting protocols, named as “mono type” and “sandwich type” and show the privilege of QD-based western blot analysis in the detection of “tracer” proteins through classical technology with colorimetric detection. Figure 6.11(B, C) presents the principle schemes of both procedures.

#### 6.4.2

##### **QD-based Immunoblot Analysis of “tracer” Proteins – Privileges over Classical Immunoblot Analysis**

QDs with emission maximum at 535 nm were used in this study. Telomere associated proteins, telomeric repeat binding factor (TRF1, a 56 kDa protein) and TRF1-interacting nuclear protein 2 (Tin2, ~40 kDa protein), were selected as proteins of interest. TRF1 and Tin2 are known to be poorly expressed in Philadelphia-positive (Ph+) cells derived from patients with chronic myelogenous leukemia (e.g., K-562 cells) and several modifications of the standard immunoblotting protocol have to be performed to identify these two proteins in K-562 cells. Details are described in Refs. [27, 86]. The blotted QD-labeled antigens (proteins) were detected directly by a fluorescence gel imaging system supplied with an appropriate emission filter. The experimental results in Fig. 6.12 represent typical blots of TRF1 and Tin2, analyzed in cell lysates by classical (C) and QD-based western blotting protocols (A, B).

Using “mono-type” QD-based western blotting technology, it was possible to detect both proteins without preliminary immunoprecipitation and concentration procedures (Fig. 6.12A). However, the fluorescence of QD-labeled TRF1 and Tin2 blots was weak. It was practically impossible to detect these “tracer” proteins directly in cell lysate, without their preliminary immunoprecipitation and concentration (Fig. 6.12C). In contrast, TRF1 and Tin2, detected in K-562 cell lysates by “sandwich type” QD-based western blotting technology, possessed a bright fluorescence as a result of biotin–avidin crosslinks (Fig. 6.12B). The images in Fig.

**Fig. 6.12.** Representative blots of “tracer” proteins TRF1 and Tin2, analyzed in K-562 cell lysate using classical (C) and QD-based (A, B) immunoblot analysis. Numbers 1–5 correspond, respectively, to protein concentrations of cell lysates (in  $\mu\text{g}$ ), applied

to each gel patch, of 1–10, 2–20, 3–30, 4–40, and 5–50. In (A) and (B) blot images were obtained by fluorescent detection, and the images in (C) were obtained by chemiluminescent detection.

6.12(A, B) were generated using an identical exposure time (15 min) and excitation/emission settings. Since avidin can interact non-specifically with other non-biotinylated proteins on the PVDF membrane, we recommend the use of neutravidin or streptavidin in “sandwich type” QD-based western blot analysis. Notably, the fluorescent signal was stable during continuous scanning in gel imager. No changes in the blot fluorescence intensity were registered between 5 and 30 min scanning – time enough for membrane imaging and data acquisition.

The higher sensitivity of QD-based methodology in comparison with classical analysis can be explained, at least partially, by the inherent sensitivity of fluorescence compared with chemiluminescence. The QD-labeled membranes can be kept in buffer at 4 °C for a week without loss of image quality. It was also possible to improve markedly the brightness of blots with serial incubations of PVDF-membrane in QD-labeled neutravidin and QD-labeled biotin. However, concentration-dependent saturation of QD-signal was detected at high protein concentrations of cell lysate (applied to each gel patch) and this procedure can be recommended for work with samples containing less than 20  $\mu\text{g}$  protein per gel patch.

The proposed QD-based immunoblotting technologies with fluorescent detection allow the possibility of quantification of the blot fluorescence, and they also

**Fig. 6.13.** Sensitivity of “sandwich type” and “mono-type” QD-based immunoblot analyses, as determined by pure soybean agglutinin (two-serial dilution starting from 20 ng per gel patch – number 1). Upper curve – “sandwich type”; lower curve – “mono type”.

shortened the time of analysis of “tracer” proteins in comparison with the standard methodology. The sensitivity of our protocols was up to 1 and 5 ng of pure protein per gel patch for “sandwich” and “mono” type, respectively (Fig. 6.13). The detection of QD-labeled immunoblotted proteins is simple, in contrast to the detection procedures of the standard western blot analysis. Standard technology requires a transfer of the chemiluminescent signal on Hyperfilms, which is a time- and cost-consuming process. Both technologies in our study were developed for detection of TRF1 and Tin2 in K-562 cells, but they can also be applied for detection of other proteins in different cellular and tissue samples.

## 6.5

### Quantum Dots for FRET Analyses, Time-resolved Fluorimetry, and Development of Optical Recognition-based Biosensors

#### 6.5.1

##### Quantum Dots for FRET-based Bioanalyses

In the past several years, FRET has been involved in many biochemical analyses and applied to the development of simple fluorescence detection techniques, in-

cluding a PCR with real-time FRET measurements; DNA hybridization analyses and formation and dissociation of hairpin structures; an elucidation of the dynamics of telomerization or DNA replication; and an investigation of interactions between proteins, nucleic acids and small molecules [23, 87–90].

The essential requirement for FRET is that the emission spectrum of the donor has to overlap with the absorption spectrum of the acceptor, and distance between donor and acceptor has to be within 1–10 nm. Reports on QDs as FRET-donors in a biological context appeared from 2001 [56, 57]; however, the full potential has not been demonstrated yet. Several elegant studies in this field have been designed and provided recently by the U.S. Naval Research Laboratory [23, 24, 58, 59]. By self-assembling acceptor dye-labeled proteins onto QD donor surfaces, two unique advantages over organic fluorophores for FRET became apparent: QD donor emission could be size-tuned to improve spectral overlap with an acceptor dye (using a size selection, it is possible to obtain QDs with emission maximum corresponding exactly to the excitation maximum of the FRET-acceptor) (a), and several acceptor dyes interacting with a single QD-donor substantially improved FRET efficiency (b). Obviously, the unique optical properties of QDs make them the most appropriate FRET-donors. However, currently there is a serious limitation in the widespread use of QDs in FRET-based bioanalyses related to the size of highly luminescent water-soluble QDs, which is usually beyond the Forster radius. Efforts are being directed to the development of small (up to 10 nm in diameter) highly luminescent water-soluble QDs with optimal FRET capacity.

### 6.5.2

#### **Quantum Dots for Time-resolved Fluorimetry**

Some of the presently described QDs possess a comparatively long fluorescence half-life and can be appropriate for time-resolved fluorimetric analyses. Figure 6.14 demonstrates the fluorescence half-life of water-soluble broad-fluorescent CdSe QDs [86]. The fluorescence half-life varied from 27 to 92 ns, depending of the emission wavelength. Lakowicz and colleagues have described sharp-fluorescent CdSe/ZnS QDs with a mean fluorescence half-life of ~17 ns and a heterogeneous intensity decay curve [91]. For comparison, the reported fluorescence half-life of commercial CdSe/ZnS QDs, dispersed in organic solvents, is approximately 10–12 ns [92–94].

### 6.5.3

#### **Quantum Dots for development of New Generation Optical Recognition-based Biosensors**

The FRET capacity and comparatively long fluorescence half-life of QDs are very promising in the evolution of optical recognition-based biosensors that can monitor rapidly the concentrations of target species in their physiological environment, in a continuous, simple and reliable manner. Presently, the most popular recognition-based optical sensors consist of surface immobilized functional

**Fig. 6.14.** Time-resolved fluorescence life-time spectra of water-soluble broad-fluorescent CdSe QDs synthesized at room temperature. For comparison, sharp fluorescent QDs synthesized at high temperature were recorded at an emission wavelength corresponding to

their fluorescent maximum. All data were recorded at an excitation wavelength of 365 nm, frequency 40 kHz, using a Hamamatsu FLS920S spectrometer. IRF = instrumental response function of the nanosecond flash-lamp.

materials – usually a thin polymer film with incorporated hydrophobic organic dye [95, 96]. These sensors possess, predominantly, a pressure or temperature sensing ability, and an ability to detect the concentration of ions and small molecular weight molecules (e.g., oxygen, carbon dioxide, etc.). They do not possess an ability to detect the concentration of middle (100–1000 Da) or high (10–100 kDa) molecular weight molecules and more complex components, since the diffusion of such substances into the film and their accessibility to the dye are strongly restricted. All presently known recognition-based optical sensors work in two dimensions and in a non-aqueous environment. They have no possibility for analysis of complex chemical and biochemical substances, as well as enzyme activities.

The leading tendencies in the development of new generation optical recognition-based biosensors are: to increase the intensity of the specific optical signal; to decrease the intensity of the non-specific noise; to ensure the possibility for detection of water-soluble target compounds in their aqueous environment; and to increase the number of simultaneously analyzed targets in one sensor device.

What can QDs offer to biosensor evolution?

QDs have attracted much attention as one of the most promising nanotransducers that have several advantages over other known nanomaterials. Figures 6.15 and 6.16 represent two common examples for the design of QD-based sensors for detection of chemical or biochemical targets and for detection of enzyme activity.

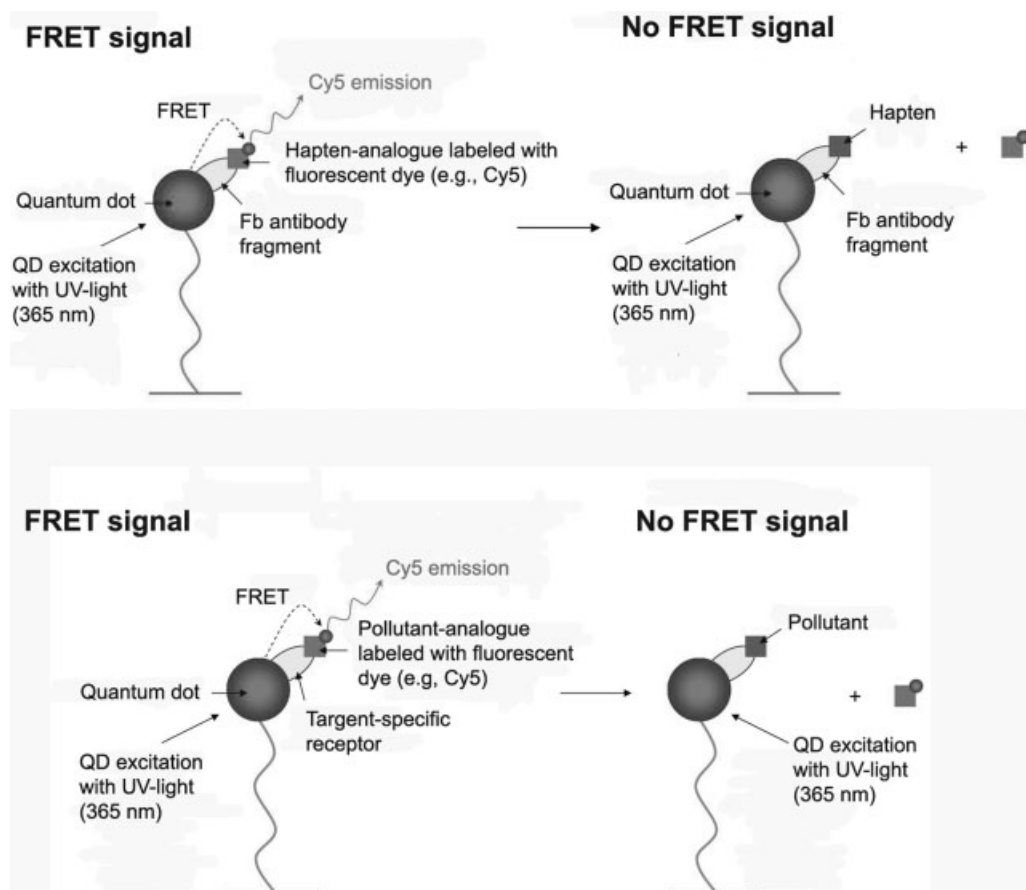

Fig. 6.15. Schemes of QD-based optical sensors for detection of more complex chemical and biochemical targets.

In the first sensor, a QD nanotransducer is conjugated with a receptor-specific for some chemical (or biochemical) target substance that has to be analyzed. The receptor is bound to target analogue, labeled with classical dye (e.g., cyanine). The analytical capacity of the sensor is based on the FRET efficiency between QD and dye. The target analogue has to be with a lower binding affinity to the receptor than the real target. Thus, it can be competitively replaced from the target, which will reflect the FRET signal in a concentration-dependent manner. In the second sensor (biosensor), a quantum dot nanotransducer is conjugated with some enzymatic substrate, e.g., double-stranded RNA (dsRNA) labeled with fluorescent quencher (e.g., black hall quencher, BHQ). The analytical capacity of this biosensor is based on the lack of fluorescence in the presence of quencher near the QD surface and the appearance of fluorescent signal if there is RNase activity leading to a

Fig. 6.16. Scheme of QD-based optical sensor for detection of enzyme activity.

fragmentation of dsRNA and removal of the quencher from the QD area. Fluorescence detection in both cases can be realized using fiber optic devices.

QD nanotransducers meet almost all requirements of the leading tendencies in the design and fabrication of new generation recognition-based optical biosensors.

Currently, only QDs manifest a large excitation/emission Stokes shift, which gives an opportunity to overcome the autofluorescence of other components in the sensor device and to minimize the noise, using filter combinations that effectively isolate the desired fluorescent signal. Moreover, the autofluorescence usually appears rapidly, while the FRET-signal appears slower and, using a time-resolved fluorimetry, it is possible additionally to increase the signal-to-noise ratio. The size-dependent multicolor coding properties of QDs render these nanoparticles as an indisputable favorite in multiplex fluorescent analyses. Thus, size-distinguished QD nanotransducers immobilized on 2D or 3D matrices will give an opportunity to develop optical sensor devices for the simultaneous detection of several targets. Presumably, it will be not necessity to separate the size-distinguished QD nanotransducers in the area of matrix platform because the unique fluorescent properties of QDs give a possibility to detect more than six fluorescent signals at the same time. Because different colors QD nanotransducers can be conjugated with different reporters, they can be functionally separated on the matrix.

Finally, the significant progress in the synthesis of highly fluorescent water-soluble QDs makes possible the fabrication of nanobiosensors for detection of biological targets and enzyme activities in their physiological environment, as well as environmental pollutants and food ingredients in aqueous solutions.

Obviously, the bridge between QD technology and fiber optic technology can open up new trends in biosensor evolution, resulting in development of ultrasensitive 3D optical sensors for multiplex detection of low, middle and high molecular weight substances, and enzyme activities, in their natural environment.

## 6.6

**Quantum Dots as New Fluorescent Standards for the Thin Calibration of Fluorescent Instrumentation**

Fluorescence-based measurements are becoming the standard for high-throughput screening technologies, sensing technologies, imaging technologies, forensic determination, genomic research, clinical diagnostics, etc. One of the critical challenges in the measurement of fluorescence is to obtain wavelength calibration. A small discrepancy in wavelength can lead to a large discrepancy in the measured fluorescence intensity. Moreover, absolute fluorescent measurements are also difficult since few fluorescent standards are available. A fluorescence standard is necessary, especially where quantification is required. At present, it is nearly impossible to quantify the fluorescence from an assay. Traditional fluorescing materials, such as organic dyes, lose their fluorescence intensity due to photodegradation and have significant disadvantages as standards. Semiconductor QDs are very promising in this application since they are typically very stable – a characteristic required for a standard. Being composed of simple inorganic compounds they are chemically relatively inert and very resistant to photochemical damage. The size-tunable fluorescent emission of QDs and the large Stokes-shift between excitation and emission give a possibility for application of QD composite materials for the thin calibration of fluorescent instrumentation.

Future efforts are being directed to the development of QD composites (consisting of QDs incorporated in transparent materials such as polymers, silica, etc.) and to applying them in fluorescent measurements – to characterize these materials and to evaluate their possible use as novel fluorescence standards for calibration of biotech instrumentation. This is the priority of all leading institutes in the field of measurements and standardization.

Fluorescent standards based on QD composites will possess the following improved characteristics in comparison with conventional fluorescent standards (based on organic dyes incorporated into transparent composite materials): a higher quantum yield (70–80% vs. 15–50% for classical standards); a higher chemical and photochemical stability; a long fluorescence life-time; a possibility for fabrication of fluorescent standards that have Stokes' shifts of several nanometers for thin calibration of the fluorescent instrumentation, which is impossible with traditional fluorescent standards.

## 7.1

### Introduction

*Escherichia coli* (*E. coli*) is a fecal coliform bacteria commonly found in the intestine of healthy humans and animals, but disease-causing pathogenic forms such as *E. coli* O157:H7 are responsible for food-borne and water-borne illness because they can rapidly produce a powerful toxin, resulting in hemorrhagic colitis or hemolytic uremic syndrome, which may lead to death, especially in children. Not only *E. coli* but also other pathogenic bacteria produce toxins (such as *Cholera*, *Salmonella*, *Pseudomonas*, etc.) and they divide in human bodies quite rapidly (doubling times are 10 to 15 min). Time, sensitivity, and accuracy of analysis are the most important limitations affecting the usefulness of microbiological methods of detection for pathogenic bacteria. Most of these microbiological detection techniques involve the binding of a non-fluorescent or fluorescent dye to the bacteria and the culturing and screening in the presence of several antibiotics for 2 to 3 days. Thus, while a specific strain is being identified, a patient may die helplessly with kidney infection from *E. coli* or *Salmonella* (from food). A quicker detection method for pathogenic strains of such bacteria is urgently needed to maintain human health around the world.

Gold-based amperometric sensors are now recognized as very promising and powerful tools in bio-fluid or biomaterial investigations and their associated clinical studies. It is expected that such sensors will not only cut down the time of detection but also guide doctors to prescribe specific drug or antibiotic therapy to save a human being without contributing unduly to the growing problem of drug resistance. In addition, subtle changes in adsorbates at electrolyte/electrode interfaces affect the AC capacitance measured in two electrode cell systems by Electrochemical Impedance Spectroscopy (EIS) and could be used to sensitively detect and distinguish any strain of bacteria present on gold surface based biosensors, provided binding specificity can be provided by a surface bound specific antibody. An understanding of the electrical polarization mechanisms in bacteria leading to the AC capacitive response and the database that catalogues this determined capac-

itance behavior of selective antibody-bound bacteria are not available. Until such knowledge is developed, EIS biosensor development will continue to proceed on a case-by-case basis, limiting progress in the next few years.

Section 7.2 of this chapter gives a detailed method for the preparation of various kinds of gold nanowires arrays (GNW), while Section 7.3 describes the method for synthesis and attachment of a linker, dithiobissuccinimidylundecanoate (DSU), to these GNW, which significantly increases the binding capacity of a specific antibody. Section 7.4 details the method of bacteria detection utilizing GNW and Electrochemical Impedance Spectroscopy (EIS). Preliminary results demonstrate the potential applications of this kind of biosensor in clinical laboratories, environmental monitoring, and the food industry to achieve rapid and sensitive detections.

## 7.2

### Template Synthesis of Gold Nano-wire Arrays for Biosensor Applications

#### 7.2.1

##### General Template Synthesis

Template synthesis is one of the ways to form nanostructured materials. The nanostructured materials are formed by confining the nucleation and growth of the material inside the ordered templates. The advantage of this method is that it can be very generally applied. Various nanostructured materials, such as conductive polymer [1–5], metals [6–11], and semiconductors [12–14], can be prepared using the same type of template. Moreover, nanostructured materials with different shapes, such as nano sized wires, rods, tubules and particles, can be prepared by controlling the growth morphology of the materials inside a template cavity [15–18]. With a two-step replication, the template nanostructure can be duplicated in most materials [19]. Template synthesis has been able to produce materials with the dimensions of only several nanometers [20, 21], which are very difficult to make by lithographic methods. Template synthesis is also suitable for mass production.

Most template syntheses reported in the literature have been accomplished by the use of a nanoporous film. To date, there are mainly two types of films: “track-etch” polymeric films and porous alumina films [22, 23]. Track-etch films are made by bombarding a polymeric material to create damaged tracks and then chemically etching these tracks into pores. These porous films are commercially available as microporous or nanoporous polymeric filtration membranes, with pore diameters ranging from 10 nm to several microns [22, 23]. The drawbacks of “track-etch” membrane are randomly distributed pores and a wide distribution of pore diameters. Porous alumina films are produced electrochemically. Masuda et al. [24–26] have reported that, under certain conditions, the pores are self-ordered. All the pores have the same diameter and are uniformly distributed across the surface. The pores are vertically aligned, perpendicular to the film surface, and hexagonally arranged. In addition, the pore diameter is adjustable by controlling the conditions

**Fig. 7.1.** Schematic illustration of the porous oxide film that grows on aluminum when it is anodized in acidic electrolytes.

of the electrochemical preparation process. A very high aspect ratio (pore length divided by the pore diameter) can be easily achieved, which is difficult to obtain by conventional lithographic techniques. Because of the regularity of the pore structure and ease of formation, the porous alumina films with pore diameters from 5 nm to more than 200 nm have been used as the template to prepare various nano-materials for applications in optoelectronic, electronic, and magnetic devices, in addition to catalysis.

The ideal structure of an anodized porous aluminum oxide film is a two-dimensional (2D) close-packed array of columnar hexagonal cells, each containing a central pore normal to the underlying metal surface and separated from it by a convex barrier-type film (Fig. 7.1). This porous  $\text{Al}_2\text{O}_3$  film is made by electrochemical anodic oxidation of aluminum in a chilled acid bath. Traditionally,  $\text{Al}_2\text{O}_3$  film is prepared to protect the metal against corrosion and to improve its abrasion and adsorption properties. The more recent and rapidly growing applications of porous anodic alumina in nano material synthesis are due to the self-assembled and well-controllable pore structure, high throughput, and low cost compared with conventional lithographic (electron beam, focused ion beam, X-ray, STM/AFM, etc.) techniques.

Anodic processes consist of the oxidation of metals and the formation of a hard oxide film, the partial dissolution of metals in the electrolyte, and the evolution of gaseous oxygen at the anode. The applied electric field sustains a continued growth of the film by causing metal ions and oxygen ions to be pulled through the growing film in opposite directions.

More than 40 years ago, Hoar and Mott [27] first proposed their field-assisted dissolution model to explain the pore initiation and growth phenomena. This electric field-assisted dissolution theory has been widely accepted since then to explain the steady-state growth of the pores [1, 28, 29]. This theory showed that pore growth is balanced by field-assisted dissolution at the bottom of the advancing pore, whose rate is determined by the local field and by the radius of curvature of

the pore base. Therefore, the applied voltage is the most important factor that affects the formation and growth of the pores. Both pore diameter and pore spacing depend on the cell voltage. Other factors, such as pH and acid aggressiveness, also affect the oxide formation. The ratio of pore diameter to pore separation is found to be independent of voltage but varies with the pH of the electrolyte and at pH higher than 1.77 a nonporous oxide film forms [26]. Relatively non-aggressive electrolytes promote thicker barrier layers, larger cells and larger pores than aggressive electrolytes under constant current density conditions. The acid aggressiveness decreases in the order of sulfuric acid > oxalic acid > phosphoric acid. In sulfuric acid, pore sizes of 15–20 nm are usually formed; while in oxalic acid and phosphoric acid 40–60 nm pores and 120–180 nm pores respectively, are more commonly found.

The reason for the self-organization of the pores is still not very clear. The driving force could be the lateral component of the electrical field at the pore bottom curvature and also, could be the mechanical stress or thermal effects [26, 28, 30]. It is generally agreed that long anodization time and low anodization temperature improve the ordering of the pores. For different acids, the best ordering occurs in different potential regions. The experimental results of Masuda et al. showed that a well-ordered hexagonally arranged pore structure was accomplished with anodization in 0.5 M  $\text{H}_2\text{SO}_4$  at 25 V, or in 0.3 M oxalic acid at 40 V, or in 0.3 M  $\text{H}_3\text{PO}_4$  at 195 V [24, 25, 31]. However, very long-period anodizations, from 16 to 160 h, were used to achieve the best ordering.

The initial surface structure of the metal plays an important role in the pore initiation mechanism [28, 32]. Yue has shown that pores would preferentially nucleate at the bottom of depressions in electropolished aluminum surfaces or at defective sites, such as grain boundaries or cracks [33]. Therefore, improved ordering of the pore structure can be, possibly, obtained in a shorter time by introducing designed “preferred sites” to facilitate the nucleation of pores in a desired way. For example, an almost defect-free porous structure has been achieved by using a SiC stamp with a hexagonally ordered array of convexes to pre-texture the aluminum surface [24]. Two-step anodization can also achieve a better ordering and form well-ordered pores with a very short aspect ratio [19]. A long-term anodization in the first step generates a well-organized porous structure at the pore bottom. After complete removal of the anodic oxide film prepared in the first step by dissolution in the mixture of chromic acid and phosphoric acid, a highly ordered array of dimples remains on the surface of aluminum metal that becomes the pore initiation sites in the second anodization step. However, the overall preparation time is still long.

Previous work has determined that the electrochemically polished aluminum surface can exhibit a very regular pattern of aligned stripes or hexagonal arranged dots, depending on the time of the electropolishing and the voltage applied [33–39]. The patterns are attributed to preferential adsorption of organic molecules on the convex portion of the electrode due to its locally enhanced electric field [39]. The wavelength of the pattern increases monotonically with the applied voltage and also depends on the effective electrolyte polarizability. When the electrochemi-

cally polished patterned surface with the right wavelength has been used for anodization, a well-organized nano-porous oxide structure was formed in a very short time. Therefore, highly ordered nano-porous aluminum oxide template can be fabricated rapidly.

### 7.2.2

#### Template Formation

The porous alumina template was fabricated using 99.999% 0.1 mm thick aluminum foil (Alfa Aesar, Ward Hill, MA). The foil was annealed in nitrogen at 500 °C for 3 h before electropolishing at 40–42 V DC for 60 s in a LECO electropolishing tank EP-50 (LECO Corporation, St. Joseph, MI) with an electrolyte consisting of 70.0 vol.% of ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ), 13.8 vol.% distilled water, 10.0 vol.% butyl cellosolve ( $\text{CH}_3(\text{CH}_2)_3\text{OCH}_2\text{CH}_2\text{OH}$ ), and 6.2 vol.% perchloric acid ( $\text{HClO}_4$ ). The electropolishing temperature was 10 °C, controlled by a Julabo® FP30 refrigerated circulating bath (Julabo USA Inc., Allentown, PA). Anodization was performed in 0.3 M oxalic acid (pH 1.6) at a constant voltage of 40 V and 3 °C for 10 min. The reaction was executed in a jacketed glass reactor with vigorous agitation. The anodization process was controlled by a digital acquisition system running a custom LabVIEW® program that logged the anodization current and controlled the applied voltage at a preset level. After anodization, the foil was immersed in 5% (by weight) phosphoric acid (pH 1) with moderate stirring for 45 min to round the pores.

Field emission scanning electron microscopy (SEM, Hitachi, Model S4500) was used to observe the anodized alumina membranes and the nano-structured gold arrays. Atomic force microscope images were taken by a tapping mode atomic force microscope (AFM, Model Dimension 3100, Veeco Instruments, Woodbury, NY). X-Ray diffraction patterns were obtained using Cu  $K\alpha$  radiation (wavelength = 1.5405 Å) on a Scintag X-ray diffractometer (Scintag Inc., Cupertino, CA).

Figure 7.2 shows a typical anodization curve of aluminum in 0.3 M oxalic acid at 40 V, 3 °C. The curve can be divided into three regions. In region I, the current density surges to a very high value in a very short time, representing the barrier oxide layer formation. Once the barrier oxide layer forms, the current starts to drop because of the lower mass transport through the oxide layer. After the current reaches a minimum, it increases again in region II, where pore nucleation occurs. Region III is the pore growth and self-adjustment region in which the dissolution of the aluminum metal and the oxide formation have the same rate.

The ordering near the pore bottom (pore advancing front) was observed to be better than that near the pore opening because of a longer self-adjustment time. Figure 7.3(a) and (b) are SEM images viewed from the top and bottom of a porous alumina film anodized in 0.3 M oxalic acid at 3 °C, 40 V for 16 h. At the pore bottom, the cells have an almost perfect hexagonal shape and uniform size. The average distance from the center of the cell to the center of the neighboring cell is 100 nm, which is also shown in the magnified cross-section image (Fig. 7.3(d)). Al-

Fig. 7.2. Dependence of anodization current on time for aluminum anodized in 0.3 M oxalic acid at 40 V and 3 °C.

though there are still a couple of defect sites, the ordering at the pore advancing front is much better than that at the pore opening.

Figure 7.4 demonstrates the impact of the initial surface structure of the aluminum metal on the pore ordering of the template. One of the electropolishing patterns containing regular stripes of wavelength of 102 nm was observed when the aluminum foil was electropolished at 41 V, 10 °C for 60 s (Fig. 7.4a). Actually, at this voltage the electropolishing pattern is at the transition from regular stripes to regular hexagons [39]. The onset of the breakdown of the stripes to dots was observed. When this pre-patterned sample was anodized, the prior electropolishing pattern impacted the initial pore nucleation and hence the final pore ordering. Figure 7.4(b) shows one sample anodized in 0.3 M oxalic acid at 40 V, 3 °C for 5 min. The pores are aligned along parallel lines, and the average distance from line to line is about 100 nm, indicating that the pores are preferentially initiated along the valleys of the stripe pattern obtained from electropolishing. For comparison, Fig. 7.4(c) is the porous structure obtained when the aluminum was not electropolished.

The templates discussed here were produced without electropolishing since array order was not important. The aluminum foil was anodized for 10 min in 0.3 M oxalic acid at 3 °C. The pores were then widened and rounded in 5 wt.%  $\text{H}_3\text{PO}_4$  for 45 min. Figure 7.4(c) shows a typical SEM image of an anodized oxide film. The average pore diameter is 65 nm with a standard deviation of 4.3 nm and the separation is 95 nm with a standard deviation of 6.2 nm. The porosity is 43% and the pore density is  $1.4 \times 10^{10} \text{ cm}^{-2}$ . To determine the anodization rate, the thicknesses of the oxide layers were measured by SEM after the aluminum metal was removed in saturated  $\text{HgCl}_2$  solution. The anodized aluminum oxide film was

**Fig. 7.3.** SEM images of an alumina oxide film, anodized in 0.3 M oxalic acid at 40 V, 3 °C for 16 h. (a) View from the top of the oxide film; (b) from the bottom side of the oxide film; (c) a cross-section image that shows that the oxide layer is 37 μm thick; and (d) a higher magnification image of the cross-section, showing the parallel columnar pores.

about 2.5 μm thick for 60-min anodization, 5.3 μm thick for 120-min anodization and 37 μm for 16-h anodization. The calculated average growth rate is about 42 nm min<sup>-1</sup>. Therefore, the estimated pore depth for 10-min anodization is around 420 nm.

### 7.2.3

#### Fabrication of Gold Nano-wire Arrays (GNW)

Gold nanowire arrays were formed by a two-step deposition procedure, which consisted of electrochemical deposition and electroless plating. Electrodeposition was carried out in a CEC/TH electrochemical cell (Radiometer Analytical, Loveland, CO) with a platinum disc counter electrode. The electrolyte was H<sub>2</sub>AuCl<sub>4</sub>·3H<sub>2</sub>O (1 g L<sup>-1</sup>; ACS reagent grade, ICN Biomedicals Inc., Aurora, OH) + H<sub>2</sub>SO<sub>4</sub> (7 g L<sup>-1</sup>). An AC voltage of frequency 60 Hz and RMS amplitude of 15 V was applied at room temperature for 1 min. The electrochemical deposition was used to drive gold ions down to the bottom of the pores and form gold metal nuclei. Electroless

**Fig. 7.4.** (a) AFM image of an aluminum surface electropolished for 60 s at 41 V, 10 °C. A regular striped structure developed. (b, c) Porous alumina oxide formed at 40 V, 3 °C in 0.3 M oxalic acid for 5 min: (b) after electropolishing and (c) without electropolishing.

deposition was used to grow gold nanowires. Electroless deposition used a commercial Neorum TWB gold plating solution (Uyemura International Corporation, Ontario, CA). For the best plating speed and quality, the deposition temperature was controlled in the range of 68–72 °C. No stirring of the solution was supplied.

Two types of gold nanowire arrays were prepared by this template synthesis method. The experimental procedure is described schematically in Fig. 7.5. The first type of structure was formed by filling the pores, so that gold was deposited just to the top of the porous alumina template surface (Fig. 7.5(a)). The gold nanowires were still embedded in the oxide template and separated from the Al metal by a 3-nm thick oxide barrier, with the tips of the wires sticking out to interact with biomolecules for later biosensor applications. The second type of surface was made by a 2.5–3 h electroless plating of gold. After the pores of the template were com-

**Fig. 7.5.** Schematic view of the procedure for preparing gold nanowire (GNW) arrays, (a) embedded in the aluminum oxide template (GNW-Al<sub>2</sub>O<sub>3</sub>) and (b) free-standing (GNW).

pletely filled with gold, gold was plated onto the top surface of the oxide template. Before use, both the oxide template and the underlying unanodized aluminum metal were removed by immersing the sample in 1.5 M NaOH at 40 °C. After the dissolution, the overplated thin (~5 μm) gold film was left with gold nanowires protruding from the surface like the bristles of a brush (Fig. 7.5b).

For the application of biosensors, the substrate materials should be compatible with and have a good affinity for biological molecules and should also be stable in air or aqueous solution for reliable measurements. Gold is a good candidate for this purpose. Gold has good affinity to biomolecules – functional groups such as thiol (–SH) or amine (–NH<sub>2</sub>) can chemically adsorb onto the gold surface. The bonds are strong enough to survive measurements in flowing liquids and even in a vacuum.

There are two common ways to electroplate metals inside the pores. The first is to electrodeposit metal from a metal ion solution by AC current. Alternating current was needed to deposit metal inside the pores because of the rectifying nature of the Al metal/oxide junction [9, 40, 41]. Another approach is to remove the aluminum metal and etch through the barrier layer of the oxide to get a through-hole oxide membrane. Then a thin layer of metal is evaporated onto one side of the oxide as the cathode, so electrodeposition by DC current can be carried out. Electroless plating has a distinct advantage over electroplating in its capability to coat a surface that is not electronically conductive, such as aluminum oxide. Martin et al.

also discovered that electroless plating allowed for more uniform gold deposition than electrochemical plating [18]. Therefore, a commercial electroless gold plating bath was chosen to grow the gold wires inside the aluminum oxide template. This plating solution is a non-cyanide solution and works at a neutral pH. Most of the conventional electroless gold plating baths are strongly alkaline [42]. However, alumina is only stable in the pH range between 4 and 9. When the pH is above 9,  $\text{Al}_2\text{O}_3$  can be dissolved and form aluminate ion ( $\text{AlO}_2^-$ ). Thereby the porous structure can be damaged.

The basic components of an electroless plating solution are a gold salt ( $\text{Au}^{z+}$ ) and a reducing agent ( $\text{Red}_{\text{solution}}$ ). This reducing agent will reduce gold ion to gold metal ( $\text{Au}_{\text{lattice}}$ ) and form an oxidized species in the solution ( $\text{Ox}_{\text{solution}}$ ) when a catalytic surface is present. The overall reaction is:

Without a catalyst, this reaction is extremely slow and, therefore, prevents gold formation in the solution. A non-catalytic surface to be plated must be activated by generating catalytic metal nuclei on the surface to obtain a practical plating rate. The catalyst metal may be any of Pd, Pt, Au, Ag, or Cu. In this work, gold seeds were put down as the catalytic sites. The deposition of gold seeds was realized by AC electrodeposition. The locally enhanced electric field will drive the metal ions down to the pore bottom and form nuclei there [43]. Gold wires were then grown on these catalytic sites by electroless plating. The length of the wires can be simply controlled by the plating time.

Figure 7.6 is the top view SEM image of an alumina membrane with gold inside the pores. The time used for electrodeposition was 1 min and for electroless deposition it was 5 min. Since the electrodeposition solution was acidic (pH 2), containing  $\text{H}_2\text{SO}_4$ , prolonged immersion in this solution with an AC voltage applied may damage the template; consequently, the electrochemical deposition was performed

Fig. 7.6. SEM image of an aluminum oxide template with gold deposited inside the pores.

for no longer than 1 min. Notably, not all the pores are filled with gold. This is probably due to the low frequency (60 Hz) of the AC voltage applied. The filling percentage increases as the frequency increased from 100 to 750 Hz for electro-deposition of Ni and Bi inside the pores of alumina films [44]. This is because more nuclei are formed at higher frequencies, promoting the deposition better. This is similar to pulse plating, which has more “throwing” power to facilitate the filling of the pores. However, a lower frequency may be preferred if a uniform growth of the wires is required [45].

Because only the gold nuclei at the pore bottoms produced by electrodeposition were catalytic sites for the electroless plating, gold was only plated inside the pores and not on the top of the oxide layer. After the pores were completely filled with gold, gold began to plate on top of the oxide film. It was found experimentally that the time needed for electroless plating to fill the pore (the average length is  $\sim 420$  nm) was about 5 min, when the temperature of the electroless plating bath was controlled between 68 and 72 °C. Owing to the special optical properties of nano-sized metal-oxide composite, the color of the gold-alumina composite changes depending on the aspect ratio of the gold wire inside the oxide [46–51]. This phenomenon was also observed in this research in that the gold-alumina changed from purple to dark blue, then green and yellow during the filling of the pores (65 nm in diameter, 420 nm long) of the oxide layer with gold.

Figure 7.7(a) and (b) shows top-view SEM images of the free-standing gold nanowires at lower and higher magnifications respectively, after the dissolution of both the alumina and the residual aluminum metal. The electroless plating was carried out for 2.5 to 3 h, resulting in an overplated gold film of about 5  $\mu\text{m}$  thick. The wires stood on this overplated gold film. According to the SEM images, the average diameter of the wire is 62 nm with a standard deviation of 6.4 nm, and the distance from the center of the wire to the center of the neighboring wire is 93 nm, with a standard deviation of 7.5 nm. This is consistent with the pore size and the inter-pore distance of the template. Notably, in Fig. 7.7(a), some gold nanowires are

Fig. 7.7. SEM images of the top view of gold nanowires. Magnifications: (a) 60k $\times$ . (b) 300k $\times$ .

**Fig. 7.8.** X-ray diffraction patterns of (a) gold nanowires embedded in a porous alumina template; (b) an electrolessly plated gold film ( $\sim 5 \mu\text{m}$  thick), and (c) free-standing gold nanowire arrays on top of the electrolessly plated gold film. The average length of the wire is about 420 nm.

lying down in two regions. They were deformed intentionally with tweezers in an attempt to measure the length of the wires.

Figure 7.8(a) shows an X-ray diffraction pattern of the gold nanowire arrays inside the alumina template. There is only one peak, at about  $2\theta = 44^\circ$ , which represents the Au(200) crystal plane. No  $\text{Al}_2\text{O}_3$  peaks appeared at this scale, indicating the oxide was probably amorphous. The X-ray diffraction pattern of the electrolessly plated gold film is shown as pattern (b) in Fig. 7.8. The peaks corresponding to Au(111), Au(200), Au(220), Au(311), and Au(222) crystal planes appeared, meaning that this electroless-plated gold film is polycrystalline with a face-centered cubic crystal structure. When the sample with free-standing gold nanowire arrays on top of the electrolessly plated gold film was scanned, again all the gold peaks appeared (pattern (c) in Fig. 7.8). This X-ray diffraction pattern is not only the diffraction pattern of the gold wires but may also have a contribution from the underlying electrolessly overplated gold film.

In this work, nanogold wire arrays were formed based on a template synthesis method. The template was a nano-porous aluminum oxide membrane produced by electrochemical anodization in 0.3 M oxalic acid. Gold nanowires were grown by filling the pores of the template by electrochemical plating and electroless plating. The gold nanowires could either be embedded in the oxide matrix or be free-standing on a thin gold film. The average diameter of the wire was 62 nm, which is consistent with the size of the pores. The wire could be as long as the depth of the pore or shorter, depending on the deposition time.

Gold has selective affinity to some functional groups, such as amine ( $-\text{NH}_2$ ) and thiol ( $-\text{SH}$ ). These functional groups exist extensively in bio-entities, such as enzymes and antibodies, which are common bio-sensing elements for the detection of a particular bio-reaction or bio-interaction. Both kinds of nano-structured gold

surfaces fabricated in this work, including the free-standing gold nanowires and the gold nanowire arrays embedded inside the porous alumina template, could be the substrates for sensor applications. Electrochemical and optical transducers can be applied. The free-standing gold nanowire arrays have a large surface area, which improves the binding capacity of bio-sensing molecules or electrochemically active species; and enhances the reaction current and double-layer charging capacitance that can be detected with electrochemical methods, such as chronoamperometry or impedance spectroscopy. Complete sealing of the cylindrical surface of the gold nanowires inside the aluminum oxide template, with only the end disk-shaped electrode exposed to the electrolyte, enables detection by electrochemical methods, such as cyclic voltammetry, because of the reduced charging current and the enhanced signal-to-noise ratio [18, 52]. The special optical properties of this nano-structured metal-oxide composite may also find use in optical sensors [49, 51].

### 7.3

#### Synthesis of a Linker and its Attachment to Gold Posts of GNW followed by Binding to Specific Antibodies

Figure 7.9 gives the synthesis of DSU [53]. In the first reaction, 11-bromoundecanoic acid (1) was added to  $\text{Na}_2\text{S}_2\text{O}_3$  in 50% aqueous 1,4-dioxane and

Fig. 7.9. Synthesis of the dithio-bissuccinimidylundecanoate (DSU) linker.

Fig. 7.10. Structures of the surfaces investigated.

refluxed for 2 h at 90 °C to yield the Bunte Salt (2). Oxidation to the disulfide was carried out by adding  $I_2$ . Surplus  $I_2$  was retitrated with 15% aqueous sodium pyrosulfite. The 1,4-dioxane solvent was removed by rotary evaporation and the suspension was filtered to yield dithio-bis(undecanoic acid) (3). Purification was achieved by recrystallization from ethyl acetate/THF(1:1). *N*-Hydroxysuccinimide (NHSA) was added to a solution of (3) in MeOH, followed by the addition of dicyclohexylcarbodiimide (DCC) at 0 °C. The reaction mixture was cooled to 25 °C and stirred for 36 h. MeOH was removed by rotary evaporation, and the product was resuspended in THF and filtered off. The crude final product (4) was purified by recrystallization from 1:1 acetone/hexane, and by silicic acid column chromatography to yield DSU (4). All intermediates were characterized by IR spectroscopy.

Initial studies were carried out using various amounts of (Goat PAb)<sub>*E. coli*</sub> to determine the degrees of direct binding to the gold plate. Competition studies were carried out among three kinds of testing surfaces (as shown in Fig. 7.10): (I) flat gold disc (FGD), (II) free-standing gold nanowire array (GNW), and (III) gold nanowire array surrounded by  $Al_2O_3$  (GNW- $Al_2O_3$ ), to determine which had the higher affinity for antibody binding. The flat gold surface (structure I) was prepared by electron beam evaporation of gold on a Si(100) n-type wafer under a vacuum of about  $1 \times 10^{-6}$  Torr. The deposition speed was around  $10 \text{ \AA s}^{-1}$ . The gold layer was 200 nm thick.

The DSU linker was applied to the surface to covalently immobilize the antibodies. Covalent immobilization of (Goat Pab)<sub>*E. coli*</sub> was accomplished by immersing the gold discs in 1500  $\mu\text{L}$  of a 1 mM DSU in MeOH solution for 30 min at room temperature [54]. After rinsing with MeOH (7 mL), the *N*-hydroxysuccinimide (NHS) terminated monolayers were dried under a stream of nitrogen gas and immediately used for immobilization of *E. coli* antibodies. Figure 7.11 depicts the self-assembly of DSU to form self-assembled monolayers (SAM) on the gold surface. Covalent immobilization takes place when a lysine residue of the antibody comes into contact with the DSU SAM to nucleophilically attack the carbonyl carbon, thereby displacing the *N*-hydroxysuccinimide to form an amide linkage (Fig. 7.12). Covalent immobilization of antibodies via SAM (Fig. 7.12) is desirable because of the tendency to increase the binding capacity of the gold surface for the antibody. This is predicted because the linker has a long carbon chain, protruding directly up from the plate, that can freely rotate in space. This creates a more steri-

**Fig. 7.11.** Formation of self-assembled monolayers with the dithio-bissuccinimidylundecanoate (DSU) linker.

cally favorable condition for the antibodies to bind to monolayers because there is less chance of antibody crowding, whereas when antibodies are directly bound to the gold nanowire surfaces without the SAM there may be crowding on the gold surface that decreases the binding capacity.

Studies of the influence of the linker on antibody binding were also carried out among the same set of three surface types.

**Fig. 7.12.** Covalent immobilization of antibodies via a DSU self-assembled monolayer.

Fig. 7.13. Schematic representation of antibody binding detection by the ELISA sandwich assay.

The binding of anti-*E. coli* antibody was determined optically by enzyme-linked immunosorbent assay (ELISA). Alkaline-phosphatase-conjugated second antibody (rabbit anti-goat IgG) was added to the gold discs after washing off unbound first antibody. The anti-*E. coli* antibody binding to the gold substrates was then quantitated optically by measuring the hydrolysis of *p*-NO<sub>2</sub>-phenylphosphates (Fig. 7.13). Tables 7.1–7.3 give the ELISA results.

From the data it was determined that, without linker, the gold surface with Al<sub>2</sub>O<sub>3</sub> (GNW-Al<sub>2</sub>O<sub>3</sub>) bound the antibodies more efficiently than the gold nanowires (GNW), although gold nanowires have a huge surface area (e.g., GNW-1 vs. GNW-Al<sub>2</sub>O<sub>3</sub>-1). It was inferred that the antibodies are not able to fit completely inside the crevices or between the wires, thereby decreasing the binding capacity. For the surface with Al<sub>2</sub>O<sub>3</sub>, it was hypothesized that the antibodies may be binding to the Al<sub>2</sub>O<sub>3</sub> as well as the Au.

Tab. 7.1. Relative affinity of (Goat PAb)*E. coli* to flat gold discs (FGD) with and without DSU linker.

	1 mM DSU (μL)	1 <sup>st</sup> antibody (μg)	2 <sup>nd</sup> antibody (μg)	O.D. <sub>405 nm</sub>
FGD-1	–	5	6	0.144
FGD-2	–	10	12	0.337
FGD-3	1500	5	6	0.224
FGD-4	1500	10	12	0.510
FGD-5	–	–	6	blank

**Tab. 7.2.** Relative affinity of (Goat PAb)*E. coli* to a gold nanowire array (GNW) with and without DSU linker.

	1 mM DSU ( $\mu\text{L}$ )	1 <sup>st</sup> antibody ( $\mu\text{g}$ )	2 <sup>nd</sup> antibody ( $\mu\text{g}$ )	O.D. <sub>405 nm</sub>
GNW-1	–	5	6	0.127
GNW-2	–	10	12	0.204
GNW-3	1500	5	6	0.648
GNW-4	1500	10	12	0.652
GNW-5	–	–	6	blank

**Tab. 7.3.** Relative affinity of (Goat PAb)*E. coli* to gold nanowire array embedded in Al<sub>2</sub>O<sub>3</sub> (GNW-Al<sub>2</sub>O<sub>3</sub>) with and without DSU linker.

	DSU 1 mM ( $\mu\text{L}$ )	1 <sup>st</sup> antibody ( $\mu\text{g}$ )	2 <sup>nd</sup> antibody ( $\mu\text{g}$ )	O.D. <sub>405 nm</sub>
GNW-Al <sub>2</sub> O <sub>3</sub> -1	–	5	6	0.192
GNW-Al <sub>2</sub> O <sub>3</sub> -2	–	10	12	0.354
GNW-Al <sub>2</sub> O <sub>3</sub> -3	1500	5	6	0.257
GNW-Al <sub>2</sub> O <sub>3</sub> -4	1500	10	12	0.590
GNW-Al <sub>2</sub> O <sub>3</sub> -5	–	–	6	blank

It was determined that the linker greatly enhances antibody binding for the free-standing gold nanowire surfaces (GNW) (e.g., GNW-3 vs. GNW-1). The presence of the linker also enhances antibody binding for the GNW-Al<sub>2</sub>O<sub>3</sub> surfaces (e.g., GNW-Al<sub>2</sub>O<sub>3</sub>-3 vs. GNW-Al<sub>2</sub>O<sub>3</sub>-1). However, the increase in antibody binding is not as great as it was for the gold nanowire surfaces (GNW-3 vs. GNW-Al<sub>2</sub>O<sub>3</sub>-3). For flat gold surfaces, DSU linker also enhances the antibody binding, but the effect is not as great as GNW and GNW-Al<sub>2</sub>O<sub>3</sub> surfaces. This may be because the flat surface does not have the crevice characteristic and, therefore, exhibits a lower binding capacity for antibodies than other kinds of surfaces.

## 7.4

### Development of Electrochemical Nano-biosensor for Bacteria Detection

#### 7.4.1

##### General Detections for Biosensors

Biosensors have attracted considerable attention and have found extensive applications. However, although there is an extensive literature on various combinations

of biological recognition elements and transducers in biosensor configurations, the conventional biosensors generally lack the combination of high-speed detection, high specific sensitivity and the ability to be integrated into a miniaturized sensor [55]. Therefore, in recent years, intensive research has been undertaken to develop the technology of portable, selective and sensitive biosensors capable of immediate results [56, 57]. The development of biosensors in this work was based on electrochemical impedance measurements on nanostructured substrates, with the aim of increasing the sensitivity, and decreasing the response time and the size of the device.

Among various transducers, electrochemical transduction strategies have distinct advantages in that they offer a much higher sensitivity and a simple, fast detection procedure. Owing to the capability of the measurement of nano- or pico-ampere current by conventional instruments, the pretreatment steps, such as separation and pre-enrichment, are no longer necessary. In addition, the equipment required for electrochemical analyses are simple and inexpensive as compared with most other analytical techniques. Furthermore, electrochemical techniques are more suitable for miniaturization, circuit integration and continuous electrical controls. With the development of microelectronics, the integrated circuit industry, nanotechnology and microfluidics, electrochemical transducers could be one of the most promising candidates for future sensor development.

Electrochemical impedance spectroscopy (EIS) was chosen as the main detection method because it is a very sensitive method that facilitates the direct measurement of the antigen–antibody interaction. This method does not require the presence of tags, such as redox probes, fluorophores, dyes or radioactive species, for the detection. This greatly simplifies the detection procedures. Moreover, EIS measurements require only a very small voltage (which is usually less than 20 mV) to be applied to the system. This small voltage applied is beneficial not only because it allows a complicated nonlinear problem to be simplified into a pseudo-linear problem during the analysis, but also because it is less destructive to the biological properties of the biomolecules, such as the activities of enzymes and antibodies, minimizing the impact on the sensitivity, stability and reliability of biosensors employing EIS.

Figure 7.14 depicts a model of the nano-biosensor. The nano-structured substrate, with biological recognition components immobilized, was the working electrode. The nano-structured substrates were gold nanowire arrays, which were fabricated as described in Section 7.2. To detect a specific type of bacteria, the biological recognition component was a bacteria-specific antibody. To enhance the binding strength and capacity, the specific antibody was covalently bound onto the gold surface through an organic “linker” molecule (Section 7.3). *Escherichia coli* (*E. coli*) was the target analyte for this sensor prototype. The reaction scheme at the electrode surface includes: (a) assembling the linker onto the gold substrates; (b) covalent binding of the anti *E. coli* antibody onto the linker; and (c) tethering of the target *E. coli* antigen. The voltage and current signals were recorded when the analyte interacted with the biological recognition component. This study was carried out using both the nano-structured gold substrates and the conventional

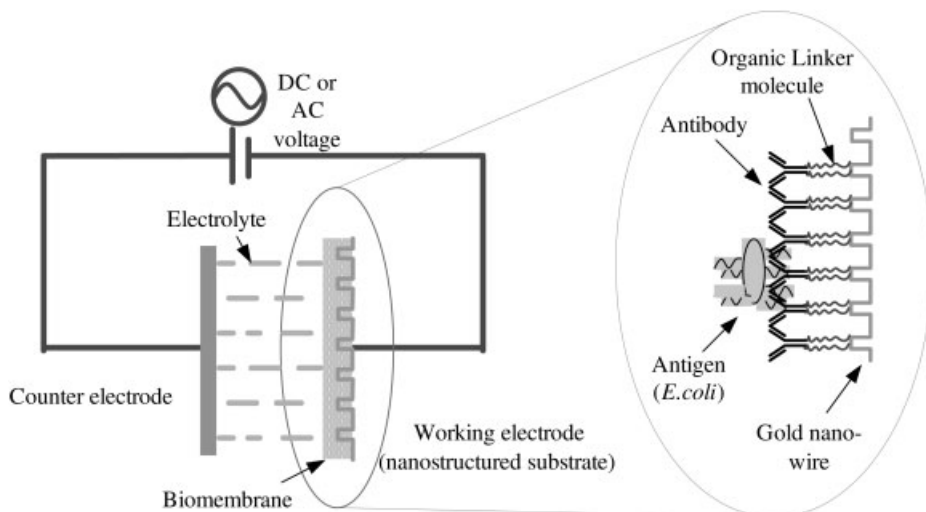

Fig. 7.14. Biosensor model for the detection of *E. coli* bacteria.

e-beam evaporated planar gold substrate. The effect of the nano-scale structure of the substrate on the detection sensitivity was investigated. Optimization of the dimension of the nano-structured gold substrates is expected in the future.

#### 7.4.2

##### Experimental Conditions

*E. coli* antigen was cultured in the Department of Chemical and Biomolecular Engineering at the University of Notre Dame from the strain – ATCC #11775 (American Type Culture Collection, Manassas, VA). The bacteria were suspended in a 0.01 M phosphate saline buffer. The number of bacteria was counted during culturing after serial dilution using an optical microscope.

The antibody used was polyclonal goat anti *E. coli* antibody (catalog # 1091) from ViroStat (Portland, Maine). The concentration of the antibody was  $0.4 \mu\text{g } \mu\text{L}^{-1}$ . Dithio-bissuccinimidylundecanoate (DSU) was synthesized as described in Section 7.3. It was used to covalently link the antibody onto the gold substrate. Thus, it is also called the “linker”. The final concentration of DSU was 1 mM, dissolved in methanol.

All electrochemical measurements were performed using a Gamry FAS1 potentiostat (Gamry Instruments, Warminster, PA). Electrochemical impedance spectroscopy (EIS) was performed in the frequency range  $10^{-2}$ – $10^5$  Hz at an amplitude of 10 mV (RMS) around the open circuit potential. A three-electrode electrochemical cell was used. The reference electrode was a saturated calomel electrode (SCE) and the counter electrode was a platinum disk. The exposed geometric surface area of the working electrode was  $0.2 \text{ cm}^2$ , defined by a silicone rubber washer.

All measurements were performed in 0.01 M phosphate buffer saline (PBS buffer) solution (Sigma, St. Louis, MO), which has a pH of 7.4 at 25 °C. All dilutions were made using Millipore [Millipore, Bedford, MA (18 M $\Omega$ )] water.

Three kinds of surfaces with the same geometric area have been studied for comparison. They are (I) vacuum evaporated gold on Si wafer (FGD); (II) free-standing gold nanowire array (GNW), and (III) gold nanowire array distributed inside the pores of the anodized alumina template (GNW with Al<sub>2</sub>O<sub>3</sub>). Figure 7.10 depicts the structures of the substrates.

The general biomolecule immobilization steps were as follows. First 1 mM DSU (20  $\mu$ L) was added to the substrate. The sample was rested at room temperature for 30 min, followed by washing in methanol. After the sample was dried under an air stream, antibody (10  $\mu$ L, 0.4  $\mu$ g  $\mu$ L<sup>-1</sup>) was added and the sample was rested at room temperature for 2 h to let the antibody interact with the DSU linker. The sample was kept wet by sealing in a glass bottle. If needed, another 10  $\mu$ L of PBS buffer was added to the sample after 1 h. The sample was then rinsed with PBS buffer to remove the loosely bound antibodies. *E. coli* bacteria were added in units from 10 to 25  $\mu$ L, depending on the final surface concentration of bacteria desired and the *E. coli* concentration of the stock solution used. After adding the bacteria, the sample was rested for another 1.5 to 2 h at room temperature to let the antigens attach to the antibodies. Finally, the sample was rinsed with PBS buffer before the electrochemical measurements.

### 7.4.3

#### Electrochemical Impedance (EIS) Detection of *E. coli*

The detection of the *E. coli* antigen was investigated by sequentially adding a certain number of *E. coli* cell onto the antibody/linker coated substrates.

The EIS data can be analyzed by an equivalent circuit model [58, 59]. However, for this *E. coli* sensor device, the equivalent circuit model analysis could be very complicated because:

- There are three layers of molecules that have been immobilized on the surface: linker, antibody and antigen. Each layer may not be completely loaded. Also, in every layer, either the organic linker or the bioentities may be immobilized at different orientations, which also results a nonuniform biomembrane.
- The substrates studied have nanostructured surfaces. These nanostructures can cause an inhomogeneous current distribution along the surface and disturb the double-layer structure.
- There is an electrostatic force between the biomolecules, which changes the polarizability of the system and influences the impedance measurements.

Therefore, this biosensor study used a simplified circuit model that contained only an overall resistance and an overall capacitance connected serially.

It was assumed that the binding of the biomolecules causes the capacitance to change and the measured imaginary part of the impedance comes mainly from

the capacitive behavior of the biomembrane. Therefore, the number of *E. coli* on the surface can be approximately determined from the system capacitance value. This overall capacitance can be calculated by the Eq. (1):

$$C = 1/[2\pi f|Z_{\text{imag}}|] \quad (1)$$

where  $|Z_{\text{imag}}|$  is the magnitude of the imaginary part of the impedance, in ohms,  $f$  is frequency in Hz, and  $C$  is capacitance in farads. Equation (1) can also be rewritten as

$$|Z_{\text{imag}}| = \frac{1}{C}\omega^{-1} \quad (2)$$

where  $\omega^{-1} = 1/2\pi f$ , in  $\text{rad}^{-1} \text{ s}$ . Therefore the capacitance  $C$  can be obtained as the inverse slope of a plot of the imaginary impedance  $Z_{\text{imag}}$  against the reciprocal frequency for the low frequency data.

#### 7.4.3.1 EIS on Flat Gold Surfaces

Figures 6.15 and 6.16 are representative EIS results on an enzyme-coated flat gold electrode with different numbers of *E. coli* bacteria attached. Figure 6.15 is the Nyquist plot. Figure 7.16 is the same result plotted as the imaginary part vs. the frequency.

The capacitances can be calculated by the reciprocal slops of  $|Z_{\text{imag}}|$  vs.  $\omega^{-1}$  (Fig. 7.17a). If the capacitance of the electrode with linker and antibody,  $4.3 \mu\text{F}$ , is

**Fig. 7.15.** Electrochemical impedance spectroscopy (EIS) on a flat gold surface with different amounts of *E. coli* bacteria attached (Nyquist plot).

Fig. 7.16. EIS on a flat gold surface with different amounts of *E. coli* bacteria attached ( $-Z_{imag}$  vs. frequency).

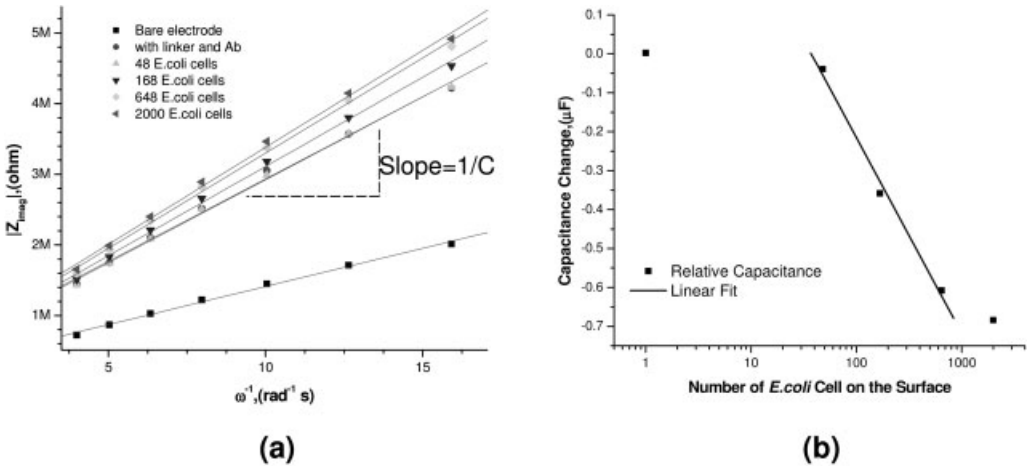

Fig. 7.17. (a)  $|Z_{imag}|$  vs.  $\omega^{-1}$ , and (b) relative capacitance change vs. the number of *E. coli* (log scale) on a flat gold electrode.

Fig. 7.18. EIS on GNW with different amounts of *E. coli* bacteria attached (Nyquist plot).

considered as a reference capacitance, Fig. 7.17(b) shows the relative capacitance change with the number of *E. coli* bacteria tethered. There is a linear relationship between the change of capacitance and the logarithmic number of *E. coli* cell on the surface when the number of *E. coli* cell is from 50 to 1000. The sensitivity of the capacitance change is about  $-0.5 \mu\text{F}$  per  $\log(\text{number of } E. coli \text{ cells})$ .

#### 7.4.3.2 EIS on GNW

On a free standing gold nanowire array, typical EIS results are shown in Figs. 7.18 and 7.19. The same calculation procedure was applied as that for a flat gold. The imaginary impedance is also linear with the reciprocal radial frequency in the low frequency range (Fig. 7.20(a)). The relative capacitance change because of the binding of the *E. coli* cells is shown in Fig. 7.20(b). A similar linear relationship between the change of the capacitance and the log scale number of *E. coli* was obtained in the concentration range from 50 cells to 2000 cells. The slope was determined to be  $-29.82 \mu\text{F}$  per  $\log(\text{number of } E. coli \text{ cells})$ . The sensor saturates at a higher concentration than a flat gold electrode.

#### 7.4.3.3 EIS on GNW with $\text{Al}_2\text{O}_3$

Figures 7.21 and 7.22 shows a typical set of the impedance results of *E. coli* attached GNW- $\text{Al}_2\text{O}_3$ . The Nyquist plots of this sensor surface have very different shapes from the previous ones. This is because of the different structure of the sensor, in other words, the gold nanowires are embedded in an insulating alumina matrix. The capacitance of this insulating oxide layer also contributes to the system overall capacitance. However, the capacitance of the oxide layer could be assumed

Fig. 7.19. EIS on GNW with different amounts of *E. coli* bacteria attached ( $-Z_{imag}$  vs. frequency).

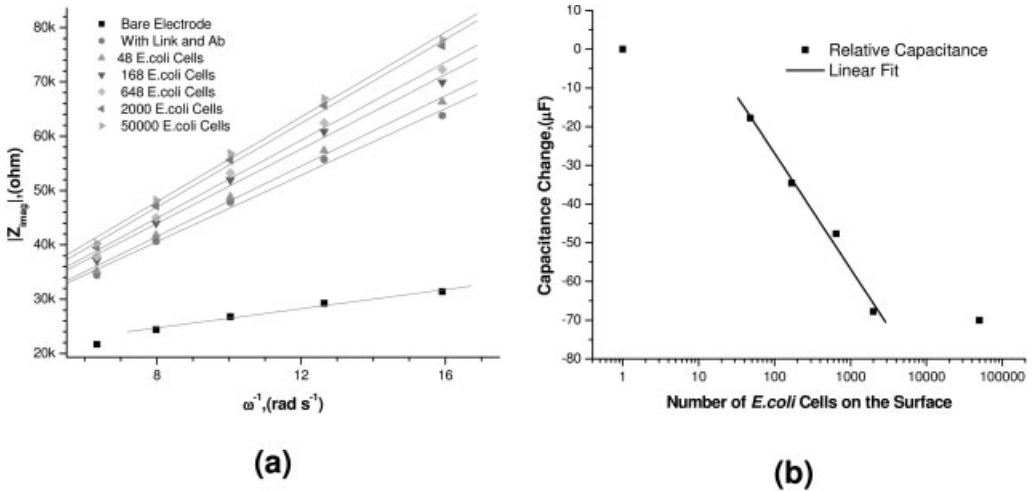

Fig. 7.20. (a)  $|Z_{imag}|$  vs.  $\omega^{-1}$  and (b) relative capacitance change vs. the number of *E. coli* (log scale) on a GNW electrode.

Fig. 7.21. EIS results for a GNW-Al<sub>2</sub>O<sub>3</sub> sample with different amounts of *E. coli* cells attached (Nyquist plot).

Fig. 7.22. Imaginary part of impedance vs. frequency of a GNW-Al<sub>2</sub>O<sub>3</sub> sample with different amounts of *E. coli* cells attached.

**Fig. 7.23.** Imaginary part of impedance vs. frequency of an anodized  $\text{Al}_2\text{O}_3/\text{Al}$  electrode in 0.01 M PBS buffer.

to be constant before and after the antigens interact with the antibodies, which means that the observed capacitance change is only due to the binding of *E. coli* cells. If the imaginary part of impedance is plotted vs. the frequency, a peak shape curve was obtained (Fig. 7.22). The imaginary impedance vs. frequency curve was a peak shape in many tests for this type of substrate. The peak frequencies for different samples were in the range 1 Hz–100 Hz. This peak is most likely due to the presence of  $\text{Al}_2\text{O}_3$  on the substrate. The impedance results of an anodized  $\text{Al}_2\text{O}_3/\text{Al}$  electrode tested in 0.01 M PBS buffer shown in Fig. 7.23 confirmed this speculation.

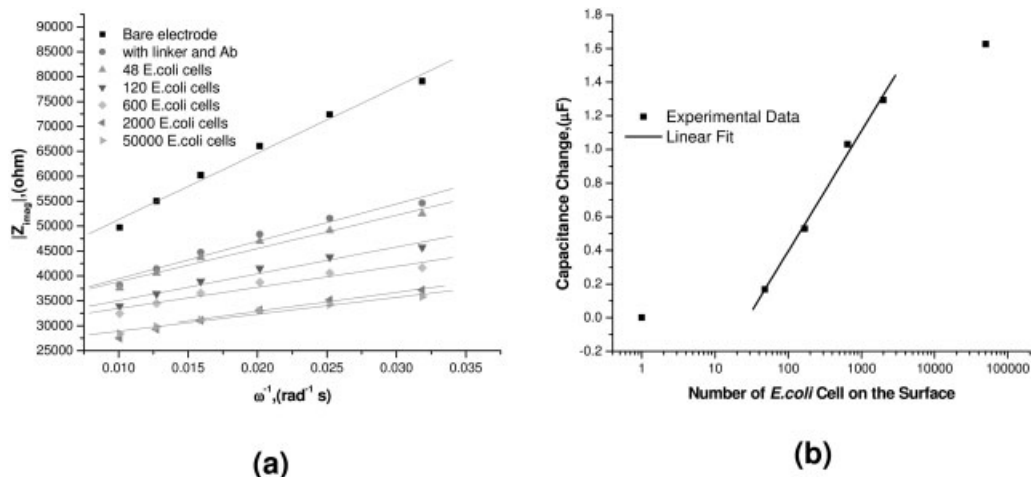

The capacitance can be calculated for this type of substrate from the data in the region of the right-half of the peak in the figure. Figure 7.24(a) shows the fitting results. If the capacitance of the electrode with linker and antibody is set as the reference capacitance, the relative capacitance change vs. the number of *E. coli* cells can be plotted as shown in Fig. 7.24(b). An increase of the capacitance with the concentration of *E. coli* has been found. The sensitivity of the linear region is about 0.36  $\mu\text{F}$  per  $\log(\text{number of } E. coli \text{ cells})$ . The reason why the capacitance increases instead of decreases after *E. coli* is bound is still not clear.

#### 7.4.4

##### Summary of EIS Detection of *E. coli* Bacteria

Immunosensors for the detection of *E. coli* bacteria have been developed based on the gold nanowire arrays formed by the template synthesis technique. A specific

**Fig. 7.24.** (a)  $|Z_{imag}|$  vs.  $\omega^{-1}$ , and (b) relative capacitance change vs. the number of *E. coli* (log scale) on a GNW- $Al_2O_3$  sample.

type of antibody was immobilized on the active gold surface by covalent binding. EIS measurements were carried out to detect the complex formation between the antibodies and antigens. A thiol-containing linker molecule was synthesized to increase the binding capacity and strength of the specific antibody. The binding of *E. coli* results in a change in the overall capacitance. This capacitance change can be monitored by impedance measurements. Different substrate structures result in different working frequency ranges (compare Figs. 17(a), 20(a), and 24(a)). The preliminary results showed that this nano-gold biosensor is able to detect every 50 *E. coli* cells with a sensor area of 0.2 cm<sup>2</sup>. For both planar and nanostructured gold substrates, the change of capacitance ( $\Delta C$ ) was linear with the logarithmic number of *E. coli* cell on the surface. However, the linear range was smaller on a flat gold surface. The detection sensitivities were determined to be the slopes of the linear portion of the curves for all substrates (Table 7.4). It can be seen that the gold

**Tab. 7.4.** Comparison of three substrates studied for *E. coli* sensor application.

Substrate	Detection sensitivity	Sensitive region
Flat gold	$-0.5 \mu F/\log(\text{number of } E. coli \text{ cell})$	50–1000 cells
Gold nanowire array (GNW)	$-29.8 \mu F/\log(\text{number of } E. coli \text{ cell})$	50–2000 cells
Gold nanowire array in the oxide (GNW- $Al_2O_3$ )	$0.36 \mu F/\log(\text{number of } E. coli \text{ cell})$	50–2000 cells

Fig. 7.25. Detection of pathogenic *E. coli* by antibody-linker-GNW biosensors.

nanowire array electrode is the most sensitive substrate according to the obtained capacitance change arising from the binding of the same amount of *E. coli* cells.

The study of the *E. coli* sensor has shown that an impedometric transduction strategy is suitable for detection of *E. coli* at low concentrations. The nanostructured materials can further improve the detection sensitivity. However, the specificity of this sensor device, as well as the long-term stability has not yet been established. The antibody used is not specific to a single strain of *E. coli* bacteria, various strains of *E. coli* can interact with this antibody.

## 7.5

### Conclusions

This chapter has described a quick method for bacteria detection using a gold nanowire based biosensor and electrochemical measurements. Detection methods have been developed with the use of gold nanowire (GNW) substrates attached to a C<sub>11</sub> linker arm in turn attached to the specific *E. coli* antibodies (Fig. 7.25). Preliminary results indicate that the GNW biosensor can detect as few as 50 *E. coli* cells with a sensor area of 0.2 cm<sup>2</sup>. However, this report gives the initial results for this novel procedure to be used in wider applications. The specificity of detection of any cell depends on the availability of a specific antibody directed to the cell surface macromolecules or antigens (Fig. 7.25). This method would be applicable to detect any cancer cells based on the antigens present on cell surfaces, such as human colon and breast cancer cells containing Le<sup>x</sup> and Sialo-Le<sup>x</sup> [60]. Antibodies against these antigens are available commercially. Further studies on the detection of cancer cells by this method are in progress.

### Acknowledgments

This chapter was written on research supported by an NSF-REU grant (Chemistry Department) and a grant-in-aid from the Bayer Corporation to Subhash Bash. Juan Jiang was the recipient of a Bayer Predoctoral Fellowship. Our thanks go to Dr. Patrick J. Boyle, Mr. Rui Ma, Mr. Joshua Henshaw, Ms. Rocio del A. Cordona, Mr. Kunal Saxena and Ms. Clare Lefave for their tireless technical help. Our special

thanks to Mrs. Dorisanne Nielsen for her help in the preparation of the final manuscript.

# Dendrimer-based Electrochemical Detection Methods

*Hak-Sung Kim and Hyun C. Yoon*

### 8.1 Overview

The use of molecularly-organized nanoscale interfaces is of great interest in efforts to enhance the analytical capabilities of biosensors. In this regard, dendrimer-based biocomposite structures, including molecularly organized monolayers and multilayers, have been developed for catalytic and affinity biosensing. As a highly organized and plurifunctional macromolecule, dendrimers find wide applications in analytical sciences. The anticipated merits of using dendrimers as the layer-forming materials are based on their structural characteristics such as homogeneity, compatible size with biomolecules, internal porosity, and the high density of functional groups. These unique characteristics make them good candidates for the building units of films on biosensor surfaces, presenting both the advantages of using polymers (plurifunctionality) and molecularly controllable nanomaterials. This chapter focuses on the fabrication of dendrimer-based biocomposite mono-/multilayers and their biosensing applications. Implementations of biointerfaces for the bioelectrocatalytic enzyme sensors with the multilayer configuration and affinity sensors based on either bioelectrocatalytic signal amplification or immunoprecipitation-voltammetric detection principles with dendrimer monolayers are covered.

### 8.2 Introduction

#### 8.2.1 Background

Molecularly organized nanostructures are of great interest in analytical sciences, molecular device technology, and biotechnology [1]. Especially, an enormous amount of research has been devoted to the development of molecularly organized

interfaces containing biomolecules as diagnostic tools (biosensors), biomimetic membranes and, recently, bioelectronic devices [2–4].

With the availability of highly controllable structuring and patterning techniques, especially the self-assembled monolayers (SAMs) methodology [5, 6], the pace of development in the related fields has greatly increased. The pioneering studies of Whitesides group regarding the mixed SAM technology and micropatterning such as microcontact printing have opened a new avenue for the technique [7–9]. By keeping in step with such developments, there have been numerous approaches for the well-organized and active biocomposite assemblies.

However, the quest continues for molecularly organized, structurally rigid, biochemically active and stable biocomposite superstructures. In this regard, the implementation of useful surface bio-functionalization methodologies as well as the introduction of novel materials having unique properties is one of the major subjects of research and development. As a promising molecule for biocomposite nanostructures, highly branched dendrimers draw much attention.

### 8.2.2

#### **Dendrimers as a new Constituent of Biocomposite Structures**

The past decade has seen expanding interest in the newly introduced synthetic dendritic polymers (dendrimers) [10, 11], which are highly branched, fractal-like macromolecules of defined molecular structure, size, and topology. The molecules are synthesized by an iterative sequence of reaction steps, or cascade synthesis, with sophisticated control in reaction conditions [12]. With the development in synthetic methodology, structurally perfect dendrimers with high purity and narrow polydispersity have been produced. The unique characteristics of dendrimers, such as structural homogeneity, molecular integrity, controlled composition, and the multiple homogeneous chain-ends available for consecutive conjugation reaction, have enabled their use as the material of choice in applications such as drug delivery, energy harvesting, ion sensing, catalysis, and information storage [13]. For these objectives, several approaches adopting dendrimers as the building block for the nanostructures have been conducted. These include deposition of dendritic multilayers via Pt-complexation, electrostatic interaction, and reaction with grafted copolymer [14–17]. Characteristics mentioned above, along with the recently recognized biocompatibility [13], merit the use of dendrimers for the fabrication of organized functional biocomposite nanostructures, comparable with those prepared with entangled linear and branched polymers. By us and other groups, the utility of the dendrimer has extended to bio-related fields [18–20].

Our recent reports demonstrate that dendrimers are advantageous as the building block for the construction of the multilayered biocomposite nanostructures and reagentless enzyme or affinity biosensors [18, 21–25]. As a building unit for organic thin films, dendrimers, as highly branched dendritic macromolecules, possess a unique surface of multiple chain-ends, and the number of surface groups can be precisely controlled as a function of synthetic generations (Fig. 8.1). For example,

**Fig. 8.1.** Characteristics of fourth-generation (G4) poly(amidoamine) dendrimers. Molecular models for dendrimer and glucose oxidase are shown for size comparison.

fourth generation (G4) poly(amidoamine) dendrimers have 64 surface amine groups. The high concentration of functional end groups of dendrimers enables synthetic modifications of molecularly ordered nanostructures. Dendrimers provide multiple conjugation sites, and the remaining groups, after film formation, are accessible for further modification with functionalization groups for specific purposes. Dendrimers of high generation numbers offer some advantages over linear or partly branched polymers, e.g., structural homogeneity, controllable composition, comparable size to the participating biomolecules, and multiple homogeneous chain-ends groups, valuable for the conjugating reactions [21].

In this respect, we have employed the G4 poly(amidoamine) dendrimer as the underlying-layer for functionalizing or micropatterning ligands on the solid surface. Besides G4 poly(amidoamine) dendrimers, poly-L-lysine and poly(allylamine) and amine-terminated cystamine SAM, all presenting surface amine functionalities, have frequently been used, and we have compared their physicochemical and biochemical properties as thin films for arraying ligands on a solid surface [26].

### 8.3 Applications for Biosensors

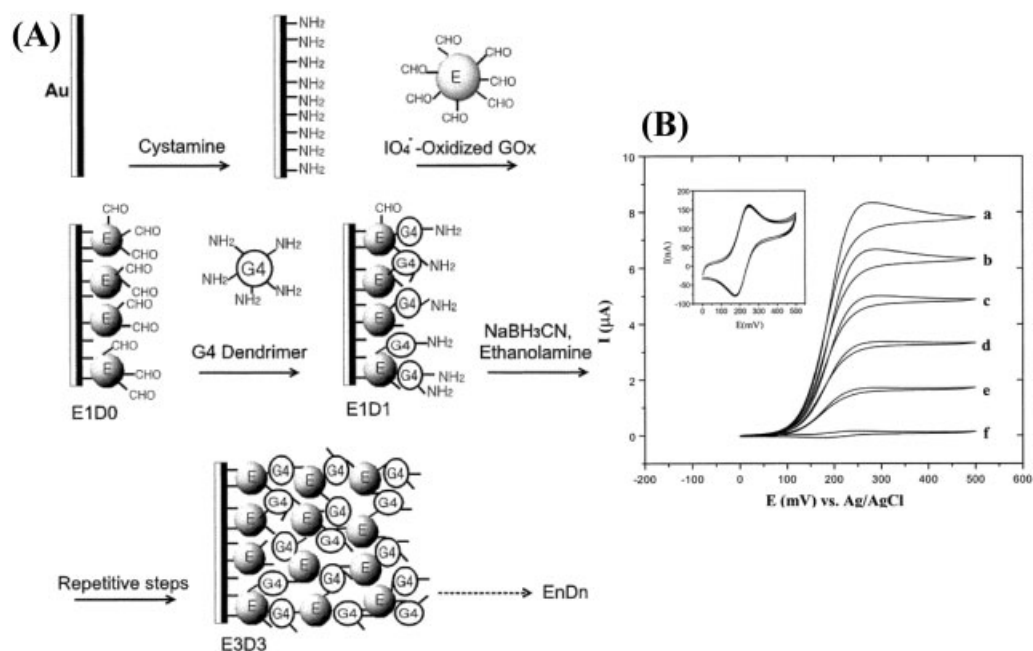

In the past decade, self-assembled monolayers, silane-modified layers, Langmuir-Blodgett (LB) layers, and polymer grafting layers compatible with biomolecules have been commonly used for the presentation of ligands or proteins on a solid surface to modulate their interactions with reacting couple molecules. These or-

ganic thin films have an expanded application in biosensors (enzyme electrodes, immunoelectrodes, DNA analyses), artificial biomimetic membranes, and, recently, bioelectronic devices. In this regard, dendrimer-based biocomposite structures, organized mono- and multilayers, have been developed for catalytic and affinity biosensing.

### 8.3.1

#### Bioelectrocatalytic Enzyme Electrodes based on LBL (layer-by-layer) Assembly with Dendrimers

For a catalytic biosensing interface, a new approach to construct a multilayered enzyme film on the electrode surface has been developed [18, 21]. Figure 8.2 shows the schematic procedure to construct a film by alternate layer-by-layer (LBL) depositions of G4 poly(amidoamine) dendrimers and periodate-oxidized glucose oxidase (GOx). Cyclic voltammograms registered from gold electrodes modified with GOx/

**Fig. 8.2.** (A) Schematic representation of a multilayered GOx/dendrimer network construction on a Au electrode surface. (B) Cyclic voltammograms of the GOx/dendrimer multilayered electrodes in the presence of 0.1 mM ferrocene-methanol as a diffusional electron-transferring mediator: (a) E5D5, (b) E4D4, (c) E3D3, (d) E2D2, and

(e) E1D1 in the presence of 20 mM glucose; (f) E1D1 in the absence of glucose, unmediated. Inset: cyclic voltammograms for each layer numbers in the absence of glucose in solution. All curves were registered in 0.1 M phosphate buffer (pH 8.0) under Ar. Potential scan rate:  $5 \text{ mV s}^{-1}$ . (Modified after Ref. [18]).

dendrimer multilayers revealed that the bioelectrocatalytic response is directly proportional to the number of deposited bilayers, i.e., to the amount of active GOx immobilized on the gold electrode surface. From analysis of electrochemical signals, the amount of active enzyme per GOx/dendrimer bilayer during the multilayer forming steps was calculated, demonstrating that the multilayer is constructed in a spatially-ordered manner. Also, by ellipsometry measurement, a linear increase of the film thickness was observed, supporting formation of the desired multilayer. The five-bilayer associated electrode (E5D5) showed a sensitivity of  $14.7 \mu\text{A} (\text{mM glucose})^{-1} \text{cm}^{-2}$  and remained stable over 20 days under daily calibrations. The proposed method is simple and applicable to the construction of thickness- and sensitivity-controllable biosensing [18].

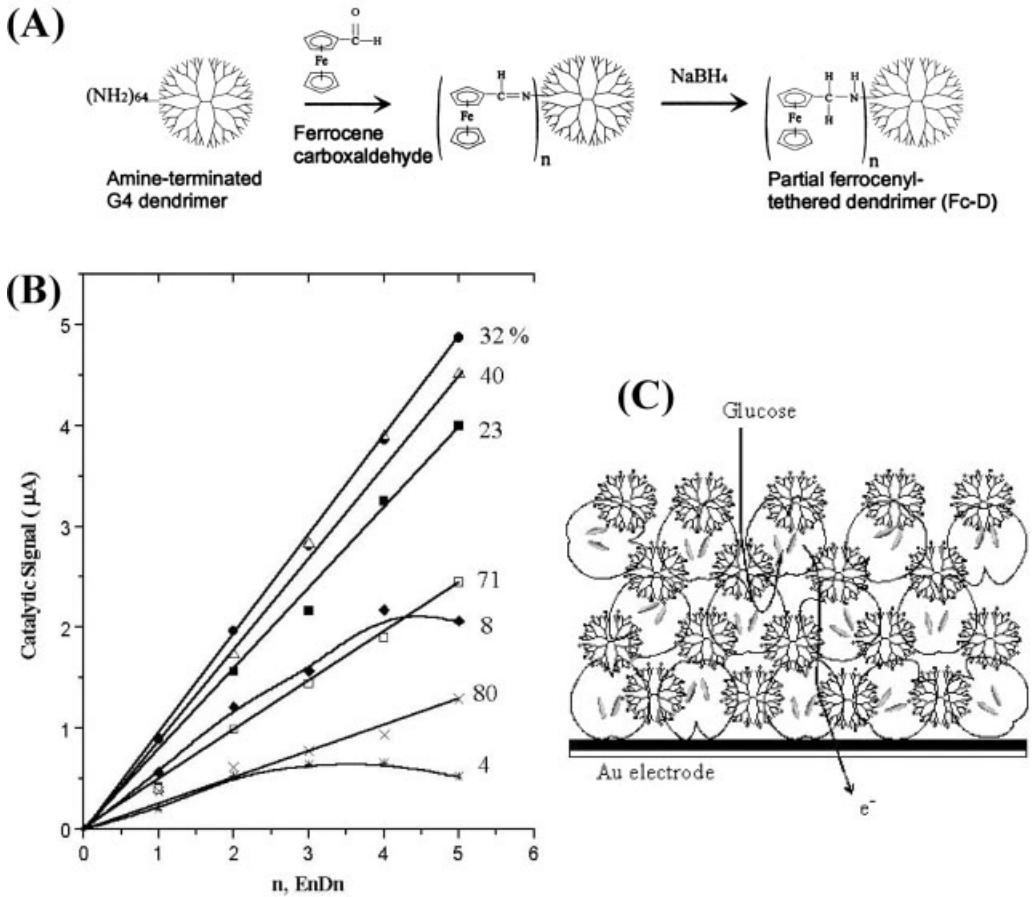

As an extension of this research, poly(amidoamine) dendrimers having surface ferrocenyl functional groups were prepared and used for the fabrication of a reagentless bioelectrocatalyzed enzyme electrode [21]. Poly(amidoamine) dendrimers having various degrees of tethering with the ferrocenyls were prepared by controlling the molar ratio of ferrocenecarboxaldehyde to amine groups of dendrimers during synthesis (Fig. 8.3A). By LBL depositions of ferrocenyl-tethered dendrimers with periodate-oxidized GOx on gold surface, an electrochemically and enzymatically active multilayer was constructed. The resulting GOx/Fc-D multilayer-associated electrodes were electrochemically characterized, and the density of ferrocenyl groups, active enzyme content, and sensitivity were analyzed. Dendrimers with 32% modification level was found to be an optimum from the analyses in terms of GOx-dendrimer network formation, electrochemical connectivity of ferrocenyls, and electrode sensitivity (Fig. 8.3B, C). With the synthesized Fc(32%)-tethered dendrimers, mono- and multilayered electrodes were constructed, and their electrochemical and catalytic properties were characterized. The bioelectrocatalytic signals from the GOx/Fc-D electrodes were directly proportional to the bilayer numbers. From this result, it seems that the electrode sensitivity is directly controllable, and the multilayer-forming strategy with ferrocenyl-labeled dendrimers is useful for the development of reagentless biosensors.

### 8.3.2

#### **Bioelectrocatalytic Immunosensors based on the Dendrimer-associated SAMs**

##### **8.3.2.1 Affinity Recognition Surface based on the Dendrimer-associated SAMs**

All biological phenomena, such as generation and development, are regulated by functional interactions of protein–protein, receptor–ligand, antigen–antibody, enzyme–substrate, and protein–XNA. Therefore, the understanding of functions of biomolecules that specifically interact with particular proteins or ligands is the main theme in life science. As a tool for the functional study of proteins, affinity recognition chip technology is important. Therefore, we have focused on surface functionalization technology that will arrange and immobilize active proteins on affinity chip surfaces. Immobilization of active proteins on solid supports with an extended lifetime is the major concern of a protein chip.

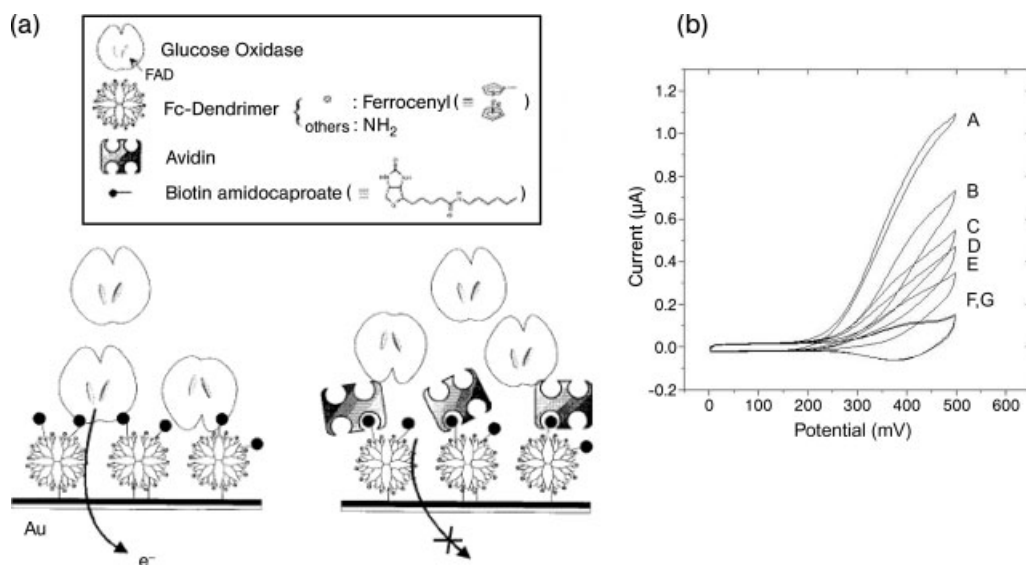

**Fig. 8.3.** (A) Schematic representation of a semi-synthetic preparation of partial ferrocenyl-tethered G4 poly(amidoamine) dendrimer (Fc-D). (B) Bioelectrocatalytic signal amplification for GOx/Fc-D electrodes containing dendrimers with various ferrocenyl functionalization levels as a function of deposited bilayer numbers. Signal values were

sampled at +370 mV vs. Ag/AgCl reference electrode from cyclic voltammetric data in the presence of 20 mM glucose. (C) Schematic representation of the idealized multilayered GOx/Fc-D network on an Au electrode surface and the anticipated biochemical and charge-transfer reactions. (Modified after Ref. [21]).

In this respect, we emphasize three considerations to obtain sufficient sensitivity and accuracy from the affinity sensor. Aside from the signal generation efficacy, which will be covered later, the surface chemistry should be specially optimized to drive efficient immobilization of proteins or ligands. (a) Proteins must be immobilized on a chip surface in a stable and satisfactorily concentrated manner. (b) The orientation of protein should be controlled for favorable bio-specific interactions at

the chip surface. (c) Nonspecific binding of molecules at the chip surface should be adequately circumvented. Additionally, and importantly, a highly sensitive detection system should be developed, by which the derived signal can be analyzed, because, in typical cases, the concentration of immobilized biomolecules on the chip is as low as  $10^{-15}\sim 10^{-14}$  mol/chip surface.

For a biospecific affinity-sensing interface, an affinity biosensor system based on avidin–biotin interaction has been developed [22]. The avidin–biotin interaction, a unique model of strong protein–ligand interaction, exhibits stronger affinity than any other antigen–antibody interactions. As the building block of an affinity sensing monolayer, a G4 poly(amidoamine) dendrimer having partial ferrocenyl-labeled surface groups was synthesized and used. The surface amine groups from dendrimers were also functionalized with biotin amidocaproate, and the biotinylated and electroactive monolayer was used for the affinity-sensing surface interacting with avidin. As shown in Fig. 8.4(A), an electrochemical signal from the affinity biosensor was generated by free enzyme GOx in electrolyte, depending on the degree of coverage of the sensing surface with avidin and subsequent surface shielding. The sensor signal decreased with increasing avidin concentration, and approached a minimum when the sensing surface was fully covered (Fig. 8.4B). The

**Fig. 8.4.** (a) Construction and proposed operational principle for an affinity biosensor based on the avidin–biotin interaction on a gold electrode surface. Molecular models of the chemicals used for electrode construction are shown. (b) Cyclic voltammograms of the affinity biosensors as a function of reacted avidin concentration: (A) 0, (B) 1 ng mL<sup>-1</sup>,

(C) 10 ng mL<sup>-1</sup>, (D) 100 ng mL<sup>-1</sup>, (E) 1 mg mL<sup>-1</sup>, and (F) 10 mg mL<sup>-1</sup>. Cyclic voltammograms were obtained in the presence of 30 mg mL<sup>-1</sup> of GOx as a signal generator and 10 mM glucose as a substrate; (G) background voltammogram in the absence of enzyme and substrate. Potential scan rate: 5 mV s<sup>-1</sup>. (Modified after Ref. [22]).

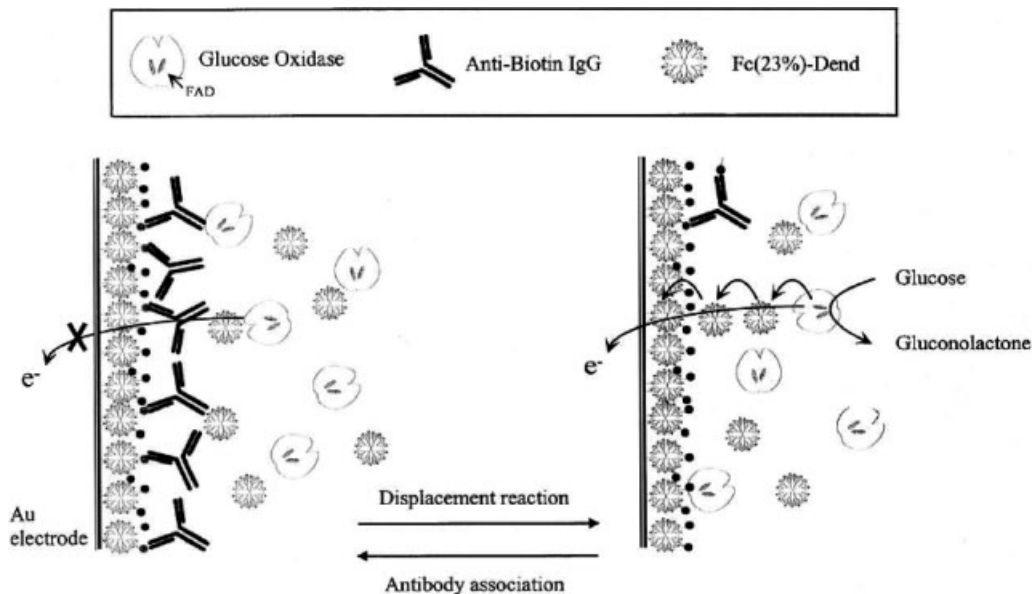

**Fig. 8.5.** (A) Molecular structures of d-desthiobiotin amidocaproate. (B) Schematic representation of the procedure employed for the biospecific association/dissociation of biomolecules at the affinity-sensing electrode surfaces. (Modified after Ref. [23]).

detection limit of avidin was about 4.5 pM, and the sensor signal was linear, ranging from 1.5 pM to 10 nM, under optimal conditions. Based on the kinetic analysis using the biotinylated glucose oxidase, an active enzyme coverage of  $2.5 \times 10^{-12}$  mol cm<sup>-2</sup> on the avidin pretreated surface was calculated, demonstrating the formation of a spatially ordered and compact protein layer on the modified sensing interface.

As an extension of this research, a new approach regarding the development of a repeatedly renewable affinity-sensing surface was presented based on the reversible association/dissociation reactions between avidin and biotin analogues [23] (Fig. 8.5). The surfaces were constructed with dendrimer monolayers, whose surface chain-end groups have been functionalized with a biotin analog, desthiobiotin, which has a reduced affinity toward avidin (Fig. 8.5A). The functionalized monolayers provided an affinity recognition interface for avidin and further biospecific interactions with biotinylated molecules. The desthiobiotin–avidin associates underwent a dissociation (displacement) reaction with free biotin treatment, and this renewed the affinity surface and provided the possibility of repeated utilization of the affinity-sensing surface. Biotinylated glucose oxidase, as a model compound for signal generation, was used for the association reaction onto the avidin preincubated surface, and voltammetric measurements were performed to track the reaction steps by registering the activity of associated enzyme. Efficient association/dissociation reaction cycle traces were found, especially for the desthiobiotin amidocaproate modified electrodes, suggesting steric limitation regarding the ligand length for the biospecific interaction. With the optimized affinity-surface construction steps and reaction conditions, continuous association/dissociation reaction cycles were achieved, which is useful as a regenerable affinity surface.

Reversible affinity interactions at the functionalized electrode have also been extended to antibodies [24]. The surfaces were constructed with dendrimer mono-

**Fig. 8.6.** Schematic representation of the idealized reactions in electrolyte and at the affinity-sensing electrodes for antibody-associated and regenerated surfaces: enzymatic catalysis, electron mediation with

Fc-D in electrolyte, and charge transfer to Au electrodes. Dimensions of the components are not drawn to scale for simplicity. (From Ref. [24]).

layers, whose surface chain-end groups have been double-functionalized with biotins and ferrocenyls for the biospecific recognition and electron transfer. The functionalized monolayers provide a platform for biospecific recognition with monoclonal anti-biotin antibodies. The bound antibodies were dissociated with free biotin treatment, and the process renewed the affinity surfaces for repeated utilization. Figure 8.6 displays the electrochemical tracking of the association/dissociation reaction cycles, based on the shielding of the electrode surface with bound antibody molecules and subsequent hindrance in electron transfer, with free-diffusing signal generator and mediator. Factors influencing the biospecific interactions and measurements were considered. With the results, continuous association/dissociation reactions have been accomplished, holding great promise for reversible affinity biosensing.

### 8.3.2.2 Electrochemical Signaling from Affinity Recognition Reactions

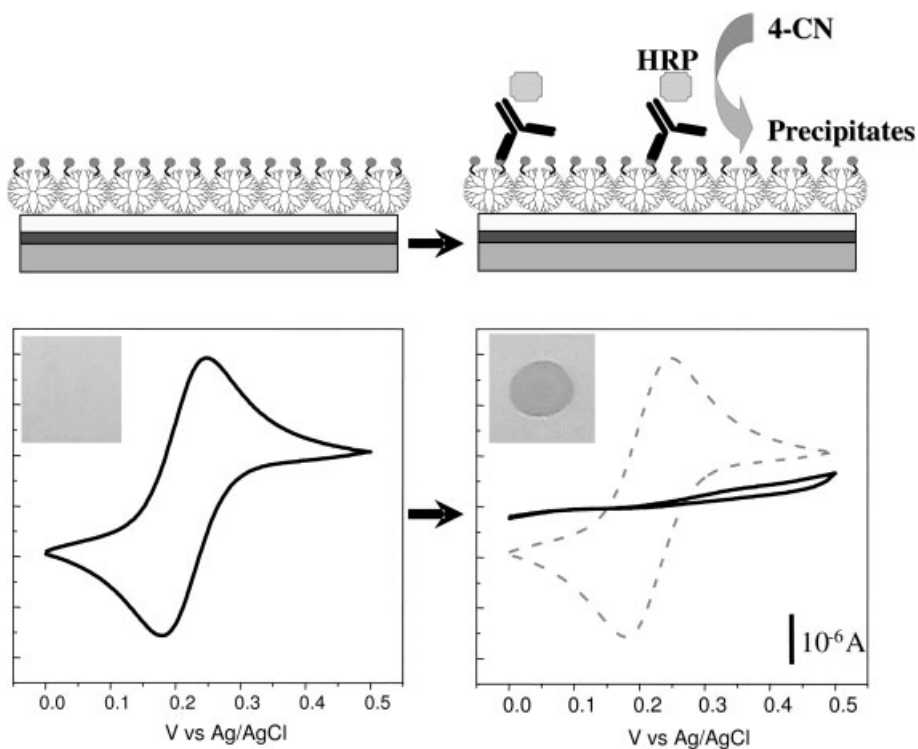

Affinity sensing has been evolved from the viewpoints of detection of immune-related molecules with minute concentration range and signaling with acceptable quantification capability. Several detection principles for affinity/immuno sensing have been developed. A detection technique such as surface plasmon resonance (SPR) spectroscopy and a quartz crystal microbalance (QCM) can recognize the concentration of bound biomolecules by changes in mass and/or surface density

(molecules/sensor area). However, notably, they are not suitable for application as portable biosensors. For SPR immunosensing, major progress has been made with bench-top scale instruments, enabling high-throughput and multiplexed analysis. In the concept of handheld biosensor/immunosensor, electrochemical methods have received the spotlight due to facile device-miniaturization and sensitive signal-quantification. Especially, recent efforts have focused on integrated devices, the so-called lab-on-a-chips [27, 28], combining the detection part with sample delivery parts based on microfluidics; thus a detection method that necessitates minimum instrumental part is highly desired. In that sense, we have focused on signaling methodologies that fulfill the needs of electrochemical detection and have developed two potential methods, including the immunoprecipitation-mediated signaling and the enzymatic back-filling immunoassay.

A signaling strategy for immunosensors that transduces biospecific affinity recognition reactions into electrochemical signals has been developed. This method combines the relatively well-known immunohistochemical reactions with electrochemistry [25]. As can be seen in Fig. 8.7, the cyclic voltammetric method, tracking the precipitation of insoluble products onto the sensing surface and the subsequent surface shielding and decrement in the electrode area, was employed for signal registration. Precipitation of insolubilities was induced by the catalytic reaction of peroxidase, which were labeled to the biospecifically associated protein or antibody molecules. We have investigated the functionalization of biotin ligand groups to the sensing monolayer and their biospecific interactions with anti-biotin antibody molecules as a model affinity recognition. The immunosensing interface was developed onto dendrimer-activated SAMs, as the base template for the functionalization of the antigen as well as generation. Additionally, the sensing system was applied for biotin/(strept)avidin couples, extending the usage of the developed strategy. With the affinity-sensing interface, a stepwise surface regeneration process has been developed, based on the combination of deposited product thin-film dissolution and bound-protein displacement reactions from the modified sensor surfaces [29]. The results exemplify the usefulness of immunoprecipitation-mediated signaling in terms of sensitivity and repeated use.

By using the developed immunosensing principle, a silicon-based immunosensor chip has been microfabricated and applied for the analysis of real samples such as blood serum [30]. Figure 8.8 shows an array-type gold electrode, which was fabricated on a silicon wafer, containing two electrode geometries of rectangular ( $100 \times 500 \mu\text{m}$ ) and circular (radius:  $50 \mu\text{m}$ ) types. These two types of electrodes showed distinct electrochemical characteristics of bulk and micro-electrodes, respectively, exhibiting different sensing parameters such as operation voltage, sensitivity, and dynamic detection range. Ferritin was employed as a model analyte for immunosensing because it has serological importance as a general marker protein for tumors and cancer recurrence. With the ferritin-functionalized immunosensor chips, biospecific interactions were performed with antiferritin antiserum and secondary antibody samples, followed by electrochemical signaling by an immunoprecipitation reaction with the label peroxidase enzyme. Under the optimized affinity-surface construction steps and signaling conditions, both types of microfabri-

SAM surfaces. A freshly prepared and biotin-functionalized surface before (left) and after target protein association and precipitation reaction steps (right). Curves were registered in a 0.1 M phosphate buffer (pH 7) containing ferrocene-methanol (0.1 mM) as a signal tracer. Potential scan rate:  $50 \text{ mV s}^{-1}$ . (Modified after Ref. [25]).

cated electrodes, including rectangular ( $100 \times 500 \mu\text{m}$ ) and circular (radius:  $50 \mu\text{m}$ ) types, exhibited well-defined calibration results as a function of ferritin concentration in antiserum samples. Furthermore, circular-type micropatterned immunoelectrodes displayed the voltammetric characteristics of microelectrodes, which is advantageous in sensor operation under a fixed potential with low signal drift compared with the bulk-type electrodes. The results support the idea that the employed signaling method with the proposed immunosensor configuration is fit for sensor miniaturization and integration to biomicrosystems and lab-on-a-chips.

The analyte for affinity sensors, especially antibody, is usually bound to the surface-immobilized capture molecule and could cause a significant signal loss during subsequent handling procedures and signaling due to its limited affinity/

**Fig. 8.8.** (A) Schematic representation of the procedure for bioaffinity interface construction and the biocatalyzed precipitation reaction for signal generation from a ferritin immunosensor. Component dimensions are not drawn to scale for simplicity. (B) Representative voltammetric sensor signal.

stability. Thus, we also focused on the signal stability of affinity sensors. The signal stability from immunosensors is usually not sufficient because the known binding constant between antigens and antibodies are several orders of magnitude lower than the well known and frequently used model of biotin–streptavidin ( $K_a = 1 \times 10^{15} \text{ M}^{-1}$ ) [23, 24]. This suggests that the antibody-bound surface undergoes a gradual change, raising the possibility of antibody detachment and signal variation. Also, supplementary label molecules such as enzymes are applied to generate electrochemical signals from immunosensors. In a typical immunoassay, the detection process requires pre-treatment of ligands or expensive commercial reagent to activate reporter molecules such as secondary antibodies because the signaling mechanism is based on the proper enzymatic labeling. Therefore, a detection strategy for electrochemical immunosensors in which the signal is not dependent on the stability of bound antibody molecules to the sensing interface would be valuable. In this regard, we have developed a signal generation method from bioelectrocatalytic immunosensors that does not require routine and cumber-

**Fig. 8.9.** Schematic representation of electrochemical immunosensing with the “back-filling” immobilization of enzyme (GOx) and bioelectrocatalysis (component dimensions not drawn to scale for simplicity). (From Ref. [31]).

some processes, including surface activation and antibody labeling or the use of labeled reporter molecules such as secondary antibodies [31]. The signaling method is based on the “back-filling” covalent immobilization of enzymes onto the immunosensor surface, circumventing the use of enzyme-tagged antibody and alleviating the signal instability from low-affinity binding (Fig. 8.9). In the back-filling assay, the electrochemical signal could be maintained despite the analyte dissociation by its low affinity with immobilized ligand because the signal generating enzyme is separated from the analyte.

As a model biorecognition reaction, a dinitrophenyl (DNP) antigen-functionalized immunosensor surface has been fabricated and the anti-DNP antibody was used as a target analyte [31]. For the construction of immunosensing surface, a poly(amidoamine) G4-dendrimer was employed not only as a building block for the electrode surface modification for antigen-functionalization but also as a matrix for binding of signaling enzyme (GOx). The non-labeled native antibody was biospecifically bound to the immobilized ligand, and the enzyme (periodate-activated GOx) reacted and back-filled the remaining surface amine groups on the dendrimer layer by an imine formation reaction. The DNP functionalization reaction was optimized to facilitate the antibody recognition and signaling; 65% displacement of surface amine to DNP was found to be an optimum (Fig. 8.10A). From quartz crystal microbalance measurements, the immunosensing reaction timing and the surface inertness to nonspecific biomolecular binding were investigated. By changing the DNP functionalization level in the calibration experiments, immunosensors exhibited distinct dynamic detection ranges and limits of detection, supporting the capability of parameter modulation (Fig. 8.10B).

**Fig. 8.10.** (A) Comparison between the DNP displacement ratio (○) and bioelectrocatalyzed signals from the back-filled GOx (●) as a function of reaction time for DNP-functionalization. Error bars represent 95% confidence limits for three tests.

(B) Calibration curves for the DNP/anti-DNP IgG affinity biosensors as a function of target protein concentration. Two types of immunosensors were tested, having different DNP-functionalization ratios of 13% (■) and 65% (□). (Modified after Ref. [31]).

### 8.3.3

#### Protein Micropatterning on Sensor Surfaces for Multiplexed Analysis

Micropatterning of biomolecules on solid surfaces has several applications, including the modulation of cell–substrate interactions in biomaterials and tissue engineering, the fabrication of array-type biosensors for multianalyte detection, and

genomic/proteomic arrays. We have patterned molecularly organized films of dendrimers having a submicrometer edge resolution on solid chip surfaces such as evaporated gold and glass using microcontact printing technique [32]. Microcontact printing is a non-photolithographic technique that is broadly applicable for the generation of micrometer scale patterns on solid surfaces, e.g., gold, silver, copper, and silicon oxide [33]. In this process, an elastomeric stamp, typically made from poly(dimethylsiloxane) (PDMS), is prepared by casting a prepolymer against a master whose surface has been patterned with a complementary relief structure using conventional photolithography. Microcontact printing has been used to pattern alkanethiolates on metallic substrates, alkylamines on reactive SAM of alkanethiolates, alkyltrichlorosilanes on metal oxides, and proteins with submicrometer spatial resolution by area-selective printing [34, 35].

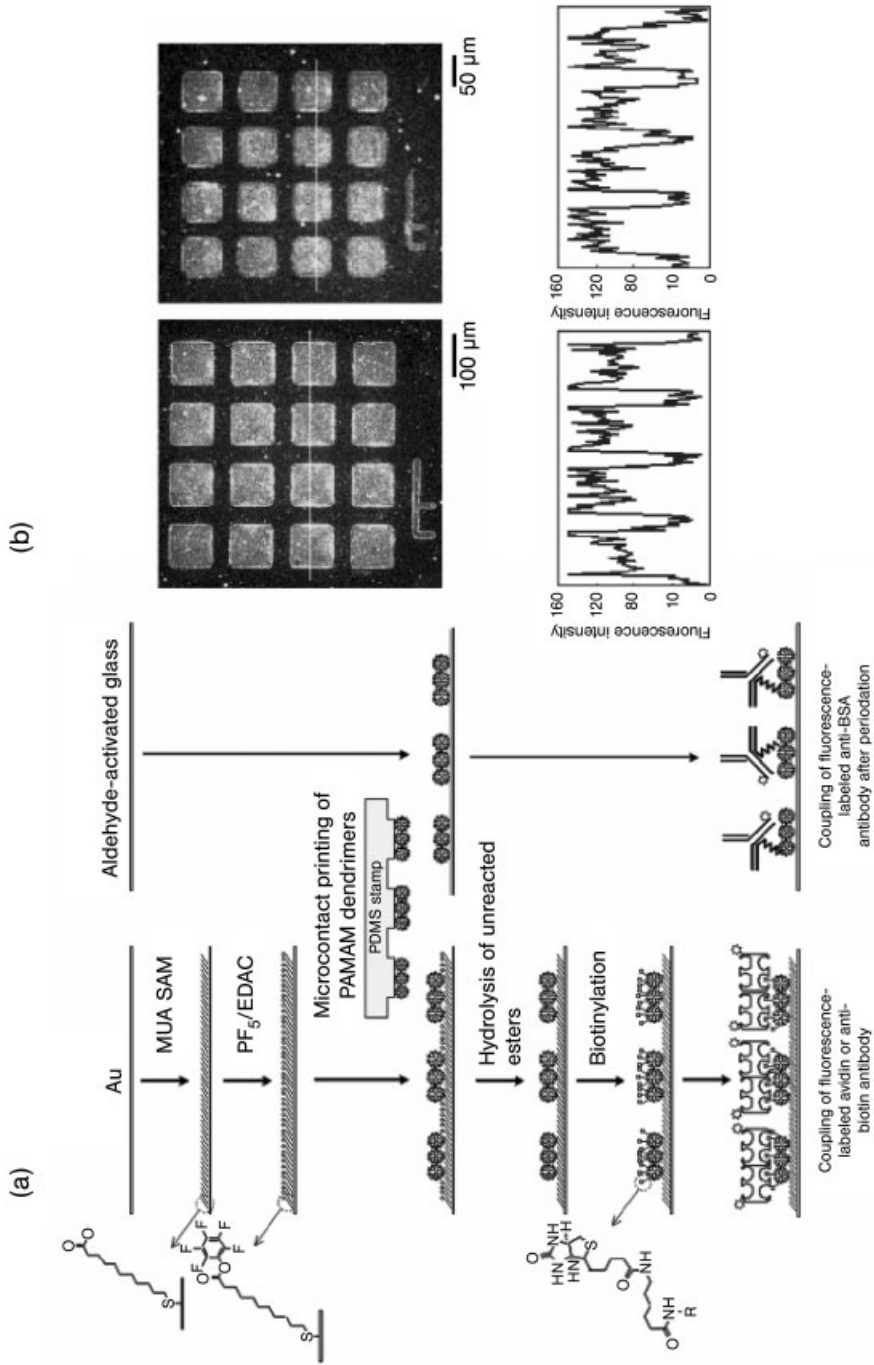

In our report [32], a patterned thin film of dendrimers was used as the underlying platform for ligand modification for the fabrication of protein microarray. Patterning of biological molecules was attempted on both gold and glass surfaces using fourth generation poly(amidoamine) dendrimer as an interfacing layer between solid surfaces and biomolecules to be patterned (Fig. 8.11). An alcoholic solution of dendrimer was employed as the inking material for the PDMS stamp. As for the patterning of avidin and anti-biotin antibody on gold, dendrimers representing amine groups were printed onto the preactivated 11-mercaptoundecanoic acid SAMs by microcontact printing, followed by biotinylation, and reacted with fluorescein-labeled avidin or anti-biotin antibody. Fluorescence analysis revealed that the patterns of avidin and anti-biotin antibody were successfully constructed within the resolution of less than a micrometer. The dendrimers were also printed onto an aldehyde-activated slide glass and reacted directly with anti-bovine serum albumin (BSA) antibodies that had been oxidized with sodium periodate. Also, distinct patterns of the anti-BSA antibodies were made with a comparable edge resolution to that of avidin patterns on gold (Fig. 8.11B). These results clearly show that dendrimers can be adopted as an interfacing layer for the patterning of biological molecules on solid surfaces with micrometer resolution, presenting a highly functionalizable microarray (plurifunctionality) made of a molecularly ordered nanomaterial.

The micropatterning technology of arranging dozens or hundreds of different biomolecules on a chip surface is required to analyze biospecific recognition events in a concurrent and massive manner. For example, 256 corrals of proteins dimensioned by  $50 \times 50 \mu\text{m}$  is made up on a  $1 \times 1 \text{ cm}$  chip surface, and a large pool of biomolecules can be distributed at the chip surface by micro-spotting. By using the developed micropatterning technique with amine-terminated dendrimer, array-

patterned chips could be made having different surface wettability or surface charge between the patterned area and background space, enabling efficient spotting and/or functionalization of target molecules. Multiplexed electrochemical affinity sensing with the micropatterned chips is being pursued, by adopting the aforementioned electrochemical signal generation strategies [25, 31].

## 8.4

### Conclusions

There has been an increasing demand for efficient analytical tools for bioassays in the fields of clinical analysis and biochemical studies. Based on this requirement, a new scientific field in bioassay has been emerging, linking bioanalytical techniques with microelectronics technology. Especially, immuno- or affinity-sensing biochip technology, registering biospecific interactions such as antigen–antibody, ligand–receptor and protein–protein recognition reactions, is under great demand in terms of assay automation and throughput/output. Additionally, recent completion of the human genome project (HGP) and flourishing genomics/proteomics have opened new research fields of high throughput and user-friendly analysis, making the development of biosensing techniques more important.

Current research trends in protein biochips are, mainly, in two directions: the first is the design of biorecognition interfaces/surfaces presenting desired characteristics such as useful surface functionality, adequate immobilization density, biocompatibility, resistance to nonspecific binding, etc. Second is the development of novel transduction techniques, particularly stressing parallel sensing with array-type sensors. In this chapter, we have summarized our recent researches regarding the development of electrochemical biosensors and platform technologies for the effective immobilization of proteins or ligands on solid surfaces. We have developed technologies that use dendrimers as the building unit for biospecific recognition layers based on SAMs technology and accumulated signaling result by using the dendrimer-associated mono-/multilayers. Currently, we are attempting to integrate proteins on chip surfaces in a form of microarrays to prototype the protein chip microsystem.

# Coordinated Biosensors: Integrated Systems for Ultrasensitive Detection of Biomarkers

*Joanne I. Yeh*

### 9.1

#### Overview

The ability to monitor biorecognition events and interactions on platforms offers pathways to the application of biological macromolecules as detectors. Coupled to the ability to precisely produce conductive elements on the nanoscale, biosensing offers unprecedented avenues for screening and detection at increasing sensitivities. Although biosensors have been an area of active investigation for several years, full realization of their potential has yet to be reached because the rates of reactions and sensitivities are significantly lower than in endogenous, biological systems. This is likely due to the random nature of how the various signal transducing units are placed relative to the electrode. Consequently, integrating the precise 3D information obtained from X-ray crystal structure analysis with nanotechnology platforms can result in a highly enhanced system. This gain is from optimization of the geometrical parameters that make up the various components of the biosensor. A nanobiosensor involves a biological molecule, linker or mediator, and nanoelectrodes; the various components can be equated with the electronic elements of a sensor as every component has to transduce the signal generated at the source (biomolecule) to the detector (electrode). Consequently, as in enzyme systems, rate improvements can occur from proximity and geometric effects, with potential enhancements of  $10^2$  to  $10^3$  at each junction. The additive consequence can be a gain of several orders of magnitude in rates, concomitantly improving sensitivities. In this chapter, the concept of coordinated biosensors is introduced, as an approach to align the signal transduction centers to enhance the kinetics of reactions. Additionally, nanoparticles are described that can further augment the systems by positioning the bioelement relative to the electrode surface. The various components of a bionanosensor and their role in enhancing the overall response of the system are described, from a structural perspective.

## 9.2

### Introduction

Several recent reviews illustrate, compare and contrast biosensor designs [1–5]. The main focus of this chapter is to provide a brief introduction of the biotechnologies behind these systems and to highlight the improvements that can be gained using an integrated approach, utilizing precise three-dimensional (3D) structural information.

The structure determination of deoxyribonucleic acid (DNA) double helix advanced the scientific world in numerous ways. This discovery led to the understanding of how DNA replication is achieved, resulting in the birth of a new field, molecular biology. The foundation for these discoveries was the X-ray diffraction data from DNA fibers [6]. This scientifically defining result highlights the value structures can have on understanding biological reactions, functions, and states. The ability to explicitly observe the exact positions of atoms of a molecule provides vast insights into important questions, such as how a biomolecule functions, potential interactions to trigger cellular activity, and regulatory mechanisms to control activity. The link between structural biology – the study of the precise conformation and location of the atoms that comprise the molecule and how the molecule folds in three dimensions – and its link to bionanotechnology can be understood from how structural results are used in biotechnological applications. Among the more traditional uses are in structure-based drug design, mutational analysis, and bioengineering. However, a revolutionary approach is to integrate structural results with nanotechnology, as described in this chapter.

Proteins and nucleic acids have diverse roles in the body and studies of their 3D structures teaches us how these function in our bodies and help us understand diseases caused by abnormal forms of these biomolecules. Just as structural biology has provided a definitive fundamental understanding of functional states of biological macromolecules, nanotechnology has provided the platform and a means to bridge the gap between fundamental scientific understanding to enhanced applications [7–11]. A direct connection between the two disciplines can be seen in size: in X-ray crystallography, the resolutions at which molecules are determined are at the atomic dimensions of  $10^{-10}$  m or angstroms (Å). When looking at protein–protein or oligomeric interactions, complexes, and organelles, the working functional “machinery” of a cell, these are on the order of hundreds of angstroms or in the nanometer range. Consequently, there exist complementarities of dimensionalities when linking structural results with nanotechnology applications.

As structural biology has had an immense impact on how scientists visualize biomolecules and their interactions, nanotechnology has changed our concept of working dimensions and applications at the single molecule level. Single eukaryotic cells are at least  $250\times$  larger than the nanodevices that are being developed. As a new field, nanotechnology already has had an immense impact on theoretical as well as empirical areas. In bioanalysis, nanoparticles can overcome many of the significant chemical and spectral limitations of more traditional reagents, leading to the ability to detect and monitor on the single molecule level. Fundamentally,

as single molecule measurements become possible, profound changes to our understanding of biochemical reactions are occurring. With the removal of ensemble averaging, distributions and fluctuations of molecular properties can be characterized, transient intermediates identified, and catalytic mechanisms elucidated. Recently, it has become apparent that models based on data obtained from a population of molecules do not most accurately reflect the true biochemical nature of reactions [12–15]. This is particularly important when applying biomolecules to various applications because the most efficient means of catalyzing a reaction, for example, would not be one based on an averaged reaction but the most active and efficient one. Consequently, the ability to discriminate differences between single molecules allows us to identify the most effective states of a biomolecule, to obtain enhanced reactions and sensitivities.

The ability to precisely see the positions of atoms from crystallographic structural analysis allows for optimally aligning the various components of a nanobiosensor. Orientation and proximity can have immense effects on activity and this can be readily seen in native biological systems. The ultimate catalysts in nature are enzymes, which have the ability to enhance reactions by  $10^5$  to  $10^{17}$ -fold. Enzymes hold reactive molecules in precise configurations one by one, orchestrating the formation and breakage of bonds to form products. Although enzyme biosensors have been under study for several years, their use have been limited by the inability to actively harness signals generated by a binding event, such as the electrons produced from a biochemical reaction. The rate constants in electrode-contacted enzymes are far lower than between enzymes and their natural electron acceptors. This decrease has been largely attributed to nonoptimal positioning of the bioelectrocatalyst with the electrode. This is because the active site of a redox enzyme is buried and electrons produced from a reaction cannot efficiently get out to the surface to be used or are not directed to the electrode so they are lost to solution. Consequently, the decreased rates of reactions and amount of enzyme required to obtain detectable signals make these enzyme-based sensors impractical and limited in their sensitivities. The application of structural insights to precisely align the biological components with nanoplatfoms can more fully realize the vision of exploiting the innate specificities and enhancements of biological reactions in detection applications. This ability to direct the placement of various active centers (e.g., electron transducing sites or other active units), allows the production of systems with enhanced sensitivities and kinetic properties. This capability is firmly rooted in incorporating results from X-ray crystallography or NMR spectroscopy, techniques allowing for the atomic resolution determination of the 3D conformation of molecules. Consequently, detection of molecular events approximating single molecule sensitivity through integrating advances gained in structural biology and nanotechnology is feasible.

### 9.3

#### Elements of a Nanobiosensor

##### 9.3.1

##### Biomolecular Components

Biosensors are chemical sensors capable of biorecognition through biochemical processes. Generally, bionanosensors contain a biological component that can be a protein (e.g. antibodies, enzymes) or nucleic acids or even whole cells [16, 17]. This bioelement is responsible for the binding and recognition of the target analyte, whether a small molecule or a large protein partner. The binding event is the basis for signal generation and a physical element, such as an electrode, captures the signal as the output. As the electrode, this component translates information from the biological element into a chemical or physical output with a defined sensitivity. The information that is detected can be chemical, energetic such as detection of light, or essentially any information that organisms innately process as all of these signals depend on biological molecules for their generation and/or signal detection and transduction. The array of potential sensory detection is vast, as combinatorial integration can potentially result in detection of multiple signals. The bioelement can consist of antibody/antigen; enzymes, particularly redox enzymes; nucleic acids including DNA, RNA; cellular components such as organelles; and synthetic or semi-synthetic materials. Some will be described briefly.

In antigen/antibody biosensing, interactions of immunogenic partners are the events being detected [19, 20]. The innate sensitivity of antibody–antigen complexes are exploited to detect the presence of antigens although conditions are usually manipulated to minimize nonspecific interactions. The structures of several antibodies have been determined to high resolution.

For enzyme-based biosensors, the detection process relies on the catalytic activity of the system. Enzymes are of great interest as they are natural catalysts, typically proteins but can also be catalytic ribonucleic acids (catalytic RNA). Enzymes can accelerate reactions  $10^5$ - to  $10^{17}$ -fold. Such magnitudes of kinetic amplification are possible through various mechanisms, including proximity and geometrical effects. The structures of enzymes show that they are mostly globular, with their active sites buried at the center or at oligomeric (multimeric) interfaces [21]. This serves to protect the active site from reacting with non-productive molecules, including solvent water molecules. This is achieved by protecting their labile active sites from bulk environment, forming a region with limited accessible and a local microenvironment. The catalytic site can thus have substantially perturbed  $pK_a$  and electronegativity values from the bulk solvent; this unique microenvironment is attained through the folded structure of the protein. Accordingly, the catalytic activity of enzymes depends on the integrity of their native protein conformations. Signals and products formed at the active site must somehow be released via a conformational change or through other means. This highlights the essential difficulties in using proteins as the source; immobilizing the protein onto an electrode surface to more directly establish electrical communication between the biocatalyst

and electrode can alter the conformation of the protein. Not only can the biocatalyst not be optimally aligned to the electrode surface upon immobilization but the signals generated in a buried active site may not be efficiently routed to allow facile communication between the biocatalysts and electrodes. Consequently, these can limit applications of enzyme biosensors as the electrode-contacted electron transfer rate constants are far lower than those between the enzymes and their natural electron acceptors [22–24]. This highlights an area of optimization in bioelectrode development, where chemical immobilization method for the enzyme can be modified to maximize the enzyme's active conformation. In addition to immobilizing, the method would provide a means of directing the signals generated at the buried active site of the enzyme to the electrode surface, increasing the signals obtained. The 3D structures of numerous enzymes have been determined and these can be used to enhance both of these important parameters.

Some of the most familiar systems involve the use of DNA-based sensors. Nucleic acid based biosensors (also called genosensors) are numerous and have been shown to detect nucleic acids at very low concentrations [25–27] (attomole levels). These types of sensors combine nucleic acid layers with electrochemical transducers for sensitivity. Several different approaches have been used to amplify signals, many based on electrochemical effects. Advantages of using nucleic acids for biosensing are their endogenous charge characteristics, allowing for electrochemical detection methods that allow for amplification. There are numerous structures of nucleic acids and most adopt canonical conformations that can be predicted based on sequence information.

### 9.3.2

#### **Nanoparticles**

Semiconductor nanoparticles coordinated to native biological macromolecules sensitive to external stimuli are attractive systems for various applications [28, 29]. As labeling reagents, undecagold particles have been used for several years in electron microscopy applications as phasing reagents. Their application in nanobiotech applications is an extension of their material properties, providing facile surface chemistries that can be exploited to further enhance optical, charge, and magnetic properties of the particles. Several types of nanoparticles have been used as biosensor components. Their function in a biosensor varies, from directing the binding of the biomolecular component to functioning as the sensor component itself. They have been used as probes, recognizing and differentiating an analyte of interest for diagnostic and screening purposes [30]. Detection of an interaction event via nanoparticle probes can be through color, mass, or other changes in physical properties [31–34].

Nanoparticles such as quantum dots, metallic nanobeads, and non-metallic particles such as those based on silica and natural materials such as chitosan and carbon nanotubes have been produced [35, 36]. In addition to their role in mediating biomolecular binding and linkage for electrochemical detection, these nanoparticles have been used in various bioanalytical formats. These include quantitation

tags in optical detection of quantum dots, substrates for multiplexed bioassays, mediators of signaling events such as those using gold-based aggregation assays, and potentially as surface catalysts for biological reactions. The sizes of nanoparticles used for most of these applications are from 2 to 50 nm [2, 30].

Another type of nanomaterial is nanopores, molecular sieves that could be transport and possibly serve as inorganic channels. These nanopores have been demonstrated to allow permeation of charged molecules when an external electric field is applied. A protein capable of forming pore structures,  $\alpha$ -hemolysin, has been inserted in lipid bilayers coating nanopores to form selective molecular sieves [37]. Other organic and synthetic nanopores have been fabricated in an attempt to form channels and detection systems capable of high throughput and specificity [38, 39]. These nanopores are typically over 5 nm in diameter and larger.

### 9.3.3

#### Nanoelectrodes

In nanoscale structures, electrons no longer behave like physical objects that flow in a continuous stream but take on wave mechanical and quantum properties and have the ability to tunnel through structures that would ordinarily be insulators. As single molecule measurements become more feasible with the advent of methods sensitive enough to study single molecule kinetics, thermodynamic, and electronics, significant deviations from ensemble measurements have been found. With the removal of ensemble averaging, distributions and fluctuations of molecular properties can be characterized, transient intermediates identified, and catalytic mechanisms elucidated. Towards facilitating single molecule measurements, nanoelectrode platforms have been investigated as nanosensors for enhancing signals.

A viable nanobiosensor must include an electrode surface that allows proteins to be immobilized yet retain their native structure. Proteins approaching a hydrophobic planar surface will denature upon contact. This phenomenon, called surface denaturation, occurs because the platform serves as a catalyst to the cooperative unfolding process whereby hydrophobic residues of a protein will interact with a surface to expose additional hydrophobic groups. Consequently, immobilization of a protein onto an electrode whose dimensions are significantly larger than the hydrodynamic radius of the macromolecule requires a spacer that will prevent or minimize surface denaturation effects. As described in the next section, peptides and DNA have been used for this purpose; furthermore, these have an additional role as a conductive bridge between the protein and electrode. However, nanoelectrode platforms with dimensions of 20–40 nm diameter and 80–100 nm center-to-center distance on an array platform mostly circumvents surface denaturation effects as their sizes and geometrical aspects results in 3D electrodes, bypassing complications that arise from planar surfaces as well as maximizing surface areas for binding proteins.

Nanoelectrodes formed from carbon nanotube and other materials can display altered properties simply by the nature of their dimensionality [40–43]. Reducing to smaller sizes can result in increased reactive surface areas as well as other ef-

fects, such as focusing of electric field due to their geometric configuration [36, 44, 45]. These are desirable effects, enhancing the system through their physical aspects. Carbon nanotube and metallic arrays have been used as electrodes, to promote electron transfer in redox reactions [36, 40, 46].

## 9.4 Coordinated Biosensors

Advantages in sensitivity and enhanced rates of reactions can be gained from integrating atomic resolution structural information with nanoelectrode arrays, to build detection devices of ultrahigh sensitivity and enhanced kinetics of reactions. In this section, a system utilizing a peroxidase consisting of the components described above will be described, to demonstrate how structural results can be applied to enhance nanobiosensors design. The enzyme NADH peroxidase has been used as the specific detector of hydrogen peroxide, converting a biological binding event into an electronic signal [47, 48]. Although this system used an oxidative metabolism enzyme, other redox proteins can be the bioelement, since detection is based on generation of electrons as the detectable signal. In addition to the traditional use of redox enzymes, other non-redox proteins can be used if the binding of a ligand triggers a conformational change that can be detected by an induced electronic event or via optical, thermal or other detectable physical changes. These interactions provide the basis for catalysis (in enzymes), recognition of antigen (with antibodies), in initiating cellular processes and signal transduction (in receptor systems). Alternatively, a virion or particles can theoretically be the bioelement of a sensor as structural information is available for many of these macromolecules. Our strategy integrates desirable properties of the individual components: the protein machinery for sensitivity and specificity of binding, peptide chemistry for aligning the various electron transducing units, and the nanoelectrodes for gain sensitivity in electronic detection.

### 9.4.1

#### **Biomolecular Conduits: Signal Transducing Mediators**

The use of redox enzymes as the source of electronic signals that can be propagated efficiently in response to a specific ligand or other physiological signal has many potential applications, such as amperometric biosensors [17, 18, 49]. A major limitation in using biomolecules in electrodes is that their incorporation is complicated by a lack of efficient pathways for the transport of electrons from their embedded redox sites to an electrode, as described above. Although electrical communication between redox proteins and electrode surfaces has been improved through various approaches [17, 19, 50–52], these methods involve contact of the enzyme at somewhat random conformations with respect to the electron relaying units, ultimately resulting in decreased rates of electron transfer. To produce electroactive biocatalysts in amperometric biosensors with sufficiently high rates of

electron transfer, the relaying units must be linked in a controlled and mechanistically relevant manner [53–57]. The following section describes harnessing of electrons through a modularly formed, redox active assembly consisting of a redox enzyme, a metallized double-helical peptide, and a gold nanoparticle immobilized onto a carbon nanotubes electrode and a gold wire derivatized with a benzenedithiol compound. Each of these components and their role in biosensing has been described before. One unique component of this bioassembly is the use of metallized peptide as the conduit of electronic signals.

Peptides and DNA linkers can be made conductive through binding of metals and functionalized to incorporate specific reactive groups. The overall redox potential is driven by the coordination of the particular metals to the peptide. The reductive potentials reflect the ease or difficulty in transitioning between oxidized and reduced states for a particular metal ion. Imidazolium chemistry is well defined and allows for the binding of divalent metals. Depending on the metal, the potentials needed to drive the oxidative/reductive states of the metals can be shifted through precise ligation [58, 59]. Consequently, application of specific coordination chemistry through various ligation groups of a peptide or DNA allows for the more directed binding and stabilization of a subsequent redox state. This is an important consideration as the peptide or DNA linkers form a junction and functions in transducing the signals from the bioelement to the electrode. Functionalization of peptides and DNA allows for targeting, in principle, of virtually any protein, as long as unique groups (e.g., reactive amines, thiols, hydroxides) are present and assessable. In addition to their roles in linking and signal transduction, they have a physical function of spacing the protein away from the surface of the electrode, helping to minimizing surface denaturation effects.

Using the unique cysteine-sulfenic acid chemistry of the Npx redox center, described below, we designed a metallizable, multi-histidine peptide (MHP), with differentially functionalized termini that linked to a specific component of the signaling assembly (Fig. 9.1) and of sufficient length to penetrate the active site.

A 33-amino acid sequence from the leucine zipper region of the GCN4 transcription factor was used to design metal binding sites along a face of the helix by introducing histidines at  $i$ ,  $i + 4$  positions [60]. These histidines bind divalent metals while still permitting the formation of a stable dimer with metals bound along each face of the double-stranded peptide, as confirmed through circular dichroism analysis. A reduced thiolate moiety at the carboxyl terminus (CT) reacts with the active site sulfenate of Npx to form a cysteine bond. Formation of the enzyme–peptide complex was confirmed by mass spectrometry (Fig. 9.2).

The peptide has a helical axis 47 Å long, sufficient to penetrate into the active site that is buried centrally in the enzyme. Before formation of the peptide–AuNP complex in the next step, cobalt metallization of the peptide was achieved by incubation of the MHP with  $\text{CoCl}_2$ , forming a substituted metallized peptide (CoMHP) (confirmed by mass spectrometry). The stoichiometry of Co to peptide duplex was determined by isothermal titration calorimetry, which resulted in a stoichiometry of 2 to 4.7, depending on conditions and design, Co per peptide strand. Further confirmation of binding to various divalent metals came through X-ray fluores-

**Fig. 9.1.** Schematic of assembly of AuNP-Co-MHP-Npx electrode through stepwise linkage of each component with adsorption of the AuNP linked complex reconstituted onto a dithiol monolayer associated with an Au electrode. An electroactive monolayer assembly consisting of NADH peroxidase enzyme (“source”), CoMHP, (“linker-conduit”), and AuNP (“electron sink”) was constructed by stepwise linkage of components and covalently connected to a monolayer on a macroscopic Au electrode.

cence spectroscopy (EXAF) measurements performed at beamline X8C at Brookhaven National Laboratory. EXAF results established that the peptide binds  $\text{Ni}^{2+}$ ,  $\text{Zn}^{2+}$ , and  $\text{Co}^{2+}$ . For the assembly, Co was used as the  $\text{Co}^{3+}/\text{Co}^{2+}$  redox couple has reported values of 0.22–0.295 V vs. SCE for imidazolium complexes [58] and 0.37 to 0.4 V for conjugated ring complexes [59]. The mechanism by which electrons are transmitted through this assembly system likely requires the formation of the  $\text{Co}^{3+}$  state, which is transiently reduced back to  $\text{Co}^{2+}$  during the transduction of electrons upon NADH binding. The structure of the MHP peptide in the presence and absence of cobalt have been determined to high resolutions of 1.6 and 1.7 Å. These results show that the peptides not only maintain their structural integrity after mutation to histidines but that their elongated structure is even more pronounced (Fig. 9.3), confirming the design principles originating from the structural results of the intact GCN4 protein.

#### 9.4.2

##### NADH Peroxidase: the Biocatalytic Element

For the peroxidase sensor [61], the assembly incorporated a bacterial NADH peroxidase (Npx), a 49 kDa flavoenzyme, that catalyzes the two-electron reduction of  $\text{H}_2\text{O}_2$  into  $\text{H}_2\text{O}$ . This reduction is initiated upon binding of the cofactor NADH, which donates two electrons through the primary redox center, FAD. Under oxidizing conditions, the electrons are passed onto a molecule of peroxide, bound to the secondary redox center, a thiolate residue. This residue progresses from the reduced thiolate ( $-\text{S}^-$ ) to the oxidized sulfenate ( $-\text{SO}^-$ ) states during the catalytic cycle [48]. The 3D crystal structures of wild-type, oxidized and reduced forms of Npx [61] have been solved to atomic resolution so that the precise conformation of the active site residues and steric limitations within the active site are well-defined.

**Fig. 9.2.** Matrix-assisted laser desorption time-of-flight mass spectrometry (MALDI-TOFMS) analysis of the complex formed upon reaction of the peptide with the NADH peroxidase (Npx). A gold nanoparticle was also part of the complex and the resulting complex molecular weight is between 66431 and 66549

daltons (Da). The molecular weights of each component are Npx (49 500 Da), MHP (3934 Da), and gold nanoparticle (13 115 Da). MS analysis can be valuable in confirming the formation of various complexes as the bioassembly consists of multiple components.

The current resulting from NADH binding to Npx and the concomitant electron transfer through the assembly was measured using an electrochemical cell consisting of the biocatalytic molecular wire assembly (“working electrode”) and an Au-wire reference electrode. Solution conditions for current measurements were the same as that used for enzyme activity measurements as these are optimized for NADH binding [47]. Before initiating the reactions, we applied a slight potential of 10 mV to the working electrode, to offset the difference in potential between the reference and working electrodes originating from immobilization of the assembly. It was expected that a charging potential may be necessary to overcome the tunneling barrier that may arise from the dithiol monolayer that bridges the AuNP to the Au bulk electrode, as reported previously [49]. However, other than the 10 mV offset potential applied, additional charging potential did not appear to be necessary in this system.

Once the system was equilibrated in the reaction buffer, an aliquot of  $\text{H}_2\text{O}_2$  solution was added. This generated a signal in the positive Y-direction, indicating that

**Fig. 9.3.** Structure of the metallizable peptide (MHP), shown in ribbon depiction, in the absence of metals, refined to 1.6 Å resolution. These structural results confirm the conformational rigidity of the peptide, which is essential for efficient electron transduction. The leucines, which hold the peptide together, are shown in gray ball-and-stick, at the interface of the two strands. Two views are shown, differing by 90° along the helical axis.

electrons were flowing through the circuit toward the working electrode from the reference electrode. The role of hydrogen peroxide is two-fold – to oxidize unreacted free thiols prior to initiating the enzyme-mediated reaction and, more importantly, to generate the  $\text{Co}^{3+}$  oxidation state of the metal. As expected, the reaction of  $\text{H}_2\text{O}_2$  has a time constant longer than that generated by NADH, whose binding initiates the electron transfer reaction mediated through the binding of the cofactor by the enzyme. Hence,  $\text{H}_2\text{O}_2$  current generation represents reactions that are not mediated through the enzyme itself but rather through oxidation effects at the surface and on the metal centers. Oxidation of metals bound in the peptide primes the assembly for electron transduction. This is an important factor and aids in driving the overall reaction from the enzyme active site to the electrode. After the  $\text{H}_2\text{O}_2$  signal returned to the starting baseline value, an aliquot of NADH was added to reach a final concentration of 0.3  $\mu\text{M}$ . The current generated in response to NADH binding reached maximum values within 100 ms, indicating fast kinetics of electron transfer. Anodic current peak density values obtained for electrodes with three different surface areas were 50 nA for an electrode coated with  $10^8$  molecules of assembly and 85  $\mu\text{A}$  for  $10^{11}$  molecules of immobilized assembly. Two concurrent processes appeared to occur with the addition of NADH – a fast electron transfer signal that is transduced through the assembly to the electrode and a slower event that is the reduction of the disulfide bond linkage between the enzyme and the metallized peptide [61]. This reduction resulted in eventual liberation of the enzyme from the assembly and limited the current producing cycles of the assembly, providing additional verification of the route of electron transfer in this system.

## 9.4.3

**Undecagold Nanoparticle: Role in Alignment and Directing Electron Flow**

For the peroxidase sensor described, an undecagold nanoparticle was used to further help align Npx on the electrode surface. A sulfo-N-hydroxysuccinimido activated carboxyl group on the AuNP allows the formation of a covalent link to the MHP through a nucleophilic attack by the amino terminus primary amine group of MHP. The AuNP-CoMHP component is reacted with the Npx enzyme to form a disulfide bond between the carboxy terminal cysteine of the peptide and the redox active cysteine of Npx. For the final reconstitution of the Npx-CoMHP-AuNP assembly onto the Au electrode, a self-assembled monolayer was formed by adsorption of 1,4-benzenedithiol (BDT) onto Au wires. This provided the reaction surface for final immobilization by reaction of the AuNP with thiols of the BDT monolayer. The tri-modular assembly was formed on an Au electrode wire with a geometrical area of  $0.25 \text{ cm}^2$  and a roughness factor of  $\sim 1.2$ , functionalized with the 1,4-benzenedithiol monolayer. Surface coverage of the electrode was determined by cyclic voltammetry scans of the 1,4-benzenedithiol derivatized electrode, which indicated a number density of thiol groups of  $3.2 \times 10^{-10} \text{ mol cm}^{-2}$ . Our first route for assembly formation prior to immobilization on the Au-electrode was non-optimal, which resulted in  $10^8$  molecules of assembly per  $0.25 \text{ cm}^2$  electrode surface. This was found to be due largely to incubation times of 1–2 h for the initial CoMHP-AuNP formation. We have found that increasing the incubation times to overnight at  $4 \text{ }^\circ\text{C}$  resulted in enhanced linkage between the peptide and AuNP, producing an electrode surface coverage of  $10^{11}$  molecules  $\text{cm}^{-2}$ .

Using the gold nanoparticle, we labeled as described above then reacted the assembly through the MHP N-terminus to carbon nanotube arrays. The reaction between the peptide's N-terminus to the carboxyl groups at the tips of carbon nanotube arrays was catalyzed by EDC/NHS chemistry. Scanning electron microscopy of the resulting array shows that the bioassembly is localized to the tips of the electrodes and that this reaction can be quantitated (Fig. 9.4).

## 9.4.4

**Integrated Signals**

Based on reaction rate enhancements reported due to proximity and orientation effects in native enzyme and receptor systems, a coordinated assembly whose components are optimally tethered on an electrode would be expected to enhance rates of reactions by up to  $\sim 100$ -fold [62, 63]. Furthermore, the tethering of a signaling assembly containing the redox enzyme onto an electrode could enhance electronic signal transduction rates by minimizing loss of signal to the solution. Particularly relevant to the formation of a bioelectrocatalytic system is the spatial orientation of the signaling unit and all its components, which must be reconstituted in a conformation that is conducive for charge transfer. Exhibition of enhanced electron transfer rates through the enzyme assembly, compared with the native rate of

**Fig. 9.4.** Scanning electron microscopy (SEM) of an NADH peroxidase assembly conjugated at the tips of highly ordered carbon nanotubes (CNTs). In the array, the CNTs are 50 nm in diameter, have walls of 3-nm thick, and exhibit an exposed length of 60 nm, a total length of 10  $\mu\text{m}$ , and a center-to-center spacing of 100 nm between adjacent tubes. The reaction conditions can be modified to link quantitatively the bioassembly onto the electrode platform.

unimolecular enzyme reduction by NADH, the electron donor, would suggest that the signaling units are aligned properly for electron transfer.

The currents measured correlate to an electron transfer rate constant on the order of  $3000 \text{ s}^{-1}$  within each assembly. This electron transfer rate is two orders of magnitude higher than the endogenous electron transfer rate from NADH to the native enzyme,  $27 \text{ s}^{-1}$ . This rate indicates that the metallized peptide is in an optimal conformation for electron transfer, and, in conjunction with the nanoparticle, forms effective conduits for the electrical signals.

An advantage to this system is that, in addition to the atomic resolution structures of Npx, the kinetics of this enzyme have been well characterized so that the rate constants of several steps in the reaction cycle are known. This information helps correlate the electron transfer rate constant derived from the assembly cur-

rents measured in this system with the native reaction rates and allows an assessment of the efficiency of the designed assembly in electronic signal transduction. Using the anodic currents and the number of assembly molecules on the electrode surface, we calculate a first-order electron transfer rate constant of  $k_{\text{et}} = 3000 \text{ s}^{-1}$ . This value is more than  $100\times$  larger than that of the reduction of the oxidized enzyme by NADH ( $27 \text{ s}^{-1}$ ), the most comparable unimolecular kinetic step characterized in the native enzyme. We believe that the rate-determining step for electron transfer in this system is the initial binding of NADH, and that subsequent steps in electron transduction are fast compared with this event.

Metallized peptides appear to be an efficient mediator of electrons. The precise mechanism by which electrons are propagated through the peptide remains to be studied although, based on the  $5.2 \text{ \AA}$  distance between cobalt ions modeled into the peptide, a hopping mechanism seems more likely than through-bond transduction. The use of metallized peptides as conduits for electronic signals can be extended to various systems, offering a convenient approach for the design of modular functional linkers. Linking of biomolecules to electronic circuitry can be essential to the design of efficient signal transduction assemblies in bioresponsive systems. The use of metal nanoparticles that act as electrical nanoplugs helps to align the enzyme on the conductive support. In our work, the AuNP appears to channel the current to the electrode to help maximize the efficiency of electron transfer.

This peroxidase biosensor initiates and conducts redox signals in the presence of  $\text{H}_2\text{O}_2$  and NADH. The current generated by the binding of NADH, the electron donor, was transduced through the molecular assembly with high efficiency. A key component of the system is the metallized peptide and the formation of  $\text{M}^{3+}/\text{M}^{2+}$  states that allow for the transduction of the electronic signal. The gain in electron transfer rates and concomitant sensitivity is likely a result of positioning of the electron transducing units (Fig. 9.5), which provides an improvement at each junction, which can additively influence the overall rates of the biocatalytic element.

## 9.5

### Conclusion

Important technological advances in the past few years have provided the tools needed to develop new technologies to monitor biorecognition and interaction events on solid devices and in solution [7, 64]. In conjunction with the ability to fabricate solid substrates with nanoscale features and precisions, biosensing offers unprecedented opportunities for screening and detection. In this chapter, the approach of integrating 3D structural information to align the various signal transducing elements in a nanobiosensor has been described. This can result in coordinated biosensing, where the elements of a biosensor are optimized geometrically to enhance kinetics of reactions.

To illustrate the concepts presented here, the NADH peroxidase biosensor was described as this was one of the first systems that demonstrated the gain that

**Fig. 9.5.** Model of the assembly based on the atomic coordinates of the NADH peroxidase and MHP. The peptide coordinates cobalt atoms (small yellow spheres) through the histidine residues at every  $i, i + 4$  positions. AuNP was modeled in as a gold sphere, to

scale with the biological molecules, with a diameter of 14 Å. The cofactors are shown in ball-and-stick, with nicotinamide adenine dinucleotide in red and flavin adenine dinucleotide in yellow.

can be obtained in by applying atomic resolution structural results to align transducing centers. These results highlight the feasibility of using these biosensors in various applications, including nanomedicine, where detecting markers of disease states requires high sensitivity to make them viable in clinical applications. This approach, applying detailed structural information at sub-nanometer resolutions, produces sensors at the nanometer dimensions that fully integrate the various biological and electronic elements to produce ultrasensitive detectors.

The efficiency, specificity, and modularity of biomolecules such as proteins and nucleic acids make them attractive material for designing highly sensitive and intelligent circuitry. Utilization of natural macromolecules as sensors exploits the inherent recognition and diversity of these molecules. Effective integration of biomolecules with nanoelectronic circuitry holds great promise for the design of compact and highly sensitive systems. Direct electronic coupling with high efficiencies between electrodes and enzymes can be achieved through several approaches and highlights the feasibility of fully utilizing biomolecules in nanobiosensors. The new field of nanomedicine, as with other studies on the nanoscale, can lead to substantially new breakthroughs in technologies, leading to new paradigms in medical detection and treatments. Many biomedical applications can benefit substantially from the use of coordinated biosensors.

# Protein-based Biosensors using Nanomaterials

*Genxi Li*

### 10.1

#### Introduction

Protein-based biosensors are fabricated based on the electron transfer between proteins (enzymes) and electrodes [1, 2]. However, electron-transfer rates between redox proteins and electrode surfaces are usually prohibitively slow [3]. On the one hand, the electroactive prosthetic groups of most redox proteins are deeply buried in the electrically insulated peptide backbones. On the other hand, unfavorable orientations and adsorptive denaturations of proteins often occur at electrode surfaces. To achieve efficient electrical communication, one approach that has been proposed, and widely employed in previous years, is based on electrochemical mediators, both natural enzyme substrates or products, and artificial redox mediators (first-generation and second-generation biosensors) [1]. First-generation biosensors have many defects, such as possible interference because of the too high applied potential, systematic complexity caused by fluctuation of the concentration of dissolved oxygen, a relatively low detection limited since the tenuity of dissolved oxygen will significantly decrease the electrical currents, etc. [4–6]. Consequently, the idea of artificial mediators has been proposed, leading to the development of second-generation biosensors. Nevertheless, redox mediators used in conjunction with redox proteins are in no way selective but rather general redox catalysts, facilitating not only the electron transfer between electrode and protein but also various interfering reactions [7]. Therefore, third-generation biosensors, which are based on the direct electron transfer of proteins, i.e., the electrical communication between the proteins and signal transducers is accomplished directly without additional mediators, have received more and more attention [2]. Third-generation biosensors are superior in selectivity both because they should be operated in a potential window close to the redox potential of the protein itself, and therefore, are less prone to interfering reactions [4] and also because of the lack of yet another reagent in the reaction sequence.

Recent breakthroughs in nanotechnology have made various nanostructured materials more affordable for a broader range of applications, and nanotechnology is playing an increasingly important role in the development of biosensors [8–11].

Owing to the unique properties of nanomaterials, direct electrochemistry and catalytic activity of many proteins have been observed at electrodes modified with various nanomaterials such as  $\text{TiO}_2$ ,  $\text{ZrO}_2$ ,  $\text{SiO}_2$ ,  $\text{Fe}_3\text{O}_4$ , metal nanoparticles, carbon nanotubes, etc. [12–17]. The sensitivity and performance of biosensors are being improved by using nanomaterials for their construction. Various nanostructures have been examined as hosts for protein immobilization via approaches including protein adsorption, covalent attachment, protein encapsulation, and sophisticated combinations of methods. Studies have shown that nanomaterials can not only provide a friendly platform for the assembly of protein molecules but also enhance the electron-transfer process between protein molecules and the electrode.

We have summarized the sensors fabricated with proteins (enzymes) in a recently published encyclopedia of sensors [1]. Later, we noticed that increasing numbers of protein-based biosensors were being fabricated by using nanomaterials. It has been necessary to focus on the application of nanomaterials in the development of protein-based biosensors. This chapter reviews protein-based biosensors according to the various sorts of nanomaterials used in their fabrication.

## 10.2

### Metal Nanoparticles

Metal nanoparticles have many unique properties: large surface-to-volume ratio, high surface reaction activity, high catalytic efficiency, and strong adsorption ability. Metal nanoparticles have been used to facilitate the electron transfer in nanoelectronic devices owing to the following important functions: the roughening of the conductive sensing interface, the catalytic properties of the nanoparticles, and the conductivity properties of nanoparticles at nanoscale dimensions that allow the electrical contact of redox-centers in proteins with electrode surfaces [8, 18]. Gold nanoparticles and silver nanoparticles are the most intensively studied and applied metal nanoparticles in fabricating biosensors, which will be specially summarized later. Other metal nanoparticles, such as palladium [19] and platinum nanoparticles [20], etc. have also been used.

#### 10.2.1

##### Gold Nanoparticles

Colloidal gold is a metallic colloid whose particles are formed by small octahedral units, called primary particles. The size of gold particles essentially depends on the way the colloid is formed [21]. To improve the stability of these particles, a kind of gold nanoparticle protected by lipid has also been invented [22]. Gold colloid has been widely used as a cytochemical label for the study of macromolecules, with transmission and scanning electron microscopy, light microscopy and freeze-etch electron microscopy, and to improve the signals of both surface-enhanced Raman spectroscopy and surface plasmon resonance [21].

In the last few years, electrochemical biosensors created by coupling biological elements with electrochemical transducers based on or modified with gold nanoparticles have played an increasingly important role in biosensor research. Gold colloid has many advantages for biosensor applications. First, gold nanoparticles can, very usefully, provide a stable surface for the immobilization of biomolecules, such that the molecules retain their biological activities. As is well known, the performance of enzyme biosensors depends not only on the nature of the enzyme molecules but also on the influences imposed on these molecules by immobilization. Modification of an electrode surface with gold nanoparticles provides a micro-environment similar to that of the redox proteins in native systems and offers the protein molecules more freedom in orientation, which can weaken the insulating property of the protein shell for the direct electron transfer and facilitate the electron transfer through the conducting tunnels of colloidal gold [21]. Second, gold nanoparticles can form conducting electrodes and are the site of electron transfer when anchored to the substrate surface, allowing direct electron transfer between redox proteins and electrode surfaces with no mediators required [23]. They can act as an electron-conducting pathway between prosthetic groups and electrode surface. They can provide useful interfaces at which redox processes of biological molecules, such as proteins or NADH, involved in biochemical reactions of analytical significance can be electrocatalyzed [23]. Xiao et al. have that reported the reconstitution of one apo-flavoenzyme, apo-glucose oxidase, on a 1.4-nm gold nanocrystal functionalized with the cofactor flavin adenine dinucleotide and integrated into a conductive film could yield a bioelectrocatalytic system with exceptional electrical contact with the electrode support [24]. Their work shows that electron transfer through the Au nanoparticles is much faster than electron transfer to  $O_2$ . Besides, various characteristics of gold colloid, such as their high surface-to-volume ratio, high surface energy, and ability to decrease the distance between proteins and metal particles, may also facilitate electron transfer between the redox sites of the proteins and electrode surface. The last advantage, but not the least, is that the size and surface morphology (important parameters when applied in biosensing) of gold colloid can be controlled easily experimentally. Colloidal gold surface morphology is vital in establishing the electrical contact between the proteins and the electrodes [25].

Taking horseradish peroxidase (HRP) as an example, although direct, non-mediated electron transfer is well known for some redox proteins and particularly for HRP [26, 27], it is usually very inefficient and is not generally used for practical biosensory devices. Zhao et al. found, in 1992, that a mixed layer of HRP and colloidal gold nanoparticles of 30 nm could be electrocatalytically active for hydrogen peroxide ( $H_2O_2$ ) reduction without the need of electro-transfer mediators [28]. In addition, immobilized HRP was reduced directly on gold colloid through an amplification effect of the enzyme–substrate interaction. It was demonstrated that the utilization of gold nanoparticles in enzyme immobilization could increase the enzyme loading without compromising charge-transfer efficiency [21]. That was to say the small size of gold nanoparticles could allow the conductive material to come into close proximity of the active center of the enzyme, which might facilitate

the electron-transfer process. The nanoparticles could also provide bioelectrocatalytic activity that can be utilized in biosensor devices. This work led to an extensive investigation of the direct electron transfer based on gold nanoparticles and immobilization of proteins, especially enzymes [15, 29–33]. Some related biosensors for  $\text{H}_2\text{O}_2$  [28, 34–38], glucose [34, 39], xanthine and hypoxanthine [34, 40–42], dopamine [43], and cholesterol [44, 45] were also reported. These biosensors exhibited high sensitivity, good reproducibility, and long-term stability.

The catalytic activity of HRP is attributed to its iron heme group, which acts as the electroactive center. Since hemoglobin (Hb) contains four heme groups, it can be utilized as the HRP substitute in the detection of  $\text{H}_2\text{O}_2$ , by virtue of its low cost and stable properties in solution [46]. In the last few years, electrochemical sensors for  $\text{H}_2\text{O}_2$  based on the peroxidase-like activity of Hb incorporated in many different kinds of materials, including colloidal gold, have been fabricated [22, 47–49]. Researchers have also made a novel Hb-based  $\text{H}_2\text{O}_2$  sensor constructed on a gold nanoparticles-modified ITO electrode [50]. Gold nanoparticles, acting as bridges of electron transfer, can greatly promote the direct electron transfer between Hb and the electrode surface without the aid of any electron mediator [51]. Thus, the Hb-immobilized gold nanoparticles-modified electrode can be developed as a third-generation biosensor for the determination of  $\text{H}_2\text{O}_2$ .

Besides HRP and Hb, other heme proteins, such as cytochrome *c* (Cyt *c*), myoglobin (Mb), have also been investigated via being immobilized with gold nanoparticles [52]. Direct electron transfer between immobilized Mb and a colloidal gold modified carbon paste electrode, in addition to a glass carbon electrode, has also been studied [53]. Cyt *c* immobilized on colloidal gold modified carbon paste electrodes can also maintain its activity and electrocatalyze the reduction of  $\text{H}_2\text{O}_2$  [54]. Meanwhile, a chitosan-stabilized gold nanoparticles-modified electrode can also be developed for biosensors [55, 56].

Fabricating a sensitive, stable glucose biosensor has long been of great interest. A novel method to fabricate a glucose biosensor has been proposed by immobilizing glucose oxidase (GOD) on gold nanoparticles, which have self-assembled on Au electrode modified with a thiol-containing three-dimensional (3D) network of silica gel [57] or with a cystamine monolayer [58]. GOD can exhibit excellent bioelectrocatalytic response to the oxidation of glucose. Researchers have also found that aqueous colloidal gold nanoparticles can enhance the activity of aqueous enzymes [59]. Mena. et al. have compared several enzyme biosensor designs, prepared by immobilization of GOD onto different tailored gold nanoparticle-modified electrode surfaces [60].

The immobilization methods for connecting gold nanoparticles with electrodes and with proteins should both be discussed in detail. Generally, there are three ways to prepare gold nanoparticles-modified electrode: (a) by binding with functional groups of self-assembled monolayer (SAMs); (b) by direct deposition of gold colloid onto the electrode surface; (c) by co-modification of mixed gold colloid with other components in the composite electrode matrix [61].

Protein or enzyme can readily be immobilized on colloid gold by dipping a protein solution onto the colloid gold modified electrode surface. The electrostatic in-

teraction between the negatively charged citrate surface of colloidal gold and positively charged groups of the protein leads to the adsorption of protein onto the electrode surface. The prepared electrodes can be characterized by several means such as cyclic voltammetry (CV), transmission electron microscope (TEM), atomic force microscopy (AFM), UV/visible spectroscopy (UV/Vis), surface-enhanced Raman spectroscopy (SERS) and electrochemical impedance spectroscopy (EIS), etc.

SAMs can provide a simple way to tailor surfaces with well-defined compositions, structures and thickness that can then be employed as specific functionalized surfaces for the immobilization of gold nanoparticles and enzymes [62]. Gold nanoparticle-modified electrode surfaces can be prepared by covalently binding gold nanoparticles with surface functional groups ( $-\text{CN}$ ,  $-\text{NH}_2$ , or  $-\text{SH}$ ) of SAMs modified solid surfaces [63–66]. Short-chain molecules, such as cysteamine (Cyst) and 3-mercaptopropionic acid (MPA), can be self-assembled on the gold disk electrode for further binding of gold nanoparticles. Biosensors based on immobilization of enzyme onto Cyst or MPA SAMs that had been previously bound onto gold nanoparticles have also been evaluated and compared [61].

An early work through fabrication of a monolayer of colloidal gold on an indium-doped tin oxide (ITO) support was performed in 1995 [67]. Either (2-aminopropyl)-trimethoxysilane or (3-mercaptopropyl)trimethoxysilane was first attached to the ITO support to yield an amine/thiol-functionalized thin film. The deposited gold thin film was quite stable and provided an active interface for the immobilization or redox-active self-assembled monolayers. The thiol functional group-derived carbon ceramic electrode (CCE) has been used to construct  $\text{H}_2\text{O}_2$  biosensors [68]. Biosensors can also be constructed by immobilizing the proteins by adsorbing them onto the nanoparticles, by crosslinking them with bifunctional agents such as glutaraldehyde, or by mixing them with the other components of composite electrodes. When HRP is immobilized on a colloidal gold monolayer formed at the gold electrode by a long “cysteamine/glutaraldehyde/cysteamine” molecular bridge, it shows an excellent electrocatalytic response to the reduction of  $\text{H}_2\text{O}_2$  [33]. This sensor shows a fast amperometric response, wide linear calibration range and low detection limit for  $\text{H}_2\text{O}_2$  determination. In addition, HRP immobilized on colloidal gold has a high affinity to  $\text{H}_2\text{O}_2$  with no loss of enzymatic activity.

Multilayers of conductive particles can give rise to porous, high-surface-area electrodes, where the local microenvironment can be controlled by the crosslinking elements. Superstructures of a controllable number of colloidal Au particle layers have been formed on a support surface by the alternate interaction of the assembly with a crosslinker and the negatively charged Au particles [69]. A two-dimensional (2D) double layer structure [70] and 3D superstructure consisting of gold nanoparticles for biosensors [71] have also been proposed. The utilization of gold nanoparticles as a building block in the construction of nanoscale functional devices has become a very promising aspect for electrochemical biosensing. The technology of derivatizing Au electrode surface by silica sol-gel and gold nanoparticles takes advantage of both self-assembly, nanoparticles, and the increased surface area of 3D electrodes. Ikeda and coworkers have demonstrated that gold nanoparticles can

self-assemble both inside the network and on the surface of the silica gel [72]. These gold nanoparticles immobilized by a silica gel 3D network can act as tiny conducting centers and facilitate electron transfer between proteins and electrodes. Based on these investigations, a HRP-based  $\text{H}_2\text{O}_2$  sensor and a GOD-based glucose sensor have been developed by embedding gold nanoparticles in thiol-containing silica sol-gel network [73]. An amperometric  $\text{H}_2\text{O}_2$  biosensor has also been reported, based on immobilizing HRP to a nano-Au monolayer supported by a carbon sol-gel derived carbon ceramic electrode [68]. This sol-gel 3D network made it possible to control the effectiveness of the electrocatalytic process, the sensitivity and response rate of the nanoparticle biosensor by controlling the thickness of thiolated polymer or sol-gel, and the number of Au particle layers associated with the electrodes.

Another feasible method to fabricate protein-based biosensor involves covalent attachment of protein molecules to a gold nanoparticle monolayer modified Au electrode, such as GOD/gold nanoparticle systems [58]. Briefly, gold nanoparticles are first self-assembled on a gold electrode by dithiol via Au-S bonds. A cystamine monolayer is then chemisorbed onto those gold nanoparticles and exposed to an array of amino groups, which would further react with aldehyde groups of periodate oxidized GOD via the well-known Schiff base reaction. By this means, GOD could be covalently attached to the gold electrode, resulting in a stable biosensing interface.

Recently, a gold nanoparticle- $\text{CaCO}_3$  hybrid material ( $\text{AuNP-CaCO}_3$ ) has been prepared and applied for sensor preparation [74].  $\text{AuNP-CaCO}_3$  can retain the porous structure and inherits the advantages from its parent materials, such as satisfying biocompatibility and good solubility and dispersibility in water; therefore, it can offer a promising template for enzyme immobilization and biosensor fabrication. HRP has been conjugated with  $\text{AuNP-CaCO}_3$  to fabricate HRP- $\text{AuNP-CaCO}_3$  bioconjugates, which were then embedded into a silica sol-gel matrix to construct a novel biosensor.

There are also many reports on fabricating biosensors by mixing colloidal gold and carbon paste to incorporate colloidal gold into the electrode. A reagentless glucose biosensor based on the direct electron transfer of GOD [75], and a renewable tyrosinase biosensor [76], have been constructed by immobilizing the corresponding enzymes onto electrodes prepared by mixing a colloidal gold solution with the carbon paste components. A renewable reagentless  $\text{H}_2\text{O}_2$  sensor has also been reported based on the direct electron transfer of HRP where HRP is mixed into colloidal gold-modified carbon paste electrodes [15]. Here, the nanoparticles are used to retain the enzymatic activity and facilitate direct electron transfer between HRP and carbon-sensing sites. In addition, nitrite sensors based on a Hb-colloidal gold nanoparticle modified screen-printed electrode and carbon paste electrode have also been developed [77, 78].

In addition to the proteins employed for the fabrication of the above-mentioned biosensors, some other proteins (enzymes) have been used. Xanthine oxidase is reported to be adsorbed onto colloidal gold that was previously evaporated on the surface of glassy carbon, which responds to xanthine or hypoxanthine in the absence

of added mediator by electrochemical oxidation of the enzymatic oxidation product, uric acid [40]. A multi-enzyme biosensor for cholesterol [44] has been constructed to detect cholesterol in serum and whole blood, by making use of HRP and cholesterol oxidase. This sensor gives an electrochemical response that correlates well with the total cholesterol concentration. The biosensor operates at a sufficiently low potential to avoid interference from many sources, and the carrageenan hydrogel enables analysis of whole blood without electrode fouling. A more recent paper reports immobilization of tyrosinase by crosslinking it onto glassy carbon electrodes modified with electrodeposited gold nanoparticles [79]. The immobilized tyrosinase retained a high bioactivity on this electrode material, displaying stable, sensitive responses to various phenolic compounds.

The immobilization of proteins on colloidal gold has also been used for the development of immunological detection methods. An electrochemical method to monitor biotin–streptavidin interaction and determine the concentration of streptavidin has been established by the use of colloidal gold as an electrochemical label [80]. Velev and Kaler have created arrays of biosensors by *in situ* assembly of gold and silver colloidal particles onto micropatterned electrodes and immobilizing antibodies (IgG) on the colloidal particles [81]. Niemeyer and Ceyhan [82] have prepared biofunctionalized nanoparticles by DNA-directed immobilization of proteins at colloidal gold. Biometallic hybrid components can be used in an immunoassay for the detection of proteins. Thanh and Rosenzweig have developed a unique, sensitive and highly specific immunoassay system for antibodies using gold nanoparticles [83]. This assay is based on the aggregation of gold nanoparticles that are coated with protein antigens in the presence of their corresponding antibodies. Au nanoparticles have also been used as electrochemical labels in genetic diagnosis application [84]. *Escherichia coli* single-stranded DNA binding protein (SSB) has been attached onto a SAM of single-stranded oligonucleotide modified Au nanoparticle, and the resulting Au-tagged SSB was used as the hybridization label for the electrochemical detection of DNA hybridization. Changes in the Au oxidation signal were monitored upon binding of Au tagged SSB to probe and hybridization on the electrode surface. These works demonstrate the emergence of a new field of application for colloidal gold in protein immobilization and biosensing.

### 10.2.2

#### **Silver Nanoparticles**

Colloidal silver is another nanomaterial often used for biosensor fabrication. Its synthesis has been well demonstrated [85]. Much attention has also been given to the quantum characteristics of small granule diameter and large specific surface area as well as the ability to quickly transfer photoinduced electrons at the surfaces of colloidal particles [86]. It is also found that surface-assembled silver nanoparticles can act as an electrical bridge that “wire” the fast interfacial electron transfer between Cyt c and pyrolytic graphite electrodes, opening up new opportunities for the *in vitro* electron-transfer process of heme proteins by using silver nanoparticles and for fabricating bioelectronic devices. Furthermore, silver nanoparticles

greatly enhance the electron-transfer reactivity of heme-proteins, such as HRP, Mb, Hb and their catalytic ability toward  $\text{H}_2\text{O}_2$  and nitric oxide [87–89]. Glucose biosensors based on immobilization of GOD in silver nanoparticles have also been fabricated [90, 91]. The studies show that the colloidal silver nanoparticles function as electron-conducting pathways between the prosthetic groups and the electrode surface, therefore the electron-transfer rate between the enzyme and the electrode is increased significantly. In addition, by the vapor deposition method, Hb and colloidal silver nanoparticles can be entrapped in a titania sol-gel matrix on the surface of a glassy carbon electrode – thus a  $\text{NO}_2$  biosensor is prepared [92].

### 10.2.3

#### Other Metal Nanomaterials

One promising metal for nanoparticles is platinum. Platinum nanoparticles with a diameter of 2–3 nm have been used with single-wall carbon nanotubes (SWCNTs) for fabricating electrochemical sensors with Nafion to form a network that connected Pt nanoparticles to the electrode surface [20]. The use of platinized carbon microelectrodes has also been reported for a glucose biosensor [93]. Nanocrystalline diamond exhibits several special properties that make it particularly suitable for biofunctionalization and biosensing [94]. As an improvement, platinum-modified boron-doped diamond microfiber electrodes were fabricated, which exhibited much higher sensitivity [95]. Electrodeposition of highly dispersed palladium nanoparticles on a glassy carbon electrode has also been reported for the construction of a glucose biosensor [96]. Another glucose biosensor has also been reported by co-depositing palladium nanoparticles and GOD onto a Nafion-solubilized carbon nanotube (CNT) film [19]. GOD can retain its biocatalytic activity and offer efficient oxidation and reduction of the enzymatically liberated  $\text{H}_2\text{O}_2$ , allowing for fast and sensitive glucose quantification.

Some glucose biosensors based on non-conducting polymer films have been reported; however, such biosensors always suffer from a low response current and a relatively high detection limit. To solve these problems, Cu nanoparticles are selected to increase the response current because it can electrochemically oxidize glucose [97]. A GOD and Cu nanoparticles-based sensor has a two times lower detection limit, a three times larger maximum current and  $2.5\times$  higher sensitivity than biosensors fabricated with no Cu nanoparticles.

## 10.3

### Metallic Oxide Nanoparticles

Some researchers have used  $\text{MnO}_2$  nanoparticles as eliminators of ascorbic acid interference to amperometric glucose and lactate biosensors [98, 99]. Others have constructed an enzyme field-effect transistor using a GOD membrane doped with  $\text{MnO}_2$  powder [100]. In this configuration,  $\text{MnO}_2$  acts as a catalyst to the decomposition of  $\text{H}_2\text{O}_2$ . Therefore, the produced  $\text{O}_2$  from the decomposition of  $\text{H}_2\text{O}_2$  can

be replenished in the glucose oxidation reaction and the dynamic range of glucose determination is extended. Researchers have also fabricated some glucose biosensors based on the co-immobilization of GOD and  $\text{MnO}_2$  nanoparticles [98, 101].

Nano titanium dioxide ( $\text{TiO}_2$ ) is now an attractive biocompatible material widely used in toothpaste and cosmetics. Due to its unique physiochemical properties and its inclination to selectively combine with some groups of biomolecules, nanosized  $\text{TiO}_2$  has been proposed as a promising interface for the immobilization of biomolecules. Attempts have been made to assemble heme proteins, including Cyt c, Mb and Hb, onto a nanocrystalline  $\text{TiO}_2$  film; the  $\text{TiO}_2$  film can not only offer a friendly platform to assemble the protein molecules, but also enhances the electron-transfer process between the protein molecules and the electrode [12]. The electrochemical characteristics of HRP entrapped in a  $\text{TiO}_2$  nanoparticles film cast on pyrolytic graphite electrode has been examined [102]. The good biocompatibility of  $\text{TiO}_2$  nanoparticles can make HRP retain its native state and show good electrocatalytic activity, which may have potential application in constructing a third-generation electrochemical biosensor.

Zirconium dioxide ( $\text{ZrO}_2$ ) nanoparticles have also been used in protein-based biosensors. As an example,  $\text{ZrO}_2$  nanoparticles 35 nm in diameter have been cast on a pyrolytic graphite electrode by dispersing them in dimethyl sulfoxide to immobilize Hb for fabrication of a  $\text{H}_2\text{O}_2$  sensor [13]. This sensor shows a high thermal stability up to 74 °C. Another example is the treatment of the surface of a platinum electrode with nanoporous  $\text{ZrO}_2$ /chitosan composite matrix to fabricate a glucose biosensor [103]. Other studies reveal that nanoporous  $\text{ZrO}_2$  has general affinity for the binding of proteins because the amine and carboxyl groups on the surface of enzyme can act as ligands to  $\text{ZrO}_2$ . Thus, the usage of glutaraldehyde in crosslinking, which always denatures an enzyme, can be avoided, and a HRP-based biosensor for  $\text{H}_2\text{O}_2$  is correspondingly constructed [104]. Moreover,  $\text{H}_2\text{O}_2$  sensors are constructed based on the self-assembly of  $\text{ZrO}_2$  nanoparticles with heme proteins (Hb and Mb) on a functional glassy carbon electrode [105].

Zinc oxide (ZnO) is another attractive semiconductor material. It has been demonstrated that ZnO with a high isoelectric point ( $\sim 9.5$ ) is suitable for the adsorption of low-isoelectric point proteins [106]. For example, low-isoelectric point tyrosinase is reported to be adsorbed on the surface of such ZnO nanoparticles, facilitated by the electrostatic interactions, and is immobilized on a glassy carbon electrode via film formation to develop a mediator-free phenol biosensor [107]. Therefore, ZnO nanoparticles deserve further investigation as an important promising candidate as support material in the fabrication of biosensors.

#### 10.4

##### Carbon Nanotubes

Carbon nanotubes (CNTs), discovered in 1991, are a new type of carbon material obtained by folding grapheme layers into carbon cylinders. They present a closed topology and tubular structure with diameters of several nanometers and lengths

to several microns. Basically, there are two types of carbon nanotubes, multiwall carbon nanotubes (MWCNTs) and single-wall carbon nanotubes (SWCNTs). They can behave as conductors or semiconductors depending on their structures, mainly on their diameter and helicity.

Carbon nanotubes have received enormous attention for the preparation of electrochemical sensors due to their unique properties, as reviewed in some publications [108–114]. Similar to the conventional electrochemical biosensors, proteins and CNTs based biosensors can also be, generally, divided into three categories: (a) first-generation biosensors via the detection of  $\text{H}_2\text{O}_2$  or  $\text{O}_2$  involved in the enzymatic reaction, (b) second-generation biosensors through the utilization of electron-transfer mediators, and (c) third-generation biosensors based on the direct electron transfer of enzymes or proteins. Especially, CNT materials have been proved to possess electrocatalytic activity toward the oxidation of  $\text{H}_2\text{O}_2$  and the reduction of  $\text{O}_2$  and can facilitate the direct electron transfer of proteins or enzymes. These features make CNTs particularly attractive for the development of first- and third-generation electrochemical biosensors [111]. Many second-generation protein-based biosensors have also been fabricated by using CNTs. For example, organic electrocatalysts, such as polynuclear aromatic dyes, have been employed, which can be stably immobilized onto CNTs and can be further used to accelerate the oxidation of  $\text{H}_2\text{O}_2$  or shuttle electron transfer between the CNTs and enzymes or proteins. Ye et al. have functionalized the MWCNTs with iron-phthalocyanines to redox-catalyze  $\text{H}_2\text{O}_2$  oxidation and have constructed a highly sensitive and selective glucose biosensor [115]. Chen et al. have co-immobilized methylene blue with HRP onto CNTs to shuttle the electron transfer between HRP and the CNTs. The modified electrode exhibited a good bioelectrocatalytic activity toward  $\text{H}_2\text{O}_2$  reduction [116].

The nano-dimensions, graphitic surface chemistry and electronic properties of carbon nanotubes make them an ideal material for use in chemical and biochemical sensing [108–114, 117, 118]. In addition, the fabricated sensors using CNTs usually show high sensitivity and stability of electrocatalysis. Although the mechanism is still not fully understood, some researchers suggest that these advantages may be attributed to the special structure of nanotubes, such as their open ends [119, 120]. The electroactive ends of the nanotubes are readily accessible to species in solution. The opened nanotube ends allow the enzyme to enter the hollow CNTs. In addition, the rigidity of the tubes allows them to be plugged into biomolecules, so enabling electrical connection to the redox centers of the biomolecules. Furthermore, the large surface area per unit volume of CNTs allows a large amount of enzyme to be immobilized within nanotubes.

However, the potential application of CNTs is still limited by (a) the CNTs tend to aggregate in most solvents; (b) electronic communication between proteins and CNTs is rather slow at pristine CNTs; and (c) strong interactions between proteins and CNTs may distort the proteins. Therefore, the biosensing applications of CNTs require rational functionalization of the CNTs to improve their solubility and biocompatibility.

The combination of CNTs with redox active protein (enzymes) appears to offer a convenient platform for a fundamental understanding of biological redox reactions

and for the development of third-generation biosensors. Direct electron transfer and bioelectrocatalysis of many proteins, such as GOD, cyt c, Mb, Hb, HRP, etc., have been investigated with CNTs-modified electrodes and their performance has been found to be much superior to those of other carbon electrodes in terms of reaction rate, reversibility, and detection limit [121–132].

GOD is the major protein employed for sensor fabrication by using CNTs. GOD has been immobilized by coating onto the surface of SWCNTs without a gross loss of enzyme activity [133]. Treatment of this bio-SWCNT sensor with both a diffusive mediator and equilibrated glucose substrate enhanced the catalytic signal by more than one order of magnitude compared with that observed at an activated macro-carbon electrode. This enhanced performance was partly due to the high enzyme loading and partly because of better electrical communication ability of the nanotubes. Other research on MWCNTs has revealed that a MWCNTs-modified glassy carbon electrode can be employed as an amperometric oxygen sensitive electrode to fabricate a glucose biosensor [134]. CNT-based glucose biosensor was also fabricated via polypyrrole [135, 136]. Recently, a CNTs-doped polypyrrole (PPy) glucose biosensor was reported [137]. Unlike other work on glucose biosensors based on CNT/PPy electrodes, where CNT was physically entrapped within the growing film, the PPy/GOD films were formed by using “oxidized” CNT as the sole charge-balancing anionic dopant. This is the first example of anionic CNT acting as dopant in the preparation of conducting-polymer enzyme electrodes. While the concept has been presented within the context of glucose sensing, it could readily be extended to other biocatalytic electrodes based on judicious selection of the enzyme.

Heme proteins have also been extensively employed to fabricate biosensors by using CNTs. The direct electrochemical response of Mb on MWCNT-modified glassy carbon electrode has been reported [16]. Mb exhibited elegant catalytic activity for electrochemical reduction of oxygen, based on which an unmediated biosensor for  $O_2$  was developed. An unmediated  $H_2O_2$  biosensor, based on the peroxidase-like activity of Mb on MWCNTs, has also been constructed [138]. Recently, the same research group reported that Mb can be strongly adsorbed onto the surface of MWCNTs with an approximate monolayer to develop an unmediated NO biosensor, with a low detection limit [139]. HRP is able to adsorb on a carbon nanotube microelectrode to transfer electrons directly with the electrode and retain its catalytic activity toward  $H_2O_2$  [124]. A  $H_2O_2$  biosensor based on Cyt c and MWCNTs has also been fabricated [140]. The enhanced electron-transfer rate was also observed in systems in which microperoxidase (MP-11) was attached to the end of aligned SWCNTs array and MWCNTs [141, 142].

Many other proteins (enzymes) have been employed to prepare various kinds of biosensors by using CNTs. For example, the direct electrochemistry of xanthine oxidase has been achieved on a SWCNTs-modified gold electrode, which may provide an attractive route for the development of biosensors [143]. Table 10.1 gives information on sensors that use other proteins (enzymes).

Understanding the interaction between CNTs and proteins should be helpful in developing protein-based biosensors using CNTs. Usually, proteins (enzymes) are immobilized onto CNTs in three ways, taking GOD as example.

**Tab. 10.1.** Protein-based biosensors using carbon nanotubes.

Protein(enzyme)	CNT	CNT immobilization matrix/electrode	Analyte	Ref.
Acetylcholinesterase (AChE)	MWCNT	Thick film strip electrode	Organophosphorus (OP) insecticides	219
L-Amino acid oxidase	CNT	Alkoxy silane sol-gel	L-Amino acid	220
Urease	CNT	Sol-gel	Urea	221
Acetylcholinesterase	CNT	Sol-gel	Acetylthiocholine	221
L-lactate oxidase	MWCNT	Sol-gel/GCE	L-Lactate	222
Putrescine oxidase	MWCNT	PDDA/GCE	Putrescine	223
Aflatoxin-detoxifizyme (ADTZ)	MWCNT	Au electrode	Sterigmatocystin	224
Choline oxidase (ChOx)	MWCNT	Sol-gel/platinum electrode	Choline	225
Cholesterol oxidase	MWCNT	Sol-gel chitosan hybrid film	Cholesterol	226
Dehydrogenase	CNT	CNT paste electrode	Glucose, NADH	227
		GCE	Glucose, NADH	228
		GCE	NADH	229
Catalase	MWCNT	GCE	H <sub>2</sub> O <sub>2</sub>	230
	SWCNT	Au electrode		231
Microperoxidase (MP-11)	MWCNT	MWCNT-Au NPs nanohybrid film	H <sub>2</sub> O <sub>2</sub>	232
Laccase	CNT	CNT-chitosan composite film	2,2-Azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid) diammonium salt (ABTS), catechol, O <sub>2</sub>	233
lactate oxidase (LOX)	SWCNT	Functionalized CNT-COOH electrode	Lactate	234
Cholesterol esterase, cholesterol oxidase, and peroxidase	MWCNT	Screen-printed carbon electrode	Cholesterol	235

(a) Physical adsorption [144]. GOD immobilized in this way usually maintains its substrate-specific enzyme activity in the presence of glucose. The tubular fibrils become positioned within tunneling distance of the cofactors without too much denaturation of the enzyme.

(b) GOD is covalently attached to the ends of the aligned tubes, which allows close approach to FAD [145]. In addition, some researchers have reported the synthesis of a fully integrated CNT protein composite system with high function density and with direct chemical bonding GOD to functionalized MWCNT under a high degree of control and specificity [146]. Recently, a highly ordered array of CNTs has been reported to serve as a universally direct nanoelectrode interface for redox proteins [147]. The site-selective, covalent docking of GOD on the CNTs tips has a marked effect on enhancing electron transfer properties.

(c) FAD is directly attached to the ends of the tubes [148]. A good example is given by Willner and his coworkers, who covalently immobilized the FAD redox center of GOD on one end of SWCNT, and the other end of the SWCNT was attached to a gold surface or another FAD to accelerate electrical communication between the electrode and redox proteins [149].

CNTs have been extensively employed in preparing different kinds of electrodes for biosensors on a larger scale. Wang et al. have reported a remarkable decrease in overvoltage for the oxidation of NADH using composites obtained by dispersing CNTs in a Teflon binder [150]. Compton et al. have proposed the use of MWCNTs abrasively attached to the basal plane pyrolytic graphite [151]. Unique electrochemistry of soluble molecules and adsorbed proteins on flat mat-like layers of SWCNTs or MWCNTs has been demonstrated. Rusling et al. have reported that Mb was covalently attached onto the ends of vertically oriented SWCNTs forest arrays used as electrodes [121]. The results suggest that the “trees” in the nanotube forest behaved electrically similar to a metal, conducting electrons from the external circuit to the redox sites of the proteins. Huang et al. [152] and Zhao et al. [153] have reported multilayers of MWCNTs and GOD through a layer-by-layer technique. Liu has reported the preparation of enzyme-polyion thin films consisting of GOD alternately assembled with poly(diallyldimethylammonium) chloride polymer on CNTs at a glassy carbon electrode [154].

CNTs have also been used to develop electrochemiluminescence (ECL) biosensors. For instance, Wohlstader et al. have reported ECL biosensors for the assay of  $\alpha$ -fetoprotein [113]. Studies revealed that CNTs were very useful for ECL-based assays. CNTs have also been used to fabricate sensors with screen-printed carbon electrode [155, 156].

CNTs array-based biosensors have also been reported. Aligned MWCNTs grown on a platinum substrate have been described for the development of an amperometric biosensor [114]. The two array systems in this work were either acid treated or air treated. The results showed that chemical etching was more effective in opening the carbon nanotubes and allowing the enzyme to enter the inner channel.

A so-called carbon nanotube paste electrode (CNTPE) has been reported in the fabrication of a glucose biosensor modified with some metallic particles [157]. The bioelectrodes were obtained by dispersing the metal particles, enzyme and

MWCNTs within a mineral oil binder. The resulting CNTPE combines the ability of CNTs to promote electron-transfer reactions with the attractive advantages of composite materials.

Microelectrodes and ultramicroelectrodes are important analytical tools because they exhibit fast response times, significantly improved Faradic-to-capacitive current ratios, and substantially reduced ohmic drops [158, 159]. Therefore, it is reasonable to develop so-called micro-biosensors. The electrocatalytic reduction of dissolved oxygen in acidic medium using microelectrodes constructed from MWCNTs has been reported [160]. Meanwhile, Martin and coworkers [161] have reported that the detection limits obtained at nanoscopic electrodes ensembles are much lower, three orders of magnitude, than the corresponding detection limits for a conventional macroscopic disk electrode. An important consideration in the future advancement of practical sensors is how to develop new immobilization strategies that are appropriate for the construction of miniature sensors, which requires precise control of film deposition on a small electrode. Electrochemical immobilization provides an elegant alternative for the deposition of enzymes on very small area electrodes of defined geometry.

Nanoelectrode ensembles based on low-site density, aligned CNTs have also been fabricated, and the electrochemical characteristics have been investigated [162]. Subsequently, the same research group developed a glucose biosensor based on CNT nanoelectrode ensembles [163]. The operation eliminates the need for permselective membrane barriers or artificial electron mediators, thus greatly simplifying the sensor design and fabrication. The same group have also fabricated CNT nanoelectrode ensembles by another method [164]. Platinum nanoparticles have been used to modify the CNT nanoelectrode ensembles and a new amperometric biosensor, based on adsorption of GOD at the platinum nanoparticle-modified CNT electrode [165]. This work combines the advantages of CNTs with Pt nanoparticles. The excellent electrocatalytic activity and special 3D structure of the enzyme electrode result in good characteristics such as a large determination range (0.1–13.5 mM), a short response time (within 5 s) and stability (73.5% remains after 22 days). Another reported glucose biosensor is also notable, due to its high sensitivity and selectivity coupled to a wide linear range, prolonged lifetime and oxygen independence [166].

CNTs are often used together with other materials (including nanomaterials) for biosensor fabrication. Early in 2002, a novel glassy carbon electrode modified by a gel containing MWCNTs and the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate (BMIPF<sub>6</sub>) was reported [167]. Wang et al. have reported on a simple avenue for preparing effective CNT-based electrochemical sensors and biosensors using CNT/Teflon composite materials [150]. Unlike early CNT-modified electrodes, the composite devices rely on the use of CNT as the sole conductive component rather than utilizing it as the modifier in connection with another electrode surface. Another novel glucose biosensor based on CNT epoxy resin biocomposite has also been reported [168]. Experimental results show that the CNT epoxy composite biosensor offers excellent sensitivity, a reliable calibration profile, and stable electrochemical properties together with a significantly lower detection

potential (+0.55 V) than the sensor with no CNT. Recently, a nanobiocomposite material based on a MWCNT-Nafion thin film for bioanalytical application has been proposed [169]. By the combination of MWCNTs, Nafion, and GOD, a novel electroanalytical nanobiocomposite thin film can be produced by simple solvent casting. Compton et al. have proposed another glucose biosensor, fabricated by immobilizing GOD encapsulated in a sol-gel matrix on basal plane pyrolytic graphite modified with MWCNTs [151]. The present carbon nanotube sol-gel biocomposite glucose sensor showed excellent properties for the sensitive determination of glucose. More recently, Yang has used sol-gel solution with highly dispersed Pt nanoparticles as a binder for MWCNTs to fabricate glucose biosensors [170]. In another study by Yang, a CNT-cobalt hexacyanoferrate nanoparticle-chitosan biopolymer system was used in the fabrication of biosensors [171]. With the introduction of CNT, this system could show significant improvement of redox activity of cobalt nanoparticles due to the excellent electron-transfer ability of CNTs. Meanwhile, CNTs have also been doped in organically modified sol-gels (ormosils) to enhance the conductive properties of the sol-gel matrixes, since the conductivity of ormosils is not good, although the porosity and biocompatibility are very favorable. Accordingly,  $\text{H}_2\text{O}_2$  and glucose sensors have been developed by entrapping enzymes in a new ormosil composite doped with ferrocene monocarboxylic acid-bovine serum albumin conjugate and MWCNTs [172, 173].

The insolubility of CNTs in most solvents is one of the limitations in the design of CNTs-based biosensing devices. A stable suspension of CNTs can be obtained by dispersing CNTs in a solution of surfactant, such as cetyltrimethylammonium bromide (CTAB, a cationic surfactant) [174]. CNTs have promotion effects on the direct electron-transfer of GOD immobilized onto the surface of CNTs. Solubilization of CNTs by Nafion, a widely used perfluorosulfonated polymer, has also been reported for both single- and multiwall CNTs [175]. Redox activity has also been dramatically enhanced at CNT/Nafion-coated electrodes. This gives a new way to fabricate amperometric biosensors. A recent interesting observation is that covalently linked composites of MWCNT and GOD composites are highly water soluble [146].

SWCNTs have been reported to combine platinum nanoparticles with a diameter of 2–3 nm for use in fabricating electrochemical sensors with remarkably improved sensitivity toward  $\text{H}_2\text{O}_2$  and glucose [176]. This work demonstrates that it is possible to obtain very small Pt nanoparticles deposited onto Nafion-solubilized SWCNT. Platinum nanoparticles are in electrical contact, through the SWCNT, with the glassy carbon or carbon fiber backing, enabling the composite structure to be used as an electrode. This composite structure may offer an excellent platform for various biosensing applications. Finally, CNTs have been combined with Fe nanoparticles to develop a glucose biosensor [177].

## 10.5 Nanocomposite Materials

Collagen/poly(acrylic acid) bilayers were once reported to be added to nanoparticle CdTe/polycation layer-by-layer films to produce porous collagen bilayers. Such

stratified multilayer systems showed successful cell attachment and survival while native nanoparticle CdTe/polycation films were strongly cytotoxic [178]. Hu et al. have made a detailed electrochemical investigation of Hb incorporated in collagen films [179]. The Hb-collagen film electrodes were also used to catalyze the reduction of nitrite, oxygen and  $H_2O_2$ , indicating potential applications of the films for the fabrication of a new type of biosensor. A novel amperometric glucose biosensor combined with an enzymatic assay of glucose level in rat brain has also been developed based on ferrocene-doped silica (FcDS) nanoparticles conjugated with a biopolymer chitosan (CHIT) membrane [180]. The formation through a water-in-oil (W/O) microemulsion method of such dye-doped silica particles clearly demonstrated their remarkable bioconjugation and photostability.

Gold nanoparticles have been widely used in the electrochemical study of proteins; however, the reversibility of Hb is not so good, because both gold nanoparticles and Hb are positive-charged, and the electrostatic repulsion may result in unfavorable orientation of Hb. It has been reported that  $\alpha$ -zirconium phosphate is an anionic material with good biocompatibility, but direct electron transfer of the anchored protein is not easily realized perhaps for the weak conductivity and lower enzyme-loading ability of ZrP [181]. To solve the problem, Chen et al. have introduced the gold nanoparticles into ZrP, based on which an excellent  $H_2O_2$  biosensor was constructed [182]. Liu et al. have also developed a  $H_2O_2$  biosensor based on the immobilization of HRP to a nano-Au monolayer, which is supported by a PAMAM dendrimer/cystamine modified gold electrode [183]. Meanwhile, Yu et al. have reported a new electrode interface by using L-cysteine-gold particle nanocomposite immobilized in the network of a Nafion membrane on a glassy carbon electrode [184].

## 10.6 Nanoparticles with Special Functions

### 10.6.1 Semiconductor Nanoparticles

Some nanomaterials used for sensors fabrication have several special functions. For instance, semiconductor nanoparticles that have recently been used for sensing applications are a highly luminescent, photostable class of fluorophore [185–187]. Colloidal semiconductor nanocrystals, often referred to as “quantum dots” or “QDs”, are single crystals a few nanometers in diameter whose size and shape can be precisely controlled by the duration, temperature, and ligand molecules used in their synthesis [185]. The synthesis process yields QDs that have composition- and size-dependent absorption and emission. Absorption of a photon with energy above the semiconductor band gap energy results in the creation of an electron-hole pair or exciton. Absorption has an increased probability at higher energies and results in a broadband absorption spectrum, in marked contrast to standard fluorophores. Luminescent QDs have unique spectroscopic properties that

include a broad adsorption spectra: size-tunable, narrow, and symmetric photoluminescence emissions ranging from UV to the near-IR range; and exceptional resistance to chemical and photodegradation along with high photobleaching thresholds [188]. Nanocrystals composed of ZnSe, CdS, CdSe, and CdTe also have emission spectra that span the visible spectrum. Researchers have demonstrated that QDs can function as fluorescence resonance-energy transfer (FRET) donors in prototype hybrid QD–protein sensors [189]. Nanosized semiconductor crystals can be effectively coupled to biomolecular units such as enzyme, to generate novel photoelectrochemical systems [190].

CdSe nanocrystals have broad absorption spectra that progressively shift to longer wavelengths with increasing particle size. These nanocrystals are tunable fluorophores with absorption characteristics that allow simultaneous excitation of different particle sizes at a single wavelength, while they exhibit a luminescent emission that spans a wide range of wavelengths in the visible spectrum [188]. Researchers have fabricated a facile, reagentless method for generating protein-based semiconducting nanoparticle sensors for small molecules using CdSe nanoparticles [187]. They used maltose binding protein (MBP) for the sensor receptor. When MBP binds with maltose, the conformation of MBP is changed, and then the movement prohibits the electron transfer to CdSe, resulting in fluorescence emission. Researchers have also described a novel and direct method for conjugating protein molecules to luminescent CdSe–ZnS core–shell nanocrystals used as bioactive fluorescent probes in sensing, immunoassay, imaging, and other diagnostics applications [188].

CdS is also a promising nanomaterial that has also been used in biosensor fabrication. The direct electrochemistry of GOD adsorbed on CdS nanoparticles-modified pyrolytic graphite electrode has been investigated [191]. The results showed that the fabricated biosensor was sensitive and stable in detecting glucose, indicating that CdS nanoparticles are a good candidate material for the immobilization of enzyme in glucose biosensor construction. Hb has also been immobilized with CdS nanoparticles on pyrolytic graphite electrode to characterize the electrochemical reactivity and peroxidase activity of the protein, and the result demonstrates that good redox waves of Hb can be achieved after this protein is entrapped in CdS nanoparticles [192]. Combined with formaldehyde dehydrogenase enzyme, nanocrystalline CdS has also been immobilized by self-assembling on a gold electrode to prepare a biological–inorganic hybrid to perform catalytic oxidation of formaldehyde [190, 193]. Researchers have also prepared an acetylcholine esterase (AChE)/CdS nanoparticle hybrid system for the photoelectrochemical detection of AChE inhibitors [194]. The photoelectrochemical charging effect of a Au–CdS nanoparticle array has also been employed to develop a sensor for acetylcholine esterase inhibitors [195].

As mentioned above, TiO<sub>2</sub> has been a popular nanomaterial for use in sensor devices. Recently, Li et al. have successfully constructed a Hb-based H<sub>2</sub>O<sub>2</sub> biosensor tuned by the photovoltaic effect of the nanoparticles [196]. The catalytic ability of the protein and the sensitivity of sensor could be greatly enhanced after UV light irradiation on the co-immobilized nanomaterial.

## 10.6.2

**Magnetic Nanoparticles**

Magnetic nanoparticles have been widely applied in various fields of biology and medicine, such as magnetic targeting, magnetic resonance imaging, diagnostics, immunoassays, RNA and DNA purification, gene cloning, and cell separation and purification etc. [197]. Thus, researchers have fabricated magneto-bioelectronics that rely on magnetic nanoparticles. Multilayer films have been prepared on the surface of a glassy carbon electrode by the deposition of chitosan/ $\text{Fe}_3\text{O}_4$  nanoparticles and phytic acid via the layer-by-layer assembly technique [198]. The multilayer films exhibited good biocompatibility, and adsorbed Hb on the film could realize direct electron transfer reactions and maintain high catalytic activity. In contrast, the orientation of magnetic particles can be controlled with a magnet, which can in turn control the electron transfer of protein-based biosensors. Accordingly, a magneto-switchable bioelectrocatalysis glucose biosensor has been prepared with magnetic  $\text{Fe}_3\text{O}_4$  nanoparticles as control factor [199]. Switchable systems that can be used as both  $\text{H}_2\text{O}_2$  biosensor and glucose biosensor have also been prepared with magnetic nanoparticles by the same research group [197]. Other magnetic nanoparticles have also been used in fabricating protein-based biosensors with good characteristics. For example, a phenol biosensor has been developed based on the immobilization of tyrosinase on the surface of modified magnetic  $\text{MgFe}_2\text{O}_4$  nanoparticles attached to the surface of a carbon paste electrode [200].

## 10.7

**Other Nanomaterials**

In addition to the above-mentioned nanomaterials, which have been largely used for sensor fabrication, there are also many other nano-materials, which either have been used for biosensing devices or may have the potential of biosensor application. One such nanostructure material is nanocrystalline silicon, often referred to as porous silicon, which, in fact, has been extensively used in sensors. Since the discovery of its strong visible luminescence at room temperature, porous silicon has attracted considerable interest in its possible use in the construction of biosensors. Its ability to emit light is due to its tiny pores that range from less than 2 nm to micrometer dimensions. In addition, porous silicon possesses a high surface to volume ratio (as much as  $500 \text{ m}^2 \text{ cm}^{-3}$ ) and it can be fabricated easily using some of the established processes of silicon technology. Porous silicon has been used as an optical interferometric transducer for detecting small organic molecules (biotin and digoxigenin), 16-nucleotide DNA oligomers, and proteins (streptavidin and antibodies) at pico- and femtomolar analyte concentrations [201, 202]. Many potentiometric biosensors based on porous silicon have been reported [203–205]. In addition, the enzymes penicillinase and lipase have separately been immobilized on the surface of porous silicon to develop biosensors for penicillin and triglycerides [206].

SiO<sub>2</sub> nanoparticles are another often used nanomaterial. The electrochemical and electrocatalytic properties of heme proteins, including Mb, Hb, and HRP in layer-by-layer films assembled with SiO<sub>2</sub> nanoparticles and the proteins have been investigated. The proteins in the films can display good electrocatalytic activities toward various substrates such as oxygen, H<sub>2</sub>O<sub>2</sub>, trichloroacetic acid, and nitrite, which has showed a potential applicability in fabricating a new kind of biosensor without using mediators [14]. SiO<sub>2</sub> nanoparticles have also been used to immobilize GOD by the sol-gel method. Experimental results show that hydrophobic SiO<sub>2</sub> nanoparticles can immobilize enzyme well, providing a good and simple approach for preparing a high quality glucose biosensor [207, 208]. Moreover, SiO<sub>2</sub> nanoparticles have been introduced into the construction of enzyme field-effect transistors (ENFETs) to create a glucose-sensitive ENFET, and the SiO<sub>2</sub> nanoparticles can provide a biocompatible environment and improve the enzyme activity, and prevent the immobilized enzymes from leakage as well [209]. In addition, boron-doped silicon nanowires (SiNWs) have been reported by Cui et al. to create highly sensitive, real-time electrically based sensors for biological and chemical species [210]. Antigen-functionalized SiNWs showed reversible antibody binding and concentration-dependent detection in real time.

Recently, a disposable glucose biosensor was reported based on co-dispersion of a diffusion polymeric mediator, poly(vinylferroceneco-acrylamide) (PVFcAA), and GOD in an alumina nanoparticulate membrane on a screen-printed carbon electrode [211]. The nanoparticulate membrane served not only biosensing, but also analyte-regulating functions. Since the membrane is highly hydrophilic, the amount of dissolved oxygen, one of the main interferants, is greatly reduced, and, thus, little interference is observed.

Arrays of nanoscopic gold tubes have been prepared by electroless deposition of the metal within the pores of polycarbonate particle track-etched membranes [212]. GOD can be immobilized onto the self-assembled monolayers of gold tubes, via crosslinking with glutaraldehyde or covalent attachment by carbodiimide coupling. Based on a similar method of template synthesis, Miao et al. have immobilized GOD in the polypyrrole nanotubes and produced a biosensor [213]. Compared with conventional techniques, this immobilization strategy greatly enhances the amount of the enzyme immobilized, the retention of the immobilized activity and the sensitivity of the biosensor.

Polyaniline nanoparticles, synthesized with dodecylbenzylsulfonic acid, can be successfully electrodeposited on the surface of glassy carbon electrodes to form nanostructured films suitable as heterogeneous mediators [214], and nanoparticles have been applied to a glassy carbon electrode surface with HRP for H<sub>2</sub>O<sub>2</sub> sensing. A sensitive and selective amperometric glucose biosensor based on platinum microparticles dispersed in nano-fibrous polyaniline has also been developed [215]. PANI has a large specific surface area, good conductivity, high reaction ability, and many microgaps between the fibers, which is very useful for sensor fabrication. This nanofibrous morphology is also beneficial to the dispersion of metal catalyst and the immobilization of enzyme.

Recently, there has been a tendency to extend the study of nanoparticles from metal and inorganic compounds to organic compounds because of the diversity offered by organic molecules [216]. It is expected that organic nanoparticles can be used in constructing sensors, bioprobes, devices, etc. [217, 218].

## 10.8

### Conclusion

Nanobiotechnology has played an increasingly important role in the development of protein-based biosensors. Owing to the unique properties of nanomaterials, such as large surface-to-volume ratio, high surface reaction activity, high catalytic efficiency, and strong adsorption ability, numerous protein-based biosensors have been well constructed with higher selectivity, better stability and a lower detection limit for the detection of even more species. In addition, the special electronic, optical and magnetic characteristics of nanomaterials are providing a platform for fabricating more novel biosensors, which might also open up new topics in the field of protein-based biosensors. Greater achievements and advances will be made by combining nanotechnology with protein science and biosensing.

### Biomimetic Nanosensors

Raz Jelinek and Sofiya Kolusheva

#### 11.1

##### Introduction

Within the burgeoning field of nanotechnology, *bionanotechnology* is an important area. Bionanotechnology is generally defined as the ability to produce biological devices and materials through molecular manipulation and specific control of the physical, chemical and biological properties of the materials employed. The goals of this increasingly visible discipline focus on the creation of functional systems that could be employed in electronic circuitry and devices, advanced materials, biomedical devices, sensors, and others. Many excellent reviews have been published in recent years on subjects at the interface between biology and nanotechnology, reflecting the increasing interest in its potential for addressing diverse scientific and technological challenges [1].

In the field of *sensor* research and development, bionanotechnology is poised to make significant contributions, and has the potential to radically alter the way sensors are designed, constructed, and implemented. As a rule of thumb, the requirements for miniaturization are ever present and are often critical in sensor design. Accordingly, utilizing bio-inspired concepts and technical approaches and introducing biologically-based detection technologies have already had considerable impact in biosensor development. In particular, the ability to harness molecular recognition in the *literal* sense – employing fewer and fewer recognition units in sensor devices – could revolutionize the way biosensors operate. Several reviews on varied aspects and exciting developments in this field have been published recently [2–6].

The present chapter discusses the nascent but rapidly expanding field of nanobiosensors, putting particular emphasis on the way concepts and methodologies borrowed from the biological world – termed “biomimetics” – contribute and shape the chemical/physical characteristics of sensor devices. Put the other way around – we have also summarized here reports depicting nanosensors designed to analyze biological and cellular systems without interference in their functions or structures. Such goals are sometimes satisfied by nanosensor assemblies that mimic certain components within the biological or cellular system investigated.

*Biomimetic* nanosensors are referred to in a rather broad sense, including various systems and applications that can be depicted as “nanotechnology”, and focusing on the interface between biology and chemistry, physics, or engineering. Similarly, “biomimetic sensors” depicted here represent important concepts, design criteria, or molecular targets that are “biological”, but include innovative components from other disciplines. The explosive growth of publications that touch in different ways on the subject of this chapter (and due to space limitations) necessitated summarizing only selected studies.

Thematically, this chapter is organized according to the roles played by biology and biomimetic assemblies in sensing devices, and mirroring this – the development of nanotechnology-based (or nanotechnology-inspired) sensing of biological and cellular systems. Specifically, Section 11.2 focuses on the description of biosensing applications relying on nanostructures, such as nanoparticles and nanotubes, for studying and detection of biological systems. Emphasis in this section is on the *nanostructures* and how their unique physicochemical properties contribute to bio-sensor designs. The spotlight in Section 11.3 is rather on biological (and cellular) systems, and the solutions nanotechnology offers to detect and elucidate molecular events in those assemblies. Section 11.4 summarizes the contribution of biological molecules as building blocks and structural components in biomimetic nano-scale sensors. Finally, Section 11.5 discusses the increasing prominence of nano-biotechnology in biomedical diagnosis. Certain overlap exists among the topics, primarily due to the interchanging roles of the sensors and biological molecules in many bio-inspired devices and applications.

## 11.2

### Nanostructures in Biosensor Design

For such a young scientific endeavor, nanotechnology has already demonstrated a noticeable role in biosensor research and development. The contributions of nanotechnology can be roughly divided between the more “conceptual” impact – pointing and demonstrating new approaches and models for biosensor design – and the practical utilization of novel or superior physicochemical properties of nanostructures in certain applications. This subsection will discuss examples for both aspects of biomimetic nanotechnology in sensors.

One of the most important recent “meeting points” between nanotechnology and the biological world has been the demonstration that nanoparticles (NPs) can be successfully incorporated and used for detection and imaging biological assemblies and cell systems. Semiconductor nanocrystals or “quantum dots”, in particular, have become an important tool in this field. The concept underlying the use of quantum dots, particularly for biological and cellular imaging, is simple and elegant (Fig. 11.1). Essentially, NPs with different sizes and compositions exhibit distinct optical properties (mainly fluorescence or luminescence) [7, 8]. NPs can be conjugated to varied biological targets, including proteins, enzymes, DNA and others, thus facilitating detection, imaging and functional analysis of biolog-

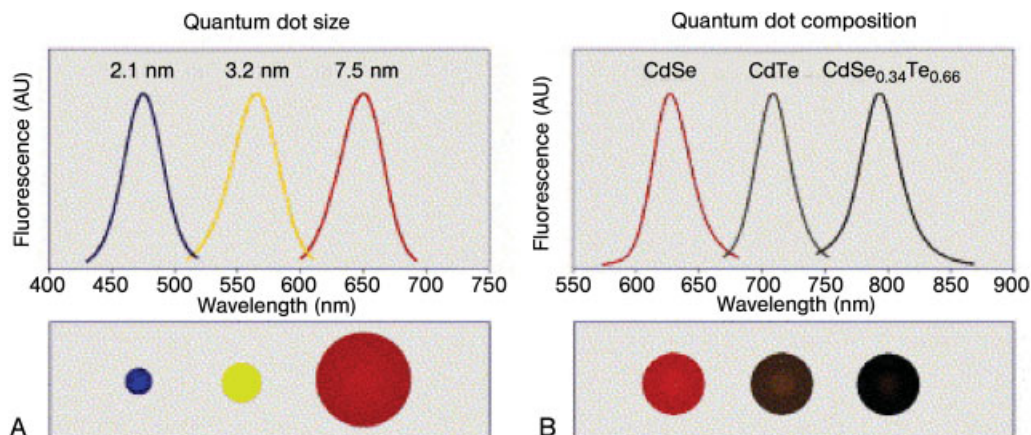

Fig. 11.1. Variation of fluorescence emitted from semiconductor nanoparticles (quantum dots), in relation to particle size and composition. (Reprinted from Ref. [7]. Copyright (2004), with permission from Elsevier.)

ical processes via the differently-labeled NPs [8–11]. Coupling of the NPs to biological molecules provides these nanosensing particulates with means of exploiting the diversity of the biological universe for varied applications. In particular, bioconjugation allows probing and pinpointing specific cellular pathways and physical environments within the cell. Semiconductor NPs were used for imaging of single cells [11], cell components [12], tissues [13], plant cells [14], and living animals [15].

An important advantage of the use of NPs for biological imaging is their often superior spectral and optical properties compared with conventional dyes [16]. In that regard, the ability to tune their optical properties through varying the particle size and molecular composition, the coupling of the recognition element to NPs with different emission wavelengths, and the relative biological inertness of the NP core all make conjugated NPs an attractive labeling tool. Semiconductor NPs are currently widely used in scientific and applied biotechnology research, e.g., for intra- and extra-cellular imaging of cancer markers, and for orthogonal detection of different molecular targets within a cell [16].

Diverse techniques have been developed for making NPs generally biocompatible, and to overcome problems of nonspecific adsorption, aggregation, and intracellular targeting in cell imaging. A simple and innovative approach has been the inclusion of semiconductor NPs within phospholipids micelles, making such assemblies easy to manipulate and introduce into cellular systems [17]. The creation of lipid/NP particles has certain advantages over covalent coupling of NPs to biological molecules. First, the assembly process is simple and does not require formation of chemical bonds between the lipids and the NPs. Furthermore, the small lipid-surrounded particulates can transport into cellular systems and microorganisms without adversely affecting their viability [17].

A critical test for the use of NPs for cellular imaging and analysis is whether these particles can be depicted as “inert” markers of cells (or specific organelles within the cell). Many studies have shown that NP incorporation does not adversely affect cell processes or cell viability [8, 11]. In that sense, NPs can be referred to as “biomimetic” in that they can become part of a biological system (the cell) without affecting its viability and biological functionalities, and augment it through providing the imaging capabilities.

Semiconductor NPs are not the only nano-scale probes used in biological imaging; however, their remarkable biological and optical versatility make them promising components for imaging and bioanalysis applications. Other types of NPs have been reported in biosensing applications. NPs composed of silica or metal atoms, for example, also allow easy surface modification aimed to incorporate labile biological functionalities [18, 19]. Zhao et al. have developed an elegant sensing technique based on bioconjugated silica NPs containing fluorescent dyes [20] (Fig. 11.2). The silica NPs were coupled to recognition elements such as antibodies recognizing specific antigens on bacterial surfaces, and additionally encapsulated high concentration of fluorescence dyes within the NP matrix. Consequently, binding of even a *single* bacterial cell yielded a detectable fluorescence signal from the intensely fluorescent NP. This approach could easily be extended to rapid pathogen detection and high-throughput screening using simple chip devices.

Gold NPs, in particular, exhibit varied uses in biological detection, in some instances comprising the basic building blocks for the biosensors, in other cases as vehicles of transmission of the induced signals. An example of the former design is the use of gold NPs in monolayers for the construction of amperometric immunosensors [21]. Here, the NPs constituted both the sensing interface as well as the substrate for biological immobilization. Another study has described the use of

**Fig. 11.2.** Schematic depiction of bacterial detection using fluorophore-containing silica NPs [20]. Binding of bacterial cells to antibody-labeled NPs causes the release of the fluorescence dyes.

**Fig. 11.3.** A biosensor design based on a metal cluster resonance bio-chip;  $h\nu_1$  and  $h\nu_2$  are the incoming and reflected light, respectively, and the shift in color is caused by

absorption due to mirror–NP layer resonance. Light absorption from the metal layer is modified by the thickness of the biological recognition layer [24].

gold NPs for assembling a surface sensor for DNA hybridization [22]. Silica NPs encapsulating luminescent markers have been prepared and used for biosensing through conjugation with biological molecules and bio-surfaces [23]. The latter work exploited advanced synthesis methods to assemble NP in distinct sizes, thus achieving controlled luminescence. This, in turn, has endowed the system with “molecular encoding” capabilities through multiplexed signaling.

Films composed of NPs forming parts of *biosensor chip* assemblies have been reported [24]. Metal nanoclusters were positioned on top of a biological recognition layer (receptor/ligands) at a nanometer-scale distance from a reflecting layer (Fig. 11.3). The surface-enhanced light absorption by the NP layer was shown to be highly sensitive to the thickness of the biological recognition assembly, thus providing means for sensing biomolecular binding [24]. The simplicity of this application stems from the enhancement of visible signals – essentially color changes detected by the naked eye – through deposition of the NPs on surfaces functionalized with macromolecules. Such bio-chip devices could find varied uses in proteomics applications, and their extension to single molecule detection is possible through surface micro-patterning and nanolithography.

Confining NPs on solid surfaces could facilitate the application of sensitive surface spectroscopic methods in a highly localized manner. Metallic NPs, particularly gold or silver, placed on solid substrates yielded a dramatic increase in the intensity of surface-enhanced Raman scattering (SERS) signals, enabling trace-level detection of varied biological compounds, including, for example, viral DNA [25]. Silver NPs coupled to biological ligands yielded improved localized surface plasmon resonance (LSPR) signals following ligand/receptor binding, making such systems potentially useful in immunoassays [26].

Biologically functionalized magnetic nanoparticles have been also contributed to bio-sensing applications. The sensing schemes in such designs do not involve *optical detection* but rather rely on the modification of the *magnetic properties* of the particles, induced through biological interactions. One such system for sensing biomolecular interactions has utilized biocompatible magnetic NPs onto which biological molecules could be chemically attached [27]. The researchers demon-

strated that differences in the aggregation state of the magnetic NPs, affected through specific biomolecular interactions involving the functionalized NPs, could dramatically alter the magnetic relaxation properties of the particles – making the system a “magnetic relaxation switch” for identification of biological analytes. A notably practical advantage of the technique is that such “relaxation sensing” could be implemented by using conventional magnetic resonance instruments.

One of nanotechnology greatest molecular players – the carbon nanotube – could also form a basis for a wide range of biosensor applications. The remarkable chemical properties of carbon nanotubes [particularly single-wall (SW) nanotubes] have already been exploited in biosensor applications. Particularly important factors when considering carbon nanotubes as nanobiosensors are their nano-scale dimensions, versatile chemical functionalization possibilities, and the ready adsorption of proteins and other biomolecules onto their surface. All these factors make carbon nanotubes ideal candidates for sensing platforms, capable of detecting analytes at extremely low molecular concentrations. Indeed, the field of carbon nanotube sensors has developed rapidly in recent years due in large part to the spectacular progress in nanotube surface chemistries [28]. Biological molecules have been attached to nanotube surfaces through covalent and noncovalent bonding, with and without pre-activation, and through the use of diverse synthetic procedures [28]. Carbon nanotubes derivatized with oligonucleotides and embedded in silica have been used, for example, for ultrasensitive DNA detection [29]. That study and other reports point to an important advantage of carbon nanotubes: their simultaneous role both as *immobilization matrixes* for the detected analytes, as well as mediators of the induced signals (generally amperometric or electrical) within the bio-sensor assemblies [30, 31].

Other recent developments straddling the chemistry/nanotechnology interface point to technologies that could play a role in biomimetic nanosensors. Molecular imprinting, for example, could become a useful tool for biosensor architectures. Molecular imprinting creates recognition sites in polymers by using template molecules; the templates are prepared by initiation of the polymerization processes while specific molecules of a particular analyte (or resembling the analyte) are incorporated within the solidifying polymeric material [32, 33]. Following the removal of the embedded analyte molecules, the polymer essentially becomes a porous framework that selectively adsorbs only the analyte molecules within the pre-shaped binding sites [34]. This kind of “template biosensing” could be compatible with nanosensor design through accurately controlling the pore dimensions, or through manipulation of the recognition surface, for example by using microgel spheres that determine the overall size of the porous framework [35]. Recent studies have employed molecularly imprinted polymers as bio-sensing templates, achieving extremely sensitive (subpicomolar) detection of biological ligands [36]. A potentially useful implementation of molecular imprinting focuses on separation applications, particularly capillary chromatography and electrophoresis [37]. Such techniques, however, often face considerable hurdles when applied to minute sample quantities. Indeed, technical challenges still exist for transforming molecular imprinting into a viable sensing technology.

### 11.3

#### Nanosensors for Probing Biological and Cellular Systems

Nanosensors applied in the context of biological systems can be roughly divided into two broad applications. One route focuses on sensor technologies designed to investigate biological *molecules* and physiological/biological *processes* (rather than the complete “living systems”), while another active research track employs nanosensing for investigating actual *living* cells or tissues. This section summarizes the contribution of nanotechnology to both applications, beginning with sensors aiming to elucidate various aspects in the primary constituents of biology: proteins, nucleic acids, carbohydrates, and others.

The protein world has probably attracted the most intense activity in nanosensor development, undoubtedly due to the broad knowledge-base and the significance of proteins in numerous biochemical and therapeutic processes. The main difference between the established and highly versatile protein bio-assays available and newly introduced nanosensor methodologies is the focus on a very limited number of molecules (preferably, sometimes, single protein molecules) in nanosensor design, rather than looking at greater populations. Similar to fluorescent markers, luminescent dyes, or radioactive tracers, a primary challenge in protein nanosensor research and development is not to affect or interfere with the structural and functional properties of the inspected molecule. Indeed, the unprecedented technical advances in biomolecular manipulation in recent years have greatly contributed to progress in this field. An experiment exemplifying these concepts was the analysis of the molecular interactions in metal transfer by the protein metallothionein. The protein was labeled at two specific locations with a fluorescent-energy donor and an acceptor, respectively [38]. Such labeling was achieved through introducing a mutation in the protein that did not affect the protein properties. Monitoring the fluorescence resonance energy transfer (FRET) between the donor and acceptor bound to the protein allowed probing fine details pertaining to varied molecular processes of the protein.

An innovative method for detection of single antigen–antibody binding events at a bio-chip surfaces has been described recently [39] (Fig. 11.4). The sensing device relied on the fabrication of an artificial pore between two electrode surfaces; the electrical current measured through the pore (or more accurately its resistivity) was sensitive to the passage of streptavidin-derivatized colloids. When antigens, for example, were specifically bound to antibodies crosslinked to the colloid surface, the size change of the colloid was reflected in the recorded current. This microfluidic bio-sensor can be constructed through conventional lithography techniques – and points to the substantial potential of “nanolithography” to produce truly “single molecule” nanosensors.

Oligonucleotide detection has also been at the forefront of nanotechnology-based sensing techniques. This is mostly due to the explosive growth of genomics as a tool for biological research and pharmaceutical R&D. The introduction of the “gene-chip” and the quest for ever higher molecular densities and sophistication of chip surfaces have been major driving forces for new scientific and technical

**Fig. 11.4.** Schematic depiction of apparatus designed to detect antigen–antibody interactions through measuring the electrode voltage across a small pore. The measured current was sensitive to the size of antibody-

functionalized colloids passing through the pores; antigen binding to the colloids modified the measured current [39]. (From Ref. [39]. Copyright (2003), National Academy of Science USA.)

breakthroughs involving nanobiosensors. Pioneering work by Letsinger and Mirkin has demonstrated that gold NPs can be used as sensitive probes for single-strand oligonucleotides [40]. The novel detection scheme was based on the colorimetric transitions of the gold NP suspension following the formation of a polymeric network, owing to hybridization between the target solubilized oligonucleotides and complementing oligonucleotide strands attached to the gold NPs. Furthermore, the red–blue transformations of the NPs were highly dependent upon hybridization mismatches – providing a unique tool for detection of DNA damage. Extending the gold NP technology, the same researchers demonstrated a simple scanner-based detection of target DNA segments using derivatized gold NPs [10]. This work also showed that the sensor signal can be further enhanced through addition of *silver* NPs to the surface-immobilized gold NPs. Of particular importance, single nucleotide mismatch could be resolved by achieving heat-induced dissociation of the hybridized gold NP network. These seminal studies have demonstrated the power of nanotechnology to introduce a new tool-kit for DNA sensing in particular, and biological sensing in general.

Other, diverse techniques have been developed to identify DNA strands with high fidelity and sensitivity. A critical requirement in many methods has been amplification of signals arising from recognition events between very dilute DNA analytes and their complementary oligonucleotides. “Nanopores” fabricated in polymer surfaces succeeded in detecting single DNA molecules, and achieved size discrimination based on strand length [41]. Another approach for high sensitivity DNA sensing involves the construction of optical fiber bundles, in which each fiber

within such “nano-arrays” can transmit precise optical signals induced by various physical changes, e.g., complementary strand binding of functionalized nano-beads [42, 43]. Detection of DNA binding through force deflection measurements on a nanomechanical cantilever array has been reported [44].

Carbohydrates appear increasingly important in different biological processes and therapeutic applications. Similar to nucleic acids and proteins, some studies have focused on the integration between carbohydrates and nanometer-size systems and devices, while other efforts were directed to integrate advanced nanotechnology-oriented concepts and instrumentation for specific detection of carbohydrates. In a similar way to the approach described above for protein engineering with fluorescent probes, ribose uptake and metabolism was monitored by flanking a bacterial ribose-binding protein with two variants of the green fluorescent protein (GFP), a popular macromolecular marker [45]. The FRET rate in such a system was inversely correlated to ribose concentration, allowing evaluation of free ribose concentrations within cells.

An intriguing study has described an amperometric biosensor facilitating high-sensitivity detection of carbohydrates through embedding nickel nanoparticles within a graphite-film electrode [46]. Essentially, the dispersion of the Ni nanoparticles within the carbon film yielded an order-of-magnitude lower detection threshold compared with conventional electrode arrangements. Similar to other NP-assisted biosensors described above, the nanoparticles in the device did not participate in the actual detection of the carbohydrate molecules, but rather provided the means for improving technical performance of the electrode. Another report demonstrated that nanometer-size amphiphilic C<sub>60</sub>-dendrimers could be employed in a biosensor construct for achieving improved association between the sensor surface and the carbohydrate analytes [47]. Binding was achieved through creating ordered Langmuir monolayers of the C<sub>60</sub> conjugates. The films could be further transferred to solid quartz surfaces, pointing to their potential applicability in biosensor design.

Atomic force microscopy (AFM), a major driving force in nanotechnology research, has also contributed to development of nanobiosensor for carbohydrates and other biomolecules. Among the most abundant uses of AFM in nanobiosensor research has been imaging of single biomolecules [48–50]. A potential high impact application of AFM has been the introduction of “dip-pen nanolithography” – placing molecules at desired locations on surfaces, and chemically manipulating molecular entities at specific locations using chemically-coated AFM tips [49]. A recent demonstration of dip-pen nanolithography for biosensing application has been the construction of bioactive protein nano-arrays on a conductive surface for detection of protein–protein interactions and proteomics applications [51]. Other biological applications of AFM have been reported. The technique was used as a tool for determination of carbohydrate heterogeneity on bacterial surfaces [52], or the observation of a non-homogeneous distribution of specific oligosaccharide units on the surface of yeast cells through derivatization of the AFM tip with lectins [53]. A novel saccharide “force fingerprinting” technique, based on the single-molecule imaging capabilities of AFM, has been reported [54].

The numerous AFM studies of biomolecules both illustrate the potential of this technique as well as the significant challenges for using single-molecule imaging and force measurements for routine biosensor applications. On the one hand, the atomic-level resolution of AFM could provide “imaging fingerprinting” for varied biological surfaces and surface-bound molecules. It might be possible, for example, to assemble an AFM image database for bacterial surfaces that might be used for rapid pathogen identification. Further contributions could be envisaged from integration of computer-aided image analysis into AFM-biosensor applications. On the other hand, formidable technical difficulties could arise from using AFM for sufficiently fast and reliable detection in biosensors. In particular, the wealth of atomic details and sensitivity of the method might lead to impracticality as a sensing method.

Nanotechnology approaches could yield information on processes occurring within lipid bilayers comprising the cell membrane. Jang et al. have inserted silicon NPs capped with a hydrophobic organic layer into the interior of lipid bilayer vesicles [55]. Photoluminescence from the highly optically-sensitive silicon NPs could be quenched by external quenchers – opening up possibilities to use the technique for detection of membrane properties such as the communication between membrane-embedded species and the external environment of a cell.

The use of biomimetic vesicles themselves as bio-sensing platforms has gained acceptance. Vesicles (also referred to as liposomes), having a simple lipid bilayer structure, can be particularly attractive for bio-sensing applications because they can be created in a range of sizes, and could enclose different dyes and optically-active compounds. Liposomes can also be made reactive/non-reactive to biological molecules, other vesicles, or cells, depending upon their lipid components and the membrane compositions of their biological target [56]. Thus, such aggregates can serve as specific detectors for pre-selected molecules, cell locations, or tissues. Somewhat related to liposomes, newly-developed “nanogels” (Fig. 11.5) consisting of nano-scale polymeric hydrogels coated with phospholipids [57] could be attractive for bio-sensing applications since they both mimic the bilayer membrane as

**Fig. 11.5.** “Nanogel” particles employed for bio-sensing applications [57]. The particle size is dependent upon the pH, making it a sensitive probe of different cellular compartments.

well as providing a rigid scaffolding for addition of optical transduction components. Nanogel particles (NGP) were shown to exhibit size sensitivity to the solution pH, making these particles potential sensor for tissue or intracellular pH changes.

Several studies have exploited the properties of *whole microorganisms* for constructing nano-scale sensor assemblies with unique features. Genetic engineering of filamentous bacteriophage allowed expression of a recognition element for ZnS nanoparticles on the phage surface (through peptide selection by affinity screening), and the NPs could then be ordered via a liquid crystal alignment of the phage [58]. This clever design resulted in NP “patterning” that could be further employed in varied nanosensor constructs.

The primary aim of biosensor design for *cellular* sensing technology is the desire to expose biochemical phenomena at the *single cell* level, and, preferably, maintain cell viability throughout the measurement. Indeed, miniaturization constitutes the core of different cellular sensing technologies, and nanotechnology could open new avenues for such applications. An interesting device addressing that goal was a nano-calorimetric sensor for measuring minute temperature changes in isolated cell suspensions, generated by biological or pharmaceutical stimuli [59]. The cellular sensor consisted of a gold and nickel thermoelectric transducer, and could produce signals upon extremely small temperature and heat changes. That report both exemplifies sensor fabrication achievements, as well as the technical and technological challenges nanobiosensor research is still facing.

Because *aqueous* environments are essential for cell viability, development of nanobiosensors for cell activity and cellular processes have greatly benefited from technical advances in micro- and nano-fluidics. Indeed, the increasing sophistication of fluidic biochips and cells has already contributed to demonstrating intriguing biosensor designs up to a single cell level. Detection of metabolic processes in few dozens bacterial cells was achieved using a microfluidic biochip prototype that could hold as little as 5 nL of a bacterial suspension [60]. Such an impedance-based biosensor of cellular metabolism could, in principle, accomplish detection of a single bacterial cell through lithographic design that would decrease the electrode size and distance between the sensor electrodes.

Being a “silent observer” to processes within a cell is a central goal in nanobiosensor research and development. An innovative method for literally “illuminating” the cell interior with biologically-inert nano-capsules has been developed by R. Kopelman [61–63]. The cell-inserted nanoprobe, denoted PEBBLEs (photonic explorers for bioanalysis with biologically localized embedding), have been fabricated from different polymeric matrixes encapsulating both a reference dye and a sensing dye [63, 64]. Owing to their small size (20–100 nm) and biological inertness, PEBBLE nanosensors can be delivered into the cell interior without compromising cell viability. Inside the cell, PEBBLEs essentially mimic cellular compartments, as they interact with and “sense” the intracellular environment. The sensitivity of the encapsulated dyes to ions and molecules have made PEBBLEs a useful platform for measuring intracellular concentrations of protons (pH),  $K^+$ ,  $Mg^{2+}$ ,  $Ca^{2+}$ ,  $Cl^-$ , oxygen, and glucose [65, 66].

Antibody-based nanoprobes have been a recent intriguing nanosensor approach for probing the interior of living cells. These devices utilize extremely thin optical fibers – less than 50 nm in diameter – derivatized with antibodies and inserted into single cells [67]. Similar to PEBBLEs, the unique advantages of these nanoprobes stem from their exceedingly small diameters, making them almost inert and non-perturbing to the inspected cells.

While different methods have been developed for probing cell interior, relatively fewer nanotechnology applications have been designed to explore processes at the cell-surface or at the external membrane of living cells. A recent study has depicted the construction of new membrane-fused fluorescent/colorimetric nano-patches for probing membrane events in living cells [68]. The nano-scale probes in that work were based on a conjugated polymer – polydiacetylene – that changes its visible color and its fluorescence emission following structural perturbations in its vicinity [68, 69]. Polydiacetylene nano-patches were attached to the cell surface through coupling to phospholipid moieties. Such membrane-incorporated lipid/polymer patches do not adversely affect cell viability, and respond to local structural perturbations within the membranes both through induction of fluorescence as well as by undergoing blue–red color changes [67] (Fig. 11.6). These chemo-engineered nanopatch-labeled cells could be used for microscopic imaging and fluorescence or visible spectroscopic analyses of physiological processes affecting the cell membrane, its structure or morphology.

One of the challenges in coupling sensor devices to biological or cellular systems is the efficient transduction of the signals (optical, electronic) from the biological assembly into the recording/analysis units. Varied methods have been developed

**Fig. 11.6.** Phase contrast microscopic images (left) and fluorescence confocal images (right) of nanopatch-labeled cells [67]. (A) Control “blue” cells; (B) cells treated with a

membrane-active substance (polymyxin-B). Fluorescence spots corresponding to the “red” nanopatches indicate membrane disruption by polymyxin-B.

to interface the biological constructs investigated with opto-electronic detectors, and this is an active field of research. The fabrication of tiny micro-electrodes has been reported, and these were successfully used for monitoring adhesion and movement of different cells [70]. The use of organic dyes as reporters for the biological/inorganic interface has also been described [71]. Surface patterning of biological chips has further allowed fabrication of multi-analyte biosensors, as well as monitoring pathological conditions *in vitro* [70].

The considerable advancement in construction of optical nano-fibers has been central to developing nanosensors for investigating and imaging cell interiors [3]. Coupling of biological recognition elements to optical fibers (generally optical fiber tips) has been another active field of research aiming to efficiently transmit biological signals to opto-electronic detection systems. Varied types of biological molecules were attached to optical fiber surfaces, including enzymes, antibodies, nucleotides, and even whole cells, making this approach highly versatile as a tool for detection of diverse analytes [42]. The increasingly sophisticated technologies for manufacturing thin, resilient optical fibers with highly uniform consistencies should significantly contribute to this nanosensing track.

Several laboratories reported the incorporation of nano-electronic devices *inside* biological systems, thus creating new biosensor designs. Ritter et al. have described the inclusion of nano-electronic sensors in a cellular neural/nonlinear network for investigating fundamental physiological aspects, including image recognition, target tracking, and others [72]. Miniaturization of the devices through nanotechnology makes possible their use as tiny probes within cells and tissues.

Technological progress in cellular nanosensor fabrication also promises to yield important insight into cell metabolite levels, also known as “metabolomics”. The capability for detecting changes in metabolite patterns at a *single cell* level (rather than in *ensembles* of cells as mostly done now) is extremely important for elucidation of specific factors and substances affecting cell functions [73]. In particular, the recent introduction of protein-based nanosensors, expressed via conventional biotechnology methods, could play prominent roles in intracellular metabolite sensing. One successful design was based on the attachment of two fluorescent proteins through a fusion protein, in which one of the proteins had calcium-binding properties [74, 75]. This nanosensor made possible analysis of  $\text{Ca}^{2+}$  levels in isolated cells as well as in living microorganisms. Another reported protein-based nanosensor employed a fluorescent marker (green fluorescent protein) fused to a bacterial periplasmic binding protein, facilitating real-time sensing of a range of cellular metabolites [75].

## 11.4

### Biological Components in Nanosensors

The extraordinary diversity of the biological universe has inspired numerous devices and structures in the materials science realm. This is particularly the case in biosensor design, in which varied biological concepts, or even actual biological

molecules, can be utilized for construction of novel sensing assemblies. In that sense, miniaturization, which constitutes the core of nano-biotechnology and nanobiosensor development, increasingly relies on the incorporation of biomolecules from different sources into the sensing devices. In most instances, biological molecules and entire microorganisms have been used as templates for construction of organized nanostructures.

“Classical” biosensor designs have generally exploited enzymatic reactions as the biological transduction component. Accordingly, enzyme immobilization and maintenance of enzyme activity have been primary tasks in biosensor development. Nanotechnology offers significant advantages and new approaches for enzyme-based biosensors. In a complementary sense, enzymatic redox systems by themselves are ideal candidates for nanobiosensor applications: electron transfer is generally highly localized and can be detected in many instances both electronically and optically. Furthermore, enzymes can be readily chemically and biologically manipulated through self-assembly and protein engineering approaches and can be assembled in modular building blocks [76].

Recent reports have described the incorporation of gold nanoparticles as “mediators” of the electrochemical signals produced by immobilized enzymes in biosensors [77]. The NPs in such studies have the potential not only to improve the electrode performance but also to participate in immobilization of the enzyme and retaining of biological activities. Another study has used the aggregation properties of gold NPs for *indirect detection* of enzyme inhibitors, some of which are known nerve gases [78]. The sensing system relied on prevention of thiocholine-mediated transformation of  $\text{AuCl}_4^-$  into growing nanoparticles through inhibiting the action of the enzyme acetylcholine-esterase needed to produce thiocholine.

Peptides and proteins have also constituted important nano-structural components in sensor systems. Diverse nano-assemblies, some with potential bio-sensor applications, have relied on controlling and manipulating the *self-assembly* properties of short peptide sequences [79]. The extensive and advanced technical capabilities of peptide and protein engineering have facilitated a remarkable plethora of peptide- and protein-based nanostructures, which could furthermore respond to external stimuli by emission of detectable signals – essentially performing a biosensor task [80].

The use of biomimetic receptors in biosensor design has led to development of fascinating hybrid systems. Artificial receptors that mimic ion channel proteins have been used for detection of diverse ionic species [81]. Interestingly, that work has shown that molecules *much larger* than the ions were actually recognized and discriminated by the receptors. A chromatic detection platform for catecholamines (such as adrenaline, noradrenaline, and dopamine) based upon nanoscale vesicles displaying synthetic catecholamine receptors at their surface has been reported recently [82]. The synthetic hosts in the vesicle assembly were incorporated within a matrix that contained both biomimetic membrane bilayers, as well as domains of a chromatic polymer reporter. This new assembly featured remarkable sensitivity and selectivity among similar ligands compared with existing receptor-based catecholamine biosensors.

DNA has been a natural component in diverse assays and sensors because molecular recognition is an intrinsic property of the molecule. The introduction of aptamer technology has been a particularly significant driving force for oligonucleotide-based molecular sensing [83]. Particularly important in this context is the possibility for carrying out various chemical modifications of aptamers, thereby attaching specific probes to the molecules [84]. The DNA ligands could then emit the desired signal (optical, fluorescent, etc.) upon binding their protein target. An example is the construction of “molecular beacon aptamers” for fluorescent detection of even minute amounts of a platelet-derived growth factor through their high affinity binding to the protein [85]. The notable strength of aptamer technology for nano-biosensing applications stems from the versatility of ligands that can be constructed and their high specific affinity, which allows precise localization onto target molecules or even cells and tissues.

An elegant nanosensor design for DNA detection using only biological components has been reported recently [86]. That construct contained an aptamer unit bound tightly to thrombin (through the aptamer peptide recognition element), thereby disrupting the catalytic action of the enzyme towards a fluorescently-labeled peptide. However, in the presence of an oligonucleotide strand complementary to a nucleic acid tethered to the aptamer, the aptamer was released from the binding pocket, facilitating peptide cleavage by thrombin and generation of a fluorescence signal (Fig. 11.7). The important aspect of this nano-scale system is

Fig. 11.7. Oligonucleotide detection by an all-biological sensor. Double strand recognition frees the thrombin binding pocket, facilitating enzymatic activity and fluorescence signal. (From Ref. [86]. Copyright (2005), The American Chemical Society.)

the use of only biological building blocks to produce a highly sensitive and specific signal. Such an assembly could be easily coupled to opto-electronic components, making a complete biological DNA nanosensor unit. The same research group has reported the application of magnetic NPs functionalized with sequence-specific DNA as substrates for endonuclease activity both as detector for complementary DNA strands, but also as novel biological “logic” circuitry [87].

DNA and oligonucleotide derivatives have been used for varied other sensing applications. DNA enzymes (referred to also as “DNAzymes”), for example, were the basis for a highly sensitive lead biosensor [88]. This clever application relied on the high specificity of DNA enzymes to metal ions such as  $\text{Pb}^{2+}$ , in which metal binding consequently resulted in a catalytic reaction – generally cleavage of the substrate strand of the DNA. In the reported application, the DNA enzyme formed a cluster of gold NPs; the presence of lead ions resulted in DNA cleavage and prevention of NP aggregation – leading to different visible colors.

DNA was one of the early examples of biological scaffolding for nano-fabrication. The molecular recognition and self-assembly properties inherent in DNA have been powerful tools for assembling complex structures that could have sensing properties. A research group at the Israel Institute of Technology has demonstrated that DNA could form the basis for varied organized nanostructures [89]. These studies demonstrated that creation of highly defined carbon nanotube constructs using DNA as a self-assembled framework had potential for bio-sensing applications [90]. The researchers exploited the “coding” inherent in DNA by directing a DNA-binding protein (a bacterial RecA protein) towards the DNA strand. This groundbreaking experiment demonstrated that DNA can constitute a molecular “toolbox” for assembling organized nonbiological nanostructures.

Nano-scale patterns constructed through “bio-inspired” approaches, such as DNA hybridization, could, indeed, become an important tool in sensor technologies. Such molecular patterning could be crucial for improving sensitivity and selectivity of the sensors, for integrating the biosensor within non-biological assemblies such as silicon chips, and for coupling of the nano-scale sensors to electro-optic devices and circuits. Different techniques have been developed for producing biomolecular patterning, e.g., microelectronic fabrication combined with DNA hybridization and chemical immobilization on chip surfaces [91, 92]. DNA and antibodies have been used for extremely sensitive detection of molecular interactions through attachment to tiny cantilevers [93]. Such sensing devices, conceptually and practically, resemble force microscopes in that the cantilever moves (or changes its shape) in response to molecular attractions between the immobilized biomolecules and their targets. Such constructs could, in principle, facilitate detection at a single molecule level; this property would depend upon the cantilever size and the immobilization methods. The “functionalized cantilever” technology could form the basis of extremely sensitive sensing devices capable of detecting minute analyte concentrations.

Several reports have depicted the coupling between nano-scale assemblies and biological molecules in sensor applications. An interesting, albeit complex, nano-

sensor platform has been described in which the luminescent protein firefly luciferase was used to assemble colloids deposited on an optical sensor surface [94]. The luciferase was utilized in this system for monitoring binding events occurring at the sensor surface, but also as a participant in the sensing mechanisms through its catalytic activity. The integration of whole cells or cell elements into inorganic biosensor devices is another promising avenue for new sensing applications. Recent progress in engineering of molecular circuits has opened the way for construction of microelectronic devices containing whole cells [95]. Indeed, the coupling of nanofabrication and bio-microelectronics could revolutionize microbiological and environmental monitoring [96].

Developments in surface manipulation through microprinting, lithography, and microfluidics continue to contribute significantly to nanobiosensor research. A recent report demonstrated, for example, the construction of a “lab-on-a-chip” using a modular architecture [97]. One of the most remarkable aspects of that work was the creation of an integrated chip for detection of biological markers through the use of highly spatially-defined microfluidic channels and reaction chambers. This device is a fine representative of the large variety of microfluidic labs-on-chips demonstrated or already commercialized for detection of minute amounts of analytes in liquid samples.

## 11.5

### Nano-biotechnology and Biomedical Diagnosis

The emphasis in nanotechnology research on manipulation of ever smaller structures has opened revolutionary new avenues for biomedical applications and strategies, an approach referred to as “nano-medicine” [98]. An often touted futuristic application of nanotechnology in the field of medical diagnosis has been the introduction of tiny “nano-robots” traveling within blood vessels and tissues, scanning for malfunction and disease. Even though such applications are still far off, initial steps towards “molecular diagnostics” have been reported. A fascinating example of a nanosensor for *in vivo* analysis has been the implanting of nanoprobes for monitoring neural tissues and therapeutic treatments of neural diseases [99, 100]. Carbon nanotubes and nanofibers, in particular, are promising candidates for diverse biomedical uses because of their unique chemical and biological reactivity profiles. Several breakthrough studies have demonstrated effects of composites containing carbon nanotubes on functionalities and behavior of nerve cells and bone-forming cells [100].

Cancer diagnosis using nano-scale devices has gained considerable interest. Two main directions are pursued in this field: (a) *in vivo* imaging – using biomimetic nano-constructs for delivering imaging agents to malignant tissues and suspected areas within the body, and (b) *ex vivo* analysis – early detection of precancerous and malignancies in fluids extracted from the body using nanostructures as platforms,

generally in high-throughput screening arrays [101]. NPs are particularly attractive candidates for *in vivo* imaging. In principle, they can undergo “orthogonal” couplings – both to molecular markers, such as fluorophores or radio-isotopes, as well as conjugated with molecular entities necessary for targeting the particles to their cellular or tissue destinations [102]. Furthermore, in addition to *imaging*, NPs can be simultaneously used as vehicles for *delivery* of therapeutic substances to desired targets – making them a highly versatile platform for cancer diagnostics and treatment.

Nanoparticles have been employed for other cancer detection applications. A recent study has described the attachment of biocompatible superparamagnetic iron oxide NPs to nucleotide repeats produced by telomerase – an enzyme for which elevated levels are associated with many malignancies [103]. Intriguingly, such magnetic nanoparticles switched their magnetic state upon binding – facilitating detection of the biologically originated signals using conventional magnetic readers [103]. Such “magnetic illumination” from the bound nanoparticles could be also captured easily by modified magnetic resonance imaging apparatus and forms the basis for high-throughput sample screening.

A different type of NPs – the “nanoshells” – has been implemented in cancer diagnostics and imaging. Nanoshells, spherical metallic shells encapsulating a dielectric core, have been successfully used for tissue imaging because of the remarkable tunability of their optical properties [104]. Specifically, the optical resonance of the particles can be tuned to the near-IR (NIR) range – in which tissues are transparent. Accordingly, bioconjugation of the nanoshells with molecular markers and contrast agents allows illumination of inner body parts and disease diagnostics.

Detection of disease biomarkers, combined with micro-array technologies and biochips, has been an increasingly active field in nanobiosensor research, with significant scientific and commercial potential at stake. Several innovative nanotechnology-based techniques have been reported in recent years for detection of biomarkers for Alzheimer’s disease. Haes et al. have employed LSPR in a nanoscale optical sensor for immunological detection of amyloid-derived ligands [105]. In this application, which is amenable for high-throughput screening, the nanosensor surface successfully mimicked a physiological environment, facilitating antibody–antigen recognition. Nanoparticles have been employed in a recent breakthrough application for detection of a soluble biomarker for Alzheimer’s disease in cerebral spinal fluid [106]. The detection scheme was based on the onset of aggregation by oligonucleotide-modified gold NPs following binding of an Alzheimer’s disease pathogenic peptide to its specific antibody, where the antibody was also attached to the gold NPs (Fig. 11.8). This elegant approach not only achieved very high sensitivity due to signal amplification from the gold NPs, but is also notable for being carried out in an actual physiological solution. Such biomimetic diagnostic systems point to future development of molecular diagnostic kits in which pathogenic markers could be identified at very early stages of disease progression.

Fig. 11.8. Bio-barcode amplification assay [106]. The assay uses gold nanoparticles functionalized with monoclonal antibodies that recognize and bind a molecular marker for Alzheimer's disease (ADDLs). Following

separation and dehybridization, the oligonucleotides can be identified. (From Ref. [106]. Copyright (2005), the National Academy of Science USA.)

## 11.6

### Conclusions and Future Directions

Biosensors (or “biological detection devices” in the broad sense of the word) are becoming ubiquitous and increasingly complex. The proliferation of biological and biomedical applications and technologies, such as high-throughput screening, biomedical monitoring and diagnosis, and molecular arrays for functional genomics and proteomics analyses, all point to the pressing need for developing new biosensor platforms, technologies, and concepts. The biological and physiological spheres would most likely be increasingly exploited for ideas and building blocks in biosensor design, a process that is already taking place.

Nature provides abundant examples for innovative nanobiosensors. Snakes' “thermal vision” organs [i.e., sensitive to infra-red (IR) electromagnetic radiation] were found to contain an intricate array of nano-pits containing specific IR receptors [107]. The highly-defined spacings between these nano-pits are assumed to play a critical role in selective light absorption at particular wavelengths within the IR spectrum – endowing the snake with environmental sensing and navigation. Elaborate multilayered spheres of IR receptors have been similarly identified in *Melanophila acuminata* beetles [108]. Such dazzling arrays could inspire new sensors and IR observation devices.

In several fields, the advantages offered by nanobiosensors are obvious. The use of nanostructures as platforms for screening of large pool of compounds, i.e., genomics, proteomics, metabolomics, etc., would have a significant impact since this would increase array densities and assay efficiency. In biomedicine and medical diagnosis, nanosensors could have a profound effect on the way diagnosis is carried out, both inside and outside the human body. “Molecular imaging” and “molecular

diagnostics” point to a future in which “smart agents” consisting of tiny molecular entities will circulate in the blood stream, aiming to identify and report on various diseases and pathological conditions. *In vitro* diagnostics will rely on nanostructures to form devices, making possible high-throughput screening and rapid analysis of millions of genetic and other biological markers for identification of disease or health risks in individuals. Such applications could realize the much touted “personalized medicine” revolution.

Close collaboration among biologists, chemists, physicists, and engineers have become a defining feature in nanobiosensor research and development, and promise to open new horizons in the field. Such efforts have led to extraordinary advances in molecular manipulation, using physical, chemical, and biological tools. The general interest in nanotechnology commercialization and increasing activity in this field by industrial entities will undoubtedly shorten the routes from bench-top to commercial applications, a process that is already happening, as witnessed by the proliferation of start-up companies dealing mainly with nanobiosensor development.

# Reagentless Biosensors Based on Nanoparticles

*David E. Benson*

### 12.1

#### Introduction

The reagentless criterion for biosensors is one of the more stringent criteria for biosensor development. However, biosensors based on nanoparticles have progressed to the point that the reagentless criterion can be applied. The advantages of reagentless biosensors are a decreased need for recalibration, increased reproducibility, and minimized leaching of molecules used for analyte detection. From a development standpoint, concepts used for developing reagentless biosensors can be applied to various optical, electrochemical and magnetic detection methods. For a biosensor to be considered reagentless, the entire sensing modality needs to be unimolecular and connected through either covalent or kinetically-stable coordinate bonds. Multimolecular sensor (“non-reagentless”) systems are well known and provide an avenue for rapid concept development. However, artifacts arise from multimolecular systems as one component is diluted more than another. A classic example of this is the constant recalibration required of glucose oxidase-based electrochemical biosensors due to mediator dilution. The advantage of a reagentless biosensor is that differential dilution artifacts have been removed. The solution to the reagentless criterion for biomolecule-modified nanoparticles is addressed through biomolecule adhesion, specifically or non-specifically, to the nanoparticle surface. Certain aspects of attachment chemistry will be discussed in this chapter with regard to the effect on biosensor performance; however, the bulk of this literature is left to other chapters in this book series and many excellent review articles [1–5]. Here we discuss the growing literature of reagentless biosensors that are based on nanoparticles.

Notably, many nanoparticle-based biosensors function well but do not meet the reagentless criteria. One methodology is to encapsulate various chemosensors and biosensors within a nanometer scale liposome or polymer (PEEBLEs) [6–9]. While this methodology is quite successful, it is beyond the scope of this chapter. This chapter covers methods to perturb nanoparticle properties to produce unimolecular biosensors, since this methodology will allow the unique properties of nanoparticulate materials to be harnessed for analytical applications. Additionally,

biotin–streptavidin, DNA hybridization probes and antibody sandwich assays are superb systems for concept demonstration, but do not meet the reagentless criterion for this chapter. Coverage of these assays is left for other chapters in this volume. Finally, several cellular biosensors meet the reagentless criterion [5]. Discussion of these biosensors is deferred to other chapters in that the sensing modality still requires the multimerization of these probes to produce changes in optical absorbance, scattering, and fluorescence. Despite these biosensors being a single molecular species, the multimerization of these species is required for biosensing, which does not meet the reagentless criterion.

Nanoparticle-based reagentless biosensor development tests the current scaling law description of nanoparticulate systems. Creation of a nanoparticle-based reagentless biosensor must center on the nanoparticle as the readout element. The biomolecule–nanoparticle interface must be altered to translate the (bio)molecular–biomolecular binding event into a change in nanoparticle properties. The scaling rules of both nanoparticles and (bio)molecular phenomena must be interlaced for reagentless biosensing with nanoparticles. Thus, the reagentless criterion provides a method to compare nanosystem scaling rules to the scaling rules that are well known for material and molecular systems.

There are three general methods for interlacing nanoparticle and (bio)molecular scaling laws to provide nanoparticle-based reagentless biosensors (Fig. 12.1): surface dielectric enhancement, catalytic activation, and biomolecular conformational modulated effects. Optical, electrochemical, or magnetic detection methods have been reported for at least one of these classes. Additionally, surface immobilized and solution-based biosensors have differential representation in each class. Dielectric enhancement, detected by surface plasmon resonance or electrical conductivity, is induced by the analyte adsorbing to a nanoparticle surface. The nanoparticles in this class are typically surface immobilized or embedded; however, local surface plasmon resonance scaling rules suggest a solution-based approach could work as well. Catalytic activation of a biomolecule–nanoparticle scaffold by a small molecule analyte provides excellent signal responses using optical, electrochemical, and magnetic detection methods. The optical and magnetic detected biosensors from this class are solution-based, while the electrochemical is inherently surface-immobilized. The use of analyte-induced biomolecule conformation changes provides a flexible method for reagentless biosensor design. While, optical solution-state biosensors in this class are typical, nanoparticles are an excellent coupling element for developing electrochemical surface-immobilized biosensors of this class. In each of these reagentless biosensor classes, the analyte–biomolecule interaction must change either the nanoparticle electronic structure or influence the environment surrounding the nanoparticle.

Here we discuss reagentless nanoparticle-based biosensors in the context of three general methods for interlacing nanoparticle and (bio)molecular scaling laws. Classification by these methods will be used to discuss relationships between detection methods, types of analyte–biomolecule interaction, and the nanoparticle scaling rules. A caveats and advantages subsection points out this relationship and finishes the discussion of each general method. Each method relies on one of

**Fig. 12.1.** Three classes of reagentless nanoparticle-based biosensors. (A) Analyte-induced changes in surface dielectric. The surface plasmon (+/−) is enhanced upon analyte binding to a biomolecule. (B) Catalytic enhancement of nanoparticle-mediated signals. Nanoparticle-facilitated electron ( $e^-$ ) transfer from an enzyme to a working electrode is

shown. (C) Biomolecular conformation changes that alter nanoparticle properties. Analyte-induced changes in protein conformation alters the distance between a nanoparticle and a reporter group, where the reporter group–nanoparticle distance changes the properties of the nanoparticle.

these related aspects more than another, which will be discussed in the conclusion section.

## 12.2

### Surface Dielectric Enhancement

Gold nanoparticles, silicon nanowires, and single-wall carbon nanotubes enhance the sensitivity in detecting analytes at material–liquid interfaces by changes in surface dielectric (Fig. 12.2). Most biosensors in this category are reagentless, in that biomolecule surface immobilization is necessary for providing selectivity. Surface dielectric changes can be detected either by changes in surface plasmon resonance (SPR) of gold coated materials or by changes in electrical conductivity of nanoscale circuits. In each of these approaches, an analyte is concentrated by a biomolecule and the build up of this analyte changes the solvent dielectric at the material–liquid interface. Sensitivity enhancements observed for both techniques come from increasing the number/strength of analyte–material interactions. Thus, intro-

**Fig. 12.2.** Analyte-induced changes in surface solvent dielectric. (A) Upon analyte binding aqueous ions and water molecules are displaced, which alters the solvent dielectric at the nanoparticle surface. Two possible configurations are shown for detection of these effects: (B) Au bilayer films with proteins or nucleic acids attached to the solvent exposed

surface and (C) Si nanowire FET devices, where the bottom is the drain and the *n*- and *p*-gate are on either side of the Si nanowire (top). Proteins or nucleic acids are attached to the Si nanowire or the exposed surface of the Au film to increase solvent and ion displacement upon analyte introduction.

duction of nanoparticles, nanotubes, or nanowires enhance preexisting material properties.

### 12.2.1

#### Gold Nanoparticle Enhanced Surface Plasmon Resonance

Various Au/Ag nanoparticle modified surfaces enhance the SPR effect, but only two primary configurations have been used for reagentless biosensing. Additional localized SPR (LSPR) detection methods have been shown in multimolecular biosensor formats; however, discussion of these methods is left for another chapter in this series [10]. For planar Au/Ag surfaces the surface plasmon propagates along the metal surface, where changes in the refractive index or surface dielectric at the metal–liquid interface will alter plasmon propagation. For Au/Ag nanoparticle templated or fabricated surfaces, the surface plasmon scattering is redirected from within the material through the nanoparticles and into solution. These corrugated Au/Ag surfaces provide enhanced detection of changes in the solvent dielectric above these nanometer scale Au/Ag surface features [11, 12]. Two experimental configurations have been used to measure the LSPR response. The classic measurement determined the minimum absorbance by a Au/Ag coated slide as a function of the angle of incident light. A change in the angle of incidence for minimum absorbance indicates a change in solvent dielectric at the Au/Ag surface. Alternatively, the amount of light reflected at the surface plasmon resonance wavelength of Au/Ag nanoparticles has been determined using a backscattering fiber optic

setup. In this approach, changes in the solvent dielectric around the nanoparticle surface will change the amount of light back-scattered to the fiber optic cable. Backscattered reflection spectra are recorded and the intensity at the surface plasmon resonance peak is monitored. Both detection systems rely on the Au/Ag nanoparticle modified surface changing the SPR response as the analyte binds to surface-immobilized biomolecules.

One reagentless LSPR-based biosensor uses an Au nanoparticle coated quartz slide for optical detection. This work is ultimately based on earlier observations that Au nanoparticles adsorbing to Au surfaces shift the minimum angle of reflection from  $54.2^\circ$  to  $55.8^\circ$  [13]. While the binding of these nucleic acid probes is non-reagentless, reversibility measurements did provide reagentless detection of the *HinF* I restriction enzyme. Discussion of the restriction enzyme reagentless biosensing is left until Section 12.3. However, changes in the intensity of the Au/Ag nanoparticle surface plasmon absorbance can also be used as a detection strategy. Frederix and coworkers [14] have demonstrated LSPR-based human serum albumin (HSA) biosensing using a quartz substrate mounted in a cuvette using a standard UV/Vis spectrophotometer. The quartz substrate had Au nanoparticles adsorbed to the surface through 3-mercaptopropyl triethoxysilane and enlarged the Au nanoparticles under electroless reduction of  $\text{HAuCl}_4$ . Anti-HSA was covalently attached to the Au modified surface [14, 15] causing an increase in surface plasmon resonance ( $\sim 634$  nm, Au;  $\sim 445$  nm, Ag) and, after subtraction of the protein contribution, the interband absorbance (250–400 nm, Au and Ag). Addition of  $2.5 \text{ mg mL}^{-1}$  HSA ( $\sim 40 \text{ }\mu\text{M}$ ) to anti-HSA modified Au nanoparticle surfaces caused a 0.002 and a 0.004 absorbance unit increase after 30 min and overnight incubation in the absence of stirring. These small, but detectable, absorbance signals demonstrated reagentless biosensing could be obtained using common instrumentation. As noted by the authors, addition of stirring to this system will increase mass transport and facilitate a more rapid response. The small absorbance response could be enhanced by using the biotin-immobilized surface shown by Nath and Chilkoti [12] with a tightly packed array of monodisperse Au nanoparticles. This work used a flow cell variant of the Frederix work to increase mass transport, but maintained detection by a UV/Vis spectrophotometer. In this study, a biotin-immobilized array of 39-nm diameter Au nanoparticles on a glass slide showed a 0.050 absorbance increase upon the binding of  $1 \text{ }\mu\text{g mL}^{-1}$  ( $\sim 20 \text{ nM}$ ) streptavidin [12]. Thus, reagentless biosensing by an array of glass-immobilized nanoparticles provides a highly accessible platform for Au nanoparticle-based reagentless biosensor development.

Au bilayer films with 100 nm spherical features allowed for wavelength-resolved backscattered reflectance detection of single-stranded DNA and fibrinogen (Fig. 12.2B) [16, 17]. In these reports, thiobutyric acid coated Au films on glass slides were EDC coupled with 100 nm diameter aminopropyltriethoxysilane coated silica nanoparticles and the second Au layer was vapor deposited over these 100 nm silica particles. Near monolayer coverage of these 100 nm features yielded an optimal LSPR response [17]. The 100 nm features of these surfaces create an array of Au nanoparticle shells that have been shown previously to provide large LSPR enhancements [18]. These Au bilayers are similar, but with larger features, to the

nanoprism arrays on Au surfaces reported by Van Duyne and coworkers [11]. Anti-fibrinogen was immobilized on these structures through biotin–streptavidin chemistry, which increased the reflected absorbance at 560 nm by 0.2 absorbance units. Addition of  $100 \mu\text{g mL}^{-1}$  ( $\sim 2 \mu\text{M}$  of monomers) fibrinogen yielded an additional 0.2 absorbance unit increase, while bovine serum albumin addition (non-specific control) yielded a 0.002 absorbance unit increase. When the neutral backbone peptide nucleic acid (PNA) or DNA is substituted for the antibody, single-stranded nucleic acids were detected in a reagentless format [16]. Biotinylated DNA or PNA probes (10-mers) from the tumor necrosis factor- $\alpha$  gene were attached to the Au corrugated surface, causing a 0.10 to 0.15 increase in absorbance at 550 nm. Addition of a complementary DNA target ( $1 \mu\text{M}$ ) with a single nucleotide mismatch yielded a less than a 0.003 absorbance unit increase, while addition of a completely complementary DNA target ( $1 \mu\text{M}$ ) yielded a 0.15 to 0.2 absorbance unit increase. The limit of detection of both the PNA and DNA immobilized biosensors were 0.1 pM of the target DNA with a 0.03–0.04 absorbance unit increase. PCR-amplified DNA targets were also detected down to  $5 \mu\text{L}$  of the 1:40 dilutions from the initial amplified mixture. Application of this reagentless biosensing strategy to the smaller Au/Ag nanoisland structures fabricated and examined by Van Duyne and coworkers [11, 19] should produce similar absorbance changes, along with over 100 nm redshifts in the surface plasmon absorbance. Therefore, these nanotemplated Au/Ag surfaces provide a surface-immobilized platform for reagentless biosensing with inexpensive instrumentation.

A hybrid photoelectrical SPR-detected device has been constructed for reagentless biosensing of acetylthiocholine [20]. Using an open circuit configured Au electrode, monolayers of Au and CdSe nanoparticles were successively chemisorbed to the Au surface (Au/Au np/CdS np surfaces, Fig. 12.3). A similar surface had been shown previously to display a photoinduced change in the minimum angle of incidence for SPR reflected light under closed circuit constant potential electro-

**Fig. 12.3.** Example of a hybrid biosensing device. Enzymatic hydrolysis of acetylthiocholine into thiocholine and thiocholine oxidation provides a pseudo-reagentless method for photoelectrochemical

injections of electrons into thin Au films (A). Electron injection to the Au surface changes the incident angle of surface plasmon resonance (B).

chemical conditions [21]. With these Au/Au np/CdS np surfaces, applying mM concentrations of triethanolamine in the presence of 1.5 mW blue LED source caused up to a  $0.4^\circ$  shift in the angle of incidence minimum. This open circuit photostimulated SPR effect comes from a  $\sim -150$  mV bias across the Au/Au nanoparticle junction and a  $-25$  mV photoinduced potential from the CdSe nanoparticle. The triethanolamine dependence of this process stems from oxidation of triethanolamine by the valence band holes of CdS, which are formed by photoexcitation. Back of the envelope calculations suggests four additional electrons are collected per Au nanoparticle during this photostimulated process. Pseudo-reagentless biosensing was then demonstrated, where acetylcholine esterase was attached to the CdS nanoparticle that in the presence of acetylthiocholine produced thiocholine. The acetylcholine esterase-produced thiocholine then mediated the photostimulated  $0.4^\circ$  shift in the minimal SPR absorbance angle of incidence at 25 mM acetylthiocholine and a 2 mM LOD. The acetylcholine LOD in this system is limited by the  $K_M$  of acetylcholine esterase, as observed by the  $\mu\text{M}$  LOD for an acetylcholine esterase inhibitor. This strategy has also been applied to an electrocatalytic biosensor (Section 12.3.1). This strategy not only demonstrates an exciting hybrid technique for nanoparticle-based reagentless biosensing, but also demonstrates the detection of a low molecular weight analyte and that electrode-immobilized metallic nanoparticles function as electron reservoirs.

### 12.2.2

#### Carbon Nanotube and Silicon Nanowire Enhanced Conductivity

Altering the conductivity of nanometer-scale electrode junctions is an alternative technique to optical surface plasmon resonance techniques for biosensor development (Fig. 12.2C). Single-wall carbon nanotubes (SWCNTs) [22] and Si nanowires (SiNWs) [23] have been used for biosensing [24, 25]. The conductivities of these devices are intimately linked to the electrostatics surrounding the SWCNTs and SiNWs. While there are different scaling effects for SWCNTs [26] and SiNWs [23], these nanotubes increase the sensitivity of conductivity measurements by increasing the interaction between the electrode carriers and the surrounding solution. Electrical conductivity detected biosensing with nanotubes is similar to SPR detected biosensing, in that the non-specific adsorption needs to be carefully excluded. While the sensing methodology is generally similar between SWCNTs and SiNWs, there are differences in device fabrication and biomolecule attachment chemistry.

Carbon nanotubes are attractive as biosensing transducers from a biocompatibility and synthetic standpoint. Covalent modification of SWCNTs for biomolecule attachment is an active area of research [24, 25]. Despite reported methods, biomolecular attachment to SWCNTs for reagentless biosensing has relied on surfactant physisorption with Tween [22]. Covalent coupling between Tween-20 and the biomolecule of interest then provides the specificity for conductivity measurements. Surfactant coating is an important issue in that the sensitivity of the conductivity response is minimized. An additional issue comes from the observation that con-

ductivity detection occurs primarily at the SWCNT–metal electrode junction, or Schottky barrier modulation [26]. Adsorption of biomolecules with an isoelectric point similar to the solution pH to the SWCNT–metal junction will give the largest change in conductivity [26]. If SWCNTs are left untreated, non-specific protein adsorption abounds due to the large hydrophobic surface area of the SWCNTs, as observed by conductivity changes. Tween-20 and other surfactants also adsorb readily and irreversibly to SWCNT surfaces [22], forming the basis for biomolecule selective attachment strategies discussed here.

Selective protein detection has been displayed by SWCNT-based biosensors in a reagentless format. Initial studies from Dai and coworkers were performed with immunoglobulin G (IgG) and the 10E3 antibody that selectively binds the U1A RNA splicing factor [22]. Each of these selective sensors were generated through carbodiimide coupling between SWCNT adsorbed Tween-20 and either staphylococcal protein A (IgG biosensor) or U1A RNA splicing factor (10E3 biosensor). The staphylococcal protein A immobilized sensor showed a 1.02-fold decrease in conductance with the addition of 100 nM IgG after 5–10 min. The IgG LOD could be 20–50 nM for this system. The U1A-immobilized sensor gave a 1.03-fold decrease in conductivity with the addition of 1 nM 10E3 antibody after 10 min, placing the LOD for 10E3 around 200 pM. As a proof of principle after a mechanistic report, human chondriotic gonadotropin (hCG) was immobilized on a SWCNT device to detect a monoclonal antibody that specifically binds hCG, termed  $\alpha$ -hCG. Addition of 10 nM  $\alpha$ -hCG to the hCG immobilized sensor yielded a 1.03-fold decrease in conductivity after 15 min. The  $\alpha$ -hCG LOD is approximately 5 nM from this report. With known solution state affinities for at least the SpA-IgG complex ( $K_D \sim 1$  pM) the sensitivity of these biosensors seems to be limited by the SWCNT conductivity. Recently, SpA and hCG immobilized SWCNT biosensors were reported with 1 pM detection of IgG or  $\alpha$ -hCG, respectively, within one minute [27]. This increased sensitivity was provided by a shadow mask lithography technique, which increased the area of SWCNT-Si/SiO<sub>2</sub> contact and increased the Schottky barrier where detection occurs. An increased conductivity response has been reported for an aptamer-immobilized SWCNT sensor [28]. The thrombin-specific DNA aptamer used in this report is one of the classic protein-specific aptamers [4]. The thrombin aptamer was carbodiimide coupled to Tween-coated SWCNTs, which yielded a sensor with 1.08-fold decrease in conductivity with the addition of 1  $\mu$ M thrombin. The thrombin LOD for this biosensor was 10 nM and the response saturated at 300 nM. Since the thrombin–aptamer dissociation constant is 100 pM in solution the sensitivity of this biosensor can be improved. Finally, glucose/glucose oxidase production of H<sub>2</sub>O<sub>2</sub> has provided a pseudo-reagentless biosensing strategy for glucose [29]. This report immobilized glucose oxidase to SWCNTs through a pyrene-modification so that, in the presence of glucose, O<sub>2</sub> would be converted into H<sub>2</sub>O<sub>2</sub> and increase the conductivity around the Schottky junction. This biosensor showed a 1.12-fold increase in conductivity after the addition of 10  $\mu$ M with a 30 s response time that lasted for at least 10 min. With the advent of SWCNT covalent modification chemistries [30] and the increased Schottky barrier

area fabrication technique [27], the sensitivity and response of SWCNT conductivity sensors can be improved from these exciting reports.

Lieber and coworkers have demonstrated SiNWs as a conductivity detected biosensing platform. SiNW-based sensors rely on the solvent dielectric surrounding the nanowire surface and not the nanowire termini at the device interface. This chemical potential of SiNWs allows for an increased interaction between the solution dielectric and carriers in the nanowire. Thus, SiNWs are potentially more sensitive than SWCNT-based conductivity devices. Additionally, the passivated SiO<sub>2</sub> layer on the SiNW surface allows for facile biomolecule immobilization chemistry. 3-(Trimethoxysilyl)propyl aldehyde treatment is typically used to provide biotin or protein modified surfaces. The increased synthetic control of doping in SiNWs also allows analyte response validation by observing the opposite conductivity response in the oppositely doped SiNW. SiNW-based conductivity devices that detect a metal ion, DNA, and proteins have been reported.

SiNW-based biosensors displayed higher sensitivities but similar conductance changes compared with SWCNT-based biosensors. The initial report of SiNW-based biosensors described a calmodulin-terminated SiNW sensor [23]. This sensor showed a reversible 1.03-fold decrease in conductance within 15 s of 25  $\mu\text{M}$  Ca<sup>2+</sup> ions. Two systems were reported for SiNW-based biosensing of DNA. Li and coworkers used a top-down lithographic method to fabricate larger diameter SiNWs [31]. Chemical immobilization of the probe DNA oligonucleotide to SiNWs yielded a biosensor with a 1.13-fold increase (*p*-type SiNW) and a 1.8-fold decrease (*n*-type SiNW) in conductivity within 30 s of adding 25  $\mu\text{M}$  complementary DNA. Lieber and coworkers used synthetic SiNWs with biotin-modified surfaces. Avidin attachment to these biotinylated SiNWs then facilitated biotinylated PNA immobilization [32]. Despite the larger distance of the probe PNA from the *p*-type SiNW surface, within 5 min a 1.25-fold increase in conductivity was observed with the addition of 100 fM complementary DNA to this biosensor. This biosensor was specific for the complementary DNA over a DNA containing a single base deletion, responsible for cystic fibrosis. A 10 fM detection limit of this PNA-modified SiNW device places this as one of the most sensitive detection methods for DNA. Direct protein adhesion was used for cancer marker biosensing, where monoclonal antibodies for prostate specific antigen (PSA) and carcinoembryonic antigen (CEA) were immobilized through aldehyde crosslinking to an array of *n*-type and *p*-type SiNWs [33]. This sensor showed a 1.10-fold increase (*p*-type) and a 1.12-fold decrease (*n*-type) in conductivity with the addition of 20  $\mu\text{M}$  PSA. The LOD for PSA in buffer was 25 fM (1.01-fold change in conductivity) while a 0.8  $\mu\text{M}$  LOD was found for PSA detection in donkey serum. Immobilization of a protein tyrosine kinase, Abl, to *p*-type SiNWs through aldehyde crosslinking chemistries yielded reagentless ATP biosensors with a 1 nM LOD [34]. The addition of 20 nM ATP caused, surprisingly, a 2.0-fold increase in conductivity. Addition of known Abl inhibitors decreased the ATP-dependent increase of the *p*-type SiNW conductivity to about 25% of the initial increase (1.25-fold increase). Given the large change in conductivity relative to the molecular weight of ATP, a protein conformation change could be responsible

for this large relative increase in conductivity but the lack of site-specific attachment chemistry makes investigation of this point difficult. Taken together, SiNWs provide a versatile platform for biomolecule attachment, microfluidic interfacing, and high analyte sensitivity for reagentless biosensing.

### 12.2.3

#### **Advantages and Caveats**

The ability to directly couple biomolecules to nanoparticles for analytical readout is a clear advantage of the surface dielectric technique. The use of nanoparticles provides an exquisite sensitivity to solvent dielectric changes localized at the nanoparticle surface. Proper attachment of biomolecules to nanoparticle surfaces adds the molecular selectivity necessary for analyte detection. Most of these devices are surface immobilized, which minimize the amount of solution handling for biosensor activation. The surface immobilized nature of these devices allows for multiplexed device fabrication and application to microfluidic separations. Integration of these sensors with microfluidic separation is required due to the necessity of sample clean-up. Changes in surface dielectric effectively increase the local analyte concentration around the nanoparticle surface. Therefore, analyte detection in complex environments will be difficult based on the small signal changes and large changes in bulk solvent dielectric. By comparison of *n*- and *p*-type Si nanowires Lieber and coworkers have addressed this issue [33, 34]; however, performing this analysis in salt water, for example, would be difficult. Therefore, additional methods for reagentless biosensing have been explored to minimize the amount of sample clean-up necessary before analysis.

## 12.3

### **Catalytic Activation**

An alternative method for developing reagentless biosensors is to couple nanoparticle–biopolymer composites with catalytic activity. The nanoparticle scaling rules used by biosensors in this class depends on whether the detection method is electrochemical or optical/magnetic. The distance dependent dissipation of this sensitivity should decay rapidly. Electrochemical biosensors that use nanoparticles take advantage of the improved electron flux at the enzyme–electrode interface that the nanoparticle provides. Scaling laws similar to the previously discussed LSPR-scaling laws are used in optical or magnetic detected biosensors in this class. The catalytic strategy can be readily employed to translate concepts from hybridization-based biosensors into reagentless biosensors for hydrolytic enzymes or reagents. While the surface dielectric methodology provides a method that integrates surface immobilization chemistry with analyte–biomolecule binding, the catalytic methodology translates multimolecular biosensing strategy into a reagentless biosensing strategy.

## 12.3.1

**Electrocatalytic Detection**

Nanoparticle-modified electrode surfaces allow multimolecular electrocatalytic biosensors to be translated into reagentless biosensors. Electrode immobilized glucose oxidase (GOx) is the classic electrocatalytic biosensor example. GOx-based biosensors provide a catalytic amplification of Faradaic current to overwhelm capacitive currents that typically dominate enzyme-immobilized electrochemical responses. Such catalytic enhancement occurs by the detection of  $\text{H}_2\text{O}_2$  resulting from  $\text{O}_2$  reduction during glucose oxidation by GOx. Catalytic amplification stores electron equivalents in small molecular products that are more rapidly transported to the electrode surface. Carbon nanotubes [35–38], Au nanoparticles [39–42], CdS nanoparticles [43], and  $\text{Fe}_3\text{O}_4$  nanoparticles [44] that are immobilized on glassy carbon electrodes also store electron, or hole, equivalents to produce electrocatalytically amplified Faradaic currents for biosensing (Fig. 12.1B). The photovoltaic LSPR biosensing scaffold discussed in the previous section calculated under photostimulated, open circuit conditions that four electrons were injected per Au nanoparticle [20]. Both increased electronic communication and enzyme stability of colloidal Au adsorbed electrodes were demonstrated ten years ago [45–47]. Integration of the reagentless electrocatalytic biosensors discussed here shows a  $\sim$ five-fold integrated current increase, by cyclic voltammetry, in non-mediated background electrocatalytic currents of enzyme-immobilized glass carbon electrodes. Most of these methods employ non-oriented physisorption or crosslinking chemistries for enzyme film formation on the electrode interface. The five-fold Faradaic current increase relative to the uncoated glassy carbon electrode was observed for carbon nanotube [35, 36, 38], Au nanoparticle [39, 42, 48], and  $\text{Fe}_3\text{O}_4$  nanoparticle [44] adsorbed glassy carbon electrodes. The potential for increased enzyme stability and electrode interaction with active enzyme makes the correlation of this five-fold increase in integrated Faradaic current difficult to justify as an increased heterogeneous electron transfer rate. Since surface immobilized electrochemical behavior is not typically observed for bare glassy carbon electrodes, derivation of differences in the heterogeneous electron transfer rate is difficult. While no comparison of Faradaic current increases were provided by adsorbing CdS nanoparticles to glassy carbon electrodes, Willner and coworkers have shown photocatalytic electron transfer in enzymes adsorbed to CdS nanoparticle [21] and CdS nanoparticle–Au nanoparticle [20] modified Au electrodes. These nanoparticle-modified Au electrodes clearly point out that electron injection to Au nanoparticles occurs [20]. Also, photocatalytic electron injection is provided by CdS nanoparticle modified Au electrodes [21]. Finally, enzymatic immobilized versions of nanoparticle-modified electrodes can reversibly activate these photostimulated effects [20, 21]. Therefore, integration of nanoparticles into enzyme immobilized electrodes provides mediator-free electrocatalytic amplification.

For reagentless electrocatalytic biosensors the detectable analytes are predominantly low molecular weight. Glucose oxidase based electrocatalytic biosensors

displayed different LODs for glucose. Single-wall carbon nanotube adsorbed electrodes with GOx have shown an increase in catalytic current with a LOD of 2 mM glucose and a response time of 30 s [35]. CdS nanoparticle modified glassy carbon electrodes were able to detect glucose by a decrease in the reductive current in cyclic voltammetry with a glucose LOD of 2 mM [43]. The decrease in reductive current upon glucose addition demonstrated slow electron injection from CdS for FAD reduction in the absence of photostimulation. The GOx adsorbed Au nanoparticle modified electrodes showed a LOD of 50  $\mu\text{M}$  but a decrease in background current with a  $-600$  mV potential (vs. SCE) upon glucose addition [41]. The Au nanoparticle based biosensor was able to detect accurately blood glucose levels (8.4 mM). Carbon nanotube modified electrodes with alcohol dehydrogenase immobilized showed an ethanol LOD of 1 mM [37], consistent with the  $K_M$  for the enzyme. Immobilization of hemeproteins provides bioelectrochemical sensors for various low molecular weight redox-active analytes. Hydrogen peroxide is a common analyte for these sensors, where the LOD for the multiwall carbon nanotube biosensors [36, 38] was  $\sim 1$  mM. The  $\text{Fe}_3\text{O}_4$  nanoparticle modified electrodes provided a 80  $\mu\text{M}$  LOD for hemoglobin- or myoglobin-immobilized electrodes and a 2  $\mu\text{M}$  LOD for catalase-immobilized electrodes.  $\text{Fe}_3\text{O}_4$  nanoparticle modified electrodes demonstrated that the sensitivity was determined by the enzyme, not the electrode. Nitrite biosensing with these  $\text{Fe}_3\text{O}_4$  nanoparticle modified electrodes [44] and with Au nanoparticle modified electrodes [42] both showed a 200  $\mu\text{M}$  LOD for sodium nitrite in the electrocatalytic mode. However, the Au nanoparticle modified electrode with hemoglobin immobilized showed a 1  $\mu\text{M}$  LOD for nitrite [42] and 50 nM LOD for NO [40] using reversible non-catalytic peak currents from cyclic voltammetry. The final example is the immobilization of the Cu-containing tyrosinase on Au nanoparticle modified electrodes, which demonstrated LODs for phenolic compounds from 150 nM (catechol) to 70  $\mu\text{M}$  (gallic acid) [39]. Tyrosinase-modified electrodes were able to detect the concentration of caffeic acid (LOD 6  $\mu\text{M}$ ) from three red and three white wines, confirmed by a colorimetric test. Overall, LODs that reflect the Michaelis constants of the immobilized enzymes are observed for electrocatalytic biosensors that use nanoparticles as an electron reservoir.

A photoelectrochemical methodology demonstrates the potential for integrating semiconducting nanoparticles into the bioelectrocatalytic systems above. Willner and coworkers have demonstrated that illumination of CdS-modified Au electrodes with acetylcholine esterase attached to the CdS nanoparticle turns on electrocatalytic current [21]. Enzymatic production of thiocholine governs this process, in that thiocholine reduces CdS valance band holes, which are formed upon photoexciting the CdS nanoparticle. Monitoring the current as a function of wavelength (6–30 mM acetylthiocholine) produced an action spectra consistent with the band edge absorbance of the CdS nanoparticles. In the presence of 380 nm wavelength light, a LOD of 5 mM acetylthiocholine was detected, and the response saturated above 30 mM. In comparison, CdS nanoparticles adsorbed on glassy carbon electrodes were able to detect the slow reduction of glucose oxidase FAD in the absence of light and glucose [43]. Taken together these experiments demonstrate that electron flow between CdS and enzymes/substrates is reversible. Application

of photostimulated electron transfer to the electrochemical-based biosensors discussed here provides a method to introduce additional detection selectivity. Semiconducting nanoparticles allow the development of such hybrid techniques, like the photostimulated LSPR effect in Section 12.2 [20], to be developed.

### 12.3.2

#### Catalytically Enabled Optical and Magnetic Detection

Enzymatic cleavage of biomolecule-tethered nanoparticles provides an alternative method for detecting enzymatic activity (Fig. 12.4). In this particular type of sensing, the biomolecule attached to the nanoparticle becomes the substrate to detect the enzyme or reagent catalyzing biomolecule hydrolysis. As biomolecule hydrolysis occurs the physical link between the nanoparticles or nanoparticle–organic fluorophore is broken. Once the nanoparticles or nanoparticle–organic fluorophore assembly dissociate, the properties of the non-modified nanoparticles and fluorophores are restored [1, 10, 49, 50]. Such a strategy has yielded pseudo-reagentless biosensors based on Au nanoparticle quenched CdSe@CdS nanoparticle emission [51], Fe<sub>3</sub>O<sub>4</sub> nanoparticle associated enhancement of spin–spin relaxation time ( $T_2$ ) of adjacent water protons [52], or magnetic field modulated cantilever deflection [53, 54]. This method might be extended to optically detected surface plasmon resonance from an Au nanoparticle assembly. While optical assays based on hydrolysis of DNA-modified Au nanoparticle assemblies exist [55, 56], the assembly and thermal denaturation steps seem to ensure specificity. It is assumed that the forces applied by magnetic field detection methods [52, 53] overcome the need for assembly and thermal denaturation. Since enzymatic cleavage uses an initial associated complex, the more effective scaling laws for nanoparticulate materials can be more readily employed for biosensor development.

To date, there is one example of a reagentless, optically-detected biosensor for collagenase [51]. In this system, a peptide that is specifically degraded by collagenase (GGLGPAGGCG) is covalently coupled between CdSe@CdS nanoparticles on the amino-terminus and Au nanoparticles on the carboxy-terminus. The covalently coupled CdSe@CdS-peptide-Au complex has the CdSe@CdS emission intensity partially quenched by energy transfer to the Au nanoparticles. Incubation with  $\sim 2 \mu\text{M}$  collagenase for 18, 39, and 47 h showed a 1.10, 1.20, and 1.35-fold increase, respectively, in CdSe@CdS emission intensity. While the response times for these

**Fig. 12.4.** Enzymatic cleavage of biomolecule tethered nanoparticle–nanoparticle or reporter group–nanoparticle pairs. Upon cleavage, the pair of chromophores no longer interact and restore the original signal of these chromophores.

collagenase biosensors are slow, the response time could be enhanced through increasing the accessibility of the peptide substrate.

DNA–magnetic nanoparticle assemblies that have been termed magnetic relaxation switches (MRS) provide magnetic resonance imaging (MRI) detected reagentless biosensing [52]. This method hybridizes two pools of covalently modified DNA–Fe<sub>3</sub>O<sub>4</sub> nanoparticle aggregates with complementary nucleotide sequences. Once assembled, the 50–100 nm DNA–nanoparticle aggregates decrease the water spin–spin relaxation time ( $T_2$ ) by two-fold. Duplex DNA formed in these hybridized assemblies contains a recognition site for the BamH I restriction endonuclease. Digestion with BamH I, but not EcoR I digestion, caused a disassembly of the aggregates and a restoration of the original  $T_2$ . Imaging microtiter plate samples within a MRI spectrometer, the Dpn I restriction endonuclease was specifically detected with methylated DNA–Fe<sub>3</sub>O<sub>4</sub> nanoparticle assemblies, while unmethylated DNA–Fe<sub>3</sub>O<sub>4</sub> nanoparticle assemblies showed no change in  $T_2$ . A similar strategy was reported where rennin and matrix metalloprotease-2 proteolytic activities were determined using peptide substrates that were biotinylated at both termini [57]. Unfortunately, the peptide substrate had to be hydrolyzed before nanoparticle assembly occurred, rendering this as a multimolecular assay. Despite the drawbacks of this second assay, catalytic hydrolysis has demonstrated reagentless biosensing can be performed using MRI.

Using larger magnetic particles, Willner and coworkers have demonstrated reagentless biosensors that detect restriction endonucleases with the application of a magnetic field [53, 54]. Atomic force microscope cantilevers were coated with Au and thiol-terminated DNA that was complementary to DNA modified magnetic particles. The duplex DNA formed on the cantilever surface contained recognition sites for restriction endonucleases. The cantilever deflection could be reversibly controlled by application of a magnet to each system. The force experienced by these cantilever systems was around 1–3 nN. In one system, ten units of either Apa I or Mse I restriction endonucleases were detected with a 5 minute response time [53]. In a different set of systems, two restriction enzyme sites were included on one DNA duplex providing an OR logic gate detection for either Apa I or EcoR I [54]. Alternatively, a mixed monolayer of duplex DNA was formed between the cantilever surface and the magnetic particle that contained recognition sites for EcoR I and Asc I on different duplex DNA strands. The mixed monolayer provides an AND logic gate detection of EcoR I and Asc I. The extension of logic gated detection strategies to microarray sensors is a particularly interesting application for biosensor development.

### 12.3.3

#### **Advantages and Caveats**

Catalytic activation schemes for biosensing with nanoparticles enhance the analyte-dependent signal. Enhancement occurs by one of two methods, either using nanoparticles to interface enzymatic electrochemical reactions or to adapt analyte–biomolecule recognition to the scaling laws of nanoparticle mediated effects. These

methods harness the unique properties of nanoparticles to detect analytes in complex mixtures. Analyte specificity, in each case, is provided by the enzymatic amplification of a Faradaic current or enzyme (analyte) mediated cleavage. However, many additional factors contribute to enzyme inhibition and the degree of inhibition varies from enzyme to enzyme. The largest caveat with enzymatic activation schemes is that surface immobilization is necessary for analyte reversible detection. Thus, use of enzymatic activation schemes for reagentless biosensing for fluorescence contrast imaging agents will only provide single-use biosensors. An obvious alternative is to couple analyte-dependent biomolecular conformation changes to provide reversible analyte detection by fluorescence contrast imaging biosensors.

## 12.4

### Biomolecule Conformational Modulated Effects

The final method for reagentless biosensing using nanoparticles is translating ligand-mediated biomolecule conformational motions into changes in nanoparticle properties (Fig. 12.5). While the previous methods have focused on directly coupling the ligand–biomolecule binding event to changes in the analytical signal, this method focuses on the detecting changes in the interaction between a reporter molecule and a nanoparticle. The reporter groups that have been described are organic compounds [58–62], a coordination complex [63, 64], or a nanoparticle [65]. With the reagentless criterion, these reporter groups have to be covalently attached to the biomolecule. Covalent bond formation is carried out through standard nucleophilic modification chemistries [66], where biomolecule-derived primary amines or thiols are modified with the reporter group. Reporter group co-

**Fig. 12.5.** Biomolecular conformation changes mediate reagentless nanoparticle-based biosensing. (A) Nucleic acid-based conformation changes will move a reporter group (the smaller ball) by 10 to 50 Å away from the nanoparticle upon complementary nucleic acid binding. (B) Protein-based conformation changes will move a reporter group by 1 to 6 Å away from the nanoparticle upon analyte binding.

valent attachment is necessary for ligand-mediated conformation changes to alter the reporter group–nanoparticle interaction. Since biomolecular conformation changes are the focal point of this method, the nanoparticle has to be site-specifically attached to the biomolecule as well. Thus, strategies for orthogonal site-specific attachment of reporter groups and nanoparticles are necessary for this method [55, 67–69]. These methods either use DNA synthesis and modification chemistry or recombinant DNA technology for protein production followed by modification chemistry. Once generated, the type of reporter compound–nanoparticle interaction that effectively reports analyte concentrations depends on the magnitude of biomolecule motion. DNA duplex formation provides the largest conformation change (10–50 Å, Fig. 12.5A), while analyte-induced protein conformation changes are much more subtle (1–10 Å, Fig. 12.5B). Therefore, this section will be organized based on the type of biomolecule (DNA or protein) used in analyte detection.

#### 12.4.1

##### **Biosensors Based on DNA Conformation Changes**

With the larger analyte-induced conformation change of DNA, more nanoparticle-based detection methods have been reported (Fig. 12.5A). Energy transfer methods are a popular method for detecting changes in biomolecule conformation [70] and provide reagentless biosensors with DNA probes. Organic reporter molecules [58, 60–62] seem to be most effective in reagentless biosensor development. Au–Au nanoparticle interactions have also been used to provide colorimetric pseudo-reagentless biosensors [65]. Three types of analytes have been detected by these DNA–nanoparticle-based biosensors: oligonucleotides, proteins, and small molecules. The oligonucleotide biosensors [58, 60, 62] used base pair recognition for sequence specific recognition. With the development of selection strategies for small molecule and protein dependent conformation changes in nucleic acids (aptamers) [71, 72], small molecule [65] and protein [61] biosensors have been developed for reagentless DNA-nanoparticle based biosensors. Aptamers provide a complementary method for reagentless small molecule and protein biosensing relative to proteins [4]. The drawback of aptamer–nanoparticle based biosensors that are currently reported is that they are pseudo-reagentless where they begin as unimolecular species but after analyte addition part of the initial system is displaced. Irrespective of this critique, these aptamer-based biosensors have introduced an important concept in reagentless nanoparticle-based biosensor development.

Aptamer–nanoparticle based biosensors provide an avenue to rapidly expand the pool of analytes that are detected by reagentless nanoparticle-based biosensors. Using exponential selection strategies (SELEX) [71, 72], various RNA and DNA sequences have been identified that bind small molecules and proteins while inducing a change in nucleic acid tertiary structure [4]. The ligand-bound conformation is typically a stem-loop structure where the base of one of the nucleic acid termini forms a duplexed stem. Stem formation then mediates a reporter molecule that is

attached to the stem forming nucleic acid terminus, moving either away from or towards the nanoparticle surface. As pointed out above, the change in the reporter group–nanoparticle distance can be between 10 to 50 Å in aptamers. Adenosine and cocaine aptamers were attached to Au nanoparticles through a thiolate-modified 3'-end of a 12-mer complementary DNA strand [65]. In the absence of adenosine or cocaine the oligonucleotide existed in an extended conformation allowing a second Au nanoparticle with a 5' thiolate-modified DNA strand complementary to the aptamer DNA. The duplex DNA formed from this second Au nanoparticle DNA was composed of seven bases from the adenosine aptamer sequence and five additional bases used to separate the aptamer sequence from the hybridization sequence of the first Au nanoparticle. When these two pools of DNA-modified Au nanoparticles are combined, the classic redshifted absorbance (~580 nm) of aggregated Au nanoparticles was observed. Due to multiple DNA molecules attached to one Au nanoparticle, a simple two Au nanoparticle complex did not occur but a larger aggregate of Au nanoparticles formed. However, the addition of 0.5 to 5 mM adenosine changed the solution from blue to red within one minute. The equilibrium absorbance ratio between 522 nm (dissociated) and 700 nm (aggregated) increased up to a saturated value of 15 with the addition of adenosine or cocaine to the cognate aptamer assemblies. While the adenosine/cocaine-mediated dissociation kinetics look monoexponential, the absorbance ratios after one minute of reaction showed two binding affinities and saturated absorbance ratios. The low adenosine/cocaine effect could be explained by dissociation of Au nanoparticles on the surface of the Au nanoparticle aggregates. Despite these effects a colorimetric assay for adenosine and cocaine with LODs of 0.5 and 0.1 mM was developed by this strategy.

Thrombin-specific aptamer modified CdSe@ZnS nanoparticles were generated and demonstrated thrombin and DNA biosensing detected by fluorescence [61]. This strategy harnessed the high quantum yield and photostability of semiconducting nanoparticles for low micromolar analyte sensitivity. The system used commercially available streptavidin-coated CdSe@ZnS nanoparticles that emitted at 525 nm. A 5'-biotin modified DNA containing the thrombin aptamer sequence was hybridized with a complementary 12-mer DNA with a proprietary organic quencher ( $\epsilon_{525} \sim 66\,000 \text{ M}^{-1} \text{ cm}^{-1}$ ) attached to the 3'-terminus. Up to 40 quencher-containing DNA equivalents needed to be added per CdSe@ZnS nanoparticle to quench the fluorescence by 95%. Addition of 0.8  $\mu\text{M}$  complementary DNA or 1  $\mu\text{M}$  thrombin to this solution increased the emission intensity by 15- and 19-fold after 50 min. Based on the greater than 15-fold signal response the LODs should be significantly below the micromolar analyte concentrations reported. This report optimized this response by adopting a superquenched approach used for FRET based detection of maltose using maltose binding protein attached to CdSe@ZnS nanoparticles [73, 74]. Clearly, the slow response time of the thrombin aptamer system, relative to the Au nanoparticle aggregate disassembly, is due to the numerous organic quenchers that need to be removed per CdSe nanoparticle for a measurable response. Again, this work presents a pseudo-

reagentless biosensor based on DNA modified CdSe nanoparticles. Nevertheless, the demonstration of a strategy for using aptamers to control the emission properties of semiconducting nanoparticles is highly significant.

The first demonstration of reagentless biosensing with nanoparticles through analyte-mediated biomolecule changes was reported by Nie and coworkers in 2002 [58]. This method was based on the observation of organic fluorophore adsorption to Au colloid surfaces as detected by fluorescence quenching and surface-enhanced Raman scattering [75, 76]. This design used a single DNA probe strand with a 3'-thiol group and a 5'-fluorescein or 5'-tetramethylrhodamine fluorophore. Upon addition of the probe DNA to the Au nanoparticle, the emission intensity from the organic fluorophore was completely quenched. After adding a four-fold excess (10 nM Au nanoparticle, 30 min incubation time, room temperature, 2–10 mM MgCl<sub>2</sub>) of a complementary DNA strand, the emission intensity of tetramethylrhodamine or fluorescein was completely restored. Addition of single-base mismatch complementary DNA strand under the same conditions caused a 50% restoration of the fluorophore emission intensity. This study went on to carefully examine the complementary DNA strand binding kinetics and DNA–Au nanoparticle thermal stabilities. Up to 5 min (40% overall response), the binding kinetics were consistent with a single exponential binding event. After 5 min multiple phases were observed that slowed the response time. Notably, the response time of this biosensor [58] is similar, if not more rapid, than the thrombin biosensor based on aptamer attached CdSe nanoparticles [61]. Thermal stability studies of the probe DNA–Au nanoparticle conjugate showed minimal increase in emission intensity at higher temperatures as opposed to the analogous molecular beacon in solution. These results suggest substantial non-specific Au nanoparticle–DNA interactions, which were clearly defined by this report. Despite these caveats this report showed, for the first time, that biomolecule conformation could be used to couple ligand binding to nanoparticle-based signal enhancements.

This fluorophore modified DNA–Au nanoparticle methodology has been extended to a fluorescence microscopy detected microfluidic device [62]. Fluorescein and Cy3 were used as the fluorophores in this study and attached to the 5' end of the DNA probe. The 3'-end of the DNA probe contained a thiol functional group that provided Au nanoparticle attachment. Au nanoparticle modified microchannels (50–90 μm) were generated by channel microfabrication followed by introducing 3-aminopropyltriethoxysilane, rinsing, and overnight incubation in Au nanoparticle solutions. The fluorophore-modified DNA probe was introduced to these microfluidic channels for 16 h and repeatedly rinsed. Minimal fluorescence was observed above background fluorescence in these rinsed channels. Fluorescence micrographs before and after complementary DNA addition (60 min incubation time) showed a significant increase in emission intensity for channels with 8 ppm of the complementary DNA. This detector was able to discriminate between DNA from denguevirus and enterovirus. This report demonstrates how a solution-based strategy with the DNA–Au nanoparticle based reagentless biosensor can be translated to a surface immobilized strategy.

Surface plasmon enhanced Raman spectroscopy has also been demonstrated for reagentless biosensing of DNA strands [60]. Plasmonic detection was provided by the use of a single strand of probe DNA with Rhodamine 6G attached to the 5'-end and a thiol on the 3' end. The DNA recognition sequence was flanked with 6-mer complementary sequences on each end to induce stem-loop formation in the absence of analyte DNA. These DNA probes were adsorbed to 50 nm diameter Ag nanoparticles and investigated in by Raman spectroscopy with the 632.8 nm line from a HeNe laser excitation source. In the absence of any additional DNA the SERS enhanced spectrum for Rhodamine was observed. Addition of a four-fold excess of complementary analyte DNA caused an eight-fold decrease in the intensity of the prominent  $1512\text{ cm}^{-1}$  vibration. All of the SERS vibrational bands decrease upon the addition; however, the higher energy and intensity bands provided the best spectroscopic handle for analysis. A sensor for the gene product of the HIV *gag* gene was then constructed. PCR amplified DNA (109 bases) was then added to this plasmonic detection biosensor. Addition of HIV *gag* amplified DNA cause a three- to six-fold decrease in SERS band intensities, while the addition of amplified DNA from human placenta (negative control) only caused a 1.5 to 2.5-fold decrease in SERS band intensities. This method removes the worry of reporter group photobleaching, since, even if photooxidation occurs, most of the SERS vibrational bands will be observed.

##### **Biosensors Based on Protein Conformation Changes**

Energy transfer methods are less prolific in reagentless fluorescence detected protein-based biosensors. The rationale for diminished reagentless energy transfer protein-based biosensors is that the ligand-induced atomic movements in proteins are smaller than in DNA. For an energy transfer methodology to function for a reagentless protein-based biosensor the distance for half-maximal energy transfer ( $R_0$ ) must be similar to the ligand-dependent change in interatomic distance. Frommer and coworkers have shown reagentless energy transfer protein-based biosensors for maltose, ribose, and glutamate [77–79]. These systems use green fluorescent proteins (GFPs) that are engineered to absorb and emit at different visible wavelengths, genetically encoded on the amino- and carboxy-terminus of the sensor protein (Fig. 12.6A). The  $R_0$ s for these GFP chromophore pairs are around 20–25 Å. Fluorophore pairs with  $R_0$ s longer than 30 Å are difficult to use as reagentless protein-based biosensing. In this case, reagentless protein-based biosensing has been achieved by intercalating organic fluorophores into cracks in the protein structure that reversibly opens and closes as ligand-induced conformation changes occur [80]. The intercalation strategy has yielded various reagentless biosensors [3, 81]. Despite the success of these reagentless organic fluorophore modified protein-based biosensors, the susceptibility of organic molecules to photodegradation remains a significant difficulty in fluorescence contrast imaging. Semiconducting nanoparticles, of course, have minimal photodecomposition and have been an at-

**Fig. 12.6.** Strategies for reagentless biosensing based on changes in protein conformation. (A) GFP-CFP protein chimeric strategy, where energy transfer efficiency from enhanced cyan fluorescent protein (green) to enhanced yellow fluorescent protein (orange) is altered as a function of analyte-induced change in protein conformation. (B) Displacement assay of a fluorescence quencher bound (shaded with orange ball) bound to a protein, where analyte binding displaces this quencher and restores emission intensity of the CdSe nanoparticle (green ball). (C) Method where the emission intensity of an

organic fluorophore (orange ball) is altered as a function of analyte binding, where a CdSe nanoparticle (green ball) is used for photon collection via energy transfer. (D) An electron transfer quenching method where a reductant or oxidant (red ball) is placed close to the CdSe nanoparticle (green ball) surface in one conformation to provide electron transfer quenching (text and Fig. 12.7). Because the protein conformation changes upon analyte binding, the distance between the reductant/oxidant and the nanoparticle will be altered and the nanoparticle emission intensity will change.

tractive target to apply similar methodologies, energy transfer or intercalation, for reagentless protein-based biosensing.

To a first approximation, energy transfer can be used for reagentless protein-attached nanoparticle biosensing. Two energy transfer based biosensing methods using maltose binding protein (MBP) have been published [59, 74]. One system used the maltose selective displacement of  $\beta$ -cyclodextran from MBP as a pseudo-

reagentless strategy (Fig. 12.6B) [74]. For this system, fluorophores were attached to a cyclodextran and energy transfer from the CdSe@ZnS nanoparticle to the cyclodextran-modified fluorophore reported the amount of maltose in solution. A 100 nM LOD for maltose was observed with a 0.1 to 10  $\mu\text{M}$  dynamic range. The dynamic range is typical for this type of strategy; however, the LOD is higher than typical due to the use of a competitive displacement strategy. This report did, though, demonstrate the effectiveness of energy transfer to proteins attached to semiconducting nanoparticles. Clearly, with this system, multiple organic fluorophores need to be adsorbed to the nanoparticle surface to substantially alter the nanoparticle emission intensity. A reagentless method based on nanoparticle–organic fluorophore energy transfer has been reported recently [59]. This report showed that CdSe@ZnS nanoparticles could function as high photon cross-section antenna. Because energy transfer directly couples the nanoparticle emission intensity to the organic fluorophore emission and absorbance properties, the interaction between the organic fluorophore (Cy3) and MBP actually mediated the changes in overall emission intensity (Fig. 12.6C). The linkage between Cy3-modified 41C MBP and emission intensity is similar to that demonstrated by previous studies [82–84]. In the end, maltose binding mediated a “turn off” signal and is still inherently linked to the relatively fast photodecomposition of organic fluorophores. Therefore, an alternative to energy transfer needs to be used for reagentless protein–nanoparticle based biosensing to take full advantage of the photonic properties of semiconducting nanoparticles.

Electron transfer quenching provides a route to reagentless protein–nanoparticle based biosensing that maintains the high photostability of the semiconducting nanoparticle. Electron transfer quenching involves an electron transfer to or from the excited state of a fluorophore followed by a back electron transfer to form the ground state to non-radiatively relax the fluorophore excited state [70]. Two proof-of-principle articles have been published for electron transfer quenching with a  $\text{Ru}^{\text{II}}$  complex modified MBP that was attached to either CdSe [63] or CdSe@ZnS nanoparticles [64]. In this system, the  $\text{Ru}^{\text{II}}$  complex reduces the valence band hole of the CdSe core, while the resulting  $\text{Ru}^{\text{III}}$  complex oxidizes the electron that remains in the conduction band of the *n*-type CdSe nanoparticle core (Fig. 12.7). When the cyclic nature of this reaction scheme is maintained, minimal photodegradation of this material occurs. This electron transfer quenching method has an exponential dependence [85] with respect to the distance between the  $\text{Ru}^{\text{II}}$  complex and the surface of the CdSe nanoparticle core. Energy transfer distance dependence varies as a function of  $R_0^6/(R_0 + r)^6$ , where  $R_0$  is the distance at which half maximal energy transfer occurs [70]. However, the  $r = 0$  point for energy transfer is at the center of the CdSe nanoparticle core [73, 74, 86] while the core–shell interface is the  $r = 0$  point for electron transfer. Based on the  $R_0$ s for energy transfer from core–shell CdSe nanoparticle donors to organic fluorophore acceptors (40–70 Å) [73, 86–88], energy transfer should have a shallow distance dependence relative to electron transfer quenching.

Benson and coworkers have shown electron transfer quenching provides a solution to reagentless small molecule biosensor design using protein–semiconducting

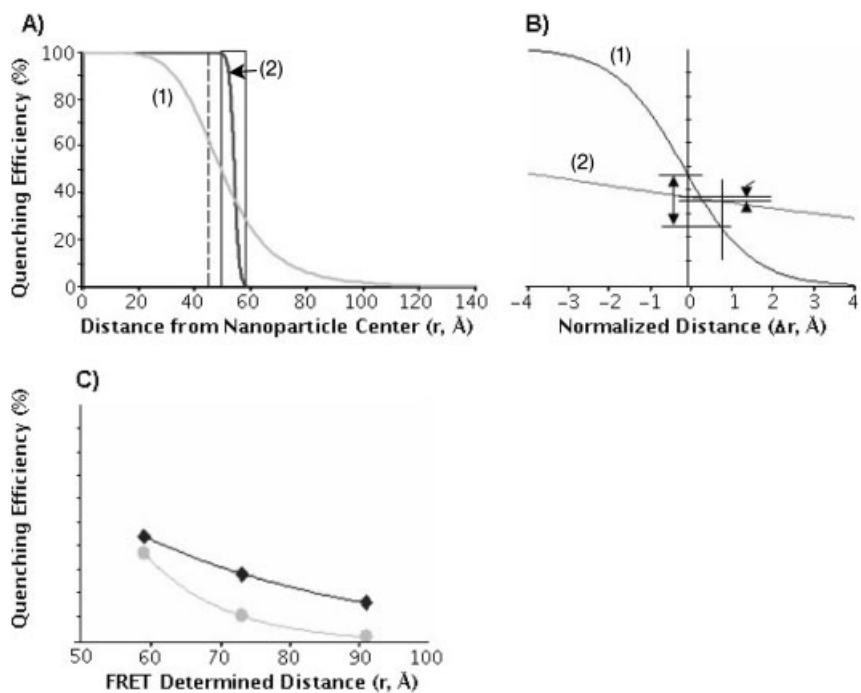

**Fig. 12.7.** Electron transfer quenching methodology. A nanoparticle ground state (CdSe) and a reductant (Red.) are placed close together. Upon photoexcitation ( $h\nu$ ) the CdSe excited state is formed with an electron in the conduction band (upper molecular orbital) and a hole in the valence band (lower molecular orbital). For a close association of the reductant with the CdSe surface, electron (charge) transport can occur from the

reductant to the valence band hole. The charge-separated state that forms ( $\text{CdSe}^-$  and oxidized reductant, Ox.) is non-emissive. The electron in the conduction band of the CdSe core will then reduce the oxidized reductant to reform the ground state. As long as the first electron transfer rate ( $k_{\text{forward}}$ ) is faster than the fluorescence emission rate ( $k_{\text{fluor.}}$ ) the nanoparticle emission intensity will be diminished and the lifetime will be decreased.

nanoparticle assemblies (Fig. 12.6D) [63, 64, 67]. This work relies on the generation of a 1:1 complex between a  $\text{Ru}^{\text{II}}$  complex modified protein and a semiconducting nanoparticle. Such a complex has been obtained through the use of kinetically stable mercaptohexadecanoate capping groups [67], as opposed to the dihydrolipoic acid capping groups used by Medintz, Mattoussi, and coworkers to facilitate multiple proteins attached per semiconducting nanoparticle [74]. Four MBPs with different surface Cys attachment sites were surveyed. When the  $\text{Ru}^{\text{II}}$ -modified MBP was bound to either CdSe or CdSe@ZnS nanoparticles that emitted at 560–570 nm, the emission intensities decreased from 1.5 to 2.3-fold [63] and 1.2 to 1.8-fold [64]. Upon maltose addition to the  $\text{Ru}^{\text{II}}$  modified MBP attached to CdSe or CdSe@ZnS nanoparticles, the emission intensity increased by 1.39 to 1.45-fold [63] or 1.13 to 1.42-fold [64]. Recently, our laboratory has confirmed that maltose-dependent changes in CdSe emission intensities correlate with changes in CdSe emission lifetimes [89] and Faradaic electrochemical currents observed for these proteins adsorbed to Au working electrodes [90]. Maltose titrations yielded dissociation constants ranging from 0.20 to 0.75  $\mu\text{M}$  (LOD 1 to 5 nm) and 0.25 to 1.00  $\mu\text{M}$  (LOD 5 to 10 nm) for the CdSe and CdSe@ZnS nanoparticle systems. The similarity of these dissociation constants to the maltose dissociation constant for MBP in solution ( $K_{\text{D}} \sim 0.70 \mu\text{M}$ ) suggests the function of MBP has not been altered by nanoparticle attachment. This is in direct contrast to the 200 to 800  $\mu\text{M}$  dissociation constants reported for the Cy3-modified 41C MBP attached CdSe@ZnS nanoparticle biosensors [59] and the 0.8 to 8.0  $\mu\text{M}$  dissociation constant determined for the fluorophore modified cyclodextran-MBP-CdSe@ZnS nanoparticle system [74]. The only nanoparticle-based perturbation seen for the  $\text{Ru}^{\text{II}}$  complex labeled systems is in the variation of the sample-to-sample dissociation constant reproducibility [63]. For MBPs that placed the  $\text{Ru}^{\text{II}}$  complex closer to the nanoparticle surface, predicted by quenching efficiency, a higher variation in the dissociation constants was observed. This suggested the  $\text{Ru}^{\text{II}}$  complex might be kinetically trapped in the hydrophobic layer surrounding the nanoparticle, which is formed by the fifteen

methylenes of the capping ligand. However, electron transfer is still observed for MBPs with the  $\text{Ru}^{\text{II}}$  complex placed away from the nanoparticle surface [63, 64]. Using K46C and K25C MBP, where the  $\text{Ru}^{\text{II}}$  complex was away from the nanoparticle surface, these MBP-CdSe@ZnS nanoparticle biosensors were shown to be selective for maltose in a ten-sugar test panel and reversibly detect maltose in an increasing glucose background [64]. Taken together, the use of electron transfer quenching provides reagentless biosensing that modulates nanoparticle emission intensity using protein–semiconducting nanoparticle assemblies.

The distance dependent changes in electron transfer and energy transfer quenching efficiencies, based on reported data, are compared relatively in Fig. 12.8. As stated above, the delocalized hole–electron pair (exciton) density in core–

**Fig. 12.8.** Comparison of energy and electron transfer quenching efficiencies in maltose binding protein based biosensors. (A) Overall comparison of energy transfer distance dependence of quenching efficiency (line 1) and electron transfer quenching efficiency (line 2). The dotted line approximates the nanoparticle radius reported by Medintz and coworkers [86]. The range of the energy transfer based distance was calculated from assuming activation-less electron transfer. The area within the box (50–58 Å) is shown in panel B. (B) The region for nanoparticle

distance determined for N282C (line 1,  $r = 0$ ) and D80C (line 2,  $r = 0$ ). Using the change in quenching efficiency for the electron transfer method [64], the expected FRET dependent change was calculated to be one tenth of the measured electron transfer change. (C) Quenching efficiency (electron transfer method [64], diamonds; energy transfer method [86], circles) for three structurally related attachment positions on MBP [64, 86] as a function of the FRET determined distances from the nanoparticle core [86].

shell nanoparticles creates different starting points for distance determinations by energy and electron transfer. Since the average emitted photon density comes from the center of the nanoparticle core the nanoparticle centroid is considered  $r = 0$   $R_o$ . Since exciton delocalization occurs significantly faster than nanoparticle emission, the closest approach for electron transfer is the nanoparticle core–shell interface and functions as the  $r = 0$  for electron transfer. Energy transfer-determined distances have been reported for CdSe@ZnS nanoparticle–Cy3 fluorophore pairs using the derived  $R_o$  of  $53 \pm 3 \text{ \AA}$  [86]. Using this radius the Cy3 quenching efficiencies of 530-nm emitting CdSe@ZnS nanoparticles (2% to 37%) yielded RET-determined distances of 59 to 95  $\text{\AA}$  for six different surface Cys attachment points for Cy3 [86]. The orientation of MBP, in the absence of maltose, on the nanoparticle surface was derived to have both domains interacting with the nanoparticle surface and the maltose binding site pointing away from the nanoparticle surface. For the Ru<sup>II</sup> complex modified MBP system, quenching efficiencies of 16% to 44% were obtained for CdSe@ZnS nanoparticle emission [64]. A rough comparison between these two published systems is presented in Fig. 12.8, where the RET determined distances of structurally related surface Cys attachment sites are compared.

Clearly, all three structurally related surface Cys attachment sites show the Ru<sup>II</sup> complex with a higher quenching efficiency than Cy3. Furthermore, maltose addition decreases the Ru<sup>II</sup> complex quenching efficiencies (–9% to –22%) [64], while no maltose dependent change in Cy3 mediated nanoparticle quenching efficiency has been reported. The differences in maltose-dependent quenching are no surprise based on the distance dependences of electron transfer and energy transfer discussed above. Figure 12.8(B) illustrates for the 282C/80C attachment site the comparison of these scaling rules, where energy transfer has a shallower distance dependence. Additionally, maltose dependent changes in quenching efficiencies for the electron transfer method are consistent with changes in the CdSe core fluorescence lifetimes [89]. However, the surprise in the Ru<sup>II</sup> complex mediated CdSe@ZnS nanoparticle quenching is the shallow distance dependence with respect to RET-derived surface Cys distance to the nanoparticle centroid (Fig. 12.8C). From a technological standpoint the shallow distance dependence of Ru<sup>II</sup> complex mediated quenching efficiencies abrogates [63] the need for Cys scanning mutagenesis methods as with organic fluorophore-MBP based biosensors [3, 81]. From a mechanistic standpoint, the Ru<sup>II</sup> complex based quenching distance dependence might be more similar to protein–protein electron transfer as opposed to intraprotein electron transfer. Beratan and coworkers [91, 92] have recently found constructive interference from structural waters in electron transfer pathways provide very shallow distance dependences in electron transfer. Interestingly, the electron transfer distances calculated ruthenated MBP-CdSe@ZnS systems (8.0 to 9.5  $\text{\AA}$ ) are similar to the distances for the cyt.  $b_5$ –cyt.  $c$  study [92]. In the end, the Ru<sup>II</sup> complex [63, 64] provides reagentless biosensing that modulates the emission intensity of semiconducting nanoparticles in a ligand dependent fashion.

Clearly, from these examples, the scaling laws of the nanoparticle and the reporter group need to be carefully considered for reagentless biosensor construction. The biomolecular conformation change strategy clearly demonstrates this

point. Nucleic acid–nanoparticle based biosensors can provide reagentless biosensors more readily using conformation change, in that the conformation change is typically greater than 10 Å. By moving a reporter group greater than 10 Å a substantial change in energy transfer and surface-enhanced Raman can be expected. Protein–nanoparticle based biosensors require more careful consideration of scaling rules since reporter groups typically are moved by 1–6 Å. Electron transfer quenching takes advantage of a less efficient methodology than energy transfer to provide a higher sensitivity to conformational motion. This is not to say that electron transfer quenching is the only solution to protein–nanoparticle based reagentless biosensing, but that it provides a scaling law that appropriately couples analyte-induced protein conformation motions into changes in the nanoparticle electronic structure.

## 12.5

### Conclusion

The three general concepts outlined here provide reagentless biosensors from biomolecules attached to nanoparticles. As demonstrated by the literature cited in this chapter, these reagentless concepts provide sensors that can be adapted to various detection platforms. More importantly, the instrumentation used for biosensing is relatively inexpensive and modular. Extension of these systems to multiplexed or array assays has been reported and should be able to be extended for various other systems. The idea that the biomolecule provides the analyte sensitivity and selectivity is at the heart of the modular detection strategies. As outlined in this volume and this series, nanoparticles provide unique properties that can be detected by various analytical techniques. The translation between analyte–biomolecule binding and changes in nanoparticle properties requires the selection of a reporting methodology (e.g., FRET, SERRS,  $T_2$  relaxation, electron transfer quenching) with an appropriate scaling law. The high surface area of nanoparticles provides a high sensitivity method to measure changes in local solvent dielectric. Biomolecule attachment to nanoparticle surfaces allows substrates for these biomolecules to alter the local solvent dielectric and properties such as localized surface plasmon absorption and electrical conductivity. Metallic and semiconducting nanoparticles can also be used as electron/hole buffers to increase electrochemical communication between enzymes and working electrodes. This strategy has allowed multimolecular bioelectrochemical sensors to be transformed into reagentless bioelectrochemical sensors. Energy transfer methods are the most popular method for coupling biomolecule and nanoparticle properties by energy transfer from organic fluorophores to metallic nanoparticles, semiconducting nanoparticles to organic fluorophores, or semiconducting nanoparticles to metallic nanoparticles. While energy transfer scaling laws facilitate enzymatic cleavage biosensors and nucleic acid–nanoparticle based biosensors, protein–nanoparticle biosensors require a coupling method with a more sensitive distance dependence. While reagentless protein–nanoparticle based biosensors that use energy transfer have been reported [59], this method

monitors differences in the emission intensity of the organic fluorophore. Electron transfer quenching provides a method to effectively couple changes in protein conformation into changes in nanoparticle emission intensity [63, 64]. Magnetic force and  $T_2$  magnetic relaxation methods, along with nanoparticle surface energy transfer [93, 94], have a much shallower distance dependence that could be used for reagentless biosensor development with enzymatic cleavage (pseudo-reagentless) or nucleic acid conformation changes. Another advantage of using nanoparticles is the advent of hybrid detection schemes, such as endonuclease detection by magnetic force measurements [53, 54], electrochemical surface plasmon resonance [20] and photoelectrochemical detection [21]. Such hybrid detection strategies provide signal selectivity on top of the analyte selectivity provided by the biomolecule. Such selectivity provides additional confidence necessary for device approval and commercialization. Finally, the development of nanoparticle based biosensors that are reagentless and reversible is an exciting frontier that requires a material, biomolecular, and molecular viewpoint that is producing sophisticated biosensors with inexpensive instrumentation.

# Pico/Nanoliter Chamber Array Chips for Single-cell, DNA and Protein Analyses

*Shohei Yamamura, Ramachandra Rao Sathuluri, and Eiichi Tamiya*

### 13.1

#### Introduction

In recent years, miniaturized systems called Lab-on-a-chip or Micro-Total Analysis System ( $\mu$ -TAS) have been examined as new systems for biochemical analyses. These systems are expected to perform DNA, protein and cell analysis for drug screening and development of novel therapies. Especially, microarray and microfluidic types of chip devices have been developed using micro- and nanotechnological techniques. These lab-on-a-chip systems can be used for high-throughput identification of large numbers of potential drug targets, e.g., DNA, protein, chemicals [1, 2]. Recent advances in the human genome project have prompted the use of the miniaturized chip devices for high-throughput analysis of the vast amount of information potentially available. To obtain as much information as possible in a short time with a minimal use of reagents, researchers require highly integrated and sophisticated devices, such as microarrays. Thus, microarrays suitable for different biomaterial assay and detection technologies have been under intense investigation [1, 2]. Microarrays have been mostly applied to the assessment of the presence of a specific base sequence, or which genes are expressed and at what level [3, 4]. They have also been employed in identification of peptides and proteins as pharmaceutical drugs [5, 6]. Although the number of human genes was reported to be approximately 30 000 from the human genomic project, the functions and expression mechanism for most of the genes remain unknown, because the fate of the genes functionality is determined after protein expression, but proteins expression is controlled by cellular function. Therefore, it is necessary to develop the microarray chip devices that can perform high-throughput screening and analysis of proteins and cells at single-cell and single-molecule level.

To achieve single-cell or single-molecule analysis, highly integrated microarray systems that can perform assays at pico- and nano-liter volume level are greatly desirable to realize post-genomic research, such as proteomics and cellomics. Single-cell analysis contributes to elucidate the functional mechanism of genes, proteins and chemical responses, which lead to clinical diagnosis and drug discovery [7]. In

recent work, some researchers reported cellular microarrays using biomaterial spotting techniques for investigating gene expression or differentiation of some kinds of cells [8, 9]. These systems can screen and detect a group of cells but not single-cell based assay from bulk cell suspension, because they have a great possibility of cross-contamination with neighboring cells due to the absence of a physical boundary. Therefore, it is necessary to construct a microarray system that can perform high-throughput analysis of single-molecule or single-cell and quantitative detection.

However, there are no reports available, to the best of our knowledge, that describe high-throughput analysis of DNA, protein and cell at single-molecule and single-cell level together at one place. Therefore, we address the analysis of DNA, protein and cell using pico- or nano-liter chamber array system in this chapter. This chapter is divided into three topics: novel multiplexed PCR, cell-free protein synthesis, and high-throughput single-cell analysis system [10–13]. The chapter ends with a look at future prospects.

## 13.2

### **Multiplexed Polymerase Chain Reaction from A Single Copy DNA using Nanoliter-volume Microchamber Array**

Polymerase chain reaction (PCR)-based techniques have become the most important part of DNA diagnostic laboratories since its first introduction in 1985 [14]. The discovery of this technology has earned its inventor, K. B. Mullis, a Nobel prize for his achievement [15], which has opened up new horizons for a limitless number of DNA-based research possibilities. Since then, qualitative PCR has been a well-established and straightforward technology, but the quantification of specific target DNA sequences in a complex sample has been a difficult task. Several variations, caused by the manipulation of nucleic acids that may occur during sample preparation, storage, or the course of the reaction hampered accurate quantification. The exponential nature of the PCR amplification can significantly magnify even minor variations in reaction conditions. Normalizing the amount of PCR products of the specific template with respect to an internal reference template has been partly successful against these variations. Since the challenge of accurate DNA quantification stimulated many researchers, a great variety of protocols already exist for the utility of quantitative PCR [16–18]. However, these methods are nearly exclusively restricted to be applied for research purposes only because of two factors they have in common: they are difficult tasks and are costly to run.

To supply the demand for faster, more accurate, and more cost-effective PCR devices with a high-throughput capacity, three important properties have directed the development of the next generation of PCR systems: automation, standardization, and miniaturization. Recently, Yang et al. have reported a high-sensitivity PCR assay in polycarbonate plastic, disposable PCR microreactors [19]. At a template concentration as low as 10 *Escherichia coli* cells (equivalent to 50 fg of genomic DNA),

221-bp product was successfully amplified within 30 min. Lee et al. [20] have described a microfabricated PCR device for simultaneous DNA amplification and electrochemical detection on gold or indium tin oxide (ITO) electrodes patterned on a glass substrate. A miniaturized flow-through PCR with different template types in a silicon chip thermocycler has also been reported to have a minimum power consumption [21]. With the flow-through PCR device of Fukuba et al. [22], 580 and 1450 bp of DNA fragments were successfully amplified from *E. coli* genomic DNA and directly from untreated cells. For temperature control of their chip, six heaters made of ITO were placed on a glass substrate to act as three uniform temperature zones. Lee et al. [23] have recently reported a bulk-micromachined PCR chip. They validated that the proposed chip amplified the DNA related to the tumor suppressor gene BRCA 1 (127 bp at 11th exon) after 30 thermal cycles in a 200-nL-volume chamber. Although most of the recent assays are accurate and sensitive, they involve the definition of very stringent limits. The PCR products are usually separated by gel electrophoresis, and the band intensities are quantified by video imaging and densitometry. Additionally, Lagally et al. [24, 25] have shown that microfluidic systems are capable of multiplexed PCR reactions and robust on-chip detection.

Microchamber arrays etched on silicon or glass have also been one of the most reported miniaturized devices for multiple simultaneous DNA amplification [26–28]. The minimum reported size for a microchamber for PCR was demonstrated by Leamon et al. in connection with PCR [29]. They reported a novel platform, namely PicoTiterPlate™, which enabled simultaneous amplification of 300 000 discrete PCR reactions in volumes as small as 39.5 pL. Following the PCR on the PicoTiterPlate™, the solution from each well was recovered, and then quantified by TaqMan assay. As for the easy integration with different applications, solid-phase amplification was also performed on PicoTiterPlate™ by immobilizing the PCR product to a DNA capture bead in each well. Thus, 370 000 beads bound with PCR product were obtained for parallel processing in numerous solid-phase applications. The volume of a microchamber for a successful PCR amplification was reduced to 86 pL by Nagai et al. [26]. However, as the sample volume was decreased, evaporation of sample solution and the introduction method of quite a small amount of solution into the reaction microchamber appeared as the major drawbacks.

In our research, for achieving simultaneous detection of several numbers of target DNA, the feasibility of our microchamber array was further improved by using TaqMan PCR [11, 12]. To the best of our knowledge, three different DNA sequences were amplified from three different DNA templates and detected in the same microchamber array simultaneously for the first time. In addition, the quantification of initial DNA concentration present in a microchamber was achieved from 0 to 12 copies per chamber, not only by monitoring the real-time fluorescence intensity but also by observing the end point fluorescence signal. Therefore, this system proves to be a promising device for the low-cost, high-throughput DNA amplification and detection for point-of-care clinical diagnosis, which can also be handled by non-specialist users.

## 13.2.1

**PCR Microchamber Array Chip System****13.2.1.1 Microchamber Array Chip Fabrication**

The microchamber array chip for DNA amplification was fabricated using micro-machining techniques, including photolithography, and anisotropic wet etching on the optically polished side of a silicon (100) wafer. The chip substrate was designed to be  $2.54 \times 7.62$  cm for compatibility with the dispensing system employed. Figure 13.1 shows the fabrication procedure, giving detailed schematic steps of the silicon chamber array chip.

Before proceeding to microfabrication, the silicon wafer was washed thoroughly with acetone and then immersed in a 60% (v/v) hydrogen fluoride solution and, finally, allowed to dry at room temperature. Subsequently, the silicon wafer surface was oxidized to silicon oxide ( $\text{SiO}_2$ ) by wet thermal oxidation at  $1000^\circ\text{C}$  for 8 h. A photo mask with 1248 chambers having a  $24 \times 52$  pattern was then printed on the surface, after being coated with a positive photoresist (OFPR-800) layer, by a photolithographic process. Soaking the chip substrate in a NMD-3 solution for 5 min removes the light exposed OFPR portions and, followed by treatment with  $\text{HF}/\text{NH}_4\text{F}$  (v/v) 10:60 volumes solution, removed the exposed oxide layer and then remaining portions of photoresist by treating with acetone. The chip substrate was then anisotropically etched with 25% (w/v) tetramethylammonium hydroxide (TMAH) in an aqueous solution to a depth of  $250\ \mu\text{m}$  for 8 h at  $80^\circ\text{C}$ . A layer of  $\text{SiO}_2$  was grown on the surfaces, including the etched chamber walls and then OFPR-800 was spin coated and further photolithography was performed to leave the  $\text{SiO}_2$  layer inside the microchamber walls. The oxidized layer and photoresist were removed by using  $\text{HF}/\text{NH}_4\text{F}$  (v/v) 10:60 volumes of solution and acetone, respectively. The microchamber feature was observed by a color laser 3D profile microscope VK-8500

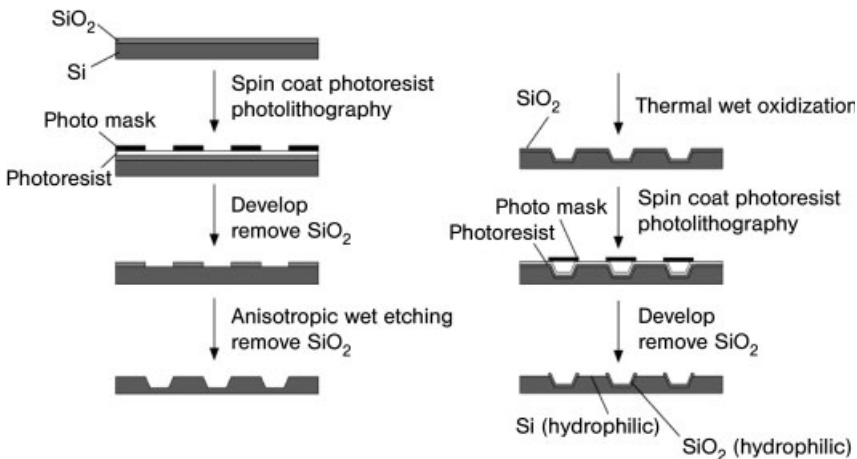

Fig. 13.1. Schematic illustration of microchamber array fabrication procedures.

**Fig. 13.2.** (A) Photographic image of the microchamber array chip. The 1248 microchambers are integrated on the  $1 \times 3$  inch. of a silicon chip. (B) Scanning electron micrograph (SEM) of a silicon microchamber array.

(KEYENCE, Japan) and scanning electron microscope (HITACHI, Japan). Each chamber was parallelepiped with dimensions of  $650 \times 650 \times 200 \mu\text{m}$ , a pitch of each microchamber of  $\sim 900 \mu\text{m}$ , and accommodates 50 nL (Fig. 13.2). The total number of chambers on each chip is of 1248. To achieve precise introduction of sample mixture into the microchamber, only the inner wall surfaces of the microchamber were prepared as hydrophilic by leaving an oxidized layer on them by photolithographic techniques, as described recently by Felbel et al. [30].

#### 13.2.1.2 Sample Loading with a Nanoliter Dispenser

The microchamber array chip was soaked in 1% (w/v) bovine serum albumin (BSA) solution overnight, then rinsed with deionized water, and dried to prevent nonspecific adsorption by coating the chamber wall. The chip was placed onto the dispensing stage of a nanoliter dispenser from Cartesian Technologies. The precise dispensing of nanoliter volumes of solutions exactly at previously determined locations had become very simple by using their technology. The volume of dispensed solution in a single microchamber was 40 nL. Mineral oil as a cover lid was coated onto the template DNA-modified chip, and 40 nL of PCR mixture, which included target-specific primers and probe, was dispensed into all of the microchambers

**Fig. 13.3.** Illustration of preparation steps for on-chip DNA amplification: (a) Different types of primers are dispensed into the microchamber and then dried. (b) Mineral oil is coated on the chip after the primer solution

has dried. (c) A PCR mixture (40 nL) with no primers is dispensed in each chamber through the oil layer. The solution sinks to the bottom and then spreads to the microchamber walls.

through the oil layer. After preparing this setup, the chip was placed onto a conventional thermal cycling system to achieve PCR reaction. Thermal cycling was initiated at 94 °C and held for 10 min, followed by 40 cycles of 94 °C for 10 s and 60 °C for 60 s. After the end of PCR amplification, the amplified DNA was observed using a charge-coupled device (CCD) camera (Hamamatsu Photonics, Japan) mounted on a fluorescence microscope (Leica, Heidelberg, Germany). The inner walls of the microchamber were rendered hydrophilic with the formation of an oxidized layer on their surfaces. After coating the microchamber array with mineral oil, the remaining hydrophobic surface of the microchamber prevented the spread of the aqueous solution to the outside of the microchamber. After dispensing of the aqueous sample solution, it first formed a droplet, which in time was replaced with the oil in the microchamber, and settled inside the microchamber with the convection of the oil (Fig. 13.3). The thickness of the oil layer had a significant effect on the protection of nanoliter-scale solutions from evaporation. The oil layer was adjusted by controlling the volume of the oil drop. As the thickness of the oil layer increased, the dispensing of the sample solution became more erroneous (data not shown). The optimum thickness of the oil layer for introduction of the sample mixture was chosen to be ~200  $\mu\text{m}$ .

### 13.2.2

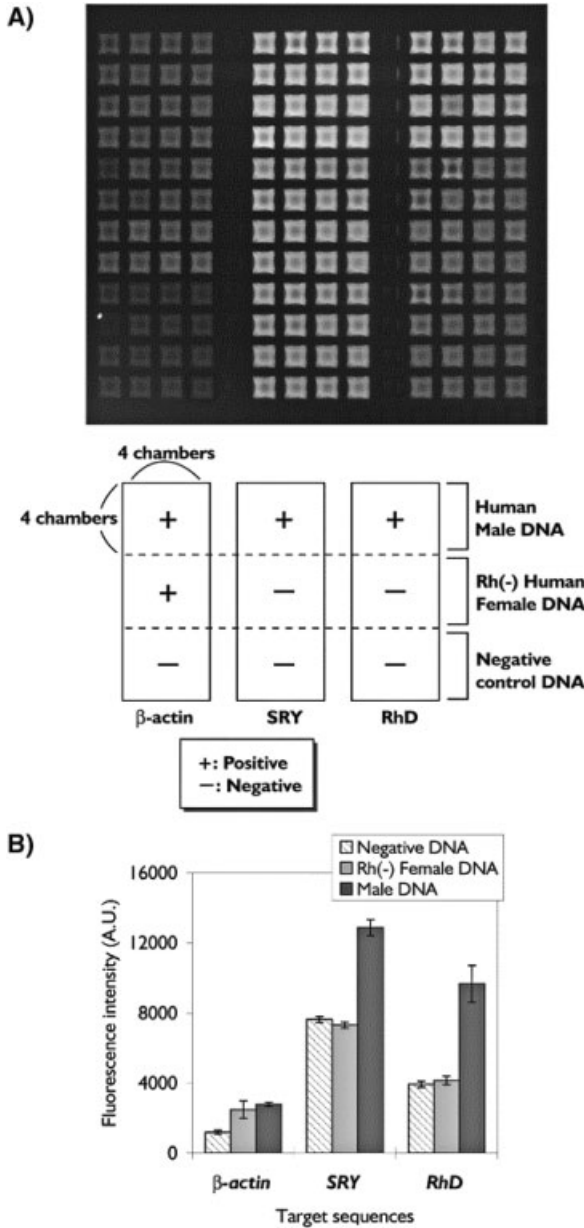

#### Multiplexed Detection of Different Target DNA on a Single Chip

Target DNA sequence was amplified specifically in a nanoliter-volume microchamber, and the microchambers, in which fluorescence signal was released, were counted in consequence to TaqMan PCR. Cross-contamination between chambers was tested by using alternate dispensings of wells containing template and those without template. A high concentration of the template DNA was introduced as alternate dispensings into the microchambers. Fluorescence signals were obtained only from the chambers, into which template DNA was introduced. No fluores-

cence was gained from the remaining chambers, into which no template DNA was dispensed. Thus, it was concluded that the selective distribution of the template DNA into the microchambers was achieved in our system.

There were several inhibition factors, such as nonspecific adhesion of biomaterials, variety in the distribution efficiency of the sample dispensing, and errors caused by PCR itself. Surface treatment of the microchamber was also an important factor affecting the efficiency of the PCR reaction. Shoffner et al. have reported several kinds of surface treatment methods that are useful for avoiding the adsorption of biomaterials on the silicon surface [31]. Erill et al. have reported a systematic analysis of material-related inhibition and adsorption phenomena in glass-silicon PCR chips [32]. Their results suggested that the previously reported inhibition of PCR by silicon-related materials was caused mainly by the adsorption of Taq polymerase at the walls of the chip due to increased surface-to-volume ratios; thus, direct chemical action of silicon-related materials on the PCR mixture was negligible. In contrast to Taq polymerase, DNA was not adsorbed in significant amounts. The net effect of polymerase adsorption could be prevented by the addition of a titrated amount of a competing protein, BSA, and the ensuing reactions could be kinetically optimized to yield efficient PCR amplifications. In our system, we combined these advantageous points of previous reports. The surface of the microchamber walls was first modified by an oxidized layer [30, 31] and then coated with BSA [32]. Only a very low fluorescence signal could be observed, when no BSA coating was employed. Thus, it was found necessary to coat the oxidized walls of the microchambers with BSA, in good agreement with the findings of Erill et al. [32]. To quantify DNA concentration, a certain number of microchambers were used as one region for only one concentration.

Figure 13.4 shows the fluorescence image of the chip after DNA amplification of three different target DNA sequences from three different DNA templates. Visual comparison of the positive fluorescence intensity signals with the negative ones greatly simplified the procedure of distinguishing which chamber contained the target DNA. If the target DNA sequence was present in the dispensed sample, a high fluorescence signal was easily obtained as a result of TaqMan PCR. Additionally, the background fluorescence intensity of the  $\beta$ -actin PCR system was much lower than that of the other two probes by using both our chip and the SmartCycler real-time PCR system (Fig. 13.4B). SmartCycler real-time PCR system results were in good agreement with the results of our chip. The difference in the background fluorescence intensity was caused by the bp distance between FAM and TAMRA dyes of the TaqMan probes. In the TaqMan probe for  $\beta$ -actin gene, FAM was only 6 bp away from TAMRA, but FAM and TAMRA were 26 and 31 bp apart in the probes for SRY and RhD genes, respectively. Such a short distance of 6 bp between the dyes caused the rapid quenching of the signal, and thus, the  $\beta$ -actin system could release much lower fluorescence signals after amplification in comparison with the other systems. Although the PCR systems in this experiment had such different background fluorescence intensities, accurate detection of TaqMan amplification for all systems was achieved by using our chip. Since Rh(-) human female genomic DNA did not contain SRY and RhD genes, almost none

**Fig. 13.4.** Multiple PCR analysis of  $\beta$ -actin, SRY, and RhD genes using three different kinds of template DNA.

(A) Photograph of the microchamber array after multiple TaqMan PCR. (B) Average fluorescence intensity values obtained from 16 microchambers.

of the microchambers showed a fluorescence signal. Both human male and female genomic DNA contained the  $\beta$ -actin gene; thus, a fluorescence signal could be observed successfully in all microchambers of the related area on the chip. The fluorescence intensity of the microchambers was also scanned and evaluated using a DNA microarray scanner and its analysis system. The fluorescence intensity values were obtained from 16 chambers. A remarkable difference between the fluorescence intensities of the positive and negative controls was observed clearly for all three DNA templates. This result indicated that our system can detect different kinds of target DNA sequences from different DNA sources simultaneously. Since TaqMan PCR required the same thermal cycling protocol for the amplification of many kinds of target sequences, it was found to be the most suitable detection technique for microchamber array PCR systems in this report. For example, the detection of genetic diseases such as Down's syndrome [33], 22q11.2 deletion syndrome [34], and  $\beta$ -thalassaemia [35] using TaqMan PCR has already been reported. These clinically important diseases can also be detected simultaneously using our microchamber array-based PCR chip.

### 13.2.3

#### **On-chip Quantification of Amplified DNA**

The initial RhD gene concentration was also quantified by using the microchamber array (Fig. 13.5A). Amplification of the RhD gene was performed by dispensing different concentrations of target DNA into the microchambers. As target DNA was increased from 0 to 12 copies per chamber, the number of the microchambers with positive fluorescence signal also increased. PCR amplification in almost the whole block of the chip was achieved by using eight copies of the target DNA. When 0.4 copies of the target DNA were used, an average of 2 out of 60 chambers ( $n = 3$ ) showed a signal above the threshold level. The average fluorescence intensity value of 1000 AU was determined as the threshold. The high fluorescence released in these two chambers could also be visually detected. Since 0.4 copies of the target DNA were enough to give a readable signal, this concentration was determined as our limit-of-detection. The chambers with positive fluorescence signals, which mean successful PCR amplification, showed easily distinguishable fluorescence intensity (Fig. 13.5A).

Figure 13.5(B) plots the number of chambers with positive fluorescence signal versus input template DNA copy number for the amplification of RhD (B) sequence. As target DNA increased from 0 to 12 copies/chamber, the number of microchambers with a positive fluorescence signal also increased. It was possible to fit the data from 0 to 8 copies/chamber into a straight line with the regression coefficients of 0.9879 for RhD sequence. The system reached a saturation plateau after DNA concentration of 8 copies/chamber, indicating that a trace amount of target DNA was satisfactory for the detection process. PCR amplification in almost the whole block of the chip was achieved by using eight copies of the target DNA. Such a behavior indicated the high detection capacity of our system, so that even a trace amount of DNA copies would be satisfactory for a precise quantification.

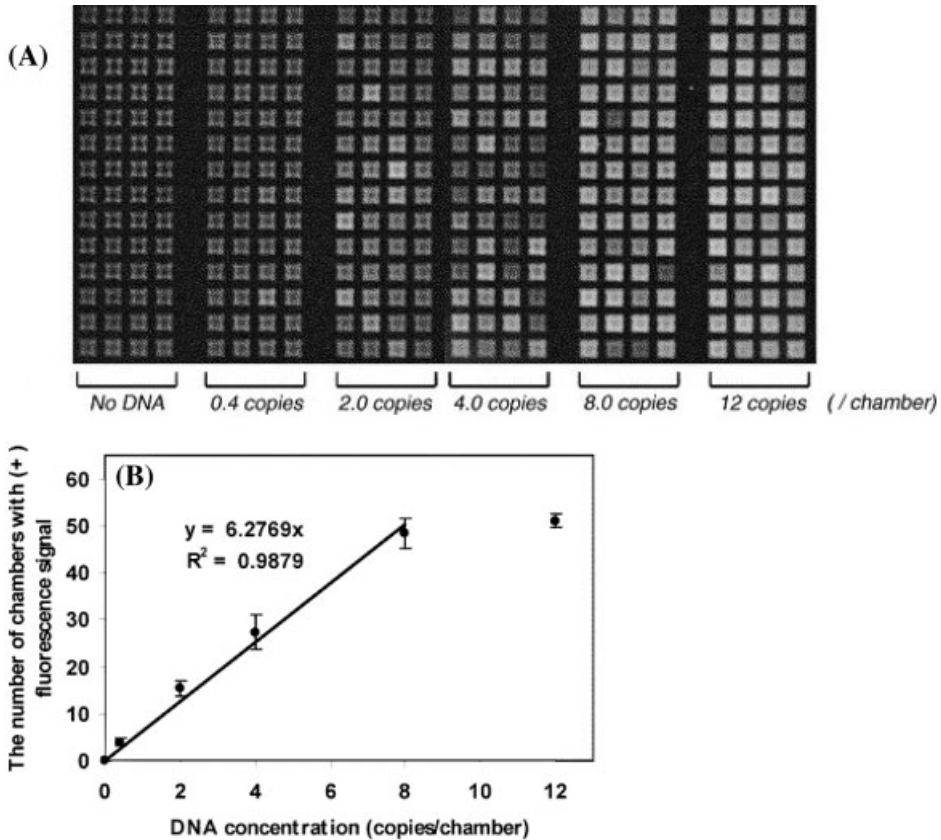

Fig. 13.5. (A) Photograph of fluorescence image for on-chip quantitative analysis of RhD gene. (B) Plot for the average number of chambers within a specific fluorescence signal range versus the number of target DNA copies related to RhD gene after TaqMan PCR.

Copy numbers above eight that would be amplified without any problems but, however, could not be quantified. Even 0.4 copies of the target DNA was enough to give a readable signal, which was determined as our limit of detection. The average fluorescence intensity value of 1000 AU was determined as the threshold. When 0.4 copies were dispensed, only two microchambers reached within the 1000–1200 AU level. One would have expected to get 4 out of 10 microchambers to be positive and 6 to be negative, if we had an average of 0.4 copies/microchamber, and every copy was intact. The polymerase concentration, annealing temperature,  $MgCl_2$  concentration, and the specific primers and TaqMan probes should have been kept under the optimum conditions in 40-nL volumes in the microchamber – a tedious task. Instrumental limitations also added to the inefficiency of PCR, when such a small volume containing such a trace amount of an-

alyte was dispensed on a microchamber array. Thus, the combined negative effects of biochemical (resulting from the TaqMan PCR itself) and instrumental limitations caused the appearance of only two microchambers out of 60 with positive signals after TaqMan PCR on our system. Our method requires only counting the microchambers that show a positive fluorescence signal as a consequence of PCR amplification. No special equipment for the detection of real-time fluorescence intensity is required for determination of DNA copy numbers. Only a simple fluorescence microscope, or a transilluminator used for gel electrophoresis, need be employed for accurate observation of the fluorescence released microchambers with positive signals.

The microchamber array chip presented could be used to amplify multiple DNA targets in combination with a nanoliter dispenser. Theoretically, the chip could be used to amplify and detect ~1200 target DNA simultaneously. The size and total number of the microchambers are determined by the dispensing system. The minimum solution volume that could be dispensed with reliability was optimized as 40 nL for our experiments. If the dispensing instrument could be improved to provide the dispensation of a lesser volume of solution, the microchamber size could become smaller, and the chip would become more integrated with a higher number of microchambers. Such further integration of our microarray PCR chips with a miniaturized thermal cycler unit is in progress in our laboratory. The microarray PCR chip reported here has significant potential to be implemented for a wide range of applications. Overall, this system is a promising candidate for mass microfabrication due to its low-cost and high-throughput detection ability.

### 13.3

#### **On-chip Cell-free Protein Synthesis using A Picoliter Chamber Array**

The progress in analyzing the human genome has shifted the focus of research from genes to proteins [36–40]. Although the number of human genes is reported to be 28 000–38 000 [41], the functions of most of them are remain unknown. A rapid and easy method for synthesizing gene products has yet to be developed. Thus, an *in vitro* protein synthesis system has been designed and constructed on the microarray to make a protein library chip. The chip has proteins arranged in an array, and can detect target molecules. Gene cloning and expression is widely used in the preparation of proteins. However, some kinds of proteins often cannot be expressed well in host cells. Our cell-free protein synthesis system could be suitable for expressing such proteins. This protein synthesis system has other advantages as well, such as labeling proteins with isotopes for detection by NMR spectroscopy [42], easy purification of the synthesized protein, and short protein synthesis time.

A highly integrated protein chip is a powerful tool for accelerating post-genomic research. Our aim is to develop protein chips directly from a DNA library using the *in vitro* protein synthesis system. Recently, a cell-free protein synthesis system

from *Escherichia coli*, rabbit reticulocytes, and wheat germ has been commercialized [43]. In this research, a rapid translation system from *E. coli* was used for protein expression. Previously, we reported the development of a large-scale integrated pico-liter microchamber arrays for PCR [27], the introduction of a novel nano-liter dispensing system suitable for DNA amplification on microchamber array chip [28], the development of a simultaneous multianalyte immunoassay method for detecting human immunoglobulins based on a protein chip and imaging detection [44], and the development of a new approach for manufacturing encoded microstructures used as versatile building blocks for miniaturized multiplex bioassays [45]. Others have reported the construction of protein chips [46, 47] or cell-free protein synthesis in small chambers [48]. Kukar et al. have detected eight samples simultaneously on one chip [46], and Kojima et al. have constructed an electrochemical immunochip including an assembly of 36 electrodes [47].

There have been reports of high-throughput screening of a mutated anti-human serum albumin single-chain antibody (anti-HSA-scFv) using an *in vitro* protein synthesis system [49, 50]. In these reports, two amino acids were mutated randomly, and over 600 mutations were screened on 96-well plates. Our newly developed chip could also be a powerful tool in similar applications.

High-throughput screening is required for the rapid elucidation of protein functions. Microscale reactions have the advantages of short reaction time and the use of a small amount of samples and reagents. Especially in a high-throughput screening system, numerous samples must be analyzed simultaneously and, if possible, economically. Thus, we have made a highly integrated protein microchamber array chip by using micro-fabrication techniques and polydimethylsiloxane (PDMS) [6]. PDMS micro-molding techniques have been used to fabricate microfluidic systems [51, 52]. Unlike traditional micro-fabrication materials, such as silicon and glass, PDMS can be bonded and manufactured easily and efficiently [53]. In addition, PDMS has some properties that are advantageous for biochemical applications such as high transparency in the 230–700 nm wavelength range, and high permeability to gases.

### 13.3.1

#### Cell-free Protein Synthesis Chip Fabrication

Photolithography has been used to fabricate thin microarray sheets using PDMS [53]. A master pattern was formed on a silicon wafer using SU-8 photoresist. The PDMS prepolymer (Sylgard-184: Dow Corning, USA) mixture was poured onto the master and covered with a transparency film (overhead projector sheet). A multi-layer stack of aluminum plates, the master pattern, PDMS, a transparency film, a glass wafer, and rubber sheets were clamped tightly and the PDMS prepolymer was baked and crosslinked at 80 °C for 2 h. The resulting thin PDMS sheet, which has over 200 000 microchambers (micro-holes), was put on a slide glass in acetone and treated with oxygen plasma to bind the sheet to the glass. A reactive ion etching (RIE) system was used for the oxygen plasma treatment. The PDMS sheet has

**Fig. 13.6.** Optical images of PDMS/glass complex chambers. (A) Rectangular chambers about  $100 \times 100 \times 15 \mu\text{m}$ ; the volume is about 150 pL. (B) Cylindrical chambers 20  $\mu\text{m}$  in diameter and 15  $\mu\text{m}$  deep; the volume is about 5 pL. (C) Cylindrical chambers 10  $\mu\text{m}$  in diameter and 15  $\mu\text{m}$  deep; the volume is about 1 pL.

micro-holes, and a hydrophobic surface. Thus, only the bottoms of the microchambers were hydrophilic and the solution easily remained in the chambers. Three different types of chips were designed and fabricated (Fig. 13.6).

The PDMS microchamber was used for *in vitro* protein synthesis. The ribosome source was based on a lysate from *E. coli* (RTS-500 kit: Roche, USA). The wild-type GFP gene contained in the kit was used as a reporter gene, and expressed on the chips. Cell-free protein synthesis reagents were prepared according to the supplier's directions. The reaction solution was composed of a mixture of *E. coli* lysate solution (0.25 mL), of the reconstituted reaction mixture (0.75 mL), of the enzyme mixture (50  $\mu\text{L}$ ), and the GFP vector at a final concentration of 10  $\mu\text{g mL}^{-1}$ . First, we dripped the *in vitro* protein synthesis solution on the chip, and removed the surplus. Next, the microchamber chip was covered with a gap cover glass, and sealed to prevent evaporation. A 20  $\mu\text{m}$  gap between the chip surface and the cover glass prevented capillary action among the chambers. The chip was then held at 30  $^{\circ}\text{C}$ , and GFP expression was detected by an optical fluorescence microscope with an FITC filter (excitation: 450–490 nm, emission: 515–565 nm).

## 13.3.2

**Cell-free Protein Synthesis using a Microchamber Array**

RIE treatment (oxygen plasma treatment) was used to bind PDMS to a slide glass. Three different types of PDMS chips were designed and fabricated (Fig. 13.6). Since the PDMS and glass construction gives the chamber structure a hydrophobic surface and a hydrophilic bottom substrate, an aqueous solution poured onto the chip enters through the holes of the array, and remains only in these microchambers. This phenomenon prevents the cross-contamination between the microchambers. This chip is also suitable for optical observations because of its transparency over a wide wavelength range. Protein synthesis was carried out on the microchamber chips with the GFP gene used as a reporter gene. Expression of GFP was detected by fluorescence using an optical microscope. Figure 13.7 shows the results of cell-free protein synthesis on the chip. Fluorescence intensity was detected within 1 h of incubation, and remained constant. In a batch system, protein synthesis is said to be inhibited by a lack of substrate or accumulated waste within 2 h [54]. In our system, cell-free protein synthesis stopped within 2 h. This result agrees with the report of Spirin et al. [54]. However, the formation of the GFP fluorescent group is known to take 1–2 h [54]; thus, it may be considered that protein synthesis stopped before the GFP fluorescence became constant. However, a similar shift in GFP fluorescence was shown in chambers with 10 (Fig. 13.8) or 20  $\mu\text{m}$  i.d.

The lowest concentration of DNA template necessary for the detection of the GFP signal was determined to be only 10 molecules of DNA per chamber. A microchamber array chip with cylindrical chambers 10  $\mu\text{m}$  wide and 15  $\mu\text{m}$  deep was used in this experiment. The volume of this chamber is about 1 pL. Thus, the concentration of a solution containing 10 molecules of DNA is about  $4 \times 10^{-5}$

**Fig. 13.7.** Fluorescent images of microchips showing the expressed GFP protein. Chambers on the chip were filled with the cell-free protein synthesis reagents. Fluorescent image of the

chambers after incubation for (A) 0 h and (B) 1 h; GFP expression was detected under an optical microscope with a FITC filter.

**Fig. 13.8.** Optical images of GFPuv expression from DNA-immobilized beads. (A) Optical image under white light; arrows indicate the presence of beads. (B) Fluorescence image of the chamber,  $\lambda_{ex.} = 400\text{--}440\text{ nm}$ ,  $\lambda_{em.} = 475\text{ nm}$ . (C) Fluorescence image of a positive control containing cell-free protein synthesis reagents with 10 fg per pL pGGFPH vector. (D) Fluorescence image of a negative control containing only cell-free protein synthesis reagents (no template DNA). Cylindrical chambers shown in the figure are 10  $\mu\text{m}$  in diameter.

$\text{mg mL}^{-1}$ . This concentration is about 1/100 to 1/500 compared with the DNA concentration utilized in conventional cell-free protein synthesis protocols. The use of a small volume chamber increases the possibility of contact between DNA and reagents, making it possible to express a protein using a trace amount of DNA.

The distribution of over 10 000 samples using a DNA spotter would take a very long time; therefore, self-layout of samples containing the DNA library was used in this study. DNA-immobilized beads were used as DNA carriers. The amount of DNA immobilized on one bead was about 200 molecules on Dynabeads M-270 Carboxylic Acid, and 10 000 molecules on Dynabeads M-280 Streptavidin (Dyna, USA). A microchamber array chip with a 10  $\mu\text{m}$  i.d. chamber was used for bead arrangement. About 60% of the chambers contained one bead; however, some chambers had multiple beads because the diameter of a bead, which is 2.8  $\mu\text{m}$ , is much smaller than that of the chamber. The design and fabrication of a new chip with

smaller chambers to allow the entry of only one bead into each chamber are currently underway in our laboratory.

With the aid of lipid, it was possible to disperse the beads into the chambers. Rhodamine-modified lipid was used instead of phosphatidylcholine, and the chip covered with lipid solution was observed both in air and in water. Interestingly, the lipid moved into the chamber when the chip was soaked in water. A chip with beads containing the GFP gene was used for *in vitro* protein synthesis. As shown in Fig. 13.8, fluorescence was observed after 1 h of incubation only in chambers that contained DNA beads. As a positive control, pGGFPH vector solution was added to the *in vitro* protein synthesis reagents at  $10 \text{ fg pL}^{-1}$ ; no template DNA was added to the *in vitro* protein synthesis reagents as a negative control. The results of these control experiments are shown in Fig. 13.8. A comparison between DNA immobilized beads and DNA in solution suggests that the amount of protein per DNA molecule in solution is greater than that on DNA-immobilized beads. Nevertheless, easy and fast manipulation of DNA immobilized beads prompted us to use this method. In the experiments shown in Fig. 13.8, DNA immobilized beads with biotin–streptavidin conjugate were used. Similar results were observed when primer-immobilized beads were used. The concentration of GFP solution was about  $10 \text{ } \mu\text{g mL}^{-1}$ , estimated from the intensity of the fluorescence. The amount of GFP protein per chamber was about 10 fg. The GFP solution did not diffuse from the chambers, indicating that the solution in each chamber is physically separated from that in other chambers.

Tabuchi et al. have made a microchamber chip with a chamber volume per chip of  $10 \text{ } \mu\text{L}$  [48]. In our case, the chamber number is much larger and the chamber volume is much smaller, which is advantageous for high-throughput applications. However, the analysis of over  $10^4$  chambers takes a long time. Therefore, a scanner-type analyzer for our system is being developed to enable automatic screening in the near future.

A new method for making a highly integrated protein chip from a DNA library using *in vitro* protein synthesis on a microchamber array has been demonstrated. The chambers are of three types, based on their volume capacity: 1, 5, and 150 pL, and the total number of chambers per chip is 10 000 (150 pL), and 250 000 (both 1 and 5 pL). The array has a hydrophobic surface of PDMS and a hydrophilic glass bottom. These structural properties provide the advantage of preventing cross-contamination among the chambers. *In vitro* protein synthesis using these chambers was achieved. The fluorescence of GFP expressed on the micro chamber was rapidly detected. GFP expression was also achieved using immobilized DNA molecules on polymer beads, which allows easy handling of the DNA molecules. Brenner et al. have described a method for cloning nucleic acid molecules onto the surfaces of  $5 \text{ } \mu\text{m}$  microbeads rather than in biological hosts [55]. A unique tag sequence was attached to each cDNA molecule, and the tagged library was amplified. A unique tag was also attached to each bead, and the tagged library was conjugated with the tagged beads.

This method allows the immobilization of one kind of DNA on a bead. Because such clones are segregated on microbeads, they can be manipulated simul-

taneously and then assayed separately. If this method can be applied to the chip described in this report, it will be possible to analyze easily a whole DNA library on a chip in a short time. In future, this system will be used for the exhaustive expression of proteins included in target cells, the functional analysis of proteins expressed from unknown genes, and the screening of artificially mutated proteins.

In this study, we have reported a highly integrated protein microarray chip using *in vitro* protein synthesis from DNA conjugated microbeads. The protein microarray system made it possible to perform high-throughput screening and analysis for multiplexed gene expression on single beads in each pico-liter chamber. In the future, this system will be applied for the expression analysis of proteins in multiplexed single-cells and the functional analysis of proteins expressed from unknown genes or cells.

### 13.4

#### High-throughput Single-cell Analysis System using Pico-liter Microarray

Cell-based assays are one of the newest tools being used to broaden and strengthen drug discovery for the identification of new therapeutic agents. They are fast becoming the assay format of choice, especially in target validation, lead identification and optimization. Cell-based assay screening is by nature more complex and automation is more difficult than biochemical screening. These assays hold the promise of increasing productivity in the discovery process and the ability to screen out compound failure earlier in the development process. The last few years have seen an increasing number of cell-based assays being used, driving the market to an anticipated \$500 million mark by 2005 [56, 57]. Cell-based assays play a very important role in the post-genomic era focusing on high-throughput functional genomics and drug discovery. High-throughput screening assays play a pivotal role in the search of novel drugs and potential therapeutics. Over the last decade, various scientific advances include the growing number of potential therapeutic targets emerging from the field of functional genomics and the rapid development of large compound libraries derived from parallel and combinatorial chemical synthetic techniques, driven by the need for improved drug discovery screening technology [58, 59]. High-throughput cell-based assays reduce the total cost in screening the specific therapeutic target for a specific disease remarkably reducing the time. High-throughput drug screening methods employed so far involve use of 96- and 384-well microtiter plates and require at least a minimum of 100- $\mu$ L-assay mixture, suggesting further miniaturized assay formats to reduce the total cost of drug screening. Combining miniaturized technology with developments in automation, sensitive signal-detection, plate formats, automated compound-delivery and data management results in highly efficient, and cost-effective, integrated miniaturized ultrahigh-throughput screening (uHTS) systems. The need to screen numerous compounds rapidly, in increasingly automated dispensing systems, and with very small reaction volumes prompted us to carry out

this study. It was of interest to develop a high-throughput cell-based assay using miniaturized microarray chip formats.

For example, each B-cell clone expresses antigen-receptors, antibodies, with a unique antigen-specificity: an antigen-specific monoclonal antibody derived from a single B-cell clone finds applications in antibody medicine and clinical diagnosis. Though each B-cell has  $10^7$  to  $10^8$  varieties of monoclonal antibody on these surfaces only small percentage of B-cells respond and produce a specific monoclonal antibody. Only one or two cells in a total of 10 000 B-cells become active and produce antigen-specific antibodies after stimulation with a hepatitis B virus (HBV) surface antigen (HbsAg) [60]. It would be impossible to make a HbsAg specific antibody taking this ratio of positive B-cells into account using recently available technologies. A flow cytometer allows us to monitor individual cells that flow through sheath fluid, but the signals of the cells become background noise, which consists of 0.1 to sometimes 1% of total cells, thus it is quite difficult to monitor a signal of a minor population of cells whose signals are buried in the noise by a flow cytometer. Further, we cannot compare the states of each cell before and after stimulation by using flow cytometer. In contrast, a fluorescence microscope allows us to observe the states of cells both before and after stimulation. However, it is difficult to observe signals of large number of cells under a microscope. Accordingly, it is difficult to monitor  $\text{Ca}^{2+}$  mobilization of a minor population of cells.

Therefore, it is necessary to construct a microarray platform that can confine a large number of single-cells and detect antigen-specific single B-cells before and after stimulation with an antigen from a bulk cell suspension. For high-throughput single-cell separation and analysis, Thorsen et al. have reported high-density microfluidic chips that contain plumbing networks with thousands of micromechanical valves and hundreds of individually addressable chambers and showed the separation of single *E. coli* cells in each chamber [61]. To achieve single-cell separation, they diluted cells to create a median distribution of 0.2 cells per compartment, so that reliable capturing of cells in each chamber is difficult. In another recent report, Anderson et al. have tested biomaterial microarrays for their effects on human embryonic stem cell growth and differentiation using populations of human embryonic stem cells [8]. However, single-cell based assay seemed to be impossible using this microarray format. Also we have reported recently a microchamber array and microfluidic chip for measuring high-throughput analysis of cellular fluorescence [62–64]. Here, we discuss an improved microchamber array to monitor  $\text{Ca}^{2+}$  mobilization of over 25 000 cells simultaneously at a single-cell level [13]. We have also developed a novel high-throughput screening and analysis system for antigen-specific single B-cells using microarray, which was carried out by detecting antigen-specific single B-cells against an antigen of interest and their retrieval by a micromanipulator for antibody DNA analysis [13]. The single-cell microarray system developed in this study does not need to use myeloma, as in the case of conventional hybridoma technique, and can screen the antigen-specific single B-cells directly from cell suspension and analyze antigen-specific antibody DNA at a single-cell level. This system is simple and easy in its operation, and quick enough for making monoclonal antibodies when compared with conven-

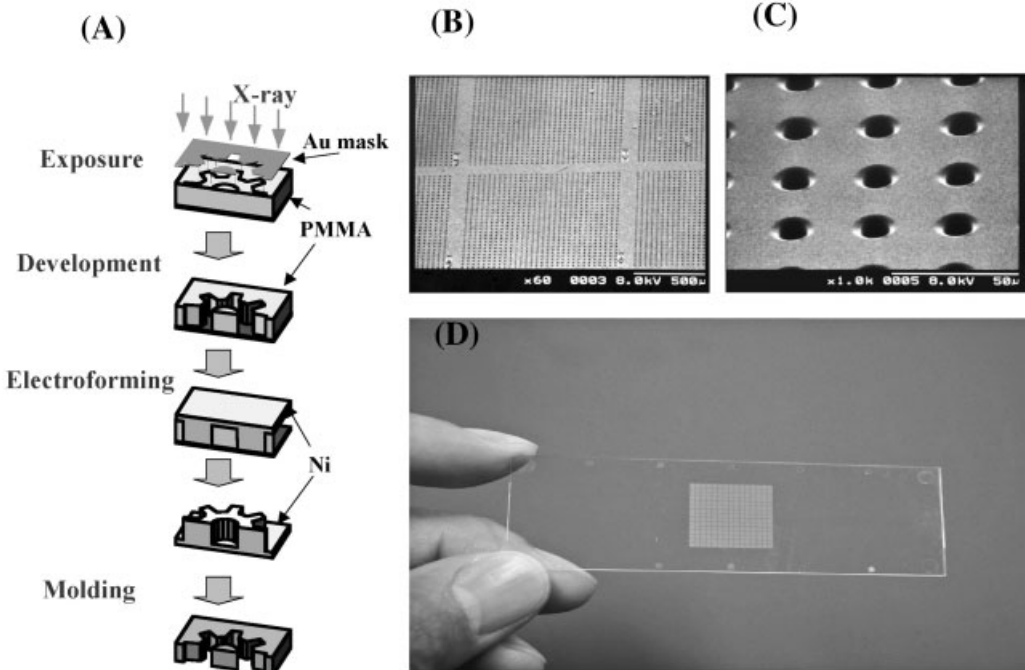

tional techniques. Moreover it can perform high-throughput single-cell analysis using chip devices.

#### 13.4.1

##### Single-cell Microarray Chip Fabrication

The microarray chip is made from polystyrene with over 200 000 microchambers ( $10\ \mu\text{m}$  width,  $12\ \mu\text{m}$  depth, and  $30\ \mu\text{m}$  pitch) by using the Lithographie Galvanoformung (LIGA) process and was performed by the Starlight Co. Ltd., Japan (Fig. 13.9A–D). Using X-ray lithography from synchrotron radiation, a poly(methyl methacrylate) (PMMA) as a resist was exposed and patterned with Au metal mask. After development of the PMMA substrate, the resulting PMMA mold was used for nickel mold construction by electroforming. Finally, a polystyrene microarray chip was fabricated from the nickel mold by injection molding (Fig. 13.9A). Each microarray chip is consisted of 225 ( $15 \times 15$ ) clusters, and each cluster consisted of 900 ( $30 \times 30$ ) microchambers. Each microchamber is cylindrical and can accommodate only a single-cell.

**Fig. 13.9.** Construction of single-cell microarray chip. (A) LIGA process for the fabrication of single-cell microarray chip. (B and C) SEM images and (D) a real picture

of the microarray chip device. The microarray chip is made from polystyrene with over 200 000 microchambers ( $10\ \mu\text{m}$  wide,  $12\ \mu\text{m}$  deep,  $30\ \mu\text{m}$  pitch).

**Fig. 13.10.** Microarray chip surface treatment studies for single-cell confinement and retrieval. (A) Optimization of RIE exposure time of chip surface for single-cell confinement and retrieval from microchambers. Contact angle (●); single-cell occupancy (○); and cell-retrieval rate (▲ closed triangle). Scanned microarray image of single-cells in 100 microchambers after (B) 20, (C) 10 and (D) 5 s RIE exposure. Each treatment showed single-cell occupancy of 83, 73 and 38%, respectively.

The microarray surface was rendered hydrophilic by reactive ion etching (RIE) treatment to make it convenient for cell studies. RIE exposure time controlled the cell adhesion on the chip surface. An increase in RIE exposure time increases the hydrophilicity of the microarray chip surface, which is inversely proportional to the decrease in the contact angle of chip surface (Fig. 13.10A). This condition is suitable for increased levels of single-cell occupancy in the microchambers because RIE treatment keeps the confined single-cell in the microchamber during the washing process, which is shown in Fig. 13.10(B–D). The polystyrene microarray chip maintained hydrophilicity character without alteration for at least one week. However, with increasing hydrophilicity, it becomes difficult to retrieve positive single-cells from microchambers, e.g., over 30-s RIE restricted the retrieval rate to <80% (Fig. 13.10A). This suggests optimization in the exposure time that suits single B-cell occupancy as well as for cell retrieval – determined to be 20 s exposure, which resulted in over 80% of single-cell occupancy and cell-retrieval rate (Fig. 13.10B). To achieve over 80% single-cell occupancy, the cell density should always be  $1 \times 10^6$  cells  $\text{mL}^{-1}$  or more, otherwise a decrease in the percentage of single-cell occupancy was observed. We succeeded in single-cell separation and retrieval on the plastic microarray chip by controlling the chip surface treatment. In contrast, we could not retrieve B-lymphocytes that adhered strongly to the glass

and silicon chip substrates, because these materials have highly hydrophilic surfaces. Further, the transparent nature of a plastic microarray chip, along with its flat bottom-surfaced cylindrical microchambers, made by the LIGA process, is convenient for visualization of single B-cells as well as retrieval of cells from microchambers by a micromanipulator under a light microscope. Thus, the single-cell microarray chip developed in this study was suitable for separation and retrieval of single cells to analyze the antigen-specific single B-cells.

#### 13.4.2

##### **Pico-liter Microarray for Single-cell Studies**

A single-cell microarray chip that was constructed by using LIGA process has over 200 000 flat-bottomed cylindrical microchambers (10  $\mu\text{m}$  diameter, 12  $\mu\text{m}$  depth) in 1.4  $\text{cm}^2$  area on a plastic wafer ( $2 \times 8 \text{ cm}^2$ ) (Fig. 13.9A–D). Characterization of such a microarray chip for single-cell studies was performed using mouse splenic B-lymphocytes. The microchamber design was made such that each chamber allowed entry of single B-cell (approximately 8  $\mu\text{m}$  diameter) and hence there is no possibility of two cells in a single microchamber. To achieve single B-cell confinement in each microchamber as well as cell-retrieval from microchambers, hydrophilicity of the microarray chip surface was controlled by adopting different timings of RIE exposure (Fig. 13.10). As the result of chip surface treatment using RIE, lymphocytes derived from mouse spleen or human blood were spread on the microarray, and over 80% of the microchambers achieved single-cell status. In addition, this novel microarray system demonstrated easy retrieval of positive single B-cells from microchambers by a micromanipulator under microscope.

In this study, we report the data from approximately 30 000 microchambers for detecting antigen-specific single B-cells, because the assay we have adopted, i.e., measurement of increase in the intracellular calcium after antigenic stimulus using Fluo-4, lasts for few minutes. During this short period a microarray scanner could scan the analyzable area of 30 000–40 000 microchambers. This number of microchambers is sufficient to screen and identify below as little as 0.1% of antigen-specific single-cells in a total B-cell population, which is the limitation of flow cytometer, as described above. The ultimate potential of this single-cell microarray can be realized by improving the assay system and the scanning speed of microarray scanner for detecting the total number of microchambers on the microarray chip.

Recently, however, researchers have reported single-cell based cultivation on microchips with the help of optical tweezers [65] and specially designed micropipette [66]. By using these systems, it would be impossible to perform high-throughput single-cell screening and analysis. Other chip systems, microfluidic devices, have been reported to perform single-cell separation and analysis from bulk cell suspension in microchannels under the influence of integrated valves and pumps [67–70], which make these systems complex in handling compared with microarray formats. Despite their complexity these devices could not guarantee capturing a

target cell, moreover they were not compatible for high-throughput analysis. The single-cell microarray developed in the present study could easily separate single-cells from a bulk cell suspension without using specialized tools.

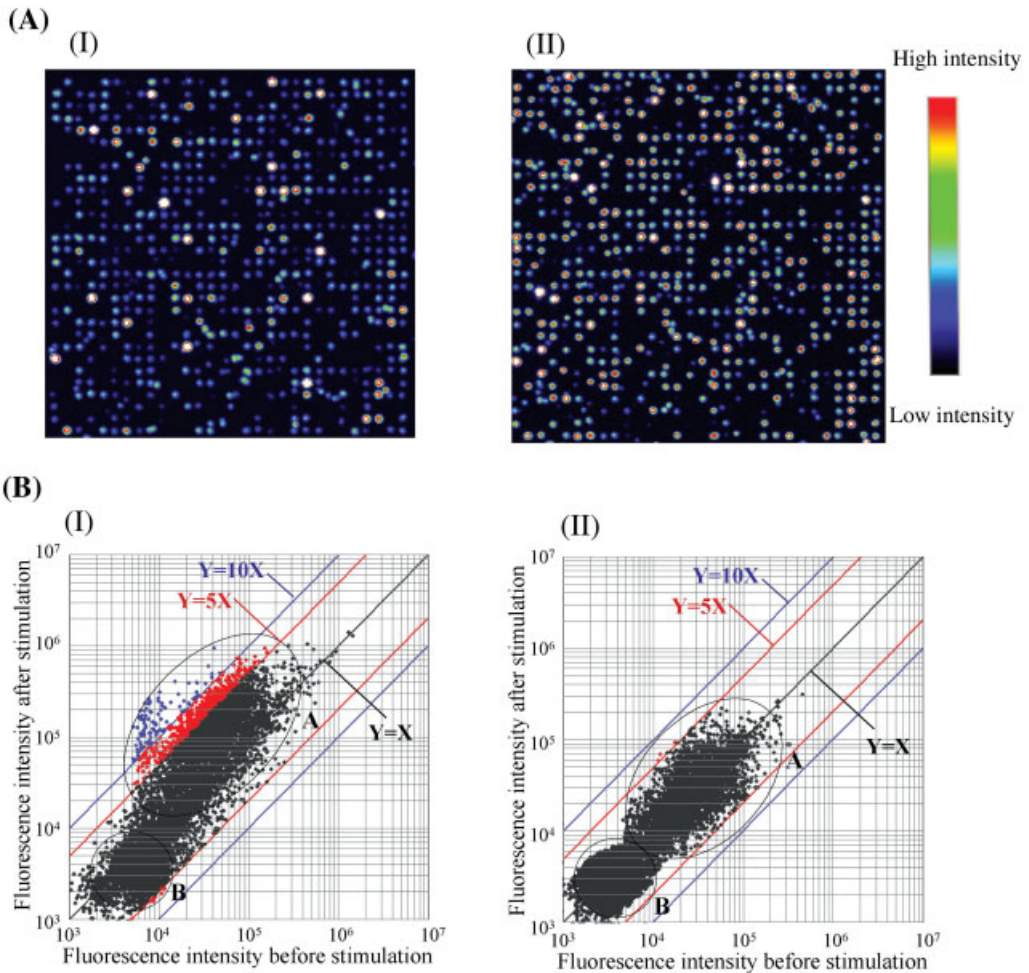

### 13.4.3

#### Single-cell Microarray System for Analysis of Antigen-specific Single B-cells

To evaluate the utility of a novel single-cell microarray system for detecting intracellular calcium, the  $(Ca^{2+})_i$  level of individual cells, we have employed anti-mouse IgM antibody as a stimulant for mouse splenic B-cells, which delivers the signals through B-cell antigen-receptors and induces a transient increase in the  $(Ca^{2+})_i$  levels. Mouse lymphocytes loaded with  $Ca^{2+}$ -indicator, Fluo-4, were applied on the chip and their fluorescence was detected with a microarray scanner before and after stimulation with anti-mouse IgM antibody (Fig. 13.11). Fluo-4 is a standard fluorescent calcium indicator [71], which enters into the cells and generates fluorescence after binding to  $(Ca^{2+})_i$ . It is known that the concentration of  $(Ca^{2+})_i$  increases after B-cells respond to antigenic stimulation [72]. In this experiment, major single B-cells on the microarray showed increases in the  $(Ca^{2+})_i$  after stimulation (Fig. 13.11A). The fluorescence intensity reached to its maximum level after 1 min stimulation, and maintained a high magnitude for 2 min and then decreased gradually (data not shown). Thus, we used a 2 min stable duration for analysis. Scatter plot analysis of individual cell's fluorescence-intensity (Fig. 13.11B) enabled us to discriminate B-cells that were activated with anti-mouse IgM antibody. The data from over 30 000 microchambers in the microarray chip revealed 68% (18 130 cells) of total splenic lymphocytes (26 650 cells) showed more than twice the fluorescence after stimulation with anti-mouse IgM (Fig. 13.11B). While cells with over a  $5\times$  increase in fluorescence (3883 cells) existed in 14% of the total splenic lymphocytes [Fig. 13.11B(I)]. Whereas most lymphocytes incubated with control antibody (anti-human IgM) showed a less than  $5\times$  increase in fluorescence intensities [Fig. 13.11B(II)].

Each B-cell expresses membrane-bound antibodies with unique antigen-specificity as antigen receptors. When B-cells were stimulated with an antigen instead of anti-IgM antibody, only a minor population of total B-cells is stimulated and their  $(Ca^{2+})_i$  increases. Previous studies reported diverse frequencies in the number of antigen-specific B-cells, ranging from 1 in  $10^2$  for rabies virus [73] to 7 in  $10^5$  for myelin basic protein [74]. However, it is quite difficult to screen and identify a minor cell population of antigen-specific single B-cells ( $<0.1\%$ ) with a flow cytometer because fluorescent signals of minor populations of cells are buried in the noise of non-specific cells. Whereas the single-cell microarray platform developed in this study could successfully screen and detect a low frequency of antigen-specific single B-cells using a single chip in one run. In addition, it also analyzes the same single-cells before and after stimulations with antigen, which a flow cytometer could not.

If antibody cDNA is recovered from an antigen-specific single B-cell that is detected with single-cell microarray, antigen-specific monoclonal antibodies can be

**Fig. 13.11.** Detection of activated single B-cells using Fluo-4 upon stimulation with anti-mouse IgM antibody. (A) Scanned images of single-cells microarray in a single cluster area of 900 ( $30 \times 30$ ) microchambers on a microarray (I) before and (II) after stimulation. Color scale represents the intensity of fluorescence emission. (B) Scattered plot analysis of single B-cell response in 32 400

microchambers area after stimulation with (I) anti-mouse IgM antibody and (II) negative control antibody. Circle A, microchambers with lymphocytes; circle B, empty microchambers; X, fluorescence intensity before stimulation; Y, fluorescence intensity after stimulation; blue line ( $Y = 10X$ ),  $10\times$  higher fluorescence intensity; red line ( $Y = 5X$ ),  $5\times$  higher fluorescence intensity.

developed. To this end, we have successfully performed retrieval of a single B-cell from the microarray by a micromanipulator system under a microscope (Fig. 13.12) and subsequent single-cell RT-PCR amplification to determine its antibody cDNA. Monoclonal antibodies are usually produced using hybridoma techniques

**Fig. 13.12.** Retrieval and antibody cDNA analysis of single B-cells derived from human blood. (A and B) Light and fluorescence microscopic images of the single B-cells on a microarray chip before cell-retrieval using a micromanipulator system. B-cells were treated with CellTracker Orange ( $\lambda_{\text{ex.}} = 541 \text{ nm}$ ,  $\lambda_{\text{em.}} = 565 \text{ nm}$ ) for observation of fluorescence from living cells. The arrows indicate a single-

cell in each microchamber, observed under the  $40\times$  lens of an inverted microscope. (C and D) Light and fluorescence microscopic images after target single-cell retrieval using a micromanipulator. The circle in (D) indicates the disappearance of fluorescence of target a single-cell that was retrieved from the microchambers.

developed by Milstein and Koeller [75]. Using conventional hybridoma methods, one hybridoma is routinely produced from  $10^5$  splenocytes [57] and, therefore, not all B-lymphocytes are screened for antigen-specificity. However, the single-cell microarray system we have developed could screen directly all the B-cell population to detect antigen-specific single B-cells and analyze the antigen-specific antibody DNA at a single-cell level. Our chip system is simple and easy in its operation, and can perform high-throughput single-cells analysis. Moreover, it provides a superior screening system for antigen-specific monoclonal antibodies that provide the source for antibody medicines.

The single-cell microarray system we have developed made it possible to perform high-throughput screening and analysis of intracellular  $\text{Ca}^{2+}$ -response at a single-cell level and analyze multiplexed single-cell status before and after antigenic stimulation on a single platform, which flow cytometry could not. Further, this system

facilitated easy retrieval of antigen-specific single B-cell from the microarray, demonstrating its novelty and superiority over conventional methods in making monoclonal antibody. This explorative study throws more light on a novel high-throughput single-cell analysis system that has tremendous potential to analyze antibody DNA of an antigen-specific single B-cell for developing highly specific monoclonal antibody as antibody medicines. It might also be applicable for detection of antigen-specific T cells, which could lead to immune therapy or gene therapy in the future.

### 13.5

#### Conclusions

Pico- and nano-liter chamber array chips have been developed that show great potential to detect and analyze DNA, protein and cell at single-molecule or single-cell level.

The microchamber (40 nL) array PCR chip presented in this chapter was used to amplify and detect quantitatively multiple DNA targets in combination with a nanoliter dispenser. This demonstrated that a microarray PCR chip can be used to amplify and detect ~1200 target DNAs simultaneously; in addition, target gene analysis at single copy level was achieved. Thus, the microarray PCR chip system has a significant potential to be implemented for a wide range of purposes such as detection of pathogenic microorganisms and clinical diagnosis.

The highly integrated protein microarray chip presented here successfully performed *in vitro* protein synthesis using a pico-liter chamber array. Furthermore, it made it possible to perform screening and analysis for multiplexed gene expression on single beads in each chamber. In future, this system will be applied for high-throughput screening and functional analysis of proteins expressed from unknown genes or cells.

The single-cell microarray system, which can accommodate single-cells in pico-liter chambers, made it possible to perform high-throughput screening and analysis of antigen-specific single B-cells and analyze multiplexed single-cell status before and after antigenic stimulation on a single platform. Further, this system facilitated easy retrieval of positive antigen-specific single B-cell from the microarray, demonstrating its novelty over conventional methods in making monoclonal antibody. The single-cell analysis system has tremendous potential to analyze antibody DNA of an antigen-specific single B-cell for developing highly specific monoclonal antibody as antibody medicines. It might also be applicable for cell therapy as personal diagnosis and development of personalized medicine in future.

Thus, the pico- and nano-liter chamber array systems discussed here could become a potential tool for high-throughput analysis of DNA, protein and cell at single-molecule or single-cell level, which could lead to clinical diagnosis and drug discovery.

## Acknowledgments

Research into *in vitro* protein synthesis on a pico-liter chamber array was supported by the grants of New Energy and Industrial Technology Development Organization (NEDO) and the Japan Society for the Promotion of Science (JSPS). The single-cell microarray chip research was carried out under the Toyama Medical Bio-cluster project, which was sponsored by the Ministry of Education, Culture, Sports, and Science, Japan.

## Index

10E3 antibody 344

### **a**

absorption-based sensors 139  
 $\beta$ -actin gene 374–375  
 adsorption, on the transducer substrate 61  
 affinity recognition surface, based on the  
 dendrimer-associated SAMs 244–252  
 AFM *see* atomic force microscopy  
 AFP *see*  $\alpha$ -fetoprotein (AFP)  
 Al<sub>2</sub>O<sub>3</sub>, EIS 230–232  
 Alexa-488 183  
 alkaline phosphatase (ALP)-loaded CNTs  
 67, 69  
 all-biological sensors 325  
 ALP *see* alkaline phosphatase  
 alumina films, porous 209–214  
 Alzheimer's disease (ADDLs), nanosensors  
 329  
 AMG *see* amyloglucosidase  
 amino-functionalized nanotubes 47  
 amperometry 91  
 amplified DNA, on-chip quantification  
 376–377  
 amyloglucosidase (AMG) 19  
 anchoring approaches, CNT-based biosensors  
 66–69  
 anodization  
 – porous alumina films 210–211  
 – two-step 211  
 antibodies  
 – 10E3 344  
 – GNWs 220–223  
 antibody–antigen interactions 15–16  
 antibody-based nanoprobe 322  
 antibody linker, GNWs 208, 220–224  
 antigen–antibody binding, biomimetic  
 nanosensors 317–318  
 antigen/antibody biosensors 262

antigen-specific single B-cells, single-cell  
 microarray system 389–392  
 aptamer–nanoparticle based biosensors 352  
 atomic force microscopy (AFM), biomimetic  
 nanosensors 319–320  
 ATP biosensors, reagentless 345  
 Au/Au np/CdS np surfaces 342–343  
 AuNP-CoMHP 270  
 avidin–biotin interaction 246

### **b**

B-cells 385–387  
 – antigen-specific single 389–392  
 back-filling immobilization 252  
 bacteria, pathogenic 208  
 bacteria detection, electrochemical nano-  
 biosensor 224–235  
 bifunctional agents 135  
 bilayer lipid membranes (BLMs) 41, 43–44  
 bioaffinity interface construction 251  
 bioanalyses  
 – FRET-based 196  
 – immunoblot 192–195  
 – time-resolved fluorimetry 197  
 bioconjugates, carbon nanotubes 12–14  
 bioelectrocatalytic enzyme electrodes, based on  
 LBL (layer-by-layer) assembly with  
 dendrimers 243  
 bioelectrocatalytic immunosensors, based on  
 the dendrimer-associated SAMs 244–252  
 bioelectronics 81–83  
 biological functionalization, CNTs 39  
 biological materials, gold nano-biosensor-  
 based electrochemical detection 208–235  
 biological systems, nanosensor probing 317–  
 322  
 biological transducers 225  
 biology, structural 260  
 biomarkers, ultrasensitive detection 259–273

- biomedical diagnosis, nano-biotechnology 327–329
  - biomimetic nanosensors 311–330
  - biomimetic vesicles 320
  - biomolecular conduits, signal transducing mediators 265–266
  - biomolecular recognition, colloidal nanocrystals 126
  - biomolecule conformational modulated effects
    - nanoparticle scaling laws 338–339
    - reagentless biosensors 351–361
  - biomolecule-functionalized CNTs, for electrochemical sensors and biosensors 45–48
  - biomolecules on CNTs, direct electrochemistry 69–72
  - bionanotechnology 311
  - biosensing
    - electrochemical 103–105
    - fullerene-based electrochemical detection methods 101–118
    - fullerene-mediated 114–118
    - with semiconductor nanocrystals 153–156
  - biosensor chip 315
  - biosensor development 56–90
    - CNTs 57–84
    - nanocantilevers 89–90
    - nanowires 84–89
  - biosensor generations 105–106
  - biosensors
    - according to IUPAC 103
    - antigen/antibody 262
    - applications of dendrimers 242–255
    - based on DNA conformation changes 352–354
    - based on protein conformation changes 355–361
    - biomolecule-functionalized CNTs 45–48
    - classical 324
    - CNT array-based 76–80
    - CNT-based 60–69
    - CNT-based electrochemical 34–38, 69–74
    - conducting polymer nanowire-based 86–88
    - coordinated 259–273
    - definition 125
    - DNA and protein 73
    - DNA-based 263
    - enzyme-based 261–263, 324
    - enzyme–CNT 72
    - evolution 105
    - glucose 87
    - mediation process 106–109
    - metal oxide nanowire-based 89
    - nano- *see* nanobiosensors, 208–235
    - non-reagentless 337
    - optical recognition-based 197–200
    - protein-based 278–297
    - reagentless 337–361
    - s-BLM 115–116
    - silicon nanowire-based 84–85
    - subtilisin-based 117
    - SWCNT glucose 64
  - biotinylated polymer layer, NTFETs 16
  - BLMs *see* bilayer lipid membranes
  - Bohr exciton radius 176
  - branching, colloidal nanocrystals 132
  - Buckyballs 58
- c**
- C<sub>60</sub> chemically modified electrodes (CMEs) 114
  - C<sub>60</sub> fullerene 101–102
    - synthesis 109
    - van der Waals surface representation 113
  - calibration of fluorescent instrumentation, standards 201
  - cancer detection, biomimetic nanosensors 328
  - carbohydrate detection, biomimetic nanosensors 319
  - carbon nanocage 58
  - carbon nanotube field-effect transistors (NTFETs) 1–21
    - coated with a biotinylated polymer layer 16
    - contact-passivated 10
    - fabrication 6–9
    - mode of operation 8
    - passivation layer 10
    - sensitivity to chemical environment 9–12
    - sensor applications 9–20
    - transistor function 8

**d**

DCC *see* dicyclohexylcarbodiimide  
 deep-tissue imaging *in vivo*, Qdots 184–190  
 dendrimer-associated SAMs  
 – affinity recognition surface 244–252  
 – bioelectrocatalytic immunosensors 244–252  
 dendrimer-based electrochemical detection  
 methods 240–256  
 dendrimers  
 – as a new constituent of biocomposite  
 structures 241  
 – biosensors 242–255  
 – G4 poly(amidoamine) 242  
 DHLA *see* dihydroliipoic acid  
 dicyclohexylcarbodiimide (DCC) 63  
 different target DNA, multiplexed detection  
 373–376  
 dihydroliipoic acid (DHLA) 135  
 dinitrophenyl (DNP) 252  
 direct electrochemistry, biomolecules on CNTs  
 69–72  
 disease biomarkers, nanosensors 328  
 dithiobissuccinimidylundecanoate (DSU)  
 220–224  
 dithiothreitol (DTT) 135  
 DNA  
 – amplified 376–377  
 – different target 373–376  
 DNA analyses, pico/nanoliter chamber array  
 chips 368–393  
 DNA–Au nanoparticles, fluorophore modified  
 354  
 DNA-based sensors 263  
 DNA biosensors 73  
 DNA conformation changes, biosensors based  
 on 352–354  
 DNA detection 17  
 – biomimetic nanosensors 325–326  
 DNA duplex formation 350–351  
 DNA enzymes 326  
 DNA hybridization 17, 326  
 DNA linkers 266  
 DNA–magnetic nanoparticle assemblies  
 350  
 DNA–nanoparticle-based biosensors 352–355  
 DNA/RNA sensors 48  
 DNA sensing  
 – biomimetic nanosensors 318  
 – with nanowires 85–86  
 DNA–SWNT conjugates 13  
 DNAszymes *see* DNA enzymes  
 DNP *see* dinitrophenyl

DSU *see* dithiobissuccinimidylundecanoate  
 DTT *see* dithiothreitol  
 dual amplification route 73–74  
 duplex DNA, OR logic gate 350–351

  - mPEG-SH SAMs 15
  - MRI *see* magnetic resonance imaging
  - MRS *see* magnetic relaxation switches
  - multi-histidine peptide (MHP) 266–269, 273
  - multi-walled carbon nanotubes (MWNTs) 3, 28, 58
    - as nanoelectrodes 29
  - multicolor quantum dots 155
  - multimodality imaging probes 191
  - multiphoton techniques, nanocrystals 145
  - multiple PCR analysis 375
  - multiplexed analysis, protein micropatterning 253–256
  - multiplexed detection, of different target DNA 373–376
  - multiplexed PCR, nanoliter-volume microchamber array 369–377
  - MWCNT-Nafion thin film 292
  - MWNT *see* multi-walled carbon nanotube
  - myoglobin (Mb) 281
    - CNTs 288
- n**
- N-Succinimidyl acrylate (NSA) 42
  - NADH *see* nicotinamide adenine dinucleotide
  - NADH peroxidase 265
    - biocatalytic element 267–269
  - Nafion, MWCNT thin film 292
  - nano-biosensors
    - bacteria detection 224–235
    - electrochemical detection of biological materials 208–235
    - experimental conditions 226
  - nano-biotechnology, biomedical diagnosis 327–329
  - nano-fibers, optical 323
  - nano-patches, membrane-fused fluorescent/colorimetric 322
  - nanobiohybrids
    - quantum dot-based 176–201
  - nanobiosensors, elements of 262–265
  - nanocantilevers, biosensor development 89–90
  - nanocomposite materials 292
  - nanocrystals
    - advantages and disadvantages 152
    - applications 153–161
    - biosensing 153–161
    - coating 137
    - colloidal *see* colloidal nanocrystals
    - colorimetric tests 139
    - fluorescence 139–146
    - fluorescence lifetime 142–145
    - functionalization 134–139
    - marketing 162–163
    - multiphoton techniques 145

- surface-enhanced resonance spectroscopy 149–151
  - surface modification 136
  - surface plasmon resonance 146–149
  - nanoelectrode arrays (NEAs) 77
  - nanoelectrodes, MWCNTs 29
  - nanogel particles (NGPs) 320–321
  - nanoliter dispenser, sample loading 372
  - nanoliter-volume microchamber array, multiplexed PCR 369–377
  - nanomaterials, purpose-built 126
  - nanoparticle scaling laws, interlacing 338–339
  - nanoparticles
    - fluorophore modified DNA–Au 354
    - magnetic 295
    - metal 279–285
    - metallic oxide 285–286
    - reagentless biosensors 337–361
    - semiconductor 293–294
    - with special functions 293–295
  - nanoporous films 209
  - nanoprobes, antibody-based 322
  - nanosensors
    - biological components 323–326
    - biomimetic 311–330
    - for probing biological and cellular systems 317–322
    - PEBBLE 321
  - nanoshells 328
  - nanostructured materials, one-dimensional 56–57
  - nanostructures, in biosensor design 312–317
  - nanotube networks 8
  - nanotubes
    - amino-functionalized 47
    - biosensor development 57–84
  - nanowire arrays, template synthesis 209–219
  - nanowire-based biosensors
    - conducting polymer 86–88
    - metal oxide nanowire-based 89
  - nanowires, biosensor development 84–89
  - near-IR QDs 185–186
  - NEAs *see* nanoelectrode arrays
  - NGP *see* nanogel particles
  - nicotinamide adenine dinucleotide (NADH) 66, 70–72
  - non-mediated biosensor 107
  - non-reagentless biosensors 337
  - noncovalent functionalization, of SWNTs 12
  - Npx-CoMHP-AuNP assembly 270
  - Npx redox center 266
  - NSA *see* N-Succinimidyl acrylate (NSA)
  - NTFET fabrication, SiO<sub>2</sub>/Si substrates 11
  - NTFETs *see* carbon nanotube field-effect transistors

  - photoluminescence (PL)
    - quantum yield 135
    - spectra 156
  - photonic explorers for bioanalysis with biologically localized embedding *see* PEBBLE

- picoliter chamber array, on-chip cell-free protein synthesis 378–383  
 picoliter microarray, single-cell analysis system 384–392  
 pico/nanoliter chamber array chips, for single-cell, DNA and protein analyses 368–393  
 PL *see* photoluminescence  
 platinum nanoparticles 285  
 PMMA *see* poly(methyl methacrylate)  
 PNA *see* peptide nucleic acid  
 POAP *see* poly-o-aminophenol  
 poly-o-aminophenol (POAP)-electropolymerized electrode 46  
 poly(amidoamine) dendrimers, fourth generation 242  
 poly(dimethylsiloxane) (PDMS) 254, 379–380  
   – microflow chip fabrication 17  
 poly(ethylene glycol) (PEG) 39, 138, 185–186, 188, 191  
 poly(methyl methacrylate) (PMMA) 386  
 poly(vinyl acetate) (EVA) 81  
 polymer-assisted solubilization, CNT-based biosensors 61  
 polymer nanojunction sensor 88  
 polymerase chain reaction (PCR), multiplexed 369–377  
 polypyrrole (Ppy) 64  
 porous alumina films 209–214  
 porous silicon 295–296  
 positron emission tomography (PET), Qdots 191  
 Ppy *see* polypyrrole  
 prohibition, anchoring approaches 66–69  
 prostate specific antigen (PSA) 345  
 protein analyses, pico/nanoliter chamber array chips 368–393  
 protein-based biosensors 73  
   – CNTs 289  
   – using nanomaterials 278–297  
   – *see also* enzyme-based biosensors  
 protein conformation changes, biosensors based on 355–361  
 protein detection 14  
   – with nanowires 85–86  
 protein micropatterning, on sensor surfaces for multiplexed analysis 253–256  
 protein nanosensors 317  
 protein synthesis, on-chip cell-free 378–383  
 proteins  
   – Qdot-based immunoblot analysis 194–195  
   – redox 44  
 purification, of CNTs 58–59  
 purpose-built nanomaterials 126

 QCM *see* quartz crystal microbalance  
 QD *see* quantum dot  
 QD-based western blotting technology 192–194  
   – mono-type 194–196  
   – sandwich-type 194–196  
*in vivo* QD imaging 185  
 QD-peptide conjugates 188  
 QD630-streptavidin 183  
 Qdot *see* quantum dot  
 Qdot-based immunoblot analysis, of “tracer” proteins 194–195  
 quantum dots  
   – basic principles 176–180  
   – colloidal 133–134  
   – conjugates 181  
   – design and synthesis 176–178  
   – fluorescence 313  
   – fluorescent detection of molecular and cellular biological targets 176–201  
   – fluorescent labeling and imaging 181–192  
   – multicolor 155  
   – nanobiohybrids 176–201  
   – optical and chemical properties 178–180  
   – Stokes shift 180  
   – water-soluble 178  
 quantum yield (QY), quantum dots 185  
 quartz crystal microbalance (QCM) 248  
 QY *see* quantum yield
- r**  
 randomly distributed CNT electrodes 30  
 reactive ion etching (RIE) 387  
 reagentless ATP biosensors 345  
 reagentless biosensors  
   – based on nanoparticles 337–361  
   – biomolecule conformational modulated effects 351–361  
   – catalytic activation 339–346  
   – gold nanoparticle enhanced surface plasmon resonance 340–342  
   – surface dielectric enhancement 340–342  
 redox enzymes, as electrodes 265–266  
 redox proteins, functionalized CNTs 44  
 restriction endonucleases detection 350  
 RhD gene 374–377  
 RIE *see* reactive ion etching  
 rolled graphene sheets 57

## Contents

<b>Preface</b>	XV
<b>List of Authors</b>	XIX
<b>1 Nanotechnology and Tissue Engineering: The Scaffold Based Approach</b>	<b>1</b>
<i>Lakshmi S. Nair, Subhabrata Bhattacharyya, and Cato T. Laurencin</i>	
1.1	Overview 1
1.2	Introduction 1
1.3	The Importance of Scaffolds in Tissue Engineering 4
1.4	Structure and Functions of Natural Extracellular Matrix 12
1.5	Applications of Nanotechnology in Developing Scaffolds for Tissue Engineering 21
1.5.1	Polymeric Nanofiber Scaffolds 23
1.5.1.1	Top-down Approaches in Developing Scaffolds for Nano-based Tissue Engineering 24
1.5.1.2	Bottom-up Approaches in Developing Scaffolds for Nano-based Tissue Engineering 33
1.6	Cell Behavior Towards Nano-based Matrices 39
1.7	Applications of Nano-based Matrices as Scaffolds for Tissue Engineering 43
1.7.1	Stem Cell Adhesion and Differentiation 43
1.7.2	Neural Tissue Engineering 47
1.7.3	Cardiac and Blood Vessel Tissue Engineering 49
1.7.4	Bone, Ligament and Cartilage Tissue Engineering 54
1.8	Conclusions 55
	References 56
<b>2 Polymeric Nanofibers in Tissue Engineering</b>	<b>66</b>
<i>Seow Hoon Saw, Karen Wang, Thomas Yong, and Seeram Ramakrishna</i>	
2.1	Overview 66
2.2	Introduction 67
2.2.1	History of Tissue Engineering and Nanofibers 67
2.3	Classification of Nanofibers 69
2.3.1	Synthetic Polymers 69
2.3.2	Biopolymers 69

VIII | Contents

2.3.3	Copolymers	70
2.3.4	Composite Polymers	70
2.4	Nanofiber Fabrication	70
2.4.1	Drawing	71
2.4.2	Template Synthesis	71
2.4.3	Phase Separation	72
2.4.4	Self-assembly	73
2.4.5	Electrospinning	73
2.5	Degradation and Absorption Kinetics of Nanofiber Scaffolds Compared with Conventional Scaffolds	74
2.6	Advantages and Disadvantages of Nanofiber Scaffolds Compared with Other Conventional Scaffolds	76
2.7	Biocompatibility of Nano-structured Tissue Engineered Implants	82
2.8	Applications of Polymeric Nanofibers in Tissue Engineering	87
2.8.1	Ophthalmology	89
2.8.2	Liver	93
2.8.3	Nerve	93
2.8.4	Skin	99
2.8.5	Bone and Cartilage	102
2.8.6	Heart and Vascular Grafts	105
2.8.7	Stem Cells	109
2.9	Innovations in Nanofiber Scaffolds	111
2.10	Conclusion	115
	References	116

**3 Electrospinning Technology for Nanofibrous Scaffolds in Tissue Engineering** 135

*Wan-Ju Li, Rabie M. Shanti, and Rocky S. Tuan*

3.1	Introduction	135
3.2	Nanofibrous Scaffolds	138
3.2.1	Fabrication Methods for Nanofibrous Scaffolds	138
3.2.1.1	Phase Separation	138
3.2.1.2	Self-assembly	138
3.2.1.3	Electrospinning	139
3.2.2	The Electrospinning Process	140
3.2.2.1	History	140
3.2.2.2	Setup	141
3.2.2.3	Mechanism and Working Parameters	142
3.2.3	Properties of Electrospun Nanofibrous Scaffolds	144
3.2.3.1	Architecture	144
3.2.3.2	Porosity	145
3.2.3.3	Mechanical Properties	146
3.3	Current Development of Electrospun Nanofibrous Scaffolds in Tissue Engineering	146
3.3.1	Evidence Supporting the Use of Nanofibrous Scaffolds in Tissue Engineering	146

3.3.1.1	Nanofibrous Scaffolds Enhance Adsorption of Cell Adhesion Molecules	146
3.3.1.2	Nanofibrous Scaffolds Induce Favorable Cell–ECM Interaction	147
3.3.1.3	Nanofibrous Scaffolds Maintain Cell Phenotype	148
3.3.1.4	Nanofibrous Scaffolds Support Differentiation of Stem Cells	149
3.3.1.5	Nanofibrous Scaffolds Promote <i>in vivo</i> -like 3D Matrix Adhesion and Activate Cell Signaling Pathway	150
3.3.2	Biomaterials Electrospun into Nanofibrous Scaffolds	151
3.3.2.1	Natural Polymeric Nanofibrous Scaffolds	151
3.3.2.2	Synthetic Polymeric Nanofibrous Scaffolds	162
3.3.2.3	Composite Polymeric Nanofibrous Scaffolds	166
3.3.2.4	Nanofibrous Scaffolds Coated with Bioactive Molecules	168
3.3.3	Engineered Tissues using Electrospun Nanofibrous Scaffolds	169
3.3.3.1	Skin	169
3.3.3.2	Blood Vessel	170
3.3.3.3	Cartilage	171
3.3.3.4	Bone	172
3.3.3.5	Muscle	173
3.3.3.6	Ligament	175
3.3.3.7	Nerve	175
3.4	Current Challenges and Future Directions	176
3.5	Conclusion	177
	References	177
<b>4</b>	<b>Nanofibrous Scaffolds and their Biological Effects</b>	<b>188</b>
	<i>Laura A. Smith, Jonathan A. Beck, and Peter X. Ma</i>	
4.1	Overview	188
4.2	Introduction	188
4.3	Methods of Formation	190
4.3.1	Electrospinning	190
4.3.2	Self-assembly	193
4.3.3	Phase Separation	194
4.4	Nanofibrous Composite Scaffolds	198
4.4.1	Inorganic Composites	199
4.4.2	Surface Modification	200
4.4.3	Factor Delivery Scaffolds	201
4.5	Biological Effects of Nanofibers	202
4.5.1	Attachment	202
4.5.2	Proliferation	203
4.5.3	Differentiation	203
4.5.4	Migration	204
4.6	Tissue Formation	205
4.6.1	Connective Tissue	205
4.6.1.1	Ligaments	205
4.6.1.2	Cartilage	205
4.6.1.3	Bone	206

4.6.2	Neural Tissue	207
4.6.3	Cardiovascular Tissue	208
4.6.3.1	Cardiac Muscle	208
4.6.3.2	Blood Vessel	208
4.6.4	Liver Tissue	208
4.7	Conclusion	209

## Preface

Tissue Cell and Organ Engineering is the title of the ninth volume of the series on Nanotechnologies for the Life Sciences. As the title indicates the book can be considered as an encyclopedia on nanotechnological approaches to tissue, cell and organ engineering. The publication of the book is timely for a number of reasons. First, with the increase in life expectancy there is an unfulfilled demand for replacing non functional tissues and organs. Second, life time for implants and vascular grafts made from conventional synthetic materials (with constituent dimensions greater than 1 micron) is limited ranging from 5 to 15 years. Third, utilization of living tissue/organ for replacement is not a practical solution as evidenced by the fact that millions of surgeries are performed annually to treat tissue and organ failure and the number of people waiting for such transplantations are more than 80,000 at any time. Fourth, there is the ever-increasing cost of health care related to tissue loss or end-stage organ failure exceeding 400 billion US dollars. Furthermore, laboratory experiments to date suggest that nanomaterials have great potential for tissue, cell and organ engineering. Until the publication of this book, there is no single source of information about how nanotechnologies are impacting various facets of tissue engineering. With close to five hundred pages, the book has turned out to be a comprehensive source of information covering different types of nanomaterials being investigated for tissue, cell and organ engineering in addition to innovative strategies for assembling functional and structural artificial tissues.

I am extremely pleased with the final product, which is a tribute to harmonious integration of tissue engineering and nanomaterials science. Such an integration is only possible due to the scholarly presentations from some thirty researchers around the world, spanning twelve chapters. My special thanks to all of them for making this project a reality. I am always grateful to my employer, family, friends and Wiley-VCH publishers, who are part and parcel of this long journey into the union of nanomaterials and life sciences. I am thankful to you, the reader, who has taken time to join this journey. I do hope you will enjoy reading the book and will find it useful in your future endeavors. Let me first give you a bird's eye view of the various facets of tissue engineering being touched by nanomaterials prior to your plunging into the more specific topics.

In comparison with nanomaterials such as nanoparticles and nanotubes, nanofibers are more suitable for use as scaffolds in tissue engineering as they are

morphologically similar to natural scaffolds and possess suitable properties such as high porosity, various pore-size distributions, and high surface-to-volume ratio. The majority of the investigations being carried out by tissue engineering researchers centers on utilization of nanofibers for development of artificial tissues. Therefore, the first four chapters in the book have been dedicated to provide an understanding of various aspects of nanofibers with respect to tissue engineering. The book begins with a chapter on *Nanotechnology and Tissue Engineering: The Scaffold Based Approach* providing an overview of the importance of nanotechnologies in developing scaffolds that closely mimic the structure and functions of the extra cellular matrix (ECM). Lakshmi S. Nair, Subhabrata Bhattacharyya and Cato T. Laurencin from the University of Virginia, USA, have demonstrated the importance of the scaffold approach for utilizing nanostructured materials in engineering ECM replacements. Of the various types of nanofibers currently under investigation for tissue engineering, polymeric nanofibers have been attracting a great deal of attention especially for applications in the area of ophthalmology, hepatic biology, nerve, skin, bone and cartilage regeneration, heart and vascular grafts, and stem cell research. Researchers Seow Hoon Saw, Karen Wang, Thomas Yong and Seeram Ramakrishna from the National University of Singapore have contributed the second chapter by bringing out an exhaustive review on *Polymeric Nanofibers for Tissue Engineering* covering different types of nanofibers, fabrication methodologies, degradation kinetics, biocompatibility and their applications in regeneration of several types of tissues. Focusing more specifically on electrospinning technology, researchers Wan-Ju Li, Rabie M. Shanti and Rocky S. Tuan from the National Institute of Arthritis, and Musculoskeletal and Skin Diseases in Bethesda, USA, demonstrate that this technology is a useful, economical, and easily set-up method for the fabrication of three-dimensional, highly porous and nanofibrous scaffolds which have been shown to support cellular activities and tissue formation. Their contribution in the third chapter, *Electrospinning Technology in Tissue Engineering*, is a thorough review on not only electrospinning technology per se but also on various chemical, physical and biological properties of nanofibers prepared using this technology. In the fourth chapter, electrospinning technology is compared with two other well known approaches, namely self-assembly and phase separation for fabrication of nano-fibrous scaffolds. Researchers from the University of Michigan in Ann Arbor, USA, systematically analyze the differences and unique characteristics of the three approaches for the development of scaffolds and their applications in tissue engineering. This chapter, *Nano-fibrous Scaffolds and their Biological Effects*, reviewed by Laura A. Smith, Jonathan A. Beck and Peter X. Ma provides some useful insights into achieving the dream of engineering three-dimensional tissue formations.

The fifth chapter in the book, *Nanophase Biomaterials for Tissue Engineering*, contributed by R. Murugan and S. Ramakrishna from the National University of Singapore is a source of information on nanoscale biomaterials in particular, ceramic and polymer-based materials that are being investigated for tissue engineering applications. In addition to the fabrication techniques for nanobiomaterials, the chapter also provides information related to their influence on cells and cell growth. In

the next chapter, the sixth, reader's attention is brought to nanotechnologies that are bringing solutions to long-standing problems with current orthopedic implants. The chapter, *Orthopedic Tissue Engineering using Nanomaterials*, written by Michiko Sato and Thomas J. Webster from Purdue University and Brown University respectively in West Lafayette, USA, discusses the effect of ceramic, metallic, polymeric, and composite nanomaterials on cellular functions particularly related to the bone. Norberto Roveri and Barbara Palazzo from the University of Bologna in Italy provide an up to date review on hydroxyapatite nanoparticles, which are being thoroughly investigated as materials for bone substitution. In the seventh chapter, entitled *Hydroxyapatite Nanocrystals as Bone Tissue Substitute*, they describe morphological, structural, chemical-physical, and surface characteristics of hydroxyapatite nanocrystals, followed by research investigations leading to understanding their high bioactivity and ability to induce bone regeneration and remodeling.

Moving away from nanofibers, ceramic nanomaterials and hydroxyapatite nanocrystals, the eighth chapter, *Magnetic Nanoparticles for Tissue Engineering*, authored by Akira Ito and Hiroyuki Honda from Kyushu University and Nagoya University respectively in Japan contains research investigations about application of the magnetic force-based tissue engineering technique (Mag-TE) to cell-seeding (termed "Mag-seeding") and its effectiveness in enhancing cell-seeding efficiency, leading to three-dimensional porous scaffolds for tissue engineering. In addition to magnetic nanomaterials, carbon nanotubes (CNTs) have been attracting the attention of life scientists. Due to their extraordinary physical, chemical, mechanical and electrical properties, in particular single-walled carbon nanotubes (SWNTs) are being touted as materials that have immense potential to interface directly with biological systems leading to innovative applications. In the ninth chapter, Peter S. McFetridge and Matthias U. Nollert from the University of Oklahoma in Norman, USA, delve deeply into the applications of SWNTs in the field of tissue engineering. The chapter, *Applications and Implications of Single-Walled Carbon Nanotubes in Tissue Engineering*, provides the history behind the electrical stimulation of cells and the reasoning behind the use of SWNTs as a conductive material to support or promote organ regeneration with specific examples of applications of SWNT in tissue engineering from the literature.

Cellular engineering is conceptually more fundamental to tissue engineering and nanotechnologies are helping in modulating cellular functions as well. In the tenth chapter, a more specific case of the effect of nanomaterials on cellular engineering related to free radical mediated oxidative stress is examined. The chapter, *Nanoparticles for Cell Engineering—A Radical Concept*, is a contribution from the laboratories of Beverly A. Rzigalinski at Virginia College of Osteopathic Medicine and Virginia Polytechnic & State University in Blacksburg, USA. The authors describe in detail potential application of three nanoparticle redox reagents viz rare earth oxide nanoparticles (particularly cerium), fullerenes and their derivatives and carbon nanotubes in preservation of cellular redox status and treatment of disease. Adding to the specific case of cellular engineering described in the tenth chapter, Jessica Winter from Ohio State University in Columbus, USA, presents in the eleventh chapter an exhaustive review on engineering of cells using nanotechnolo-

gies. The chapter aptly entitled *Nanoparticles and Nanowires for Cellular Engineering* is a one-stop source of information on applications of nanostructures to cellular engineering in general and for manipulating specific cellular components. The chapter deals with a gamut of issues on nanomaterial-based cellular engineering related to a wide spectrum of biomedical applications ranging from tissue engineering, intracellular tracking, biosensing and drug delivery. The final chapter of the book is an excellent review on *Nanoengineering of Biomaterial Surfaces* contributed by Ashwath Jayagopal and V. Prasad Shastri from Vanderbilt University in Nashville, USA. In this chapter, a variety of surface engineering techniques are presented for achieving micro- and nanoscale surface features, in addition to their applicability in the construction of hard and soft materials and three-dimensional geometries relevant to cellular and tissue engineering. This chapter brings to close the first comprehensive treatise on nanotechnological approaches for tissue, cell and organ engineering and I am very confident that the book will be a knowledge base for further advances that are bound to take place in the near future.

and Cato T. Laurencin*

## 1.1

### Overview

Biodegradable porous three-dimensional (3D) structures have been extensively used as scaffolds for tissue engineering to temporarily mimic the structure and functions of the natural extracellular matrix (ECM). The ECM functions to provide 3D structure with mechanical and biochemical cues to support and control cell organization and functions. Even though macro- and micro-fabrication techniques enabled the development of highly porous 3D scaffolds that could support the adhesion and proliferation of cells, their ability to closely mimic the complex nanostructured topography and biochemical functions of the ECM is far from optimal. However, recent developments in nanofabrication techniques have afforded various nanostructured bioactive scaffolds. These include top-down approaches such as electrospinning and phase separation to develop nanofibrous scaffolds from polymer solutions or bottom-up approaches such as self-assembly to develop nanofibrous scaffolds from specifically designed bioactive peptide motifs. Although significant improvements are needed for these nanofabrication processes to produce scaffolds that could precisely mimic the structure and functions of the ECM, the developments so far have significantly enhanced our ability to recreate the natural cellular environment for regenerating tissues.

## 1.2

### Introduction

Tissue engineering has now emerged from the stage of infancy demonstrating proof of principle and developing various functional tissues using different approaches to the stage of an established scientific discipline capable of developing viable products for clinical applications. Tissue engineered skin can be considered as one of the first commercialized products developed using the principles of tissue engineering. In addition to clinical applications, tissue engineering has also

raised significant interest as a novel tool for investigating cell and developmental biology and developing novel drugs using tissues grown in 3D environments [1].

The ultimate goal of tissue engineering is to address the current organ shortage problem, i.e., development of an alternative therapeutic strategy to autografting and allografting, two common approaches currently used to repair or reconstruct damaged tissues or organs. Autografts and allografts have several shortcomings that significantly limit their applications. These include limited availability and donor site morbidity associated with autografts and risk of infection and immunogenicity associated with allografts [2]. Conversely, regeneration or repair of tissue using tissue engineering approaches attempts to recreate functional tissue using bioresorbable synthetic materials and other required components that can be routinely assembled and reliably integrated into the body without any of the above-mentioned adverse side effects. Tissue engineering thus holds promise to revolutionize current health care approaches to improve the quality of human life in a practical and affordable way.

The term “tissue engineering” was coined in 1987 during a National Science Foundation (NSF) Meeting inspired by a concept presented by Dr. Y.C. Fung of the University of California at San Diego [3]. At a subsequent workshop held by NSF in 1988, tissue engineering was defined as “the application of principles and methods of engineering and life sciences to obtain a fundamental understanding of structure–function relationships in novel and pathological mammalian tissues and the development of biological substitutes to restore, maintain and improve tissue functions” [4]. However, widespread interest of the scientific community in tissue engineering was triggered by two phenomenal reviews: one by Nerem [5] on cellular engineering and another by Langer and Vacanti on tissue engineering [6]. These reviews discuss in depth, for the first time, the possibilities of tissue engineering and presented some of the preliminary studies demonstrating proof of the concept. Figure 1.1 shows the process of tissue engineering [7]. The field of tissue engineering has now developed into a highly interdisciplinary science and has attempted to recreate or regenerate almost every type of human tissue and organ [8]. This was possible within a short time due to the highly multidisciplinary nature of the tissue engineering approach, which makes use of the combined efforts of basic and material scientists, cell biologists, engineers and clinicians. Several different definitions for tissue engineering followed the NSF consensus definition due to the interdisciplinary approach and our laboratory defines tissue engineering as “the application of biological, chemical and engineering principles towards the repair, restoration or regeneration of living tissues using biomaterials, cells and factors, alone or in combination”, describing the different possible approaches for tissue engineering [9]. Thus, three or more approaches are currently used to regenerate tissues using the principles of tissue engineering. One approach is the guided tissue engineering that uses a biomaterial membrane to guide the regeneration of new tissue; another approach called cell transplantation uses the application of isolated cells, manipulated cells (gene therapy) or cell substitutes to promote tissue regeneration. A third approach uses biomaterial in combination with bioactive molecules called growth factors to induce and guide tissue regenera-

Fig. 1.1. Scheme showing the process of tissue engineering. (Adapted from Ref. [7] with permission from Elsevier.)

tion and a fourth, the most extensively investigated approach, uses biomaterials in combination with cells (with and without biological factors). Within the cell–biomaterial combination approach two different methods are used, a closed system and an open system. In a closed system cells are protected from the immune response of the body by encapsulating in a semi-permeable membrane that can allow nutrient and waste transport to keep them functional. In an open system, the cell–biomaterial construct is developed *in vitro* and is directly implanted in the body. In the open system, biomaterials are used to develop supporting matrices or scaffolds for cell implantation. Bioresorbable polymers (both synthetic and natural polymers) are commonly used for fabricating scaffolds. Several fabrication techniques are used to develop porous 3D scaffolds from these biomaterials. The function of the scaffold is to guide the regeneration of new tissue and to provide appropriate structural support, i.e., to mimic the structure and functions of natural extracellular matrix (ECM). The exogenous cells delivered through the scaffolds along with endogenous cells are used to regenerate or remodel the damaged tissue. During this process the bioresorbable scaffold will degrade and disappear resulting in the formation of remodeled native tissue [8]. Research to date has identified different cell sources, including stem cells that, when combined with degradable, matrices can form 3D living structures. The technique has led to the development of many tissues in the laboratory scale such as bone, ligament, tendon, heart valves, blood vessels, myocardium, esophagus, and trachea. However, several engineering and biological challenges still remain for successful clinical translation of the labo-

ratory research to make tissue engineering a reliable route for organ/tissue regeneration. These include mimicking the complex structure and biology of the ECM using synthetic materials, controlling cell interactions using artificial scaffolds, vascularization of cell–scaffold constructs, development of efficient bioreactors for *in vitro* culture, storage and translation [10]. The present chapter reviews progress made in tissue engineering to overcome some of the engineering and biological challenges in developing ideal 3D synthetic scaffolds by harnessing nanotechnology and material science.

This chapter also overviews the importance of mimicking the structure and functions of the ECM when developing ideal scaffolds for tissue engineering and the recent developments and advantages of nanotechnology assisted techniques to fabricate scaffolds that closely mimic the ECM.

After the present section, which gives a brief introduction to tissue engineering, Section 1.3 lays out the importance of scaffolds in tissue engineering and the need for mimicking the structure and functions of the ECM. Section 1.4 reviews the important aspects of the structure and functions of the ECM that need to be mimicked to develop ideal scaffolds for tissue engineering. Section 1.5 includes in-depth examination of the applications of nanotechnology in developing ECM mimic nanostructured scaffolds for tissue engineering. Section 1.6 reviews some recent studies, demonstrating the advantages of nanostructured scaffolds for tissue engineering, and Section 1.7 overviews some of the current applications of nanostructured scaffolds for engineering different tissues.

### 1.3

#### The Importance of Scaffolds in Tissue Engineering

The importance of the extra-cellular matrix (ECM) in cellular assembly and tissue regeneration was demonstrated by the pioneering works of Mina Bissell along with others [11]. The cells in mammalian tissues are connected to the ECM which provide three-dimensionality, organize cell–cell communications and provide various biochemical and biophysical cues for cellular adhesion, migration, proliferation, differentiation and matrix deposition. Their studies have shown the significant differences in behavior of cells when grown in two-dimensional (2D) and 3D environments [11].

Even though 2D cell culture techniques have been extensively used by cell biologists to derive valuable information regarding cellular processes and cell behavior, in the light of recent studies it is evident that *in vivo* tissue response can be simulated only through 3D cell culture techniques [12]. Considering the complex biomechanical and biochemical interplay between cells and the ECM, it is apparent that tissue engineers will be unable to address the biological subtleties if the cells are grown on 2D biomaterials before implantation in the body.

The strategy of using bioresorbable porous synthetic scaffolds as artificial ECM was introduced by Langer and Vacanti in 1988 [13]. This seminal paper significantly influenced investigators throughout the world in the practical area of scaf-

fold based tissue engineering and has led to hundreds of research articles and patents to date.

A bioresorbable  $\alpha$ -hydroxyester was used as the candidate polymer in the first study by Langer's group for developing the scaffolds. The  $\alpha$ -hydroxyesters being aliphatic polyesters have the ability to undergo hydrolytic degradation *in vivo* and therefore could resorb and disappear once regeneration is complete. Studies that followed have shown that the properties of the biomaterial play a crucial role in the success of the tissue engineered construct. Since the dynamics of different tissues vary significantly, appropriate materials need to be carefully chosen to satisfy the properties required. This knowledge has led to the design and development of several bioresorbable polymeric biomaterials to fabricate scaffolds for engineering different types of tissues [14]. These include synthetic polymers such as  $\alpha$ -hydroxyesters, polyanhydrides, polyphosphazenes, polyphosphoesters and natural polymers such as collagen, gelatin, chitosan and hyaluronic acid [15, 16]. Among these, synthetic polymers are mostly preferred for developing tissue engineering scaffolds due to immunogenic problems and batch by batch variations associated with many of the natural polymers.

Apart from the properties of the materials, the 3D architecture of the scaffold is very important when attempting to mimic the structure and functions of the natural ECM. Several unique fabrication processes have been developed to form 3D porous structures from bioresorbable materials as scaffolds for tissue engineering [9, 17]. These 3D structures have been primarily designed to direct tissue growth by allowing cell attachment, proliferation and differentiation. Most of these fabrication processes have been designed based on a set of criteria that have been identified as crucial to promote cellular infiltration and tissue organization. Some of the basic requirements of scaffolds for tissue engineering, summarized by Agarwal and Ray [18], are that they should be:

- Biocompatible.
- Bioresorbable and hence capable of being remodeled.
- Degrade in tune with the tissue repair or regeneration process.
- Highly porous to allow cell infiltration.
- Highly porous and permeable to allow proper nutrient and gas diffusion.
- Have the appropriate pore sizes for the cell type used.
- Possess the appropriate mechanical properties to provide the correct micro-stress environment for cells.
- Have a surface conducive for cell attachment.
- Encourage the deposition of ECM by promoting cellular functions.
- Able to carry and present biomolecular signals for favorable cellular interactions.

Various studies have been performed so far, using macro- and micro-fabrication techniques, to form 3D scaffolds that could address the requirements listed above to develop ideal synthetic scaffolds with some success. The results of these studies have been extensively reviewed [17, 19–23]. Particulate leaching can be considered as one of the first techniques widely used to develop micro-porous matrices from

**Fig. 1.2.** Porous bioresorbable poly(L-lactic acid) foams developed by particulate leaching. (Adapted from Ref. [24] with permission from Elsevier.)

biodegradable polymers for tissue engineering applications (Fig. 1.2) [24–26]. The technique has several advantages such as ease of processing, ability to develop foams from wide range of polymers, and the ability to control the pore size by varying the size of the porogen. However, the porogen leaching process has some serious limitations to fabricate scaffolds for tissue engineering, such as the inability to completely remove the porogen from the porous matrix and to control the pore shape and maintain interconnectivity between pores. Consequently, several modifications to the particulate leaching method as well as new fabrication techniques were developed. Some of the newer processes include sintered microsphere process and rapid prototyping.

Sintered microsphere matrix fabrication technique of Laurencin was developed as a robust technique to fabricate 3D porous structures with reproducible porosities and interconnected pore structure [27, 28]. Sintered microsphere matrices are developed by heat sintering bioresorbable polymeric microspheres (Fig. 1.3)

**Fig. 1.3.** SEM showing the 3D porous structure of a PLAGA scaffold formed by the sintered microsphere fabrication process. (Adapted from Ref. [29] with permission from Elsevier.)

**Fig. 1.4.** SEM showing human osteoblast attachment and infiltration in porous PLAGA sintered microsphere matrix. (Adapted from Ref. [29] with permission from Elsevier.)

[27, 28]. Poly(lactide-*co*-glycolide)s (PLAGA) having different ratios of lactic acid (LA) and glycolic acid (GA) were used as the polymers to develop sintered matrices. Polymeric microspheres are prepared by the commonly used solvent evaporation technique [27, 28]. The sintered microsphere matrices demonstrated controllable pore size and interconnectivity depending on the size of the microspheres used to fabricate the matrices. Thus, the pore size of the scaffolds could be varied from 100 to 300  $\mu\text{m}$ , depending on the size of the microspheres used. The 3D porous sintered microsphere scaffolds were investigated as potential candidates for bone tissue engineering and showed appropriate mechanical properties for orthopedic applications. The osteoconductivity of the porous 3D matrices were evaluated using human osteoblast cells and showed good osteoblast attachment and infiltration (Fig. 1.4) [28, 29]. An *in vivo* evaluation demonstrated the efficacy of the bioresorbable sintered microsphere matrix in healing a critical segmental bone defect in a rabbit model [30]. Figure 1.5 shows the X-ray of a bone defect site implanted with a sintered microsphere matrix after eight weeks of implantation. The study showed the formation of new bone throughout the entire structure of the implant indicating significant bone regeneration at the defect site. The fabrication process led to the development of porous scaffolds having high interconnectivity and good mechanical integrity, with the percentage pore volume of the matrices equal to  $\sim 40\%$ .

Recently, different types of computer-assisted design and manufacturing processes (CAD/CAM) were investigated as potential methods to develop scaffolds

**Fig. 1.5.** Radiograph of a defect site implanted with sintered microsphere matrix, bone marrow cells and BMP-7 after 8 weeks of implantation, showing significant bone regeneration.

having controllable pore size, shape and porosity. One of the first developed computer assisted techniques for scaffold fabrication was solid free form fabrication or 3D printing. In this process a complex 3D structure is first designed using CAD software. An inkjet printing of a binder on appropriate polymer powder layers is then used to fabricate the porous structure based on the computer model. Even though complex structures can be designed and fabricated using this automated process, the preciseness of the technology has various limitations imparted by the size of the polymer particle, size of the binder drop and the type of the nozzle tip [31]. Another rapid prototyping technique extensively investigated for developing porous scaffolds for tissue engineering is fused deposition model (FDM) developed by Hutmacher [22, 23]. The FDM can be used to develop 3D structures from a CAD or an image source such as computer tomography (CT) or magnetic resonance imaging (MRI) of the object. The computer design is then imported into software that mathematically slices the model into different horizontal layers. The FDM extrusion head and the platform are then synchronized to deposit fused polymeric melt based on the computer model, one layer at a time. Figure 1.6 shows a porous 3D structure developed from a bioresorbable polymer poly(caprolactone) (PCL). The FDM process has several advantages, such as the ability to precisely control the pore size, pore morphology and pore interconnectivity. The process enables also the development of multiple-layer designs and different localized pore morphologies needed for multiple tissue types or interfaces. Another advantage of FDM is the good mechanical properties and structural integrity of the scaffolds due to the use of mechanically stable designs and proper fusion between individual material layers. However, the fabrication process has some limitations that make it less than an optimal method for developing porous matrices for tissue engineering applications. These include the limitations associated with the processing technique such as the requirement of temperature, the need for materials that are appropriate for fused deposition, the necessity of supporting structures to construct complex structures, and variable pore openings observed along different axis [32].

**Fig. 1.7.** (A) Pro/Engineer rendered CAD image of prototype PPF construct. The series of slots and projections test the interslice PPF registration ( $50 \times 4$  mm). (B) Three-dimensional structure developed from CAD model data from PPF. (Adapted from Ref. [33].)

Several stereolithographic techniques were investigated to develop porous 3D matrices from polymers to overcome the problems associated with temperature-assisted fabrication methods. Stereolithographic techniques have been extensively used to develop 3D structures from photopolymerizable polymer solutions such as poly(propylene fumarate) (PPF) in presence of photoinitiators (Fig. 1.7A and B) [33]. Preliminary studies showed the feasibility of developing structures having controlled pore sizes ( $50\text{--}300\ \mu\text{m}$ ) and different layer thicknesses using a highly controlled laser light source.

Most of the techniques described above are used to develop 3D structures from synthetic hydrophobic polymers. However, a wide range of techniques using hydrophilic polymers have also been investigated to develop novel structures as cell delivery vehicles. Hydrophilic polymers are good candidates to develop tissue engineering scaffolds due to their high water content and ability to mimic the properties of various tissues. One such technique is the use of photolithography to pattern hydrogel films with hydrophilic porous structures [34].

The fabrication techniques discussed so far have been developed to fabricate acellular scaffolds that are populated with appropriate cells after fabrication for tissue engineering applications. However, this process has the limitation of obtaining uniform cell distribution throughout the scaffold even with the use of bioreactors during *in vitro* culture. Therefore some studies have also focused to develop materials and fabrication processes to form cellular scaffolds. These studies have led to the development of different types of stimuli sensitive hydrophilic polymers that can be used to encapsulate cells under mild conditions to form cellular scaffolds [35, 36]. Cells can be uniformly distributed in the aqueous stimuli sensitive polymer solutions before the gelling process (Fig. 1.8) [37]. Attempts are currently underway to combine this process with the lithographic techniques to form cell incorporated 3D structures under very mild conditions.

**Fig. 1.8.** Photomicrograph showing chondrocytes encapsulated within a hydrogel after 21 days in culture stained using Live dead stain (green shows live cells and red shows dead cells). (Adapted from Ref. [37] with permission from Elsevier.)

Another strategy recently developed to form structures with uniform distribution of cells throughout the scaffold is cell printing [38]. This approach combines rapid prototyping procedures with microencapsulation to print viable free form structures using bio-ink with custom-modified ink-jet printers. One advantage is the feasibility of placing quickly and precisely various cells layer by layer to develop multi-cell systems. However, the process is still in its infancy and further research is necessary with regards to developing appropriate bio-ink, optimizing the rheologic and surface properties of the inks, and designing printers optimized for these properties [39]. Another strategy is organ printing, which makes use of nature's ability to assemble many tissue forms such as blood vessels. The technology is based on the hypothesis that when cell aggregates are placed in close approximation they can assemble to form a disc or tube of tissue (Fig. 1.9) [40–42]. This process is also still in its infancy, has various scaling up limitations and further studies are needed to demonstrate the potential of the approach.

The previous discussion demonstrates the importance of the ECM in tissue repair and regeneration and serves as a brief overview of the attempts made to mimic the structure of the ECM using polymeric biomaterials and various macro/micro fabrication techniques to develop interconnected porous structures having porosities in the micron range. These studies have led to the design and synthesis of novel bioresorbable materials with unique chemistries, fabrication of 3D structures having different properties and demonstrated the feasibility of growing cells in appropriate 3D forms *in vitro* and *in vivo* with the help of these scaffolds. Figure 1.10(A and B) shows the feasibility of developing an artificial ear on the back of a mouse using a bioresorbable PCL scaffold having the macroscopic shape of an ear seeded with chondrocytes [43].

Even though these materials and fabricated 3D structures showed the feasibility of 3D organization of cells into tissue, they are far from being ideal for develop-

ing fully functional tissues and organs *in vivo* in a reproducible way under clinical setting.

So far, most of the biomaterial design has focused on developing materials that are capable of degrading at a rate that matches tissue regeneration, have the ability to degrade into non-toxic degradation products and can support the adhesion and proliferation of cells without placing much emphasis on the bioactivity of the materials. Conversely, most fabrication techniques are focused on developing scaffolds with macroscale properties, such as the ability to provide sufficient transport prop-

erties (interconnected microporous structure), and adequate mechanical properties (to match the properties of the tissue to be replaced or repaired).

However, the organization of the cells, and hence the properties of the tissue, are highly dependent on the structure of the ECM, which has a hierarchical structure with nano-sized features. Figure 1.11 shows the ultrastructure of collagen fibrils in human aortic valves, illustrating the nanoscale topographic features of the native tissue [44]. Thus, successful fabrication of a fully functional tissue is a far more complex and involved process that requires the creation of an appropriate environment at both a micro- and nano-scale level to allow for cell viability and function along with macroscopic properties [45]. In fact, just as important as these structural features are the biological principles that govern cell–cell and cell–matrix interactions. These interactions form the basis of cellular performance and appropriate tissue organization and are controlled by various biochemical cues present in the natural ECM. The recreation of this process requires the incorporation of various bioactive molecules in synthetic porous scaffolds with molecular precision to mimic the functions of the ECM. Recently, a paradigm shift has been observed from developing macro/micro-structured scaffolds to nanostructured bioactive scaffolds in an attempt to improve tissue design and reconstruction in reparative medicine [46, 47].

#### 1.4

##### Structure and Functions of Natural Extracellular Matrix

Since the ultimate goal of tissue engineering is to develop tissue substitutes that could temporarily mimic the structure and functions of damaged tissue to be replaced, it is crucial that the engineered substitutes mimic the natural tissue structurally and functionally for successful regeneration. Extensive research performed in different areas such as tissue and organ development during embryogenesis, the

normal tissue healing process, tissue structure and functions and development of various characterization techniques at the micro- and nano-scale levels have significantly enhanced our ability to mimic native tissue. The human body is a very complex structure that is organized in a hierarchical way with body composed of systems, systems composed of organs, organs composed of tissues and tissues composed of cells, vasculature and extracellular matrix. In tissues, the ECM provides the structured environment with mechanical and biochemical cues that enable the cells to interact with each other and with the ECM to allow for control of growth, proliferation, differentiation and gene expression.

The ECM is composed of a physical and chemical crosslinked network of fibrous proteins and hydrated proteoglycans with glycosaminoglycan side chains (collectively called the physical signals) in which other small molecules (such as growth factors, chemokines and cytokines) and ions are bound. Figure 1.12 shows the ultrastructural features of an ECM with a condensed basement membrane and the stromal tissue [48]. The ECM proteins are mainly composed of more than 20 different types of collagens as well as elastin, fibrillin, fibronectin, and laminin [49]. In the natural environment these macromolecular ECM components are secreted by the cells and then modified and assembled to form the matrix during the tissue development and repair process. Among the ECM proteins, type I collagen is mainly involved in the formation of the fibrillar and microfibrillar structure of the ECM. Type I collagen molecules ( $\sim 300$  nm long and  $\sim 1.5$  nm in diameter) are packed to form collagen fibrils. Each collagen fibril displays a characteristic

**Fig. 1.12.** Ultrastructure of ECM matrix. Adjacent to an epithelial cell (E) is the basement membrane with its amina lucida (LL) and lamina densa (LD). The interstitial

matrix contains collagen fibrils and is close to the basement membrane anchoring fibrils (AF), composed of type VII collagen fibrils. (Adapted from Ref. [48].)

**Fig. 1.13.** Structure and orientation of collagen fibrils of various tissues. (A) Mature rat ligament-collagen fibrils are primarily aligned along the long axis of the ligament. (Adapted from Ref. [51] with permission from

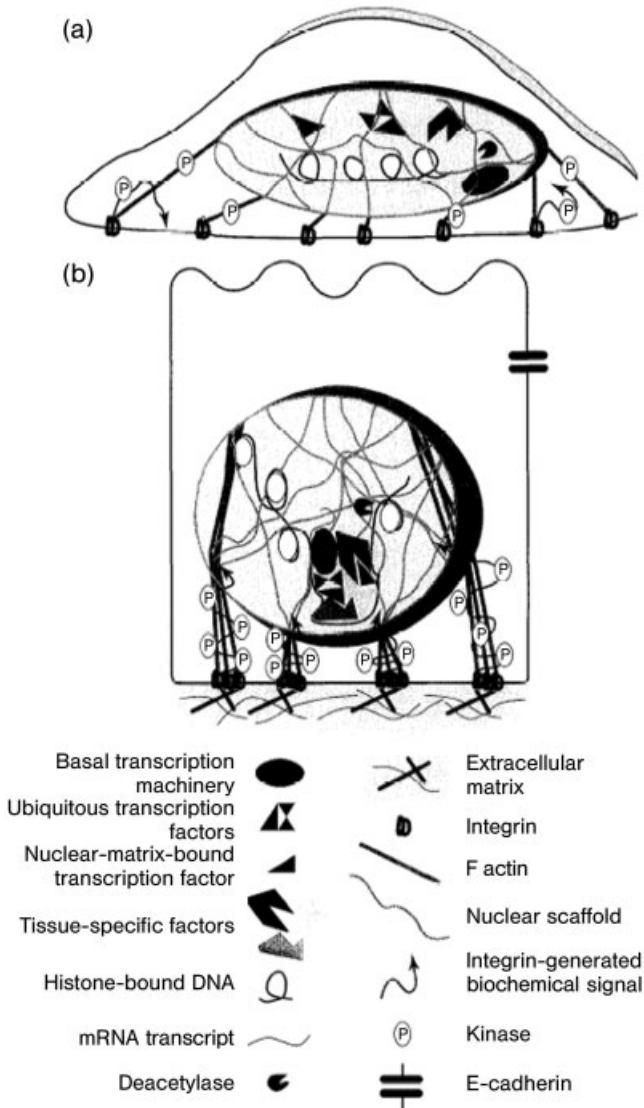

Elsevier.) (B) Mineralized fibrils in trabecular bone without the non-fibrillar matrix. (Adapted from Ref. [52] with permission from Elsevier.) (C) Articular cartilage. (Adapted from Ref. [53] with permission from Elsevier.)

~67 nm D-repeat with uniform or multi-model diameter distribution varying from ~25 to 500 nm and several micrometers in length, depending on the nature of the tissue. All of these molecules are arranged in a unique tissue specific 3D architecture [50]. Figure 1.13 shows the different arrangement patterns of collagen fibrils as observed in three different types of tissues (A: ligament; B: bone; and C: articular cartilage) [51–53]. Fibrils show varied orientation in different tissue types that give the appropriate physical and mechanical properties to the tissue. Collagen fi-

brils are further bundled together to form collagen fibers. The hierarchical structure of the ECM has length scales, varying from a few nanometer (nm) to millimeter (mm) that control the cellular functions and corresponding tissue properties. The fact that cells are highly sensitive to the environmental structural features has been demonstrated using *in vitro* cell culture studies on nanopatterned surfaces fabricated by electron beam lithographic techniques. These studies revealed that the cells are sensitive to nanoscale dimensions and could react to objects as small as 5 nm [54]. This can be attributed to the structural details ECM presents to the cells *in vivo*. Thus, the 3D hierarchical structure of the ECM significantly affects cellular behavior and hence tissue functions through topographical cues.

However, the function of the ECM is not just to provide an inert support for cellular adhesion. Almost all of the molecules present in ECM have both structural and functional roles. The ECM serves mainly to organize cells in space to give them form, provide them with environmental signals, to direct site-specific cellular regulation, and separate one tissue space from another. Thus the orientation and position of cells with respect to each other is dictated by the ECM and the orientation varies with different tissues. This is achieved by providing chemical cues such as insoluble signals or factors of the ECM which could interact with the soluble signals of cells along with the structural features to promote adherence, migration, division and differentiation of cells. In a natural tissue the ultimate decision of cellular processes such as adhesion, proliferation, differentiation, migration and matrix production takes place as a result of this continuous cross-talk between cells and ECM effectors [55]. Figure 1.14 shows a schematic representation of various interactions taking place between cells and ECM during tissue organization and function [50].

At least three mechanisms have been identified through which the ECM can regulate cell behavior. The first mechanism is through the composition of the ECM such as various proteins and glycosaminoglycans, which is highly tissue and cell specific. The second mechanism is through synergistic interactions between growth factors and matrix molecules. The growth factors are found to bind with the ECM through the glycosaminoglycan side chains or protein cores and this increases the stability of growth factors and creates the appropriate cellular environment or niche to regulate cell proliferation and differentiation. The third mechanism is through the cell surface receptors or integrins that mediate cell adhesion to extracellular matrix components [56]. The integrin–ECM ligand interactions play a major role in anchoring cells to the ECM. An integrin is  $\sim 280$  Å long and consists of one  $\alpha$  (150–180 kDa) and one  $\beta$  ( $\sim 90$  kDa) subunit, both of which are type I membrane proteins [57]. About 18 $\alpha$  and 8 $\beta$  subunits that can form 24 different heterodimers have been identified so far and the ligand specificity of the integrin is determined by the specific  $\alpha\beta$  subunit combination [58]. Integrin-mediated cell adhesion to the ECM occurs through a cascade of processes. First cell attachment occurs where cell attach to the surface with ligand binding through integrins to withstand gentle shear forces followed by cell spreading. Next organization of actin into microfilament bundles or stress fibers occurs. In the last stage the formation of focal adhesion occurs, which links the ECM to molecules of the actin

**Fig. 1.14.** Scheme showing the various interactions between cells and the ECM during tissue organization and repair. (a) Flattened cells in the absence of ECM. Due to incompatible cytoskeletal organization no signals originating from integrin receptors can be properly propagated. (b) In the presence of ECM, binding of ECM components to integrin receptors induces integrin clustering and generates biochemical signals. Cytoskeleton filaments intimately associated with the cytoplasmic domains of the integrins are

modified and reorganized to facilitate interaction of the incoming signals with downstream mediators. This reorganized cytoskeleton can evoke further architectural changes via its association with the nuclear matrix. The subsequent nuclear reorganization brings together incoming signaling molecules, transcriptional activators, histone deacetylases, and the basal transcriptional machinery to promote the assembly of a functional transcriptional complex on the gene. (Adapted from Ref. [50] with permission from Elsevier.)

cytoskeleton. The focal adhesion is mainly composed of clustered integrins and other transmembrane molecules. In this process, the integrins have two-fold activities, anchoring the cells to the ECM and signal transduction through the cell membrane [59]. This allows for continuous cross-talk between ECM and cells which is highly crucial for proper tissue functioning [60].

Several studies have been performed to characterize and analyze the largest and most stable types of contacts between the ECM and cells. These include focal adhesions, focal contacts or adhesion plaques, fibrillar adhesions and hemidesmosomes (Table 1.1) [61]. Several morphological criteria have been used to characterize the

**Tab. 1.1.** Characterization of cell–matrix contact structures.

Contact type	Dimensions	IRM Image separation from substratum	Characteristic associations
Close contact	(Associated with lamellipodium)	Grey in IRM 30–50 nm from substratum	Submembranous densities parallel to F-actin meshwork at plasma membrane
Filopodium	20–200 $\mu\text{m}$ long 0.2–0.5 $\mu\text{m}$ diameter	grey in IRM	core bundle of F-actin, integrins, syndecans
Focal contact/focal adhesion/	0.25 $\mu\text{m}$ wide 1.5 $\mu\text{m}$ long	Black in IRM 10–15 nm from substratum	At termini of microfilaments, contain integrins, syndecan-4, low tensin content
Hemidesmosome	Plaque ca. 0.15 $\mu\text{m}$ by 0.04 $\mu\text{m}$	–	Connect to intermediate filaments, contain $\alpha 6\beta 4$ integrin, plectin, BP230
Matrix assembly sites/fibronexus/fibrillar adhesions	ca. 3–5 $\mu\text{m}$ long	White in IRM 100 nm from substratum	ECM cables align parallel with microfilaments, contain $\alpha 5\beta 1$ and tensin
Podosomes	0.2–0.4 $\mu\text{m}$ diameter	Dark in IRM	Core bundle of actin perpendicular to substratum, in macrophages contain $\beta 2$ integrins, fimbrin
Spike or microspike	2–10 $\mu\text{m}$ long 0.2–0.5 $\mu\text{m}$ diameter	Grey in IRM	Core bundle of F-actin, contain fascin

contact type and size of the contact including evaluation of phase-dark structures detected by phase contrast or interference reflexion microscopy (IRM), electron-dense and organized structures detected by transmission electron microscopy and cell surface topography detected by scanning electron microscopy (SEM) [61]. Table 1.1 shows that even though the size of a cell is  $\sim 10\ \mu\text{m}$ , the activities leading to cell adhesion and the following processes take place mainly at the nanometer level.

Detailed studies on integrin-mediated cell adhesion to the ECM clearly point to the importance of ECM ligands on cell behavior. In addition to the structure and size of the ECM–cell contact points, several studies have been performed to elucidate the biological molecules involved in the interactions. The results of these studies have significantly influenced tissue engineers and have become a great tool in their attempts to recreate a natural cellular environment using synthetic scaffolds. Many of the identified biological molecules have been utilized to decorate synthetic scaffolds to form ligand-functionalized matrices to increase their bioactivity. Various surface modifications or one-dimensional nanotechnological modifications are used to develop ligand functionalized scaffolds [62].

Several cell recognition motifs such as fibronectin, vitronectin, collagen and laminin present in the natural ECM have been used to modify the surface of biomaterial scaffolds to increase their bioactivity [63–65]. Even though preliminary studies show significant promise in developing biomimetic scaffolds, the modification of matrices using bioactive proteins has several limitations. Proteins are bioactive molecules and can elicit an immunological response as they are mostly isolated from different sources and also possess the risk of associated infections. Another serious limitation associated with protein surface modification is that the surface topography and chemistry of the synthetic matrix could influence the orientation and conformation of the attached or adsorbed protein, thereby affecting its functionality. Owing to the low stability of the proteins, the immobilization process as well as subsequent storage could also affect its patency.

The breakthrough research that revolutionized the biomimetic surface modification approach towards biomaterials development is the finding that low molecular peptides from ECM proteins such as the tetrapeptide “arginine-glycine-aspartate-serine” (GRGDS) sequence could significantly modulate cellular behavior [66, 67]. Following this, several RGD-containing sequences were found in other ECM proteins and several other short linear adhesive sequence motifs have also been identified as active molecules to promote cell adhesion, proliferation and migration. Several studies have been performed to elucidate the mechanisms by which these sequences could interact with cells. The tetrapeptide and tripeptide sequences such as arginine-glycine-aspartate can bind to members of the integrin family of the transmembrane receptors, thereby activating a series of signaling events within the bound cells favorably affecting their functions [67–72]. The RGD sequence has been quickly identified as a potential candidate to develop biomimetic scaffolds and extensive research has followed. Because the RGD sequence is present in multiple ECM proteins such as fibronectin, laminin, collagen and vitronectin, a broad range of cell types could respond to this peptide sequence. Furthermore, small peptide sequences are highly stable compared to the corresponding proteins [73], they

are cost effective [74], can be packed densely on surfaces due to their small size, and can selectively address one type of cell adhesion receptors for controlled cell adhesion during multicellular tissue development [68].

Various techniques have been attempted to immobilize these biological motifs on synthetic biomaterial surfaces to increase their bioactivity [75]. Stable immobilization of these ligands to the surface is crucial for proper functioning, as the peptide sequence should be able to withstand the cells contractile forces during initial attachment and prevent internalization by cells [76, 77]. The most extensively investigated approach to covalently immobilize the RGD sequence on surfaces is by using active functional groups such as hydroxyl, carboxyl or amino groups on the RGD and polymer surfaces, involving carbodiimide chemistry [75]. For polymers devoid of these functional groups, several approaches were attempted, such as coating the surface with a polymer having such active groups such as polylysine [75, 78] and coating with RGD modified pluronics via hydrophobic interactions [75, 79]. Another approach to incorporate active groups is by copolymerizing with a monomer having active groups such as acrylic acid [75, 80] or lysine in the case of poly(lactic acid-co-lysine) [75, 81]. Another extensively investigated approach is chemical or physical surface modification of biomaterials such as alkaline hydrolysis [75, 82], oxidation [75, 83], reduction [75, 84], etching [75, 85] or plasma deposition [75, 86].

Even though immobilization via carbodiimide chemistry is a versatile approach to covalently immobilize RGDs on various surfaces, it is not a highly selective process as RGD has two reactive groups (amino and carboxyl) and therefore can lead to various un-wanted side reactions. A recent study has demonstrated the feasibility of incorporating RGDs on the surface of polymers without the various functionalization routes described above. The approach is called chemoselective ligation. Under mild conditions, selected pairs of functional groups are used to form stable bonds with RGD without interfering with other functional groups [87]. Thus thiol-functionalized surfaces can be modified using bromoacetyl containing RGD cyclopeptides [88] or a thiol-containing RGD can be linked to maleinimide-functionalized surfaces under mild conditions [89]. Benzophenone or aromatic azide functionalized RGD has been developed as a versatile technique to immobilize RGDs on the surface [90–92] by streptavidin–biotin capture [93].

In addition to direct linking, attachment of RGD to surfaces using spacers significantly increases the activity of immobilized RGDs. This increased activity has been attributed to the ability of RGD peptide binding site to reach the hollow globular head of an integrin. Several studies have confirmed a spacer length of 35–40 Å is optimal for maximum activity [75, 94]. However, recent studies on the crystal structure of the ligand bound extracellular domain of the  $\alpha V\beta 3$  integrin show the RGD binding site on the surface region of the head of the  $\alpha V\beta 3$  integrin, suggesting that it is only a few angstroms deep [71]. This indicates that spacers may not be needed for the ligand–integrin interaction. The experimental improvement in activity of RGDs with spacers found in some studies has been attributed to the spacer presumably contributing to the surface roughness of the substrates [75].

All of these approaches have shown the feasibility of covalent attachment of

RGDs on the surface of polymeric biomaterials and several studies were also performed to demonstrate the bioactivity of RGD immobilized surfaces. Numerous polymers, various immobilization techniques, different RGD peptides and different cell types were used to investigate the biological activity of biomimetic surfaces. The cell behavior towards RGD modified surfaces has been found to depend on various parameters such as the structure and conformation of RGD as well as the density and arrangement of RGD on the surface. Some of the RGD peptides investigated include RGD, RGDS, GRGD, YRGDS, YRGDG, YGRGD, GRGDSP, GRGDSG, GRGDSY, GRGDSPK, CGRGDSY, GCGYGRGDSPG, and RGDSPASSKP peptides [75]. One study systematically investigated the cell attachment activity of different types of RGDs including RGD, RGDS (from fibronectin), RGDV (from vitronectin) and RGDT (from collagen) immobilized on polymeric surfaces. The study demonstrated that tetrapeptides show distinct increases in cell attachment compared to tripeptides indicating that peptides with higher integrin affinity bear higher cell attachment [80]. No significant differences in cell attachment between the tetrapeptides were observed [80]. Another study showed that cyclic RGD peptides on surfaces can show higher activity than linear molecules, which has been attributed to their higher stability and increased  $\alpha\beta3$  binding of cyclic peptide compared with linear molecules [95].

Another unique application of RGD modified biomaterials is the development of materials that can promote selective adhesion of various cell types. Since it has been found that each cell type has its own typical pattern of different integrins, RGD peptides could be used to promote selective cell adhesion on a surface by modifying the surface with an appropriate RGD [69]. Some *in vitro* studies have demonstrated the feasibility of integrin specificity of RGD leading to selective cell adhesion on RGD modified surfaces [69]. The study showed that fibroblasts rather than endothelial cells preferably adhered to a RGDSPASSKP (which is selective to  $\alpha5\beta1$ ) modified surface [96]. Similarly, enhanced fibroblast attachment was observed to an  $\alpha5\beta1$  integrin selective GRGDSP peptide functionalized surface where as  $\alpha5\beta3$  selective cyclic G\*PenGRGDSPC\*A supported higher smooth muscle cell and endothelial cell densities [97]. However, no data is currently available to show if such modification holds for more complex *in vivo* environments since cells could express more than one type of integrin and also because the integrin expression pattern of a cell is a highly dynamic phenomenon.

The surface density of RGD on the material also has a profound effect on the number of cells attached as well as cell spreading, cell survival, focal contact formation and to some extent proliferation. Studies have shown a sigmoidal increase in cell attachment with RGD concentration on the surface, indicating a critical minimum density for cell response [94]. Thus Neff et al. demonstrated that maximum proliferation of fibroblast occurred on surfaces with intermediate surface concentration ( $\sim 1.33 \text{ pmol cm}^{-2}$ ) [79]. Another study by Massia and Hubbell using RGD functionalized glycophasse glass surface has shown that a minimal amount, as low as  $1 \text{ fmol RGD peptide cm}^{-2}$ , is sufficient for cell spreading on the surface and as low as  $10 \text{ fmol cm}^{-2}$  sufficient for formation of focal contacts and stress fibers [98].

However, a higher RGD peptide concentration requirement has been reported for polymers and has been attributed to the entropic penalty that results from attachment of a peptide to flexible polymer chain compared to a rigid glass surface as well as the inefficient transmission of forces through polymer surfaces [75, 99]. Studies have shown that in addition to surface concentration, the mode of presentation of ligands also could affect integrin behavior [100]. One study by Maheshwari et al. evaluated surfaces with controlled overall peptide density and controlled nanoscale spatial ligand distribution with an overall RGD distribution of 0.15–20.50 nmol cm<sup>-2</sup> [101]. The results demonstrated that a significantly higher fraction of fibroblasts showed higher shear stress resistance and exhibited well-formed stress fibers and focal contacts when the ligand was presented in a clustered versus a random individual format. The use of a higher affinity peptide GRGDSPK afforded a lower RGD density of 0.06–0.88 nmol, showing that activity of the RGD is also very important [102].

Nanoscale RGD clustering on the surface of biomaterials seems to be a promising approach to elicit favorable cell responses with minimal amounts of RGD peptides. Studies are ongoing to determine the technique that could be used to create nanoscale clustering on the surface as well as to determine which arrangement elicits a particular cell response.

Thus the foremost challenge in developing a tissue engineered construct is the development of a resorbable synthetic microenvironment that could closely mimic the complex hierarchical micro-nano architecture of the ECM along with the molecular level spatial organization of biological cues found in native tissue *in vivo*.

## 1.5

### Applications of Nanotechnology in Developing Scaffolds for Tissue Engineering

Nanotechnology has been defined as “research and technology development at the atomic, molecular and macromolecular levels in the length scales of approximately 1–100 nm range, to provide a fundamental understanding of phenomena and materials at the nanoscale and to create and use structures, devices and systems that have novel properties and functions because of their small and/or intermediate size” [103]. Nanotechnology has emerged as an exciting field that deals with both the design and fabrication of structures with molecular precision. Nanotechnology enables the control and manipulation of individual constituent molecules/atoms to have them arranged to form the bulk macroscopic substrate. The uniqueness of the nanotechnological approach is that it considers spatial and temporal scales at the same time, thereby forming an excellent technique to develop hierarchical structures. The biological milieu that tissue engineers attempt to mimic using synthetic materials and techniques is a highly complex system with spatial and temporal levels of organization that span several orders of magnitude, with different levels nested within higher order levels (nm to cm scale). To study and mimic this complex system, highly sophisticated technology is required. For instance, the

visualization and characterization of these biological structures, processes, and their manipulation require sophisticated imaging and quantitative techniques with spatial and temporal control at or below the molecular level.

Recent developments in nanotechnology have revolutionized the visualization and characterization of biological processes in various ways. The capability of imaging living cells after implantation is very crucial in studying cell behavior and processes *in vivo*. The recent developments in nanotechnology assisted fluorescent probes such as quantum dots (QD) have significantly improved our capability of *in vivo* imaging. QDs are nanocrystals or nanoparticles with size ranging from 1 to 10 nm with unique photophysical and photochemical properties not available with conventional organic fluorophores [104].

Similarly, the scanning probe microscopic techniques (SPM) provide a great tool to investigate atomic and molecular level biological phenomena even though its potential in biology is yet to be realized. One of the most extensively investigated SPM techniques for tissue engineering application is atomic force microscopy (AFM). AFM has provided various strategies to investigate the interactions of living cells with the ECM [105]. AFM has also enabled the visualization of nano-scale biomolecules and significantly contributed to the in-depth understanding of their structure and role in biological process [106].

The developments in current nanoscale fabrication techniques have also significantly increased our understanding of nanoscale features on cellular behavior and tissue organization. Several nanoprinting/etching/electron beam lithographic techniques have been developed to form substrates with large areas of controlled nanoscale features. *In vitro* studies using these substrates confirmed the importance of nanoscale topography of scaffolds for developing tissue *in vitro* [107–110]. One study examined the interaction of fibroblasts with nanoscale islands having heights varying from 10 to 95 nm on polymer films. The fibroblasts underwent rapid organization of cytoskeleton and improved adhesion during initial reaction to the islands with concomitant cell spreading. The lamellae of the cells on the islands also showed many filopodia showing better interaction with the islands. Another study by Dalby et al., using nano- and micro-patterned surfaces has demonstrated the importance of nanoscale features in modulating human mesenchymal bone marrow stromal cell (HBMSC) adhesion [111]. HBMSCs were found to be well-spread and attained normal morphologies on polymer thin films similar to the morphology cells attained on flat topographies. However, the cells on nanofeatured surfaces were found to respond to the nanofeatures. This included cells conforming to the shape of the nanosized pits (Fig. 1.15A – 310 nm deep and 30  $\mu$ m wide), filopodia production, contact guidance and production of endogenous extracellular matrix. On nanometer depth grooves, the cells were found to be highly aligned along the groove direction showing pronounced contact guidance (Fig. 1.15B – 500 nm deep and 5  $\mu$ m wide). The study demonstrated that the nanoscale features of the substrates could elicit significant control over cell adhesion, cytoskeletal organization, cell-growth, and production of the osteoblastic markers osteocalcin and osteopontin [111].

To recreate structures having features at the nanoscale level, novel nanotech-

niques that enable the conversion of existing macromolecules into nanostructured forms or development of novel structures from atomic or molecular constituents with spatial organization of biofunctionality are needed. It is presumed that these developed nanostructures, due to their ability to interact with cells and tissues at a molecular (subcellular) level with a high degree of functional specificity, would allow a greater extent of integration than previously attainable. Thus, research in this direction is ongoing to develop structures that could temporarily mimic the structure and functions of the ECM as ideal scaffolds for tissue engineering using various nanofabrication processes.

Nanofabrication techniques have shown the feasibility to develop nanostructured scaffolds that better mimic the structure of the ECM compared to the structures developed by macro/micro fabrication techniques. Two different approaches are currently under investigation to develop synthetic nanostructured scaffolds that could resemble the structure of nanoscale collagen fibrils of the ECM as scaffolds for tissue engineering. The first approach can be considered as a “top-down approach” which uses synthetic polymeric materials to develop nanostructures using various nanofabrication processes. The second approach can be considered as a “bottom-up approach” and is based on short peptides or block polymers that can assemble into nanofibers by a self-assembly process.

### 1.5.1

#### **Polymeric Nanofiber Scaffolds**

As discussed earlier, collagen fibrils are the major building blocks of the natural ECM and they have diameters in the range 50–500 nm and orientation in different directions depending on the tissues. A logical method to develop scaffolds for tissue engineering is to mimic the structure of collagen fibrils, i.e., by using synthetic polymeric nanofiber matrices. Developments in nanofabrication techniques have

enabled the fabrication of synthetic nanofiber matrices from a wide range of polymers. Polymeric nanofibers have been defined as fibers having diameters less than  $1\ \mu\text{m}$  and are developed from synthetic and natural polymers [112]. Fibers with diameters ranging from 1–1000 nm and a very high surface area can be developed by the nanofabrication processes. Thus a nanofiber with a diameter of 100 nm has a specific surface area of  $1000\ \text{m}^2\ \text{g}^{-1}$  [113]. Porous matrices developed using polymeric nanofibers have excellent structural and mechanical properties, high axial strength combined with extreme flexibility, high surface to volume ratio, high porosity ( $>70\%$ ), and variable pore sizes – all of these properties are highly beneficial for cell adhesion, migration and proliferation.

#### 1.5.1.1 Top-down Approaches in Developing Scaffolds for Nano-based Tissue Engineering

The top-down approach is considered as a classical approach used to size down macrostructures to smaller sizes using various fabrication techniques. Several top-down techniques have been developed to form polymeric nanofibers from preformed macromolecules such as electrospinning, phase separation and templating [112, 114, 115].

**Polymeric Nanofibers by Electrospinning** Electrospinning has developed into a promising, versatile and economical technique to produce nanostructured scaffolds for tissue engineering [112, 116]. Figure 1.16 shows the schematic of the electrospinning process. Briefly in an electrospinning process an electric field is applied to a pendant droplet of polymer solution at the tip of a needle or capillary attached to a syringe or pipette. The polymer solution feed to the needle/capillary is controlled using a syringe pump or allowed to flow under gravity. The electrode can be either inserted in the polymer solution or connected to the tip of the needle. When an electric potential is applied to the droplet, the droplet will be subjected to couple of mutually opposing forces. One set of forces (surface tension and viscoelastic forces) tend to retain the hemispherical shape of the droplet and another set

Fig. 1.16. Scheme of the electrospinning process.

of forces (due to the applied electric field) tend to deform the droplet to form a conical shaped “Taylor cone”. Beyond a threshold voltage, the electric forces in the droplet predominate and at that point a narrow charged polymer jet will be ejected from the tip of the Taylor cone. However, the viscosity of the polymer solution plays a crucial role in maintaining the ejected jet. If the viscosity of the polymer solution is low, the ejected jet break into droplets by a process called “electrospraying”. For solutions with higher viscosities, the ejected jet travels in a nearly straight line towards the grounded collector for some time due to the stabilization imparted by the longitudinal stress of the external electrical field on the charge carried by the jet. However, at some point along the course, the jet reaches a point of instability due to the repulsive forces arising from the opposite charges in the jet. The unstable jet then passes through a series of bending instabilities and it tends to bend back and forth following a bending, winding, spiraling and looping path in three dimensions. This bending instability of the jet has been demonstrated using high speed videography. During this process the polymer jet is continuously stretched resulting in significant reduction of the fiber diameter. This, along with the rapid evaporation of the solvent from the ultrathin jets results in the formation of ultrathin fibers that are deposited on a grounded collector surface [117–122].

Extensive studies have been performed to investigate the fundamental aspects of the process of electrospinning to determine the parameters that modulate the morphology and diameter of the electrospun fibers and for determining appropriate conditions for developing fibers from a wide range of polymers [112, 123–126]. These studies have clearly demonstrated the flexibility of the electrospinning process. Electrospun nanofiber scaffolds can be developed from a wide range of polymers with varying physical, chemical, and mechanical properties, thereby creating scaffolds with varying strength, surface chemistry, degradation patterns (in the case of matrix developed from bioresorbable polymers) and physical properties. The electrospinning process also enables co-spinning two or three different polymers, which further extends the ability to control the properties of the resulting scaffolds/matrices. Another advantage of electrospinning process is the feasibility of developing composite nanofiber scaffolds/matrices by incorporating small insoluble particles such as drugs or bioactive particles within polymeric nanofibers. Since the shape of the nanofiber scaffold/matrix depends on the properties of the collector, complex and seamless 3D structures can be developed using the appropriate collectors.

**Parameters that Affect the Electrospinning Process** Extensive studies have been undertaken to determine the parameters/variables that affect the electrospinning process. These include system parameters, solution properties and processing variables. The system parameters include the nature (chemistry and structure) of the polymer, molecular weight of the polymer and molecular weight distribution of the polymer. Solution properties include viscosity, elasticity, conductivity and surface tension of the polymer solution. The processing variables in the electrospinning process are electric potential, flow rate of the polymer solution, concentration of the polymer solution, the distance between the tip and the target,

ambient parameters such as solution temperature, humidity, air velocity in the electrospinning chamber, and motion of the target screen [112, 124, 126].

Most studies correlated the electrospinning parameters/variables to fiber diameter and/morphology. The effect of molecular weight of polymer on the process of electrospinning was evaluated using poly(ethylene oxide)s (PEO) of different molecular weights electrospun under identical conditions and by following the morphology of the fibers [127]. Figure 1.17(A–C) shows the effect of polymer molecular weight on the morphology of resultant nanofibers. In this study viscosity, surface tension and conductivity of all the solutions were kept constant to correlate the morphology of fibers to the molecular weight. Electrospinning of the low molecular weight polymer (20 000) resulted in the formation of mostly beads rather than fibers (Fig. 1.17A). Increasing the molecular weight to 500 000 resulted in the formation of fibers, however, with spindle shaped defect structures or beads (Fig. 1.17B). A further increase in molecular weight to  $4 \times 10^6$  resulted in the formation of bead-free fibers (Fig. 1.17C). The formation of bead-free structures with high molecular weight PEO has been attributed to the increasing entanglement of the polymer chains with high molecular weight polymer.

The effect of electric potential and polymer concentration on the morphology and diameter of electrospun polymer fibers were demonstrated by Katti et al. using a bioresorbable polymer poly(lactide-*co*-glycolide) (PLGA) [128]. PLGA dissolved in a dimethyl formamide–tetrahydrofuran (1:3) mixture was used for electrospinning. The study demonstrated that the concentration of the polymer solution has a significant effect on the diameter and morphology of the electrospun fibers. Figure 1.18(A–C) shows the morphologies of PLGA fibers formed from polymer solutions having different concentrations. A lower polymer concentration ( $0.15 \text{ g mL}^{-1}$ ) resulted in the formation of beaded nanofibers (Fig. 1.18A). Increasing the polymer concentration ( $0.2 \text{ g mL}^{-1}$ ) significantly reduced the probability of bead formation (Fig. 1.18B). The concentration also showed significant effects on the diameter of the resulting fibers. At low concentration ( $0.15 \text{ g mL}^{-1}$ ), fibers having diameters  $\sim 270 \text{ nm}$  with beads were formed and increasing the concentration to  $0.2 \text{ g mL}^{-1}$  increased the diameter of the fibers to  $\sim 340 \text{ nm}$  with minimal amount of beads. A further increase in concentration to  $0.25 \text{ g mL}^{-1}$  resulted in the formation of fibers having diameters  $\sim 1000 \text{ nm}$  with apparently no bead formation (Fig. 1.18C). Increase in fiber diameter with increasing solution concentration followed a power law relationship. The same behavior has been observed for different polymer systems by other investigators [123, 129]. Demir et al., using polyurethane solution, have shown that fiber diameter can be correlated to polymer concentration as proportional to the cube of the polymer concentration [130].

Similarly the electrospinning voltage has a profound effect on the morphology and diameter of the fibers. An increase in electric voltage decreases the diameter of electrospun fibers up to a certain voltage and above that tends to increase the fiber diameter [126, 128]. Spinning voltage has been found to strongly correlate with the formation of beads. Deitzel et al. have shown that an increase in electrical potential increases the feasibility of formation of beads along the fibers [131].

In addition to varying the polymer concentration and the electric potential the

**Fig. 1.17.** Morphology of fibers formed by the electrospinning process using poly(ethylene oxide)s of different molecular weights: (A) 20 000, (B) 500 000, and (C)  $4 \times 10^6$ . (Adapted from Ref. [127] with permission from Elsevier.)

**Fig. 1.18.** Morphology of fibers formed by the electrospinning of PLGA solutions having varying polymer concentrations ( $\text{g mL}^{-1}$ ): (A) 0.15, (B) 0.2, and (C) 0.25. (Adapted from Ref. [128].)

diameter and morphology of electrospun polymer nanofibers can be modulated by the addition of various additives to the spinning solution. One study by Zong et al. has shown that addition of ionic salts to the polymer solution can significantly reduce the bead formation and could result in thinner fibers. This has been attributed to the higher charge density of the jet due to the presence of ionic salts. The higher the charge carried by the jet, the greater will be the pull or elongation force the jet will experience under the electrical field, resulting in fewer beads and thinner fiber [132].

The electrospinning process can also result in the formation of fibers having various cross-sectional features in addition to circular fibers, as demonstrated in the case of various polymers. Fibers having varying shapes have been created such as flat ribbon, bent ribbon, ribbons with other shapes, branched fibers and fibers that were split longitudinally from larger fibers from different polymers and polymer–solvent systems [133]. Figure 1.19 shows the SEM of fibers having varying cross-sectional shapes. The occurrence of skin on the polymer jet accounts for a number of these observations. The phenomenon has been attributed to various causes, including contribution of fluid mechanical effects, electrical charge carried by the jet, and evaporation of solvent from the jet. In addition to varied cross-sectional features, fibers have been found to form with surfaces having varying nanotopographies such as nanopores or ridges. The formation of these structures

**Fig. 1.19.** SEM showing the fibers having varying cross-sectional shapes. (A) Flat ribbon formed from 10% solution of poly(ether imide). (B) Branched fibers from 16% HEMA. (C) Round fibers with skin collapsed to form longitudinal wrinkles. (Adapted from Ref. [133].)

have been attributed to various parameters such as the nature of the solvent, glass transition temperature of the polymer, solvent–polymer interactions, and environmental parameters such as humidity and temperature [134–136].

Nanofibers deposited by electrospinning using a static target result in the formation of a non-woven matrix composed of randomly oriented fibers. However, properties of fiber matrices can evidently be improved, if the fibers could be aligned in appropriate directions. This is particularly important for developing scaffolds for tissue regeneration as this would enable the development of scaffolds with specific orientation and architecture. Aligning the fibers formed by the process of electrospinning, however, is very difficult to achieve because during electrospinning process the jet trajectory follows a complex 3D whipping and bending path towards

**Fig. 1.20.** SEM showing PEO nanofibers: (A) Aligned fibers and (B) randomly deposited fibers. (Reprinted from Ref. [139] with permission from Institute of Physics Publishing.)

the target rather than a straight line. Several attempts have been performed to develop aligned electrospun polymeric nanofibers. Earlier attempts were performed using a high speed rotating cylinder collector [137]. However, fiber alignment could be achieved only to a certain extent using this process, presumably due to the low control that can be achieved over a polymer jet that undergoes chaotic motion. In another attempt, an auxiliary electrical field was applied to align the fibers which substantially improved the fiber alignment [138]. Another successful approach to align electrospun nanofibers was developed by Theron et al. using a thin wheel with sharp edge device. The thin edge of the wheel helped to concentrate the electrical field so that almost all of the spun nanofibers were attracted and wound to the bobbin edge of the rotating wheel [139]. Figure 1.20(A and B) shows the SEMs of aligned PEO nanofibers developed using the thin wheel with sharp edge collector and randomly deposited fiber matrix using conventional static collector. Another approach investigated is the use of a frame collector and has been found to significantly improve the alignment of nanofibers [140]. In this process, however, the extent of alignment depends significantly on the frame material. Figure 1.21 shows the SEM of aligned PLLA-CL copolymer fibers formed by the frame method.

In addition to the above techniques, several processing techniques were also attempted to increase the versatility of the electrospinning process. These include electrospinning the mixture of polymer with sol-gel solution [141], electrospinning blend polymer solutions [142], electrospinning polymer solution containing nanomaterials to form composite matrices [126], core-shell nanofiber spinning [143] and side by side/multijet electrospinning of different polymers (to increase the rate of fiber deposition and develop matrices having unique properties such as biohybrid matrices) [144–146].

The electrospinning process is a very mild fabrication process. This makes it very attractive for developing structures for biomedical applications. Studies have shown the ability of electrospun fibers to preserve the biological activity of highly sensitive biomolecules encapsulated within the fibers during the electrospinning

**Fig. 1.21.** Aligned PLLA-CL nanofibers formed by the frame method. (Adapted from Ref. [140] with permission from Elsevier.)

process. Hamdan et al. have encapsulated RNase and trypsin in poly(2-ethyl-2-oxazoline) nanofibers by electrospinning [147]. The enzymes were found to preserve their biological activity after being encapsulated within the nanofibers. Another study by Jiang et al. demonstrated the feasibility of incorporating model proteins such as bovine serum albumin and lysozyme within PCL nanofibers with preservation of their biological activity [148]. A novel electrospinning fabrication process called coaxial spinning was recently developed to encapsulate water-soluble macromolecules within hydrophobic nanofibers [143]. The fibers developed are called core-shell nanofibers where the aqueous phase containing the protein solution forms the core of the fiber surrounded by the hydrophobic polymer layer. The thickness of the core and the shell can be adjusted by the feed rate of the inner dope. Circular dichroism and SDS-PAGE studies on the released lysozyme and BSA encapsulated in the core-shell fibers revealed that both the proteins maintained their structure and bioactivity after encapsulation. The core-shell structures could have several advantages, such as improved protection of the encapsulated molecules and feasibility of achieving their controlled delivery when used as a macromolecular delivery vehicle for biomedical applications, including tissue engineering.

The mechanical properties of non-woven nanofiber matrices developed from bioresorbable polymers have been investigated. Thus, nanofiber matrices developed from PLAGA with LA:GA ratio of 85:15 showed a tensile strength similar to that of natural skin [149]. Ding et al. have demonstrated that the mechanical properties of non-woven nanofiber matrices could be further modulated by developing blend nanofibrous matrices using multi-jet electrospinning [144]. Another study by He et al. has demonstrated the low stiffness of non-woven polymeric nanofiber matrices compared to large diameter dacron grafts using poly(L-lactic acid-co-caprolactone) copolymer (PLLA-CL) nanofiber matrices. The low stiffness of the matrix makes it a suitable candidate for vascular graft applications [150]. The nanofiber matrix developed from PLLA-CL showed an ultimate strain of  $175 \pm 49\%$ . This high distension property has been attributed to the ability of the randomly oriented fibers to rearrange themselves in the direction of the stress. Another study compared the mechanical properties of nanofiber matrices with microfiber matrices developed

from poly(L-lactide-co-caprolactone) [PLCL] by the electrospinning process [151]. Three matrices composed of fibers with diameters of  $\sim 0.3$ ,  $\sim 1.2$ , and  $\sim 7$   $\mu\text{m}$  were investigated. The differences in fiber diameter could lead to differences in specific density of the resultant matrices. The matrix composed of the smallest diameter fibers ( $\sim 0.3$   $\mu\text{m}$ ) gave the densest matrix. Also, the Young's modulus of the densest matrix ( $\sim 0.3$   $\mu\text{m}$ ) was the highest followed by the matrix composed of fibers having diameter 1.2  $\mu\text{m}$ . The matrix composed of fibers with diameter  $\sim 7$   $\mu\text{m}$  showed the lowest Young's modulus. This indicates that nanofiber matrices could show better mechanical performance than microfibrinous matrices of the same material presumably due to the increase in fiber density. In terms of the mechanical properties of aligned nanofiber matrices developed by electrospinning, the nanofiber matrices showed different properties along different directions [152]. The ultimate strength of the aligned polyurethane fiber matrices ( $3520 \pm 30$  kPa) was significantly higher than randomly deposited fiber matrices ( $1130 \pm 21$  kPa) [153].

In summary, these studies demonstrate the feasibility of developing polymeric nanofibers with diameters ranging from 1 to 1000  $\mu\text{m}$  from a wide range of polymers using the process of electrospinning. The diameter and morphology of the nanofibers can be controlled to a great extent by varying the process parameters/variables that govern the electrospinning process. The properties of the matrices fabricated using polymeric nanofibers can be modulated by varying the properties of the polymer, co-spinning or multiple spinning polymer mixtures, incorporating nanoparticles or fillers, varying the rate of deposition as well as varying the properties of the target. The feasibility of aligning the fibers significantly increases the ability to modulate the properties of nanofiber matrices for biomedical applications. Another notable advantage of the electrospinning process is the cost effectiveness compared to other nanofabrication techniques.

**Polymeric Nanofibers by Phase Separation** Phase separation is another type of top-down approach used to develop polymeric nanofiber matrices from different polymer solutions. This technique has been found to be effective in developing nanofibrous matrices having high porosities (up to 98.5%) from biodegradable polymers and has been investigated for tissue engineering applications [154].

Liquid-liquid phase separation can be achieved by lowering the temperature of a polymer solution having an upper critical solution temperature. The phase separation at low temperature could lead to the formation of a continuous polymer-rich and polymer-lean solvent phases. The removal of solvent from the phase separated system at low temperature affords a scaffold with an open porous structure [154, 155]. Thus the development of nanofibrous porous matrices using phase separation of polymer solution takes place in five steps. Polymer dissolution in a solvent system, phase separation and gelation, solvent extraction from the gel with water, freezing and freeze drying under vacuum [114]. Similar to the electrospinning process, various processing variables can be controlled to modulate the properties of the nanofibrous matrices formed by phase separation process. These include type of solvent and polymer, polymer concentration, solvent exchange, thermal treatment and order of procedures [114].

**Fig. 1.22.** SEM micrographs of PLLA fibrous matrices prepared from PLLA/THF solution with different PLLA concentrations at a gelation temperature of 8 °C: (A) 1% and (B) 5% (w/v). (Adapted from Ref. [154].)

Ma and Zhang have developed 3D continuous nanofibrous structures that could mimic the structure of the ECM using biodegradable poly(L-lactic acid) [PLLA]. Fibers of the nanofiber matrix exhibited diameters in the range 50–500 nm. Figure 1.22(A and B) shows the SEM of PLLA fibrous matrices prepared from 1% (w/v) and 5% (w/v) PLLA/THF solution. The figures demonstrate the feasibility of varying the porosity of matrices by varying the concentration of the polymer solution. The higher the concentration of the solution, the lower was the porosity of the matrices formed.

Another advantage of fabricating nanofibrous matrices using the phase separation technique is that it allows for incorporation of macropores along with nanopores in the matrices by adding various porogens such as sugars, inorganic salts or paraffin spheres to the mold with the polymer solution during phase separation [156]. Figure 1.23(A and B) shows macro-nano porous matrices of PLLA fabricated by the combined porogen leaching phase separation method. Thus the phase separation process is a mild processing technique that provides the flexibility to control the properties of the nanofiber matrices such as fiber diameter, interconnectivity, porosity and size of the pores.

### 1.5.1.2 Bottom-up Approaches in Developing Scaffolds for Nano-based Tissue Engineering

Bottom-up approaches are based on self-assembly, a ubiquitous natural phenomenon that harnesses the physical and chemical forces operating at the nanoscale to assemble small building blocks into larger structures. Thus, the basic principle of the bottom-up approach is molecular self-assembly, which is the spontaneous organization of molecules under near thermodynamic equilibrium conditions into structurally well-defined and stable arrangements through non-covalent interactions [157]. These interactions include weak non-covalent bonds, such as hydrogen bonds, ionic bonds, hydrophobic interactions, van der Waals interactions and water-mediated hydrogen bonds [158]. The development of a self-assembling sys-

**Fig. 1.23.** (A) SEM micrograph of PLLA nano-fibrous matrix with particulate macropores prepared from PLLA/THF solution and sugar particles; particle size 250–500 nm. (B) SEM micrograph of PLLA nano-fibrous matrix with an orthogonal tubular macropore network prepared from PLLA/THF solution and an orthogonal sugar fiber assembly. (Adapted from Ref. [156].)

tem requires the design and development of small building blocks that can spontaneously self-assemble and be stabilized to form functional nano/microstructures. Recently, there has been significant interest in using self-assembly to develop nanostructured scaffolds for tissue engineering.

The most extensively investigated self-assembled nanostructured scaffolds for tissue engineering application are developed from peptide molecules. In 1993, Zhang et al. demonstrated the feasibility of an aqueous solution of a 16-residue ionic self-complementary peptide to spontaneously associate to form a macroscopic membrane [159]. The ionic complementary oligopeptides used in the study have regular repeating units of positively charged residues (lysine or arginine) and negatively charged residues (aspartate or glutamate) separated by hydrophobic residues (alanine or leucine). The membrane was highly stable to varying pHs and temperatures [159]. SEM of the self-assembled membrane revealed that the structure is composed of nanofibers with diameters ranging from 10 to 15 nm. The study raised interest in self-assembling peptide motifs and led to the development of different self-assembling peptide structures capable of assembling into unique nanostructures. Thus different types of self-assembling peptides have been identified to form different self-assembled structures such as nanofibers, nanotubes, nanowires and nanocoatings. Among these the Type I peptides also called molecular Legos developed by Zhang et al. have been identified as a potential peptide motif for developing self-assembled scaffolds for tissue engineering. These peptide motifs are called molecular Legos because at the nanometer scale they resemble the Lego bricks that have pegs and legs in a precisely determined organization. These peptides form  $\beta$ -sheet structures in aqueous solution resulting in distinct hydrophilic and hydrophobic surfaces [158–160]. The hydrophobic surface shields the peptide motif from water, thereby enabling them to self-assemble as in the case of protein folding *in vivo*. Then complementary ionic bonds will be formed with regular repeats on the hydrophilic surface. The complementary ionic sides have been

classified into different moduli based on the chemistry of the hydrophilic surface, i.e., having alternating positive and negative charged amino acid residues with different intervals. Depending on the moduli, these molecules could undergo ordered self-assembly to form nanofibers. These nanofibers, due to their high aspect ratio, in turn associate to form nanofiber scaffolds that closely mimic the porosity and gross structure of the ECM, making them potential candidates as tissue engineering scaffolds [161]. Figure 1.24(A) illustrates the formation of nanofibrous structures using molecular Lego. “PuraMatrix” a commercially developed ECM mimic self-assembling molecular Lego system has been found to be suitable for performing 3D tissue culture *in vitro*. The nanofiber scaffolds formed from these peptide motifs are formed of interwoven nanofibers with diameter of  $\sim 10$  nm and pores of  $\sim 5$ – $500$  nm with very high water content ( $>99.5\%$ ) (Fig. 1.24B).

Naturally occurring amino acids were used in developing peptide motifs in these studies. However, studies by Stupp et al. demonstrated the feasibility of using building blocks other than natural amino acids to create amphiphilic peptides. The peptide amphiphiles were developed from appropriate amino acids using solid phase peptide chemistry and the NH terminus of the peptide sequence was then alkylated to form the amphiphilic molecule. The amphiphilic peptides (PA) molecules are composed of a peptide segment containing 6–12 amino acids coupled via an amide bond to a fatty acid chain that varies in length from 10 to 22 carbon atoms. Even at very low concentrations of 0.25% (w/v) these molecules can self-assemble to form a gel structure composed of a network of cylindrical nanofibers with diameter ranging from 5 to 8 nm, depending on the length of the self-assembling molecules. The matrices were highly hydrated ( $>99.5\%$ ) and the mechanical integrity of such a highly hydrated matrix has been attributed to the high aspect ratio of the nanofibers composing the matrix. These molecules are custom developed so that they can self-assemble to form nanostructured scaffolds that could structurally and biologically mimic the structure of the ECM of specific tissue type. Thus, a composite nanostructured matrix has been developed as potential scaffolds for bone tissue engineering. The scaffold was designed to mimic the ECM of natural bone by self-assembling peptide motifs with appropriate amino acids and mineralizing the matrix *in vitro* [162]. In this study the peptide amphiphile was designed as follows. To make robust nanofibers four consecutive cysteine amino acids were incorporated in the sequence. The cysteine residues were incorporated as they could form disulfide linkages between adjacent molecules upon oxidation to stabilize the supramolecular structure. The formation of the disulfide linkage, however, is a reversible process. A phosphoserine residue was incorporated into the peptide sequence, so that after self-assembly the resulting fibers will have highly phosphorylated surface. These groups are specifically incorporated in the PA to increase the mineralizing capacity (nucleation and deposition of hydroxyapatite an essential inorganic component of natural bone) of the nanostructured scaffold. Anionic groups are known to promote nucleation and deposition of hydroxyapatite on synthetic materials and phosphorylated groups are particularly important in the formation of calcium phosphate minerals. Thus, the phosphorylated surface of self-assembled nanofibers could promote the nucleation and deposition

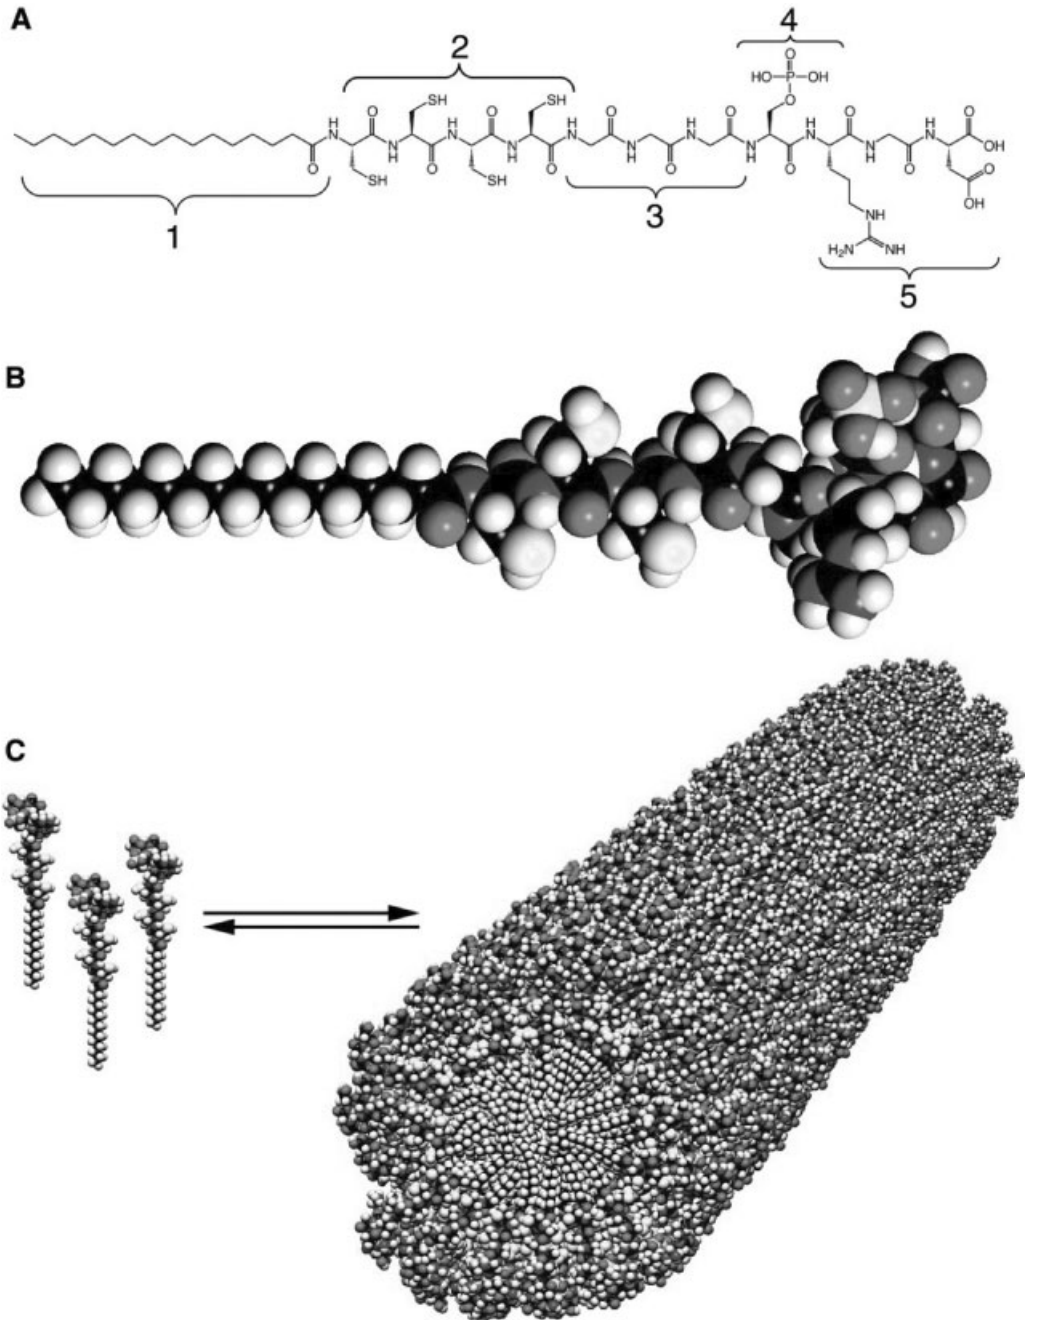

**Fig. 1.24.** Fabrication of various peptide materials. (A) Peptide Lego, also called ionic self-complementary peptide, has 16 amino acids,  $\sim 5$  nm in size, with an alternating polar and nonpolar pattern. The peptide motifs could form stable  $\beta$ -strand and  $\beta$ -sheet structures. The peptide motifs undergo self-assembly to form nanofibers with the nonpolar residues inside (green) and positive (blue) and negative (red) charged residues forming complementary ionic interactions, like a checkerboard. These nanofibers form interwoven matrices that produce a scaffold hydrogel with very high water content ( $\sim 99.5\%$ ). (Adapted from Ref. [161] with permission from Elsevier.) (B) AFM image of the nanofiber scaffold (PuraMatrix). (Adapted from Ref. [161] with permission from Elsevier.)

of hydroxyapatite (HA). To improve the cell adhesivity of the self-assembled nanofiber matrix, an RGD sequence was also incorporated in the peptide. Figure 1.25 shows the structure of the PA molecule designed to self-assemble to form nanofiber scaffold for bone tissue engineering.

The nanofiber scaffold was developed from the PA as follows. The cysteine residues of the PA were first reduced to thiol groups at higher pH. The resulting PA was found to be highly soluble in water. The pH of the aqueous solution was then reduced to 4.0, at that point the material rapidly became insoluble due to the formation of network structure. Cryo-transmission electron microscopy (Cryo-TEM) showed that the gel is composed of a network of fibers that are  $7.6 \pm 1$  nm in diameter and up to several micrometers long. Figure 1.26(A and B) shows the ultrastructure of the gels formed by self-assembly with and without covalent stabilization. The ability of the nanofiber matrix formed from the PA to nucleate hydroxyapatite (HA) along the fiber axis was also demonstrated by incubating the nanofiber matrix in appropriate salt solution (Fig. 1.26C). Another interesting property of the self-assembled gel is its reversibility. The self-assembled matrix could disassemble at higher pHs. Even though the study demonstrated for the first time the feasibility of designing and developing bioactive self-assembled system to mimic the properties of the ECM, it has certain disadvantages. The significant

**Fig. 1.25.** (A) Chemical structure of the peptide amphiphile. Region 1 is a long alkyl tail to make the peptide motif amphiphilic. Region 2 is composed of four consecutive cysteine residues for disulfide linkages. Region 3, a flexible linker region of three glycine residues, provides

disadvantage of this system is the low stability of the self-assembled structure at physiological pH unless internally crosslinked by covalent bonds. Another study was therefore performed to demonstrate the feasibility of developing self-assembled structures that are stable at physiological pH using PAs with opposite charges based on the electrostatic attraction of the opposite charge [163]. Mixed systems having oppositely charged PAs were used to develop self-assembled systems capable of assembling at physiological pH due to electrostatic attraction. This ability of these materials to undergo mild self-assembly and gelation at physiological conditions and the ability to decorate them with bioactive motifs makes them potential candidates for various biomedical applications.

In addition to peptide motifs, synthetic proteins were also investigated to develop self-assembled matrices. Thus Petka et al. used a recombinant DNA method to cre-

ate artificial proteins that can undergo reversible gelation in response to pH or temperature. The developed proteins consist of terminal leucine zipper domains flanking a central flexible water-soluble polyelectrolyte segment [164]. In near neutral solution, a 3D network can be formed by coiled-coil aggregates of the terminal domains and the polyelectrolyte segment prevent precipitation of the chain and retain the solvent. An elevation of pH or temperature leads to dissolution of the gel, resulting in the formation of viscous polymer solution. Similarly Nowak et al. developed a diblock copolypeptide amphiphile containing charged and hydrophobic segments, which were found to form hydrogels with high temperature stability [165]. The ability of this system to form gel under mild conditions makes them potential candidates for biomedical applications.

Both top-down and bottom-up approaches have significantly contributed to the development of nanostructured matrices as scaffolds for tissue engineering. The top-down approaches currently used to develop nanofiber matrices such as electrospinning or phase separation are highly economical and easily scalable processes. Furthermore, nanofiber scaffolds with finely controlled physical and mechanical properties and complex structures can be developed due to the versatility of the fabrication processes. The bottom-up approach even though is a more involved process that requires highly specific building blocks for spontaneous self-assembly has several advantages from a biomaterials point of view. The matrix formation via a mild self-assembling process makes it a very attractive process for *in vivo* applications. Another advantage is the ease of incorporating specific bioactive motifs as the building blocks that when combined with the nanostructured topography of the resulting matrix could better mimic the structure and functions of the extracellular matrix. The major disadvantage of the self-assembly process, however, is its relative inability to generate complex patterns for biological devices due to its homogeneous character.

## 1.6 Cell Behavior Towards Nano-based Matrices

Several studies have confirmed the fact that cells prefer to live in a complex nanostructured environment composed of pores, ridges and fibers of the polymeric nanofiber matrices that mimics the structure of the ECM compared to 2D matrices or microfiber matrices. Kwon et al. have evaluated the adhesion and proliferation potential of human umbilical vein endothelial cells (HUVEC) on three different types of PLL-CL fiber matrices composed of fibers having diameters  $\sim 0.3$ ,  $\sim 1.2$ , and  $7 \mu\text{m}$  [151]. Figure 1.27 shows the SEMs of HUVECs cultured for 1 and 7 days on electrospun matrices having fibers of different diameters (0.3, 1.2, and  $7 \mu\text{m}$ ). The matrix composed of the smallest diameter fibers ( $0.3 \mu\text{m}$ ) and the medium diameter fibers ( $1.2 \mu\text{m}$ ) showed higher cell adhesion and proliferation than matrix composed of fibers having diameter  $7 \mu\text{m}$ . The morphology of the cells on 0.3 and  $1.2 \mu\text{m}$  fiber matrices were comparable but differed significantly from that on the matrix composed of  $7 \mu\text{m}$  diameter nanofibers. Thus the matrices com-

**Fig. 1.27.** SEM showing the morphologies of HUVECs cultured for 1 and 7 days on PLCL (50/50) electro-spun fibers having different diameters ( $\mu\text{m}$ ): (A) 0.3, (B) 1.2, and (C) 7. (Adapted from Ref. [151] with permission from Elsevier.)

posed of 0.3 and 1.2  $\mu\text{m}$  diameter fibers promoted the adhesion, spreading and proliferation of cells and the cells were found to be anchored on many fibers on the surface of the matrices. The quantitative determination of cell adhesion on these two matrices did not show any statistically significant differences in cell proliferation. However, the cells on the 7  $\mu\text{m}$  fiber matrix were found to be rounded and showed significant decrease in cell proliferation compared to the other two matrices. This low cell adhesion and proliferation on microfiber matrix has been attributed to the large interfiber distance or a very low surface density of fibers that could not permit cell adhesion between the neighboring fibers.

Schindler et al. have investigated the ability of nanofibrillar matrix to promote *in vivo*-like organization and morphogenesis of cells in culture [166]. The synthetic nanofibrillar matrices were prepared by electrospinning a polymer solution of polyamide onto glass cover slips. The matrices were found to be composed of fibers of diameters  $\sim 180$  nm and a pore diameter of  $\sim 700$  nm. The surface smoothness of the matrix was found to be within 5 nm over a length of 1.5  $\mu\text{m}$ , which is similar to the 3D organization of fibers in the basement membranes. NIH 3T3 fibroblasts, normal rat kidney (NRK) cells and breast epithelial cells were used for the *in vitro* evaluation. The organizational and structural changes of the intracellular components (actin and focal adhesion components) of the cells were measured as a function of adhesion when cultured on nanofibrous matrices and compared with the responses to cells on glass substrate. Fibroblasts plated on the glass substrate were well spread with an elaborate checkerboard pattern of stress fibers (Fig. 1.28A). Cells on the nanofiber matrix, however, showed significant changes in the morphology and shape. Compared to cells on the glass substrates, the cells on the nanofiber matrices were more elongated and bipolar with thinner actin fibers arranged parallel to the long axis of the cell. Notable increases in the formation of actin-rich lamellipodia, membrane ruffles and cortical actin were also observed

**Fig. 1.28.** Comparison of the F-actin network, focal adhesion components, fibronectin organization and integrin antibodies for NIH 3T3 fibroblasts cultured on glass substrates and nanofiber matrices. (A, C, E, G, I) are cells

on glass substrates and (B, D, F, H and J) are cells on nanofiber matrices (see text for details). (Adapted from Ref. [166] with permission from Elsevier.)

(Fig. 1.28B). Staining of vinculin (a prominent component of focal complexes and focal adhesions that links cytoskeleton, plasma membrane and the ECM) of fibroblasts cultured on glass substrate showed a parallel streaked structure (Fig. 1.28C). However, the streaked staining for vinculin within cells on nanostructured matrix was limited to the edge of the lamellipodia with a more diffuse staining throughout the cell cytoplasm (Fig. 1.28D). Similar to actin distribution, such pattern of vinculin labeling correlates with cellular differentiation and morphogenesis *in vivo*. The cells were also stained for focal adhesion kinase (FAK) which functions as a central mechano-sensing transducer in cells. Cells cultured on glass demon-

Fig. 1.28 (continued)

strated a streaky pattern of FAK labeling similar to the pattern obtained for vinculin (Fig. 1.28E). However, for cells on nanofiber matrix, the localization of FAK was found to be more punctuated and less well defined (Fig. 1.28F). Previous studies using breast epithelial cells have correlated this loss of FAK localization at focal adhesions to morphogenesis and differentiation [167]. The distribution of fibronectin on the cell surface cultured on glass substrate for 24 h revealed a classic linear pattern of fibrils (Fig. 1.28G). The cells on the nanofiber matrix, however, showed a thicker network of more randomly deposited apically localized fibrils indicating that they are permissive for the assembly of a matrix that can promote the formation of 3D-matrix adhesions (Fig. 1.28H). Staining for  $\beta 1$  integrin for NPK cells was punctuated when cultured on glass substrate for 24 h (Fig. 1.28I). However, the cells on nanofibrous matrix showed an organized long slender aggregate staining pattern, indicating the localization of  $\beta 1$  integrin in focal adhesions (Fig. 1.28J).

The ability of nanofiber matrices to promote morphogenesis was demonstrated by culturing T47D epithelial cells on glass and nanofiber coated glass matrices [166]. The T47D cells were used in the present study as they have been demonstrated to form duct like tubular structures and spheroids under conditions that promote morphogenesis. After 5 days in culture, a mixed population of multicellular structures comprised of tubules and spheroids were found on nanofiber matrix. At day 10, multicellular spheroids were dominant compared to tubules. Figure 1.29(A) shows a confocal series through a multicellular spheroid showing a lumen formed on nanofiber matrix. The figure shows the ability of T47D cells to grow into a complex multilayer structure on a nanofiber matrix. The cells cultured on

**Fig. 1.29.** (a) A series of confocal sections of a multicellular spheroid composed of T47D breast epithelial cells grown on nanofibers and stained with phalloidin-Alexa Fluor (A–D). (b) Cells after 10 days of culture on glass substrate. (Adapted from Ref. [166] with permission from Elsevier.)

glass surface, in contrast, formed a monolayer with groups of F-actin fibers (Fig. 1.29B). These studies demonstrated the advantages of using nanofiber matrices compared to microfiber matrices or 2D surfaces in developing 3D tissues, demonstrating their potential as ideal scaffolds for tissue engineering application.

## 1.7

### Applications of Nano-based Matrices as Scaffolds for Tissue Engineering

Due to the unique properties and favorable cell behavior towards nanofiber matrices, different nanofiber matrices developed by top-down and by bottom-up approaches have been investigated as potential scaffolds for developing various tissues. The following section overviews nanofiber-based matrices as scaffolds for tissue regeneration.

#### 1.7.1

##### Stem Cell Adhesion and Differentiation

As stem cells have been identified as one of the most appropriate cells for tissue engineering, the interaction of nanofiber matrices with stem cells raise significant

interest. The unique ability of nanofiber matrices to support the growth and differentiation of stem cells into appropriate lineages have been demonstrated using self-assembled protein nanofiber matrices. Silva et al. have demonstrated the feasibility of encapsulating neural progenitor cells (NPCs) in self-assembled bioactive peptide amphiphiles and the ability of the cells to differentiate to appropriate lineage [168]. NPCs were selected as they are extensively used to replace lost central nervous system cells after degenerative or traumatic insults. Owing to the design flexibility of peptide amphiphiles as described earlier, unique PA was developed for form self-assembled scaffolds that could provide favorable environment for NPCs. The peptide motif designed to develop the scaffold was composed of a pentapeptide epitope isoleucine-lysine-valine-alanine-valine (IKVAV). The epitope has been selected because it is present in laminin, a cell adhesive protein present in the ECM and known to promote neurite sprouting and direct neurite growth. In addition to the neurite sprouting epitope, a GLu residue was also incorporated in the peptide that could give the peptide a net negative charge at pH 7.4. The rest of the molecule is composed of four Ala and three Gly followed by an alkyl tail of 16 carbon atoms.

The peptide was soluble in aqueous media and upon addition of cell suspension the cations present in the cell culture media screened the electrostatic repulsion, allowing the molecules to self-assemble due to hydrogen bond formation. Upon self-assembly the bioactive motifs were found to be placed on the surface. Figure 1.30 shows the SEM of nanofiber matrix formed by the self-assembly of peptide amphiphiles. A control amphiphile was also developed with a non-physiological sequence of glutamic acid-glutamine-serine (EQS) to compare the cell response to the bioactive self-assembling PA. Even though the control matrices allowed the encapsulation of the progenitor cells by self-assembly, the encapsulated cells did not sprout neuritis or differentiate morphologically or histologically.

The NPCs encapsulated within the peptide amphiphile self-assembled matrix was found to be viable throughout the period of study of 22 days. No differences in cell viability between the encapsulated cells and cells cultured on polylysine 2D

**Fig. 1.30.** SEM showing the morphology of scaffold developed from an IKVAV nanofiber network by adding cell culture media to the peptide amphiphile. The sample is dehydrated

and critical point dried caged in a metal grid to prevent network collapse during sample preparation for SEM. (Reprinted with permission from Ref. [168].)

**Fig. 1.31.** Immunohistochemistry showing  $\beta$ -tubulin III of neurons and astrocytes of cells encapsulated in self-assembled bioactive gels (A) (after 1 day in culture) and laminine-coated

cover slips (B) (after 7 days in culture).  $\beta$ -Tubulin III is stained green, differentiated astrocytes (glial cells) are labeled orange. (Reprinted with permission from Ref. [168].)

films were found demonstrating that sufficient diffusion of nutrients, bioactive factors and oxygen is taking place through the highly hydrated nanofiber matrix. Immunocytochemistry demonstrated the differentiation of NPCs encapsulated in the bioactive self-assembled PA matrix to neurons. Furthermore, the results were found to be statistically significant when compared to cells grown on laminin or lysine coated surface. Differentiated neurons were labeled for  $\beta$ -tubulin III and glial fibrillary acidic protein to detect neurons and astrocytes. After only 1 day in culture, 35% of the cells encapsulated within the bioactive nanofiber scaffold stain positive for  $\beta$ -tubulin (Fig. 1.31A). At the same time only less than 5% of the cells in the bioactive scaffold showed astrocyte differentiation even after 7 days in culture (Fig. 1.31A). This is a positive observation since inhibition of astrocyte proliferation is important in the prevention of the glial scar a known barrier to axon elongation following CNS trauma. Cells cultured on 2D laminine coated substrate did not show such differentiation and at the same time showed significant astrocyte proliferation (Fig. 1.31B). Encapsulation in the nanofiber scaffold led to the formation of large neurites after only 1 day ( $57 \pm 26 \mu\text{m}$ ) where as cells grown on laminin or lysine did not form neurites at that time. TEM evaluation of cells encapsulated within the gels after 7 day showed a healthy and normal ultrastructural morphology. The high migrating ability of the cells encapsulated within the gels was also demonstrated by tracking the distance between the center of each neurosphere and cell bodies as a function of time. The study demonstrated the potential of bioactive self-assembling nanofiber scaffolds as stem cell delivery vehicles.

The differentiation ability of progenitor cells into different lineages on polymeric nanofiber matrices developed by electrospinning was demonstrated recently by Li et al., using multipotent human mesenchymal stem cells (MSC). The study demonstrated the feasibility of nanofiber matrices to support the adhesion and differen-

tiation of these cells into different lineages [169]. PCL nanofiber matrices were used for the study. The matrix was found to be composed of randomly oriented nanofibers having diameters  $\sim 700$  nm. The MSCs seeded on the nanofiber matrices were found to attach and remained viable. For multi-lineage differentiation of the cells the MSC seeded nanofiber matrices were placed under specific differentiation promoting culture conditions (Fig. 1.32). Thus, under adipogenic conditions (media with dexamethazone, 3-isobutyl-1-methylxanthine and insulin), the cell-polymer constructs developed into an adipose like tissue with the cells expressing appropriate gene expression. The incubation of the cell seeded nanofiber matrices in chondrogenic media resulted in the formation of a cartilaginous tissue composed of cells showing characteristic chondrocyte phenotypes. The authors observed that the chondrogenic differentiation of MSC on nanofiber matrices takes place even at low cell population compared to 2D cultures or cells encapsulated in hydrogels presumably due to the unique interactions of the cells with the nanostructured topography of the matrix. Incubation of the cell seeded nanofiber matrix in osteogenic media ( $\beta$ -glycerophosphate, ascorbic acid and dexamethasone) resulted in the formation of a dense bone-like tissue with the cells showing characteristic osteoblast phenotypes. The study thus demonstrated that electrospun nanofiber scaffolds can support chondrogenic, osteogenic and adipogenic differentiation and, therefore, are candidate scaffolds for the fabrication of multi-component tissue constructs.

### 1.7.2

#### Neural Tissue Engineering

Nerve tissue engineering can be considered as one of the most promising approaches to restore central nervous system function. Several studies have evaluated the efficacy of nanofibrous matrices as scaffolds for neural tissue engineering. In one study Yang et al. determined the efficacy of PLLA nanofiber matrices developed by phase separation process as scaffold for neural tissue regeneration [170]. The fiber diameters were  $\sim 196$  nm with a matrix porosity of  $\sim 85\%$ . Neural stem cells (NSC) were used in the study. Upon NSC seeding and culturing for a day, the cells were found to randomly spread over the surface of the polymer scaffold without much differentiation. By day 2 the cells had progressively grown throughout the scaffold, with a neurite length twice that of the cell body, and migration of cells

---

**Fig. 1.32.** SEM showing nanofiber-MSC constructs maintained with and without differentiation media (A–F adipogenic; G–L chondrogenic; and M–R osteogenic). (A, D, G, J, M, P) Cross sections; (B, C, E, F, H, I, K, L, N, O, Q, R) top views. In adipogenic cultures (D–F), globular, round cells were evident, while fibroblast-like cells were found in the control cultures (A–C). In chondrogenic cultures (J–L), round chondrocyte-like cells were embedded in a thick layer of ECM that was not found in the control group (G–I). In osteogenic cultures (P–R), mineralized nodules were formed in the constructs. In contrast, control cultures (M–O) contained primarily fibroblast-like cells, and mineralization was not seen [169] with permission from Elsevier.

**Fig. 1.33.** SEM showing the magnified view of a differentiated cell with long neurite cultured on a nanofiber matrix developed by phase separation. (Adapted from Ref. [170] with permission from Elsevier.)

into the porous matrix also occurred (Fig. 1.33). The study showed the feasibility of nanofibrous scaffold to act as a positive guidance cue to guide neurite outgrowth.

Efficacy of aligned polymeric nanofiber matrices as a scaffold for the growth and differentiation of neural NSCs was further evaluated by Yang et al. using PLLA nano/microscaffold [171]. The cell adhesion and differentiation pattern on the aligned nanofiber matrices were compared to aligned microfiber matrices formed by electrospinning as well as random micro and nanofiber matrices. The aligned nanofiber matrices were composed of fibers having diameter  $\sim 300$  nm and microfiber matrices were composed of fibers having diameter  $\sim 1.5$   $\mu\text{m}$ . The average fiber diameters of the random nano and microfiber matrices were  $\sim 250$  nm and  $1.25$   $\mu\text{m}$  respectively. NSC attached and formed an elongated spindle-like shape on all the surfaces. The direction of NSC elongation and neurite outgrowth was found to be aligned with the direction of aligned fibers and showed classical contact guidance. The cells on random fiber matrices in contrast showed significantly different phenotype. In terms of differentiation, more cells were found to be differentiated on aligned nanofiber matrix (80%) than on aligned microfiber matrix (40%) demonstrating that nanofiber alignment has profound effect on cell differentiation. Since successful nerve regeneration rely on the extensive growth of axonal process, the neurite length of cells on the matrices was evaluated. The neurite length of NSCs on aligned nanofiber matrix was significantly higher than aligned micromatrix or random matrices. Figure 1.34 shows the SEM micrograph of NSC on aligned nanofiber matrix. The cells body shows an apparent bipolar elongated morphology with the outgrowing neuritis. Both cell elongation and neurite outgrowth followed the same direction of PLLA nanofibers. The figure also shows significant interaction between NSCs and the aligned fibers. Some filament-like

**Fig. 1.34.** SEM showing the interaction of NSC on an aligned PLLA nanofiber matrix. Bar = 5  $\mu\text{m}$ . (Adapted from Ref. [171] with permission from Elsevier.)

structures, presumably focal adhesions, extend out from the NSC cell body and neurite and attach to the nanofiber. This study thus demonstrated that aligned nanofiber matrix could improve NSC differentiation and support neurite out-growth compared to other matrices evaluated.

### 1.7.3

#### **Cardiac and Blood Vessel Tissue Engineering**

One of the major reasons for the failure of synthetic small diameter vascular grafts is adverse blood biomaterials interactions resulting in an acute occlusion followed by a chronic intimal hyperplasia. The ability to engineer vascular grafts using biodegradable scaffolds could lead to the development of synthetic grafts with long-term patency. One of the most extensively investigated approaches to prevent graft occlusion is to improve the antithrombogenicity of graft materials by seeding them with endothelial cells. But the development of a stable endothelial covering on the surface of synthetic materials is difficult due to the high sensitivity of the endothelial cells.

Mo et al. have evaluated the efficacy of polymeric nanofiber matrices as scaffolds for growing endothelial and smooth muscle cells [172]. P(LLA-CL) nanofiber

matrices developed by the process of electrospinning were used as the 3D scaffold in the study. Endothelial cells and smooth muscle cells were cultured on the nanofiber matrices for 7 days. Both SMC and EC adhered and spread on nanofiber matrices with the cell number, showing a significant increase from day 1 to day 7. This indicates the ability of the cell to attach and proliferate on the nanofiber matrix. Immunohistochemical evaluation of adhered ECs on the nanofiber matrix showed appropriate EC phenotype expression, indicating favorable interaction of the cells with the matrix.

Even though self-assembly of bioactive peptide motifs can be considered as the direct method to develop bioactive nanofiber matrices, He et al. have recently demonstrated the feasibility of improving the bioactivity of electrospun nanofibers by surface modification. They modified the surface of a P(LLA-CL) nanofiber matrix to improve the efficacy of the matrix towards endothelial cell attachment and proliferation [150]. The surface of p(LLA-CL) nanofiber matrix was functionalized by plasma modification and the nanofiber matrix surface was then coated with collagen. Human coronary artery endothelial cells (HCAECs) were used to evaluate the efficacy of the coated nanofiber scaffold compared to uncoated scaffold. The cells on uncoated scaffold were rounded in shape without significant spreading (Fig. 1.35A). More cells were found to be attached on the collagen-coated p(LLA-CL) nanofibers than uncoated nanofiber matrix since collagen is the main structural and functional protein present in ECM (Fig. 1.35B). Immunohistochemical evaluation of the cultured cells showed the preservation of endothelial phenotype by the cells on the coated nanofiber matrix.

Similarly a collagen coated PCL nanofiber matrix was evaluated for improve SMC adhesion and interaction [173]. Coating the nanofibers with collagen improved the cell adhesion on the fibers, with cells preserving their characteristic phenotype.

**Fig. 1.35.** SEM images of HCAECs cultured on (A) uncoated P(LLA-CL) nanofiber matrix and (B) collagen-coated p(LLA-CL) nanofiber matrix after 3 days in culture. (Adapted from Ref. [150] with permission from Elsevier.)

Another related study was performed by the same research group to evaluate the effect of cell behavior towards scaffolds that combine nanostructure and bioactivity. Poly(ethylene terephthalate) a non-degradable polymer extensively investigated for developing vascular graft was fabricated into a nanofibrous structure using the process of electrospinning [174]. The nanofibers were then surface modified to attach a bioactive protein gelatin. The surface-modified fiber scaffolds were then seeded with HCAECs and cultured for 7 days. The surface-modified nanofiber matrix showed improved cell adhesion and maintenance of phenotypic activity. These results showed that combining the nanostructure of the scaffold with the bioactive molecule could positively promote cell–matrix and cell–cell interactions, inducing them to express the phenotypic shape.

The effect of fiber orientation on SMC attachment and proliferation of nanofiber matrices was evaluated using aligned nanofiber scaffolds of P(LLA-CL) [140]. Aligned fibers were developed by the process of electrospinning using the wheel with a sharp edge collector. SMCs were found to adhere on aligned nanofiber scaffold as early as within 1 h of seeding and the cells tend to elongate along the direction of the nanofibers. After 3 days in culture, SMCs proliferated approximately along the longitudinal direction of the nanofiber length, which formed an oriented pattern similar to those in native artery. The cell number significantly increased at day 7 and the surface of the nanofibrous scaffold was covered with a continuous SMC monolayer with a regular direction from left to right along the nanofiber alignment. The cell adhesion and proliferation on aligned nanofiber matrix was significantly higher than on 2D film of the same polymer. Figure 1.36 shows the SEM of aligned SMC on aligned nanofiber matrix. Further, the distribution and organization of cytoskeleton proteins inside SMCs were parallel to the direction of the nanofibers (Fig. 1.37). The study demonstrated for the first time the feasibility of using an aligned nanostructured scaffold to mimic natural vessel architecture and the ability of cells to orient along the fiber axis to mimic the natural orientation.

One elegant method to incorporate biofunctionality into nanofiber scaffolds is the use of self-assembling peptides decorated with appropriate protein motifs. Gen-

**Fig. 1.37.** LSCM micrograph of immunostained  $\alpha$ -actin filaments in SMC after 1 day of culture on aligned nanofiber matrix. (Adapted from Ref. [140] with permission from Elsevier.)

ove et al. recently developed biomimetic self-assembled peptide scaffolds and evaluated the function of human aortic endothelial cells seeded on the scaffolds [175]. The self-assembling protein motifs were developed based on the functionality of basement membrane, which is composed mainly of laminin and collagen. Two peptide sequences present in laminin (YIGSR and RYVVLPR) are known to promote cell adhesion, cell migration and endothelial cell tubular formation, and a peptide sequence in collagen Type IV (TAGSCLRKFSTM) shown to promote the adhesion and spreading of bovine aortic endothelial cells, were selected to develop novel functionalized peptide motifs for self-assembly. The functionalized peptides were developed by solid-phase synthesis and found to self-assemble to form hydrogel under physiological conditions (Fig. 1.38). Four different scaffolds were investigated in the study, unmodified self-assembled peptide scaffolds, composed of RAD 16-1 (AcN-RADARADARADARADA-CONH<sub>2</sub>), YIG (10%) modified scaffold, RYV (10%) modified scaffold and TAH (10%) modified scaffold. Cell numbers increased about two-fold in modified peptide scaffolds compared to unmodified scaffolds, indicating that cell could sense and respond to the functionalized material. In addition, the matrix could modulate endothelial cell growth only when the sequence was physically attached to the nanofiber matrix, showing the importance of spatial distribution of the bioactive molecules on the nanostructured scaffolds. The peptide scaffolds in general also enhanced the endothelial cell phenotype, such as NO synthesis and deposition of basement membrane components (laminin I and collagen IV), suggesting the potential of these scaffolds in recreating the endothelial microenvironment.

Another application for which biodegradable nanofiber matrices have been evaluated is for developing scaffolds for engineering myocardium. Shin et al. have evaluated the potential of PCL nanofiber matrix as a cardiac graft by assessing the interaction of rat cardiomyocytes with the nanofiber scaffold [176]. The average di-

**Fig. 1.38.** (A) Model representing the peptide RAD16-1 (unfunctionalized peptide) and peptide YIG (functionalized). (B) Model representing the double  $\beta$ -sheet tape of a self-assembled peptide nanofiber of a mixture composed of RAD16-1 and YIG (9:1). (Adapted from Ref. [175] with permission from Elsevier.)

ameter of the fibers used to develop the scaffold was  $\sim 250$  nm. The cardiomyocytes attached well on the scaffold and after three days in culture the cardiomyocytes started to contract (Fig. 1.39). The contractions were ubiquitous and synchronized. The mechanical property (softness) of the scaffold was found to be highly appropriate to allow the spontaneous contraction of the cardiomyocytes. The cardiomyocytes were also found to form a tight arrangement and intercellular contacts throughout the entire mesh and stained positive for cardiotypical proteins. However, the system has some limitations for *in vivo* application. The limited thickness of the scaffold might not be able to provide sufficient function when used alone to cover an infarcted area. Therefore, a modified multilayered nanostructured nanofibrous graft was developed [177]. PCL nanofiber matrices composed of fibers having diameters of  $\sim 100$  nm were developed and cardiomyocytes were cultured on nanofiber matrices for 5–7 days. After that layering of the individual grafts (five

**Fig. 1.39.** SEM of the cross-section of a cardiac nanofibrous mesh, showing complete coverage of the mesh with cardiomyocytes. (Adapted from Ref. [176] with permission from Elsevier.)

layers) were performed by gently placing layers on top of each other. The layered constructs were incubated for 2 h at 37 °C without media for interlayer attachment and then cultured for 14 days in culture media. Multilayered scaffolds initially showed weak and unsynchronized contractions but became stronger and synchronized with time. H&E staining of the constructs demonstrated the interconnections between the layers. The immunohistochemistry study showed the presence of connexin43 in multilayered graft, indicating that the cells are rebuilding gap junctions, and synchronized contractions in multilayered grafts. *In vivo* studies using these grafts are under way.

#### 1.7.4

#### Bone, Ligament and Cartilage Tissue Engineering

Nanofiber matrices were also investigated for developing scaffolds for bone, ligament and cartilage tissue engineering. Li et al. used PLGA nanofiber matrices to culture MSCs and demonstrated that nanofibrous matrices could support the adhesion and proliferation of these cells [149]. Yoshimoto et al. used PCL nanofiber matrices to culture MSCs under dynamic conditions in osteogenic media to evaluate the feasibility of developing bone *in vitro* [178]. The average fiber diameter of the scaffold was ~400 nm. The MSCs were seeded on the nanofiber matrix and cultured for 4 weeks under dynamic conditions. MSCs were found to attach and proliferate throughout the nanofiber matrix. Furthermore, the cells migrated inside the scaffold and produced an extracellular matrix of collagen throughout the scaffold (Fig. 1.40). After 4 weeks in culture the cell polymer construct was noticeably harder and the extracellular matrix was calcified throughout the matrix, as evidenced from histology.

Polyurethane nanofiber scaffold was used to evaluate the effect of nanofiber alignment on the cellular response of human ligament fibroblasts (HLF) and to evaluate the influence of HLF alignment and strain direction on mechanotransduction [153]. A rotating collecting target was used to develop aligned nanofibers. After 3 days in culture, the HLFs on the aligned nanofibers were spindle shaped

**Fig. 1.40.** SEM showing a cell nanofiber construct after 4 weeks in culture. Globular accretions, abundant calcification and collagen bundles can be seen. (Adapted from Ref. [178] with permission from Elsevier.)

and oriented (similar to *in vivo* ligament fibroblast morphology) along the nanofiber direction and the aligned nanofiber formed tissue-like oriented bundles that were confluent over the entire surface within 7 days. The HLFs on randomly oriented nanofiber scaffold were not oriented, but when the scaffold was subjected to uniaxial strain the cells reorganized their spindle shape and became organized. There were significant differences in the ECM production by oriented and un-oriented cells on the matrices, indicating that cell morphology plays a significant role in ECM production. Furthermore, the aligned HLFs on the nanofiber structure were more sensitive to strain in a longitudinal direction. The study demonstrated that aligned nanofiber scaffold forms a promising structure for developing tissue engineered ligament due to its biomimetic structure and the ability to provide a mechanical environment ligament cells encounter *in vivo*.

Li et al. using PCL nanofiber scaffold demonstrated the efficacy of nanofiber scaffold to support the differentiation of MSCs to chondrocytes as a viable method to engineer cartilage *in vitro* [179]. The three-dimensional MSC seeded constructs display a cartilage-like morphology containing chondrocyte like cells surrounded by abundant cartilaginous matrix (Fig. 1.41). The level of MSC chondrogenesis using nanofiber scaffold was found to be higher than in high density pellet cultures commonly used for MSCs. This study demonstrated that biodegradable nanofiber scaffold due to its microstructure resemblance to a native ECM effectively supported MSC chondrogenesis.

A self-assembling peptide hydrogel scaffold has also been investigated as scaffolds for cartilage repair and regeneration [180]. A KLD12 peptide was developed, the aqueous solution of which was found to form a hydrogel when exposed to salt solution or cell culture media. The encapsulated chondrocytes showed a round morphology with cell viability of 89% immediately after encapsulation. Cell division of encapsulated chondrocytes in peptide hydrogel was found to be much higher than agarose control cultures. Histological evaluation of the encapsulated cell-hydrogel construct showed the formation of cartilage-like ECM rich in proteoglycans and type II collagen. Time dependent accumulation of this ECM was paralleled by increase in stiffness of the material showing the deposition of mechanically functional neo-tissue. This study demonstrated the potential of self-assembling peptide hydrogel as a scaffold for the synthesis and accumulation of a true cartilage-like ECM within a 3D cell culture for cartilage tissue repair.

## 1.8

### Conclusions

Nanotechnology assisted fabrication processes are changing the way bioresorbable scaffolds are being developed for tissue engineering. Novel nanofabrication processes have enabled the development of nanostructured scaffolds that could closely resemble the structure of the ECM, and studies using bioactive nanostructured scaffolds have demonstrated the importance of nanostructure in cell-matrix and cell-cell interaction. Even though top-down and bottom-up approaches developed

**Fig. 1.41.** Morphology of differentiated chondrocytes in cell pellet (CP) culture and using PCL nanofiber matrix. (A) Top view of CP with round chondrocyte-like cells on the surface. (B) Cross-sectional view of CP, showing thick ECM. (C) Top view of nanofiber

matrix, showing the presence of round, ECM-embedded chondrocyte-like cells. (D) Cross-sectional view of nanofiber matrix, showing a thick, dense ECM-rich layer. (Adapted from Ref. 179] with permission from Elsevier.)

to fabricate nanostructured scaffolds have several advantages of their own, several limitations still hinder the translation of many of these technologies for clinical applications. Future studies will rely on a combination of both approaches as necessary as well as combining these with lithographic techniques to develop hierarchical nanostructures with spatially presented biological cues for developing optimal scaffolds for tissue engineering.

# Polymeric Nanofibers in Tissue Engineering

*Seow Hoon Saw, Karen Wang, Thomas Yong,  
and Seeram Ramakrishna*

### 2.1

#### Overview

Advances in tissue engineering in recent decades has sparked interest in fabricating polymeric fibers, in particular nanofibers, as scaffolds for biomedical applications. The unique properties of nanofibers, such as high surface area, remarkable surface properties and superior mechanical properties, have great potential for a wide variety of applications in medicine, biotechnology and engineering. Among the many features of nanofibers, biocompatibility is the most crucial aspect of tissue engineering. The materials that are mainly used are biopolymer and biodegradable synthetic polymers. Researchers have shown that polymeric nanofibers can be fabricated using various processing techniques such as self-assembly, phase separation and electrospinning.

This chapter reviews the applications of nanofibers in different aspects of tissue engineering. Studies have been carried out to optimize the properties of nanofiber scaffolds for applications in ophthalmology, hepatic biology, nerve, skin, bone and cartilage regeneration, heart and vascular grafts, and stem cell research. Numerous studies have shown that nanofibers that closely mimic the extracellular matrix in natural tissues have potential as scaffolds for tissue regeneration. They provide interconnected pores that facilitate transport of nutrients and growth factors to the cells as well as providing a stable structural support, which are essential for effective tissue engineering.

In nerve regeneration, nanofibers have been shown to effectively control the neurite outgrowth rate and orientation that are critical for the repair of the damaged nervous system. Similarly, the ability to control the morphology, proliferation, adhesion and alignment of smooth muscles cells and endothelial cells cultured on nanofibrous scaffolds provides a possible avenue for successful tissue engineering of blood vessels. Suitable bioactive nanofibers for proliferation of osteoblasts in guided bone regeneration, and dermal fibroblasts for burns and chronic wound treatment have also been reported. Studies on nanofibers for stem cell proliferation

and differentiation are still in their infancy but the potential for biomedical applications is tremendous.

Although most of these studies are at the laboratory level, researchers foresee that polymeric nanofibers have good prospects in the near future. Advances in material science, manufacturing technology and design aspects of polymer nanofibers are necessary to realize their full potential in medicine, biology and engineering.

## 2.2

### Introduction

Nanotechnology is a rapidly expanding field and the products resulting from research have increasingly entered into our daily lives. This chapter reviews potential applications of nanofibers, fiber fabrication techniques, and illustrates some of the current studies carried out to optimize the properties of nanofiber scaffolds for applications in ophthalmology, hepatic biology, nerve, skin, bone and cartilage regeneration, heart and vascular grafts, and stem cell research. The advantages and disadvantages of the nanofiber scaffolds are discussed and compared with conventional scaffolds in terms of their physical properties, performances and functionalities for tissue engineering applications. This chapter will contribute to the understanding of nano-scale polymeric fibers, which will facilitate the development of nanofibers with defined properties for specific applications to accelerate advanced research in tissue engineering.

#### 2.2.1

##### History of Tissue Engineering and Nanofibers

Tissue engineering is a discipline that involves the application of the principles and methods of engineering and life sciences towards a fundamental understanding of structure–function relationships in normal and pathological tissues and the development of biological substitutes to restore, maintain or improve functions [1]. It is a relatively novel and emerging field that involves knowledge of bioengineering, the life sciences, and the clinical sciences with the aim of solving the serious medical problems of tissue loss and organ failure [2]. A new functional living tissue is created with the help of the growth and interaction of cells with a matrix or scaffolding to guide tissue development.

Previously, this area of science was called reconstructive surgery and, later, renamed as tissue engineering when attention was focused on fabricating living replacement parts for the body in the laboratory. Tissue engineering has developed at a logarithmic rate, and with researchers realizing the realistic potentials of this new discipline, many concepts and techniques that can be applied to saving lives

Fig. 2.1. Advances in tissue engineering.

are becoming a reality. Figure 2.1 shows a comprehensive summary of the advances made in tissue engineering.

Scaffolds for tissue engineering are an important aspect as they provide the optimized environment for cell survival, proliferation and differentiation, and also for the formation of tissues for desired tissue engineering applications. Constructing scaffolds for tissue engineering purposes is a challenging task as there are many factors that need to be taken into consideration, e.g., the implants must not be able to induce an immune response that can cause inflammation or rejection, a proper substrate is needed for cell survival and differentiation, and an appropriate environmental condition for tissue maintenance is required [3]. Research in the last decade has aimed to design and develop optimized scaffolds for tissue regeneration.

The field of nanotechnology was introduced by Drexler (1986) [4], and subsequently this has become a highly researched topic and promising area for applications in various industries, in particular biomedical applications. Fibers of nanoscale diameter, called nanofibers, were developed and found to be good candidates in the areas of molecular filters, tissue regeneration, drug delivery system, protective clothing, nanosensors and many more. Researchers have realized that polymeric nanofibers have unique properties such as high surface area, remarkable surface properties and superior mechanical properties, making them good candidates as tissue regeneration scaffolds. Thus, the potential of scaffolds in tissue engineering is enormous and studies have been carried out to gain a better understanding of the interactions between cells and the polymeric nanofibers in order to optimize scaffold designs for tissue engineering applications.

## 2.3

### Classification of Nanofibers

Nanofibers are classified based on the materials of which they are fabricated: biodegradable synthetic polymers, biopolymers, copolymers and composite polymers, which will impart unique properties to the nanofibers for specific applications.

#### 2.3.1

##### Synthetic Polymers

A wide variety of synthetic polymers have been commonly used for fabricating nanofibers. In the area of tissue engineering, using synthetic polymers to fabricate nanofibers provides many advantages. Many studies have been performed to evaluate the potential of using these polymers in different tissue engineering applications. Some synthetic polymers such as aliphatic polyesters, poly(L-lactic acid) (PLLA), poly(glycolic acid) (PGA) and polycaprolactone (PCL) have biodegradable properties that are important for the development of biodegradable implants, scaffolds for tissue engineering, and controlled drug delivery. On the other hand, non-biodegradable synthetic polymers are frequently used for permanent or temporary prostheses in the area of biomedical applications, and are not commonly used as biological grafts. As they are not biodegradable, they satisfy the requirement of being sufficiently strong, flexible and hard to withstand the fatigue due to constant motion and friction. Some examples of commonly used non-biodegradable synthetic polymers are poly(vinyl chloride) (PVC), poly(tetrafluoroethylene) (PTFE) and poly(dimethyl siloxane) (PDMS).

Generally, synthetic polymer nanofibers have a major advantage of being mechanically stronger as well as greater flexibility, therefore making them highly durable scaffolds for replacement of desired tissues. In addition, synthetic polymers have another advantage, i.e., they can be produced relatively easily in large quantity with reproducible properties. This allows a consistency in the quality of scaffolds or devices fabricated for tissue engineering applications where obtaining reproducible results is important for determining future applications of the polymer. The degradation rate of the synthetic polymer would also be easier to determine and refine, making them more specific for desired applications. However, the main disadvantage is that synthetic polymers lack biocompatibility, which is a critical issue in tissue engineering.

#### 2.3.2

##### Biopolymers

In recent years, researches have started using natural biopolymers to fabricate nanofibers. Some of these successfully electrospun biopolymers are silk [5, 6], fibrinogen [7], collagen [8], gelatin [9], chitosan [10] and chitin [11]. Natural biopolymers used in tissue engineering are often components in the extracellular ma-

trix (ECM) produced by cells, giving them a better biocompatibility and providing a better environment for tissue regeneration. This in turn improves the cell attachment and growth on these nanofibers. However, variation in the quality of natural biopolymers is inevitable as they are extracted from different sources, and batch variations are unavoidable even when the biopolymers are extracted from the same source, thus affecting the reproducibility of studies. In addition, it is generally more difficult to obtain submicron or nano-sized fibers from natural biopolymers than from synthetic polymer nanofibers because of the relatively low molecular weight of the polymer and the limited solvent availability to dissolve biopolymers.

### 2.3.3

#### **Copolymers**

To overcome certain limitations of synthetic and natural biopolymer, researchers have developed copolymers and blends to fabricate nanofibers. With their unique and favorable properties combined, this enhances their usefulness as scaffolds in tissue engineering, examples are collagen-blended poly(L-lactide-co- $\epsilon$ -caprolactone) (PLLA-CL) [12], collagen/PCL [13], and gelatin/PCL [9]. Besides copolymers and blended nanofibers, surface modification is another means of improving the biocompatibility of nanofibers for specific tissue engineering applications, some examples are gelatin-grafted poly(ethylene terephthalate) (PET) nanofiber mats [14], collagen type I or gelatin grafted PLLA films [15], collagen-coated PLLA-CL nanofibers [16], concentrated hydrochloric acid treated PGA nanofibers [17], and galactosylated poly( $\epsilon$ -caprolactone-co-ethyl ethylene phosphate) (PCLEEP) nanofiber scaffolds [18].

### 2.3.4

#### **Composite Polymers**

In general, most synthetic and natural biopolymers lack certain properties such as material strength and biocompatibility. Researchers have included additives to the nanofibers to confer beneficial properties, making them specific for tissue engineering applications. Studies have revealed that composite nanofibers have better material strength and performance than synthetic and natural biopolymers nanofibers, and this is mostly due to the high surface area to volume ratio, thus providing a greater interaction between the additives and the nanofibers. In tissue engineering, examples of some composite polymers used to fabricate nanofibers are poly(L-lactide-co-glycolide) (PLGA)/chitin [19], polycarbonate urethane (PCU)/carbon [20], and gelatin/PCL [9].

## 2.4

### **Nanofiber Fabrication**

Polymeric nanofibers can be fabricated by several techniques, including drawing, template synthesis, phase separation, self-assembly and electrospinning.

Fig. 2.2. Schematic diagram of the drawing technique.

#### 2.4.1

##### Drawing

Drawing is a process whereby nanofibers are produced when a micropipette with a tip few micrometers in diameter is dipped into a droplet near the contact line using a micromanipulator and then withdrawn from the liquid at about  $1 \times 10^{-4} \text{ m s}^{-1}$  (Fig. 2.2). When the end of the micropipette touches the surface, the drawn nanofiber is then deposited. To draw fibers, a viscoelastic material is required so that it can endure the strong deformation and at the same time it has to be cohesive enough to support the stress that build up in the pulling process. This method can be considered as dry spinning at a molecular level [21]. Nanofibers have been fabricated by the drawing method with citrate molecules [22]. The droplet of solution is deposited on a surface to allow evaporation to take place. After a few minutes of evaporation, due to the capillary flow, the edge of the droplet is more concentrated and the drawing process can begin.

#### 2.4.2

##### Template Synthesis

Template synthesis involves utilizing a template to achieve nanofibers. Aligned polyacrylonitrile nanofibers have been fabricated by this method, using aluminum oxide membrane as the template [23]. In this particular process, when the pressure of the water is increased, it forces the polymer solution through the cylindrical nanopores of the membrane (Fig. 2.3). Once the extruded polymer comes into contact with the solidification solution, it solidifies and forms nanofibers. The diameter of the nanofibers depends on the diameter of the pores of the membrane. This method has been used to obtain nanotubules and nanofibrils of polymers, metals, semiconductors and carbons.

Fig. 2.3. Schematic diagram of template synthesis.

### 2.4.3

#### Phase Separation

Phase separation of a homogenous polymer–solvent solution can be induced in several ways, e.g., thermal induced phase separation (TIPS). When the polymer solution undergoes a decrease in temperature, two phases would form, a polymer-rich phase and a polymer-lean phase. Gradually, gelation would occur causing the polymer-rich phase to form a network structure when the solvent is removed via extraction, sublimation or evaporation. The spaces that were occupied by the solvent in the polymer-lean phase become pores [24] (Fig. 2.4). Generally, matrices made by solid–liquid phase separation have a greater pore size than by liquid–

Fig. 2.4. Diagram showing nanofibrous matrix obtained by phase separation.

liquid phase separation. Common materials used for this process are PLLA and PLLA-CL. Fiber dimensions achievable by this process range from 50 to 500 nm [25]. The mechanical properties of nanofibrous mats so-fabricated can be customized by altering the polymer concentration. Various porous structures can be achieved with this method by varying the thermodynamic and kinetic parameters [26]. Although the phase separation method is an easy process, it can only be applied to a few polymers.

#### 2.4.4

##### **Self-assembly**

Self-assembly is a complex process that involves individual, pre-existing components to organizing themselves into desired patterns and functions. Several factors significantly affect this process, including the peptide sequence if the self-assembly is based on protein–ligand interactions, concentration, pH, presence of salt, and time (or kinetics) [27]. By varying these parameters, nano-scale or macro-scale structures with great stability and functionality can be constructed. Polymeric nanofibers have been constructed by self-assembly through multiple processes of polymer chain annealing, crosslinking, dissolution and cleaving [25]. In the annealing process, polymer chains are annealed end to end, and are crosslinked chemically, thermally or by UV irradiation. The crosslinked polymers are immersed in chemicals to dissolve the continuous non-crosslinked polymer phase to disentangle the nanofibers. Further modifications involve cleaving and loading the nanofibers with chemicals to yield desired nanofiber morphology and chemical structures. By this method, nanofibers ranging from a few to 100 nm in diameter have been fabricated.

#### 2.4.5

##### **Electrospinning**

Electrospinning is a technique used to fabricate polymeric nanofibers by means of an electrostatic force [21]. This cost effective and simple method was invented back in 1934 by Formhals [28]. The principle involves applying a high voltage to the surface of the polymer solution, and when the surface tension is overcome, an electrically charged jet is ejected. The electrical forces cause the discharged jet to stretch, forming a long and thin jet. At the same time, the solvent evaporates before the nanofiber is collected on a grounded collector. Figure 2.5 illustrates schematically the electrospinning process. To date, a great variety of polymer nanofibers have been successfully prepared by electrospinning when compared with other methods mentioned above that can fabricate nanofibers from only a limited number of polymers. With further advancement in this technology, electrospinning has the greatest potential for the mass production and industrial processing of nanofibers.

Electrospinning is influenced by many factors: the most significant is the properties of the polymer solution, e.g., viscosity, conductivity, and surface tension. Controlled variables such as distance between the needle tip and the collector, voltage

Fig. 2.5. Schematic diagram of the electrospinning technique.

applied, type of collector and feed rate have to be considered, too. Ambient parameters such as humidity, pressure and the type of atmosphere in the electrospinning environment also play a role [29]. With this knowledge, different morphology, structures and arrangements of nanofibers can be achieved by varying the parameters.

As most electrospun nanofibers are in the non-woven form, researchers have spent tremendous time and effort in controlling the alignment of the nanofibers. Several set-ups have been designed, such as the cylinder collector with high rotating speed [8, 30], auxiliary electrode/electrical field [31], parallel conducting collector [32], knife edge disk [33], frame collector [34] and many more. Currently, the thinnest electrospun nanofibers achievable are 3 nm in diameter [25]. Huang et al. (2003) have provided a more comprehensive review of electrospun nanofibers [35].

Comparing all of the above techniques, only drawing, template synthesis, phase separation and electrospinning are simple to perform. However, these processes have a common limitation, i.e., most of the polymeric nanofiber production process is currently only possible at the laboratory level, with the exception for electrospinning, which may be the only technique that has the potential for mass production.

## 2.5

### Degradation and Absorption Kinetics of Nanofiber Scaffolds Compared with Conventional Scaffolds

One of the factors required of a tissue regeneration scaffold is that it needs to be biodegradable. As the tissue grows into the porous structure of the scaffold, it is

difficult to remove the scaffold after the tissue has regenerated. Therefore, the scaffold is only required to maintain its volume, structure and mechanical stability just long enough for adequate tissue formation. The rate of the biodegradation needs to be adjusted so that it is able to match the rate of tissue formation. When degradation occurs, the breakdown products released should not induce any inflammation or cause toxicity to the body [36]. The biodegradation rate of the scaffold is influenced by many factors. One common method used to determine the rate is by placing the scaffold in phosphate-buffered saline (PBS) at 37 °C in an incubator (*in vitro*) or implanted into animals (*in vivo*), and biodegradability can be measured by the amount of mass loss, strength loss and the changes in morphology.

Conventional scaffolds such as hydrogels, sheets, meshes, and foams have been widely used in tissue engineering. Many studies were carried out to evaluate their degradation, e.g., Lee et al. (2004) [37] have shown that poly(aldehyde guluronate) (PAG) hydrogel crosslinked with poly(acrylamide-*co*-hydrazide) (PAH) had a weight loss of about 8% at the end of 60 days in Dulbecco's Modified Eagle Medium (DMEM). Generally, nanofibers have a very high surface area to volume ratio, and this will affect the degradation kinetics when compared to more conventional fibers. Studies showed that PGA nanofibers exhibited a rapid degradation rate and was left with a residual weight of approximately 40% at 20 days in PBS. Even after only 1 day of degradation, some PGA nanofibers have already started to undergo hydrolytic degradation and, after 4 days a significant amount of fibers was degraded. At the end of 12 days of degradation, the nanofiber matrix had become chunks of shorter fiber fragments [38]. In contrast, PGA microfiber non-woven matrix, which has been commercialized as a tissue engineering scaffold, only started to degrade at day 3, as shown by surface defects or microcracks. After several days, the surface defect degraded further to form a rupture in the microfiber [39]. The difference in the degradation rate between the microfiber and the nanofiber is probably due to the fiber diameter, which relates to the surface area. This property of rapid degradation is especially beneficial for temporary tissue regeneration scaffolds. However, studies have shown that the breakdown product from PGA was able to cause dedifferentiation as well as reduce proliferation rate of vascular smooth muscle cells. Therefore, PGA would not be the optimal scaffold for vascular tissue engineering [40]. As PGA nanofibers have a faster degradation rate, more breakdown product would be produced in a shorter period and this would cause more dedifferentiation and reduction of the proliferation rate when compared to conventional scaffolds.

Other degradation kinetic studies include that of Zong et al. (2005) [41], which showed that non-woven PLLA scaffold of an average fiber diameter of 1  $\mu\text{m}$  had 90% remaining weight after about 20 days of degradation. The thickness of the scaffold also plays an important role in the degradation rate. With a reduction in the thickness of PLGA films, the degradation rate significantly decreased as there is faster diffusion of the degraded products, thus minimizing autocatalyzed hydrolysis [42].

### Advantages and Disadvantages of Nanofiber Scaffolds Compared with Other Conventional Scaffolds

Textile technologies have been utilized to produce the earlier tissue engineering scaffolds consisting of fibrous biodegradable polymer fabrics with an average diameter of 15  $\mu\text{m}$ . It has been used alone or in combination with other non-woven biodegradable polymers, such as PGA (Fig. 2.6a), PGA/PDLLA and PGA/PLLA for the engineering of cartilage [43, 44–46], tendon [47], ureter [48], intestine [49], blood vessels [50, 51], heart valves [46, 52] and other tissues [46]. However, the limitations of these scaffolds are a lack of structural stability to withstand bio-mechanical loading, low mechanical strength, fast degradation rate, difficulty in controlling pore shape and limited fiber diameter variations [53, 54].

Other conventional scaffolds developed using particulate leaching techniques [55, 56] and phase separation techniques have diameters of the order of a few to tens of microns. The fibers are not uniformly distributed and are not suitable for tissue engineering applications [55]. In the particulate leaching method, a polymer solution is cast into the salt-filled mold with the desired size. After the solvent is allowed to evaporate, the salt crystals are leached away using water to form the pores in the scaffold (Fig. 2.6b). It is relatively easy to prepare, the pore size can be controlled by the size of the salt crystals, and the porosity by the salt/polymer ratio. However, this method of scaffold preparation is not able to control the pore shape and interpore opening of the scaffolds. To improve these aspects, the three-dimensional (3D) printing (free-form fabrication) technique was adopted to fabricate scaffolds. In this process, a binder is ink-jet printed onto sequentially laid polymer powder layers [57] where computer-assisted design and manufacture (CAD/CAM) is used to design complex-shaped objects. This method was initially explored at Massachusetts Institute of Technology, USA [58–60]. The precision of this process is severely limited due to the smallest possible powder particle size achievable and pixel size of the binder drops (usually a few hundred  $\mu\text{m}$ ), and po-

sitioning of the printer nozzle [61]. Membrane lamination is another technique that can be used to fabricate scaffolds by laminating membranes and introducing the peptides and proteins layer by layer during the fabrication process. This method will produce porous 3D structures [62]. The limitations of this process are less interconnected pore networks in the scaffold and the lack in mechanical properties. Solvent cast polymer–salt composites have also been extruded into a tubular geometry [63]. The disadvantages of producing the scaffold using this method are extensive use of highly toxic solvents, long duration for solvent evaporation (days to weeks), labor intensive fabrication process, limitation to thin structures, residual particles in the polymer matrix, irregularly shaped pores, and insufficient interconnectivity.

All the above-mentioned methods do not allow tissue engineers to design and fabricate scaffolds with a completely interconnected pore network, and a highly regular and reproducible scaffold morphology. However, many researchers have successfully developed high-performance polymer fibers with a high degree of fiber orientation using conventional fiber spinning techniques such as wet spinning, dry spinning, melt spinning, and gel spinning. Wet spinning is the oldest of these processes and it involves submerging the polymer solvent into a chemical bath, followed by precipitation and solidification of the polymer fiber. Dry spinning is achieved by evaporating the polymer solution in a stream of air or inert gas to solidify the fibers. In melt spinning, the molten polymer is forced through a spinneret and the fibers are directly solidified by cooling. Gel spinning is achieved by binding the polymer chains at various points in the liquid crystal state and further cooled in liquid bath after passing through air to produce the fibers [64–67]. With these methods, many different high-performance and functional polymer fibers have been produced and commercialized for many applications in the various industries.

Several complex molecular processes are involved in conventional fiber fabrication processes such as the spinning and drawing techniques. The ultimate state of molecular order in the polymer fibers depends on process variables such as stress, strain, temperature, time, length and length-distribution of the molecules [65]. Polymer fibers developed by these techniques have diameters in the range of microns (10–100  $\mu\text{m}$ ) and are classified as microfibers. The advantages of polymer microfiber are its flexibility which is easily controlled during structure formation, and the superior mechanical properties [68]. These fibers have been used in making ropes, satellite tethers, and high-performance sails. Polymer composite microfibers have found applications in aircrafts, boats, automobiles, sporting goods and biomedical implants. Several significant fiber properties such as ultraviolet resistance, electrical conductivity and biodegradability have been brought to good use.

The specific features of microfiber are fully exploited in industry, which exceeded previous performance level, and this led to the research, development and production of nano-diameter fibers or nanofibers with remarkable properties. When a fiber diameter is reduced to the nanometer scale, the surface area to volume ratio is significantly increased and this property has been exploited by many researchers for applications in various industries such as medicine, biotechnology and engi-

neering [36]. There are more than 70 research groups worldwide investigating electrospun polymer nanofibers [69] and this is due to the unique properties of nanofibers when compared with the conventional macromaterials and polymer microfibers. Being as thin as less than 10 nm in diameter [35], nanofibers exhibit a larger surface area per unit mass of the order of  $10^3 \text{ m}^2 \text{ g}^{-1}$  [70], permitting easier addition of surface functionalities as well as providing better mechanical properties. As a result, mats of these nanofibers are being tested for use in filter media, scaffolds for tissue engineering, protective clothing, reinforcement in composite materials and sensors [71]. The increased surface area, micro-scale interstitial space with high interconnectivity, good morphological stability, controlled fiber diameter, and sheet thickness make polymeric nanofibers an ideal scaffold for tissue engineering applications as it allows a significant amount of cell–surface interaction [69]. Polymeric nanofibers as well as other nano-structured materials such as nanotubes, nanowires, nanocrystals, nanorods and nanospheres are actively studied to uncover the many potentially advanced technological applications [72]. Several fabrication techniques are currently being investigated to develop nanofiber matrices from polymers: template synthesis, phase separation, drawing, self-assembly, and electrospinning (Section 2.4). Among these, electrospinning [33] is an efficient method to develop polymeric fibers with diameters in the nanometer range, and has attracted a great deal of attention recently. In addition to the small fiber diameter and pore size, and lightweight scaffolds that can be fabricated, electrospinning is an inexpensive and easy way to produce nanofibers from many types of polymers.

One of most crucial features of nanofibers is the huge availability of surface area per unit mass (Fig. 2.7). It provides a remarkable capacity for the attachment or release of functional groups, absorbed molecules, ions, catalytic moieties and

Fig. 2.7. Effect of the fiber diameter on surface area [73].

**Fig. 2.8.** Proliferation of fibroblast cells on four types of scaffolds: (red) 3D braided structure consisting of 20 bundles of 20  $\mu\text{m}$  filaments; (green) 150–300  $\mu\text{m}$  PLGA sintered spheres; (blue) non-woven, consisting of PLGA nanofibrils; (yellow) unidirectional bundles of

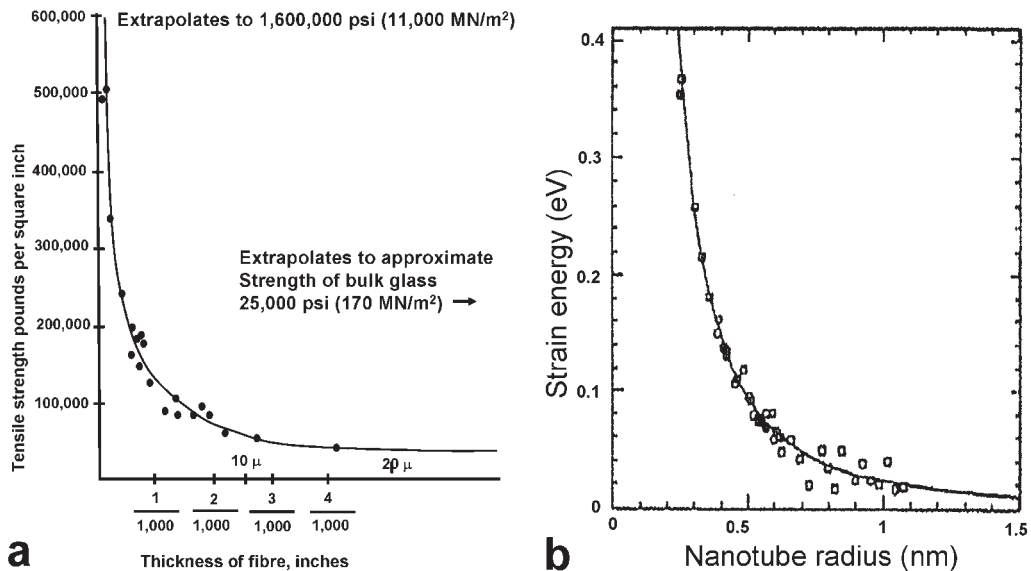

20  $\mu\text{m}$  filaments. Proliferation was determined by the thymidine uptake of the cell as a function of time. Clearly, the PLGA nanofiber scaffold is the most favorable for cell growth [73].

nanometer-scale particles of many kinds [73]. The high surface cohesion of nanofibers is capable of trapping tiny particles that are less than 0.5  $\mu\text{m}$  in size. The porosity and pore size of nanofiber membranes are important for application in tissue engineering. Nano-scale fibrous scaffolds can provide an optimal template for cells to attach, migrate, and grow. Mammalian cells can attach and organize well around fibers with diameters smaller than the diameter of the cells [74] and this is mainly due to the nano-scale interaction between the cells and the many biologically functional molecules and extracellular matrix components [54]. In a study of osteoblast bioactivity cultured on matrices consisting of 3D braided filaments, microspheres, non-woven nanofibrils, and microfilaments (Fig. 2.8), nanofibrils had the best support for cell growth and proliferation as determined by thymidine uptake [75]. This study also showed that a small fiber diameter facilitates greater available surfaces for the cell adhesion and migration. Non-woven mats formed from nanofibers have additional advantages of controllable pore size, high porosity, and permeability [76]. These remarkable properties motivate extensive interests in using these materials for applications in industries, especially in the biomedical fields. Composites nanofibers have been identified as potential candidates for high technology applications [35] due to its unique physical and mechanical properties. Hence, nano-featured synthetic scaffold design is one of the exciting new areas in tissue engineering.

Some recent studies showed that electrospun nanofibers can be collected in the form of highly oriented arrays that are able to elicit favorable biological responses due to their ability to mimic the biological microarchitecture and act to support and guide cell growth [33, 35, 67, 77]. Converting biopolymers into fibers and net-

works that mimic native structures will ultimately enhance the utility of these materials, as large diameter fibers do not mimic the morphological characteristics of the native fibrils [65]. The various properties of electrospun nanofibers such as mechanical strength, fiber diameter, porosity, and biocompatibility are dependent on the properties of the polymer type. Electrospun nanofibers fabricated from polyesters, polyurethanes, silicones, and poly(ethylene-co-vinyl acetate) (PEVA) have been identified as potential candidates for medical applications and have been fabricated as drug delivery devices, wound dressings and prosthetic devices such as vascular grafts [78–80] (Section 2.8). In the area of wound healing, electrospun nanofibrous membrane showed good and immediate adherence to wet wound surface where it attained uniform adherence to the wound surface without any fluid accumulation. The rate of epithelialization was increased and the dermis was well organized in the nanofibrous membrane, providing a good support for wound healing. The porosity of the nanofibrous membrane promotes evaporative water loss, excellent oxygen permeability and fluid drainage from the wound [81, 82]. Nanomaterial scaffolds have also been observed to enhance the functions of osteoblasts, such as adhesion, synthesis of alkaline phosphatase, and deposition of calcium-containing mineral compared with conventional scaffolds [83], and promote greater than  $1.7\times$  the osteoblastic cell attachment of conventional scaffolds. Nanofibrous scaffolds have also shown to adsorb four times more serum proteins than conventional scaffolds. More interestingly, the nanofibrous architecture selectively enhanced protein adsorption including fibronectin and vitronectin, even though both scaffolds were made from the same PLLA material. These results demonstrate that the biomimetic nanofibrous architecture serves as superior scaffolding for tissue engineering [84]. However, as-spun nanofibrous matrix can quickly lose its structural integrity or biological functionality in an aqueous environment such as in the human body [85]. Bhattarai et al. (2005) [85] have investigated the cellular compatibility of electrospun chitosan nanofibers incorporated with 40 wt.% poly(ethylene oxide) (PEO) but the nanofibrous matrix swelled readily in water and completely lost its fibrous structure in a few days. This would limit its application where a prolonged material functionality *in vivo* is required. Thus, processing conditions and mechanisms that would yield the desirable nanofibrous structure and material properties need to be investigated in order to construct nanofibrous matrix that exhibit good structural integrity to promote cell attachment and potentially serve as scaffold materials for tissue engineering.

Nanomaterials are unique as they are stronger than bulk materials. As fiber diameter decreases, the strength of the fiber (in this particular case glass fiber) increases exponentially [86] and this is probably due to the reduction in structural flaws of the glass fibers (Fig. 2.9a). Dresslhaus et al. (2000) [87] have described that, in the case of nanotubes, as the radius of matter gets smaller the strain energy per atom increases exponentially (Fig. 2.9b), contributing to over 30 GPa of increased strength. These unique characteristics in addition to their light weight, high permeability and the ability to absorb toxic materials enable these materials to be developed into high-performance filters, catalysis systems as well as for novel military fabrics [35]. Nano-sized fibers that can conduct electrical current and respond to electronic stimuli over metal contacts have also been developed. Norris

and colleagues (2000) [88] found that polyaniline/PEO sub-micron fibrils have a response time an order of magnitude faster than bulk polyaniline/PEO in a doping–doping experiment. El-Aufy et al. (2003) [89] also demonstrated a significant increase in conductivity using sub-micron polyethylene dioxythiophene (PEDT) conductive fiber mat or when the fiber diameter decreases (Fig. 2.10). This effect is probably attributed to the intrinsic fiber conductivity effect or the geometric surface and packing density effect. However, nanofibers of smaller diameter have also been reported to exhibit lower and less stable conductivities. Zhou et al. (2003) [90] fabricated electrospun polyaniline/PEO nanofibers with diameters below 15 nm and found that the nanofibers were in fact electrically insulating. Many factors play important roles in polyaniline-based conductometric sensors, and one has to balance these factors to fully realize the potential of nano-structured conducting polymers. In some instances, “old-fashioned” materials may provide more desirable sensing characteristics [91]. Although the nanofiber films demonstrated faster responses, they exhibited lower sensitivity than conventional thin films. Researchers have shown that high surface area nanofibril structures do not effectively enhance sensor sensitivity due to the relatively open structure inherent in the many polymeric materials, and the adverse contribution from the interfibrillar contact resistance associated with nanofiber films [92, 93].

Current research focuses on the exploitation of these unique properties of nanofibers to improve their performance and functionalities for various applications. Improvement in the electrospinning technique has also been a focus of many research groups to refine and improve the properties and features of nanofibers. This

**Fig. 2.10.** Log of fiber diameter (nm) versus conductivity ( $S\text{ cm}^{-1}$ ). As fiber diameter decreases from 260 to 140 nm, the electrical conductivity of PEDT nanofibers showed almost two orders of magnitude increase [89].

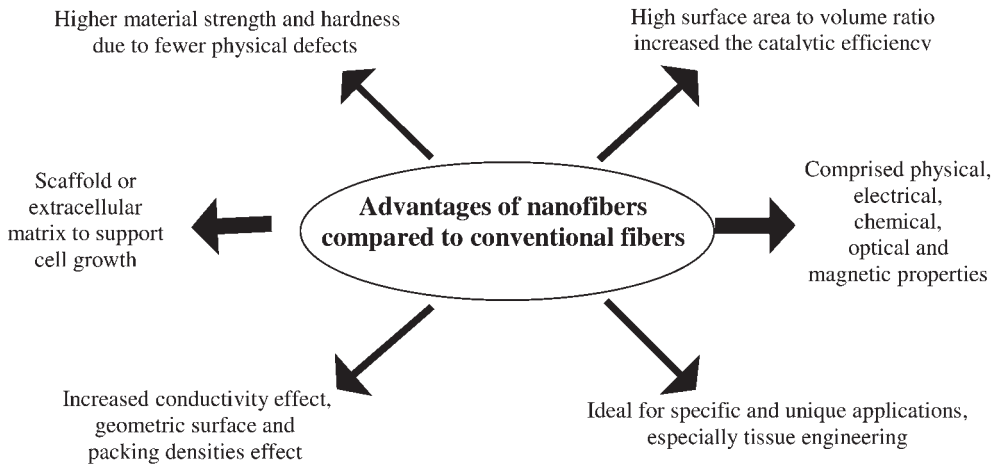

is because electrospinning is a simple process to fabricate polymer nanofibrous materials for high-performance applications. Nano-scale fibers have the potential to revolutionize many industries. During the past decade, rapid technological advances in the areas of surface microscopy, silicon fabrication, biochemistry, molecular biology, physical chemistry, and computational engineering have enhanced and enabled research and implementation of nanotechnology in academia and industry. Figure 2.11 summarizes the advantages of nanofibrous scaffolds.

## 2.7

### Biocompatibility of Nano-structured Tissue Engineered Implants

The objective of tissue engineering is to develop reproducible and biocompatible 3D scaffolds that act as bio-matrix composites to support cell in-growth in tissue repair and replacement procedures [65]. Researchers have focused on making such scaffolds with synthetic biopolymers and/or biodegradable polymer nanofibers [94–96]. Polymeric nanofibers have been widely studied as potential tissue engineering materials for biomedical applications. As a matrix, nanofibers mimic the structure and certain functions of the natural extracellular matrix to restore, maintain or improve the function of human tissues. Being biocompatible, nanofibers have been used for the replacement of structurally or physiologically deficient tissues and organs in human [35].

Biocompatibility is described as the ability of an implant (biomaterial, biotextile, prosthesis, artificial organ, biomedical device) to be accepted by the cellular and biological response from the host environment and does not have the potential to

**Fig. 2.11.** The many advantages of nanofibers.

elicit an immunological or clinically detectable primary or secondary foreign body reaction [53, 97, 98]. It should be compatible with tissues in terms of mechanical, chemical, surface and pharmacological properties. *In vivo* biocompatibility testing of the biomaterials requires introduction of the implant into the biological environment to evaluate adverse reactions [99], such as alterations in homeostatic mechanisms, magnitude and duration of these altered homeostatic mechanisms if any, to determine the host biocompatibility response to the implant. If the implants are not rejected by the body, the following phases of recovery will be initiated: resolution (response of the biological environment to the injury and the presence of the implant), restitution (the return of the tissue environment to its normal structure and with the implant) and reorganization (the result of the wound healing response initiated by the injury and the presence of the implant). In addition, the rate of polymer biodegradation will also affect the biocompatibility of the implant in the biological system. Jayaraman and colleagues (2004) [71] have demonstrated that mats made of nanofibers from biodegradable polymers may be helpful in adjusting the degradation rate of specified biomaterials in the *in vivo* environment. Although no reports have been established on the influence of nanofiber diameter on the degradation behavior of polymers in the *in vivo* environment, there is evidence that the diameter of fibers do affect the degradation features and related mechanical properties of the materials [100]. In an *in vivo* study carried out in our laboratory on electrospun PLGA nanofibers tubes [101] that act as nerve guidance conduits, we observed that there was no inflammatory response after a month's implantation of the nanofiber nerve guidance conduit to the right sciatic nerve of the rat. Nerve growth factors or Schwann cells [102, 103] could be introduced into the nanofiber conduits to increase the biocompatibility of the nanofibers and hence improve the quality of the nerve regeneration and lead to clinical applications.

Polymeric nanofibers have been fabricated from various natural and synthetic biodegradable nanofibers [71] and most of the research on nanofibers for tissue engineering applications has centered on *in vitro* cell culturing to evaluate cell adhesion, proliferation, gene expression and extracellular matrix secretion [104]. Natural polymers are generally preferred over synthetic polymers in tissue engineering due to their tissue compatibility and biodegradation products which are readily resorbed into the body. In addition, nanofibers made from natural materials usually have better cell interactions than synthetic polymer nanofibers. Thus, the surface properties of the scaffold have been modified by adding surface coatings of collagen, gelatin, heparin, albumin or pyrolytic carbon to enhance the biocompatibility of the scaffold [69].

The most commonly used naturally derived polymers as tissue engineering scaffolds are collagen and chitosan [105]. Scientists are able to fabricate these nanofibers with diameters in the range of 100 nm to a few microns [8]. Collagen is a natural substrate for cell attachment, growth and differentiation. It provides considerable strength in its natural polymeric state. Collagen is also important in the design of tissue engineered devices [106] and it meets the requirements in wound healing since it has higher gas permeation and is able to protect the wound from infection and dehydration [81]. Venugopal et al. (2005) [107] fabricated nanofiber matrices from biodegradable PCL incorporated with collagen and showed that human dermal fibroblasts were able to grow, proliferate and migrate inside the matrices. These scaffolds support the attachment and proliferation of the cells and can be used as dermal substitutes for skin regeneration. In another study, Matthews et al. (2001) observed that smooth muscle cells cultured on electrospun collagen (calfskin) nanofiber matrix were able to grow into the nanofiber network [8]. Other studies showing infiltration of cells into the nanofiber networks include chondrocyte cultured on electrospun collagen type II scaffolds [108], human bone marrow stromal cell (BMSC) cultured on electrospun silk fibroin based-nanofibers [6], and human keratinocytes and fibroblasts proliferation on silk fibroin-based nanofibers [5].

Chitosan, a biologically renewable, biodegradable, non-antigenic and biocompatible natural polymer [105], is widely studied in wound dressing, wound healing [109], drug delivery systems [110], bone tissue engineering [111–113] and in various tissue engineering applications [114–117]. Electrospun chitosan nanofibers incorporated with synthetic polymers such as chitosan/poly(vinyl alcohol) and ultrathin hybrid nanofibers containing chitosan and PEO have been prepared by Ohkawa et al. (2004) [118], Duan et al. (2004) [119] and Bhattarai et al. (2005) [85]. Chitosan nanofibers with controllable size and alignment to form non-woven mats or 3D porous structures will provide an unlimited source for the development of natural scaffolds for tissue engineering [85]. Elastin, another structural protein of the extracellular matrix, has been successfully electrospun into elastin-mimetic peptide polymer nanofibers. The elastic property of elastin nanofibers has been capitalized on for the engineering of arterial blood vessels [96, 120].

In bone tissue engineering, nano-structured composites consisting of nano-hydroxyapatite and collagen (nHAC) have been developed by co-precipitation of hy-

droxyapatite (HA) and collagen [121], and mineralizing type I collagen sheet with hydroxyapatite [122, 123]. Preliminary *in vitro* and *in vivo* studies indicate that nHAC is bioactive and biodegradable [124]. However, its mechanical properties were too weak for practical application. To improve the mechanical strength, a nano-HA/collagen/PLA (nHAC/PLA) scaffold has been developed [124] which has high biocompatibility and strength, and serve as a promising scaffold in traditional bone-defect repair and in bone tissue engineering. Osteoblast cultured on the nHAC/PLA nano-composites performed well in adhesion, proliferation and maturation that accompanied the morphological change from spindle shaped to predominantly polygonal morphology. To further enhance nHAC mechanical properties, Zhang et al. (2003) [125] integrated nHAC composite with a small fraction of Ca-crosslinked to alginate to produce a porous structure that mimicked the composition of natural bone as well as to increase the osteoconductive activity of the scaffold. Polysaccharide alginate possesses good biocompatibility and provides satisfying mechanical support. Fibroblasts and osteoblasts co-cultured with nHAC/Ca-alginate composite exhibited good cell morphology, adhesion and proliferation, inferring the composite as a good scaffold material for bone tissue engineering. Although the efforts in fabricating natural polymer-based fibrous structures are encouraging, much remains to be explored and improved, especially in *in vivo* applications.

The uses of biocompatible synthetic polymer nanofibers have been widely investigated to evaluate their feasibility as scaffolds for applications in tissue engineering. Materials that have been used are polyesters, polycaprolactone, poly(amino acids), polycarbonates, poly(ethylene glycol) and many more. Polyesters such as PLA, PGA and copolymers of lactide/glycolide are among the most commonly used biomaterials for drug delivery [126] and tissue engineering. They break down to naturally occurring metabolites and degradation requires only water. Fine fibers produced from PLA and PGA by electrospinning for tissue engineering applications have been intensively investigated [30, 127]. ECM-like scaffolds fabricated from PLLA nanofibers by phase separation promote cell growth, proliferation and migration into the interstices of the nanofiber network [128, 129]. A nano-3D PLGA scaffold constructed by solvent casting and salt leaching processes had been shown to be biocompatible and support human bladder smooth muscle cells adhesion, growth and proliferation [130]. Cells cultured on nano-dimensional scaffolds showed a corresponding increase in cellular protein production when compared to cells cultured on conventional, micro-dimensional scaffolds. In addition, evidence in pressure experiments showed that, in general, scaffolds and resident cells experiencing a sustained pressure stimulus of 10 cm-H<sub>2</sub>O functioned similarly to those experiencing atmospheric (control) pressures. These results suggest that the novel porous, nano-dimensional PLGA scaffold is promising for *in vivo* replacements of the urinary bladder wall. Webster et al. (2005) [83] observed that the functions of osteoblasts such as adhesion, synthesis of alkaline phosphatase, and deposition of calcium-containing mineral showed an increase on nanofibrous PLGA scaffolds compared with conventional ceramics. Since both the nanofibrous PLGA and conventional ceramics share the same chemistry, material phase, porosity, and pore

size, the study implies that the surface features created by adding nanophase compared with conventional titania was a key parameter that enhanced functions of osteoblasts. Such nanophase ceramics (or nanomaterials in general) require further attention as orthopedic tissue engineering materials [83].

PCL is compatible with soft and hard tissue and is used as resorbable suture material, in drug delivery systems, and as bone graft substitutes. It has been incorporated into other synthetic polymers to create an ideal scaffold for the cell growth. Fetal bovine chondrocytes seeded on a nanofibrous PCL scaffold and cultured in serum-free medium maintained their chondrocytic phenotype by expressing cartilage-specific extracellular matrix genes that were evaluated by reverse transcription-polymerase chain reaction (RT-PCR). PCL nanofibers not only promoted the phenotypic differentiation but also promoted chondrocyte proliferation when cultures were maintained in serum-containing medium [131]. Adult bone marrow-derived mesenchymal stem cells cultured in a PCL nanofiber scaffold were induced to form chondrocytes in the presence of transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1), as evidenced by chondrocyte-specific gene expression and synthesis of cartilage-associated extracellular matrix proteins. The chondrogenic ability of stem cells cultured in a PCL nanofiber scaffold was comparable to that observed for stem cells maintained as cell aggregates or pellets [132]. Yoshimoto et al. (2003) [133] seeded mesenchymal stem cells (MSCs) derived from the bone marrow of neonatal rats on electrospun PCL nanofibers as well and cultured the cells in osteogenic culture medium under dynamic culture conditions. At 4 weeks, the material was covered by multiple cell layers and mineralization occurs together with the existing type I collagen on the PCL nanofiber. Besides supporting the chondrocytes and stem cells, PCL nanofibers have also been observed to support the attachment of cardiomyocytes. Shin et al. (2004) [134] developed a cardiac nanofibrous mesh by culturing cardiomyocytes on electrospun nanofibrous PCL scaffold. The nanofibrous mesh acted as an extracellular matrix for cell growth and was supported by a wire ring that played a role as a passive load for the contracting cardiomyocytes. The cells on the scaffold were observed to start beating after 3 days of culture. In addition, cells cultured *in vitro* for 14 days were found to attach well on the PCL mesh and expressed cardiac-specific proteins such as  $\alpha$ -myosin heavy chain, connexin43 and cardiac troponin I. Block copolymers of PLLA and PCL (PLLA-CL) electrospun into non-woven and aligned nanofiber scaffolds have been reported to support the adhesion and proliferation of human coronary artery endothelial and smooth muscle cells, with a future application in blood vessel tissue regeneration [135–137]. In addition, PLGA and PCL nanofibers have been successfully utilized by Li et al. [131, 132, 138] to culture fibroblasts, cartilage, and bone marrow-derived mesenchymal stem cells. These reports showed that biocompatible synthetic polymeric nanofiber scaffolds were capable of enhancing cell attachment and proliferation.

Poly(*p*-dioxane) (PPDO) is a hydrophobic polyester that possesses good biocompatibility, flexibility and tensile strength. It degrades to non-toxic compounds and can be used in the body safely [139]. It has been applied to different applications in the medical field [140–142], such as surgical sutures [143] and drug delivery sys-

tem [141]. Poly(ethylene glycol) (PEG) is another widely used biocompatible polymer. PEG is a simple linear polyether that exhibits outstanding physiochemical and biological properties, and possesses good hydrophilicity and solubility in water and organic solvents. It lacks toxicity, and does not induce immunological effect, allowing it to be used for many biomedical and biotechnological applications [144, 145]. When PEG is coupled to PPDO, the conjugated product possesses the beneficial properties of both individual polymers. PLLA conjugated to PEG is another block copolymer that possesses properties desirable for tissue engineering applications [146–148]. The synthesis of a novel biocompatible block copolymer consisting of PPDO, PLLA and PEG (PPDO/PLLA-b-PEG) by Bhattarai et al. (2004) [82] takes advantage of the combined properties of these polymers to further enhance biocompatibility. NIH 3T3 fibroblast cells seeded on the PPDO/PLLA-b-PEG nanofibrous structure were shown to maintain their phenotypic shape and guided growth according to the nanofiber orientation. PEO is another biocompatible polymer that has been used in food, cosmetics, personal care products and pharmaceutical. Electrospun poly(ethylene-co-vinyl alcohol) nanofiber mat can also support the growth of smooth muscle cells and fibroblast [80].

## 2.8

### Applications of Polymeric Nanofibers in Tissue Engineering

With the advancement in tissue engineering in the past decades, researchers realized that nanofibers have potential as scaffolds in tissue regeneration. These nanofibers can be fabricated from either natural or synthetic polymers for various applications in tissue engineering (Table 2.1). The rationale for using nanofibers is based on the principle that cells organize and attach well around fibers with a diameter smaller than that of the cells [74]. In addition, non-woven polymeric nanofibers mimic the nano-scale fibers that are present in the natural extracellular matrix. They provide interconnected pores that facilitate transport of nutrients and growth factors to the cells as well as providing a stable structural support, which are essential for effective tissue engineering. A unique characteristic of the nanofibers is its huge surface area-to-mass ratio, in the range of  $10\text{--}10^3\text{ m}^2\text{ g}^{-1}$  for a fiber diameter of around 500 nm [98], and this makes them suitable to host various functionalities and be applied to a broad range of applications in life sciences and sensor applications. Therefore, studies have been performed to optimize the properties of the nanofiber scaffolds in the areas of ophthalmology, hepatic biology, nerve, skin, bone and cartilage regeneration, heart and vascular grafts, and stem cell research as well as drug delivery application [149]. Tissues can be engineered at different levels of complexity (Fig. 2.12) [150]. Using this knowledge of nanotechnology, tissue engineered products with highly predictable biological and physical properties can be obtained.

In nerve regeneration, nanofibers have been shown to effectively control the neurite outgrowth rate and orientation that are critical for the repair of the damaged nervous system. Similarly, the ability to control the morphology, proliferation, ad-

hesion and alignment of smooth muscles cells and endothelial cells cultured on nanofibrous scaffolds provides a possible avenue for successful tissue engineering of blood vessels. Suitable bioactive nanofibers for proliferation of osteoblasts in guided bone regeneration, and dermal fibroblasts for burns and chronic wound treatment have also been reported. Studies on nanofibers for stem cell proliferation and differentiation are still in their infancy but the potential for biomedical applications is tremendous.

### 2.8.1

#### **Ophthalmology**

Every part of the human eye plays an important role in providing clear vision. The cornea is the primary component of the ocular optical system that refracts light onto the retina for vision and act as a tough protective barrier for the delicate internal eye tissues [151]. It is an avascular and transparent tissue that consists of three main layers: outer stratified epithelium, stroma of cell network within a hydrated collagen–proteoglycan matrix, and inner endothelial layer. Nerve activity is crucial for the maintenance of overall corneal health. Innervation loss can cause “dry eye” [152], a pathological condition that will decrease the sensitivity of the cornea and/or caused the erosion of the cornea epithelial. When the sensitivity is lost, the cornea can be affected by a wide variety of disorders [153–156] and becomes vulnerable to irreparable injury, ulceration, eventual loss of vision or blindness [157, 158].

Cornea disease is a major cause of vision loss [159] and it affects more than 10 million individuals worldwide [160]. Transplantation of human donor corneal graft is the widely accepted treatment in the hope of visual recovery [151]. However, transplant donors are limited and worldwide demand exceeds supply. This situation will worsen with an aging population and increased used of corrective laser surgery [161]. Patients with conditions such as autoimmune disorders, alkali burns, graft rejection or recurrent graft failures will have a lower success rate in corneal transplantation [162]. Furthermore, there is a risk in the transmission of infectious agent [163]. Therefore, an alternative for these patients is the replacement of the damaged cornea with an artificial substitute. The structural and immunological simplicity of the human cornea, and the importance of nerve innervations for optimal function, make it an ideal tissue for tissue engineering studies. The ideal artificial cornea (keratoprosthesis) should consist of materials and structures that support adhesion and proliferation of cornea epithelial cells in order to form an intact continuous epithelial layer [163]. It should be permeable to provide appropriate exchange of nutrient and fluid, light transparent and non-toxicity to cells.

In the early 1950s until the 1990s, a few synthetic polymers were used extensively for the manufacture of keratoprostheses. Poly(methyl methacrylate) (PMMA) [164–168] was used as intraocular lenses into human patients. Poly(2-hydroxyethyl methacrylate) (PHEMA) hydrogels have a long history of proven biocompatibility in the cornea [169–182]. Polyurethanes [183–185], poly(glyceryl monomethacry-

late) (PGMA) [186–188], PEO, and poly(vinyl alcohol) (PVA) hydrogels [189] were proposed and/or used episodically as keratoprosthesis materials. Corneal epithelial cells have been preseeded onto PVA and transplanted into rabbit corneas, where they remained adherent and proliferated for 1 to 2 weeks [190–193].

Research in synthetic cornea replacement is essential since most artificial cornea is still plagued with poor adhesion to the host tissues and does not promote reinnervation [194]. Scientists from Argus Biomedical, Australia, have claimed to successfully develop an artificial cornea, named Alphacor. It is made of a biocompatible, flexible, hydrogel material similar to a soft contact lens. It contains a central clear zone, consisting of a transparent gel PHEMA that provides refractive power and a peripheral skirt or rim made of an opaque, porous, high-water PHEMA that encourages the eye to heal over the device. Alphacor has been under clinical study since 1998 and was FDA-approved in August 2002. The replacement cornea is designed to minimize the risk of complications, and to replace the scarred or diseased cornea of the eye that has a history of multiple graft failures [195]. Using collagen-copolymer implants, Li et al. (2003) [160] reported successful growth of stratified epithelium and stromal fibroblast, and nerve innervations into the implant. In two other studies, collagen-copolymer scaffolds designed to mimic the natural ECM matrix and crosslinked to TERP5 copolymer synthesized from *N*-isopropylacrylamide were shown to allow cell growth on the surface [196] and as well as cell ingrowths [197]. Cell adhesion factors may be incorporated into the biosynthetic matrices to promote cell growth and nerve innervations.

The retina is the other part of the eye that has received extensive research in tissue engineering. It has a complex, multilayered architecture that consists of polarized photoreceptor cells that are closely related to the retinal pigment epithelium (RPE), nerve innervations, and rich supply of blood capillaries [198]. The integrity of the RPE layer is critical to the survival and functions of photoreceptors and hence patterns the vision. Retinal degeneration such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD) affect over a million people in USA alone, where they suffer from irreversible visual disability. Photoreceptor cells will lose their functions when the degeneration happens at the outer retina and this will affect the cells that connect and support the photoreceptors of the inner nuclear layer. Conventional treatment of the disease such as retinal progenitor cell (RPC) grafts is not sufficient to create the complex cytoarchitecture on a large scale, especially when multiple retinal layers have been lost or disrupted [199, 200]. Studies have shown that delivery of RPCs using typical bolus injection of RPCs leads to a large degree of cell death [201]. In addition, the widespread intraretinal migration frequently observed with these cells may not be desirable in all settings. A tissue engineering approach using a biodegradable polymer scaffold with the appropriate architecture may improve the survival and promote the organized differentiation of grafted RPCs in retinal degeneration and injury.

Recently, RPCs have been isolated from the mature eye [202, 203] to develop retina [204, 205] and these cells may be able to replace photoreceptors [206]. Lavik et al. (2005) [198] (Fig. 2.13) seeded RPCs onto porous degradable PLGA scaffolds fabricated by anisotropic phase inversion [207] and by liquid–liquid phase separa-

Fig. 2.13. PLGA scaffold prepared using the solid-liquid phase separation technique [198].

tion [208]. The results of this work indicate that degradable polymer scaffolds improve the survival of RPCs in retinal degeneration model, promote differentiation of RPCs, and provide physical guidance to the RPCs resulting in a more normal anatomical organization (Fig. 2.14).

There are very few comprehensive and systematic reports on the functional relationship between nanofibers and applications in ophthalmology. One of the most recent studies is by Zhong et al. (2005) [209] who seeded rabbit conjunctiva fibroblasts (RCF) on electrospun random collagen-glycosaminoglycan (GAG) blended nanofibrous scaffolds with a fiber diameter range 100–600 nm. The results showed that the nano-sized scaffold increased the proliferation of rabbit conjunctiva fibroblast on the scaffolds (Fig. 2.15). Since collagen and GAG are components of the natural ECM, their incorporation into scaffolds has been used extensively for *in vitro* cell-ECM interactions studies and as platform for tissue biosynthesis [210–217]. Traditional collagen gels can self-assemble into a nano-scale fiber-like superstructure [218], but their application is limited due to the poor physical strength. However, aligned nanofibers possess higher mechanical strength than random

**Fig. 2.14.** Seeding of RPCs that are stained green on the solid–liquid phase separated scaffolds for (a) 1 and (b) 3 days. (c) Cross section of the scaffold at 3 days post seeding. The green fluorescence RPCs were

nanofibers [16], and this fiber alignment feature can be used to increase the physical strength of collagen nanofibers. In a study conducted in our laboratory in collaboration with the Singapore Eye Research Institute [219], it was shown that aligned nanofiber scaffold seeded with RCF exhibited lower cell adhesion but higher cell proliferation than the random scaffold. This is likely due to the aligned

**Fig. 2.15.** Scanning electron microscope (SEM) micrographs of (a) electrospun collagen-GAG scaffolds, and (b) RCFs on collagen-GAG scaffolds after 7 days culture [209].

orientation of the fibers, which may control cell orientation and at the same time strengthen the interaction between cells and fibers. This may indirectly increase the overall physical strength of the biological scaffolds. From these results, application of nano-scale collagen or collagen-GAG scaffolds in ophthalmology is significant as the nano-scale dimension of these electrospun nanofibers mimic that of native ECM found in our body and at the same time promote tissue biosynthesis, guide cell growth, and maximize the rate of tissue regeneration [136, 210–221].

### 2.8.2

#### **Liver**

The cells in the liver are highly organized into structural units called liver lobules. These cells or hepatocytes are radially disposed in the lobules, piling up to form one cell thick layers, alike to the bricks of the wall. These cell plates are directed from the periphery of the lobule to its center. In human, these lobules are in close contact with one another, forming sponge-like structures. A unique feature of the liver is its ability to regenerate following injury or resection and tissue engineering methodologies have been applied to assist in liver regeneration. Nano-structured biomaterials have been used to enhance the development of liver replacement devices [222]. In a study by Chua et al. (2005) [18], growth of primary rat hepatocytes on PCLEEP nanofiber scaffolds conjugated with galactose ligands to achieve a bio-functional construct was evaluated. PCLEEP was shown in earlier reports to have good tissue compatibility and low cytotoxicity to the cells [223–225]. Galactose-conjugated substrates have been reported to mediate hepatocyte adhesion, minimize involvement of integrin-mediated signaling pathways, and reduce the loss of hepatocyte phenotype [226]. In this study, hepatocytes cultured on the galactosylated PCLEEP nanofibrous scaffold exhibited comparable functional profiles in terms of cell attachment, ammonia metabolism, albumin secretion, and cytochrome P450 enzymatic activity, when compared with hepatocytes cultured on functional 2D matrix. In addition, hepatocytes cultured on galactosylated nanofiber scaffold formed smaller aggregates of 20–100  $\mu\text{m}$  that engulfed the functional nanofibers and created an integrated spheroid-nanofiber construct, resulting in reduced cell detachment from the nanofibrous scaffold, and form stable immobilized hepatocyte spheroids throughout the period of culture (Figs. 2.16 and 2.17). Such functional nanofiber scaffolds can be incorporated into a bioartificial liver assist device design, and with their textured and porous nature may promote hepatocyte scaffold interaction, improve the stability of the attached cells, maintain their differentiation functions, and, finally, remain stable against the perfusion and shear forces in the bioreactor.

### 2.8.3

#### **Nerve**

Neural tissue engineering (NTE) is a promising and challenging field that involves various disciplines, such as grafting processes, polymer bioprocess and surface

**Fig. 2.16.** SEM images of hepatocytes after 8 days of culture. Hepatocytes cultured on galactosylated film (Gal-film) formed rounded spheroids that did not integrate with the

scaffold (a, b). In contrast, hepatocytes cultured on galactosylated-nanomesh (Gal-nanomesh) showed aggregates that engulfed the functional nanofibers (c, d) [18].

chemistry modifications, as well as involving cell–cell and cell–matrix interactions that occur during development, remodeling and restoration of neural cells [227]. Nerve tissue repair is an important treatment concept in human health care as it directly impacts on the quality of life. However, restoring the nerve function after traumas or diseases has been a great challenge for neurobiologists and neurologists, as the central nervous system (CNS), such as brain and axons, do not regenerate on its own in their native environment. In the peripheral nervous system (PNS), healing of severed peripheral nerves may be impaired by the growth of fibroblastic connective tissues that will disrupt and prevent the proximal neuron from growing towards and reattaching to the distal stump [69]. Attempts to replace lost or dysfunctional neurons using tissue transplantation or peripheral nerve grafting method have been intensely sought for over a century [228]. The purpose is to restore the function in damaged or diseased regions. However, these methods always encountered problems such as donor shortage and immunological problems associated with infectious diseases [229]. To overcome some of these problems, alternative approaches are being investigated that use biomaterials to influence the function and differentiation of cultured or transplanted cells to enhance nerve regeneration [230–233].

The ultimate goal of neural tissue engineering is to achieve suitable biointeractions for a desired cell response that is required to compensate for the loss of tissue function [234] through *in vivo* induction of a neural circuit or *in vitro* fabrication

**Fig. 2.17.** SEM images of freeze-fractured hepatocytes on Gal-nanomesh after 8 days of culture. PCLEEP nanofibers can be found within the hepatocyte aggregates (a, b).

However, no fibers were observed in some hepatocyte aggregates, which may be attributed to degradation of the biodegradable PCLEEP nanofibers (c, d) [18].

of a tissue structure. Engineered polymer scaffolds that can serve as extracellular matrix are crucial to support the fundamental cell processes. Recent advances in the NTE provide optimism by creating a permissive environment for nerve regeneration [163, 235–237]. The ECM of the nervous system is crucial in guiding neural outgrowth and may be relevant to the process of regeneration. It consists of the collagen types I, II, III, IV and V, the noncollagenous glycoproteins and the GAGs [238, 239]. A great variety of natural ECM components exist in fibrous form and structure, some examples include collagen, fibronectin and laminin. All of them are characterized by well-organized hierarchical fibrous structures, ranging from nanometer to millimeter scale [240]. Hence, a nano-structured porous scaffold with interconnective pores and large surface area is needed as an alternative to natural ECM for better cell ingrowths in a three-dimensional fashion.

Polymers can be used as scaffold to promote cell adhesion, maintenance of differentiated cell function without interfering proliferation, template to organize and direct the growth of cells and help in the function of extracellular matrix [241]. Several methods have been reported to fabricate polymeric nanofibers or submicron fibers: phase separation [242], electrospinning [243] and self-assembly [244]. Yang et al. (2004) [245] have shown the potential of the PLLA nanofibrous porous scaffold, prepared by phase separation in nerve tissue engineering. The scaffold mim-

icked the structure of the natural ECM and was shown to support neural stem cells differentiation and outgrowth of the neurites. In another study, Spilker et al. (2001) [246] demonstrated that cells obtained from nerve explants were able to construct and restructure the walls of porous collagen-GAG matrices *in vitro*, suggesting that contractile cells may be capable of restructuring the extracellular component of the nerve wound environment *in vivo*. Electrospinning is able to fabricate fibrous scaffolds with desired properties [136, 247] to create biocompatible thin structures with useful coating design and surface properties that can be deposited on implantable devices to facilitate the integration of these devices into the body. This is exemplified in electrospun silk-like polymer with fibronectin functionality for making biocompatible films, which were used on prosthetic devices aimed to be implanted in the central nervous system [94].

Advanced techniques to produce a complex, degradable guidance channels that precisely mimic a natural repairing process in the human body have been investigated [248–251]. Various biomaterials or polymers have also been investigated for their suitability in nerve tissue engineering applications [101]. These synthetic conduits have been fabricated from materials such as polyurethane, polyorthoester, glycolide trimethylene carbonate, PLGA, PGA, poly(D,L-lactic acid) (PDLLA) and PLLA-CL [63] (Table 2.1). Early nerve regeneration studies used biotextile incorporated with appropriate growth factors to join the two neural stumps. The proximal neuron regenerates and can bridge gaps as wide as 8 mm, so as to re-establish distal neural activity [69]. In another study, the bioresorbable implant (trimethylene carbonate-co- $\epsilon$ -caprolactone) seeded with Schwann cells showed a significant increase in growth, ensheathment and peripheral nerve myelination [252]. In a recent study by Bini and colleagues (2004) [101], nerve guidance channel was fabricated by electrospinning PLGA biodegradable polymer nanofibers onto a Teflon mandrel. The biological performance of the conduits was examined in the rat right sciatic nerve model with a 10 mm gap length. There was no inflammatory response after the implantation of the nanofibrous nerve guidance conduit. Five out of eleven rats showed nerve innervation into the conduits after a month of implantation (Fig. 2.18). None of the implanted conduits showed tube breakage. This showed that the nanofibrous nerve guidance conduits have the necessary flexibility to adapt well inside a living system, a porous structure that make it permeable for gaseous and nutrient exchange in the conduit lumen to promote the nerve regeneration, are biocompatible, and showed no inflammatory response, which is clinically desirable in minimizing adhesions of an implanted conduit to surrounding tissues.

Nerve regeneration in the CNS is much more difficult than in the PNS and this is probably due to the glial cells in the CNS, which act as a barrier to the regenerating axons and create an unfavorable environment for axon regeneration after trauma or injury [237, 239]. Another reason would be the dissimilarities in the ECM components between PNS and CNS to assist and promote nervous regeneration [239]. In the PNS, the linear orientation of ECM components at the peripheral stump of a damaged nerve provide terrain well suited for axonal regrowth, whereas such framework is not available in the ECM of the CNS to assist axonal growth

**Fig. 2.18.** The regenerated nerve cable after a month of implantation [101].

[238, 253]. The nanofibrous scaffolds are well suited for CNS tissue engineering due to two unique properties. Firstly, the morphology and architecture are similar to the natural ECM, which is the foundation of creating reproducible and biocompatible 3D scaffolds for cell attachment, differentiation and proliferation. Secondly, the nanofibrous scaffolds are highly porous structures with a wide variety of pore diameters, allowing fluid transportation while inhibiting glial scars. Moreover, with the electrospinning technique, aligned nanofibrous scaffolds can be fabricated to

**Fig. 2.19.** C17.2 cells cultured on aligned (a, c) and random (b, d) PLLA nanofiber scaffolds for 1 day (a, b) and 2 days (c, d). Parts (a) and (b) are phase contrast light microscope images of cells attached on aligned nanofibers and random nanofibers, respectively. guide neuronal regeneration in both the central and peripheral nervous systems [254].

Yang and colleagues (2005) [254] designed an electrospun aligned PLLA nanofibrous scaffold to evaluate the efficacy in promoting neuron differentiation and guiding neurite outgrowth of C17.2 cells *in vitro*. The aligned nanofiber scaffold is anticipated to provide better contact guidance effects on the neurite outgrowth. C17.2 is a primordial, multipotent self-renewing cell that can be used as neuron precursors, and is involved in the normal development of cerebellum, embryonic neocortex and other structures upon implantation [251, 255, 256]. The cells are capable of differentiating without interaction with adhesion molecules such as laminin, fibronectin, collagen, poly-L-lysine or Matrigel™, which are generally required as permissive substrates in neurite outgrowth. This offers the convenience of investigating the physical effects of PLLA fibrous scaffolds because the coating of adhesive molecules will affect the surface topography of the scaffold. The *in vitro* results of this study showed that the fiber alignment had a strong effect on the cell phenotype: neural cells on aligned fibers grew parallel to the fiber orientation, and the aligned nanofibers improved neurite outgrowth when compared with random or microfibrinous scaffolds (Figs. 2.19 and 2.20). The results suggest that the aligned nanofibrous scaffold may be a suitable nerve guidance channel for both CNS and PNS regeneration.

Researchers have not only explored the use of biomaterials for neural tissue engineering. A silicon-based electronic device for neural network applications has been developed by Fan et al. (2002) [257]. They investigated the adhesion of neural cells from substantia of prenatal rat on silicon wafer with different nanotopographic features of between 20 and 70 nm in dimension produced by etching. The cell adhesion and viability were significantly improved on the nano-featured surface. The results strongly suggested that nanotopography could improve the

**Fig. 2.20.** SEM micrographs of neural stem cells seeded on (a) aligned and (b) random nanofiber for 2 days, showing the cell–matrix adhesion between the neural stem cells and PLLA fibers. Bar = 5  $\mu\text{m}$  [254].

response of neural cells and be used in designing neurochips as proposed by researchers such as Weis and Fromherz at the Max-Planck Institute for Biochemistry, Germany, and Pine and colleagues at the California Institute of Technology, Pasadena, California [222].

#### 2.8.4

##### **Skin**

Extensive burns or skin damaged by ambustion and injury require comprehensive therapy to repair the conditions, to prevent dehydration and infection. Dressing of wound is aimed to protect, remove exudates, inhibit exogenous microorganism invasion, and improve appearance [81]. Many studies have been done in the past 30 years to develop and enhance the skin regeneration by tissue engineering. In 1962, Winter [258] showed that covering the wound with a polyethylene film significantly improves the epithelialization of the wound in a shorter time. Protection was further accomplished by covering the wound with a dressing such as artificial skin constructed from either natural or synthetic polymers [259]. Wound areas that are kept just damp may heal faster, but accumulation of exudates under the dressing can cause infection [260]. Currently, autograft is a standard treatment in wound dressing. It is done by removing a section of the skin from another part of the body and grafting onto the wound. However, the removal of the dermis and epidermis is a serious operation and the availability of healthy skin can be limited if the burnt areas are widespread [261]. Recent developments in the regeneration of skin by tissue engineering have overcome these difficulties, especially in the use of polymer nanofibers for wound healing.

The objective of tissue engineered wound dressing is to produce an ideal structure, which gives higher porosity and good barrier. The materials must be selected carefully to produce high quality barrier properties and oxygen permeability. Electrospun nanofibrous membranes have potentials as wound dressing. This is because the membrane attained uniform adherence on wet wound surface without any fluid accumulation [82]. It can meet the essential requirements of wound healing such as high gas permeation and protection of wound from infection and dehydration. Khil and colleagues (2003) [81] have shown that the rate of epithelialization was increased and the dermis was well organized in wound covered with electrospun nanofibrous polyurethane membrane, which provided a good support for wound healing. The wound dressing showed controlled evaporative water loss, excellent oxygen permeability and promoted fluid drainage ability due to the porous nature of the nanofibers and the inherent properties of polyurethane. Polyurethane is frequently used in wound dressing because of its good barrier properties and oxygen permeability. Woodley and colleagues (1993) [262] reported that semi-permeable dressings, many of which are constructed from polyurethane, enhanced wound healing. The permeability of the wound dressing is crucial to prevent accumulation of fluid between the wound and the dressing. The fluid absorbed in the wound dressing will keep the wound moist and this will inhibit wound desiccation. Researchers have also tried to determine the effect of occlusive dressings on the

healing of wound prepared by polyurethane [263–266]. The disadvantage of the semiocclusive dressings is that fluid will accumulate under the dressings after a few days [267] and aspiration of the wound is required to prevent leakage and infection.

Another polymer that is frequently used for wound dressing is PCL, a biodegradable polymer characterized by a resorption time in excess of one year [268] but is known to be susceptible to enzymatic degradation [269]. Various degradative enzymes such as collagenases, matrix metalloproteinases, gelatinase A and stromelysin-1, which are secreted by macrophages, epidermal cells and fibroblasts for cell migration and repair during wound healing have been established to degrade PCL [270]. PCL and collagen nanofiber membranes have been used as wound dressings [107]. This structured membrane improves the mechanical integrity of the matrix, and provides a high level of surface area for cells to attach due to its 3D features and high surface area to volume ratio when compared to polymer film (Fig. 2.21). This PCL/collagen membrane will possess both the mechanical properties and cell binding affinity derived from the unique properties of PCL and collagen, respectively. In this study, fibroblasts were shown to migrate inside the collagen nanofibrous matrices mimicking the structure of the dermal substitute. Collagen synthesized by fibroblasts is a good surface active agent and will en-

Fig. 2.21. Fibroblast cell attachment and growth on PCL and collagen nanofibers [107].

hance the attachment of keratinocytes to the surface of artificial dermis in serum free medium. It is assumed that the fibroblasts on the artificial dermis can release biologically active substances, such as cytokines, which induce invasion of the wound site by fibroblasts and other immunological cells during the early synthesis of the new skin tissue. The dynamic architecture of the fibers such as pore size and fiber alignment allows the cells to grow into the nanofiber matrices to form a dermal substitute for many types of wound healing. This nanofiber-based fibroblast-cultured dermal substitute maintains the moist environment on the wound surface and thereby promotes wound healing.

The incorporation of collagen in polymer scaffolds has been demonstrated in many studies to promote cell growth and proliferation. Using human osteoblasts, Coombes et al. (2002) [271] demonstrated that PCL composite films consisting of non-crosslinked collagen mats support higher cell growth than unmodified PCL films. In another study, Dai et al. (2004) [272] found that composite films of collagen and PCL are favorable substrates for growth of fibroblasts and keratinocytes and may find utility for skin repair. To improve on this further, Huang and colleagues (2001) [273] developed a convenient, non-toxic, and non-denaturing process to fabricate collagen-containing nanofibers with diameters ranging from 100 to 150 nm, and non-woven fabrics, which they proposed based on the materials excellent properties to have potential applications in wound healing, tissue engineering and as haemostatic agents. Fine fibers of biodegradable polymers have also been developed to be directly sprayed or spun onto the injured location of the skin, forming a nanofibrous mat dressing, which encourages wound healing by the formation of normal skin and elimination of scar tissue that would occur in a conventional treatment [274–277]. Two patents have been filed [278, 279] where researchers produced a skin mask by directly electrospinning fibers that contain pH-adjusting compound onto the skin surface to protect and eventually heal the wound.

The main advantages of non-woven nanofibrous membrane mats for wound dressing are their pore size, usually from 500 nm to 1  $\mu\text{m}$ , which is small enough to protect the wound from bacterial penetration, and the high total nanofiber surface area of 5 to 100  $\text{m}^2 \text{g}^{-1}$ , which is extremely efficient for fluid absorption and dermal delivery. A commonly used wound dressing in hospitals is Tegaderm™ developed by 3M (USA), which is a thin polyurethane membrane that is permeable to both water vapor and oxygen but impermeable to microorganisms. In one study, electrospun nanofibrous membrane showed excellent and immediate adherence to wet wound surface compared with the dermis of wound covered with Tegaderm™ (3M, USA), which was also reported to be inflamed [81]. The rate of epithelialization was increased, the dermis was well organized, and fluid accumulation was not observed in electrospun nanofibrous membrane group [81, 82]. These result indicate that the electrospun nanofibrous membrane provided a good means for wound healing. In addition, histological examination confirmed that epithelialization rate was increased, and the exudates in the dermis were well controlled by covering the wound with the electrospun membrane. Thus, nanofibrous membrane prepared by electrospinning could be properly employed as wound dressings.

## 2.8.5

**Bone and Cartilage**

Only in recent years have researchers gained a better understanding of stem cell biology and their potential for bone and cartilage repairs and regeneration, and this has accelerated the development of biomaterial scaffolds for tissue engineering research in this discipline. The surface properties of biomaterial regulate the cell phenotype through their capacity to support and spatially display the crucial adhesion contacts [280, 281]. Nano-scale features have also been used to design the scaffolds for culture of osteoblasts and mesenchymal stem cells [221]. Recent advances in stem cell biology have shown that MSCs can differentiate into cells of mesenchymal tissues such as bone, cartilage, muscle, tendon, ligament and fat, and are expected to play important roles in the repair of skeletal defects [282, 283]. Osteoblasts derived from MSCs of neonatal rats cultured on poly(D,L-lactide-co-glycolide) foam were observed to deposit minerals and form 3D bone-like structures in the foam [284]. In another report, a non-woven PCL nanofibrous scaffold was fabricated and its potential evaluated in bone tissue engineering with rat mesenchymal stem cells [133, 285]. It was observed that the polymer constructs were covered with multiple cell layers, mineralized, and impregnated with type I collagen. Besides synthetic polymer, researchers have used natural polymers such as silk to produce nanofibrous scaffolds [6]. Human bone marrow stromal cells were cultured on electrospun silk fibroin fibers with an average diameter of 700 nm. These silk matrices supported bone marrow stromal cell attachment and proliferation with higher cell density than for native silk fibroin matrices.

The 3D structure of these nanofibrous scaffolds are characterized by a wide range of pore diameter, high porosity, high surface area to volume ratio, and morphological architectures similar to the natural structural fibrillar proteins in the native ECM. These physical characteristics promote favorable biological responses of cells by enhancing cell attachment and proliferation as demonstrated by Li and colleagues (2002) [138] when they developed an electrospun PLGA nanofibrous scaffold that has potential as a possible alternative replacement for bone, cartilage and skin tissue engineering. Fibroblast and bone marrow-derived mesenchymal stem cells seeded on this structure tend to maintain phenotypic shape and guided growth according to the nanofiber orientation. Li et al. (2003) [131] further evaluated a novel, 3D non-fibrous PCL scaffold composed of electrospun nanofiber for its ability to maintain chondrocytes in a mature functional state. Nanofibrous cultures maintained in the supplemented serum-free medium produced more sulfated proteoglycan-rich cartilaginous matrix, and supported cellular proliferation than monolayer cultures. In another study, Li et al. (2005) [132] evaluated the effects of growth factors incorporated in the scaffolds on cell growth. When the adult human bone marrow-derived MSCs were cultured on a PCL nanofibrous scaffold in the presence of transforming growth factor- $\beta$  (TGF- $\beta$ ), the MSCs differentiated to chondrocytic phenotypes, expressing chondrocyte-specific genes such as collagen type II, IX, and XI, aggrecan, and produced cartilage-associated extracellular matrix proteins. The level of chondrogenesis in the nanofibrous scaffold was com-

**Fig. 2.22.** SEM images of osteogenic cells grown on diverse titanium surfaces. Control samples, (A) Ti alloy and (E) cpTi, exhibit a smooth surface, while etched ones, (C) Ti alloy and (G) cpTi, are characterized by a unique nanotopography. At 6 h, no significant

differences were detected in cell shape between control (B and F) and nanotextured (D and H) surfaces. The predominant cell shape was polygonal, with cells showing either thin cytoplasmic extensions or large veil-like ones. cp: commercially pure, Ti: titanium [286].

parable to cell aggregates or pellet cultures, which are the established procedures in inducing chondrogenesis. In addition, the mechanical properties of the cell-nanofibrous construct were superior to those developed from pellet cultures. These studies suggested that nanofibrous structure may be a suitable candidate scaffold biomaterial for bone and cartilage tissue engineering applications.

Nanotexturing has also been reported to provide the necessary attachment surfaces on the scaffolds for cell to grow. This was demonstrated by Oliveira et al. (2004) [286] who reported that nanotexturing of titanium-based surfaces upregulates the early expression of bone sialoprotein and osteopontin in osteogenic cell cultures (Fig. 2.22). Badami et al. (2005) [287] determined how chemical and topographical features affect adhesion, morphology, orientation, proliferation, and osteoblastic differentiation of MC3T3-E1 model osteoprogenitor cells, and found that osteoprogenitor cells were able to adhere and proliferate on a random fused fiber topographies and mean fiber diameters ranging from 0.14  $\mu\text{m}$  to 2.1  $\mu\text{m}$ . In the presence of osteogenic factors such as  $\beta$ -glycerophosphate, and L-ascorbate-2-phosphate, cell density on fibers was equal or greater than on smooth surfaces. Cells attached to electrospun substrates exhibited a higher cell aspect ratio than cells on smooth surfaces. This study demonstrated that surface topography introduced by electrospun fibers with an average fiber diameter of 0.14–2.1  $\mu\text{m}$  affects cell morphology and cell proliferation. Carbon nanotubes and nanofibers have several potential properties that make these materials beneficial in the development of

novel devices for bone reconstruction [20]. The dimensions of carbon nanofibers or nanotubes mimic that of collagen fibrils (0.1–8  $\mu\text{m}$  in diameter) in the bone. In one study, Elias et al. (2002) [288] investigated the functions of human osteoblasts cultured on carbon nanofibers with diameters of  $<100$  nm. Osteoblasts were observed to increase in proliferation, synthesis of alkaline phosphatase and deposited more extracellular calcium on carbon nanofiber with diameters  $<100$  nm. The enhanced mineral deposition in this study demonstrated the potential of carbon nanofibers as a material for orthopedic implants. The enhanced function of the osteoblasts is suggested to be due to similarity of the dimension of carbon fibers to that of hydroxyapatite crystals found in physiologic bone. Smaller diameter carbon nanofibers (60–100 nm) have been suggested as suitable for use in orthopedic/dental implant material designs and this may be due to the increase in osteoblast and decrease in osteoblast competitive cells such as fibroblasts, chondrocytes, and smooth muscle cells adhering to the carbon nanofibers [20]. These studies demonstrated that nano-scale carbon fibers could promote osteoblast adhesion, and the application of nanotopography could create an environment favorable for bone cells.

Studies have determined that nanofibrous structure could enhance protein adsorption, including fibronectin and vitronectin, and hence enhance the osteoblast attachment [84, 289]. Woo et al. (2003) [84] hypothesized that nanofibrous PLLA scaffolds, which they developed to mimic the bone extracellular matrix microenvironment, have potential to adsorb serum proteins to enhance cell growth. The 3D porous PLLA scaffolds they developed had interconnected spheroid pores of between 50 and 500 nm with nanofibrous architecture walls. This nanofibrous scaffold adsorbed  $4\times$  more serum protein than the non-fibrous scaffold. In another study, Wei and Ma (2004) constructed a nHAP/polymer composite with high porosity from a dioxane–water mixture solvent system using thermally induced phase separation techniques for bone tissue engineering and observed that the protein adsorption was three-fold higher in the fibrous scaffold compared with non-fibrous scaffold [289]. The adsorbed serum proteins may have a role in enhancing cell attachment and proliferation on nano-structured surfaces compared with micro-structured surfaces [290–295]. Incorporation of chemical additives to the nanofibers has also been reported to enhance cell growth. Recently, Fujihara and colleagues (2005) [296] fabricated a new type of guided bone regeneration membrane from electrospun PCL/ $\text{CaCO}_3$  composite nanofibers (Fig. 2.23). SEM images showed the presence of  $\text{CaCO}_3$  nanoparticles on the surface of the PCL nanofibers. *In vitro* studies showed that osteoblast attachment was encouraged on the composite nanofibrous membrane, and good cell proliferation was observed.

In its native environment, self-healing of articular cartilage is rarely possible [297]. Hence, various clinical procedures have been evaluated in articular cartilage repairs, in particular tissue engineering approaches [298, 299]. Successful cartilage tissue engineering depends on the ability of chondrocytes to accumulate into a 3D architecture. Chondrocytes for articular cartilage therapy are isolated from the cartilage of the patients. However, low numbers of chondrocytes can be harvested from each isolation procedure and expansion of the cells is inevitable [131]. This

**Fig. 2.23.** (a) PCL/CaCO<sub>3</sub> composite nanofibers, and (b) osteoblast on guided bone regeneration membranes [296].

procedure will also result in the cellular dedifferentiation of the cells [300]. To overcome the dedifferentiation issue, the cells can be redifferentiated upon seeding low passage cells in 3D matrix environments such as alginate, agarose [301, 302] or other scaffolds [303]. Hydrogel formatted biopolymers have limited applications for cartilage tissue engineering and this is due to the lack of long-term mechanical stability and controlled degradation time [303], while synthetic polymers with defined chemical composition provide tailored properties to fit the requirements of engineered tissue scaffolds. The unique architecture of the electrospun 3D synthetic polymer scaffold may provide an ideal environment for both the induction of redifferentiation and the maintenance of differentiated chondrocytes [131]. In cartilage, this synthetic ECM-like structure is crucial to provide mechanical support for the tissue and interacts with the chondrocytes [304, 305].

The above studies implicate the advantages of electrospun nanofibers as scaffolds for bone and cartilage tissue engineering as evidenced by growth of osteoblasts, chondrocytes and mesenchymal stem cells on these fibers. Nanofibrous meshes could provide a better mechanical structure and spatially control cell-scaffold interaction compared with conventional systems. This is based on the observation of osteogenesis and chondrogenesis of the bone marrow-derived stem cells on the nanofibers media.

#### 2.8.6

##### Heart and Vascular Grafts

Blood vessels play important roles in distributing blood to the body for gaseous and nutrient exchange. One of the major causes of mortality in the world is cardiovascular or vascular disease that results when the heart, arteries or veins are dysfunctional. Due to the high statistics of this disease, much effort in tissue engineering has been geared towards developing a viable vascular substitute as an alternative treatment.

Tissue-engineered blood vessels have a long history, beginning with PMMA tubes as vascular grafts back in the late 1940s [306]. In the early 1950s, textile grafts were first introduced with the development of the first fabric graft by Voothees (1952) [307]. This subsequently led to the use of PET (Dacron) as a vascular graft substitute by Julian and DeBakey in 1958 [308] who believed that a woven material would be less thrombogenic than a smooth material. However, numerous studies have shown that absorbable vascular grafts would allow the regeneration of new functional arteries [309, 310]. In 1979, Bowald reported a fully bioresorbable graft made of a rolled sheet of Vicryl as vascular substitutes [311, 312]. Bioresorbable woven PGA grafts were also evaluated as vascular substitutes in rabbit models by Greisler (1982) [313] and Greisler et al. (1985) [314]. All these grafts performed only modestly in terms of patency, immunological tolerance, and thrombogenic response.

Currently, a more practical approach for tissue engineering implantation is to use polymer based vascular conduits. However, vascular grafts constructed from synthetic polymers have only been used successfully for large diameter, but not for small diameter, vessels (<6 mm). To date, there are no acceptable synthetic grafts for small diameter blood vessels and autologous grafts have to be harvested from the patients for transplantation. However, this process is time consuming and complications may arise, increasing the time of recovery for patients. In addition, there is a limit on the number of autologous grafts that can be harvested from the patient for transplantation and, at times, the autologous grafts may be diseased and are not suitable for transplantation.

Understanding the basic structure of the blood vessel is important in order to construct a blood vessel scaffold. It consists of three main layers: *tunica intima* (innermost lining), *tunica media* (middle lining) and *tunica adventitia* (outermost lining). The *tunica intima* includes an endothelial lining and an underlying layer of connective tissue of elastic fibers. The *tunica media* contains concentric sheets of smooth muscle tissue in a structure of loose connective tissue, and the *tunica adventitia* contains collagen and elastic fibers [315]. Constructing a blood vessel scaffold is a complex task, and the chances that thrombosis or hyperplasia may arise are high, resulting in vascular graft failure. Rejections can also be another problem when the cellular and humoral immune system detects the graft as a foreign body.

Endothelization is a promising approach to prevent thrombogenesis and intimal hyperplasia. These endothelial cells secrete bioactive substances such as heparin sulfate and nitric oxide, which prevent the smooth muscle cells from overproliferating, as well as cover the scaffold to minimize attachment of platelets to the scaffold to initiate thrombogenesis. Obtaining an endothelized surface on a biodegradable polymer scaffold has become an attractive model for replacing the small diameter blood vessel. Studying the interaction of endothelial cells and polymeric nanofiber scaffold helps researchers optimize the cell growth conditions on the vascular grafts. Surface roughness is one of the parameters that even subtle differences in can affect endothelization. Studies comparing the adhesion of the human vascular artery endothelial cells on a smooth solvent-cast PLLA surface

and a rough electrospun PLLA surface showed an inverse relationship between surface roughness and endothelial cells adhesion and proliferation rates [316].

Endothelialization is limited when endothelial cells are exposed to blood circulation resulting in cell detachment from the surface. Introduction of biomolecular cell recognition sites on the surface of the vascular graft such as extracellular matrix proteins will enhance cell attachment through receptor–ligand binding with the endothelial cells. In He et al. (2005) [16], human coronary artery endothelial cells (HCAECs) were cultured on collagen-coated PLLA-CL nanofiber mesh (NFM) and its growth compared with cells cultured on PLLA-CL NFM and the tissue culture polystyrene surface (TCPS). The endothelial cells cultured on the collagen-coated NFM had the same typical spreading morphology as the TCPS, in contrast to the rounded morphology of cells cultured on the PLLA-CL NFM (Fig. 2.24). This study clearly demonstrated that the cytocompatibility of PLLA-CL nanofibers was increased when coated with collagen. This is important in achieving an anti-thrombogenic layer for a successful vascular graft. Endothelial cells were cultured on collagen-blended PLLA-CL nanofibers with various PLLA-CL:collagen weight ratios of 4:1, 2:1, 1:1 and 1:2. The cell viability increased with increased collagen content in the blended nanofibers (Fig. 2.25). In addition, there was an enhancement of cell adhesion and spreading on the blended nanofibers when they were grown in culture medium without serum and growth factors [12]. In another

**Fig. 2.24.** (a)–(c) Laser scanning confocal images of endothelial cells, stained with CMFDA (5-chloromethylfluorescein diacetate), that are cultured on TCPS, PLLA-CL nanofiber mats and collagen-coated PLLA-CL nanofiber

mats, respectively. (d)–(f) Scanning electron micrographs of endothelial cells cultured on TCPS, PLLA-CL nanofiber mats and collagen-coated PLLA-CL nanofiber mats, respectively [16].

**Fig. 2.25.** Viability of HCAECs grown on TCPS, collagen nanofibers, collagen-blended PLLA-CL nanofibers (BNF) with different weight ratios of PLLA-CL to collagen (BNF 1:1, BNF 2:1, BNF 4:1), PLLA-CL nanofibers, and collagen-blended PLLA-CL film [12].

study, gelatin grafted PET nanofiber mats were shown to improve endothelial cell proliferation and preserved the cell phenotype. On the gelatin grafted PET nanofiber mats, the cells were observed to exhibit polygonal spread out morphology, in contrast to rounded morphology of cells cultured on the PET nanofiber mats [14]. Alternatively, modifying the physical properties of scaffold surface, such as enhancing hydrophilic property, changing the pore size, and altering the surface roughness, have been reported to increase endothelization on the scaffolds [316].

Another important population of cells in the blood vessels is the smooth muscle cells. Studies have shown that human coronary artery smooth muscle cells (HCASMCs) were able to attach and grow in the direction of the axis of the nanofibers, expressing a spindle-like contractile phenotype when cultured on electrospun aligned PLLA-CL nanofibers (Fig. 2.26), which closely mimics the behavior of cells in native vessels. The adhesion and proliferation of the HCASMCs on the aligned nanofibers was significantly increased compared to that on the solvent-cast polymer film. PLLA-CL aligned nanofiber is seen as a potential scaffold for blood vessel engineering applications.

In the native blood vessel, the most abundant proteins are collagen and elastin. Collagen provides the resistance against rupture and elastin confers elasticity. There are studies showing that pretreatment of nanofibers would enhance cell growth. Buttafoco et al. (2005) [317] have reported that collagen-elastin nanofibrous mesh crosslinked with *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide hydrochloride and *N*-hydroxysuccinimide enabled smooth muscle cells to grow

**Fig. 2.26.** Confocal images of HCASMCs immunostained for  $\alpha$ -actin filaments cultured (a) on aligned nanofibrous scaffold, (b) on aligned nanofibrous scaffold, overlay image on the aligned fiber, and (c) on TCPS.

well as a confluent layer. Studies by Boland et al. (2004) [17] showed that pretreatment of small diameter electrospun PGA fibers with concentrated hydrochloric acid significantly increased rat cardiac fibroblast proliferation. To date, constructing a viable blood vessel substitute is a challenging task as many criteria need to be fulfilled. One of the criteria may be the use of nanofiber scaffolds for blood vessel tissue engineering.

### 2.8.7

#### Stem Cells

Stem cells are undifferentiated cells that have the capacity for both self-renewal, proliferate and differentiate to one or more types of specialized cells [318]. These unique characteristics of stem cells are crucial in the applications of *in vivo* therapies such as treating leukemia and repairing injured myocardium by the injection of stem cells that will differentiate and proliferate into the desired cell type. However, this approach relies on the pre-existence of extracellular matrix proteins [319]. The two major types of stem cells are embryonic stem cells, derived from the inner

cell mass of early aborted fetuses and capable of differentiating into almost any cell type, and adult stem cells of hematopoietic or mesenchymal origin, which are less versatile for tissue engineering applications. However, the use of adult stem cells in therapy incurs less ethical and medical issues since the cells are harvested from the patient, incorporated into a tissue engineered construct and then returned to the individual without the need for immunosuppression [318].

The majority of mammalian cells are anchorage dependent and are mostly derived from mesenchymal stem cells [320]. MSCs are multi-potential cells that can differentiate into bone, cartilage, fat, muscle, marrow stroma, and other cell types when induced by the appropriate biological cues *in vitro* [282, 321]. Their potential for expansion, lineage-specific differentiation, and derivation from autologous sources suggest that human mesenchymal stem cells (hMSCs) can be a possible candidate cells for tissue engineering and regenerative therapies [132]. Research has shown that when MSCs are cultured in the presence of suitable media containing differentiation-promoting agents and growth factors the cells differentiated into osteoblasts [322], adipocytes, and chondrocytes [323]. Human MSCs have been isolated from many adult human tissues [324–331], especially from the bone marrow, which is also a major source and reservoir for hematopoietic stem cells [332]. The capture, expansion, and differentiation of these stem cells are required before incorporation into a tissue engineered construct for successful tissue regeneration.

An ideal biomaterial scaffold for stem cell tissue engineering application should be able to support multi-lineage cell types since most tissues and organs are multiphasic in nature [333]. There are a few successful examples of engineered multiphasic tissues such as the osteochondral construct which consists of bone and cartilage tissues [334–338]. The approach involves the integration of the chondral construct and the osteo-construct after they are separately fabricated from stem cells [336] or differentiated cells [337]. Another approach would be using the cell pellet culture system, which has been widely used to investigate the MSC chondrogenesis [323, 324, 339–341]. In two of those studies, human MSCs exhibited chondrogenic properties when cultured in a cell pellet system [323, 324]. However, constructs derived from the cell pellet culture system are small and uniformly weak in mechanical properties, making them unsuitable for repair of larger cartilage defects.

Alternatively, nanofibrous scaffold is a potential candidate scaffold for a cell-based tissue engineering approach as well as a potential carrier for MSC transplantation. In a study, Li et al. (2005) [132] compared the chondrogenic activities of bone marrow-derived MSCs seeded on PCL nanofibrous scaffolds to cell pellet culture system in the presence of TGF- $\beta$ 1 as chondrogenic growth factor. The results showed that the level of MSC chondrogenesis on nanofibrous scaffolds is enhanced compared to the cell pellet culture system (Fig. 2.27). From this observation, it was proposed that the 3D PCL-based nanofibrous scaffold is able to serve as a bioactive carrier for MSC transplantation for cartilage repair. In a later study, Li et al. (2005) [333] tested a 3D PCL nanofibrous scaffold for its ability to support and maintain multi-lineage differentiation of bone marrow-derived human MSCs.

**Fig. 2.27.** Morphology of day 21 cell pellet and nanofibrous scaffold MSC cultures examined by SEM. (A)–(D) cultures maintained without TGF- $\beta$ 1; (E)–(H) cultures treated with TGF- $\beta$ 1. (A) Top view of cell pellet, revealing a roughened surface; (B) cross-sectional view of cell pellet, showing the presence of native collagen-like fibers; (C) top view of nanofibrous scaffold, showing fibroblast-like cells covering the surface; (D) cross-sectional view of nanofibrous scaffold, showing cells covered with ECM, and integrated with PCL nanofibers; (E) top view of cell pellet, with round chondrocyte-like cells on the surface; (F) cross-sectional view of cell pellet, showing thick ECM; (G) top view of nanofibrous scaffold, showing the presence of round, ECM-embedded chondrocyte-like cells; and (H) cross-sectional view of nanofibrous scaffold, showing a thick, dense ECM-rich layer. Bar = 10  $\mu$ m [132].

In this *in vitro* study, the cells seeded onto the scaffold were induced to differentiate along adipogenic, chondrogenic or osteogenic lineages by culturing in specific differentiation media. It was reported that multi-lineage differentiation of MSCs is fully supported within the nanofibrous scaffolds. These two studies suggested that the PCL-based nanofibrous scaffold is a promising candidate scaffold for cell-based, multi-phasic tissue engineering. This is further supported by Boudriot and colleagues (2005) [320] who studied the differentiation of human MSCs when cultured onto 3D electrospun PLLA nanofibers for 21 days. The mesenchymal stem cells clearly preferred a guided growth along the nanofibers and revealed no signs of cell death (Fig. 2.28). In addition, osteogenic differentiation of the mesenchymal stem cells was also observed. The results showed that the use of electrospun nanofibers as scaffolds for stem cells is promising in tissue engineering.

## 2.9 Innovations in Nanofiber Scaffolds

Even though nanofibrous scaffolds are widely used for tissue engineering applications, they are increasingly being used as vectors for controlled delivery systems such as for drugs, and this is due to their high surface area and nano-scale dimen-

Fig. 2.28. (a) hMSC morphology on nanofiber scaffold; (b) seeded hMSC [320].

sions. Annually, millions of people [342] have been administered with various drugs and proteins such as human growth factors and hormones encapsulated or incorporated with polymers to assist delivery in the treatment of diseases or to improve health [343]. In drug delivery systems, the ideal drug dosage is the minimum amount delivered to the diseased site and effectively absorbed. Uptake of drugs by the body is influenced by the solubility of the compound in aqueous environment, modifications to the compound to assist solubility, and the ease of releasing the drug into the system is facilitated by the degradation of the coating or encapsulating materials of the drugs [35]. Hence, polymeric materials in the form of nano or micro particles, hydrogels and micelle [344] have been developed as vectors for drug delivery. The principle of drug delivery with polymer nanofibers is based on the dissolution rate of a particulate drug which increases with a corresponding increase in the carrier surface area. The nano-dimensions of these polymeric delivery materials will allow the drugs to be more effectively delivered to the target sites and this will improve the therapeutic effects of the drugs and at the same time reduce undesirable side effects associated with the drugs. As such, the usage of polymer nanofiber membranes has become the main focus of research for drug delivery applications [21].

Nanofiber mats prepared from PLA, PEVA and their blend have been incorporated with the drug tetracycline hydrochloride [345, 346]. The PLA nanofibers showed an instantaneous release of the drug while the drug release profiles of PEVA and PLA/PEVA blend gradually increased over 120 h. Zong et al. (2002) [347] have prepared bioabsorbable nanofiber membranes from PDLA incorporated with the antibiotic Mefoxin and a burst drug release profile was observed within the first 3 h, and a 90% release rate was achieved after 50 h. Even though the release profile of the drug is important, it is essential that the drug remains active upon release. Kim et al. (2004) [344] have evaluated the bioactivity of released Mefoxin incorporated in PLGA nanofibrous membrane to inhibit *Staphylococcus aureus* growth. Incorporation of Mefoxin in the polymer did not diminish the antibiotic activity and the released Mefoxin effectively inhibited bacterial growth.

Drugs incorporated into the nanofibers have a tendency to release in a burst profile when administered directly into the biological system, as shown by the earlier studies [344–347]. This release profile may not be suitable for some drugs that have to be released gradually, such as hypertension drugs. In an effort to better control drug release, Verreck et al. (2003) [348] placed the electrospun hydroxypropylmethyl cellulose (HPMC) nanofibrous membranes that contained the drug itraconazole into a hard gelatin capsule that is traditionally used to encapsulate drugs. Nanofibers in the capsule gradually released the drug over 20 h compared with the nanofiber membranes without the capsule, which released 100% of the drug within 4 h. This unique approach using pharmaceutical hard gelatin capsule for drug release from nanofiber is able to control the drug release rate by changing the amount of drug incorporated, minimizing the distribution of fiber diameter, and drug distribution in a nanofiber. The diffusion of drugs through the inter-fiber pores in an aqueous environment is another important issue in order to understand the drug release manner from nanofibers. Verrick et al. (2003) [349] used poorly water-soluble drugs, itraconazole and ketanserin, as model compounds while segmented polyurethane was selected as the non-biodegradable polymer. At low drug loading, itraconazole was released from the nanofibers in a linear function. Initial burst release of the drug was not observed. As for ketanserin, a bi-phasic release pattern was observed where two sequential linear release phases were noted. These release phases may be temporally correlated with drug diffusion through the polymer and through formed aqueous pores, where the latter require some time to materialize in the aqueous environment.

Modification to the polymeric nanofibers is an alternative to control drug release. Zeng et al. (2003) [350] have fabricated PLLA nanofibers with cationic, anionic and nonionic surfactants as additives, to evaluate the release profiles of typical drugs such as rifampin (a drug for tuberculosis) and paclitaxel (an anticancer drug). They found that the surfactants can reduce the diameter of electrospun fibers as well as control the size distribution of the nanofiber diameter. The constant rate of drug release is in-line with the degradation rate of the nanofibers. Therefore, the distribution of fiber diameter may play an important role in controlling the drug release rate. Such nanofibers may find clinical applications. Table 2.2 summarizes studies conducted using nanofibers for the drug delivery system. Electrostatic spinning is an efficient and simple technique to prepare the drug-laden nanofiber for potential use in oral, topical, and even *in vivo* delivery of drugs despite its recent application in the pharmaceutical industry. Several recent publications suggest that it may be of high value in the formulation of poorly water-soluble drugs by combining nanotechnology and solid solution/dispersion methodologies [351].

Current therapies to regenerate or replace various tissues (e.g., bone, blood vessels, skin, liver, eye, and nerve) in the body depend on the delivery of growth factors [352]. Growth factors are crucial to achieve successful tissue regeneration as substitutes for biological functions of damaged and injured organs. These growth factors help to create a more favorable environment to enhance tissue regeneration. In addition to the growth factors, this environment can be achieved by providing various biomaterials as cell scaffolds to promote cell proliferation and differen-

tiation. Growth factors such as fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), TGF- $\beta$ , platelet derived growth factor (PDGF), and angiopoietins are often required to promote tissue regeneration. This is because they can induce angiogenesis, promoting a sufficient supply of oxygen and nutrients to effectively maintain the biological functions of cells transplanted for organ substitution. Biodegradable polymers have been developed to provide localized and sustained growth factor release [343, 353–358], as well as to introduce plasmid DNA that encodes the growth factors [359, 360], to desirable targets in human body. However, the success rate of current efforts is limited due to the poor *in vivo* stability of the growth factors, the mode of delivery, and the necessity for numerous signals to complete the regeneration process. Ma (2004) [54] has designed a conceptual model using a bioactive scaffold integrating nanofibrous architecture with 3D biomimetic surface modification to control growth factor release (Fig. 2.29). The design uses the architectural features of collagen to provide a high surface area for cell attachment and new matrix deposition, as well as an open structure that will allow an interactive environment for cell–cell, cell–nutrient, cell–matrix, and

**Fig. 2.29.** Schematic of a “biomimetic nano-scaffold”. The scaffold combines the novel nanofibrous architecture of an interconnected pore network with microspheres for controlled release of putative regenerative factors. (Adapted from Figure 10 of Ma [54].)

cell–signal molecule interactions. The challenge of finding an appropriate delivery mechanism for these signaling proteins, and to determine the time and dosage of delivery, could possibly be achieved by capitalizing on the unique characteristics of nano-scale polymeric fibers.

## 2.10 Conclusion

Nanotechnology is a diverse and interdisciplinary area of research. This research discipline promotes the innovation of new nano-scale materials and devices with improved properties and functionalities. Nanotechnology has the capacity to revolutionize in many areas of applications such as surface microscopy, silicon fabrication, biochemistry, molecular biology, physical chemistry and computational engineering. However, safety concerns of nanomaterials in everyday life and its social, political and regulatory implications have been discussed extensively despite commercialization of some products made of nano-based materials. Nanofiber technology is an important research area in nanotechnology and the understanding of nanofiber processing methodologies is essential for the overall advancement of

nanotechnology. Current research in nanomaterials may not only lead to the development of superior functions but also provide a means to deliver these special functions to higher order structures. Nanofibrous scaffolds designed to elicit specific cellular responses through the incorporation of signaling ligands (e.g., growth factors and adhesion peptides) or DNA fragments are particularly promising for advanced tissue repairs and regeneration, while nanoparticles and nanospheres are able to control the release of therapeutic agents, antibiotics, genes and vaccines to the target cells.

The electrospinning technique provides an inexpensive and convenient method to produce nanofibers from various types of polymers with controlled variations in polymer characteristics such as fiber diameter, pore size, high surface area, and lightweight scaffolds. This technology has made it possible to manufacture products such as permeable nanofiber mats and nanofiber tubes for biomedical applications, which have proven difficult to fabricate before and most probably would not have been in existence using fabrication technologies presently available. The availability of new materials will play a critical role in developing advanced applications in disease diagnosis and treatment. Further research and development is required to improve the biocompatibility and potential applications of nanofiber scaffolds. The incorporation of nanofibers into useful devices requires in-depth understanding of the parameters influencing nanofiber processing and the resulting fiber characteristics, cell–nanofiber interactions in the biological system, and the integrative process to existing technologies or applications. These are some of the many challenges that need to be taken into account when using nanofibers for tissue engineering and biomedical applications.

## Electrospinning Technology for Nanofibrous Scaffolds in Tissue Engineering

*Wan-Ju Li, Rabie M. Shanti, and Rocky S. Tuan*

### 3.1

#### Introduction

Annually, millions of Americans suffer tissue loss or end-stage organ failure at a health care cost exceeding \$400 billion, representing nearly one-half of all medical related costs in the United States [1]. Approximately 80 000 of these patients will await solid organ transplantation, and based on the figures from the United Network for Organ Sharing (UNOS) only 27 037 solid organs were transplanted in the United States in 2004. Also, according to the American Association of Tissue Banks (AATB), 1.3 million bone grafts and 94 000 soft tissue (e.g., tendon, meniscus) grafts were performed in the United States in 2003. The current standard-of-care for the replacement of lost or damaged organs and tissues includes transplantation of whole organs from one individual to another (allografts), transplantation of a patient's own tissues from one region of the body to another (autografts), or by the utilization of synthetic materials (alloplasts). Although these therapeutic modalities have had much success in clinical practice, each is associated with significant complications. For instance, allografts are restricted due to limited supply of donor organs and tissues, potential sequelae of chronic immunosuppression, and risk of host immunorejection. Alloplasts or synthetic materials, also have the potential of eliciting an adverse body response, and often fail over time due to wear and fatigue. Therefore, tissue engineering has emerged as a promising alternative for the reconstitution of lost or damaged organs and tissues, circumventing the secondary complications associated with autografts, allografts, and alloplasts.

Three general strategies were devised in the early 1990s for the engineering of new tissue: (1) delivery of cells or cell substitutes, (2) local or systemic delivery of tissue inducing substances, (3) and delivery of scaffolds containing both cells and inductive agents [1]. These approaches typically require some sort of carrier in the form of a biomaterial scaffold to guide the delivery of cells, inductive agents, or a combination of the two to the area of interest. In the same capacity, this biomaterial scaffold can also facilitate the growth and regeneration of new tissue. Figure 3.1 illustrates the general concept of tissue engineering based strategy for therapeutic applications. Briefly, target cells (differentiated/undifferentiated) expanded

**Fig. 3.1.** The general concept of tissue engineering. (A) Human tissue or cell donors and recipients. (B) Harvested and isolated cells. (C) Cells expanded in tissue cultures. (D) Cells cultured in tissue engineered scaffolds and induced by biochemical and mechanical signals. (E) Cellular constructs maintained in bioreactors.

*in vitro* cultures, usually in cell culture flasks, are cultured in three-dimensional (3D), highly porous biomaterial scaffolds (natural/synthetic) under biologically favored conditions. After a period of culture time, the cellular scaffold receiving chemical and physical growth-needed stimuli turns into a natural tissue-like cellular implant. Furthermore, these biologically functional scaffolds play a critical role in the tissue engineering process, for they provide a 3D structure for cellular functions such as attachment, migration, proliferation, and differentiation and/or serve as vehicles for the delivery of cells to the implant site. The success of this process is determined by the biological and functional similarity of the engineered tissue with native tissue. In summary, whether the biomaterial scaffold serves as a 3D matrix for *in vitro* culture or functions as a template to recruit surrounding host cells to conduct the repair process, a principal objective of scaffold design for tissue engineering is to create a structure that can simulate the native extracellular matrix (ECM) until cells seeded within the scaffold and/or derived from the host tissue can synthesize a new, natural matrix.

To achieve this goal, a scaffold material must be carefully selected and the scaffold architecture should be properly designed to ensure biocompatibility with the seeded cells. Ideal characteristics for a scaffold include (a) biocompatibility (no cell toxicity before and after degradation of the scaffold material); (b) promotion of cellular activities such as cell adhesion; (c) biodegradability with a controlled rate of degradation that corresponds with tissue growth within the scaffold; (d) a 3D highly porous structure with an interconnected network of microscopic spaces to allow tissue growth and permeation of nutrient medium; (e) favorable mechanical properties; and (f) a highly reproducible and adaptable fabrication process for different shapes or sizes. These characteristics are determined by the material selection and the method of scaffold fabrication [2].

Both chemical [3] and physical properties [4] of a scaffold affect cell behavior, ultimately determining the fate of a tissue-engineered scaffold. Progress has been made in the improvement of the chemical biocompatibility of scaffolds through the use of natural polymers [5] or synthetic polymers that incorporate bioactive peptides, such as those containing the arginine-glycine-aspartate (RGD) sequence [6]. Conversely, there has been relatively limited work on the effect of physical properties, such as the 3D architecture of a scaffold, on cell behavior. Cells respond differently to geometrically distinct biomaterial substrates [7]. Specifically, previous studies have demonstrated that cells behave differently when cultured on either two-dimensional (2D) or 3D substrates [8, 9]. For instance, chondrocytes dedifferentiate when cultured on a 2D surface [10], but maintain a stable phenotype when cultured in a 3D agarose hydrogel [11]. Fibroblasts cultured in a 3D environment developed a 3D profile of matrix adhesion, leading to a distinct cytoskeletal organization and induction of specific cell signaling pathways, compared with those cultured on 2D substrates, implying the *in vivo* relevance of 3D matrix adhesion. Similarly, the advantage of using 3D structures for cell culture has also been shown to have an effect on the maintenance and differentiation of embryonic stem cells [12]. For instance, biomimetic 3D cultures significantly increase hematopoietic differentiation efficacy of embryonic stem cells over their 2D counterparts. The biological relevance of 3D cultures is most likely a consequence of cell–matrix interactions that proceed in a complicated, bidirectional (outside-in and inside-out) manner [13], and are likely to be critical for effective tissue engineering or regeneration. While much is known about the biology of cell–matrix interactions in 2D cultures, relatively little is known about this process in 3D matrices. To date, two models of 3D environments have been proposed to elucidate the details of this interaction: substrates with a 3D topography, and 3D scaffolds. The former is useful for studying the effects of geometrical variables on cellular activities, but not directly applicable to tissue engineering. Since 3D scaffolds can be fabricated into desired shapes and form interconnected pores to allow tissue ingrowth, they are readily applicable for tissue engineering.

Recent studies have also shown that cells on substrates with varying topography, fabricated using precisely controllable techniques, behave quite differently, suggesting that cells are able to recognize and distinguish geometric properties of substrates, such as shape and/or roughness. For example, Tuan's and Curtis's groups have reported that surface roughness had an effect on osteoblast, endothelial cell, and fibroblast morphology, cytoskeletal properties, and proliferation [14–16]. Other studies have reported that adhesion, proliferation, synthesis of alkaline phosphatase, and deposition of a calcium-containing mineral were all enhanced when osteoblasts were cultured in a nanophase ceramic, compared with micro-grain size ceramics [17, 18]. Increased functions of osteoblasts have also been correlated with a decrease in the diameter of carbon nanofibers [19]. These observations suggest that a scaffold composed of nanometer-scale components is biologically preferred, which is consistent with previous studies reporting that cells favor nanotopographic biomaterial surfaces [18]. As a result, nanometer structural components should be preferred for the fabrication of functional tissue-engineered scaffolds.

This chapter differs from previously published review articles [20–24] that focus on the electrospinning process and the characterization of electrospun nanofibrous scaffolds by covering in much greater detail the breadth of electrospinning technology and its applications in tissue engineering. Notably, by taking advantage of our research expertise in cell and tissue engineering, we particularly focus on the biological mechanisms and activities enhanced by nanofibers while also reviewing the most up-to-date findings for the development of electrospun nanofibrous scaffolds and the engineering of nanofiber-based tissues. In this chapter, we first emphasize the importance of tissue engineering for clinical applications, introduce electrospun nanofibrous scaffolds by discussing the mechanisms and parameters influencing the properties of electrospun nanofibrous scaffolds, and, finally, review the current development of electrospun nanofibrous scaffolds in tissue engineering applications.

## 3.2

### **Nanofibrous Scaffolds**

Among nanostructures, nanofibers are more suitable for use as the basic component of a scaffold compared with nanoparticles, due to their continuous structure. The advantage of a scaffold composed of ultrafine, continuous fibers are high porosity, variable pore-size distribution, high surface-to-volume ratio, and, most importantly, morphological similarity to natural ECM [25]. The combination of these features makes nanofibrous structures a favorable scaffold for tissue engineering, as shown by several studies described below.

#### 3.2.1

##### **Fabrication Methods for Nanofibrous Scaffolds**

Several techniques based on different physical principles have been used to fabricate nanofibrous scaffolds with unique properties.

###### 3.2.1.1 **Phase Separation**

Phase separation is often utilized as an alternative technique for scaffold fabrication. In most cases, the polymer is dissolved in a solvent at a low temperature, and then the resulting polymer and solvent phases are quenched to create a two-phase solid. The solidified solvent is then removed by sublimation, leaving a porous polymeric scaffold behind. In brief, the polymer is dissolved, gelled, and extracted using various solvents. The advantage of using phase separation to fabricate nanofibrous scaffolds is that the shape and size of the pores can be controlled by the addition of porogens [26]. Conversely, a limitation of the foam-like structures produced by phase separation is their compliance and lack of pore interconnectivity.

###### 3.2.1.2 **Self-assembly**

By definition, self-assembly is the spontaneous organization of molecules into well-defined and macroscopic aggregates [5, 27]. The principle of molecular self-

assembly is ubiquitous in biological systems, e.g., the aggregation of lipid molecules into micelles in an aqueous environment. In contrast to processes such as electrospinning (see below), which are based on a top-down approach (i.e., materials are broken down into their respective components), self-assembly is based on a bottom-up approach (i.e., materials are assembled molecule by molecule).

On a molecular level, self-assembly is mediated by weak, non-covalent bonds, i.e., ionic bonds, hydrophobic interactions, van der Waals interactions, and water-mediated hydrogen bonds [5]. Aside from the balance of these forces, an additional crucial factor of the self-assembly process is complementary shape among the components [27]. To date, much of the work on self-assembly in tissue engineering has focused on the fabrication of 3D nanofibrous structures from amphiphilic peptides. In brief, when placed within an aqueous solution, the hydrophobic and hydrophilic domains within these peptides interact via the aforementioned forces to form distinct strong and fast-recovering hydrogels, with hydrophobic interactions being the principle force that drives the molecules together [28].

Self-assembled 3D nanofibrous scaffolds also closely mimic the porosity and gross structural scale of the natural ECM. Matrices composed of interwoven nanofibers with a diameter of 5–8 nm, and pores of 50–200 nm diameter [28, 29] have been observed by scanning electron microscopy and atomic force microscopy. The biocompatibility of these scaffolds is demonstrated by their ability to support cell proliferation and differentiation [29, 30]. In extended *in vitro* cultures of bovine chondrocytes within a peptide hydrogel, the chondrocytes encapsulated within the 3D scaffold retained their morphology and developed a cartilaginous extracellular matrix rich in proteoglycans and collagen type II, biochemical markers of a stable chondrocyte phenotype [30].

An advantage of using self-assembly to fabricate nanofibers is that the amino acid residues present may be chemically modified for the addition of bioactive moieties. Furthermore, self-assembly is carried out in aqueous salt solution or physiological media, thus avoiding the use of organic solvents and reducing cytotoxicity.

### 3.2.1.3 Electrospinning

Electrospinning technology has become popular for the fabrication of tissue engineering scaffolds in recent years (Fig. 3.2). This is a result of the growing interest in nanotechnology and the unique properties and relative ease of fabricating scaffolds using this process. Scaffolds fabricated by electrospinning have a totally different appearance and structure to those made by self-assembly and phase separation. Furthermore, electrospinning technology is exceptionally useful for the fabrication of tissue engineered scaffolds, for not only is the electrospinning equipment economical, but the preparation and fabrication phases are relatively quick compared with phase separation and self-assembly. In addition, the electrospinning system is easy to set up and can be modified to fabricate nanofibrous scaffolds that meet specific requirements for structural or mechanical needs. The advantages of electrospinning technology make it suitable for both small quantity production for laboratory research use and mass production for industrial use. In terms of the properties of scaffolds produced by the different methods, electrospun

**Fig. 3.2.** Growth of research using electrospinning technology. The increasing number of scientific publications containing the keyword “electrospinning” indicates the upward trend of electrospinning applications.

nanofibrous scaffolds contain interconnected pores, and possess mechanical and structural stability, that provide superiority over scaffolds fabricated by phase separation and self-assembly. The following sections detail the fabrication technique, properties, and clinical applications of electrospun nanofibrous scaffolds.

### 3.2.2

#### The Electrospinning Process

##### 3.2.2.1 History

Electrospinning was developed based on observations of the “electrospray” phenomenon first described by Lord Rayleigh in 1882 [31]. He discovered that a highly charged droplet was unstable and would break down into smaller droplets when passed through a voltage gradient, a property known as the “Rayleigh instability”. Rayleigh proposed that disruption of the droplet surface tension was the result of forces generated through Coulombic repulsion. After this initial study, Zeleny further investigated the electrospaying of aqueous solutions [32, 33], and Dole et al. experimented with electrospays of dilute polymer solutions [34]. In addition, Vonnegut and Neubauer electrospayed water and other liquids [35], and Drozin found that electrospayed droplets resembled a highly dispersed aerosol [36]. These seminal studies laid the foundation for what was to become the electrospinning phenomenon.

Electrospinning is a direct extension of the electrospaying phenomenon, as both processes are based on the same physical and electrical mechanisms. The main difference between the two is that electrospaying produces small droplets, whereas electrospinning produces continuous fibers. In 1934, Formhals electrospun fine fibers from a cellulose acetate solution and was granted a series of U.S. patents on this technology [37]. In 1966, Simons found that more viscous solutions favored the formation of longer fibers [38]. Baumgarten designed an apparatus with an infusion pump to electrospin acrylic fibers, and discovered that the diameter of fibers

Fig. 3.3. Schema of the electrospinning apparatus (see text for details).

could be controlled by the polymer feed rate from the infusion pump [39]. Finally, Larrondo and Manley electrospun polypropylene and produced polyethylene nanofibers in 1981 [40–42]. The recent, surging interest in nanotechnology has engendered renewed attention to this convenient, economical technology that enables engineers to produce nanofibers for various applications.

#### 3.2.2.2 Setup

The electrospinning apparatus is quite simple, with only three major components: a high voltage power supply, a polymer solution reservoir (e.g., a syringe, with a small diameter needle) with or without a flow control pump, and a metal collecting screen (Fig. 3.3). A high voltage power supply with adjustable control should be able to provide up to 50-kV DC output and, depending on the number of electrospinning jets, multiple outputs that function independently are needed. A reservoir is used to store the polymeric solution and is connected to a power supply to form a charged polymer jet. Either a syringe with a metal needle or a capillary with a metal tip in the polymer solution may be used to charge the polymer solution. Polymer flow can be driven by gravity if the syringe is not horizontally placed. However, to eliminate the experimental variables, a syringe pump is usually used to control the precise flow rate. The fiber collecting screen should be conductive and can be either a stationary plate or a rotary platform or substrate. The plate can produce non-woven fibers, while a rotary platform can produce both non-woven and aligned fibers.

Currently, there are two standard electrospinning setups, vertical and horizontal. With increasing interest in this technology, several research groups have developed more sophisticated systems that can fabricate more complex nanofibrous structures in a more controlled and efficient manner [43, 44]. For example, motor-controlled multiple jets and fiber-collecting targets provide a means for fabricating a single nanofibrous scaffold composed of multiple layers, with each layer derived from a different polymer type. Additionally, this technology can be used to fabricate polymer composite scaffolds where the fibers of each layer represent the amal-

gamation of different polymer types. The multiple jet setup is not only useful for making multi-layer nanofibrous scaffolds, but is also efficient for the production of a large quantity of scaffolding material. Notably, the electrospinning apparatus is usually set up in a chemical fume hood to remove organic vapor. In addition, a closed, non-conductive environment with temperature and humidity control is required to avoid interference from environmental factors, such as air turbulence.

### 3.2.2.3 Mechanism and Working Parameters

To initiate the electrospinning process, a selected polymer material is dissolved in the appropriate solvent and this solution is loaded into a syringe. A high-voltage electric field is created between the needle and the collecting screen by the use of a power supply and electrodes. When the polymer solution is extruded slowly by a syringe pump and/or gravity, a semispherical polymer solution droplet is formed at the tip of the needle. With increasing voltage, the polymer droplet elongates to form a conical shape known as the Taylor cone [45], causing the surface charge on the polymer droplet to increase with time. Once the surface charge overcomes the surface tension of the polymer droplet, a polymer jet is initiated [46]. The solvent in the polymer jet evaporates during travel to the collecting screen, increasing the surface charge on the jet. This increase in surface charge induces instability in the polymer jet as it passes through the electric field [45]. To compensate for this instability, the polymer jet divides geometrically, first into two jets, and then into many more as the process repeats itself. The formation of nanofibers results from the action of the spinning force provided by the electrostatic force on the continuously splitting polymer droplets. Nanofibers are deposited layer-by-layer on the metal target plate, forming a non-woven nanofibrous mat.

Although the electrospinning/electrospinning technology has been utilized for more than a hundred years, the mechanisms by which nanofibers are formed, much less controlled, have yet to be completely elucidated. Although several studies have been carried out to investigate the mechanism of fiber formation to reproducibly control scaffold design, little theoretical clarity has been achieved. During the electrospinning process, a uniform fibrous structure is created only under optimized operating conditions. Both extrinsic and intrinsic parameters are known to affect the structural morphology of the nanofibers [47]. Specifically, extrinsic parameters, such as environmental humidity and temperature, in addition to intrinsic parameters, including applied voltage, working distance, and conductivity and viscosity of the polymer solution, need to be optimized to produce uniform nanofibers. Generally speaking, the intrinsic parameters are more critical in determining the nanofiber structure. Two major structures are usually found in the nanofibrous mat fabricated by the electrospinning process – a uniform, continuous fibrous structure or a bead-containing fibrous structure. Variation in the relative abundance of these two structures is determined by the relative contributions of the four intrinsic parameters during the electrospinning process.

**Polymer Solution Viscosity** Polymer solution viscosity, a parameter directly proportional to the concentration of the polymer solution, is the most critical factor in

controlling the structural morphology of the nanofibrous structure. For fiber formation, polymer viscosity should be in a specific range, depending on the type of polymer and solvent used. Fong et al. used polyethylene oxide (PEO) to study nanofiber formation in different PEO viscosities, and found that a range of viscosity between 1 and 20 poise is suitable for electrospinning uniform nanofibers [48]. Below this range, a bead-containing nanofibrous structure was created. With increasing viscosity, spherical beads became elongated into spindle-shaped ones, and the number of beads in the structure was reduced. Similarly, Liu et al. also reported that a different specific range of viscosity was appropriate for the formation of uniform nanofibers composed of cellulose [49]. In addition, recent studies conducted by Deitzel et al. [50] and Demir et al. [51] have shown that a more viscous polymer solution resulted in larger fibers. Taken together, these studies indicate that there exist polymer-specific, optimal viscosity values for electrospinning.

**Applied Charge Density** Charge density, as the amount of charge per unit surface area of the polymer droplet, is determined by the applied voltage, the working distance, and the conductivity of the polymer solution. Applied voltage is used to provide the driving force to spin fibers by imparting charge to the polymer droplet. The working distance is defined as the distance between the tip of syringe and the collecting plate and, together with the applied voltage, can influence the structural morphology of nanofibers. Demir et al. suggested that when higher voltages are applied more polymer is ejected to form a larger diameter fiber [51]. Similarly, high voltage conditions also created a rougher fiber structure. Zong et al. proposed an approach to increase charge density on the surface of the droplet by adding salt particles to reduce bead formation [52]. However, their conclusion was that a high charge density produced thinner fibers, a finding not corroborated by Demir et al. [51].

**Polymer Solution Conductivity** The conductivity of a polymer solution is mainly determined by the polymer type, solvent used, and the availability of ionizable salts. A more conductive polymer solution carries more electric charge during the electrospinning process, with the as-spun fibers generating a stronger repulsive force, which facilitates the formation of bead-free, uniform fibers. Therefore, the general rule for the production of uniform electrospun nanofibers is to electrospin a highly conductive polymeric solution. Since most synthetic biodegradable polymers such as the commonly used poly( $\alpha$ -hydroxy esters) do not carry a charge, it is preferred to increase the solvent conductivity. As a result, a dipolar aprotic solvent, *N,N*-dimethylformamide (DMF), which has a high dielectric constant and dipole moment, is added to enhance the solution conductivity [53]. An additional approach entails the use of salts to increase chargeable functional groups in polymeric solutions. The addition of benzyl triethylammonium chloride (BTEAC) [54] or sodium chloride [55], for instance, enhances polymer solution conductivity, in turn reducing fiber size, while producing bead-free fibrous structures. Natural polymers, though, such as collagens, which contain functional groups, usually carry charges when dissolved in solution; however, the polyelectrolyte characteristic

and hydrogen bonding potential of natural polymers limit the choice of solvents. The use of highly polar fluorinated or acid-based solvents can prevent complicated polymer–polymer and polymer–solvent interactions to smooth the electrospinning process.

### 3.2.3

#### **Properties of Electrospun Nanofibrous Scaffolds**

##### 3.2.3.1 **Architecture**

An electrospun nanofibrous scaffold has a macro-architecture that is defined by the gross structure of the entire scaffold. The macro-architecture can be machined into a desired dimension and shape, depending on the type of tissue being engineered. However, the micro-architecture is defined by the porous, fibrous structure composed of nanofibers, with the more commonly seen micro-architecture being either a non-woven or an aligned fibrous structure.

**Non-woven Nanofibrous Scaffolds** Upon ejection from the nozzle of a needle, a polymer jet travels spirally at a high speed in the space between the tip of a needle and the fiber-collecting plate. The jet path is a complicated 3D curve and thus nanofibers are deposited on the target platform in a random manner, resulting in a non-woven structure [56]. Nevertheless, under optimal electrospinning conditions, a homogeneous nanofibrous mat will be formed, with fiber direction in the structure being equally oriented in every direction and polygonal, interconnected pores of various sizes formed between nanofibers. Although deposited fibers lay on and barely contact each other, the interlocking between fibers helps to maintain the micro-architecture of the nanofibrous scaffold. Shape and size of pores are altered only when the structure is subjected to loading.

**Aligned Nanofibrous Scaffolds** While such randomly oriented scaffolds are useful, a significant number of natural tissues exhibit a preferred fiber alignment. This fiber alignment endows tissues with unique functional material properties that depend on the testing direction and location. For example, in tendon and ligaments, tensile properties are 200–500× higher along the fiber direction (the direction over which the force is transmitted) than those perpendicular to the fiber direction [3]. In articular cartilage, tensile properties are greatest in the superficial zone of the tissue and highest along the prevailing collagen (split line) direction [4, 5]. As the goal of tissue engineering is to recapitulate the functional properties of the native tissue, new techniques have been developed for engineering tissue anisotropy.

The strategies in controlling nanofiber alignment generally focus on the as-spun fiber-assembly methods, using either an electrostatic field and/or specially designed collectors such as a rotary target [57] and patterned electrodes [58]. Theron et al. have utilized a rotary disc as a fiber collector to electrically and mechanically align nanofibers [57]. The sharp edge of the disc provides a physically sharp point that serves as an electrode to attract positive-charged nanofibers. The sharp point accumulates charge and generates a strong electrostatic field. The rotary sharp edge acts like a continuously moving, charged band that forces nanofibers to align

on a limited strip that winds around the circumference of the disc. In addition, the rotary movement of the disc provides a tangential force, further aligning and stretching nanofibers at the same time. Fiber alignment in this initial study is relatively satisfactory, but the amount of collected aligned nanofiber is limited due to the narrow sharp edge. To increase aligned nanofiber production for tissue engineering applications, it is suggested that a disc is replaced by a drum or a shaft with a large surface area [59]. Doing so will efficiently produce a larger and thicker nanofibrous mat, but without any precise control of fiber alignment. One of the solutions is to increase the rotational speed. Several studies have shown that the nanofiber alignment in a mat is highly dependent on the rotational speed of the drum or shaft [59]. Nanofiber alignment increases with the rotational speed of the collecting surface, and plateaus after reaching an optimal value.

Another practical approach to align nanofibers utilizes a fiber collector consisting of two rectangular conductive electrodes placed on a highly insulating substrate and separated by an air gap [58]. Nanofibers, due to a preferential electrostatic field, are deposited on the electrodes uniaxially across the air gap. The air humidity, in which the electrospinning is carried out, is the major factor affecting the fiber alignment using this approach. Nanofiber alignment increases with the carried charge of as-spun nanofibers and is also enhanced by the reduction of air humidity, since the higher humidity discharges the nanofibers. In addition, fiber orientation is partially determined by the amount of charge left on the deposited nanofibers. The retained charge on deposited nanofibers improves the orientation through electrostatic repulsions between the fibers. Altering the pattern of the electrode array can change the orientation of uniaxial nanofibers and may be useful to fabricate a scaffold with a complicated aligned nanofibrous pattern.

### 3.2.3.2 Porosity

The internal porous structure of void spaces, or porosity, is a physical component of a biomaterial scaffold that is also dependent on the architectural scale. These pores serve as pathways for mass transport (convection and diffusion), while also providing void space for cells to form new tissues [60]. One technique for measuring the pore diameter distribution, total pore volume, and total pore area of a structure is mercury porosimetry. Utilizing this technology, a 91.63% porosity was reported for electrospun nanofibrous scaffolds, indicating a highly porous structure [25]. This study also reported a total pore volume of  $9.69 \text{ mL g}^{-1}$ , a total pore area of  $23.54 \text{ m}^2 \text{ g}^{-1}$ , and a pore diameter ranging broadly from 2 to  $465 \text{ }\mu\text{m}$  [25]. While some of these pores are too small to influence the migration of cells and facilitate invasion of blood vessels within the scaffold, nutrients and metabolic wastes are still able to pass through these nano-sized pores, thus enhancing engineering of the tissues. In addition, the high porosity of these scaffolds should present a wider path for mass transport, improving cell survival within the scaffold [60].

Although precise control of the pore size in nanofibrous scaffolds is challenging, efforts have been made to fabricate large-pore nanofibrous scaffolds in a more controllable manner. Lee et al. have combined electrospinning technology and salt leaching/gas foaming methods for the fabrication of an electrospun fibrous scaffold with dual-sized pores [61]. In addition to intrinsic pores formed between

nanofibers, micro-sized pores created by salt particles are distributed in the scaffolds using this modified approach. As porous scaffolds fabricated by the conventional salt-leaching method, pore sizes in electrospun nanofibrous scaffolds are determined by the dimension of the salt particles. The dual-pore, electrospun nanofibrous scaffolds represent an enhanced porous structure for more efficient cell migration and nutrition/waste exchange.

### 3.2.3.3 Mechanical Properties

As previously discussed, tissue engineering aims to utilize natural and synthetic biomaterials to simulate the 3D environment of the natural ECM. Tissue-engineered scaffolds thus also need to match the mechanical properties of the natural environment. The mechanical properties (strength, toughness, modulus, and ductility) of a scaffold are determined by both its structure (macrostructure, microstructure, and nanostructure) and its material properties [60]. Matching the mechanical properties of a scaffold to that of the natural ECM is critically important so that once grafted the progression of tissue healing is not limited by mechanical failure of the scaffold [60]. Furthermore, the mechanical properties of the scaffold can affect cell morphology, proliferation, and differentiation [62].

The process of electrospinning provides ultrafine nanoscale structures that not only geometrically and topologically simulate the natural ECM, but may also mimic the mechanical properties of the natural tissue microenvironment. To accurately investigate the mechanical behavior of nanofibrous scaffolds, it is essential to measure the mechanical properties of individual fibers that make up the scaffold [63]. Such tensile testers must possess the capability of measuring the small load and elongation required for the deformation of these ultrafine fibers, including individual fibers [63, 64]. In a previous study of the mechanical properties of individual electrospun poly( $\epsilon$ -caprolactone) (PCL) nanofibers, it was shown that mechanical properties varied with fiber diameter, i.e., both tensile strength and yield stress decreased with increased fiber diameter, while an increase in fiber diameter resulted in an increase in strain at break [63]. While in this study it was shown that the strain of break increases with an increase in fiber diameter, yield strain was found to decrease with an increase in fiber diameter, and there was also no apparent correlation between Young's modulus ( $E$ ) and fiber diameter [63]. In summary, the high ductility, and low strength and stiffness of the PCL nanofibers observed in this study depend on the physical properties of the polymer (i.e., low  $T_g$ ) and fiber diameter.

## 3.3

### Current Development of Electrospun Nanofibrous Scaffolds in Tissue Engineering

#### 3.3.1

##### Evidence Supporting the Use of Nanofibrous Scaffolds in Tissue Engineering

#### 3.3.1.1 Nanofibrous Scaffolds Enhance Adsorption of Cell Adhesion Molecules

Cell adhesion is one of the most important aspects of cell interaction with a biomaterial. It is the first cellular event to take place after cells are seeded onto a biomaterial.

terial surface; cell migration, proliferation, and/or differentiation take place only after cells are securely adhered [65]. In native tissues, cells bind via integrins to specific binding sites in the tissue ECM, consisting of specific peptide sequences recognized by the integrins [66]. However, synthetic polymers do not have natural cell binding sites, and cell adhesion to a polymeric scaffold is therefore necessarily mediated by plasma/serum proteins adsorbed onto the polymer surface. Protein adsorption to the polymer surface is affected by the hydrophilicity [67] and the surface energy of the polymer [68]. Cells attach to many ECM proteins, including fibronectin, vitronectin, collagens, and other matrix proteins [69]. Nikolovski et al. showed that vitronectin, compared with fibronectin, was the predominant matrix protein adsorbed from serum-containing medium onto poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) [70]. Woo et al. recently reported that nanofibrous scaffolds for tissue engineering show enhanced adsorption of cell adhesion ECM molecules, which may therefore enhance cell adhesion [71]. The high surface-area-to-volume ratio of electrospun nanofibrous scaffolds should result in higher adsorption of vitronectin and fibronectin molecules than other scaffolds. In fact, approximately four times as much serum proteins adsorbed to nanofibrous scaffolds compared with scaffolds with solid pore walls. Moreover, fibronectin and vitronectin preferentially adsorbed to the nanofibrous scaffold at a level that was 2–4× higher than those adsorbed to the solid-walled scaffold [71]. Although the mechanisms by which a nanofibrous scaffold acts as a selective substrate are not yet known, it is clear that the enhanced adsorption of cell adhesion matrix molecules enhances cell adhesion.

#### 3.3.1.2 Nanofibrous Scaffolds Induce Favorable Cell–ECM Interaction

In a native environment, cells are in contact with the ECM and neighboring cells, and cell–matrix interaction act as key regulators of cellular activities [72]. Cells synthesize, assemble, organize, and maintain ECM macromolecules, while the ECM functions to provide structural protection to the resident cells and acts as a messenger regulating cellular activities such as proliferation or differentiation [73]. In postnatal life, the ECM continuously undergoes dynamic turnover to respond to environmental changes caused by biochemical stimulation or mechanical loading. In particular, mechanical signals are transmitted from the environment via the ECM network to cells, which respond to these signals by remodeling the ECM to adapt to the environmental change [74]. Extrapolating from these native interactions, a scaffold that serves as a functional, temporary ECM must involve optimal cell–matrix interactions, as well as cell–cell interactions.

Several reports have demonstrated that nanofibers as scaffolds are more favorable than microfibers, suggesting cell activities can be regulated by the size of the fiber [75, 76]. One such study evaluated the influence of the structural properties of biomaterial scaffolds on the biological activities of chondrocytes cultured in microfiber- and nanofiber-based scaffolds [75]. The results show that chondrocytes seeded into microfibrous scaffolds display dedifferentiated, fibroblast-like morphology, whereas chondrocytes seeded onto nanofibrous scaffolds maintain a chondrocyte-like morphology (Fig. 3.4). Large, organized stress fibers, commonly found in cells in monolayer culture also appear in cells seeded onto microfibrous

**Fig. 3.4.** Ultrastructural morphology of acellular and cellular PLLA microfibrous and nanofibrous scaffolds examined by SEM. (A) A PLLA microfibrous scaffold showing random orientation of microfibers with a diameter ranging from 15 to 20  $\mu\text{m}$ . (B) A PLLA nanofibrous produced by the electrospinning process, showing random orientation of ultrafine fibers with diameters ranging from

500 to 900 nm, defining a matrix with interconnecting pores. (C) Spread cellular sheets composed of fibroblast-like cells spanned between microfibers in the microfibrous culture after 28 days. (D) Cellular aggregates composed of globular, chondrocyte-like cells grew on nanofibers in the nanofibrous culture after 28 days. Bar = 10  $\mu\text{m}$ .

scaffolds. However, cells seeded in nanofibrous scaffolds do not display a similar cytoskeletal structure. Cell activities such as proliferation and the production of a cartilaginous ECM are enhanced in nanofibrous cultures compared with microfibrous cultures. Overall, these results demonstrate the biological effects of different-sized fibrous biomaterial scaffolds, and suggest that a nanofibrous scaffold is a more effective scaffold for cartilage tissue engineering.

Another study also reported a similar conclusion of nanofibers outperforming microfibers [76], in terms of the biological response of neural stem cells cultured on nanofibrous and microfibrous scaffolds. Unlike the comparison of fibers with a two-order difference in Li's study [75], 300 nm nanofibers were compared with 1.5  $\mu\text{m}$  microfibers. The results of this study show that a greater percentage of neural stem cells cultured on nanofibrous scaffolds exhibit a neuron-like morphology when compared with microfibrous scaffolds. In addition, the average neurite length of neural stem cells on a nanofibrous scaffold is significantly longer than that of cells on a microfibrous scaffold, suggesting that nanofibers enhance the neurite outgrowth.

One possible explanation for the enhanced performance of nanofibrous scaffolds is that nano-scale fibers, smaller than a cell by two-orders resembling native ECM, create the 3D environment that has spatial advantage in promoting cell–matrix interaction, whereas a scaffold composed of micro-scale fibers with the same order size as a cell does not have such an advantage.

### 3.3.1.3 Nanofibrous Scaffolds Maintain Cell Phenotype

Chondrocytes isolated from cartilage and cultured *in vitro* readily undergo dedifferentiation when plated as monolayers, but will redifferentiate and re-express their phenotype maintained in a 3D environment such as collagen gels. Nanofibrous scaffolds have been shown to support the potential of dedifferentiated chondrocytes to redifferentiate *in vitro* [77]. In this study, fetal bovine chondrocytes were

seeded onto nanofibrous scaffolds, or as monolayers on standard tissue culture polystyrene (TCPS) as a control substrate. Gene expression analysis shows that chondrocytes seeded on the nanofibrous scaffold and maintained in a serum-free, ITS+ supplemented medium continuously maintain their chondrocytic phenotype by expressing cartilage specific ECM genes, including collagen types II and IX, aggrecan, and cartilage oligomeric matrix protein (COMP). Specifically, expression of the collagen type IIB splice variant transcript, which is indicative of the mature chondrocyte phenotype, is up-regulated. Chondrocytes exhibit either a spindle or round shape on the nanofibrous scaffold, in contrast to the flat, well-spread morphology seen in monolayer TCPS cultures. Organized cytoskeletal actin stress fibers are only observed in the cytoplasm of cells cultured on TCPS. Histologically, nanofibrous cultures maintained in supplemented serum-free medium produce more sulfated proteoglycan-rich, cartilaginous matrix than monolayer cultures. In addition to promoting phenotypic differentiation, the nanofibrous scaffold also supports cellular proliferation when the cultures are maintained in serum-containing medium. These results indicate that the biological activities of chondrocytes are crucially dependent on the architecture of the extracellular scaffolds as well as the composition of the culture medium, and that the nanofibrous scaffold acts as a biologically preferred scaffold/substrate for proliferation and maintenance of the chondrocytic phenotype.

#### 3.3.1.4 Nanofibrous Scaffolds Support Differentiation of Stem Cells

Stem cells, including embryonic and adult stem cells, are promising cell sources for tissue engineering because of their extensive expansion and differentiation capability. Therefore, the biomaterial scaffold used to culture stem cells should be able to support basic stem cell processes, such as proliferation, self-renewal, and differentiation.

Embryonic stem cells (ESCs), different from mesenchymal stem cells (MSCs) isolated from adult tissues, are derived from the inner cell mass of a blastocyst [78]. ESCs have been considered as having the potential of unlimited differentiation, whereas MSCs are more restricted in their differentiation potential. The technique of controlling the fate of ESCs *in vitro* is complicated and far from mature. One of the requirements for the growth of ESCs is the presence of basement membrane matrix or feeder layers of embryonic fibroblasts. Basement membrane matrix or feeder cell layers provide chemical and physical cues to the ESCs, and maintain their ability to self-renew and differentiate [79]. A nanofibrous structure resembling a basement membrane matrix has been used to culture ESCs to maintain their aforementioned “stemness” properties [80]. The results show that ESC-nanofibrous cultures have significantly larger colonies of undifferentiated cells and enhanced proliferation compared with controls cultured on glass coverslips and same-polymer-films, suggesting that the physical cues from the unique geometry of nanofibrous surfaces regulate cellular activities.

Compared with the uncertain future of ESCs in the clinic, owing to ethical and legal issues, adult stem cells provide a promising cell source for stem cell based-tissue engineering. MSCs are undifferentiated, multipotential cells that are capable

of giving rise to cells characteristic of several tissues, including the connective tissue lineage [81]. Advantages of using MSCs include the fact that MSCs can be isolated from many different adult tissues, such as bone marrow [81], fat [82], umbilical cord blood [83], muscle [84], and synovial membrane [85]. In addition, nanofibrous scaffolds support multi-differentiation of MSCs [86]. In this study, MSCs from bone marrow maintained in nanofibrous scaffolds differentiated along adipogenic, chondrogenic, or osteogenic lineages when induced with specific differentiation media. Gene expression analysis and immunohistochemical detection of lineage-specific marker molecules confirmed the formation of nanofibrous constructs containing cells differentiated into the specified cell types. These results demonstrate the full support of multi-lineage differentiation of MSCs within nanofibrous scaffolds and the feasibility of tissue-engineering multiphasic constructs using a single cell source, which is of particular relevance to the development of multiphasic tissue constructs.

#### 3.3.1.5 Nanofibrous Scaffolds Promote *in vivo*-like 3D Matrix Adhesion and Activate Cell Signaling Pathway

The observations presented above strongly suggest that nanofibrous scaffolds serve as synthetic ECM networks to provide both chemical and physical stimuli to cells via direct interaction with the cells surface. Unique geometric features of the extracellular matrix, especially ultrafine structure, are generally believed to play a direct and/or indirect role in the regulation of cellular activities. However, studies about cell–nanofiber interactions are new, and the specific mechanisms of how the unique properties of nanofibers enhance cellular activities are largely unknown. From the recently published studies, integrin receptors, cytoskeleton, and signal pathways involving focal adhesion kinase (FAK), Rho, Rac, and Cdc42 GTPases are likely to play a significant role in regulating cells cultured on nanofibrous cultures [87, 88]. Schindler et al. have demonstrated that nanofibrous cultures promote *in vivo*-like cell morphology of both fibroblasts and kidney cells [87]. They also showed that both cells cultured on nanofiber surface have less defined, punctate patterns of vinculin and FAK, molecules mediating cell adhesion, at the edge of lamellipodia. In response to the accumulation of cell adhesion molecules at the edge of cells, a notable increase is observed in the formation of actin cytoskeleton-rich lamellipodia, membrane ruffles, and cortical actin. Such cellular response is also found in 3D cultures on basement membrane matrix, but not on 2D cultures. Instead, in a flat culture on glass, more vinculin and FAK are accumulated in a streaky pattern, promoting the formation of well-defined actin filaments. The decrease of FAK at the adhesion site, characteristic for cells in tissue, is called “3D-matrix adhesion”. Different from focal adhesion and fibrillar adhesion commonly formed *in vitro* on flat surfaces, 3D-matrix adhesion takes place in a 3D culture, suggesting that such *in vitro* cultures may bring the cells closer to *in vivo* conditions [13]. Thus, nanofibrous cultures should promote the formation of 3D-matrix adhesion and simulate the *in vivo* microenvironment.

In addition to the formation of 3D-matrix adhesion, nanofibrous cultures also demonstrate different expression profiles of components of cell signaling pathways

that mediate cell morphology and cytoskeletal organization. These components include members of the family of Rho GTPases, Rho, Rac, and Cdc42, each controlling distinct downstream signal pathways [88]. Cells cultured on a nanofibrous surface extensively activate Rac, which consequently enhances cell proliferation rate and increases the deposition of fibrillar fibronectin. The activated Rac is also found to accumulate at the lamellopodial edge, intracellular vesicles, and dorsal membrane ruffles, often formed in migrating cells and cells cultured in other 3D environment. The activation of Rho and Cdc42 is not as significant as that of Rac. Both GTPases were mildly elevated in the nanofibrous culture than on glass at the early phase of cell attachment. However, the extent of Cdc42 mediating cell polarity decreases along the culture. The nanofibrous scaffolds can dramatically induce the preferential activation of Rac GTPase, suggesting that nanofibrous scaffolds can provide physical as well as spatial cues to activate intracellular signaling pathways that are essential to mimic *in vivo*-like tissue growth.

### 3.3.2

#### **Biomaterials Electrospun into Nanofibrous Scaffolds**

Many polymeric biomaterials have been used for tissue engineering applications, including non-biodegradable and biodegradable polymers, with the latter consisting of both natural and synthetic polymers. Non-biodegradable polymers can be utilized to engineer tissues requiring substantial mechanical stability, such as ligament or muscle. However, their long-lasting nature interferes with tissue turnover and remodeling. Therefore, more attention has been devoted to biodegradable polymers in tissue engineering. Polymer biodegradation, by the combined effect of enzymatic and hydrolytic activities, generates space within the scaffold that facilitates cellular processes, such as proliferation and the deposition of newly synthesized ECM. To date, more than one hundred different biodegradable polymers have been successfully electrospun and over thirty of them have been used for various tissue-engineered applications. Table 3.1 summarizes the polymers used in electrospinning, their potential applications, and the evaluation criteria employed in each study.

#### 3.3.2.1 **Natural Polymeric Nanofibrous Scaffolds**

Because of their more biologically favorable polymeric chemistry towards cell and tissue growth, natural polymers have recently been fabricated into various 3D, tissue engineering scaffolds. Two groups of biocompatible natural polymers electrospun into nanofibers have been used for tissue engineering applications: protein-based and carbohydrate-based polymers. Protein-based polymers include collagen, gelatin, elastin, silk fibroin, and fibrinogen, and carbohydrate-based polymers include chitin, chitosan, and hyaluronan. Recently, natural polymers have been electrospun into nano-/micro-fibers that are structurally similar to ECM protein fibers.

**Collagen** Collagen, the most abundant protein family in the body, has been extensively used for *in vitro* and *in vivo* tissue engineering. Among the at least 19 differ-

PGA = poly(glycolide), PLGA = poly(lactide-co-glycolide), PLLA = poly(L-lactide), PDLLA = poly(D,L-lactide), PEG = poly(ethylene glycol), PCL = poly( $\epsilon$ -caprolactone), MMT = montmorillonite, P(LLA-CL) = poly(L-lactide-co- $\epsilon$ -caprolactone), P(CL-EEP) = poly( $\epsilon$ -caprolactone-co-ethyl ethylene phosphate), PNmPh = poly[bis(*p*-methylphenoxy)phosphazene], PHBV = poly(3-hydroxybutyrate-co-3-hydroxyvalerate), PEU = polyetherurethane, PEUU = poly(ester urethane)urea, PPDO = poly(*p*-dioxanone), PU = polyurethane, PET = polyethylene terephthalate, PEVA = poly(ethylene-co-vinyl alcohol), PS = polystyrene, PDS = polydioxanone, LMWH = low molecular weight heparin, PVA = poly(vinyl alcohol), CA = cellulose acetate, PEO = poly(ethylene oxide), Col I = collagen type I, Col II = collagen type II, Col III = collagen type III, HA = hyaluronic acid, TE = tissue engineering, SEM = scanning electron microscopy, TEM = transmission electron microscopy, DSC = differential scanning calorimetry, WAXD = wide-angle X-ray diffraction, SAXS = small angle X-ray scattering, AFM = atomic force microscopy, XRD = X-ray diffractometry, NMR = nuclear magnetic resonance, XPS = X-ray photoelectron spectroscopy, EDX = energy dispersive X-ray, ATR-IR = attenuated total reflectance infrared spectroscopy, FTIR = Fourier-transform infrared spectroscopy, TGA = thermogravimetric analysis.

ent collagen types, collagen type I is the major collagen in connective tissues and collagen type II is exclusively abundant in hyaline cartilage. Both collagen types I and II have been fabricated into different scaffolds, mostly in a gel-format, to repair tissue defects *in vivo* [89, 90]. Collagen electrospinning provides an *in vitro* method to create a preformed, nanofibrous collagen scaffold that closely mimics the native collagen network [43, 91–97]. For instance, Matthews et al. have demonstrated that, under optimal working parameters, electrospinning can be adapted to fabricate collagen types I and III nanofibers [91]. Electrospun fibers of skin-derived collagen type I and placenta-derived collagen type III were shown to be more uniform than fibers of placenta-derived collagen type I, suggesting that the diameter of electrospun collagen fibers varies with tissue origin and collagen type. Interestingly, electrospun collagen type I nanofibers exhibit the periodic banding pattern typical of native collagen, further demonstrating the potential of electrospinning in the fabrication of natural collagen fibers. Collagen type II has also been successfully electrospun. Being a major fibrous component of the ECM in hyaline cartilage, collagen type II networks are extremely important in cartilage regeneration. Electrospinning collagen type II is a promising approach to reconstruct collagen networks *in vitro*. However, one of the drawbacks on using electrospun collagen scaffolds is their rapid degradation in culture. A study by Shields et al., comparing the properties of crosslinked and non-crosslinked scaffolds using glutaraldehyde as the crosslinking agent, found crosslinking to increase the diameter of collagen fibers as well as the thickness of the scaffold [97]. This study also demonstrated that electrospun collagen type II fibers are relatively larger but mechanically weaker than native collagen fibers. Although not fully recapitulating the properties of the native collagen type II network formed in cartilage, electrospun collagen type II scaffolds still hold promise in cartilage tissue engineering due to their ability to closely mimic the natural ECM.

**Gelatin** Gelatin is the denatured form of collagen type I, a natural protein-based polymer that is extensively used in the biomedical and food industries. Unlike the triple-helical collagen from which it is derived, the denatured protein chain of gelatin is readily soluble in water at room temperature. Tissue engineered scaffolds made of gelatin usually require treatment with a crosslinking agent to maintain their structural integrity in a physiological environment, due to their ready dissociation in physiological solution. It is also common for gelatin to be grafted or blended with other polymers in the preparation of tissue engineering scaffolds [98, 99]. Like most protein polymers, gelatin contains amine and carboxylic groups, which are easily ionized in water to carry charge. This polyelectrolyte property of gelatin, coupled with its strong hydrogen bonding makes electrospinning of a gelatin aqueous solution quite challenging [43, 93, 95, 100]. In a study by Huang et al., highly polar fluorinated solvents were used to prepare a gelatin solution with an optimal concentration for electrospinning [101]. This study also showed that the mechanical performance of a gelatin mat is determined by fiber morphology, which is dependent on polymer concentration. For instance, an increase in the average diameter of gelatin fibers from 100 nm to 1.9  $\mu\text{m}$  was achieved by increasing polymer con-

centration, with smaller uniform fibers being mechanically stronger than larger uniform fibers.

**Elastin** Elastin is a highly water-insoluble protein that functions as a “perfect coil” to provide elasticity to tissues that need to be stretched and recoiled. However, it is rare for elastin to be used alone as a material to fabricate tissue engineering scaffolds [94, 95]. Elastin-containing tissues generally also contain collagen fibers [102, 103]. For instance, tissues such as skin, lung, and blood vessels are composed of collagen fibers for tensile properties and elastin fibers for elastic properties. Nagapudi et al. used a genetic engineering approach to synthesize recombinant elastin-mimetic proteins, and which were electrospun into nanofibers with different properties [104]. Elastin-mimetic proteins dissolved in a highly polar fluorinated solvent were electrospun into smaller fibers, compared with those dissolved in aqueous solution, suggesting that different fibrous morphologies of natural polymers could result from the use of different solvents, such as highly polar fluorinated solvent and water.

**Silk Fibroin** Besides collagen, silk fibroin is another protein-based, natural polymer most commonly used for electrospinning. With a long history of textile use, beginning with the ancient Chinese, silk has recently been applied for the fabrication of tissue engineering scaffolds [105–111]. One of the most significant properties of silk is its excellent mechanical properties. Natural silk is produced by spiders or silkworms, with different composition and properties among species. A study by Ohgo et al. comparing three electrospun silk fibroin nanofibers suggested that silk fibroins from two different silkworms and genetically engineered silk-like protein each required individual optimal polymer concentration for electrospinning [107]. In addition, the engineered silk-like protein nanofibers were reported to be smaller than the natural silk fibroin nanofibers, and the mechanical strength of silk fibroin nanofibrous mats was also dependent on silk fibroin type.

**Fibrinogen** Purified from blood plasma, fibrinogen is a globular protein that plays a critical role in wound healing. In the presence of thrombin, fibrinogen gives rise to fibrin which forms fibrous clots that have found use as a clinical fixative, due to its natural role in wound healing. Fibrin has recently attracted scientific attention for use as a scaffold to deliver cells [112, 113] or growth factors [114] for tissue engineering. Due to the high surface area to volume ratio available for clot formation, electrospun nanofibrous fibrinogen mats are highly suitable for wound dressing and hemostatic products. Wnek et al. have fabricated and characterized electrospun fibrinogen scaffolds [115], and found the fibrinogen mats to be composed of uniform, randomly orientated fibrinogen nanofibers. Notably, the electrospun fibrinogen fiber typically exhibited a granular appearance with 22.5 nm banding, characteristic of native fibrinogen. Consistent with the finding of studies using other polymers, the fiber diameter was shown to increase from 80 to 700 nm with increasing in polymer concentration. The electrospun fibrinogen mats were also shown to have substantial structural integrity and good handling, with an elastic

modulus comparable to that of PGA. The most important characteristic of electrospun fibrinogen mats was their high surface area-to-weight ratio of  $41\,000\text{ cm}^2\text{ g}^{-1}$ , making electrospun fibrinogen mats ideal for wound dressing products. However, the risk of immune cross-reactivity may limit the use of fibrinogen for scaffold applications.

**Chitin and Chitosan** Chitin and chitosan are biocompatible and biodegradable natural polymers, used in biomedical applications and cosmetics. Chitosan (poly-D-glucosamine) is derived from chitin (poly-N-acetyl-D-glucosamine), a polysaccharide formed in shellfish exoskeleton, which has received more attention in biomaterial development than chitin due to its solubility. Therefore, chitosan has been critically considered as a candidate biomaterial for tissue engineering scaffolds [116–118]. Chitosan carries a high cationic charge density and can interact with various anionic polymers, such as chondroitin sulfate, to form a hydrogel scaffold [119]. Different from a hydrated scaffold, an electrospun scaffold is a preformed, nanofiber-based scaffold with a definite structure [120–122]. Min et al. used radiation to depolymerize chitin to increase its solubility for electrospinning [120]. In this study, the electrospun chitin nanofibers started to form at a viscosity at which the required polymer chain entanglement occurs. Fiber diameters vary from 40 to 600 nm, but most fibers are less than 100 nm. The authors also demonstrated that chitosan nanofibrous scaffolds electrospun using deacetylated chitin showed no significant changes in terms of scaffold size and fiber diameter after this transformation. Significantly different from Min's approach, Geng et al. directly electrospun a chitosan solution [122], prepared by dissolving chitosan in concentrated acetic acid, into chitosan nanofibers with an average diameter of 130 nm. The authors suggested that the use of concentrated acetic acid to decrease surface tension of chitosan solution and increase the charge density of the jet, facilitated the formation of uniform chitosan nanofibers. Other factors affecting fiber morphology include chitosan molecular weight, solution concentration, and charge density of electric field. For each parameter, there is a narrow window of optimal working conditions for defect-free nanofiber formation to occur. Generally, a viscous chitosan polymer solution prepared from a higher molecular weight chitosan is preferred, with electrospinning done in a moderate charge density electric field.

**Hyaluronan** The most commonly used carbohydrate-based natural polymer in tissue engineering is hyaluronan (hyaluronic acid), a polysaccharide composed of repeating glucuronic acid and N-acetylglucosamine. Like chitosan, unmodified hyaluronan is hydrophilic and is commonly produced in a gel-format scaffold. A hyaluronan-based scaffold is inherently unstable and thus has limited application in tissue engineering. Thus, approaches have been developed to increase the resistance of hyaluronan to degradation, including esterification [123] and crosslinking [124]. Modified hyaluronan can be fabricated into scaffolds with pre-formed structures, and several *in vitro* and *in vivo* studies have reported cell proliferation and synthesis of ECM using these modified hyaluronan scaffolds [125, 126]. It is difficult to form uniform size fibers from hyaluronan using electrospinning because of

the high viscosity and surface tension of the hyaluronan solution. Um et al. reported on several approaches to prepare a hyaluronan solution that has sufficient molecular entanglement in a rapidly evaporated solvent, while still maintaining low viscosity and surface tension [127]. One of the approaches blended two hyaluronan polymers of low and high molecular weight, resulting in increased molecular entanglement but not viscosity. Another approach consisted of adding ethanol in the polymer solution, which facilitated solvent evaporation as well as reduction in surface tension. However, although the approaches seemed rational, these results, while satisfactory, were limited. Therefore, further approaches entailed adding an air-blow system close to the spinneret, providing both electrical and air-blowing shear forces as well as heat, to facilitate hyaluronan nanofiber formation, and the new setup is named an “electro-blowing” system. In the electro-blowing apparatus, the hyaluronan solution was heated to reduce viscosity and surface tension, and was electrospun by both electrical (voltage) and mechanical (air blow) force. Lastly, air-blowing significantly improved solvent evaporation and fiber stretch, and the electro-blowing system produced hyaluronan nanofibers with a fiber diameter ranging from 49 to 74 nm.

### 3.3.2.2 Synthetic Polymeric Nanofibrous Scaffolds

**Poly( $\alpha$ -hydroxy esters)** The most commonly used biopolymers for nanofiber production are of the biodegradable poly( $\alpha$ -hydroxy ester) based polymer family. PLA, PGA, their co-polymers, poly(lactic-co-glycolic acid) (PLGA), and poly( $\epsilon$ -caprolactone) (PCL) are biodegradable polymers approved by the U.S. Food and Drug Administration, with a long history in medical applications. *In vivo*, complete degradation of poly( $\alpha$ -hydroxy esters) results in the production of natural metabolites, such as lactic acid, which are subsequently converted into CO<sub>2</sub> and water, and eventually removed by the respiratory and urinary systems, respectively [128]. Thus, poly( $\alpha$ -hydroxy esters) are metabolized into non-toxic end-products that are not accumulated in the body.

PGA is a polymer of glycolic acid and has been extensively used in various biomaterial applications. Due to its high crystallinity, it is insoluble in general organic solvents, with highly fluorinated solvents being the only exception. Consistent with the trend found in other polymers, the PGA fiber diameter, ranging from 110 nm to 1.19  $\mu$ m, increases with polymer concentrations from 0.05 to 14.3 wt.%. PGA polymer in a higher concentration solution encounters stronger molecular entanglement, resulting in thicker fibers during the electrospinning [129, 130].

PLA, with the addition of a methyl group, is more hydrophobic and more soluble in organic solvents, and degrades more slowly than PGA [131]. The three stereoisomers of PLA [D, L, and D,L] differ in the position of a methyl group in the lactic acid monomer, and exhibit distinct properties. For example, PLLA has a higher melting temperature than PDLLA because of its higher order crystal structure. However, PDLLA, composed of l and d stereoisomers, degrades faster than PLLA. The properties of various PLA polymers are determined by the stereochemistry of the PLA isomers. PLLA is a semicrystalline polymer, whereas PDLLA is an

amorphous polymer. During the preparation process, both PLLA and PDLLA are soluble in most organic solvents, such as chloroform. Commonly, DMF is added to increase the polymer conductivity, enhancing the fiber formation. Electrospun PDLLA and PLLA fibers share similar morphology, fiber density ( $0.27\text{--}0.31\text{ g cm}^{-3}$ ), and porosity (75–78%) [132]. However, the average diameter of semicrystalline PLLA fibers is larger than that of amorphous PDLLA fibers when both polymers are used at the same concentration, suggesting that a stronger polymer molecular entanglement exists in PLLA fibers.

PLGA is a widely used biodegradable polymer because of its flexibility of copolymerizing different ratios of PLA and PGA. Depending on the ratio of copolymerization, PLGA has different subtypes with each exhibiting different properties. PLGA has been extensively used in medical products and was one of the first biodegradable polymers electrospun for tissue engineering applications [133]. The PLGA copolymer has an amorphous structure, because the constituent PGA and PLA molecules are unable to pack tightly to one another. Katti et al. and Berkland et al. have both used PLGA for electrospinning to investigate the parameters affecting fiber morphology [134, 135]. Their results showed that, in addition to polymer concentration and charge density, orifice diameter also has an effect on the morphology and diameter of electrospun fibers. Smaller nanofibers tend to be produced from smaller orifices. The area density of electrospun fiber mats increases linearly with electrospinning time. Among the working parameters, polymer concentration is the major parameter affecting fiber morphology. Li et al. have shown that nanofibrous PLGA scaffolds have an interconnected-porous structure with more than 90% porosity and sound mechanical properties, ideal properties for tissue engineered scaffolds [25].

Another member of the poly( $\alpha$ -hydroxy ester) family is poly( $\epsilon$ -caprolactone) (PCL), also a semicrystalline biodegradable polymer. Compared to other polyester family members such as PLA, PGA, and PLGA, PCL has been used less frequently as a material for fabricating biomaterial scaffolds, mainly because of concern over its slower degradation kinetics [136]. However, the improved resistance to hydrolytic attack and lower cost than other biodegradable polymers also make PCL an attractive polymer for the fabrication of electrospun nanofibers [53, 77, 99, 100, 137–146]. The rationale for using a biodegradable polymer with a longer half-life is to provide a structurally stable environment that is able to initiate and promote cell growth for a sufficient period of time. Lee et al. characterized the morphology, crystallinity, and mechanical properties of electrospun PCL meshes produced by electrospinning PCL solutions prepared in different solvents; they found that surface tension, viscosity, and electric conductivity of PCL solutions depended on the addition of DMF [53]. DMF can efficiently enhance the electrospinning process by decreasing fiber diameter by decreasing the surface tension and viscosity of the polymeric solution, and also by increasing polymer conductivity and the dielectric constant. It is also known that the electrospinning process reorganizes PCL polymer chains and, compared with unprocessed PCL, electrospun nanofibers have a reduced crystallinity.

Although poly( $\alpha$ -hydroxy ester) members are classified in the same polymer fam-

ily, electrospun scaffolds derived from these polymers exhibit distinct degradation and mechanical properties [25, 129, 132, 147]. Studies comparing the degradation of electrospun nanofibers of various poly( $\alpha$ -hydroxy esters) have shown that PLLA and PCL fibers were able to resist hydrolytic attack for the duration of the study. However, all of the remaining polymers underwent severe degradation, including both structural collapse and gross shrinkage. A similar study conducted by Zong et al. demonstrated that PLGA 75:25 and PDLLA degrades at a much faster rate than PLGA 10:90 and PLLA [132]. One of the reasons for this more rapid degradation could be the high surface area of nanofibrous scaffolds, thereby allowing more water contact at the polymer surface, accounting for the vulnerability of small fibers, like nanofibers, to hydrolytic attack. Zong et al. also proposed that the electrospinning process lowers the glass transition temperature of PLGA copolymers to a value very close to their incubation temperature (37 °C); the relaxation of extended amorphous chains near the glass transition temperature thus causes shrinkage under incubation condition. Given the rapid degradation of some nanofiber formulations, many research groups have focused their efforts on electrospinning PLLA or PCL alone, or copolymerized with other biodegradable polymers, to fabricate polymer scaffolds with more desirable, long term stability.

**Poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV)** PHBV is a member of the polyester family, and represents a new class of biodegradable polymers, recently attracting attention for tissue engineering applications. The co-polymerization with hydroxyvalerate renders PHBV with enhanced mechanical and degradation properties, thus extending the application to scaffold fabrication. Choi et al. investigated the feasibility of PHBV electrospinning and attempt to reduce fiber diameter by increasing the conductivity of the polymeric solution [54]. PHBV fibers electrospun from various concentrations of polymeric solutions range from 1 to 4  $\mu\text{m}$ . However, efforts to manipulate electrospinning parameters such as voltage and concentration were not effective in bringing the fiber diameter below 1  $\mu\text{m}$ . To increase the conductivity of the polymeric solution, favorable for smaller fiber formation, benzyl triethylammonium chloride (BTEAC) was added to the PHBV solution. The addition of BTEAC resulted in a reduction of the size of the electrospun fibers and the needed polymer concentration for producing uniform fibers, suggesting the conductivity of the PHBV solution plays a major role affecting the fiber diameter and morphology of PHBV fibers. In addition, the degradation of the electrospun fibrous mat is relatively slow in the first 12 days, but the disintegration of the structure accelerates after that, and results in a dramatic weight loss.

**Poly(ethylene-co-vinyl alcohol) (PEVA)** PEVA is a semi-crystalline, biocompatible but not biodegradable polymer. Recently, it has been electrospun and evaluated for its potential in tissue engineering scaffolds. PEVA is a hydrophilic polymer that is insoluble in aqueous solution due to the presence of both vinyl alcohol and ethylene groups. Most hydrophobic polymers have the property of slow degradation, whereas most hydrophilic polymers exhibit a rapid degradation rate. The de-

sired property makes PEVA a potential material ideal for tissue engineering scaffolds. PEVA needs to be dissolved in dimethyl sulfoxide or lower alcohols. Kenawy et al. have prepared the PEVA solution by dissolving PEVA in a 70% alcohol solution (rubbing alcohol) at 65 °C for electrospinning [148]. Interestingly, the polymer tends to precipitate when sitting in room temperature for several hours. Therefore, electrospun PEVA needs to be processed before precipitation occurs, and is carried out in a setup designed to maintain the solution temperature. This study also demonstrated a consistent finding of fiber diameter increasing with increase in solution viscosity. The diameter of fibers electrospun from higher concentrations of polymer solutions is higher than the  $\mu\text{m}$  level. In these structures, fibers are fused at their contact points, instead of being individually stacked, suggesting that strong molecular entanglement exists in the highly concentrated PEVA polymer solution. Another remarkable observation is that PEVA electrospinning is extremely efficient. The usage of PEVA, disinfected by dissolving in rubbing alcohol, combined with the efficiency of the PEVA electrospinning, could be ideal for wound dressing application.

**Poly(ethylene terephthalate) (PET)** PET, referred to also by the trade name “Dacron”, has largely been used in biomaterial applications, especially in blood vessel prostheses, since PET is inert and does not interact with blood cells. Ma et al. investigated how electrospinning time affects the thickness and porosity of electrospun PET scaffolds [98]. The electrospun PET nanofibers fabricated using optimal parameters ranged from 200 to 600 nm. The thickness, mass per area, and porosity of the PET fiber mats all increase with increasing electrospinning time. However, there is no linear relation between these factors. A likely explanation is that not all the as-spun nanofibers were collected onto the sampling area, because, in their setup, there was uneven fiber deposition onto the fiber-collecting surface.

**Polyurethane (PU)** PU is a non-biodegradable biomaterial with good blood and tissue compatibility, which is primarily used in vascular implants or wound dressing. PU is ideal for applications for tissue engineering products that require stable mechanical properties or structural integrity. Unlike most studies in which the polymer concentration was manipulated to control fiber morphology, Khil et al. have optimized fiber morphology by controlling solvent composition [149]. They electrospun a PU solution, prepared from pure DMF or tetrahydrofuran (THF) or mixed solvents with different DMF/THF ratios, and found that the mixed solvent produced more uniform, small fibers. Electrospun fibers prepared from pure DMF were smaller and irregular, whereas those from pure THF were relatively larger and uniform. Solvents could loosen the polymer coil, thereby affecting the viscosity of a polymer solution. In this study, the different solvent compositions loosened the polymer coil to various extents, resulting in different viscosities. The mixed solvent reduced the surface tension and viscosity of PU solution, and the addition of DMF increased the conductivity of the solution, which together contributed to the formation of uniform fibers.

**Poly(ethylene oxide) (PEO)** PEO is a commonly used biomaterial for tissue engineering because of its capability to gel *in situ*. A PEO gel can be directly injected into an irregularly shaped defect site and photopolymerized to help tissue repair [150, 151]. However, the inherent, soft mechanical properties of the PEO hydrogel and the depth limit of the injection site that permits sufficient energy present a major challenge for using PEO hydrogel. Preformed PEO scaffolds with a defined porous structure is another scaffold option. PEO is one of the earliest polymers processed for electrospinning because it is easy to prepare and can be dissolved in both organic and aqueous solvents. Much of the current knowledge on the electrospinning process is in fact based on results using PEO. Because of the ease of forming uniform nanofibers, PEO, is often blended with another polymer in the electrospinning of tissue engineering scaffolds [106, 152, 153].

### 3.3.2.3 Composite Polymeric Nanofibrous Scaffolds

Current scaffold development aims to incorporate many polymer types for the fabrication of biomaterial scaffolds that are able to respond to the biological activities of cells while meeting specific host tissue site requirements. Regardless of whether a double, triple, even quadruple polymer blend/mix is used, a tissue engineering scaffold made of a polymer blend should still retain the properties of each polymer type. Therefore, it is expected that electrospinning of a polymer blend/mix will create novel composite scaffolds with enhanced performance for tissue engineering. Another practical reason for electrospinning a blend of polymers is that often the polymer of interest cannot be electrospun into uniform fibers without the addition of the “electrospinning-driving” polymer. Regardless of the goal, the challenge of electrospinning a polymer blend is to optimize the standard electrospinning parameters, which are further complicated by the interplay of the properties of multiple polymers. Hence, a sound understanding of polymer and solvent chemistry is important in identifying favorable electrospinning parameters. Three general composite nanofibrous scaffolds, natural–natural, synthetic–synthetic, and natural–synthetic, have been developed and characterized for their properties and potential applications.

**Natural–Natural Composites** Electrospinning of multiple natural polymer blends can yield a mixture of natural nanofibers that closely mimic the native ECM. A large percentage of native tissues contains both collagen and elastin fibers that are frequently subjected to tensile and elastic loading, respectively. Electrospun fibrous scaffolds composed of collagen types I and III, and elastin have been fabricated to replicate the native ECM of blood vessels [94]. The fiber diameter found within the native ECM of blood vessels ranges from 270 to 710 nm, which is slightly larger than the 100 to 680 nm diameter range of nanofibers electrospun from blends of collagen types I and III. Aside from protein–protein mixtures, the protein-based silk and carbohydrate-based chitosan blend has been electrospun into nanofibers as well. In the silk fibroin/chitosan blend for electrospinning, the addition of chitosan increases the viscosity and conductivity of the blend solution, thus enhancing the formation of smaller, uniform nanofibers [111]. One possible explanation for

this phenomenon is that chitosan carries ionizable, amino groups, and increases the conductivity of the silk fibroin, which is ideal for electrospinning. Nevertheless, the formation of uniform nanofibers discontinues after excessive chitosan is added. Silk fibroin and chitosan in the blend solution may form hydrogen bonds, suggesting that optimizing the electrospinning of a blend natural polymer is more complicated than for pure natural polymers. It is reasonable to expect that the nanofiber mat is composed of individual, blended nanofibers rather than a mixture of different mono-polymer nanofibers.

**Synthetic–Synthetic Composites** The synthetic–synthetic blend is commonly used to fabricate scaffolds with the combined properties of composite polymers. Polymers, such as PLA and PCL, are biodegradable, biocompatible, and hydrophobic whereas poly(ethylene glycol) (PEG) is hydrophilic, non-immunogenic, and non-biodegradable. In mixing PLA and PEG, the resultant PLA/PEG blend is more hydrophilic than PLA and also more biodegradable than PEG. In addition, the co-existing properties of hydrophilicity and biodegradability can be programmed by manipulating the ratio and the type of composed polymers. For instance, PLGA nanofibrous scaffolds shrink during degradation; thus, by blending of PLGA and PEG-PLA one can effectively resist scaffold shrinkage [154]. In addition to improvements in biodegradation, the polymer blend has been shown to exhibit flexible mechanical properties that can be altered by the ratio of composed polymers. For example, the elastic PEVA nanofibrous mat becomes stiffer after PLA is added for blend electrospinning [155].

**Natural–Synthetic Composites** The mixing of natural and synthetic polymers can be a major challenge for electrospinning since solvents workable for both polymers are limited. Therefore, the choice of solvent becomes a primary consideration after determining the blend components. Many natural polymers are difficult to electrospin into nanofibers, especially when dissolved in water, since their polyelectrolyte characteristic interferes with fiber formation. One alternative is to add synthetic polymers such as PEO to facilitate nanofiber formation. The natural polymer/PEO blend in aqueous solution can be electrospun, and the use of organic solvents may be avoided. Duan et al. have systematically characterized the properties of chitosan/PEO blend solutions and their electrospun fibers [153]. They concluded that the chitosan/PEO blend retains conductivity, surface tension, and viscosity, and favors the formation of smaller, uniform nanofibers, compared with pure chitosan or PEO solutions.

Another completely different blending approach is to physically, rather than chemically, mix two polymer nanofibers together using multiple jet electrospinning. In this approach, natural and synthetic polymers are placed in two separate containers and electrospun simultaneously to form a natural/synthetic nanofibrous composite. For example, poly(vinyl alcohol) (PVA) and cellulose acetate (CA) are electrospun onto the same target area [156]. With this method, PVA and CA nanofibers disperse into each other as a direct result of physical blending. When the PVA/CA ratio of the blend is reduced, mechanical properties, such as tensile

strength and fiber elongation, are decreased, but the average fiber diameter increases. Further investigations are needed to assess whether the mechanical property changes are due to polymer composition, fiber size, or a combination of the two.

#### 3.3.2.4 **Nanofibrous Scaffolds Coated with Bioactive Molecules**

A natural ECM scaffold contains bioactive peptides, such as RGD sequences, but is often mechanically too weak or rapidly degraded for tissue engineering applications. Conversely, a synthetic polymeric scaffold has tailorable properties to meet the physical requirements, but lacks the native biocompatibility. There is, therefore, a need to develop methodologies to incorporate and optimize bioactive motifs, such as the RGD peptide, for the synthesis of biocompatible polymeric scaffolds that possess the advantages of both natural and synthetic polymers. Unlike natural–synthetic composite nanofibrous scaffolds fabricated from electrospinning a blend polymer, nanofibrous scaffolds coated with bioactive molecules are produced by coating natural polymers to the surface of synthetic nanofibrous scaffolds. This after-work addition can avoid alteration of the properties of the natural polymer during the electrospinning. The most commonly used approaches for the incorporation of bioactive agents on a polymeric surface include simple coating and covalent linking. The simple coating process is easy and fast but the coated agents detach shortly, depending on the coating surface properties, whereas the covalent linking process is more laborious but the coating should be more stable.

Collagen coated electrospun scaffolds have been developed by simply placing nanofibrous scaffolds in a collagen solution. The simple coating works for most synthetic polymers, but the efficiency and effectiveness of the coating are dependent on polymer surface properties such as charge, chemistry and geometry. Collagen type I has been coated on PCL [142] and P(LLA-CL) [157] electrospun nanofibrous scaffolds, which are used for culturing different cells for various tissue engineering applications. Although there is no direct measurement to evaluate the efficiency of the collagen coating on the scaffolds, cell response, i.e., the promotion of specific biological activities, indirectly demonstrates the presence of collagen coating on electrospun fibrous scaffolds.

Electrospun nanofibrous scaffolds made of either hydrophobic or hydrophilic synthetic polymers are usually inert and lack functional groups for direct covalent linkage of bioactive peptides or domains. To create functional groups for the covalent bonding, surface processing techniques, such as acid/base treatment, chemical activation, and oxidization, are used. For instance, studies have reported on the modification of PET nanofiber surfaces by gelatin grafting [98]. The process starts with the creation of hydroxyl groups on PET nanofibers using formaldehyde, grafts with methacrylic acid, and covalent linkage of gelatin using carbodiimide. The results show that more gelatin is grafted to PET nanofibers than to the film counterpart, and the grafting occurs throughout the entire scaffold surface. In addition, gelatin grafting significantly increases the hydrophilicity of the PET surface, suggesting that covalently grafting bioactive proteins or peptides to a nanofibrous scaffold is an effective approach for the modification of the hydrophobic properties of the scaffold.

### 3.3.3

## Engineered Tissues using Electrospun Nanofibrous Scaffolds

### 3.3.3.1 Skin

Skin is the largest tissue covering the body and provides physical and chemical protection of the body from harmful sources such as heat and microbial organisms. The top layer is the epidermis containing melanocytes and the dermis lies directly underneath the epidermis.

In the body, cells and tissue matrices interact via complex chemical and physical processes. Due to the sophisticated architecture of the skin with its various layers, it is difficult for current synthetic 3D matrices to simulate such processes. Therefore, electrospinning has been used to spin natural and synthetic polymers to fabricate biomaterial scaffolds that more closely mimic the tissue matrix of skin. In a study by Venugopal et al., PCL, collagen type I, and collagen type I-coated PCL nanofibers were electrospun to fabricate a substitute for skin regeneration [144]. In this study, fibroblasts from normal human skin attached and spread on all three nanofiber matrices; however, the interaction between cells and nanofiber matrices varied with the scaffold material. For instance, collagen nanofiber matrices showed a significantly higher level of fibroblast proliferation than control monolayer culture. Conversely, PCL fibers showed a significantly lower level of cellular proliferation than control monolayer culture. The results of this study also showed normal morphology and confluence of cells on control monolayer culture and collagen nanofibers. However, while PCL nanofibers were able to support cell growth, they showed no confluence compared with collagen coated PCL nanofibers. As a result, this study proved that PCL fibers are able to partially support the growth of skin fibroblasts, while the presence of collagen on the scaffolds greatly enhances the interactions between cells and nanofibers. The advantage of using a collagen coated PCL composite nanofibrous scaffold is to incorporate the biological and mechanical properties of each polymer, with collagen type I providing a favorable milieu for skin fibroblasts and biodegradable PCL improving the mechanical integrity of the matrix. Therefore, electrospun 3D nanometer sized fibers provide a potential scaffold for skin regeneration. Min et al. electrospun silk fibroin into nanofibers and then coated the fibers with collagen type I, fibronectin, and laminin to evaluate cell response to different ECM coatings on silk fibroin nanofibers [109]. In addition, they also used different cell types, human oral and epithelial keratinocytes and gingival fibroblasts, to measure cell attachment and spreading on the nanofibers. In terms of the effect of various ECM coatings, collagen type I coated nanofibers were shown to more actively promote attachment of keratinocytes, compared with laminin or fibronectin coated nanofibers, and, interestingly, even to a polystyrene surface. Cells adhered to and spread on the surface of silk fibroin nanofibers, and then started to migrate along the fibers, forming a 3D cellular network well integrating with nanofibers. The similar cellular response in a nanofiber scaffold is also demonstrated in the previous study using fibroblasts in PLGA nanofibers [25]. Beside the attempt of using silk fibroin nanofibers as scaffolds for skin regeneration, chitin/PLGA nanofibrous scaffolds cultured with keratinocytes

and fibroblasts have also shown great promise in skin tissue engineering since chitin has proved to have good wound healing properties [158]. The chitin/PLGA nanofibrous scaffolds, taking advantages of the desired properties of chitin and PLGA for tissue engineered scaffolds, exhibit improved hydrophilicity and sound mechanical properties. Cells attach better in the chitin/PLGA than the PLGA-only nanofibrous scaffolds. In the preliminary cell study, the same cell types used in the silk fibroin scaffolds show a similar trend of cell attachment and spreading in various ECM coated chitin/PLGA nanofibrous scaffolds. Collagen type I coated chitin/PLGA nanofibrous scaffolds enhances cell attachment and spreading in the scaffolds, which is critical for cellular activities in skin regeneration using the tissue engineering approach.

#### 3.3.3.2 Blood Vessel

Blood vessels are a part of the circulation system, and function as a channel to transport oxygen and nutrient to the body tissues or remove metabolic waste for replenishment. There are three types of blood vessels found in the body: arteries, veins, and capillaries. Each of them has a different structure and various functions. Vascular related disorders are one of the leading fatal diseases around the world, and one of the current treatments is the use of vascular grafts in bypass surgeries. In terms of material types, grafts are either biological (autograft, allograft, and xenograft) or synthetic. Although there is fair success with these conventional grafts, challenges such as the availability of small vascular grafts still remain. Vascular tissue engineering is promising for creating cellular vascular grafts with desired dimensions.

The tissue engineered artery fabricated using electrospun scaffolds has been extensively investigated recently. Boland et al. have fabricated a vascular scaffold by assembling two electrospun nanofibrous tubes composed of different collagen/elastin ratios with cultured dermal fibroblasts, aortic smooth muscle cells, and umbilical vein endothelial cells in the outer, middle, and inner layers of the scaffold, respectively, to simulate the anatomical three layers of an artery [94]. After culturing in a bioreactor, the engineered artery exhibits a tri-cellular layer architecture in cross section. One of the critical requirements for tissue engineered arteries is to have satisfactory mechanical properties to bear compliance strength and burst pressure. Therefore, Stitzel et al. blended PLGA with collagen and elastin to produce an electrospun tri-polymeric fibrous scaffold, thus increasing the strength of the original collagen/elastin scaffold and rendering it mechanically comparable to a native artery [102]. Both endothelial and smooth muscle cells cultured in the scaffolds exhibit favorable cell attachment and growth. Further *in vivo* testing found no signs of toxicity. In addition to studies that focus on the design of a tissue engineered vascular graft, several studies have reported the effects of surface roughness and fiber orientation on the cellular activities of vascular cells [159, 160]. Xu et al. have demonstrated that endothelial cells cultured on electrospun fibrous scaffolds exhibit less-spread cell morphology, compared with those on smooth surfaces [159]. An increase in cell attachment and proliferation was also observed on the smooth surface culture. Another study has shown that smooth

muscle cells exhibit a spindle-like contractile phenotype, while cytoskeletal proteins, such as  $\alpha$ -actin and myosin filaments, are oriented along the direction of aligned nanofibers [160]. Fiber alignment using electrospinning supports the construction of a tissue engineered vascular graft that contains a middle, smooth muscle layer that mimics the circumferentially oriented nature.

### 3.3.3.3 Cartilage

Adult cartilage is formed mainly at the articular joint and is a specialized tissue that consists of chondrocytes, ECM macromolecules, and water. Chondrocytes synthesize and maintain the ECM in cartilage while the ECM functions to provide structural protection to residing cells and to act as a regulatory messenger for cell activities. Cartilage tissue engineering aims to replace damaged cartilage and restore biological function. A main research focus in our laboratory is the development of cartilage tissue engineering using the electrospinning technique.

We have recently compared the biological response of chondrocytes seeded onto 3D PCL nanofibrous scaffolds to that of cells seeded as monolayers on standard tissue culture polystyrene (TCPS) [77]. Gene expression analysis (Fig. 3.5) showed that chondrocytes seeded on the nanofibrous scaffold maintained their chondrocytic phenotype by expressing cartilage-specific ECM genes, including collagen types II and IX, aggrecan, and COMP. Specifically, expression of the collagen type IIB spliced variant transcript, indicative of the mature chondrocyte phenotype, was significantly up-regulated. Chondrocytes exhibited a round shape on the nanofibrous scaffolds, in contrast to a flat, well-spread morphology seen in monolayer

**Fig. 3.5.** Reverse transcription-polymerase chain reaction (RT-PCR) analysis of expression of cartilage associated genes in fetal bovine chondrocytes seeded onto tissue culture polystyrene (TCPS) or PCL nanofibrous scaffolds. On culture days 0, 7, 14, and 21 total RNA was extracted and RT-PCR performed with gene-specific primer pairs, including collagen type II (Col II), collagen IX (Col IX), aggrecan (AGN), cartilage oligomeric matrix protein

(COMP), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as a house keeping gene. Cells cultured on nanofibrous scaffolds showed strong induction of mRNA expression of collagen types II and IX, aggrecan, and COMP after 21 days. More importantly, the alternatively spliced mRNA variant of collagen type II, the IIB(\*), was expressed only in the nanofibrous scaffold cultures.

**Fig. 3.6.** Histological analysis of MSC cultures seeded into a PCL nanofibrous scaffold and maintained in a chondrogenic medium supplemented with TGF- $\beta$ 1 for 21 days. Sections from the upper and lower portions of the 3D constructs were stained with hematoxylin and eosin (H&E) (A, B) and Alcian blue (C, D). H&E staining showed flat fibroblast-like cells on the top zone (\*), round chondrocyte-like cells embedded in lacunae (arrows) in the middle zone (\*\*), and small, flat cells at the bottom zone (\*\*\*). Alcian blue staining showed the presence of sulfated proteoglycan-rich ECM in the construct. Bar = 10  $\mu$ m.

cultures on TCPS. Histologically, nanofibrous cultures produced more sulfated proteoglycan-rich, cartilaginous matrix than monolayer cultures. These results indicate that the biological activities of chondrocytes are crucially dependent on the dimensionality of the extracellular scaffolds, and that nanofibrous PCL may be a biologically preferred scaffold/substrate for proliferation and phenotype maintenance of chondrocytes.

In another study [140], we specifically compare the chondrogenic activities of MSC–nanofiber cultures to those of high-density cell pellet cultures, a commonly used culture system for studying chondrogenesis of MSCs *in vitro*. MSCs cultured in nanofibrous scaffolds in the presence of TGF- $\beta$ 1 differentiate into a chondrocytic phenotype, as evidenced by chondrocyte-specific gene expression and the synthesis of cartilage-associated ECM proteins. The level of chondrogenesis observed in MSCs seeded within nanofibrous scaffolds is comparable to that observed for MSCs maintained as cell aggregates or pellets. The 3D MSC-seeded constructs display a cartilage-like morphology, containing chondrocyte-like cells surrounded by abundant cartilaginous matrix (Fig. 3.6). Due to the physical nature and improved mechanical properties of nanofibrous scaffolds, particularly in comparison to cell pellets, these findings suggest that the nanofibrous scaffold is a practical carrier for MSC transplantation, and represents a candidate scaffold for cell-based tissue engineering approaches to cartilage repair.

#### 3.3.3.4 Bone

Bone is a hard, solid connective tissue that provides structure and protection to the body. To support external loading and absorb shocks, bone has a unique structure

and chemical composition. The bone structure is composed of two layers of different density of bones. The outer layer is compact bone and the inner layer being spongy bone. Bone is always undergoing dynamic remodeling carried out by two different cell types, the osteoblast for building bone and the osteoclast for digesting bone. In addition, the bone marrow contains numerous MSCs that are capable of differentiating into various connective tissue cells to replenish them.

Cells used in bone tissue engineering include osteoblasts, osteoprogenitor cells, and MSCs. Each of these cell types, depending on their nature, requires a different culture environment. MSCs are a highly promising cell source for tissue engineering applications because of their multi-differentiation capabilities and their expandability [81]. Applications of MSCs for bone tissue engineering requires that the cells are seeded within electrospun nanofibrous scaffolds that will permit and/or promote osteogenic differentiation. Yoshimoto et al. and Shin et al. have reported on the osteogenic differentiation of MSCs in PCL nanofibrous scaffolds cultured *in vitro* and *in vivo* [137, 138]. In their study, MSCs from rat bone marrow seeded in PCL nanofibrous scaffolds are cultured in a rotatory oxygen-permeable bioreactor with the osteogenic medium. This environment promotes MSCs to differentiate into osteoblast-like cells producing collagen type I and minerals in the scaffold. In addition, the bioreactor improves oxygen and nutrients diffusion, enhancing cell growth in the nanofibrous scaffold. Initial osteogenic differentiation of MSCs is carried out in the *in vitro* model. Further assessment of bone formation included implanting the MSC loaded nanofibrous scaffold pre-induced and -cultured in a bioreactor in a rat model. The new osteo-matrix is deposited throughout the entire harvested cellular constructs, resulting in a white, smooth appearance and stiffer properties. The preliminary results of new bone formation using MSC–nanofiber constructs are encouraging. To actively induce bone formation, osteoconductive calcium carbonate has been coelectrospun with PCL nanofiber to fabricate a nanofibrous composite scaffold. The addition of calcium carbonate increases the mineralization in the cellular constructs, an early sign of bone formation. The composite scaffold combining the osteogenic promotion of nanofibers and the osteoconductivity of calcium carbonate is also suggested for guided bone regeneration therapy to repair jaw and alveolar bone defects.

#### 3.3.3.5 Muscle

Muscles make up most of the body and account for almost half of body weight. Skeletal muscle covering the skeleton functions to move the body, cardiac muscle making up the heart contracts in a rhythmic movement, and smooth muscle forming internal organs perform the unconscious actions. The three types of muscles are composed of different kinds of cells and ECM protein compositions.

Skeletal muscle tissue is composed of bundles of highly oriented and dense muscle fibers, each representing a multinucleated cell derived from myoblasts. Therefore, the engineering of skeletal muscle tissue necessitates the use of a bio-material scaffold that will allow cells to align parallel to one another. Electrospinning, as previously illustrated, provides a technique that not only can generate nanoscale non-woven fibers, but this technique also offers the versatility of align-

ing fibers to yield an ideal scaffold architecture for skeletal muscle tissue engineering. In a study by Riboldi et al., DegraPol®, a degradable block polyesterurethane, was electrospun to fabricate a biomaterial scaffold to engineer skeletal muscle tissue using mouse C2C12 muscle progenitor cells [161]. Preliminary experiments in this study found C2C12 line cells to be compatible with the electrospun scaffold by adhering, proliferating, and differentiation into myotubes on the electrospun scaffolds [161]. More specifically, the authors showed that after 3 days of culture of C2C12 cells in differentiation medium there was formed elongated, multinucleated, myosin heavy chain expressing myotubes that preferentially aligned with the direction of the scaffold fibers. C2C12 cells were also viable on the electrospun scaffold up to 7 days of culture. By aligning myofibers to one another, scaffolds may be engineered with the ability to generate sufficient force for contraction of differentiated C2C12 cells. While the tendency of utilizing microfibrinous polymeric scaffolds has yielded promising results in driving myofibers development and orientation along the scaffold, the high tensile modulus and low-yield elongation of these microfibrinous polymeric scaffolds is inadequate to withstand the mechanical stimulation needed for dynamic culturing methods needed for skeletal muscle tissue engineering [161–163].

A critical factor for successful regeneration of myocardium in a tissue engineered scaffold is that the scaffold structure should be flexible for cardiomyocyte contraction, sustain a reasonable tension for cell morphology maintenance, and have a good integrity for handling. To fulfill this purpose, Shin et al. have cultured primary cardiomyocytes from rat ventricles on PCL nanofiber suspended wire rings [139]. Interestingly, unlike a rigid scaffold, the flexibility of the nanofibrous network applies limited restriction on cell contraction. The cardiomyocytes on the nanofibers start the ubiquitous and synchronized contraction after 3 days of culture. In addition, cells within the scaffold exhibit spindle, multi-angular muscle-cell-like morphology, and also express cardiac-specific markers such as tropomyosin and connexin43. The wire ring applies a tensile force on the suspended nanofibers, which may be transferred to stretch cells, which is critical for the maturation of the cardiomyocyte. In another study, rat cardiac fibroblasts are cultured in acid-treated PGA scaffolds to evaluate the proliferation of cells cultured in PGA scaffolds with different fiber sizes and surface chemistry [130]. Cells proliferate significantly more rapidly in acid treated, smaller nanofibers, suggesting that the acid treated surface exposes more carboxylic and hydroxylic groups that favorably attract cell attachment molecules, such as fibronectins and vitronectins, to enhance cell attachment; thus more cells can grow on a bigger surface area in a scaffold with smaller fibers.

Functional tissue engineered smooth muscle is essential for the development of complex tissue engineered organs. Flexible, anisotropic properties of smooth muscle provide internal organs the capability of constant movement and the expansion for additional content storage. Electrospinning has been applied to microintegrate smooth muscle cells into nanofibrous scaffolds to fabricate a cell–nanofiber composite [44]. The mechanical properties of the composite are in an adequate range to meet the requirements for soft tissue application. After culturing in a perfusion

bioreactor, the cellular composite exhibits a high density of smooth muscle cells in a uniform distribution. The smooth muscle is successfully engineered by the microintegration process based on the electrospinning, which can be adopted to tissue engineer other tissues as well.

#### 3.3.3.6 Ligament

The ability of electrospun nanofibrous scaffolds to mimic the architectural scale of the native ECM provides them with great potential for the engineering of ligaments. The ligament is a tough fibrous band of slightly elastic connective tissue that provides stability to skeletal joints. The specialized cells that make up ligaments are called fibroblasts. The matrix of ligaments is made up of collagen fibrils with a diameter of  $\sim 60$  nm; therefore, nanofibrous scaffolds should provide ligament fibroblasts with a structure that closely mimics the native matrix [164]. A study investigating the effects of fiber alignment on the ECM generation of human ligament fibroblasts (HLF) on PU electrospun nanofibers showed that cells cultured on aligned nanofibers were spindle-shaped and oriented in the nanofiber direction, while cells on non-aligned nanofibers had no directionality [164]. After 7 days of culture, HLF cells on aligned nanofibers showed a significant change in their ECM with increase collagen synthesis compared with non-aligned fibers, although cell proliferation was not affected by fiber directionality [164]. A significant increase in cell attachment and proliferation on nanofiber scaffolds was also observed, as compared with cast PU membranes. Therefore, this study demonstrates that the biomimetic nature of aligned electrospun nanofibers provides an architectural environment similar to that which ligament fibroblasts normally encounter *in vivo*.

#### 3.3.3.7 Nerve

Unlike other parts of the body, the central nervous system (CNS) cannot generate new neurons or regenerate damaged nerves itself. Cell-based tissue engineering strategies using multipotential cells have been investigated as a therapy for specific neurologic disorders (i.e., paralysis of extremities). Due to the complexity of the architectural organization of the CNS, polymeric scaffolds should provide a suitable 3D carrier for cell delivery. Electrospinning presents a sophisticated technique to fabricate an ECM-like matrix. Recent studies have investigated the potential of electrospun 3D scaffolds, both aligned and non-aligned, in neural tissue engineering using a multipotent neural stem cell (NSC) line, C17-2, derived from a neonatal mouse cerebellum [76, 165]. Yang et al. have investigated the morphology and cell adhesion response of NSC to PLLA non-aligned nanofibrous scaffolds [165]. Phase-contrast microscopy revealed that C17-2 cells seeded on the scaffolds adhered to the scaffolds and started to differentiate on the fibrous scaffold 10 h after seeding, and by 24 h around 70% of cells exhibited a spindle-like shape with extended processes. An additional study by Yang et al. compared the response of C17-2 cells to aligned versus non-aligned electrospun PLLA nanofibers [76], and reported that after 2 days of culture significant changes in the phenotype of cells based on directionality had occurred.

Successful nerve regeneration is dependent upon extensive growth of axonal processes. The study by Yang et al. found no significant effect of fiber alignment when comparing aligned (1.5  $\mu\text{m}$ ) and non-aligned (1.25  $\mu\text{m}$ ) microfibrinous scaffolds. However, the directionality did have an effect when comparing aligned (300 nm) and non-aligned (250 nm) nanofibrous scaffolds. The results indicate that the presence or absence of a directionality effect is dependent on architectural scale. The average neurite length of C17-2 cells on aligned nanofibrous scaffolds was calculated as 100  $\mu\text{m}$  and 75–80  $\mu\text{m}$  on aligned and non-aligned microfibrinous scaffolds, respectively. These results show a significant relationship of a decrease in fiber diameter increasing neurite outgrowth.

### 3.4 Current Challenges and Future Directions

To date, many different polymers have been successfully electrospun and characterized for numerous intended applications. However, limited progress has been made on fabricating tissues using nanofibrous scaffolds. Unlike nanofiber applications in composites and electronics, tissue engineering applications of nanofibrous polymeric scaffolds still require further extensive biological analyses in addition to physical characterization to determine if they are suitable for the promotion of tissue growth. Recent studies have focused on the introduction of different new polymers for electrospinning, as well as testing and characterizing the physical properties of electrospun nanofibrous polymeric scaffolds, with less emphasis on biological evaluation. To move to the next developmental phase of nanofibrous scaffold-based tissue engineering, cellular and molecular analyses are necessary to understand the interaction between nanofibers and cells. A better understanding of cell–nanofiber interactions, based on the structural and functional similarity between nanofibers and native ECM, is critical to successful tissue engineering.

Functional nanofibrous scaffolds providing structural and mechanical support for tissue growth as well as actively inducing favorable biological activities should be the future aim of research on electrospun nanofibrous scaffolds. Peptide domains, such as RGD on ECM molecules, bind to cell surface receptors, activating cellular signaling pathways to elicit cellular response. Therefore, to promote cellular activities, efforts should be devoted to developing methodologies to incorporate and optimize bioactive motifs or peptides into the electrospun nanofibrous scaffold, ultimately creating biologically active scaffolds. In addition to matrix-bound signal proteins on ECM, soluble bioactive molecules such as growth factors are important for the regulation of cellular events, including proliferation and differentiation [166]. Biodegradable polymers have long been used as drug delivery systems to deliver therapeutic agents because they can be designed to undergo programmed degradation in a controlled fashion [167]. Incorporation of growth factors, such as transforming growth factor-beta (TGF- $\beta$ ) or insulin-like growth factor (IGF), into a nanofibrous scaffold may be used as an additional strategy for the control of tissue growth. Ideally, it is desirable to fabricate nanofibrous scaffolds

that are capable of releasing, in a controlled manner, one or more growth factors to act on specific cellular functions at different times. A nanofibrous scaffold housing multiple growth factors may be produced using a selected combination of biodegradable polymers, each releasing one or more specifically adsorbed growth factors as a function of its own degradation profile. These characteristics, once optimized and taken together with the “tissue-engineering”-friendly nature of the nanofibrous scaffold, should make this a highly promising candidate scaffold system for tissue regeneration applications.

### 3.5

#### Conclusion

Electrospinning technology is a useful, economical, and easily set-up means of fabricating of 3D, highly porous, nanofibrous scaffolds that have been shown to support cellular activities and tissue formation. Conversely, tissue engineering is a revolutionary, cell-based therapy with a higher promise for clinical applications. Together, tissue engineering and regeneration with the application of electrospun polymeric nanofibers is an exciting example of the power of the rapidly emerging field of nanotechnology.

## 4 Nanofibrous Scaffolds and their Biological Effects

*Laura A. Smith, Jonathan A. Beck, and Peter X. Ma*

### 4.1 Overview

Natural extracellular matrix (ECM) contains nanofibrous structures. To develop optimal scaffolds (synthetic temporary ECMs) for tissue engineering/regeneration, researchers mimic the natural ECM to recreate fibrous structures at this size scale. These nanofibrous scaffolds may eventually provide a better environment for tissue formation. Three different approaches toward the formation of nanofibrous scaffolds have emerged: self-assembly, electrospinning and phase separation. Each of these approaches is different and has a unique set of characteristics, which lends to its development as a scaffolding system. For instance, self-assembly can generate small diameter nanofibers in the lowest end of the range of natural extracellular matrix collagen, while electrospinning has generated large diameter nanofibers, often on the upper end of the range of natural ECM collagen. Phase separation, however, has generated nanofibers in the same range as natural collagen and allows for the design of macropore structures. Utilizing these three techniques, composite scaffolds have also been formed that contain minerals and biological factors to enable the scaffolds to more effectively mimic the natural ECM's bioactivities. These nanofibrous scaffolds have been shown to promote cellular attachment, proliferation and differentiation when compared to more traditional scaffolds that do not have nanofibrous structures. Nanofibrous scaffolds have been used to engineer various tissues such as cartilage, bone, vascular, cardiac, and neural tissues. This chapter briefly reviews the three fabrication techniques for nanofibrous scaffolds and their applications in tissue engineering.

### 4.2 Introduction

Tissue engineering is an interdisciplinary field that applies the principles of engineering and the life sciences to the development of biological substitutes that restore, maintain, or improve tissue function [1]. Essentially, there are three possible

approaches to tissue engineering [1, 2]: use of isolated cells or cell substitutes to replace the cells that supply a needed function; delivery of tissue-inducing substances such as growth factors to a targeted location; and growing cells in a three-dimensional (3D) scaffold. The first two approaches may be suitable for small, well-contained defects. However, only the third, using a scaffold to direct cell growth, is suitable to engineer larger tissue blocks with predesigned shapes. As such, more tissue engineers are utilizing scaffolds in their studies of neo-tissue formation.

With this approach, biomaterials play a pivotal role [3, 4]. To properly direct cell growth and tissue formation, scaffolds should have certain vital characteristics. The scaffold should provide a suitable surface for the attachment, proliferation, and differentiation of cells and provide an appropriate 3D template to guide the tissue growth to its final shape [5, 6]. To enhance cell adhesion and subsequent tissue formation, a high surface-to-volume ratio is desirable [7, 8]. An open porous network with a suitable pore size should be contained in the scaffold to allow for uniform cell seeding and for mass transport of signaling molecules, nutrients, and removal of metabolic waste. The scaffold should also degrade at the rate of tissue formation, yet have enough mechanical strength to provide temporary support while the tissue is forming. Biocompatibility is important. Neither the scaffold nor its degradation products should be toxic to cells. Finally, because of its importance in cellular behavior with respect to morphology, cytoskeletal structure and functionality, the scaffold should allow cellular interactions similar to those in the natural extracellular matrix (ECM) [9–11]. To meet all these criteria, tissue engineering scaffolds are often designed to mimic the natural ECM until the host cells repopulate and synthesize a new matrix [12, 13].

The most abundant protein in the ECM is collagen. Over 25 distinct collagen chains have been identified, the most abundant of which is type I [14]. Type I collagen molecules are composed of three collagen polypeptide chains wound around each other to form a ropelike superhelix. Collagen molecules assemble further into higher-order polymers called collagen fibrils, which in turn are assembled into collagen fibers. The diameter of collagen fibers typically ranges from 50 to 500 nm.

Type I collagen, as a result of being the primary component of the ECM, has been used in many medical materials, particularly in soft tissue repair [15]. Type I collagen is relatively bioinert because of its helical structure and because the primary sequence of type I collagen is well-conserved across species lines [16]. Despite these advantages, the use of collagen in tissue engineering scaffolds remains questionable for the following reasons: concern of pathogen transmission, difficulties in handling, and limited control of mechanical properties, biodegradability, and batch-to-batch consistency [17]. To combat this, several synthetic tissue engineering scaffolds with nano-scale structures are being developed to mimic the ECM. The success of these scaffolds hinges on their ability to replicate the dimensional scale of living tissue in both the micro- and nanometer scale, which will aid in the maintenance of cell phenotype and provide a structurally, mechanically and biologically compatible cell–material interface [18].

As you progress through this chapter, the methods of forming nanofibrous scaf-

olds are first addressed along with modification methods to further tailor the scaffolds for biological applications. This is followed by the biological effects of nanofibrous architecture on cultured cells and the neo-tissue formation. The chapter follows the linear development of tissue engineering from scaffold to tissue formation, and provides the most up-to-date comprehensive review of the field.

### 4.3

#### Methods of Formation

Three principle methods have been employed in the fabrication of nanofibrous scaffolds for use in tissue engineering. They are self-assembly, electrospinning, and phase separation. Although very different from each other, these approaches are at the cutting edge of technology. Each method is detailed in this section.

#### 4.3.1

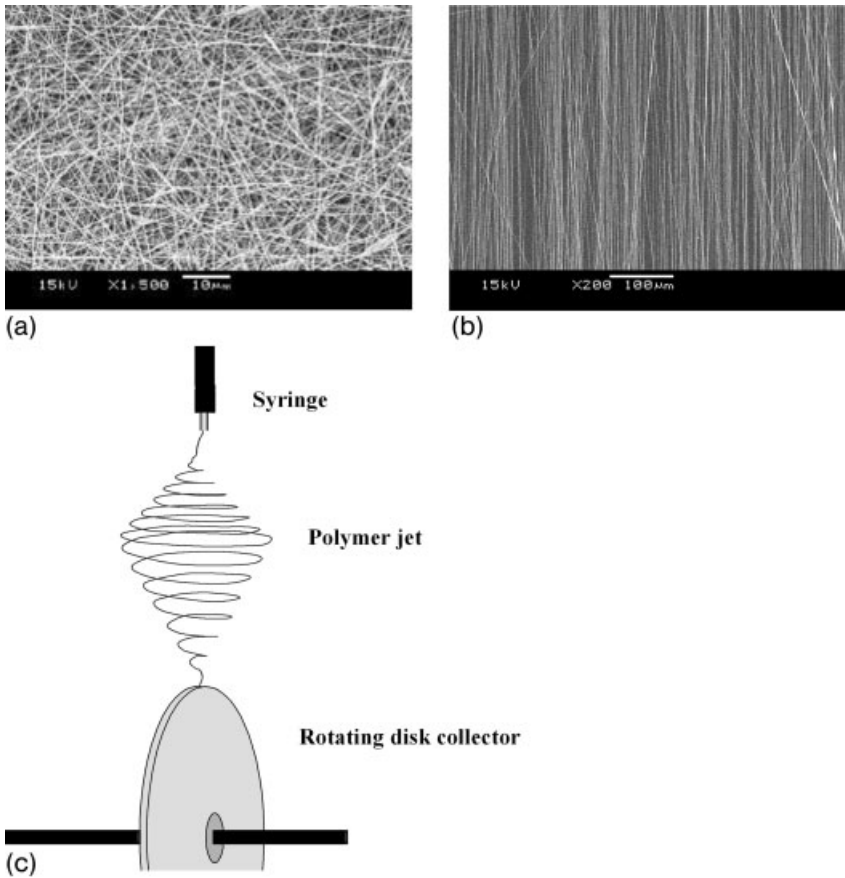

##### Electrospinning

Since it was first patented in the 1930s, electrospinning has been used in polymer-processing [19]. It is a relatively simple process in which an electric field is used to draw a polymer solution (melt) from an orifice to a collector. Application of a high voltage (typically 5–30 kV) to the tip of a needle causing the polymer to form a Taylor cone is required for electrospinning. When the electrical field strength exceeds the surface tension (surpassing a critical voltage), a fiber jet is ejected from the Taylor cone to the collector (Fig. 4.1). The solvent evaporates from the polymer solution as the jet travels through the air. This process leaves behind a randomly oriented fiber matrix on the electrically grounded target [20–23].

Electrospinning typically is used to produce thin two-dimensional (2D) non-woven sheets; however, thicker 3D meshes are possible [24]. To maintain nano-

**Fig. 4.1.** Schematic diagram of a typical electrospinning apparatus: (A) Polymer solution loaded into a syringe; (B) syringe needle; (C) polymer nanofiber jet; (D) grounded target, which can be either stationary or rotating; (E) power supply.

**Fig. 4.2.** (a) Randomly oriented nanofibers are created when a static collector is used. (b) Aligned nanofibers can be manufactured using a rotating collector. (Reprinted with permission from Ref. [25] © 2005, Elsevier.) (c) Diagram of a rotating collector. (Reprinted with permission from Ref. [27] © 2004, Elsevier.)

scale diameters throughout these meshes, a low extrusion rate must be used, leading to long fabrication times. It has been proposed that 3D meshes could more quickly be produced using multiple orifices simultaneously [24]. In this type of arrangement, the rate of mesh formation will be proportional to the number of orifices. Figure 4.2(a) shows SEM micrograms of a typical electrospun nanofibrous mesh [25]. However, electrospinning has yet to produce designed pore structures. Despite such shortcomings, electrospinning has been widely explored due to its capacity of generating nanofibers and the fabrication simplicity.

Electrospinning has been used to form scaffolds from many different biomaterials, including poly(lactic-*co*-glycolic acid) (PLGA), poly(caprolactone) (PCL), poly(ethylene oxide) (PEO) and poly(vinyl alcohol) (PVA) in water or organic solvent [26]. Nanofibrous mats of collagen, silk protein, elastin-mimetic peptide, fibri-

nogen, casein and lipase enzyme, and even DNA have been formed using electrospinning [20–23]. The use of electrospinning with regard to naturally occurring biomaterials has been limited in comparison to synthetic polymers because of the difficulty in finding appropriate solvents.

Typically, electrospun fibers produced are randomly oriented on the collection plate. However, random fiber orientation is not always ideal. Many tissues are anisotropic and have a clearly defined directionality. Examples of anisotropic tissues include muscle, bone, blood vessels, and nerves. Several methods have been developed to create mats with oriented fibers for use in these types of tissue engineering projects. The first method involves the use of a rotating drum as the grounded target rather than a static plate. As the drum spins, the fibers naturally align themselves (Fig. 4.2) [27]. A modification on the rotating drum concept that offers more versatility utilizes modified polymer solution system pushed through a microfluidic chamber in close proximity to a rotating collection grid. This system achieves variable fiber alignment from linear to S shaped curves dependent on the rate of collection grid rotation [28].

Besides dynamic collection grids, post-drawing can also be used to create oriented nanofibers [29]. In this method, the fibers are prepared using a static collection grid. Following electrospinning, the mat is drawn by stretching and then annealed under constant strain. Mats created in this manner not only contain uniaxial oriented fibers but also crystal orientation. Uniaxial oriented fibers can also be created with a special collector composed of two pieces of electrically conductive substrates separated by a gap [30]. The electrostatic fields created by the separated conductors cause the fibers to bridge the gap perpendicularly. This method is limited by the electrostatic interactions between the conducting collectors, meaning that only narrow meshes are possible.

The dimensions of electrospun fibers vary, depending on the material used. However, in general, the diameters of electrospun fibers are at least one order of magnitude smaller than those produced by conventional extrusion techniques [24]. Yet, this is still generally at the upper end of the diameters present in the native ECM. Ko and coworkers created nanofibrous PLGA matrices with fibers having diameters between 500 and 800 nm [26], while Vacanti and coworkers fabricated PCL matrices with an average fiber diameter of 400 nm ( $\pm 200$  nm) [31]. Chaikof and coworkers have also created electrospun nanofibers, with diameters in the 100–150 nm range, by combining collagen and PEO [32]. Pure collagen solutions have also been fabricated using electrospinning techniques [33–35]. Bowlin and coworkers have demonstrated electrospun collagen, with an average diameter of 250 nm, that exhibits the 67-nm banding typical of native collagen fibrils [34].

Although electrospinning is a relatively simple and quick method that can be applied to many different types of biomaterials, there is inherent difficulty in creating scaffolds with well-organized pore architectures with complex geometries. The diameter of most electrospun fibers is near the upper limit for the natural size of collagen fibers (50–500 nm) with some even reaching into the micro-scale. These are the two primary shortcomings of electrospinning.

## 4.3.2

**Self-assembly**

Although molecular self-assembly is a rather new laboratory technique for the formation of nano-scale scaffolds, it is prevalent in the natural world. Molecular self-assembly is a “bottom up”, rather than a “top down” approach. Self-assembly is described as the reversible process by which preexisting parts are organized into an ordered system. By definition, molecular self-assembly is the spontaneous association of molecules under equilibrium conditions into stable, structurally well-defined aggregates joined by non-covalent bonds [36]. Although non-covalent bonds such as hydrogen bonds, ionic bonds, van der Waals interactions, and hydrophobic interactions are rather weak in isolation, taken in concert they govern the self-assembly of biological macromolecules [37].

As mentioned, self-assembled molecules are ubiquitous in nature. One example of molecules that readily self-assemble into higher order structures is phospholipids. Phospholipids are the principal component of the plasma membrane in cells. In aqueous solutions, phospholipids readily self-assemble to form several structures, including vesicles, micelles, and tubules. One advantage of molecular self-assembly is that fiber diameters can be produced that are much smaller than those produced using electrospinning.

Schnur et al. [38] pioneered the work of molecular self-assembly using lipid tubules. Several molecule types have been utilized in molecular self-assembly. Zhang, Rich, Holmes, et al. [39] have created self-assembled structures using ionic self-complementary oligopeptides. These oligopeptides contain alternating regions of hydrophobic and hydrophilic amino acids, and, in water, they freely organize themselves into stable  $\beta$ -sheet structures. Exposure to monovalent alkaline cations or physiological conditions, the oligopeptides can assemble into hydrogels with interwoven 10–20 nm diameter nanofibers and 50–200 nm diameter pores [39–41].

Peptide-amphiphiles (PA) have also been fabricated and will self-assemble to form nano-structured fibers [42, 43]. Stupp and coworkers [42] demonstrated that a molecule composed of a carbon alkyl tail and several peptide regions will self-assemble to form nanofibers with a diameter of  $7.6 \pm 1$  nm. The nanofibrous scaffolds formed by this method are evident in Fig. 4.3. More recently, Stupp and coworkers [44] have reported preliminary results that indicate that PA self-assembled molecules can be used to encourage angiogenesis.

The PA is synthesized using solid-phase chemistry that ends with the alkylation of the N-terminus of the peptide and contains the following features: a long alkyl tail that conveys hydrophobic characteristics to the molecule; four consecutive cysteine residues that form disulfide bonds to polymerize the structure; a linker region containing three glycine residues to provide the hydrophilic head group the flexibility from the rigid crosslinked regions; a phosphorylated serine residue that interacts strongly with calcium ions and helps to direct mineralization; and Arg-Gly-Asp (RGD), a cell adhesion ligand. The cysteine, phosphorylated serine and RGD sequence are specific characteristics of the peptide portion of the PA [42].

Similar to PAs, diblock copolypeptides containing charged and hydrophobic seg-

**Fig. 4.3.** TEM images of PA molecule (a) self-assembled by drying directly onto a TEM grid without adjusted pH, and (b) another PA molecule self-assembled by mixing with  $\text{CaCl}_2$ . Image (a) is negatively stained with phosphotungstic acid whereas (b) is positively stained with uranyl acetate. In both cases the same fibrous morphology is observed, as is seen by pH-induced self-assembly. (Ref. [43] © 2002 by National Academy of Science, USA.)

ment have also been utilized to form rigid hydrogels in water for tissue engineering applications [45–47]. These hydrogels contain 1–30  $\mu\text{m}$  water-containing pores surrounded by a nanofibrous gel matrix [46]. The diblock copolypeptides hydrogels are thermally stable under physiological conditions [45] and reorganize quickly after mechanical deformation due to the low molecular mass of the diblock copolypeptides [47]. However, the pore size is on the lower side and may not be ideal for tissue regeneration.

Molecular self-assembly has also been proven using molecules other than peptides or PAs. For example, Liu et al. reported the self-assembly of polyphenylene dendrimers into  $\mu\text{m}$ -long nanofibers [48, 49]. Perutz [50–52] demonstrated the formation of nanotubes from polyglutamines.

As mentioned, tissue engineering scaffolds should ideally have large pore spaces to allow for cell accommodation and mass transport. One of the restrictions of self-assembled scaffolds is the limited ability to form macro size pores. Degradation of self-assembled scaffolds is also an issue that will need to be addressed. In addition, the mechanical properties of these scaffolds will need to be increased before self-assembly can be used in tissue engineering applications that require load bearing. Nevertheless, self-assembled materials are often hydrogels, which are convenient for injection.

#### 4.3.3

#### Phase Separation

Phase separation processes have been used for some years to create porous polymer membranes for filtration and other applications [53]. However, the use of ther-

mally induced phase separation (TIPS) in the preparation of tissue engineering scaffolds is fairly new [54]. In this process, a temperature change results in the separation of the polymer solution into two phases; one having a low polymer concentration (polymer-lean phase) and one having a high polymer concentration (polymer-rich phase). Conversely, the polymer-lean phase is sometimes referred to as the solvent-rich phase and the polymer-rich phase, in this naming methodology, is referred to as the solvent-lean phase. Once the phase separation has occurred, the solvent is removed by extraction, evaporation, or sublimation. As the polymer-rich phase solidifies, this process leaves behind a network of pores referred to as the polymer foam. The properties of the foam can be tailored to meet specific needs. Thermally induced phase separation does not automatically lead to materials with nanometer scale architecture. For example, our laboratory has used TIPS to develop polymer and polymer/bioceramic composite scaffolds that do not have the nanofibrous structure for tissue engineering [55, 56].

Ma and colleagues have recently developed a novel phase separation process to fabricate nanofibrous materials from polymers [13]. A distinct advantage of the phase separation process is that it can be combined with other manufacturing techniques (such as particulate leaching or three-dimensional printing) to design complex 3D structures with well-controlled pore morphologies [6, 12, 57, 58]. The rest of this section will discuss how such phase separation is used for nanofibrous scaffold fabrication for tissue engineering applications.

An appropriate liquid–liquid phase separation seems critical for nanofibrous structure formation, but does not occur in all solvent systems. The selection of solvent system and phase separation temperature are vital to nanofiber formation. When the system and conditions are right, liquid–liquid phase separation can result in a 3D continuous fibrous network with nano-scaled architecture similar to natural type I collagen [59, 60]. The fibers formed in this manner have diameters ranging from 50 to 500 nm and the scaffolds can have a porosity in excess of 98% [13]. Figure 4.4 is an image of a nanofibrous PLLA scaffold, and as can be seen, this scaffold closely resembles collagen in the ECM.

**Fig. 4.4.** SEM micrograph of a nanofibrous PLLA matrix prepared from 5.0% (wt/v) PLLA/THF solution at a gelation temperature of  $-18^{\circ}\text{C}$ . (Ref. [13] © 1999, John Wiley & Sons.)

The TIPS process for nanofibrous structure formation typically occurs in five steps [13]: polymer dissolution, phase separation and gelation, solvent exchange from the gel with water, freezing, and finally freeze-drying (sublimation) under vacuum. Although each step is necessary, gelation is the step that determines the type of structure that will be formed. At high temperatures, the solution is homogeneous. When the polymer solution is cooled, phase separation into a polymer-rich and polymer-lean phase can occur. Liquid–liquid phase separation usually occurs via one of two routes: nucleation and growth or spinodal decomposition [61].

When a polymer that crystallizes, such as PLLA, is used the phase separation process becomes much more complicated. In addition to phase separation, polymer crystallization can also occur. In these cases, kinetics become important because the solution will experience driving forces for both liquid–liquid phase separation and polymer crystallization. When the liquid–liquid phase separation is faster than the polymer crystallization that leads to the nucleation of crystalline domains in the polymer-rich phase, the morphology of the porous network is largely dependent on the initial liquid–liquid phase separation. The selection of phase-separation temperature should accordingly promote the desired liquid–liquid phase separation [62].

As mentioned earlier, proper selection of solvents is critical in liquid–liquid phase separation. The solvent must have a freezing point (crystallization temperature) lower than the liquid–liquid phase separation temperature of the polymer solution. Otherwise, the solvent may crystallize before the liquid–liquid phase separation occurs. In addition to phase separation temperature and solvent selection, the final morphology of the polymer matrix is dependent on the concentration of polymer solution and the molecular weight of the polymer [59]. For example, a very low concentration of polymer will typically result in a powder-like structure, whereas a higher concentration will result in a foam.

Tissue engineers desire scaffolds not only with fibrous networks that mimic the ECM, but also with designed 3D architecture of interconnected pores. In scaffolds, macroscopic pores ( $>100\ \mu\text{m}$ ) are vital for proper cell seeding, distribution, migration, and neovascularization.

Here we present a few examples to illustrate how to combine liquid–liquid phase separation with other technologies to create scaffolds with the proper 3D shape, pore architecture, and nano-scale fibers. To form a nanofibrous matrix with a macroscopic pore network, TIPS can be combined with particulate leaching techniques [12]. For example, a polymer solution can be dripped over salt or sugar crystals. The system is then cooled, inducing liquid–liquid phase separation. Next the scaffold is immersed in water to simultaneously extract the solvent and leach out the salt/sugar crystals. The scaffold is then frozen and, finally, freeze dried. The resulting scaffolds (Fig. 4.5) have a nano-scale fibrous architecture with macroscopic pores. Although sugar/salt leaching creates well-formed pores, it is difficult to control the amount of interconnectivity. Interconnectivity of pores is important for cell migration, cell signaling, and for mass transport (transport of nutrients to the cells and removal of metabolites from the cells).

To better control the interconnectivity of the macroscopic pores in a scaffold, our

**Fig. 4.5.** SEM micrograph of a PLLA nanofibrous matrix with particulate macropores prepared from PLLA/THF solution and sugar particles. Particle size 250–500  $\mu\text{m}$ , original magnification  $\times 50$ . (Ref. [12] © 2000, John Wiley & Sons.)

laboratory has developed a dispersion technique to create paraffin microspheres to be used as porogens. The interconnectivity of the pores can be controlled through thermal bonding of the paraffin microspheres. Paraffin dissolves in THF, and for this reason, THF cannot be used as the polymer solvent, and alternate solvents must be implemented [6]. Following phase separation, hexane is used to leach out the paraffin. The matrix is then frozen and lyophilized. This process results in a scaffold with well-controlled interconnected spherical macropores and nanofibrous pore walls (Fig. 4.6) [6].

Phase separation can also be combined with rapid prototyping techniques or solid free-form (SFF) fabrication. In SFF fabrication a computer-aided design program is used to design a 3D scaffold. To create a nanofibrous scaffold, a negative mold is first generated using SFF fabrication techniques. The polymer solution is then dripped over this mold. Following phase separation, the mold is leached out

(a)

(b)

heat treated for 40 min. Sphere size range  $d = 250\text{--}420\ \mu\text{m}$ . Original magnification (A)  $\times 50$  and (B)  $\times 8000$ . (Reprinted with permission from Ref. © [6] 2004, Elsevier.)

**Fig. 4.7.** SEM micrograph of the internal pore structure of a scaffold fabricated using the reverse SFF fabrication technique. (Ref. [58] © 2003, John Wiley & Sons.)

and the matrix is processed as described previously. SFF fabrication makes possible the construction of scaffolds with complex 3D structures. Figure 4.7 shows an example of a scaffold formed by combining this reverse SFF fabrication and phase separation [58].

In addition to being combinable with other processing techniques to design macropores, phase separation is also a desirable method for forming tissue engineering scaffolds because it can produce nanofibers in the size range similar to that of natural collagen. Furthermore, phase separation does not require expensive equipment or complicated synthesis schemes and can be easily adapted to a small laboratory setting or large-scale industrial production.

Each technique, molecular self-assembly, electrospinning, and phase separation, provides unique strengths in the area of nano-scale tissue engineering scaffolds. As each area develops further, it is likely that niches will be created where a particular method better suits the needs of certain tissue engineers. As scientists better understand and mimic the ECM, scaffolds will undoubtedly be created that provide the characteristics necessary to move tissue engineering off the laboratory bench and into widespread clinical applications.

#### 4.4

#### **Nanofibrous Composite Scaffolds**

Utilizing the above three techniques, composite scaffolds have been formed that contain minerals and biological materials to enable the scaffolds to better mimic the natural ECM's surface chemistry. Although nanofibrous scaffolds provide an improved base architecture, the surface characteristics affect cellular response to a material by influencing the rate and quality of new tissue formation. Specifically, the surface chemistry and topography determine whether protein molecules can adsorb, and the conformation of adsorbed proteins on the surface. This in turn

affects cellular attachment, alignment, proliferation and differentiation. Most materials used to fabricate nanofibrous scaffolds lack the biological recognitions of the ECM on their surface. These scaffolds can be altered through the inclusion of molecules and biological recognition sites to more closely mimic natural ECM of the tissues they are trying to emulate.

#### 4.4.1

#### Inorganic Composites

Most mineralized tissues, like bone, contain both organic and inorganic molecules. In natural mineralized tissues, hydroxyapatite (HAP), a plate or spindle-shaped crystal, is found between collagen fibrils in the ECM [63]. HAP is the main component of the inorganic bone matrix, and the major site of mineral storage in bone and the body. Bone contains 99% of the calcium and 88% of the phosphate in the body. The HAP crystals within the matrix measure up to 200 nm in length and offer a large surface area available for mineral exchange, about 10 m<sup>2</sup> per 1 g of bone [64].

By incorporating HAP into scaffolding, one attempts to increase mineralized tissue formation through mimicking natural mineral content and ECM base architecture. HAP-containing polymer scaffolds possess good mechanical and osteoconductive properties [5]. Nano- and micro-size HAP particles have been incorporated with nanofibrous PLLA scaffolds created by phase separation to yield highly porous scaffolds with improved mechanical strength and increased protein adsorption [65]. Particularly interesting is that the nano-sized HAP provides improved characteristics relative to micro-sized HAP in scaffolds [65].

HAP can also be deposited onto the surface of nanofibrous scaffolds using simulated body fluid. This allows the HAP to have nano-features within the larger deposited masses. This technique has been utilized to deposit HAP on phase separated PLLA scaffolds (Fig. 4.8) [57] and electrospun poly(3-hydroxybutyrate-co-3-hydroxyvalerate) nanofibers [66]. Similarly, electrospun PCL and PLGA nanofibers

**Fig. 4.8.** SEM micrographs of nanofibrous PLLA/nHAP (90:10) composite scaffolds incubated in 1.5X SBF for varying (a) 4 days and (b) 30 days. (Ref. [57] © 2006, John Wiley & Sons.)

have been combined with calcium carbonate [67], yielding similar advantages for mineralized tissue formation.

#### 4.4.2

#### Surface Modification

When mineralized tissue is not the goal, yet the base polymer used to create the scaffold does not possess the most desirable surface characteristics, the scaffold surface can be modified to obtain more desirable characteristics to promote cell-scaffold interaction. These modifications can be as simple as plasma treatment or allowing ECM proteins to adsorb to the scaffold [68]. For instance, PCL nanofibers have been air-plasma treated to introduce  $-COOH$  groups and then gelatin was allowed to adsorb to the surface [69]. There is a concern over the penetration depth and uniformity of the plasma treatment. More advanced and controlled modifications are desired.

Using electrospinning, a molecule such as gelatin can be blended with polymer and then drawn through the electrospinning process to form nanofibrous scaffolds, as was done by Zhang et al. using PCL and gelatin mixtures [70]. Furthering this concept of multiple species electrospinning, coaxial electrospinning techniques have been developed, which allow for nanofibers to be produced with different core and shell materials. This means that the core and shell material do not necessarily need to be compatible. For instance, Zhang et al. have produced nanofibers with a PCL core and a collagen shell for tissue engineering purposes [71].

Another strategy in surface modification is to use a completely synthetic system. In this approach a biologically active peptide is grafted onto the surface. For instance, a galactose ligand has been covalently conjugated to poly(acrylic acid) spacers, which were UV-grafted onto poly( $\epsilon$ -caprolactone-co-ethyl ethylene phosphate) nanofibers [72]. As such, peptide scaffolds have been made containing the biologically active motifs of laminin I and collagen IV, two important proteins in the basement membrane [73].

Alternatively, peptide amphiphiles containing either biologically active sequences or structures potentially could be assembled on the surface of nanofibrous scaffolds. Fields, Tirrell and coworkers have illustrated the validity of such a coating using PA molecules that consist of a  $\alpha 1$  (IV) 1263-1277 collagen sequence Gly-Val-Lys-Gly-Asp-Lys-Gly-Asn-Pro-Gly-Trp-Pro-Gly-Ala-Pro ([IV-H1]) connected to a long-chain mono- or di-alkyl ester lipid [74–78], which assembles into stable triple helices under physiological conditions [78], and have been shown to favorably support cell adhesion when coated on surfaces [76]. This work illustrates that surface chemistry can be mimicked with this type of PAs. However, it has yet to be developed for scaffold modifications.

In our laboratory, a few easier implementing and effective techniques have been developed for 3D surface modification of complex shaped scaffolds. For example, physical entrapment of gelatin along with chemical crosslinking has been used to modify nanofibrous PLLA scaffolds [79]. This is an advancement beyond adsorp-

tion because it immobilizes the gelatin on the surface of the nanofibrous scaffold, ensuring that the gelatin does not wash away in a tissue culture environment. After 4 weeks of culture, osteoblasts on nanofibrous scaffolds modified with this method showed increased proliferation and collagen fiber bundle formation over the unmodified control scaffolds [79]. This indicates that this surface modification does not have the depth penetration problems that more simplistic modification like plasma-treated surfaces encounter in 3D applications.

An electrostatic layer-by-layer self-assembly technique has also been used to improve the surface characteristics of nanofibrous PLLA scaffolds with gelatin [80]. Similar to physical entrapment with chemical crosslinking, self-assembly has led to increased osteoblast proliferation over unmodified control scaffolds [80]. Histological sections of nanofibrous scaffolds with the self-assembly modification showed a more even distribution of cells throughout the scaffolds after 2 weeks of culture than unmodified control scaffolds [80].

#### 4.4.3

#### Factor Delivery Scaffolds

As the drive to mimic the ECM continues, more nanofibrous scaffolds will likely contain biological modifications to more appropriately tailor their characteristics to the desired application. Similarly, investigators are moving beyond simply mimicking the ECM to incorporating the release of factors to promote healing and tissue formation from the scaffolds. To date, the antibiotic Cefoxitin has been released from nanofibrous PLGA scaffolds by several groups [81, 82]. PDLA nanofibers have been used to release Mefoxin, a similar antibiotic to Cefoxitin, by others [83]. Beyond antibiotics, the lipophilic anti-tumor drugs, doxorubicin and paclitaxel, have been released from PLLA nanofibers studied [84]. Ibuprofen, an anti-inflammatory drug, has had its release from PLGA/PEG-g-chitosan nanofibers [85]. Polyurethane nanofibers have been used to study the release of Ketanserin, a selective 5<sub>2</sub>-setotonin antagonist, and Itraconazole, an anti-fungal drug [86].

The release of plasmid DNA from PLGA and PLA-PEG nanofibrous scaffolds has also been studied [2, 87]. Besides DNA, a few biological growth and differentiation factors have been delivered from nanofibers. Human  $\beta$ -nerve growth factor has been released from electrospun PCL/ethyl ethylene phosphate nanofibers [88]. Systems for the delivery of biologically active proteins are often far more difficult to engineer than those for drug or nucleotide release because of the sensitivity of proteins to conformational changes that render them biologically inactive, thus limiting the available methods and necessitating their protection from harsh conditions. Wei et al. have developed a system for release of platelet derived growth factor (PDGF) and/or other biologically active factors from micro-spheres evenly distributed within nanofibrous PLLA scaffolds [89]. Incorporation of the micro-spheres into the nanofibrous scaffolds decreased the initial burst release of the PDGF and extended the release of biologically active PDGF in a controlled fashion [89].

## 4.5

### Biological Effects of Nanofibers

The ultimate goal of tissue engineering is to develop biological substitutes that restore, maintain or improve tissue function within the body. Developing nanofibrous scaffolds that better mimic the ECM is one step further down the road to achieving functional neo-tissue formation.

Regardless of the method used to form the nanofibrous scaffolds or further process the scaffolds, these scaffolds seem to possess certain advantages over more conventional scaffolds. They seem advantageous when it comes to cellular adhesion, proliferation, migration and differentiation. Increased cellular adhesion and proliferation, along with more rapid differentiation into mature cell types, have been observed with several cell types [17, 27, 90–93]. However, engineering tissues using nanofibrous scaffolds is still at the early stages. Notably, there is limited data and a systematic study of the biological effects of nanofibers on cell function and tissue development has yet to be completed.

#### 4.5.1

##### Attachment

Suitable attachment is the first step to successful neo-tissue formation, since most cell types require anchorage to proliferate, migrate and differentiate [94]. Woo et al. [17] found that the cell adhesion proteins fibronectin, vitronectin, and laminin adsorbed to the nanofibrous scaffolds much more than solid-walled control scaffolds. They also found that this effect is not simply due to increased surface area since different proteins adsorbed at different levels, which suggests the selective interaction of the proteins with the nanofibrous matrix [17].

Cells seem to react to this increased adhesion protein presence on the nanofibers by up-regulating integrins, a family of transmembrane proteins involved in adhesion of cells to the ECM and each other. Specifically, normal rat kidney cells upregulate expression of  $\beta 1$  integrin [91], while chondrocytes upregulate expression of integrin  $\alpha 2$  on nanofibrous surfaces [92]. Beside up-regulation of  $\beta 1$  integrin, normal rat kidney cells organize their  $\beta 1$  integrin in long, slender aggregates on the nanofibers while on glass expression was concentrated in the cell body [91], as seen in Fig. 4.9, on nanofibrous surfaces. Similarly, NIH 3T3 fibroblasts have been shown to express vinculin, a prominent component of focal adhesions that connect the cytoskeleton and plasma membrane with the ECM, strongly in the edge of lamellipodia with more diffuse staining throughout the cell cytoplasm on nanofibrous surfaces [91]. The expression and distribution of these important adhesion molecules are thought to correlate with cellular morphogenesis *in vivo* [91] and the change in cellular interactions between nanofibrous scaffolds and traditional scaffolds, which contain flat walls.

Three days after seeding calvarial cells on both nanofibrous and traditional scaffolds, Woo et al. found that the cells on nanofibrous scaffolds had many long processes that intermingled with the nanofibrous scaffold and connected to neigh-

**Fig. 4.9.** Comparison of  $\beta 1$  integrin organization in normal rat kidney cells. Indirect immunofluorescence on (a) glass and (b) nanofibers. (Reprinted with permission from Ref. [91] © 2005, Elsevier.)

boring cells, while cells on traditional scaffolds had only a few processes [95]. Furthermore, cells on the nanofibrous scaffolds were actively synthesizing and secreting molecules [95].

The increased adsorption of adhesion proteins from serum-containing media and the cellular response at least partially explains the increased attachment of numerous cell types on various nanofibrous scaffolds. For instance, neural progenitor cells attach faster to nanofibers than to the control surfaces [90]. Pre-osteoblasts [17], calvarial cells [95], smooth muscle cells [27], fibroblasts [91], normal rat kidney cells [91] and multipotent neural stem cells [90] have also shown preferential adhesion on nanofibers over controls.

#### 4.5.2

##### **Proliferation**

After cells attach to a scaffold, they must reproduce by duplicating their contents and dividing in two to develop into new tissue [94]. Several cell types have shown increased proliferative capability on nanofibers over various time periods [27, 91, 92, 96]. Specifically, normal rat kidney cells have shown increased proliferation on nanofibers relative to control at 24 h [91] and high density chondrocyte cultures increased proliferation over 3 weeks on nanofibrous scaffolds relative to control [92]. The authors have also observed this trend with pre-osteoblasts over the course of 12 days. In the context of neo-tissue formation, quicker proliferation will limit the invasion of scar tissue *in vivo* and lead to faster differentiation and functional tissue formation.

#### 4.5.3

##### **Differentiation**

Differentiation is the process by which cells undergo a change to an overly specialized cell type from a more immature cell type. This process is different for each

cell type. However, nanofibrous materials appear to quicken differentiation of multiple cell types. Fibroblasts have shown more differentiated characteristics on an electrospun nanofibrous substrate [91]. These fibroblasts, along with normal rat kidney cells, express 40–50% less actin on nanofibers than on control substrates at 24 h, which also suggests an increase in differentiated characteristics [91].

Nanofibrous scaffolds have also shown the ability to direct more immature cells to a desired lineage. This has been studied with neural progenitor cells [93], multipotent neural cells [90] and neonatal murine cavariar cells [95]. In these cases, nanofibrous scaffolds have aided in the differentiation of neurons relative to other neuronal support cells. Compared to control scaffolds, nanofibrous scaffolds allow the neonatal murine cavariar cells to differentiate to osteoblasts faster and enhance the expression of phenotypic markers [95]. Specifically, bone sialoprotein was found to be expressed approximately 8–10× higher on nanofibrous scaffolds than on solid-walled scaffolds.

Nanofibrous scaffolds have also shown ability to aid in the redifferentiation of cells that have regressed to a more immature state during cell culture [92]. This particular feature will aid in tissue formation of chondrocytes and hepatocytes, both of which revert to immature cell types during culture.

#### 4.5.4

#### Migration

To form neo-tissue, cells must be able to infiltrate the scaffold and move throughout it. This movement of cells across the scaffold and pore surfaces is a highly complex process that is dependent on the actin-rich cortex beneath the plasma membrane, which pushes the plasma membrane outward to form a leading edge. Next the actin cytoskeleton must attach to the substrate and provide the traction necessary to move the bulk of the cytoplasm [94]. Many ECM proteins, such as fibronectin, are thought to aid in and direct migrating cells toward their final destination [94]. As discussed in the attachment section, the preferential adsorption of attachment proteins including fibronectin, and the concentration of transmembrane attachment proteins and focal adhesion in localized areas could potentially explain the increased migrant capability of cells on nanofibrous scaffolds. This is particularly evident in a study by Semino et al., in which hippocampal slices were cultured on nanofibrous hydrogel scaffolds [97]. The nanofibrous scaffolds allowed for deeper penetration (~500 μm relative to the ~150 μm of the control surface) [97]. Over time the cells migrating into the space were of different lineages. Glia cells were the first to infiltrate the nanofibrous scaffold followed by neural progenitor cells, which then proliferated and differentiated to form a framework for neuron tissue formation within the nanofibrous scaffold [97]. A similar phenomena has been seen by simply placing neural progenitor cells on nanofibrous scaffold [93]. This indicates that cells on nanofibers, independent of tissue type, are capable of increased navigation.

## 4.6

### Tissue Formation

In the human body, tissues and organs are organized into 3D structures. Each tissue or organ has its own specific characteristic architecture depending on its biological function. This architecture provides appropriate channels for mass transport (movement of signaling molecules, nutrients, and metabolic waste) and spatial cellular organization (cell–cell and cell–matrix interactions), both of which are thought to be important for appropriate tissue function [12]. As such, scaffolds for each particular tissue engineering application need to be designed with sensitivity to the cellular requirements of the tissue it is generating.

#### 4.6.1

##### Connective Tissue

Connective tissue mainly functions to bind and support other tissues. As such, connective tissue contains a sparse cell population scattered throughout an ECM composed of fibrous webs embedded in a uniform foundation, all of which is generally secreted by the cell population [98]. However, there is great diversity in the cellular requirements for various connective tissues. In the context of this discussion we will examine three types, ligaments, cartilage and bone.

##### 4.6.1.1 Ligaments

Ligaments are fibrous connective tissue that connects bones together at joints. To do this, ligaments contain numerous collagenous fibers organized into parallel bundles that maximize non-elastic strength [98]. It is this organization that a scaffold must mimic to successfully generate a new ligament. This has been attempted with scaffolds containing oriented nanofibers seeded with human ligament fibroblasts [96]. Shortly after seeding, the human ligament fibroblasts oriented themselves in the direction of the nanofibers and assumed the appropriate spindle-shaped morphology [96]. After 7 days in culture, oriented bundles were present in a tissue-like formation [96] (Fig. 4.10).

##### 4.6.1.2 Cartilage

Rather than acting as a connector like ligaments, cartilage acts as a cushion between vertebrae and the ends of some bones and reinforces tissue such as the windpipe. As such, the ECM of cartilage is much different from that of ligaments and contains an abundance of collagenous fibers embedded in a rubbery matrix of chondroitin sulfate [98].

Overall, cartilage tissue engineering has been relatively successful even with micro-sized fibers [99, 100]. Nanofibrous materials have been reported to promote chondrocyte proliferation [101, 102], differentiation [92] and the secretion of the suitable ECM [101–103]. Interestingly, in a study by Li et al., chondrocytes on nanofibrous scaffolds were the only ones found to express collagen type IIB, a col-

**Fig. 4.10.** Histological sections of ligament regenerated on nanofibrous scaffolds: human ligament fibroblasts on aligned nanofibers after 7 days of culture. (Reprinted with permission from Ref. [96] © 2005, Elsevier.)

lagen type found only in mature chondrocytes [92]. While in another study, Li et al. found collagen X down-regulated on nanofibrous scaffolds, and yet the chondrocytes had morphology similar to native cartilage and still produced the correct sulfated matrix [103]. This seems to suggest that, in this study, the scaffold potentially interacted with the cells in a way similar to that of collagen X, triggering the decrease in its expression.

#### 4.6.1.3 Bone

Bone is a mineralized connective tissue that supports the body and a major skeletal component that is constantly changing and remodeling itself based on the current needs of the organism. This remodeling is done to help bone fulfill one or more of its primary functions within the organism. These functions include supporting and protecting soft tissues, providing the rigidity necessary for locomotion, regulating calcium and phosphate, and providing a site for hematopoiesis [104]. Although bone can remodel and repair itself, it cannot repair large defects caused by trauma or degenerative disease on its own, which is why tissue engineers are interested in *de novo* bone generation.

After 1 week or more of *in vitro* culture on a nanofibrous scaffold, collagen type 1 has been observed throughout the scaffold [31, 95, 105]. After three or more weeks of *in vitro* culture, up-regulation of bone markers such as alkaline phosphatase, bone sialoprotein and osteocalcin on nanofibrous scaffolds relative to control have been observed [103, 106]. The notable exception to this is collagen type I, a major component of the bone ECM [103]. As with cartilage, it is possible that the nanofibrous scaffolds interact with the cells in a similar manner to native collagen, limiting the cells' need to express it. This has been supported by Woo et al., who administered 3,5-dehydroproline to inhibit collagen fibril formation and found alpha-2 integrin and osteogenic markers expressed on the nanofibrous scaffold but not the control scaffolds [95, 106].

In a 10-day study of osteoblastic phenotype development in neonatal murine

cavariar cells,  $\alpha 1$  collagen and Runx2 expression were shown to be initially up-regulated on the nanofibrous scaffolds compared to solid-walled scaffolds. However, as the experiment continued the expression levels for both markers approached the expression levels on the nanofibrous scaffolds, while both bone sialoprotein and osteocalcin once observed were substantially higher on the nanofibrous scaffolds compared with solid-walled scaffolds [95]. The authors have also observed the up-regulation of bone sialoprotein and osteocalcin and the down-regulation of collagen type I over the course of 6 weeks with pre-osteoblasts on nanofibrous scaffolds compared with solid-walled scaffolds.

Small globular mineral deposits have been observed within nanofibrous scaffolds in as early as 2 weeks using primary calvarial cells [95]. In this study, large mineral deposits existed along the nanofibers, indicating mineral development along the nanofibers. This is supported by the authors' own observations of mineralization emanating from within areas of the synthetic nanofibrous scaffold. This architecture allows for cellular penetration within the synthetic matrix [107].

In terms of successful bone generation, Vacanti and coworkers found that after 4 weeks *in vitro* and 4 weeks *in vivo* vascularization, mineralization and embedded osteocyte-like cells can be seen in electrospun nanofibrous scaffolds [105].

#### 4.6.2

#### Neural Tissue

Neural tissue is composed of neurons and support cells. Neurons transmit signals to direct other tissues' function via nerve impulses throughout the body while the support cells provide structure for the tissue and protect, insulate and generally support the neurons. This tissue has a limited capacity to regenerate, but is vital to normal body function.

Nerve impulses are passed from one neuron to the next at synapses where a projection from the first neuron approaches the body of a second neuron [98]. To achieve this sort of order within a scaffold, neurons grow neurite projections with growth cones to interact with other cells. Several nanofibrous scaffolds have showed increased neurite outgrowth relative to control [25, 90, 93, 108]. At times, this increased outgrowth has been as much as 100  $\mu\text{m}$  [25]. It has been generally observed that the nanofibrous scaffold acts as a guide for neurite outgrowth [25, 108]. When the nanofibers are aligned this growth tends to be in the direction parallel to the nanofibers and the cells tend to have a more elongated shape similar to *in vivo* [25].

Since neuronal progenitor cells are difficult to isolate, much of neuronal tissue engineering relies on the migration of progenitor cells from tissue. This has been documented with nanofibrous scaffolds [93, 97]. Once these progenitor cells migrate, they must differentiate to provide the necessary neurons and support cells for proper function of the neuronal tissue. Nanofibrous scaffolds promote increased differentiation compared to control scaffolds [90, 93, 97]. Although complete *de novo* neural tissue has yet to be formed on nanofibrous scaffolds, great potential and interest exist to pursue *de novo* tissue formation of this tissue type.

## 4.6.3

**Cardiovascular Tissue**

The cardiovascular system is responsible for the transport of nutrients and wastes to and from cells. The heart acts as the pump driving the system and the vascular tissue acts as tubes directing the path of collection and exchange of nutrients and waste. As such, disruption in the function of this system is life threatening and must be repaired quickly. This section concentrates on cardiac muscle and blood vessels.

4.6.3.1 **Cardiac Muscle**

The regenerative capability of cardiac muscle is particularly limited, making it the most challenging tissue to regenerate in the cardiovascular system [109]. To combat this, nanofibrous self-assembling RAD12-II peptide scaffolds have been developed by Lee and coworkers that can be injected into the heart to promote cardiac muscle regeneration. When injected into the left ventricle wall of adult mice, endothelial cells invaded, organized and matured into the appropriate structure to support smooth muscle cell migration, which allowed for the formation of arterioles [110]. Red blood cells located within the arterioles indicate that they were functionally connected to the vascular system. This led to the migration of cardiac progenitor cells that differentiated into myocytes [110]. Inclusion of myocytes in the scaffold greatly increases myocyte density within the scaffold over a much shorter period of time. When implanted with embryonic stem cells this same self-assembling RAD12-II peptide scaffold promoted the controlled differentiation of the cells to cardiomyocytes [110]. During *in vitro* cultures, the self-assembling RAD12-II peptide scaffold promoted endothelial and myocardial cell survival and synchronized contraction of the generated muscle [111].

4.6.3.2 **Blood Vessel**

Blood vessels are composed of smooth muscle and endothelial cells. Similar to previously discussed tissue types, alignment of nanofibers aids in blood vessel function. The aligned nanofibrous scaffolds have been shown to prompt the alignment of smooth muscle cells parallel to the fiber direction, which increases vessel strength [27]. This alignment has also been shown to increase initial adhesion and proliferation on the scaffold, which leads to quicker functional blood vessel formation [27].

The second cellular component of blood vessels, endothelial cells, also benefit from culture on nanofibrous scaffolds. Human aortic endothelial cells cultured on nanofibrous scaffolds form confluent layers similar to those formed on collagen type I gel or Matrigel [73]. The scaffolds also promote nitric oxide release which is a marker of endothelial cell phenotype [73].

## 4.6.4

**Liver Tissue**

Liver is a multipurpose organ that aids in the digestion of fats, the uptake and release of glucose, synthesis of plasma proteins and the detoxification of many

**Fig. 4.11.** SEM images of hepatocytes after 8 days of culture: (a, b) Hepatocytes cultured on a Gal-film formed spheroids that did not integrate with the substrate; (c, d) in contrast,

hepatocytes cultured on Gal-nanomesh afforded aggregates that engulfed the functional nanofibers. (Reprinted with permission from [72] © 2005, Elsevier.)

poisons and metabolic waste [98]. Regeneration of liver tissue in a functional form has proven incredibly difficult. However, nanofibrous scaffolds have brought renewed efforts. Nanofibrous scaffolds appear to increase hepatocyte function in comparison to control scaffolds [72, 112]. Hepatocytes on nanofibrous scaffolds also exhibit a more uniform spheroid-like distribution than on control scaffolds [72]. Figure 4.11 illustrates these differences in interaction between hepatocytes and nanofibrous and non-fibrous materials.

#### 4.7

#### Conclusion

To date the most successful neo-tissue generation has involved connective tissues [100, 101, 113]. As evident by the developments in cardiac muscle formation, headway is being made with more metabolically demanding and complex tissues. However, the holy grail of tissue engineering still remains the development of complete patient-specific organs available on demand [2, 114]. To achieve this, scaffolds must not only provide structural support but also biological cues [115]. Increased knowledge about cellular interactions with the native ECM and nano-structured scaffolds will facilitate more functional scaffold development.

Hopefully, this chapter has provided some insight into the crucial role tissue engineering scaffolding plays in this drive for 3D neo-tissue formation [4, 17, 116] through its focus on nanofibrous scaffolding fabrication and the biological advantages of nanofibrous scaffolding structures in mimicking the ECM.

## 5 Nanophase Biomaterials for Tissue Engineering

*Ramalingam Murugan and Seeram Ramakrishna*

### 5.1 Introduction: Problems with Current Therapies

Tissue or organ failure, resulting from traumatic or non-traumatic destruction, gives rise to a major health problem that directly affects quality and length of patient's life. These circumstances often call for surgical treatments to repair, replace, maintain or augment the functions of affected tissue or organ using some additional functional components to facilitate quality life to the patient. They have been traditionally treated with the help of tissue or organ procured from the donor site. Depending on the location of reimplantation of the procured tissue or organ (also called graft), they are termed as autograft, allograft, or xenograft (Fig. 5.1) [1]. If the graft is implanted in the same patient, it is termed as autograft and if it is placed in another individual of the same species it is termed as allograft. If the graft is placed in another species, then it is termed as xenograft. Among them, autograft is considered as a gold standard and has long been used with good clinical results, but the supply of autograft is limited. Conversely, allograft and xenograft are not much preferred due to the possibility of pathogen transfer and graft rejection. Furthermore, procurement of living tissue/organ is complex, expensive, and requires an additional surgery. Notably, over 8 million surgical procedures are performed annually to treat tissue and organ failures in the United States of America itself, as per medical statistics [2–4]. Over 80 000 patients are still awaiting tissue and organ transplantations. In this regard, a potential solution is needed to overcome the limitations of traditional tissue transplantation methods and, at the same time, to increase the accessibility and long-time survivability of the tissue implants.

These limitations have instigated the search for alternative approaches and have resulted in the emergence of the concept of tissue engineering, whereby tissue or organ failure is addressed by using synthetic materials cultured with appropriate cells harvested from patient or donor and then implanted in the patient's body where tissue regeneration is required. The synthetic materials used for this purpose are generally called biomaterials. Biomaterial by definition is a substance or a combination of substances, other than drugs, derived either from natural or syn-

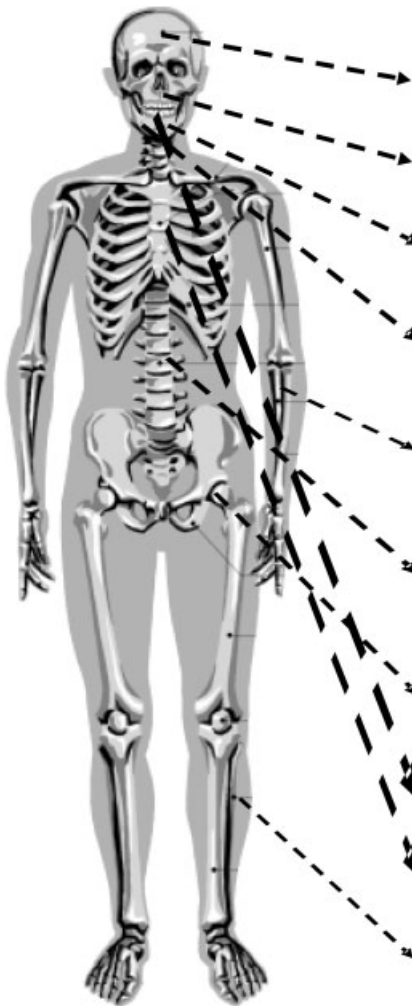

Fig. 5.1. A schematic of tissue transplantation. (Adopted and modified from Ref. [1].)

thetic origin that can be used for any period of time as a whole or as a part of the system that treats, augments, or replaces any tissue, organ, or functions of body [5]. Biomaterials have the advantage of eliminating the surgical process in procuring tissue or organ encountered in the traditional graft procedures, and eliminating the chance of graft rejection or transmission of infectious diseases. In addition, the availability, reproducibility, and cost-effectiveness make the biomaterials more suitable for tissue engineering applications. Figure 5.2 gives some of the clinical uses of biomaterials. Although biomaterials have been used in human health care systems for more than 50 years, the medical community still faces many problematic cases due to the biomaterials' failure before fulfilling their intended functions. There are many reasons for such failure, but one of the prime factors is related to lack of sufficient tissue regeneration around the biomaterials immediately after implantation, which occurs mainly due to the poor surface interaction of biomaterials with the host tissue. In this concern, it is essential to design biomaterials with superior surface properties (e.g., surface area and surface roughness) to facilitate favorable host tissue interactions for their long-term survivability, and to enhance tissue regeneration. High surface area is one of the key properties of biomaterials, which influences cell adhesion and cell density. Surface roughness is another key determinant factor for the occurrence of sufficient host tissue interactions. It has been hypothesized that cell–matrix interactions are governed by surface properties and their imperative interactions found to occur within 1 nm of the implant surface [6]. Apart from surface chemistry, it is also worth mentioning that the cells live in a complex mixture of pores, ridges, and fibers of extra cellular matrix (ECM) in a nano-featured environment. This is because cells attach, organize, and grow well around the fibers with diameters smaller than those of the cells [7]. These information eventually lead to the concept of nanophase biomaterials

Clinical uses	Biomaterials
Cranial bone defects	Bioactive glass, alumina, HA, HA-collagen
Maxillofacial reconstruction	HA, bioactive glass, alumina, zirconia, HA -PE, Bioglass -PE, PTFE -carbon
Alveolar ridge augmentation	HA, TCP, bioglass, Alumina, HA-PLA, HA -collagen, HA -PLGA
Periodontal defects	HA, TCP, bioactive glass, HA -PLA, HA -PLGA, HA -collagen
Bone void fillers	HA, TCP, bicoral, calcium sulfate, PMMA, HA -collagen, bioactive glass -ceramic composite
Spinal surgery	HA, bioactive glass, HA -collagen, PET -silicon, bioglass -PU
Orthopedic prostheses	Alumina, zirconia, stainless steel, Ti, Ti -6Al-4V, Co -Cr -Mo -Ni, A -W glass ceramics, HA -PE, HA-collagen, bioactive glass -coated biomaterials, HA -coated biomaterials, Carbon fibers -PE
Dental implants	Ti, Ti-6Al-4V, stainless steel, PE, alumina, HA
Cardiovascular systems	PU, silicon rubber, carbon, PTFE, PE
Skin substitutes	Collagen, collagen -glycosaminoglycan, collagen -silicon

Fig. 5.2. Clinical uses of biomaterials.

(herein called nanobiomaterials) for tissue repair and regeneration. The nanobiomaterials are therefore perceived to be more beneficial in tissue engineering than their microscale counterparts.

This chapter introduces the role of the nanobiomaterials in the success of tissue engineering. Numerous articles describe the potential of biomaterials in tissue engineering applications, but only a very few studies emphasize the impact of nanobiomaterials in constructing tissues or organs. This chapter focuses mainly on nanobiomaterials, in particular ceramic and polymeric nanobiomaterials, and examines prospects for their applications in tissue engineering. The following sections discuss the basic aspects of tissue engineering and the key factors for their

success, fabrication methodologies and properties of widely used nanobiomaterials, and current scenarios of nanofibrous scaffold processing techniques. The chapter culminates with a discussion on how these materials influence cell growth functions with illustrated experimental examples.

## 5.2

### Tissue Engineering: A Potential Solution

Tissue engineering is emerging as a significant solution for the traditional tissue and organ transplantations. Tissue engineering is a multidisciplinary theme that applies the principles and methods of engineering and life sciences towards the development of viable substitutes capable of repairing or regenerating the functions of damaged tissue that fails to heal spontaneously. Tissue repair is a process, which involves the usual inflammatory cell cascade, followed by matrix deposition and then a remodeling process, which attempts to regenerate the damaged tissue into healthy tissue. In contrast, tissue regeneration involves gradual replacement of damaged tissue with identical healthy tissue. The major advantage of the tissue engineering approach is that tissues can be perfectly reconstructed in such a way that they match exactly the patient's requirements and can be transplanted into the patient's body with a minimal surgical intervention, which eventually conquers several limitations encountered in the conventional tissue transplantations.

The prime concept of tissue engineering is to harvest a small biopsy of specific cells from the donor site, seed them on a scaffold to culture a specific tissue, and transplant the cultured tissue into the defective site of the patient's body that needs tissue regeneration. The ability to satisfy these criteria is largely dependent on three key factors: (a) the cells that create tissue, (b) the scaffold that gives structural support to cells, and (c) cell–matrix (scaffold) interactions that direct the tissue growth (Fig. 5.3). Among them, cells are the prime determinant factor for the success of tissue engineering because they are the basic units of all life. There are different types of cells that could be used for tissue reconstruction, which are commonly categorized as mature cells (non-stem) and stem cells. Although the use of mature cells dates far back, they are generally differentiated cells, which give rise to low rate of proliferation. As an alternative, stem cells have gained much recognition recently, owing to their ability to overcome many of the limitations of mature cells. The potential of stem cells are briefly discussed in Section 5.3, with experimental examples. The scaffold is another important determinant factor for the success of tissue engineering, which basically provides a structural support for the cells to grow in the three-dimensional (3D) space into a specific tissue. The success of the scaffold typically depends on the quality of starting material and the fabrication methodology (much discussed in Sections 5.4 and 5.5, respectively). Cell–matrix (scaffold) interactions is another key determinant factor for the success of tissue engineering because it greatly influences tissue growth. As aforementioned, cell–matrix interactions are governed by surface properties and their imperative interactions found to occur within 1 nm of the implant surface. Furthermore, the

Fig. 5.3. Key factors contributing to the success of tissue engineering.

growth of new tissue depends on the way the seeded cells interact with the scaffold. In this regard, cell seeding density must be optimized to enhance the cell–matrix interactions. However, several growth factors and biological molecules are also involved in the cell–matrix interactions (Section 5.6).

### 5.3

#### Stem Cells: The Essentials

A key factor in tissue engineering approach for repair or regeneration of defective tissue is the use of appropriate cell source. Currently, there are various cells available corresponding to specific tissues. Although the use of mature cells has a successful history and remains an important source for tissue engineering, rapid advances are being made in identifying new cell types that has the capacity to transform into specific cell type that may be required to produce appropriate tissue. Stem cells have recently been recognized as a promising alternative to mature cells owing to their enormous potential in generating a spectrum of tissues with adequate functions. With the advances of cell biology, several well-characterized tissue-specific stem cells are currently available for tissue engineering.

Stem cells, by definition, are immature or undifferentiated cells that are able to renew by themselves and differentiate into more specialized type of cells/tissues in response to appropriate signals and cell plasticity. A diverse range tissues can now be engineered using stem cells, from epithelial surfaces to skeletal tissues. This ability allows them to act as a good repair system for the defective tissue or organ of our body. Stem cells are generally classified into three types: totipotent (e.g., zygote), pluripotent (e.g., embryonic stem cells), and multipotent (e.g., mesenchymal stem cells). The totipotent stem cells are capable of producing any type of cells/tis-

sues. The pluripotent stem cells are capable of producing most of the cells/tissues, whilst multipotent stem cells produce a limited number of cells/tissues with specific functions. Stem cells are also categorized into embryonic or adult cells according to their source of origination. Embryonic stem cells, as their name suggests, are derived from the early stage of an embryo. Although embryonic stem cells research is thought to have much greater potential than adult stem cells, several ethical and legal controversies still exist concerning their use for humans. Besides, some of the important clinical and safety issues also hinder their use to a certain extent. Conversely, adult stem cells have considerable biological and clinical interests. Basically these are undifferentiated cells found in differentiated adult tissues. They are also called somatic stem cells. The potential advantage of using adult stem cells is that the patient's own cells could be easily isolated, expanded in culture with appropriate functions, and then transplanted into the patient's body where tissue regeneration is required. By this approach, there is no chance of immune rejection and certain ethical and legal issues can also be conquered. These cells are typically harvested from bone marrow. The bone marrow chiefly constitutes two distinct stem cells: (a) hematopoietic stem cells (HSCs), which are responsible for the formation of blood cells, and (b) mesenchymal stem cells (MSCs), which are responsible for the formation of bone cells.

Mesenchymal stem cell transplantation is considered as a promising method to improve various tissue functions of mesenchymal origin. MSCs are one of the well-characterized populations of stem cells residing in various adult mesenchymal tissues; thereby they are well adopted for tissue engineering with considerable interest and, subsequently, for clinical practice. These cells were first recognized by Friedenstein and group in the 1960s, wherein they noticed that an adherent, fibroblast-like cell population could have the ability to regenerate the essentials of normal bone [8]. Notably, the early investigations using these cells are mainly focused on bone tissue engineering. Nowadays, these cells are being applied to various tissue engineering, including cartilage, myocardium, liver, nerve, spinal cord, and dermal tissues. The advantages of using MSCs are that they can be easily harvested from the donor site and cultured into a spectrum of tissue-specific phenotypes of mesenchymal origin, such as bone, cartilage, muscle, marrow stroma, and tendon (Fig. 5.4) [9–11]. These features attracted the attention of the biomedical community towards stem cell-based therapy, in particular MSCs. The list of tissues with the potential to be engineered has recently grown progressively due to the advances in stem cell biology and sophisticated characterization techniques, which indicates the prospects for future MSCs-based tissue engineering.

Notably, once cells are isolated from their natural environment, they tend to lose their phenotype and differentiated functions. It is really a great challenge to refurbish the cell phenotypic expression and differentiated functions without hindering proliferation under laboratory conditions. A few studies have reported the direct delivery of cell suspension without using scaffolds [12, 13], but these processes encountered difficulties in having poor control over the localization of transplanted cells; thereby, notably, the cell expression may not be achieved without a suitable scaffold. Numerous investigations have reported the effective delivery of MSCs us-

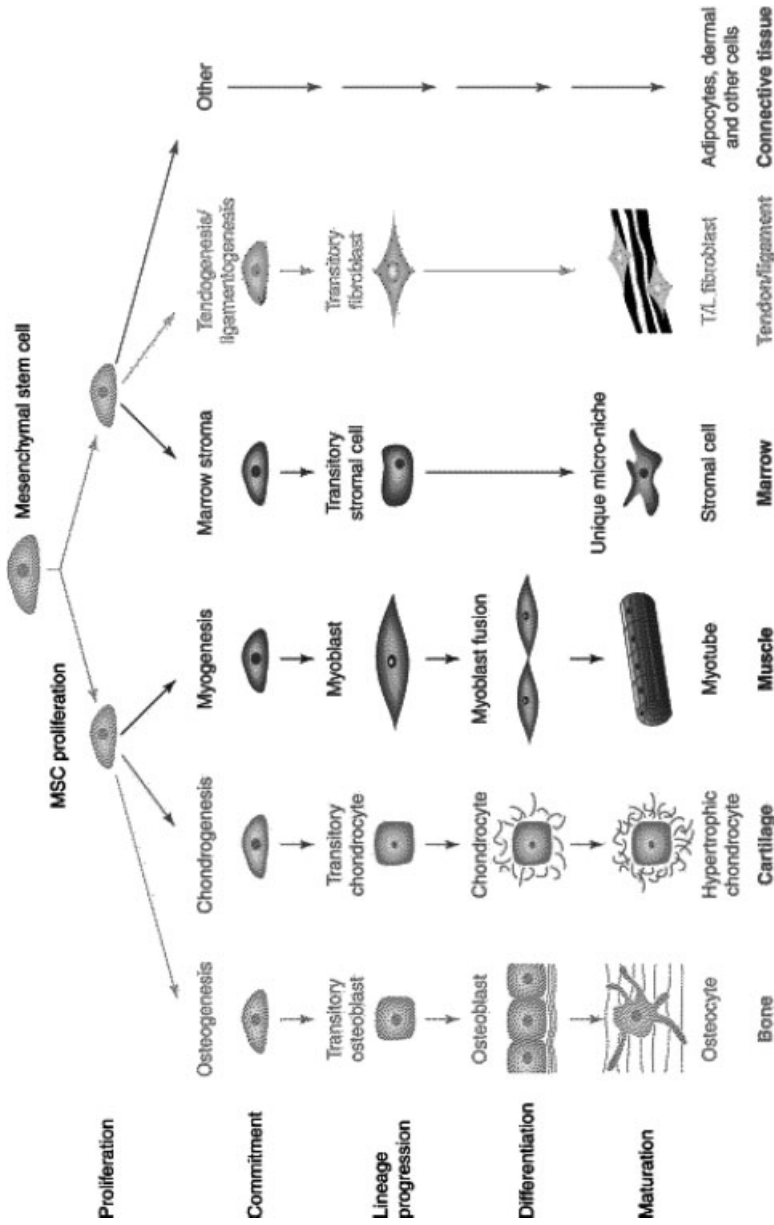

Fig. 5.4. Schematic of mesengenic process, showing stepwise cellular transitions from the putative mesenchymal stem cell to highly differentiated phenotypes. (Adopted with permission from Ref. [11].)

ing scaffolds made of polymers, ceramics, and their composites [14–16]. Recently, Li et al. [17] have reported the ability of MSCs to differentiate into chondrocytic phenotype, a cartilage-specific tissue. First, they fabricated the nanoporous biodegradable polymer scaffolds using poly( $\epsilon$ -caprolactone) (PCL) by the electrospinning method followed by *in vitro* assessment of chondrogenesis, in the presence of transforming growth factor- $\beta$  (TGF- $\beta$ ). The results indicated that the MSCs are capable of giving rise to chondrocytes and also stimulate the synthesis of cartilage-associated ECM proteins throughout the scaffold. Therefore, they suggested that the electrospun PCL scaffold is a practical carrier system for MSCs transplantation in tissue engineering-based cartilage repair. Another interesting study, reported by Yoshimoto et al. [18], demonstrated the ability of MSCs to differentiate into osteoblastic phenotype. To facilitate this, the authors manufactured the nano-featured PCL scaffolds by electrospinning, and their ability of MSCs differentiation was studied under *in vitro* cell culture conditions. They found that the scaffolds provided a suitable environment to stimulate the MSCs to differentiate into osteoblastic phenotype, a bone-specific tissue. Furthermore, the scaffolds supported the synthesis of ECM of type I collagen throughout the matrix, which is a good sign of mineralized tissue formation; thereby, the authors suggested that the PCL scaffold may be a potential candidate for bone tissue engineering. This experimental information suggests that most of the cells are anchorage-dependent and will not survive if delivered without a suitable scaffold. Processing a perfect scaffold with all the qualities similar to natural ECM is, therefore, of great importance for tissue engineering.

#### 5.4

#### Nanobiomaterials: A New Generation Scaffolding Material

Recent progress in nanoscience and nanotechnology has drastically increased the success rate of nanobiomaterials as a scaffolding material in tissue engineering. Scaffold, by definition, is a temporary supporting structure for growing cells and tissues. It is also called synthetic ECM, which plays a significant role in supporting the cells to accommodate. These cells then undergo proliferation, migration, and differentiation in 3D and eventually lead to the formation of a specific tissue with appropriate functions. Numerous studies have reported the prospects of nanobiomaterials as tissue scaffolds. Nanobiomaterials generally refers to biomaterials with the basic structural unit less than 100 nm (nanostructured), crystalline solids with a grain size less than 100 nm (nanocrystals), ultrafine powders with an average particle size less than 100 nm (nanopowders), and extremely small fibers with a diameter less than 100 nm (nanofibers). A nanometer is a billionth of a meter ( $10^{-9}$  m). For ease of understanding, Fig. 5.5 illustrates the scale of some of natural and manmade things, highlighting nanoscale items [19]. Notably, all hard and soft tissues of our body contain plenty of cells living in ECM at the nanoscale hierarchical structure elegantly designed by the Mother Nature. For example, bone tissue can be considered as an assembly of various levels of hierarchical structural

units designed on many length scales ranging from macro to nano, using essential organic and inorganic components, to facilitate multiple functions required for tissue formation (Fig. 5.6) [20]. The nano- or micro-featured environment of the ECM is critical for the proper functions of cells and tissues. The cells can, reportedly, attach and organize better around the nanobiomaterials than around their micro-scale counterparts because of their typical surface properties [21]. The fact is that nanobiomaterials have more atoms and crystal grains at the surfaces, and possess higher surface area to volume ratio, than conventional microscale biomaterials, making the surface of nanobiomaterials more reactive to cultured cells (during *in vitro*) and to host tissue (during *in vivo*), and thus greatly enhancing the cell-matrix interactions, leading to faster tissue regeneration. In this regard, the rate of tissue regeneration will be greater for nanobiomaterials than for conventional biomaterials. Nanobiomaterials are, therefore, perceived to be beneficial for tissue engineering applications as a new generation scaffolding material. To facilitate these measures, the scaffold should possess a few essential characteristics, which are discussed below.

#### 5.4.1

##### Characteristics of Scaffold

The structural and behavioral characteristics of the tissue scaffold are critical to ensure normal cell activities and performance of the cultured tissues. An ideal scaffold for tissue engineering should possess all the qualities of a natural ECM and should function in the same way as that of ECM under physiological conditions. However, there is no clear guideline as to which characteristic defines the so-called ideal scaffold. Notably, the characteristics of a scaffold vary according to the tissue types where the scaffold is to be applied. For example, scaffold for engineering

Tab. 5.1. Characteristics of tissue scaffold.

Characteristics	General remarks
Biocompatible	Biologically compatible to host tissue, i.e., should not provoke any rejection, inflammation, and immune responses
Biodegradable	The rate of degradation must perfectly match the rate of tissue regeneration and the degraded product(s) should not harm the living tissues
Vascular supportive	Should provide channels for blood supply for fast and healthy tissue regeneration
Non-toxic	Should not evoke toxicity to tissues
Non-immunogenic	Should not evoke immunogenic response to tissues
Non-corrosive	Should not corrode at physiological pH and at body temperature
Porosity with interconnected pores	To maximize the space for cellular adhesion, growth, ECM secretion, revascularization, adequate nutrition and oxygen supply without compromising mechanical strength
3D structure	To assist cellular ingrowth and transport of nutrition and oxygen
High surface area to volume ratio	To accommodate high density cells
Surface modifiable	To functionalize chemical or biomolecular groups to improve tissue adhesion
Adequate mechanical strength	To withstand hemodynamic and other biological forces <i>in vivo</i>
Sterilizable	To avoid toxic contamination

bone tissues requires an osteoconductive feature but it is not required for engineering nerve or dermal tissues. Table 5.1 gives some of the basic characteristics of a perfect scaffold for generalized tissue engineering applications. Any scaffold, irrespective of applications, should be biocompatible, meaning that it should not provoke any rejection, inflammation, and immune responses. The scaffold should provide a 3D template with interconnected porous architecture for the maximum loading of cells, tissue in-growth, and transportation of nutrients and oxygen. It should be able to facilitate several biochemical and biological process, in synthesizing specific proteins, required for a healthy tissue growth in the bodily environment. Notably, most tissue engineering applications require scaffolds that are bio-

degradable, but the rate of degradation must match the rate of tissue regeneration. The scaffold should be mechanically strong to withstand hemodynamic and other biological forces *in vivo*, otherwise it may hinder tissue formation. Besides, the scaffold should have high surface area to facilitate better cell adhesion and interaction with each other, and should also have a surface roughness similar to that of natural tissues for the occurrence of enhanced host tissue interactions. The scaffold should also be vascular supportive because cells will not survive without an adequate blood supply. Finally, the scaffold should be stable during storage, and must be sterilizable, to avoid toxic contaminations, without compromising any structural and other related properties. The pragmatic success of tissue scaffold is not only dependent on the above measures but also on appropriate communication between the cells, tissues, and the host system as a whole.

#### 5.4.2

#### **Types of Scaffolding Materials**

The materials used to manufacture scaffold play a key role in supporting the growth of cells, which are cultured on the scaffold. In this regard, selection of materials is of great importance for the success of tissue engineering. Based on the facts discussed in Section 5.4, nanobiomaterials are perceived to be more beneficial than their microscale counterparts owing to their superior surface characteristics. Nanobiomaterials currently investigated as scaffolding materials for tissue engineering applications can be classified into four types: metals, ceramics, polymers, and composites thereof (Table 5.2). Each type of material has its own distinct properties that can be advantageous for specific tissue engineering. The choice of materials depends on the type of tissue to be reconstructed. For example, metals and ceramics are widely used for manufacturing scaffolds for hard tissue applications, whilst polymers are used for soft tissue applications, and composites are considerably used for both the applications due to their mechanical properties (Table 5.3) [22–24]. This information helps clinicians to choose a right material for a specific application. In the following sections we focus on the widely used nanobiomaterials, in particular ceramic and polymeric nanobiomaterials, for tissue engineering applications.

##### 5.4.2.1 **Ceramic Nanobiomaterials**

Ceramics represent a class of nanobiomaterials that is widely used as a scaffolding material in hard tissue repair and regeneration (e.g., bone). The ceramics used in tissue engineering can be classified into three major groups corresponding to their ability to interact with host tissue: (a) bioinert (e.g., alumina and zirconia), (b) bioactive (e.g., HA and bioglass), and (c) bioresorbable [e.g., tricalcium phosphate (TCP)]. It is desirable, for bone tissue engineering, that the scaffolding material mimic the natural bone in chemical composition and phase structure, to facilitate better osteointegration and other related functions. In this regard, HA [hydroxyapatite,  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ ] may be considered a good choice of scaffolding material. We, therefore, focus on the properties and the various processing methodologies of

Tab. 5.2. A broad classification of nanobiomaterials.

Nanobiomaterials	Advantages <sup>a</sup>	Disadvantages	Applications	Examples
Metals & alloys	Strong, tough, ductile	Dense, may corrode, difficult to make	Load-bearing bone implants, dental restoration, etc.	Nanostructured titanium and Ti-6Al-4V alloys
Ceramics	Bioinert Bioactive Bioresorbable High resistance to wear, corrosion resistance	Brittle, low toughness, not resilient	Low weight-bearing bone implants, dental restoration, tissue scaffolds, bone drug delivery, etc.	Nano alumina Nano HA Nano TCP
Polymers	Flexible, low density, resilient, surface modifiable, chemical functional groups	Low stiffness, may degrade	Tissue scaffolds, drug delivery, breast implant, sutures, skin augmentation, blood vessels, heart valves, etc.	Collagen and PLLA nanofibers
Composites	Strong, design flexibility, enhanced mechanical reliability than monolithics	Properties might be varied with respect to fabrication methodology	Tissue scaffolds, drug delivery, dental restoration, spinal surgery, etc.	Nano HA-collagen, nano HA-PLLA

<sup>a</sup> Common characteristics of nanobiomaterials, such as biocompatibility, high surface area, etc. are not highlighted.

HA in detail. HA possesses most of the qualities required for bone tissue engineering, in particular biocompatibility, bioactivity, and osteoconductivity. Table 5.4 gives a compilation of some of the physical, mechanical, chemical, and biological properties of HA that make it an appropriate scaffolding material [1, 23–29]. As per the literature survey, several methods for processing HA, either from natural sources (e.g., coral exo-skeleton and animal bone) or from synthetic sources (e.g., inorganic chemical synthesis), have been reported [30–36], but these studies concentrated on microscale HA.

Recently, nanoscale HA has received much attention owing to its superior surface functional properties over its microscale counterpart, particularly surface area and surface roughness, which are the most imperative properties of nanobiomaterials.

rials because of enhanced cell–matrix interactions. For the past few years, significant research effort has been devoted to the production of nanosize HA [37–39], to obtain high surface reactive materials with enhanced physicochemical and biological properties compared with their microscale counterparts and, at the same time, quite similar to natural bone mineral. It has also been proved that the nano HA, compared with conventional HA, promotes osteoblast adhesion, differentiation and proliferation, which leads to enhanced formation of new bone tissue within a short period [21, 40]. With reference to this information, nano HA may be considered as a unique class of ceramic scaffolding material for bone tissue engineering. The nano HA can be synthesized by many different methods, including solid state [41], wet chemical [42, 43], hydrothermal [44, 45], mechanochemical [46], pH shock wave [47], and microwave processing [48]. Table 5.5 depicts some of the general remarks on these methods, and the detailed processing conditions of nano HA are described in the following sections.

Tab. 5.5. Methods involved in the synthesis of nano HA.

Methods	Grain sizes (nm)	General remarks	Ref.
Solid state	500	Inhomogeneous, large grain sizes, irregular shapes, reaction temp.: 900–1300 °C	41
Wet chemical	20–200	Nano size grains, low crystallinity, homogeneous, reaction conditions: room temp. to 100 °C at elevated pH	42, 43
Hydrothermal	10–25	Homogeneous, ultrafine particles, reaction condition: high temp. and high pressure atmosphere	44, 45
Mechanochemical	<20	Easy production, semi-crystallinity, ultrafine crystals, room temp. process	46
pH shock wave	300	High-energy dispersing, nonporous, monocrystalline particles	47
Microwave	100–300	Uniformity, nanosize particles, time and energy saving	48

**Solid-state Reaction** Solid-state reaction has generally been used for the processing of HA at high temperature. HA powders synthesized by this method usually have irregular shapes with larger grain size, and they quite often exhibit heterogeneity in the phase composition, owing to chemical reactions resulting from small diffusion coefficients of ions within the solid. A general formation of HA using the solid-state method is based on Reaction 1:

The key ingredients of this reaction are basically in the solid phase, in which  $\text{CaCO}_3$  acts as a calcium precursor and  $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$  acts as a phosphorous precursor in the formation of HA. The solid-state reaction typically takes place at a very high temperature ( $\sim 1000$  °C). A method for the preparation of HA fibers was introduced using a solid-phase reaction [41]. With this method, the HA fibers were produced by heating a compact consisting of calcium metaphosphate fibers with calcium hydroxide particles at 1000 °C in air, and treated subsequently with dilute aqueous HCl solution to remove unwanted secondary phase substitution such as CaO. The obtained fibers were characterized by various analytical

methods, and the results confirmed the formation of HA with nanostructural features. Therefore, the solid-state reaction can be considered as one of the methods for the production of nano HA.

**Wet Chemical Method** This method is one of the promising methods, widely used in synthesizing nano HA at low temperature, in contrast to the solid-state reaction. HA powders synthesized by using this method have a homogeneous phase composition, but are poorly crystallized owing to the low temperature process. One common wet chemical method of synthesizing HA is based on Reaction (2), which uses calcium hydroxide and orthophosphoric acid as calcium and phosphorous precursors, respectively.

Recently, rod-like nano HA was synthesized by this method [42]. In brief, a  $\text{H}_3\text{PO}_4$  solution (0.3 M) was added drop-wise to a 0.5 M  $\text{Ca}(\text{OH})_2$  solution under continuous stirring at room temperature, while the pH was kept above 10.5 by the addition of ammonia solution. Stirring was maintained for a further 16 h after complete addition of the reactants. The precipitate thus obtained was further aged for a week and was examined for phase purity and chemical composition using various analytical methods. The results indicated the possibility of producing phase pure, nanosize, and rod-like HA by a wet chemical method. Our group, Murugan et al. [38, 43], have also synthesized HA nanoparticles by using this method, and have extensively studied their physicochemical and physiological properties at body pH. The results clearly showed the enhanced resorbable characteristics of nano HA compared with their microscale counterpart, owing to their larger surface area to volume ratio, which ultimately makes the nano HA highly surface reactive. Based on these experimental data, the wet chemical method is one of the most promising methods for the production of nano HA.

**Hydrothermal Process** This hydrothermal process involves the reaction of an aqueous solution of calcium and phosphorous precursors at ambient temperature and pressure for the production of nano HA. It enables the synthesis of crystallized HA with homogenous phase composition. The HA so-prepared is easily sinterable, owing to the effects of high temperature and high pressure aqueous solutions. Zhang and Consalves [44] have synthesized nano HA by precipitating the precursors under hydrothermal conditions, and they studied its thermal stability in detail. By using this approach, they obtained rod-like, nano-sized HA with an average crystal size of 10 to 24 nm, according to the composition of the precursors. They prepared various HA powders with a Ca/P ratio ranging from 1.66 to 1.73. In another interesting study [45], the efficacy of nano HA as filler in fabricating tissue scaffold has been reported. The authors produced nano HA by a hydrothermal method. In brief, 2 g of ammonium phosphate dissolved in 37.5 mL of de-ionized water was added to 5.9 g of calcium nitrate dissolved in 22.5 mL of de-ionized water under stirring, and the pH of solution was adjusted to 12 by adding ammo-

nia. The solution was then autoclaved under hydrothermal conditions (170 °C and 19.5 MPa) and subsequently aged for 5 h. The precipitates thus obtained were cooled to room temperature, repeatedly washed with distilled water to remove traces of ammonia and ammonium nitrate, dried at 80 °C overnight, and then ground to a fine powder. Characterization of the powders indicated the formation and purity of HA. The HA particles were ellipsoidal-shaped with needle-like morphologies. The particles were, on average, approximately 25 nm wide and 150 nm long with aspect ratios ranging from 6 to 8, indicating nanostructure features. The authors further investigated the efficacy of nano HA as filler in polymer matrix in fabricating porous 3D tissue scaffolds. The results showed that the scaffold consisting of nano HA and polymer should be suitable for non-load sharing tissue engineering applications as compared with scaffold made of polymer alone, owing to their enhanced compression modulus.

**Mechanochemical Route** Production of nano HA by the mechanochemical route has gained interest in recent years, owing to its simplicity. The processing conditions involved in this method slightly differ from the conventional wet chemical method. Notably, the purity of material synthesized by conventional wet chemical method depends on the reaction pH, whereas reaction through the mechanochemical route need not be under precise pH control. Nakamura et al. [46] have reported the synthesis of nano HA by using this method. The HA was prepared directly by milling a mixture of  $\text{Ca}(\text{OH})_2$ ,  $\text{H}_3\text{PO}_4$  and a dispersant, an ammonium salt of polyacrylic acid. The reaction was carried out at room temperature. The prepared HA powders have relatively crystallized particles in the nanometer regime. The average crystallite size was 20 nm. The authors suggested some of the merits of this method, which include (a) assisting deprotonation from brushite to form HA and (b) keeping high dispersibility and low viscosity of reaction sol. This method is of particular interest in synthesizing nano HA with ultrafine crystallite sizes.

**pH Shock Wave Method** Another interesting method for the production of nano HA is pH shock wave. Koumoulidis et al. [47] have reported the synthesis of HA in the form of lath-like monocrystalline particles using the precursors of  $\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O}$  and  $\text{CaCl}_2$ . They employed high-energy dispersing equipment to synthesize nano HA. The prepared HA was characterized by various analytical methods to determine the phase composition, structure, and texture. The results showed that the material has a different Ca/P molar ratio (1.43 to 1.66) with respect to processing conditions. The crystal grains of HA were 140–1300 nm long, 20–100 nm wide, and 10–40 nm thick. With reference to experimental results, this method seems to be quite interesting because it creates appropriate hydrodynamic conditions for lath-like particle growth in the [001] direction, which could not be obtained by using conventional mechanical stirring equipment.

**Microwave Processing** Microwave-assisted synthesis of ceramic nanobiomaterials is a relatively new method, which has recently been of interest in synthesizing nano HA. Sarig and Kahana [48] reported the processing conditions for the rapid

formation of nanocrystalline HA. Briefly, the recipe for the synthesis of nano HA is: the HA powder was precipitated from  $\text{CaCl}_2$  10 mM aqueous solution (A) and  $\text{NaH}_2\text{PO}_4$  6 mM aqueous solution (B). The solution A was used without admixture, whereas the solution B was made with a concentration of 25 ppm with respect to L-aspartic acid and 150 ppm with respect to  $\text{NaHCO}_3$ . Both solutions were kept at pH 7.4 by admixture of Trizma. This pH was selected to make the HA appropriate for medical applications. Equal volumes of solutions A and B (250 mL each) were introduced simultaneously into a 1000 mL beaker, which was put into a 2450 MHz microwave oven at maximum power for 5 min. The microwave-irradiated mixture was then quenched in ice for 30 min. The resultant precipitate was filtered off, washed with water, and dried overnight at 55 °C. The powder thus obtained was characterized and found to be bouncy and free-flowing. It was composed of spherulites of about 2–4  $\mu\text{m}$  in diameter, and the spherulite was composed of ultrafine platelets of about 300 nm. Notably, the powder exhibited a quite peculiar behavior on storage, in contrast with commercial apatites. Commercial powders usually tend to aggregate and form large solid lumps, whereas the powder produced by this method remained free-flowing after 3 years of storage in non-hermetically closed containers. Yang et al. [49] further reported the sintering effect of HA by using microwaves. They synthesized HA by precipitating the calcium and phosphorous precursors at 95 °C with a pH of 9 to 11.5. The HA green samples were sintered by microwave heating and the results were compared with other HA green samples sintered by a conventional heating method. The results clearly indicated that the HA prepared by microwave processing was denser and had a finer grain size than those prepared by the conventional heating method, which is the merit of microwave processing. Overall, microwave-assisted synthesis offers the advantages of uniform heating throughout the volume with very efficient transformation energy within a short period; thereby, it may be considered as a suitable method for the production of HA nanocrystals.

#### 5.4.2.2 Polymeric Nanobiomaterials

Polymers, the largest class of biomaterials, are made up of repeated small and simple chemical units called monomers. The term “polymer” was derived from two Greek words, *polys* meaning “many” and *meros* meaning “units”. Polymers in the form of nanofibers are considered as a unique class of scaffolding material and are in demand for various tissue engineering applications compared with other types of nanobiomaterials, owing to their functional properties, design flexibility, and surface modifiability. The polymer nanofibers used for this purpose are commonly called polymeric nanobiomaterials. A nanofiber generally refers to a fiber having a diameter size in the range of 1 to 100 nm. Although the polymer nanofibers have many desirable characteristics, they tend to possess low mechanical strength (e.g., low stiffness) compared with nanophase metals and ceramics; thereby, they are often used in soft tissue reconstructions, but are also used in hard tissue reconstructions in conjunction with nanophase ceramics. The following sections focus on the major classification of polymers and emphasize widely used biodegradable

polymers in the process of nanofibrous scaffolds for tissue engineering applications.

Polymers used in tissue engineering can be grouped into (a) naturally-derived and (b) synthetic polymers. Naturally-derived polymers are biodegradable. Collagen, gelatin, and chitosan are a few notable examples. Synthetic polymers can be either biodegradable or non-biodegradable. Poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and poly(lactic-co-glycolic acid) (PLGA) are notable examples of biodegradable polymers, and poly(ethylene) (PE), poly(ethylene terephthalate) (PET), and poly(tetrafluoroethylene) (PTFE) are notable examples of non-biodegradable polymers. In most circumstances, biodegradable polymers, either from natural or from synthetic origin, are considered as good choice for tissue engineering rather than non-biodegradable polymers. However, degraded products from the biodegradable polymers must be non-toxic and should not elicit any foreign body reaction. Based on their astonishing qualities, we further focus our attention on some of the widely used biodegradable polymers, both naturally-derived and synthetic, in tissue engineering applications.

**Naturally-derived Biodegradable Polymers** Collagen is the most widely used naturally-derived polymer in designing scaffolds for tissue engineering. It is a primary structural protein of the natural ECM and hence natural collagen has various functional characteristics favorable for cells and tissue growth. Although many types of collagen exist in a living organism, the most abundant forms in native tissue are types I and III. Type I collagen is composed of two  $\alpha_1$  (I) chains and one  $\alpha_2$  (I) chain in the triple helix pattern with a fiber diameter of about 50 nm. Type III collagen is composed of three  $\alpha_1$  (III) chains with fibers ranging from 30 to 130 nm in diameter. Structurally, collagen is composed of three polypeptides ( $\alpha$ -chains) that are each coiled into a left-handed helical pattern, and then these three chains are wrapped around each other into a right-handed helical pattern, resulting in well-organized rope-like fibers of great structural strength. The triple-helical domain has a characteristic primary structure, where glycine in every third amino acid generates repeating (Gly X-Y)  $n$  units, where X is alanine or proline, and Y is hydroxyproline. In general, collagen extracted from natural tissues is capable of eliciting an immunogenic response upon implantation; thereby direct use of this type of collagen is limited. Nowadays, a purified form of collagen known as reconstituted collagen, which has relatively lesser immunogenic response, is produced by various biochemical methods and is commercially available for tissue engineering applications.

Gelatin is a denatured form of collagen, obtained by acidic and alkaline process, widely used in tissue engineering as a scaffolding material. There are two types of gelatin, namely A and B, which are identified by the method of processing from the native collagen. Gelatin A can be obtained by the extraction of collagen by acidic treatment, and gelatin B can be obtained by the extraction of collagen by alkaline treatment. Gelatin B has a higher content of carboxylic groups than gelatin A owing to their biochemical processing. Although gelatin is a denatured form of

collagen, it has its own functional properties. Gelatin is a highly biocompatible, bioresorbable, non-toxic, and non-immunogenic natural polymer. It does not elicit any noticeable antigenic response and has a low coagulation activity towards platelets. Based on these characteristics, gelatin has some individual importance as a scaffolding material for various tissue engineering.

Chitosan is also a naturally-derived polymer (polysaccharide), which is obtained by alkaline deacetylation of chitin. The chitin is extracted from the exoskeleton of shellfish. Basically, this process consists of two steps: (a) deproteination of the shells with a dilute sodium hydroxide solution and (b) decalcification with a dilute hydrochloric acid solution. The chitin thus obtained is subjected to N-deacetylation by treatment with a 40–45% of sodium hydroxide solution followed by purification procedures, resulting in chitosan. Chemically, it is a copolymer of  $\beta(1-4)$  linked 2-acetamido-2-deoxy-D-glucopyranose and 2-amino-2-deoxy-D-glucopyranose. It is a weak base and thus it is insoluble in water and in a few organic solvents, but it is soluble in dilute aqueous acidic solution with  $\text{pH} < 6.5$ . It is a biocompatible, biodegradable, and non-toxic polymer. It shows good antimicrobial and antifungal activities. Due to its natural abundance and specific physicochemical and biological properties, it is used in tissue engineering applications. Further, its plasticity and adhesiveness make chitosan a suitable binder for various biomedical applications.

**Synthetic Biodegradable Polymers** Synthetic biodegradable polymers play an increasingly pivotal role in tissue engineering. These polymers offer many advantages over naturally-derived polymers in that they can be easily tailored to provide a wide range of functional properties; in particular, freedom from concerns of immunogenicity. Further, they are easily processable, surface modifiable, and sterilizable. Notably, not all the polymers are widely used in tissue engineering, but there are a few polymers (e.g., PLA, PGA, and PLGA) that have been approved for clinical applications by the US Food and Drug Authority, which can be considered for tissue engineering applications.

PLA is one of the most frequently used synthetic polymers in designing tissue scaffolds, owing to its functional characteristics that favor cell and tissue growth. It has two enantiomeric forms: (a) the left-handed (L-lactide), and (b) the right-handed (D,L-lactide). These two enantiomers have different degradation rates. Hydrolysis is the principal mode of degradation and it is greatly affected by the hydrophilicity and crystallinity of the polymer. The degradation products of PLA are non-toxic. The L-lactide is widely used for tissue engineering applications owing to its superior biocompatibility and prolonged biodegradation compared with D,L-lactide. Furthermore, it possesses high strength and modulus. The D,L-lactide possesses, in contrast, low strength and modulus, and undergoes rapid biodegradation.

PGA is the simplest form of linear aliphatic polyester, being used in various tissue engineering applications. It is also a biocompatible and a biodegradable polymer. It can be synthesized by ring-opening polymerization of glycolic acid, but does not form any enantiomers like PLA. It is highly crystalline and is a hydro-

philic polymer. The percent crystallinity ranges from 45 to 55. Owing to its hydrophilic nature, it is completely absorbed within 4 to 6 months upon implantation. It exhibits a high tensile strength, modulus, and is also stiff, making it suitable for biomedical applications.

PLGA is a copolymer that consists of PLLA and PGA macromolecular units. By changing the composition of copolymeric units, the rate of degradation and mechanical strength of PLGA can be manipulated. This kind of copolymer has less crystallinity and degrades faster than homopolymers. For example, a copolymer of 50% PGA and 50% PLLA degrades much faster than each homopolymer. The composition of copolymer also significantly affects its percent crystallinity. For example, a copolymer of 90% PGA and 10% PLLA has high crystallinity, whereas a PGA-to-PLLA ratio from 25/75 to 75/25 is relatively amorphous. Owing to its biocompatibility and tunable biodegradability, PLGA is widely used in various tissue engineering applications.

## 5.5 Nanofibrous Scaffold Processing: Current Scenarios

Processing nanofibrous scaffolds with structural features similar to natural ECM is essential for tissue engineering. Numerous studies have been conducted in processing tissue scaffolds quite similar to natural ECM in the authors' laboratory [50–52]. These scaffolds possess high surface area, high aspect ratio, high porosity, small pore size, and low density. These features are essential for the improvement of cell adhesion, which is a significant issue in the initial stage of tissue engineering because cell migration, proliferation and differentiation functions typically depend on the cell adhesion. Although tissue scaffolds can be manufactured by multiple methods, very few methods have the ability to produce scaffolds with nanofibrous structure, which include self-assembly [53, 54], phase separation [55, 56], and electrospinning [57, 58]. Table 5.6 depicts the comparative merits and demerits of these methods. Some of the key aspects of these methods, along with illustrated examples, are briefly described in the following sections.

### 5.5.1 Self-assembly

The past few years has seen great interest in self-assembling processes for manufacturing scaffolds suitable for tissue engineering. Self-assembly is simply a process in which individual, pre-existing components organize themselves into an ordered structure required for specific functions without human intervention. The key challenge in self-assembly is to design molecular building blocks that can undergo spontaneous organization into a well-defined pattern that mimics complex biological systems. Self-assembly takes place by non-covalent bonding, which typically includes hydrogen bonding, ionic bonding, hydrophilic and van der Waals

Tab. 5.6. Comparison of various nanofibrous scaffold processing methods.

Scaffold processing methods	General descriptions	Level of processability	Level of productivity	Merits	Demerits
Self-assembly	A process in which atoms, molecules, and supramolecular aggregates organize and arrange themselves into an ordered structure through weak and non-covalent bonds; typically involves a bottom-up approach	Difficult	Lab scale	Mimic the biological process in certain circumstances	Complex process, limited to a few polymers, unable to produce long and continuous fibers with control over fiber orientation
Phase separation	A process that involves various steps, typically raw material dissolution, gelation, solvent extraction, freezing and drying, leading to the formation of nanofibrous foam-like structure	Easy	Lab scale	Simple process, tailorable mechanical properties	Limited to a few polymers, longer processing time, unable to produce long and continuous fibers with control over fiber orientation
Electro-spinning	A process that essentially employs electrostatic forces for the production of polymer nanofibrous scaffolds; typically involves a top-down approach	Relatively easy	Lab and industrial scales	Simple and cost effective process, capable of producing long and continuous fibers with control over fiber orientation; versatile to many polymers	Use of high voltage apparatus

interactions. Although each of these forces is rather weak, their collective interactions could produce a very stable structure that could match the structural features of biological systems.

Recently, peptide-amphiphile (PA) nanofibers were developed by a self-assembling process for cell transplantation [53] and to direct biomineralization of HA [54]. Beniash et al. [53] have demonstrated the feasibility of PA molecules to self-assemble into 3D nanofibrous scaffold under physiological conditions, and their efficacy in cell entrapment was studied. The results indicated that cells entrapped in the nanofibrous network can survive and proliferate well, which suggests that the self-assembled PA system could be used for cell transplantation or other related tissue engineering applications. Hartgerink et al. [54] have further revealed the potential of self-assembled PA nanofibrous scaffold to direct self-biomineralization. They reported a PA molecule that self-assembles into a nanostructural gel and mimics some of the key features of the natural ECM of bone tissue. They processed the PA nanofibers with negatively charged surfaces because it is believed that this promotes biomineralization by establishing local ion supersaturation. The experimental results confirmed that the PA fibers are capable of nucleating HA on their surfaces. It was also noticed that the c-axes of HA crystals are co-aligned with the long axes of PA fiber that nucleates the structural orientation between collagen and HA observed in the natural bone tissues. Therefore, this self-assembled system could be promising for mineralized tissue repair.

### 5.5.2

#### Phase Separation

Phase separation is an interesting method used for manufacturing tissue scaffolds, which involves various processing steps, typically raw material dissolution, gelation, solvent extraction, freezing, and drying. Of course, these steps to convert the polymer into a nanofibrous structure would take a prolonged time. The unique advantage of this method lies in the possibility of designing 3D nanostructures without using any special equipment. Furthermore, the porosity and mechanical properties of scaffold can be controlled to some extent, but it is very difficult and perhaps not feasible to maintain the fiber orientation. Tissue scaffolds using poly(L-lactic acid) (PLLA) were recently fabricated by the authors' group using this phase separation method [55]. They processed scaffolds with highly porous and fibrous structures close to natural ECM. The fiber diameters ranged from 50 to 300 nm with an average of 150 to 250 nm, according with the polymer concentration used in the experimental process. The scaffolds were further evaluated with neural stem cells under *in vitro* cell culture conditions. The results indicated that the cells differentiated well on the nanofibrous scaffolds and the scaffolds served as a positive cue in supporting neurite outgrowth. This study, therefore, suggests that PLLA nanofibrous scaffolds would be promising for neural tissue engineering. Another study, reported by Chen and Ma [56], manufactured nanofibrous PLLA scaffolds with interconnected spherical macropores by a phase separation method, with the aim of mimicking the fibrous architecture of type I collagen protein. By using this

method, they were able to control the structure of the scaffolds, in particular the macroscopic shape, the spherical pore size, interfiber distance, and the fiber diameter at the nanometer size; thereby, the phase separation method has gained considerable interest in processing scaffolds for tissue engineering.

### 5.5.3

#### **Electrospinning – A New Approach**

Although the above methods have been employed to produce nanofibrous scaffolds, they often encountered some difficulties, especially in controlling the fiber orientation of the scaffolds. For the success of tissue engineering, it is desirable to control not only the fiber diameter but also the fiber orientation of scaffolds. For various tissue engineering applications, it is necessary to produce scaffolds with control over fiber orientation because alignment of the fibers predominantly influences the cell growth. Therefore, importance is given to a method that facilitates a well-defined fiber orientation and control over fiber thickness. Recently, considerable efforts have been made world-wide to process nanofibrous scaffolds with fiber orientation by so-called electrospinning.

Electrospinning is a straightforward, cost-effective, and versatile technique that essentially employs electrostatic forces to produce polymer fibers, ranging in diameter from a few microns down to tens of nanometers. This technique was first introduced by Zeleny in 1914 [59]. Later, Formhals contributed much to the development of electrospinning and, prolifically, obtained several patents in the 1930s and 1940s [60–64]. In those days it was called electrostatic spray or electrostatic spinning, and subsequently renamed as electrospinning in the 1990s. However, this technique was not adopted for tissue engineering as a tool for manufacturing tissue scaffolds at the time of invention, but it was used in other industrial applications. Recently, it has been revitalized and has been successfully applied in processing nanofibrous scaffolds suitable for tissue engineering. The precise merit of this technique is that it could produce scaffolds with most of the structural features required for tissue engineering. It also offers many advantages over conventional scaffold methodologies, e.g., it can produce ultrafine fibers with spatial orientation, high aspect ratio, high surface area, and having control over pore geometry. These are some of the favorable characteristics to be considered for better cell growth because they directly influence the cell adhesion, cell expression, and transportation of oxygen and nutrients. In this light, electrospun scaffold can serve as a good tissue scaffold and could provide spatial environment for the growth of new tissue with appropriate functions.

##### **5.5.3.1 Experimental System**

Figure 5.7 illustrates schematically the basic configuration of electrospinning [24], which consists of three major components: (a) a spinneret, (b) a fiber collector, and (c) a high-voltage power system. As illustrated in the figure, the spinneret is directly connected to a syringe, which acts as a reservoir for the polymer solution to be electrospun. This polymer solution can be fed through the spinneret with the

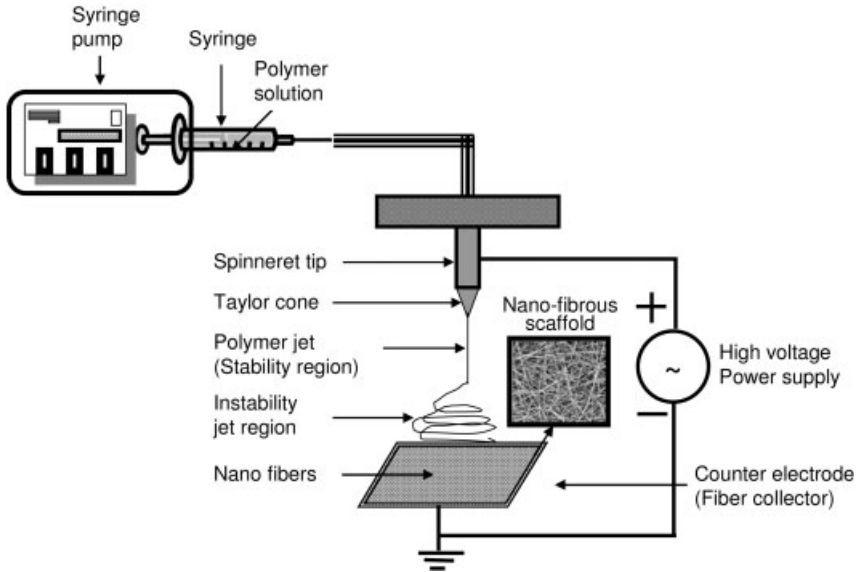

Fig. 5.7. Schematic of the electrospinning system. (Adopted and modified from Ref. [24].)

help of a syringe pump at a steady and controllable feed rate. The feeding rate can be controlled, corresponding to the concentration of polymer solution. Notably, the material to be spun by this technique must be viscous, but the viscosity may vary, depending on the type of materials used. The fiber collecting device is positioned immediately below the spinneret, with an appropriate gap. A high-voltage/low-current power system is required for the conversion of polymer solution into a charged polymer jet. The electric power (usually up to 30 kV) is applied across the spinneret and the grounded metallic counter electrode (fiber collector) to facilitate ejection of the charged jet from the spinneret tip towards the surface of the fiber collector.

### 5.5.3.2 Spinning Mechanism

Although the experimental design and functional components of electrospinning seems to be extremely simple, mechanism involved in the spinning of polymer nanofibers is rather complicated. Upon applying an optimized electric potential to the spinneret, a pendent droplet of the polymer solution at the tip of the spinneret gets electrified, thereby inducing charge accumulation on the surface of the droplet that subsequently allows the droplet to deform into a cone, known as Taylor's cone [65]. This deformation is commonly caused by two electrostatic forces: (a) electrostatic repulsion between the surface charges of the droplet and (b) Columbic force exerted by the strong external electric field applied [66]. Once the applied electric field surpasses a critical value (threshold), the electrostatic force tends to exceed the viscoelastic force and the surface tension of the polymer droplet; thereby, a

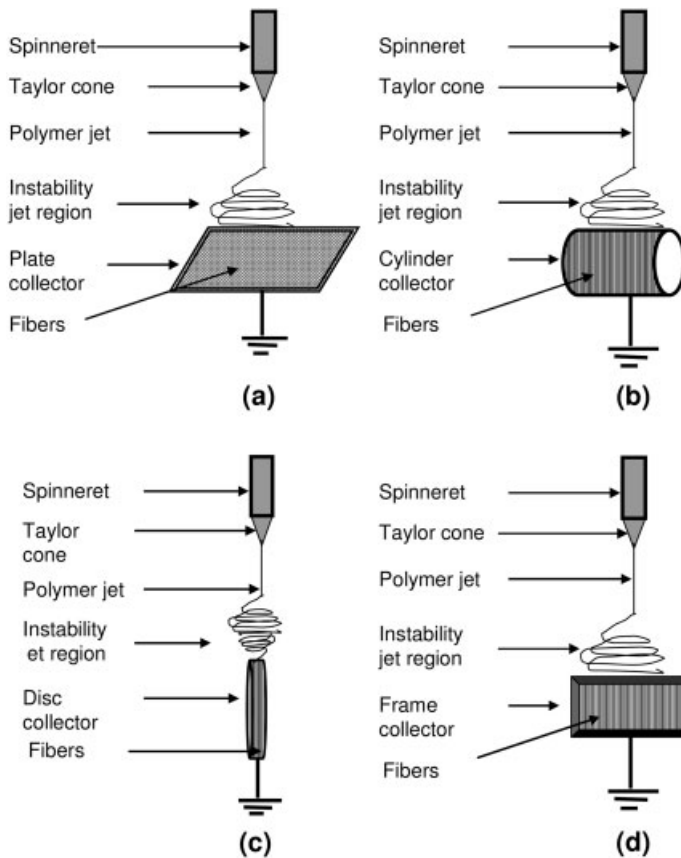

Fig. 5.8. Types of fiber collector.

fine charged polymer jet is forced to eject from the tip of the Taylor cone. This polymer jet then moves toward the counter electrode, accompanied by rapid evaporation of the solvent molecules and, while in transit, the different polymer strands in the jet are separated out due to the mutual repulsion, a phenomenon called “splaying” [67], which gives rise to a series of ultrafine dry fibers. These fibers can be collected on a grounded metallic target (fiber collector) and are typically in the range of a few micrometers to nanometers.

Notably, different types of fiber collectors are available, corresponding to spatial orientation (Fig. 5.8). For example, rotating-type collectors can be used to obtain aligned nanofibers, whilst static-type collectors can be used to obtain random nanofibers. The alignment of the fibers is rather complicated and numerous parameters influence the fiber orientation, including the rotational speed and shape of counter electrode, the concentration of polymer solution, the dielectric constant of the solvent, the strength and shape of the electric field, and the environmental conditions such as relative humidity and temperature.

**Fig. 5.9.** SEM micrographs of electrospun nanofibrous scaffolds made of (a) collagen, (b) poly(L-lactide), showing scattered nanopores, (c) poly(L-lactide), showing randomly-oriented fibers, and (d) poly(L-lactide), showing well-aligned fibers. (Adopted with permission from Refs.[57, 68, 58, and 58], respectively.)

### 5.5.3.3 Electrospun Nanofibrous Scaffolds

This section explicates how electrospinning can be adopted to produce nanofibrous scaffolds using a few biodegradable polymers suitable for tissue engineering. Matthews et al. [57] have processed collagen nanofibrous scaffolds; Fig. 5.9(a) shows a representative scanning electron microscopy (SEM) image of such a scaffold. The results indicate that the scaffold is composed of randomly-oriented nanofibers with an average diameter of  $100 \pm 40$  nm. The morphology of collagen structure is quite analogous to the natural ECM; therefore, they suggested that it may be used as a good scaffolding material in tissue engineering. Bognitzki et al. [68] have revealed the possibility of spinning PLLA nanofibrous scaffolds with nanopores. Figure 5.9(b) is a representative SEM micrograph of such a scaffold, showing that each fiber has a beautiful porous structure with well-defined nanopores. The average pore was 100 nm wide and 250 nm long. The size and density of the pores can be controlled by manipulating the spinning parameters. Elongation of the pores along the fiber axis, which is obvious from the SEM micrograph of Fig. 5.9(b), is the result of a uniaxial extension of the polymer jet in the high electric potential.

Recently, our group, Yang et al. [58], also reported the feasibility of spinning PLLA nanofibrous scaffolds suitable for tissue engineering. A representative SEM

micrograph of the scaffold is shown in Fig. 5.9(c), which provides a complete detail on size, shape, and pores of the scaffold architecture. The average fiber diameter was 700 nm and the fibers are randomly orientated. They revealed that spatial orientation of the nanofibers mainly depends on the concentration of polymer solution and rotational speed of the fiber collector. Yang et al. [58] further reported the feasibility of spinning PLLA nanofibrous scaffolds with well-defined fiber orientation perfectly suitable for tissue engineering. Briefly, the spinning conditions to obtain such scaffolds are: first, PLLA was dissolved in dichloromethane and *N,N*-dimethylformamide (70:30) at a concentration of 2%. The polymer solution was extruded at a constant flow rate ( $1.0 \text{ mL h}^{-1}$ ) by keeping the distance between the spinneret tip and the fiber collector at 10 cm. A high voltage power supply (12 kV) was applied to the tip of the spinneret using a regulated DC power system. Once the applied voltage reaches the threshold, continuous long and ultrafine fibers eject from the spinneret tip and deposit on the surface of the fiber collector. Note that a sharp-edge rotating disc was used as a fiber collector in this study. A representative SEM micrograph of such a nanofibrous scaffold is shown in Fig. 5.9(d). The results show that a high order of alignment on the fiber orientation was obtained, with fiber diameters ranging from 100 to 400 nm (average is 300 nm). The nanofibrous scaffolds with fiber orientation could be potentially ideal for tissue engineering since the fiber orientation of the scaffolds very much influences cell orientation and phenotypic expression [69]. Therefore, manufacturing nanofibrous scaffolds with fiber orientation is of great importance for the success of tissue engineering, which is now practically possible by the so-called electrospinning method.

## 5.6

### Cell–Matrix (Scaffold) Interactions

#### 5.6.1

##### Cell–Ceramic Scaffold Interactions

As mentioned above, ceramic nanobiomaterials, particularly nano HA, have considerable interest in tissue engineering, owing to their excellent cell compatibility and bio-activity. Several studies have reported *in vitro* and *in vivo* assessments of the biological responses to nano HA. Table 5.7 lists a few notable examples of tissue scaffolds made from HA-based nanobiomaterials [70–76]. Recently, Huang et al. [70] have reported the *in vitro* assessment of the biological response to nano HA. They prepared the nano HA by a precipitation reaction, and the nano HA suspension was subsequently electrospayed onto glass substrates using a novel processing route to maintain nanocrystals of HA. The *in vitro* cell-compatibility of nano HA was studied with human osteoblast-like cells. The obtained results are shown in Fig. 5.10. Figure 5.10(a) shows that the prepared HA particles are in the nanometer size range (50–80 nm long), and there are no secondary phase observed as evidenced by X-ray diffraction analysis (Fig. 5.10b), which confirms the phase

purity of nano HA. The results of *in vitro* cell culture studies confirmed the ability of nano HA in supporting cell adhesion and growth. The cells were able to attach to the nano HA surfaces and maintain their osteoblastic morphology with visible filopodia attached to nano HA particles (Fig. 5.10c). There were large areas of confluent cells after seven days of culture and fiber-like ECM was produced (Fig. 5.10d), which provides evidence for the better cell–matrix interactions.

The *in vitro* response of sol–gel derived nano HA with human MSCs was investigated to confirm their biocompatibility and bioactivity [71]. The *in vitro* results showed that the human MSCs adhered to nano HA and exhibited better proliferation signals on their surface. Evidence of proliferation of MSCs was observed with a tendency to spread onto the surface as if forming groups, thus supporting not only biocompatibility but also enhanced bioactivity of the material. This behavior is considered important, since it simulates, on an artificial surface, several steps of the cell-cycle occurring in a tissue environment, with no need for an interfacial protein scaffold. The authors concluded that these surfaces interact with the MSCs in a manner that might be useful for tissue engineers to design scaffolds as an alternative to biological ECM. Porous biomaterials are of great interest in tissue engineering as cells and tissues invade pores for their extensive growth, and they also help the transportation of nutrient and oxygen supply to the cells. Besides, the pores provide a mechanical interlock, thereby leading to a firmer fixation of the biomaterials upon implantation. As bone tissue grows well into the pores, it is expected to increase the strength of the implanted biomaterial. *In vitro* studies on the enhanced functions of osteoblasts (bone-forming cells) on ceramic nanobiomaterials have been reported [72]. The authors extensively studied select functions of osteoblasts on nano HA (with grain size of 67 nm) and conventional HA (with grain size of 179 nm) using *in vitro* cellular models. Osteoblasts were seeded onto the HA substrates and cultured under standard cell culture conditions. The results of cell culture studies provided evidence of increased osteoblast proliferation onto nano HA when compared with conventional HA and with to reference substrate (borosilicate glass). Although the osteoblast proliferation trend was similar on nanophase and conventional HA after 1 day of culture, it was significantly greater on nano HA after 3 and 5 days of culture, indicating that the nanophase provides highly adhesive substrate to facilitate better cell adhesion and long-term cell growth. The results further provided evidence of enhanced long-term functions, in particular synthesis of alkaline phosphatase and concentration of calcium in the ECM, of osteoblasts cultured on nano HA than on conventional HA.

Notably, though the nano HA serves as an excellent bone tissue scaffold, it behaves as a typical brittle material; thereby it is used only in certain bone tissue repair applications. To improve reliability, it is necessary to introduce some biocompatible reinforcement agents or matrix materials. However, introduction of foreign materials may decrease the reliability of HA; thereby, choosing the reinforcement agents or matrix materials is of great importance. A composite of nano HA with collagen is perceived to be beneficial in improving the reliability of nano HA, and, at the same time, both are the key components of natural bone tissue (Fig. 5.6). Osteogenic cell-engineered HA/collagen nanocomposite scaffold structures were

developed using culture techniques as well as conventional methods, and their *in vitro* cellular functions were studied [73]. It was noticed that the scaffolds supported well the cellular growth and related functions, leading to new bone formation. Later, a 3D bone-resembling nanocomposite matrix using nanoHA/collagen/osteoblasts was developed in conjunction with PLA [76]. This system supported cellular adhesion, proliferation, and migration. Interestingly, the cells penetrated deep into the matrix to about 200–400  $\mu\text{m}$  within a short period (12 days), probably owing to its composition and structural similarity to natural bone tissue, thereby providing a promising scaffold for bone tissue engineering. In this light, ceramic nanobiomaterials clearly represent a unique and promising class of scaffolding material for tissue engineering applications, but they are limited to hard tissue repair and regeneration.

### 5.6.2

#### Cell–Polymer Scaffold Interactions

This section briefly describes how the polymer nanofibrous scaffolds influence cell growth and related functions. Matthews et al. [57] have processed collagen nanofibrous scaffolds and the *in vitro* cellular compatibility was studied using smooth muscle cells. The results suggest that the scaffold has excellent biocompatibility, cellular compatibility, and capability of promoting cells in-growth and related functions (Fig. 5.11a). This study thus demonstrated the feasibility of using collagen as a good tissue scaffold. Yang et al. [58] processed the PLLA nanofibrous scaffolds, with randomly-oriented fibers, and the *in vitro* cellular compatibility was studied using neural stem cells. The results suggest that the scaffold has excellent biocompatibility, cellular compatibility, and is highly supportive to cell differentiation and related functions. The results further indicated that most of the cells have a bipolar shape with extended neurites and the neurites outgrowth was randomly spread over the scaffold (Fig. 5.11b), a good sign for cell–matrix interactions under *in vitro* cell culture conditions.

Yang et al. [58] also reported the feasibility of processing PLLA nanofibrous scaffolds with well-aligned fibers and the *in vitro* cellular compatibility was studied using neural stem cells. They observed the influence of fiber orientation on the cell growth. Figure 5.11(c) shows a representative phase contrast light microscopy image of cell cultured scaffold. The results indicated that cells were well attached to the scaffold and showed an extensive neurite-like outgrowth, which is a good sign for their differentiation. Interestingly, the results revealed that the cells elongated and their neurites outgrew along the direction of the fiber orientation, which shows the significance of spatial orientation of the fibers on cellular growth behavior. To observe expression of the cytoskeleton proteins of neural stem cells as well as the relationship between the cytoskeleton proteins and fiber orientation of the scaffolds, laser scanning confocal microscopy (LSCM) was performed; Fig. 5.11(d) shows a representative micrograph. The results show that the cells exhibited a classical contact guidance by growing parallel to the fibers. In addition, most of the differentiated cells show a bipolar shape with two extended neurites, which

**Fig. 5.11.** SEM micrographs showing cell–matrix interactions within the electrospun nanofibrous scaffolds made of (a) collagen, (b) randomly-oriented poly(L-lactide) nanofibers. Phase contrast light microscopy (c) and LSCM

emerged from the regions of the somas, parallel to aligned fibers and were symmetrically distributed around the soma. However, some exceptional cases were also noticed (indicated by arrows). Although neurites outgrowth was not affected by the fiber orientation during the initial period, they all turned through large angles to grow in the direction of fiber orientation, which implies the significance of fiber orientation in directing cell growth. The information thus obtained from the above experimental examples provides evidence for the enhanced performance of polymeric nanobiomaterials for tissue engineering applications.

## 5.7

### Concluding Remarks

Being the first inventor, nature sets high standards for researchers who design implants for tissue repair and regeneration. Tissue engineering is emerging as a potential alternative to traditional tissue transplantations, whereby tissue or organ failure is addressed by implanting tissue-engineered nanobiomaterials that holds

the ability to enhance the tissue growth with appropriate functions. Although preliminary investigations seem to support the impact of nanobiomaterials in tissue engineering, significant advancements are necessary to realize their full potential in clinical use. On the other hand, the nanobiomaterials are relatively less available than their microscale counterparts. Presently, there is a trend towards using nanobiomaterials due to their sophisticated surface functional properties, which are favorable for cell growth and host tissue interactions. This is an exciting time to be involved in nanobiomaterials in order to formulate them as a clinically ideal scaffolding system for tissue engineering, with great challenges and also great expectations ahead.

## Glossary

*Adult stem cell:* An undifferentiated cell found in a differentiated tissue that is able to self-renew and to differentiate into tissue-specific cell types from which it originated.

*Allograft:* Tissue or organ transplanted from one individual to another of the same species.

*Alloplast graft:* Any synthetic material substituted to repair or replace defective parts of the body.

*Artificial organ:* A medical device or implant intended to replace the body organs.

*Autograft:* Tissue or organ transplanted within the same body.

*Biactivity:* Ability of the implant, to play a vital role in the metabolic processes of living body.

*Bioceramics:* Inorganic and nonmetallic materials that are compatible with biological tissues.

*Biocompatibility:* Ability of the implant to perform with an appropriate host response in a specific application.

*Biodegradability:* Susceptibility of implant to be decomposed by a living organism.

*Bioinert:* No host response to the material.

*Biomaterial:* Any synthetic material that is biocompatible with the tissues and the body upon implantation. It can be metal, ceramic, polymer, and a composite of each.

*Biom mineralization:* A conversion process mediated by an organic matrix in which inorganic derivatives are produced by living organisms, especially microorganisms.

*Biopsy:* Removal of a small portion of tissue, usually for the purpose of making a diagnosis.

*Bone:* A rigid, yet dynamic connective tissue consisting of calcium phosphate based minerals embedded with collagen fibers in conjunction with osteogenic cellular elements.

*Bone marrow stromal cell:* A kind of stem cell found in bone marrow that has the ability to generate bone, cartilage, and other connective tissues.

*Cell:* Fundamental, structural, and functional unit of all living beings that is composed of an outer membrane enclosing protoplasm and nucleus.

*Collagen:* A fibrous structural protein that function to hold tissues together.

*Composite:* A heterogeneous combination of two or more materials.

*Corrosion:* A chemical or electrochemical degradation of metals due to surrounding environmental factors.

*Differentiation:* A process whereby an unspecialized cell acquires the features of a specialized cell.

*Electrospinning:* A fiber processing technique, which utilizes electrostatic forces to produce extremely fine fibers ranging from a few micrometers to nanometers in diameter.

*Embryonic stem cell:* An undifferentiated cell found in an embryo that is able to produce a spectrum of specialized cell/tissue types.

*Extracellular matrix:* The surrounding material of a cell, including ground substances and fibers.

*Fiber:* The individual strands of material that form a nonwoven construct.

*Graft:* A transplant.

*Growth factors:* A heterogeneous group of substances capable of enhancing tissue growth.

*Hard tissue:* The general term for calcified structures of the body (e.g., bone and tooth).

*Hematopoietic stem cells:* A stem cell from which all blood cells develop.

*Hydroxyapatite:* A calcium phosphate-based material, with chemical composition  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ , that is abundant in bone minerals.

*Immunogenic:* Capable of stimulating an immune response.

*Implant:* Any medical device or prosthesis inserted or grafted in the human body.

*Implantation:* A surgical procedure by which medical device or prosthesis is placed in human body either temporarily or permanently.

*In vitro:* A biological study performed in the laboratory. In other words, outside the living body.

*In vivo:* A biological study performed inside the living body.

*Mesenchymal stem cell:* A cell derived from the immature embryonic connective tissue.

*Metabolism:* A general term used to designate all biochemical changes that occur to substances within the body by either anabolism or catabolism.

*Micro:* A unit prefix meaning one millionth (1/1 000 000).

*Modulus:* One of several measures of strain versus applied stress (e.g., Young's modulus).

*Monolithic:* Made from a single material.

*Multipotent:* Ability of a single stem cell to develop into a small number of cell types of the body that have a specific function.

*Nano:* A unit prefix meaning one billionth (1/1 000 000 000).

*Nanobiomaterials:* Biomaterials composed of particles or grains having nanometric tolerances; a nanometer is equal to  $10^{-9}$  m.

*Non-trauma:* Any injury or wound caused by disease.

*Organ:* A differentiated part of an organism adapted for a definite function.

*Osteoconduction:* An action associated with in-growth of capillaries and migration of bone-forming cells from the host into 3D matrix.

*Pathogen:* Any organism that is capable of producing disease.

*Phenotype:* Observable characteristics of an organism, resulting from the interaction of its genotype with the environment.

*Plasticity*: Ability of stem cells from one adult tissue to generate the differentiated cell type of another tissue.

*Pluripotent*: Ability of a single stem cell to develop into many different cell types of the body.

*Polymer*: Long-chain high molecular weight material consisting of repeated monomer units.

*Porosity*: A ratio of void volume to total volume expressed in terms of percentage.

*Proliferation*: Expansion of cell population by continuous division of a single cell into two identical daughter cells.

*Prosthesis*: A medical device that is capable of replacing the organs or tissues.

*Protein*: A large biomolecule composed of one or more chains of amino acids in a specific sequence.

*Resorption*: Dissolution of a substance.

*Scaffold*: A temporary structural construct or matrix used to support the cells for accommodation during tissue fabrication.

*Stem cell*: An undifferentiated cell that is capable of producing specialized types of cells.

*Stem cell-therapy*: A treatment in which stem cells are induced to differentiate into specific types of cells/tissues for the purpose of tissue repair.

*Surface area*: The total area of exposed surface of an object.

*Tissue*: A collection of similar cells and their surrounding intercellular substances.

*Tissue engineering*: Development of human tissues or organs in the laboratory from cells removed from the patient or other sources.

*Totipotent*: Ability of a single stem cell to develop into all types of cells/tissues of the body.

*Toughness*: The amount of energy absorbed by a material before breakage.

*Transplantation*: Surgical transfer of tissue or organ from one place to another.

*Trauma*: Any injury or wound caused by an external force.

*Vascular*: A medical term pertaining to blood vessel.

*Xenograft*: Tissue or organ transplanted from one species onto a different species.

## 6 Orthopedic Tissue Engineering Using Nanomaterials

*Michiko Sato and Thomas J. Webster*

### 6.1 Preface

Over the past nine decades of administering bioimplants to humans, most synthetic prostheses consist of material particles and/or grain sizes with conventional dimensions (on the order of 1 to  $10^4$   $\mu\text{m}$ ). But the lack of sufficient bonding of synthetic implants to surrounding body tissues has, in recent years, led to the investigation of novel material formulations. One such classification of materials, nanomaterials (or materials with constituent components less than 100 nm in at least one direction), can be used to synthesize implants with similar surface roughness to that of natural tissues. Natural tissues have numerous nanometer features available for cellular interactions since they are composed of many nanostructures (specifically, proteins).

Several nanophase biomedical implants are currently being investigated, and are likely to gain approvals for clinical use in the near future. The critical factor for this drive is the increasingly documented special, biologically-improved material properties of nanophase implants compared with conventional grain size formulations of the same material chemistry. In this manner, the present chapter highlights a novel property of nanophase materials that makes them attractive for use as implants: enhanced cyto-compatibility leading to increased tissue regeneration. Active works are focused in the domains of orthopedic, dental, bladder, neurological, vascular, cartilage, and cardiovascular applications. However, only orthopedic applications, which are the closest to clinical applications, will be emphasized here. In fact, the field of incorporating nanotechnology into orthopedics has matured enough to present exciting *in vivo* data. This entry will thus articulate the seeming revolutionary changes and the potential gains nanostructured materials can make for bone implant technology. This chapter will first cover problems with current orthopedic implants and then how nanotechnology is providing solutions as pertaining to the use of ceramics, metals, polymers, and composites thereof. Lastly, critical hurdles that need to be addressed before nanophase materials can be used in orthopedics are discussed. This chapter is different from other chapters on the use of nanotechnology towards orthopedic tissue engineering as it covers, for the first

time, *in vivo* studies that highlight increased bone growth on nanostructured compared with currently used materials.

## 6.2

### Introduction: Problems with Current Implants

Since 1990, the total number of hip replacements, which is the replacement of the femoral and hip bones, has been steadily increasing [1–7]. In fact, the 152 000 total hip replacements in 2000 is a 33% increase from the number performed in 1990 and a little over half of the projected number of total hip replacements (272 000) by the year 2030 in the United States alone [1–4]. However, in 1997, 12.8% of the total hip arthroplasties were simply due to revision surgeries of previously implanted failed hip replacements [1–4].

The fact that such a high percentage of hip replacements performed every year are revision surgeries is not surprising when you consider the life expectancy of the implant versus that of the patient receiving the implant. Consistently, over 30% of those requiring total hip replacements have been below the age of 65 and even those at 65 have a life expectancy of 17.9 years [5–7]. Females, which make up the majority of those receiving total hip replacements, have a life expectancy of 19.2 years at the age of 65. Since the longevity of implants ranges only from about 12–15 years, even most of those that receive bone implants at the age of 65 will require at least one revision surgery before the end of their lives [5–7].

For the dental community the story is not any better. Since dental implants may be necessary for the young and old alike, it is imperative that they are able to last for the duration of the patient's life. Recent studies have found that dental implants that have been used in over 300 000 cases in the United States have up to a 96% success rate (meaning that the implant was not mobile and was non-inflamed) after five years, 80% after ten, and less than 75% after 15 years [1–7].

The above strongly suggests that the longevity of the prostheses is a reoccurring problem for the orthopedic/dental community that has to be dealt with since current approaches clearly fail. Orthopedic implant failure can be due to numerous reasons, including poor initial bonding of the implant to juxtaposed bone, generation of wear debris that lodges between the implant and surrounding bone to cause bone cell death, and/or stress and strain imbalances between the implant and surrounding bone causing implant loosening and eventual failure [8]. Although there are many reasons why implants fail, a central one is the lack of sufficient bone regeneration around the implant immediately after insertion [8]. Shockingly, about a quarter of dental implant failures are attributed to incomplete healing of the implant to juxtaposed bone (for those that failed between three and six months) [1–7]. Importantly, this leads to eventual implant loosening and regions for possible wear debris to situate between the implant and surrounding bone further complicating bone loss [8–11].

To improve this performance and hence extend the lifetime of bone implants, it is essential to design biomaterial surface characteristics that interface optimally with select proteins and subsequently with pertinent bone cell types. That is, im-

**Fig. 6.1.** Cell recognition of biomaterial surfaces controlled by initial protein interactions. Initial protein interactions can influence cell adhesion and, thus, the degree of bone tissue formation on biomaterials. Changing the material properties will alter the protein interactions and influence subsequent cell function. (Adapted and redrawn from Ref. [13], with permission.)

mediately after implantation, proteins will adsorb from plasma to biomaterial surfaces to control cell attachment and eventual tissue regeneration (Fig. 6.1) [12, 13]. Initial protein interactions that mediate cell function depend on many biomaterial properties, including chemistry, charge, wettability, and topography [12, 13]. Of significant influence for protein interactions is surface roughness [14–18], and this represents the promise of nanophase materials in bone implant applications.

### 6.3 A Potential Solution: Nanotechnology

Nanotechnology embraces a system whose core of materials is in the range of nanometers ( $10^{-9}$  m) [19–29]. The application of nanomaterials for medical diagnosis, treatment of failing organ systems or prevention and cure of human diseases can generally be referred to as nanomedicine [28, 29]. The branch of nanomedicine devoted to the development of biodegradable or non-biodegradable prostheses falls within the purview of nano-biomedical science and engineering [28, 29]. Although various definitions are attached to the word “nanomaterial” by different experts, the commonly accepted concept refers nanomaterials as that material with the basic structural unit in the range 1–100 nm (nanostructured), crystalline solids with grain sizes 1–100 nm (nanocrystals), individual layer or multilayer surface coatings in the range 1–100 nm (nanocoatings), extremely fine powders with an average particle size in the range 1–100 nm (nanopowders) and, fibers with a diameter in the range 1–100 nm (nanofibers) [19, 20].

Since nature itself exists in the nanometer regime, especially tissues in the hu-

**Fig. 6.2.** Nanocomponents of bone provide a high degree of nanostructured surface roughness for bone cells. (Adapted and redrawn from Ref. [31], with permission.)

man body [30], clearly, nanotechnology can play an integral role in the biological milieu. Specifically, bone is composed of numerous nanostructures – like collagen and hydroxyapatite that, most importantly, provide a unique nanostructure for protein and bone cell interactions in the body (Fig. 6.2) [31]. Although mimicking constituent components of bone is novel in itself, there are additional reasons to consider nanomaterials for orthopedic applications: their special surface properties compared with conventional (or micron constituent component structured) materials [24–27]. For example, a nanomaterial has increased numbers of atoms at the surface, grain boundaries or material defects at the surface, surface area, and altered electron distributions compared with conventional materials (Fig. 6.3) [27]; in summary, nanophase material surfaces are more reactive than their conventional counterparts. In this light, clearly, proteins that influence cell interactions that lead to tissue regeneration will be quite different on a nanophase compared with conventional implant surfaces (Fig. 6.1).

Despite this, the evolution of orthopedic implants has centered on the use of materials with non-biologically inspired micron surface features [32, 33], mostly changing in chemistry or micron roughness but not degree of nanometer roughness (Fig. 6.4). In this manner, it should not be surprising why the optimal material to regenerate bone has not been found.

### 6.3.1

#### **Current Research Efforts to Improve Implant Performance Targeted at the Nanoscale**

Nanoscale materials currently being investigated for bone tissue engineering applications can be placed in the following categories: ceramics, metals, polymers, and

**Fig. 6.3.** Special surface properties of nanophase materials. (a) Higher number of atoms at the surface for nanophase compared with conventional materials. (b) Nanophase materials have higher surface areas, possess greater numbers of material defects at the

surface, and altered electron delocalization. Such special properties will influence protein interactions for controlling cell functions. (Adapted and redrawn from Ref. [25], with permission.)

composites thereof. Each type of material has distinct properties that can be advantageous for specific bone regrowth applications. For example, hydroxyapatite, a ceramic mineral present in bone (Fig. 6.2), can also be made synthetically. Ceramics, however, are not mechanically tough enough to be used in bulk for large-scale bone fractures; nonetheless, they have found applications for a long time as bioactive coatings due to their ionic bonding mechanisms, which are favorable for osteoblast (or bone-forming cells) function [34].

Unlike ceramic materials, metals are not found in the body. However, due to their mechanical strength and relative inactivity with biological substances, metals (specifically, Ti, Ti6Al4V, and CoCrMo) have been the materials of choice for large bone fractures [32, 33]. Polymers exhibit unique properties (such as viscosity, malleability, moldability) and possess mechanical strength that is comparable to many soft (not hard) tissues in the body [35]. To date, because of their excellent friction properties, polymers (like ultrahigh molecular weight polyethylene) have been primarily used as articulating components of orthopedic joint replacements [35].

**Fig. 6.4.** Conventional grain size of currently used orthopedic implants. Bar = 10 and 2.5  $\mu\text{m}$  for the left and right micrograph, respectively.

Additionally, some polymers (particularly the polyester family) can be resorbed or degraded in the body, which opens the window for controllable repair of damaged bone that is actively being investigated in tissue engineering circles. Lastly, composites of any or all of the above can be synthesized to provide a wide range of material properties to increase bone implant performance [36]; such ability to tailor composite properties to specific orthopedic applications makes them attractive.

Due to the numerous materials currently being used and investigated in orthopedics, this review will cover selected efforts to create nanoscale surfaces in all of these categories: ceramics, metals, polymers, and composites. Several current and potential materials that have shown promise in nanotechnology for bone biomedical applications, as well as needed future directions, will be emphasized.

#### 6.3.1.1 Ceramic Nanomaterials

**Increased Osteoblast Functions** The first report correlating increased bone cell functions with decreased material grain or particulate size into the nanometer regime dates back to 1998 and involves ceramics [37]. Such reports described that *in vitro* osteoblast (bone-forming cell) adhesion, proliferation, differentiation (as measured by intracellular and extracellular matrix protein synthesis such as alkaline phosphatase), and calcium deposition was enhanced on ceramics with particulate or grain sizes less than 100 nm [37–46]. Specifically, this was first demonstrated for a wide range of ceramic chemistries, including titania (Fig. 6.5), alumina, and hydroxyapatite [39]. For example, four, three, and two times the amount of calcium-mineral deposition was observed when osteoblasts were cultured for up to 28 days on nanophase compared with conventional alumina, tita-

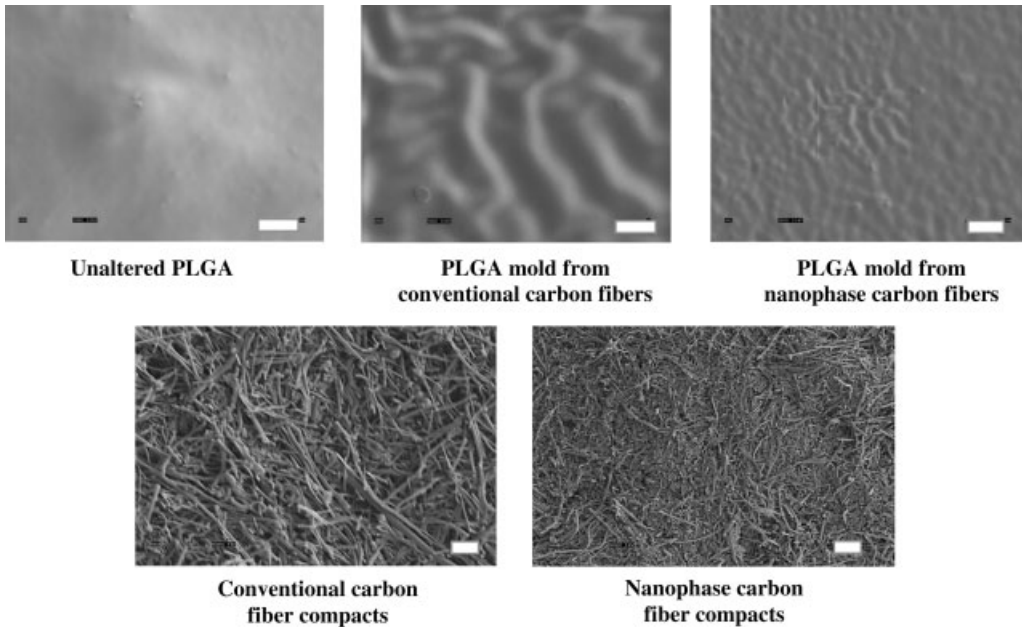

**Fig. 6.5.** (a) Conventional and (b) nanophase titania. One of the first studies correlating increased osteoblast function with decreasing ceramic grain size was carried out on titania as pictured here. (From Ref. [39], with permission.)

nia, and hydroxyapatite, respectively [41]. Notably, for each respective nanophase and conventional ceramic mentioned in these first reports, similar chemistry and material phase were studied [37–46]. That is to say, only the degree of nanometer surface features was altered between respective nanophase and conventional alumina, titania, and hydroxyapatite. This is important since as previously discussed, it is well known that alterations in surface chemistry will influence bone cell function [8, 32–36], but this was the first time changes in the degree of nanometer roughness alone were reported to enhance bone cell responses [37].

Although these studies provided preliminary evidence that osteoblast functions can be promoted on nanostructured compared with conventional materials regardless of ceramic chemistry, Elias et al. further described a study where the topography of compacted carbon nanometer fibers were transferred to poly(lactic-co-glycolic acid) (PLGA) using well-established silastic mold techniques [47]. The same was done for compacts composed of conventional carbon fibers. Figure 6.6 illustrates the successful transfer of nanometer compared with micron surface features from the carbon nanometer compared with conventional fiber compacts, respectively [47]. Importantly, osteoblast adhesion increased on PLGA molds made from nanometer compared with conventional carbon fibers [47]. Increased osteoblast functions were also observed on the starting materials of nanometer compared with conventional carbon fiber compacts [47]. In this manner, this study provided further evidence of the importance of nanometer surface features (and not chemistry) in promoting functions of bone-forming cells.

Equally as interesting, a step-function increase in osteoblast performance has been reported at distinct ceramic grain sizes: specifically, at alumina and titania spherical grain sizes below 60 nm [39]. This is intriguing since when creating alumina or titania ceramics with average grain sizes below 60 nm, a drastic increase in osteoblast function was observed compared with respective ceramics with grain sizes just 10 nm higher (i.e., those with average grain sizes of 70 nm) [39]. This

**Fig. 6.6.** Poly(lactic-co-glycolic acid) (PLGA) molds of conventional and nanophase carbon fiber compacts. To highlight the importance of nanometer surface roughness regardless of substrate chemistry, studies have shown increased functions of osteoblasts on PLGA molds of nanophase compared with conventional carbon compacts. In addition, increased functions of osteoblasts have been found on compacts composed of nanometer compared with conventional carbon fibers. Bar = 1  $\mu\text{m}$ . (From Ref. [47], with permission.)

critical grain size for improving osteoblast function is also of paramount importance since numerous other special properties (such as mechanical, electrical, catalytic, etc.) of materials have been reported when grain size is specifically reduced to below 100 nm [19–27]. With this information, evidence has been provided to show for the first time that the ability of nanophase ceramics to promote bone cell function is indeed limited to grain sizes (or subsequent surface features) below 100 nm, specifically those below 60 nm [39]. Thus, another novel size-dependent property of nanostructured ceramics has been elucidated by these pioneering studies.

Although an exact explanation as to why greater bone regeneration is observed on smaller grain size ceramics into the nanometer regime is not known, the importance of this specific grain size in improving osteoblast function is connected with interactions of vitronectin (a protein known to mediate osteoblast adhesion with linear dimensions remarkably similar to the critical grain size of 60 nm mentioned above) [40, 44]. Moreover, as previously mentioned, several studies have indicated that vitronectin and other proteins important for osteoblast adhesion are more well-spread and, thus, expose amino acid sequences to a greater extent when interacting with nanometer compared with conventional ceramics [40, 44]. Intriguingly, numerous investigators have confirmed that the minimum distance between

protein ligands (such as arginine-glycine-aspartic acid or RGD) necessary for cell attachment and spreading is in the nanometer regime (specifically, from 10 to 440 nm, depending on whether the study was completed with full proteins, protein fragments, or single RGD units) [48–53]. Therefore, an underlying substrate surface that mediates protein spreading (as opposed to protein folding) to expose such ligands coupled with a nanometer surface roughness, to further project such ligands to the cell, may promote cell adhesion due to this optimal ligand spacing.

**Increased Osteoclast Functions** In addition to studies highlighting enhanced osteoblast functions on nanophase ceramics, increased functions of osteoclasts (bone-resorbing cells) have been reported on nanospherical compared with larger grain size alumina, titania, and hydroxyapatite (HA) [45]. Specifically, osteoclast synthesis of tartrate-resistant acid phosphatase (TRAP) and subsequent formation of resorption pits was up to two-times greater on nanophase than on conventional ceramics such as hydroxyapatite. Coordinated functions of osteoblasts and osteoclasts are imperative for the formation and maintenance of healthy new bone juxtaposed to an orthopedic implant [8]. Frequently, newly formed bone juxtaposed to implants is not remodeled by osteoclasts and thus becomes unhealthy or necrotic [34]. At this time, the exact mechanism of greater functions of osteoclasts on nanophase ceramics is not known, but it may be tied to the well-documented increased solubility properties of nanophase compared with conventional materials [25]. In other words, due to larger numbers of grain boundaries at the surface of smaller grain size materials, increased diffusion of chemicals (such as TRAP) may be occurring to subsequently result in the formation of more resorption pits.

Collectively, results of promoted functions of osteoblasts coupled with greater functions of osteoclasts imply increased formation and maintenance of healthy bone juxtaposed to an implant surface composed of nanophase ceramics. In fact, although not compared with conventional grain size apatite coated metals, some studies have indeed demonstrated increased new bone formation on metals coated with nanophase apatite [54]. As shown in Fig. 6.7, bone formation can be clearly seen on the surface of metals coated with nano-apatite, whereas there is no indication of new bone formation on the underlying metal without the coating [54]. Incidentally, coating metals with nanophase HA has been problematic [55]. For example, due to their small grain size, techniques that use high temperatures (like plasma spray deposition) are not an option since they will result in HA grain growth into the micron regime [55]. To circumvent such difficulties, some investigators have allowed nanophase HA to precipitate on metal surfaces; this can be time consuming and not very controllable [54]. In contrast, others have developed novel techniques that use high-pressure based processes that do not significantly create elevated temperatures to coat nanophase ceramics on metals so as to retain their bioactive properties (Fig. 6.8) [56].

**Decreased Competitive Cell Functions** Importantly, it has also been shown that competitive cells do not respond in the same manner to nanophase materials as osteoblasts and osteoclasts do [40, 47, 57]. In fact, decreased functions of fibro-

**Fig. 6.8.** Nanophase hydroxyapatite (HA) coated on titanium. Due to elevated temperatures, traditional coating techniques, such as plasma spray deposition, cannot be used to coat metals with nanophase ceramics.

This process, developed by Spire Biomedical (Bedford, MA), uses high pressure at low temperatures so as to not allow for grain growth. Bar = 1  $\mu\text{m}$  (upper left).

blasts (cells that contribute to fibrous encapsulation and callus formation events that may lead to implant loosening and failure [8]) and of endothelial cells (cells that line the vasculature of the body) have been observed on nanophase compared with conventional ceramics [40]. Indeed, the ratio of osteoblast to fibroblast adhesion increased from 1:1 on conventional alumina to 3:1 on nanophase alumina [40].

Previously, such selectively in bone cell function on materials has only been observed through delicate surface chemistry (such as through the immobilization of peptide sequences such as Lys-Arg-Ser-Arg or KRSR) [58]. It has been argued that immobilized delicate surface chemistries may be compromised once implanted due to macromolecular interactions that render such epitopes non-functional *in vivo*. For these reasons, notably, studies demonstrating selective enhanced osteoblast and osteoclast functions with decreased functions of competitive cells on nanophase compared with conventional materials have been conducted on surfaces that have not been chemically modified by the immobilization of proteins, amino acids, peptides, or other entities [40, 47, 57]. Rather it is the unmodified, raw material surface that is specifically promoting bone cell functions.

Fibroblast function was also investigated in the same study that was previously mentioned in which Elias et al. transferred the topography of compacted carbon nanometer compared with conventional fibers to PLGA using well-established silastic mold techniques (again please refer Fig. 6.6) [47]. Similar to the observed greater osteoblast adhesion already noted, decreased fibroblast adhesion was measured on PLGA molds synthesized from carbon nanometer compared with conventional fibers [47]. Again, this was the same trend observed on the starting material of carbon nanometer compared with conventional fiber compacts [47]. Thus, this

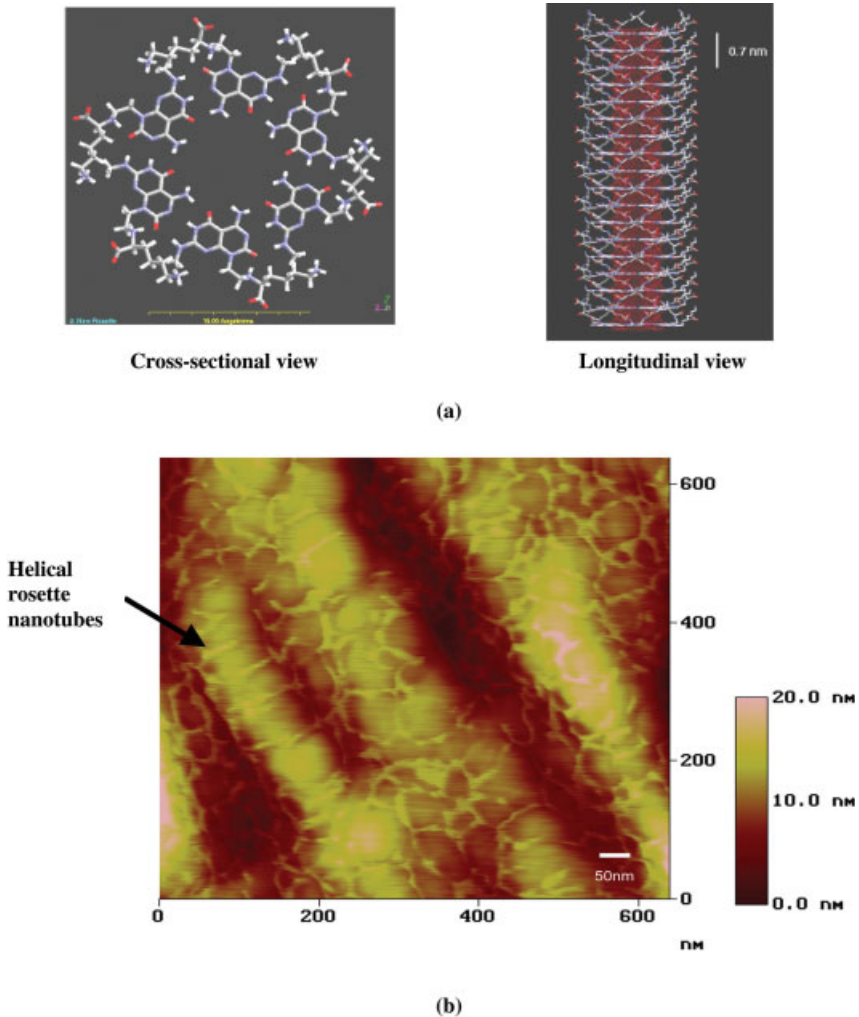

**Fig. 6.9.** Transmission electron microscope image of alumina nanofibers. Compared with spherical conventional alumina, increased functions of osteoblasts have been reported on nanophase fibrous alumina. Scale bar = 10 nm. (From Ref. [57], with permission.)

study demonstrated the importance of a nanometer surface roughness (and not chemical composition of the material) in decreasing functions of fibroblasts that may lead to undesirable fibrous encapsulation and callus formation events inhibiting osseointegration of orthopedic implants with surrounding bone.

**Increased Osteoblast Functions on Nanofibrous Materials** Recently, researchers have further modified nanophase ceramics to simulate not only the nanometer dimension but also the aspect ratio of proteins and hydroxyapatite crystals found in the extracellular matrix of bone [57]. For example, consolidated substrates formulated from nano-fibrous alumina (diameter: 2 nm, length > 50 nm; Fig. 6.9) increased osteoblast functions in comparison with similar alumina substrates formulated from the aforementioned nanospherical particles [57]. Specifically, Price et al. determined a two-fold increase in osteoblast cell adhesion density on nanofiber versus conventional nanospherical alumina substrates, following only a 2 h culture [57]. Greater subsequent functions leading to new bone synthesis has also been reported on nanofibrous compared with nano and conventional spherical alumina [57]. Thus, perhaps not only is the nanometer grain size of components of bone important to mimic in materials, but the aspect ratio may also be key to simulate in synthetic materials to optimize bone cell response.

Another classification of novel biologically-inspired nanofiber materials that has been investigated for orthopedic applications is self-assembled helical rosette nanotubes [59]. These organic compounds are composed of guanine and cytosine DNA pairs that self-assembled when added to water to form unique nanostructures (Fig. 6.10). These nanotubes have been reported to be 1.1 nm wide and up to several millimeters long [59]. Compared with currently used titanium, recent studies have indicated that osteoblast function is increased on titanium coated with helical rosette nanotubes (Fig. 6.10) [59]. Although in these studies it has not been possi-

**Fig. 6.10.** Helical rosette nanotubes. (a) Drawings of the cross-sectional and longitudinal views of self-assembled helical rosette nanotubes. (b) Helical rosette nanotubes coated on titanium. Note the

nanophase dimension of these organic tubes. Increased osteoblast function has been observed on helical rosette nanotubes coated on Ti. (From Ref. [59], with permission.)

ble to separate the influence of nanometer dimensions from the effects of nanotube chemistry on cell functions, these nanotubes are clearly another category of novel nanostructured materials that can be used to promote bone formation. It is also intriguing to consider what role self-assembled nanofibers may play in orthopedics since bone itself is a self-assembled collection of nanofibers.

In this context, notably, only nanophase materials can mimic the unique aspect ratio of hydroxyapatite and proteins found in the extracellular matrix of bone; it is not possible for micron-sized materials to simulate the unique nanometer constituent components of bone. As previously mentioned, results concerning the importance of nanofibrous materials in promoting functions of osteoblasts have been reported for carbon and polymer molds of carbon nanofibers (Fig. 6.6) [47]. These findings consistently testify to the unprecedented ability to create nanomaterials to mimic the dimensions of components of physiological bone to promote new bone formation.

#### 6.3.1.2 Metal Nanomaterials

Although much more work has been conducted on nanophase ceramics to date, several recent studies have focused on the analysis of bone regeneration on nanophase metals. Metals investigated to date include titanium,  $Ti_6Al_4V$ , and CoCrMo [60]. While many have attempted to create nanostructured surface features using chemical etchants (such as  $HNO_3$ ) on titanium, results concerning increased bone synthesis have been mixed [35]. Moreover, through the use of chemical etchants it is unclear to what the cells may be responding – changes in chemistry or changes in topography. For this reason, as was done for the ceramics in this review, it is important to focus on studies that have attempted to minimize large differences in material chemistry and focus only on creating surfaces that alter in their degree of nanometer roughness.

One such study by Ejiofor et al. utilized traditional powder metallurgy techniques without the use of heat to avoid changes in chemistry to fabricate different particle size groups of Ti,  $Ti_6Al_4V$ , and CoCrMo (Fig. 6.11) [60]. Increased osteoblast adhesion, proliferation, synthesis of extracellular matrix proteins (like alkaline phosphatase and collagen), and deposition of calcium containing mineral was observed on respective nanophase compared conventional metals [60]. This was the first study to demonstrate that the novel enhancements in bone regeneration previously seen in ceramics by decreasing grain size can be achieved in metals.

Interestingly, when Ejiofor et al. examined spatial attachment of osteoblasts on the surfaces of nanophase metals, they observed directed osteoblast attachment at metal grain boundaries (Fig. 6.12) [60]. Because of this, the authors speculated that the increased osteoblast adhesion may be due to more grain boundaries at the surface of nanophase compared with conventional metals. As was the case with nanophase ceramics [40, 44], it is plausible that protein adsorption and conformation at nanophase metal grain boundaries may be greatly altered compared with non-grain boundary areas and/or conventional grain boundaries; in this manner, protein interactions at grain boundaries may be key for osteoblast adhesion.

#### 6.3.1.3 Polymeric Nanomaterials

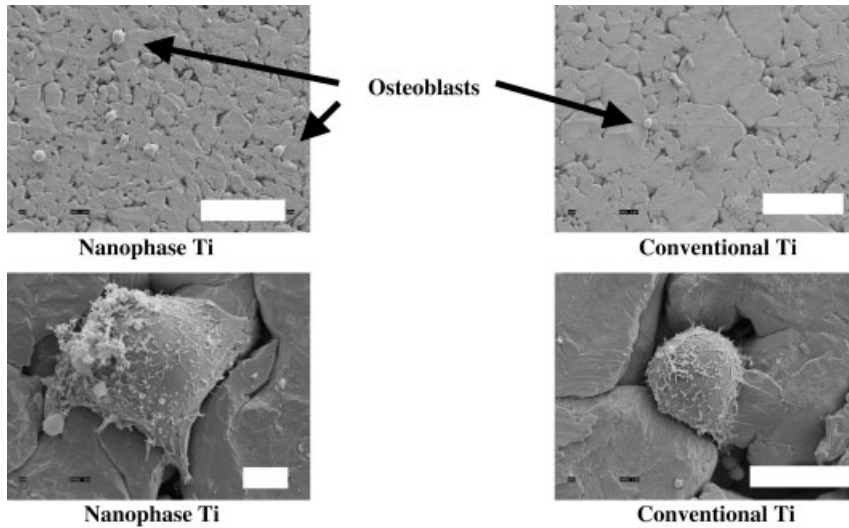

For ceramics and metals, most studies conducted to date have created desirable nanometer surface features by decreasing the size of constituent components of the material, e.g., a grain, particle, or fiber. However, due to the versatility of poly-

**Fig. 6.11.** Scanning electron micrographs of nanophase metals. Increased functions of osteoblasts have been observed on nanophase compared with conventional c.p. Ti, Ti6Al4V, and CoCrMo. Scale bar = 1  $\mu\text{m}$  for nanophase

Ti/Ti6Al4V and 10  $\mu\text{m}$  for conventional Ti/Ti6Al4V. Scale bar = 10  $\mu\text{m}$  for nanophase and conventional CoCrMo. (From Ref. [60], with permission.)

mers, many additional techniques exist to create nanometer surface roughness values. In addition, polymers contribute even further to rehabilitating damaged tissue by, possibly, providing a degradable scaffold that dissolves within a controllable time while the native tissue reforms. Techniques utilized to fabricate nanometer features on polymers include e-beam lithography, polymer demixing, chemical

**Fig. 6.12.** Scanning electron micrographs of adherent osteoblasts on nanophase c.p. Ti. Directed osteoblast adhesion on nanophase metal grain boundaries has been reported. Scale bar = 100  $\mu\text{m}$  for top and 10  $\mu\text{m}$  for bottom; adhesion time = 30 min. (From Ref. [60], with permission.)

etching, cast-mold techniques, and the use of spin-casting [60–68]. For those that have been applied to orthopedics, chemical etching followed by mold casting and polymer demixing techniques have received the most attention [61, 62].

For chemical etching techniques, polymers investigated to date include poly(lactic-co-glycolic acid) (PLGA; Fig. 6.13), polyurethane, and polycaprolactone [62, 64–66]. The idea proposed by Kay et al. has been to treat acidic polymers with basic solutions (i.e., NaOH) and basic polymers with acidic solutions (i.e.,  $\text{HNO}_3$ ) to create nanosurface features [62]. While only on two-dimensional (2D) films, Kay et al. observed greater osteoblast adhesion on PLGA treated with increasing concentrations and exposure times of NaOH. As expected, data was also provided indicating larger degrees of nanometer surface roughness with increased concentrations and exposure time of NaOH on PLGA. Park et al. took this one step further and fabricated three-dimensional (3D) tissue engineering scaffolds by NaOH treatment of PLGA [64]. When comparing osteoblast functions on such scaffolds, even though similar porosity properties existed between non-treated and NaOH treated PLGA (since similar amounts and sizes of NaCl crystals were used to create the pores through salt-leaching techniques), greater numbers of osteoblasts were counted on and in NaOH treated PLGA [64]. Unfortunately, due to these fabrication techniques, it is unclear whether the altered PLGA chemistry or nano-etched surface promoted osteoblast adhesion; however, in light of the previous studies mentioned in this review, the authors of that study suggested the

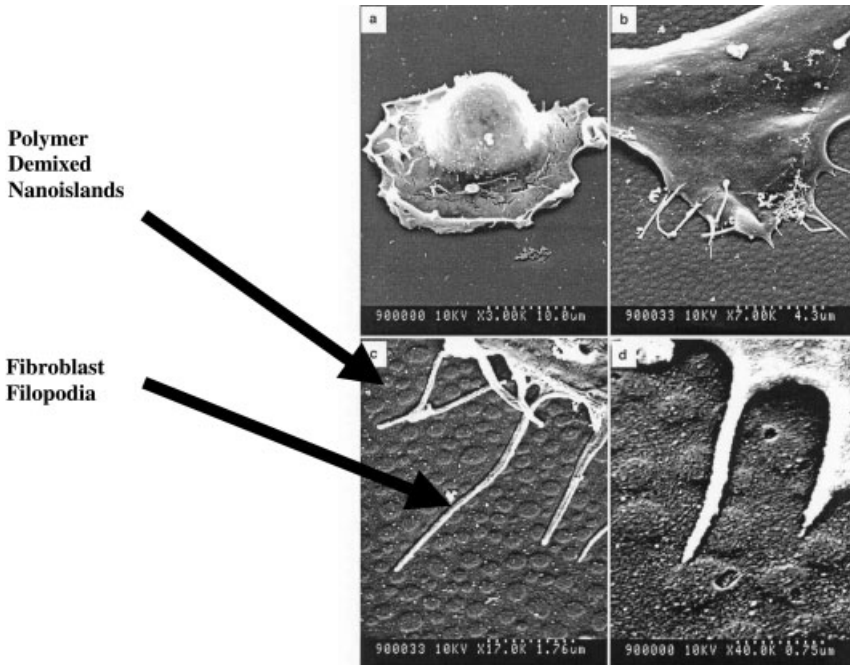

**Fig. 6.13.** Scanning electron micrographs of conventional and nanophase PLGA scaffolds. Increased osteoblast functions have been demonstrated on nanophase PLGA scaffolds. Scale bar = 10  $\mu\text{m}$ . (From Ref. [64], with permission.)

nanometer surface roughness of the NaOH-treated PLGA played an important role [64].

Studies have also been conducted on cell responses to polymers with changes in nanometer surface roughness without changes in chemistry. Specifically, Li et al. utilized polymer demixing techniques to create well-controlled nanometer islands of polystyrene and poly(bromo-styrene) [67]. Although osteoblast functions have not been tested on these constructs to date, fibroblast morphology was significantly influenced by incremental nanometer changes in polymer island dimensions (Fig. 6.14). Again, this study points to the unprecedented control that can be gained over cell functions by synthesizing materials to have nanometer surface features.

Although not related to orthopedic applications, vascular and bladder cell responses have also been promoted by altering the topography of polymeric materials in the nanometer regime [62, 64, 66, 68]. In these studies, chondrocytes [62], bladder [66], and vascular smooth muscle cell [65] adhesion and proliferation were greater on 2D nanometer surfaces of biodegradable polymers such as PLGA, polyurethane, and polycaprolactone; similar trends have recently been reported on 3D PLGA scaffolds [68].

**Fig. 6.14.** Polymer nanoislands created by demixing polystyrene and poly(bromo-styrene). Altered cell functions have been observed on polymer nanoislands compared with conventional polymer topographies; (a)–(d) represent increased magnification. (From Ref. [67], with permission.)

#### 6.3.1.4 Composite Nanomaterials

Due to the previous information of increased osteoblast function on ceramics and polymers, investigators have also determined bone cell function on nanophase ceramic polymer composites (Fig. 6.15). Specifically, studies conducted to date show promoted osteoblast responses on composites of PLGA combined separately with nanophase alumina, titania, and hydroxyapatite (30:70 wt.% PLGA:ceramic) [62, 69]. For example, up to three times more osteoblasts adhered to PLGA when it contained nanophase compared with conventional titania particles [62]. Since similar porosity (both % and diameters) existed between PLGA with conventional compared with nanophase titania, another novel property of nanophase ceramic composites was elucidated in this study: increased osteoblast functions. This is in addition to numerous reports in the literature highlighting greater toughness of nanophase compared with conventional ceramic:polymer composites [21–23].

Moreover, promoted responses of osteoblasts have also been reported when carbon nanofibers were incorporated into polymer composites; specifically, three

**Fig. 6.15.** Scanning electron micrographs of poly(lactic-*co*-glycolic acid) (PLGA):titania composites. Increased osteoblast function has been observed on polymer composites containing nanophase compared with conventional ceramics. Scale bar = 10  $\mu\text{m}$ . (From Ref. [69], with permission.)

times the number of osteoblasts adhered on polyurethane (PU) with increasing weight percentages of nanometer not conventional dimension carbon fibers (Fig. 6.16) [70]. As mentioned, reports in the literature have demonstrated higher osteoblast adhesion on carbon nanofibers in comparison with conventional carbon fibers (or titanium (ASTM F-67, Grade 2) [70]), but this study demonstrated greater osteoblast adhesion with only a 2 wt.% increase of carbon nanofibers (CN) in the PU matrix. Up to three and four times the number of osteoblasts that adhered on the 100:0 PU:CN wt.% adhered on the 90:10 and the 75:25 PU:CN wt.% composites, respectively [70]. This exemplifies the unprecedented ability of nanophase materials to increase functions of bone cells whether used alone or in polymer composite form.

**Fig. 6.16.** Scanning electron micrographs of poly-ether-urethane (PU):carbon nanofibers (CN) (wt.%) composites. Increased functions of osteoblasts have been observed on polymer composites containing carbon nanofibers. Scale bar = 1  $\mu\text{m}$ . (From Ref. [70], with permission.)

### 6.3.2

#### ***In Vivo* Compared with *In Vitro* Studies**

Of course, in any new field of biomaterials, it is completely natural to conduct extensive *in vitro* analysis before conducting *in vivo* studies. The *in vitro* studies emphasized in the previous sections provided key preliminary promise for the use of these materials in orthopedics. Moreover, they provided an important mechanism as to why osteoblasts prefer nanophase over conventional materials. To date, though, there have been few *in vivo* studies that specifically address increased new

**Fig. 6.17.** SEM pictures of uncoated and coated porous titanium. Coating process maintained the nanoscale features of hydroxyapatite (HA) after coating on titanium.

bone growth on materials of the same chemistry but altering only in grain or particle size. That is, while some *in vivo* studies were presented in the early sections, they did not specifically evaluate the influence of grain size on *in vivo* new bone growth. However, one study exists that utilized a novel coating process developed at Spire Biomedical (call IonTite™) to deposit nanocrystalline particles of hydroxyapatite (HA) onto porous titanium scaffolds (Fig. 6.17). Importantly, when implanted into the calvaria of rats for 6 weeks, increased bone infiltration was seen only on titanium scaffolds coated with nanocrystalline HA (Fig. 6.18). That is, little to no bone ingrowth was measured on either uncoated titanium or titanium coated with conventional (or microcrystalline HA) after the same time period. This exciting *in vivo* data confirms the promising *in vitro* data of increased responses from osteoblasts on nano compared with micron HA. Furthermore, while much work is still needed (as outlined in the next section), this *in vivo* study may begin to pave the way for the widespread use of nanophase materials either in bulk or as coatings on traditionally used bone implant materials.

**Fig. 6.18.** Increased bone ingrowth for Ti coated with nanocrystalline HA by IonTite™. Implantation time = 6 weeks. Stain = Sanford (blue indicates bone and red indicates collagen).

#### 6.4

#### Considerations and Future Directions

Although preliminary attempts to incorporate nanophase materials into orthopedic implants seem promising, numerous urgent questions still remain about this new field. First and foremost, the safety of nanoparticles once in the human body remains largely unanswered both from a manufacturing point of view and when used in full or as a component of an implantable device. Since such particles are smaller than many pores of biological tissues, this information will, clearly, have to be obtained before further consideration of implantable nanomaterials is undertaken. Such nanoparticles can easily become dislodged from implants during surgical implantation or from fragmentation of articulating components of a joint prosthetic composed of nanophase materials. Although preliminary *in vitro* studies highlight a less adverse influence of nanometer compared with micron particulate wear debris on bone cell viability [71, 72], many more experiments are needed especially *in vivo* to evaluate their efficacy.

In addition, once exact optimal nanometer surface features are elucidated for increasing bone regeneration, inexpensive tools that can be used in industry will be required. In this context, if the only nanofabrication devices that can be used to synthesize desirable nanometer surface features for bone regeneration are e-beam lithography or other equally expensive techniques, industry may not participate in this boom of nanotechnology at the intersection of tissue engineering. Inexpensive, but effective, nanometer synthesis techniques must continually be a focus of many investigators.

Still, the direction of the nanotechnology should be and is geared towards dealing with these issues. For example, according to the U.S. government's research agenda, the current and future broad interests in nano biomedical activity can be categorized in three broad related fronts [28, 29]:

1. Development of pharmaceuticals for inside-the-body applications – such as drugs for anticancer and gene therapy.
2. Development of diagnostic sensors and lab-on-a-chip techniques for outside-the-body applications – such as biosensors to identify bacteriological infections in biowarfare.
3. Development of prostheses and implants for inside-the-body uses.

Whereas the European governments emphasize commercial applications in all three fronts above, according to Malsch [29], the U.S. government tends to gear towards fundamental research on biomedical implants and biodefense, leaving commercial applications to industry. Both classifications identify nanophase biomedical implants as of potential interest. The biological and biomimetic nanostructures to be used as an orthopedic implant involve some sort of an assembly in which smaller materials later on assume the shape of a body part, such as hipbone. These final biomimetic, bulk nanostructures can start with a predefined nanochemical (like an array of large reactive molecules attached to a surface) or nanophysical

(like a small crystal) structure. It is believed that by using these fundamental nanostructured building blocks as seed molecules or crystals, a larger bulk material will self-assemble or keep growing by itself.

In summary, significant evidence exists that highlights changes in cellular functions on materials with nanoscale surface features, particularly in the bone arena. Clearly, nanomaterials as mentioned here are at their infancy and require much more testing before their full potential can be realized. However, even if nanophase materials never make it to the marketplace due to safety concerns, we have already learned much about how cells interact with nanostructured surfaces through their application in the orthopedic environment.

## Hydroxyapatite Nanocrystals as Bone Tissue Substitute

Norberto Roveri and Barbara Palazzo

## 7.1

### Overview

Nanoscience, where the properties of materials are exploited to innovative amazing applications, is involved in the size-dependent chemical and biological activity of bone substitute materials, which is indeed a fascinating field. The present chapter reviews the synthesis and chemical–physical characteristics of hydroxyapatite (HA) nano-crystals, which have excellent properties to represent an elective material covering a wide range of applications for bone substitution. We start from an examination of biogenic bone and tooth hydroxyapatite nanocrystals morphological and chemical–physical characteristics. The highlighted concepts have been used to review up-to date main new ideas on the preparation of synthetic apatitic bone substitutes mimicking the above biogenic properties, among which the nano-size is the basis of their self-assembly, self-mineralization and bone regeneration ability.

Hydroxyapatite (HA) nanocrystals with high bioreabsorbability containing foreign ions and mimicking bone HA chemical–physical and physiological behaviour have been described. We have pointed to their possible use in preparing scaffolds with a porosity simulating that of spongy bone and upon which cells can be seeded, thereby developing “*in vitro* autologous bone”. Biologically inspired HA nanocrystals/collagen composites have been reviewed, focusing on the role of a self-assembling strategy in conditioning the bone repairing activity of this biomaterial. Furthermore, considering that calcium phosphate/collagen composites are not limited to loading application, the possibility of preparing bio-inspired coating on the surface of metallic implants could be an advantageous approach.

Finally, surface functionalization of HA nano-crystals with bioactive molecules makes them able to transfer information and to act selectively on the biological environment and can be considered one of the main future challenges for innovative bone substitute materials.

## 7.2

### Introduction

Biomaterials represent one of the most interesting and interdisciplinary areas of science, where chemical, biological, engineering scientists are contributing to human health care and improving the quality of life. Skeletal deficiencies resulting from trauma, tumors or abnormal development are common, and are usually treated by surgical intervention. As a consequence, there is an increasing demand for materials that can potentially replace, repair or even regenerate injured or diseased bone tissue. Currently, autografts and allografts, or, alternatively, surface-treated metals, inorganic, polymeric and polymeric/inorganic hybrid materials, are applied for the reconstruction of skeletal defects [1]. Due to the limited supply of autografts, and the potential for pathogen transfer and possible stress shielding around the surrounding bones, none of the currently used biomaterials can provide completely the required properties. The enormous need for bone grafts and recent progress in biomaterial science have resulted in the newly evolving approach of “bone tissue engineering” [2–4]. This may be performed by using cell transplantation and culturing on biodegradable scaffolds for the development of hybrid constructs aiming at the regeneration of bone tissue [5].

Calcium phosphates are an interesting subject of research and development in the preparation of biomaterials for bone substitution. Calcium phosphates used as bone grafts can be classified either bioinert or bioactive. Bioinert phosphates have no influence in the surrounding living tissue; by contrast, bioactive materials exhibit the ability to bond with bone tissues. Initially, bioinert materials used in clinical applications were chosen because of their lack of chemical reactions with the environment, which could yield an undesirable outcome. The bioactivity of a bone substitute material can be evaluated through its chemical reactivity with the environment. This reactivity can be evaluated *in vitro* by means of an artificial solution simulating body fluids, and *in vivo* when the material is in contact with physiological fluids, towards the production of newly formed bone. The bioactivity of some reabsorbable calcium phosphate bioceramics is so high as to induce, in repairing a skeletal section, not only replacement of the damaged part but to substitute it, regenerating new bone.

This review focuses on nanosized hydroxyapatite, which is an elective biomaterial for bone substitution. Hydroxyapatite nano-crystals are similar to the mineral component of bone for composition and attempt to mimic the features, structure and morphology of natural bone crystals by their nanosize, blade-like shape, low degree of crystallinity and high surface reactivity.

## 7.3

### Biogenic Hydroxyapatite: Bone and Teeth

Bone and teeth of vertebrates are natural composite materials constituted of calcium phosphate in the form of hydroxyapatite (HA) and organic matter prevalently

**Fig. 7.1.** Deproteinized bone hydroxyapatite nanocrystals observed by transmission electron microscopy. Scale bar = 100 nm. (Reproduced by permission from Ref. [10].)

formed of proteins and polysaccharides. Biological HA can only be represented ideally with the formula  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ . It is not stoichiometric as many cations replace  $\text{Ca}^{2+}$ , such as  $\text{Mg}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ , and some anions replace  $\text{PO}_4^{3-}$  and  $\text{OH}^-$ , such as  $\text{CO}_3^{2-}$ ,  $\text{HPO}_4^{2-}$ ,  $\text{P}_2\text{O}_7^{4-}$ ,  $\text{SiO}_4^{4-}$ , and  $\text{CO}_3^{2-}$ ,  $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{Br}^-$ . The carbonate content of bone hydroxyapatite is about 4–8 wt.% [6] and increases with the age of the individual [7, 8] with increasing  $\text{CO}_3^{2-}$  groups substituting  $\text{OH}^-$  sites (type A carbonate apatite). Conversely,  $\text{CO}_3^{2-}$  groups substituting  $\text{PO}_4^{3-}$  sites (type B carbonate apatite) is the prevalent type in young humans [9]. The nano-sized carbonate hydroxyapatite bone crystals have a blade shape approximately 25 nm wide, 2–5 nm thick and about 60 nm long, as can be appreciated in the Transmission Electron Microscopy (TEM) image shown in Fig. 7.1 [10].

Bone tissues can be defined as mineral–organic composite materials. The organic–mineral phase ratio can vary, depending on species, tissue location, age, diet and pathologies [11], [12].

In mammal long bone (cortical bone), the organic matrix represents 22 wt.%, mineral 69 wt.% and the rest (9 wt.%) is the water associated with the organic matrix or with the mineral. The organic matrix is mainly composed of type I collagen (90 wt.%) that would act as template upon which the first mineral crystals were formed [13]. The not yet completely elucidated mechanism of cell-mediated collagen mineralization may be considered a sequence of events requiring the interaction of many different promoting or inhibiting factors [14]. It is widely accepted that matrix vesicles are formed by release of budding from osteoblasts surfaces [15–18], inside which the amount of calcium and phosphate raise to a saturation level, favorable for deposition of amorphous calcium phosphate, octacalcium phosphate and/or brushite with later transformation into HA [19]. The apatite nuclei from matrix vesicles act as templates for new crystal proliferation, which spread into the adjacent collagenous matrix [18]. Type I collagen is produced by osteoblasts and then processed outside the cell, ending in the surrounding extracellular

space, where the fibrils self-assemble into mature collagen fibrils that undergo biomineralization. For this reason, bone is the typical example of an “organic matrix-mediated” mineralization process [10]. Each collagen I polypeptidic chain contains a helical domain with 338 contiguous repetitions of the sequence (Glycine-X-Y) where X and Y are often proline and hydroxyproline. Each individual chain coils in a triple-stranded helix, stabilized by interchain crosslinking. The triple-stranded helical filaments of uniform size (280 nm long, 1.5 nm wide) and a molecular mass of about 285 kDa present N and C non-helicoidal terminal domains [20]. Figure 7.2(a) reports the collagen fibril structure as a revised quarter-stagger model

**Fig. 7.2.** Quarter stagger model of collagen fibers: (a) alignment of collagen gap regions to form grooves. In them HA crystals grow with crystallographic *c*- and *a*-axes preferentially aligned parallel to the collagen fiber axis and groove directions, respectively (b). (Reproduced by permission from Ref. [10].)

where molecules are lined up head-to-tail in rows that are staggered of 64 nm along their long axis. Each molecule is transposed by 64 nm with respect to the previous one, and is divided into five sectors, the first four are 64 nm long and the fifth is 25 nm long. This arrangement, stabilized by strong intermolecular crosslinks, produces a regular array of small gaps, 40 nm long and about 5 nm wide, referred to as “hole zones” which are considered to be the *loci* of the nucleation and growth of hydroxyapatite nanocrystals. Adjacent hole zones overlap to form grooves structured in parallel rows along the main axis of the three-dimensional (3D) fibril structure, allowing hydroxyapatite to grow into plate-shaped nano-crystals, oriented such that the crystallographic *c*-axis is preferentially aligned along the collagen fibril axis (Fig. 7.2b) [21]. Utilizing the coincidence, in orientation, between HA crystallographic *c*-axis and collagen fibrils main axis, X-ray diffraction patterns recorded using conventional and synchrotron radiation sources at both wide and low angles from single osteons and osteonic lamellae have allowed to determination of the orientation of hydroxyapatite crystallites and, consequently, collagen fibrils in bone [22–25]. The bone of vertebrates can be considered as a “living biomaterial” since inside it there are cells under permanent activity. The osteoblasts remain trapped inside the mineral phase, evolving towards osteocytes, which continuously maintain the bone formation activity.

In teeth, dentine, which resides within the central regions of the tooth, is similar in structure and composition to bone. Enamel on the outside of tooth, however, has a high inorganic content, close to 95 wt.%, which is constituted mainly of long thin ribbon-like crystals of carbonated hydroxyapatite. The “spaghetti-shaped” nano-crystals are arranged in bundles oriented in three different directions, associated with a matrix of proteins excluding collagen (Fig. 7.3). Amelogenins, present in relatively large amount in the early stages of enamel formation, are degraded and removed by up to 5 wt.% as the hydroxyapatite crystals grow [10]. Apatite nanocrystals grow with their *c*-axis preferentially oriented parallel to the long axes of the microribbons [26]. Dental enamel does not contain cells and as a conse-

**Fig. 7.3.** Scanning electron micrograph of enamel carbonated hydroxyapatite “spaghetti shaped nanocrystals” arranged in bundles oriented along three different directions. Scale bar = 10  $\mu\text{m}$ . (Reproduced by permission from Ref. [10].)

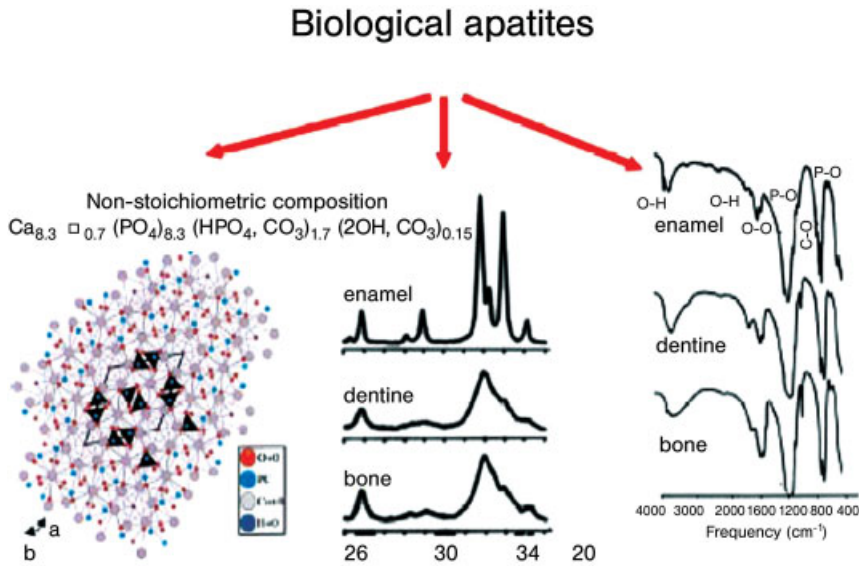

Fig. 7.4. Crystal structure of natural carbonate hydroxyapatite. Powder X-ray diffraction patterns and infrared spectra of enamel, dentine and bone are given. (Reproduced by permission of Ref. [27].)

quence of it any degradation or damage cannot be biologically repaired, evidencing the need for synthetic enamel biocompatible materials repairing tooth deterioration.

Biogenic hydroxyapatite exhibits special behavior due to its nano-size dimensions, low degree of crystallinity, non-stoichiometric composition, crystalline surface disorder and presence of carbonate ions in the crystal lattice. Figure 7.4 shows the crystal structure of biological hydroxyapatite, together with the X-ray diffraction patterns and infrared spectra of enamel, dentine and bone [27].

#### 7.4

##### **Biomimetic Hydroxyapatite: Porous and Substituted Apatites**

In the last decade advanced technology has been utilized to synthesize a new generation of inorganic alloplastic materials that mimic natural bone and can function as a scaffold upon which cells can be seeded, developing “*in vitro* autologous bone” [28–30].

The aim is to provide synthetic 3D scaffolds onto which cells are cultured and the artificial piece can be colonized both under *in vitro* and *in vivo* conditions. To control the interaction with biological entities much attention has been devoted to charactering the surface properties of the scaffolds. The use of nanosized hydroxyapatite to prepare apatitic bioceramics with tailored microstructure and porosity

opens up many possibilities. In fact poorly crystalline HA nanocrystals, in addition to the excellent biological properties of HA such as non-toxicity and lack of inflammatory and immunitary responses, have a high bioresorbability. This further property allows this kind of bioceramic to be completely replaced by neo-formed bone.

The bioresorbability of hydroxyapatite under physiological conditions can be modulated by modifying its degree of crystallinity which can be obtained by implementation of innovative synthesis with a nanodimensional control. Sol-gel, spray-drying, hydrothermal synthesis, recently reviewed [31], have been developed to obtain nanoparticles with high specific surface area, high bioresorbability and containing foreign ions, mimicking bone hydroxyapatite chemical-physical and physiological behavior [32–35].  $Mg^{2+}$  ions which cause acceleration of nucleation kinetics of hydroxyapatite and inhibit its crystalline growth [36], are present in high concentration in bone tissue during the initial phases of osteogenesis and tend to disappear when the bone is mature [37]. Similar behavior can be reproduced in synthetic  $Mg^{2+}$ -substituted hydroxyapatites characterized by a low degree of crystallinity and an high bioresorbability. Carbonate apatite containing different amounts of  $Mg^{2+}$  can be synthesized by dropping solutions of  $NaHCO_3$  and  $H_3PO_4$  simultaneously into a  $Ca^{2+}$  and  $Mg^{2+}$  basic suspension [38], or, under aqueous conditions, by employing a cyclic pH variation technique [36]. The replacement of magnesium for  $Ca^{2+}$  in the hydroxyapatite structure and its destabilizing effect on hydroxyapatite crystallization has been widely investigated [39–41]. The effect of magnesium in limiting the degree of hydroxyapatite crystallinity has been utilized to synthesize powders that form agglomerates of about 10–25  $\mu m$  from primary particles about 30–50 nm in size. The contemporary substitution of 0.25–0.30 of  $Mg^{2+}$  relative to  $Ca^{2+}$  and a carbonation fraction between 0.07 and 0.13 relative to  $PO_4^{3-}$  optimizes the most favorable and biomimetic stoichiometry, reflecting as much as possible the composition of bone tissue. An *in vivo* experiment performed filling defects in rabbit femur with granules of the carbonate Mg-HA showed that a period of one month is enough for this filler to be completely replaced by new bone tissue [42]. After preparing powders that preserve the composition of natural apatite, the next step is to use them to design implants having a biomimetic porosity. Porous HA with a morphology simulating that of spongy bone (Fig. 7.5) (porosity varying from a microporosity of  $>1 \mu m$  to a macroporosity ranging from 300 to 2000  $\mu m$ ) has been prepared using various technologies to control pores dimension, shape, distribution and interconnections. HA ceramics processed by high-temperature treatment [43] present a significant reduction of reactivity and growth kinetics of new bone. New formation methods at lower temperatures have been developed, allowing one to obtain porous bioceramics with a low degree of crystallinity. Colloidal processing [44], starch consolidation [45, 46], gel casting and foams out [47] have yielded excellent results, producing bioceramics with a bimodal distribution of the pores size that can be modified as a function of the sintering conditions.

Porous coralline HA can be synthesized by a hydrothermal method for HA formation directly from natural sea corals [48] and HA replaces aragonite whilst preserving its porous structure. The biaxial strength of coralline apatite could be

**Fig. 7.5.** SEM images of a porous apatitic bioceramic mimicking spongy bone porosity, having a macroporosity ranging from 300 to 2000  $\mu\text{m}$  (scale bar = 1 mm) (a) and microporosity of  $>1 \mu\text{m}$  (scale bar = 10  $\mu\text{m}$ ) (b).

improved due to a unique double treatment that includes a nano-coating layer to cover meso- and nanopores. In this two-stage process, the coral is fully converted into hydroxyapatite and then coated with a sol-gel-derived apatite (Fig. 7.6a–c). This new material can be applied to bone graft applications where high strength requirements and longevity are pertinent [49, 50].

The interconnected network of pores promotes bone in-growth, but also allows bioceramics to be utilized as drug delivery agents, by inserting different bioactive molecules. Many studies have demonstrated that hydroxyapatite ceramics can be used to deliver steroids, antibiotics, proteins, hormones, anticancer drugs. The aim has been to develop devices able to deliver the appropriate drug amount for a relatively long period of time, whilst minimizing the concentration of the drug in the bloodstream and other organs and the potential side effects produced by systemic administration. Porous ceramics closely mimicking spongy bone morphology have been synthesized by impregnation of cellulosic sponges with poorly crystalline HA water suspension [51]. These porous ceramics have been tested as controlled drug delivery bone grafts to evaluate the fundamental parameters that control release kinetics. A theoretical approach, based on the use of the Finite Element Method, was adopted to describe the Ibuprofen-lysine and Hydrocortisone Na-succinate release kinetics, comparing the numerical results with the experimental ones [52].

An alternative approach to tissue engineering, which uses cells seeded onto macropores of these HA scaffolds to promote bone ingrowth, is represented by filling the macro and micropores with gelatine, which can act as cell nutrient and/or delivery agent of bioactive molecules [53].

If bioceramics are used in powder form for bone filling applications, the HA powder is usually mixed with a polymeric carrier matrix to avoid migration out of the implant region. Both non-absorbable [poly(methyl methacrylate) [54], polyethylene [55] and polysulfone] and biodegradable (poly(lactic acid) [56], polyglycolic acid, collagen, cellulose and starch [57, 58]) polymeric matrices can be used, even

**Fig. 7.6.** SEM images of (a) *Goniopora* coral morphology, (b) *Goniopora* coral converted into pure HA, and (c) sol-gel derived nanocoated surface of previously converted *Goniopora* coral (scale bar = 500  $\mu\text{m}$ ). (Reproduced by permission of Ref. [49].)

if the non-biodegradability reduces drastically the bioactivity of the HA crystals. Biodegradable polymers are widely used in the medical field as scaffolds in tissue engineering. Among natural polymers, those from the vegetable kingdom are sometimes preferred to those of animal origin to avoid immunogenic reactions. Alginates, a family of unbranched binary copolymers are extracted from marine brown algae. They form insoluble hydrogels for binding with bivalent cations like

Ca<sup>2+</sup> and, as a consequence, of it calcium crosslinked alginate hydrogels have been utilized in many biomedical applications, including cell transplantation and drug delivery [59–61]. A biomimetic composite has been prepared by direct nucleation of HA on alginate copolymer, exploiting a self-assembly process and a typical egg-box structure can be obtained in samples with a 60/40 HA/Alg. wt ratio [62].

HA nucleation on alginate leads to the nucleation of HA nanocrystals – the polymer prevents further growth. In fact the X-ray diffraction pattern of the HA-alginate scaffold shows the characteristic diffraction maxima of poorly crystalline bone-like apatitic crystals, and TG analysis reveals that HA nanocrystals are 4 wt.%-carbonated [63]. An alginate-HA nanocrystals scaffold seeded with MG63 cells, cultured for 7 days and then subjected to morphological analysis has been shown to favor cell growth while maintaining their osteoblastic functionality [64]. An alginate-Mg carbonated HA nanocrystals bone filler has been patented for orthopedic and odontoiatric implantations [65].

### Biologically Inspired Hydroxyapatite: HA–Collagen Composites and Coatings

Biological organisms are the only true intelligent systems capable of acting as a real “functional material”. However, recently, synthetic biologically inspired materials have been prepared with the aim of reproducing, even if only partially, some specific functionalities of biological tissue. Presently, the induction of spontaneous self-assembling of molecules by building intelligent interfaces capable of interactive responses is a real possibility that resembles what occurs in living organisms. The driving forces governing the self-assembly are essentially hydrogen bonding, Van der Waals electrostatic forces and electron-transfer interactions [66, 67].

New methods of synthesis have been developed to utilize the capacity of biological systems to store and transfer information at a molecular level to obtain the spontaneous self-assembly of these entities into a superior architectural arrangement. These syntheses are denoted “biologically inspired” because they reproduce an ordered structure and an environment very close to the biological one. As the complex hierarchic structure of bone originates from the nano-sizes of the first apatite crystals inside the gap regions of collagen fibril structure, nanotechnology concepts and techniques are predominant in preparing biologically inspired bone grafts materials. The *in vitro* self-assembly of collagen molecules induced by thermal or pH variation, to form native fibrils, illustrates that collagen molecules themselves contain all of the structural information necessary for the assembly [68, 69]. Teloepitides-free type I collagen molecules have been utilized as a storehouse of information to nucleate carbonated hydroxyapatite nanocrystals inside the self-assembled collagen fibers (Fig. 7.7a and b) [70].

The two components hydroxyapatite nanocrystals and collagen fibrils, exhibit strong chemical and structural interactions that show a complete analogy of the synthesized composite with natural bone. The apatite crystals have nanometric dimensions, acicular-shaped morphology, and preferential orientation of their *c*-axis

**Fig. 7.7.** TEM micrographs of synthetic biologically inspired self-assembled collagen fibers/HA nanocrystals composites showing HA nanocrystals nucleated inside the self-assembled collagen fibers (scale bar = 100

nm) (a) and acicular-shaped HA nanocrystals subsequently grown onto the collagen fibers surface (scale bar = 100 nm) (b). (Reproduced by permission of Ref. [71].)

parallel to the direction of orientation of collagen fibers [71]. X-ray diffraction analysis revealed not only the crystal preferential orientation, but also a poor degree of crystallinity very close to that of bone apatite reported in Fig. 7.4. Further evidence of the chemical interaction between collagen fibrils and inorganic crystals is furnished by FTIR analysis. In fact the  $\text{COO}^-$  groups of collagen are the sites for a possible interaction with HA, and in the FTIR spectra of synthetic HA–Collagen composite a shift of the  $\text{COO}^-$  antisymmetric stretching band from  $1340\text{ cm}^{-1}$  of pure collagen to  $1337\text{ cm}^{-1}$  can be appreciated, resembling what is observed for naturally calcified collagen [72]. The adsorption band at  $870\text{ cm}^{-1}$  present in the FTIR spectra of HA–collagen composite indicates that the nucleation of hydroxyapatite nanocrystals onto collagen implies carbonation of the apatite phase. Moreover, the carbonation can be assigned only to the B position, as confirmed by the absence of the band at  $880\text{ cm}^{-1}$  and by EDS analysis, which reveals that the increase in C content, due to  $\text{CO}_3^{2-}$  groups, corresponds to a decrease in P concentration, maintaining almost constant the stoichiometric ratio  $\text{Ca}/(\text{C}+\text{P})$ . The interaction of HA with collagen seems to prevent carbonation in the A position, probably by blocking access to  $\text{OH}^-$  groups [73]. Carbonation of synthetic hydroxyapatite nanocrystals reduces their crystalline degree increasing the similarity with bone inorganic phase and, especially, raising their bioactivity and biodegradability [74, 75]. Histological sections of implants in rabbit femur after two months showed, along with osteoblastomas, osteoclastic-like cells revealing that hydroxyapatite nanocrystals–collagen fibrils composite induces an active remodeling process, characterized by simultaneous osteoclastic phagocytosis and osteoblastic osteogenesis. The bone tissue reaction of hydroxyapatite nanocrystals–self-assembled collagen fibrils composite was examined in rat tibias to clarify the new bone formation mechanism [76]. This biologically inspired composite was implanted into tibias of rats, and observed at different days after implantation. Bone tissue reactions of the composite demonstrated osteoclastic resorption of the biomaterial, followed by new bone formation by osteoblasts. Alkaline phosphatase

activity has been observed in the neighborhood of the composite and new bone was actively formed around these sites in a way very similar to the reaction of a transplanted autogenous-bone. Detailed study on these bone reactions is currently progressing, and it has been assumed that the substitution process of the composites to new bone occurs as follows:

1. Formation of the composite debris via erosion by body fluid.
2. Phagocytosis of the debris and the composite surface by macrophages.
3. Induction of osteoclastic cells on the composite surface and resorption of the composite via a similar process to that of bone.
4. Induction of osteoblasts to the resorption lacunae created by osteoclastic cells and formation of new bone in the surroundings of the composite.

These reactions have not been reported on other HA/Collagen composite materials [77, 78] synthesized without using the self-organization process, which causes difference in cell reaction. In fact it is the bone-like nanostructure that can deceive the bone-related cells into starting the remodeling process. The hydroxyapatite nanocrystals–self-assembled collagen fibrils composite can be successfully utilized as an artificial bioinspired material in both the orthopedic and dental fields as an *in vivo* filler and an *in vitro* tissue regenerator.

Nevertheless, calcium phosphate/collagen composites exhibit weak mechanical behavior which can be improved by chemical crosslinking collagen, but at the expense of reducing their bioreabsorbability [79]. Calcium phosphate/collagen composites are limited to non-loading applications, but are particularly suitable to prepare bioactive coatings onto the surface of metallic implants with the aim of accelerating bone formation and implant fixation. Because of the presence of collagen fibers inside this kind of hybrid composite, a coating of it on metallic implants cannot be made by plasma spray or physical vapor deposition. Instead, electrolytic deposition appears to be the most promising technical procedure. Calcium phosphate coatings have been synthesized by electrochemical deposition from different  $\text{Ca}^{2+}$  and  $(\text{PO}_4)^{3-}$  solutions, in acid and in basic conditions [80–83], but also without conditioning pH by adding acid or basic reagents (Fig. 7.8a) [84]. Many technical difficulties have arisen in making a homogeneous and uniform collagen/calcium phosphate coating by electrolytic deposition on top of metallic supports. A collagen/calcium phosphate coating has been crystallized on an apposite electrode, but is not surface stable and is spontaneously chipped off forming a precipitate [85]. A bioactive multilayer collagen/calcium phosphate coating has been obtained by electrocrystallization of calcium phosphate on titanium electrode where the collagen was previously physically absorbed on the surface, but the thickness and the collagen/mineral composition ratio are strongly limited [86]. A double-layered collagen fibril/octacalcium phosphate composite coating on silicon substrates has been recently obtained by electrolytic deposition. The Si cathode surface is covered by a 100 nm thin layer of calcium phosphate coating on top of which a 100  $\mu\text{m}$  thick collagen fibril/octacalcium phosphate cluster composite layer is formed [87].

Electrolytic deposition of a biomimetic, bone-like self-assembled collagen fibrils/

**Fig. 7.8.** SEM micrograph of coatings, electrolytically deposited on titanium plate, consisting of (a) apatite synthesized from  $\text{Ca}(\text{NO}_3)_2$  and  $\text{NH}_4\text{H}_2\text{PO}_4$  solutions (scale bar =  $10\ \mu\text{m}$ ) and (b) self-assembled collagen fibrils/HA nano-crystals composite, both obtained without conditioning solution pH by adding acid or basic reagents (scale bar =  $2\ \mu\text{m}$ ). (c) TEM image of the collagen/HA composite shown in (b) (scale bar =  $200\ \text{nm}$ ).

HA nano-crystals composite coating on titanium plates has been performed, using  $\text{Ca}(\text{NO}_3)_2$  and  $\text{NH}_4\text{H}_2\text{PO}_4$  solutions in a purely helical type I collagen molecule suspension. The use of dilute electrolytic solutions, low current density at the cathode and room temperature affords a coating composed of poorly crystalline carbonate hydroxyapatite nano-crystals that nucleate inside and around the reconstituted collagen fibrils distributed in a homogeneous network on Ti plate surface (Fig. 7.8b).

If the telopeptides-free collagen molecule assembling takes place during the crystallization of the apatite phase, the neo-forming collagen fibrils mineralize with a close structural relationship to the inorganic phase. FTIR analysis of this composite shows a shift of  $\text{COO}^-$  stretching of collagen resembling natural mineralized collagen fibers. This biomimetic feature of nanocrystals that nucleate and grow inside the fibrils is of interest only at the beginning of the calcification process, which continues with the massive growth of HA nanocrystals onto the collagen fibrils surface (Fig. 7.8c).

These two different kinds of collagen fibers mineralization resemble what has been observed in the self-assembled collagen fibers–hydroxyapatite nanocrystals in aqueous solutions [71]. The FTIR adsorption band at  $870\ \text{cm}^{-1}$  and the absence of that at  $880\ \text{cm}^{-1}$  observed for the composite coating allows assigning the car-

bonation of the hydroxyapatite only to the B position, closely resembling the carbonation of bone apatite.

These results [84, 88] suggest auspicious applications in the preparation of medical devices such as biomimetic bone-like composite-coated metallic implants with a loading capability deriving from the metal core and having, at the same time, a bioactive surface that accelerates bone formation and implant fixation.

## 7.6

### Functionalized Hydroxyapatite: HA Nanocrystals – Bioactive Molecules

An important question in biocompatibility is how the device or material communicates its structural make-up to direct or influence the response of proteins, cells, and the organism to it. For devices and materials that do not leach undesirable substances, this communication occurs through the surface structure; the body reads the surface structure and responds. The distribution of ions and molecules on the surface of all condensed matter has a special organization and reactivity and requires novel methods to be tailored above all because these ions and molecules may drive many of the biological reactions that occur in response to the biomaterial.

HA nanocrystals exhibit a high surface area (from 60–130 up to 180 m<sup>2</sup> g<sup>-1</sup> for natural ones) characterized by an elevated surface disorder in which the ions stoichiometry is not maintained. This property is considered responsible for the higher HA nanocrystals reactivity in respect to the larger ones and can be affected by the crystals shape. In fact the crystals expose different planes to the biological environment as a function of their shape (plate, acicular or needle shape) even if they exhibit the same surface area. Needle and plate shape (about 100 nm and 15 nm sized) synthetic HA nanocrystals TEM images are shown in Fig. 7.9(a) and (b) respectively. Only in recent years has high-resolution electron microscopy (HREM) been successfully applied to investigate hydroxyapatite structure to discern different calcium phosphate phases that often coexistent in the same crystalline granule. Among the rather few HREM studies on hydroxyapatite, some refer to the material itself [89], others to HA thin films [90]. This kind of analysis allows us to view the surface disorder at the boundaries of the crystallites constituting the single nanocrystals (Fig. 7.10a). Furthermore, HREM at high resolution allows us to observe the HA nanocrystals interplanar spacing (Fig. 7.10b), permitting discernment between HA and OCP, which are both elongated along the *c*-axis.

Surface functionalization of HA nanocrystals by bioactive molecules is an innovative approach not only to modulate but also to drive their reactivity. In this way HA nanocrystals will not only guarantee, for instance, either osteointegration or osteoinduction enhanced properties but they will also perform, by stimulating specific cellular responses, at the molecular level.

Only in recent years have scientists begun to use biomolecules for the synergistic coupling of crystals synthesis and functionalization. In fact, previous studies have limited the use of biomolecules as simple growth inhibitors of HA crystallization,

**Fig. 7.9.** TEM images of synthetic HA nanocrystals that are (a) needle shaped (approx 100 nm in size; scale bar = 200 nm) and (b) plate shaped (approx. 15 nm in size; scale bar 100 nm).

rather than considering their use as a strategy to fine-tune the bioactivity of the nanoparticles [91, 92]. Studies of the effect of biological molecules onto hydroxyapatite crystal growth have been related directly to physiological or pathological calcification processes. Particular interest has been dedicated to amino acids, which are compounds of major importance for living organisms, even because their con-

**Fig. 7.10.** HREM images of HA deposited by laser showing (a) the grain boundaries of crystallites with different orientation at low magnification and (b) in a single crystallite the interplanar spaces  $D_{hkl} = 0.82$  and  $0.38$  that are characteristic of HA. (Reproduced by permission of Ref. [90].)

centration is controlled by physiological mechanisms and they enter inside the cell environment by simple diffusion [93, 94]. The effects of 4-hydroxyproline, tyrosine and serine (amino acids with uncharged polar side groups), glycine, cysteine, cystine, and glutamine (amino acids with neutral polar side groups) and lysine, which is an amino acid with a basic side group, on HA crystallization have been studied by the “constant composition technique” [95–97]. Using this technique, the chemical potentials of the species in the working solution are kept constant during the crystallization process by the stoichiometric addition of reactants and therefore the crystal growth reaction is performed under pseudo-steady-state conditions. Diverse inhibiting activities were observed as a function of the different amino acid side group. These studies have shown that crystallization kinetics are affected by blockage of the active growth sites on the crystal surface.

Considering that the presence of proteins, (and hence amino acids) in biological materials is intrinsic to the bioactivity of HA, amino acids can be considered as agents that can increase the bioactivity of the synthetic HA. Concerning this, aqueous colloids of positively charged amino acid-functionalized HA nano-rods less than 80 nm long and ca. 5 nm wide have been synthesized by hydrothermal crystallization [98]. The colloidal stabilization and its positive zeta potential, together with FTIR spectroscopy data, were consistent with a general model in which the  $\alpha$ -carboxylate of the amino acid was preferentially bound to the crystal surfaces, inducing a crystal growth inhibition predominantly onto the Ca-rich surfaces during the initial stages of crystallization. To better define the surface  $\text{Ca}^{2+}$  role on amino acid linking, calcium deficient hydroxyapatite nanocrystals (CDHA) were synthesized in the presence of differently charged amino acids (alanine, cysteine, arginine, aspartic acid). The data obtained suggest a binding model in which the amino acid amino group is preferentially bound to the CDHA crystals, probably through a phosphorus amiditic linkage, such that the negatively charged carboxylate group exposed at the crystal/solvent interface determines the surface charge. In fact, zeta potential measurements showed that the CDHA/amino acids nanoparticles had an enhanced negative charge with respect to CDHA synthesized in the absence of amino acids [99]. The isoelectric point of the amino acid used as additive during the synthesis strongly affects the nanocrystals morphology and crystallites dimensions.

An innovative improvement of the functionalization process is represented by the synthesis of apatite nano-crystals surface loaded with bioactive molecules that promote a desirable cellular response if released with controlled kinetics. To reach this goal, it is a priority to investigate the chemical mechanisms of the binding and desorption of bioactive molecules by crystals surface. In fact, bioactive ceramics with drug delivery function, previously described, adsorb and release molecules through a mechanism dominated predominantly by physical parameters, such as carrier porosity and dimensions, bioactive molecule steric hindrance and environment diffusive conditions.

Slurries of hydroxyapatite have been successfully used to investigate the link and release processes of cisplatin, one of the most frequently prescribed drugs for the treatment of several solid tumors. Chemotherapeutic treatments applied locally to

osteosarcoma can result in tumor inhibition and much less-toxic systemic values of released drugs. Both the adsorption and release process of cisplatin were found to depend significantly on the ionic composition of the aqueous media used [100]. In fact, at a constant pH of 7.4, significantly more cisplatin is adsorbed by the hydroxyapatite crystals from a free buffer solution than from a buffered solution containing chloride ions. The amount of hydroxyapatite-bound cisplatin desorbed into solution was also progressively increased as a function of the increasing concentration of chloride in the equilibrating solution. These results suggest that it is the hydrated positively charged derivatives of cisplatin, whose hydrolysis is inhibited in chloride-rich solution, that are involved in the adsorption of cisplatin by the surface phosphate-rich hydroxyapatite crystals. Further work has demonstrated that subtle variations of the chemical–structural characteristics of the apatitic crystals affect both the adsorption and desorption of the drug cisplatin [101].

Adsorption isotherms obtained in ultrapure water and kinetic release in EPES buffer saline solution (containing chloride to favor release of the adsorbed platinum complex) indicate that cisplatin kinetics increase with decreasing crystallinity, the latter being associated with either smaller nanocrystals dimensions or greater surface area, which is strictly related to the amount of surface lattice defects which create active binding sites [102].

On the other hand, apatitic phase for bone specific delivery of geminal bisphosphonates (BPs) – a class of drugs that have been developed for use in various diseases of bone, tooth and calcium metabolism – are currently under investigation [103]. BPs are compounds characterized by two phosphonate groups attached to a single carbon atom, forming a “P-C-P” structure which is affine to  $\text{Ca}^{2+}$  ions. As a consequence, they strongly bind to calcium phosphate crystals and inhibit bone resorption by hindering their growth, aggregation and dissolution. However, BPs *in vivo* action mechanism involves cellular effects that are added to the surface physicochemical outcome of inhibiting HA crystal growth [104, 105]. Interestingly, while the affinity of BPs for bone mineral hydroxyapatite is the basis for their use as inhibitors of bone resorption, at the same time their coordinating abilities towards ions present on apatitic surfaces might be extended to design new delivery system for bone targeted drugs. In this context, calcium phosphate ceramics have been shown to be good biocompatible carriers for BPs, such as 1-hydroxy-2-(imidazol-1-yl-amino)-ethylidenebisphosphonic acid (Zoledronate) that is efficient for the treatment of post-menopausal osteoporosis and bone metastases [106]. A simple mathematical model was designed that correctly described the Zoledronate–calcium phosphate interaction at equilibrium, in simplified media such as ultrapure water or phosphate buffers [107]. However, the chemical link occurring between the BPs and calcium on the surface of HA nanocrystals is so strong that the BPs release kinetics appear affected by the bioresorbability of apatitic nanocrystals [108].

Because of the affinity of bisphosphonate groups to calcium, Keppler has proposed platinum compounds containing aminobisphosphonate ligands, which are expected to have a selective tropism for bone apatite and, at the same time, to present the well-known cytotoxic activity typical of platinum complexes [109]. Bis(ethy-

lenediamino)diplatinum medronate ( $[\text{Pt}_2(\text{C}_2\text{H}_8\text{N}_2)_2(\text{CH}_2\text{P}_2\text{O}_6)]$ ) has been linked to two different biomimetic synthetic hydroxyapatite nanocrystals having the same composition but different physicochemical properties such as crystal shape, crystallinity, domain size, and specific surface area. A detailed surface characterization of the drug-loaded HA nanocrystals, necessary to determine the surface stoichiometry, has been carried out on the Pt complex/HA conjugate by Attenuated Total Reflection (ATR) spectroscopy and XPS (X-ray Photoelectric Spectroscopy) analyses. Results have shown a Pt/N ratio very close to that of the not-linked bis(ethylenediamino)diplatinum medronate, confirming that it does not undergo degradation, as concerned the Pt–N bound, during absorption onto the apatite nanocrystals [102].

Finally, an innovative approach to fine-tune the cellular response to implanted apatite nanoparticles, without using the release of bioactive molecules can be ob-

Fig. 7.11. (a) TEM image of needle-shaped magnetic HA nanocrystals (scale bar = 100 nm). (b) Magnetic susceptibility of apatite nanocrystals synthesized in the presence of

different amounts of the magnetite complex. Curves 2 and 3 are for samples that contain double and triple, respectively, the amount of complex in the sample for curve 1.

tained inducing a specific physical property onto apatite nanocrystals. With this aim a bone-like nanocrystalline apatite showing magnetic properties has been synthesized using a magnetite complex as a co-reagent (Fig. 7.11a) [110, 111]. The magnetic susceptibility of this material shows an increase in magnetization as a function of magnetite complex content (Fig. 7.11b). The well-known bioactive properties of the poorly crystalline apatite, along with the magnetic responsiveness of such HA nanocrystals, make this innovative material an attractive potential candidate for selective heating by external electromagnetic induction and then for bone anticancer hyperthermia treatment [112].

## 7.7

### Conclusion and Future Challenges

Synthesis of substituted, biomimetic, biologically inspired, functionalized hydroxyapatite nano-crystals has been described and their morphological, structural, chemical–physical, surface characterization has been evaluated to explain their high bioactivity and ability to induce bone regeneration and remodeling. The discussion should be enough to describe how size is a crucial factor in determining the HA bone substitutes chemistry in the nano-regime.

Even if spontaneous self-organization is a fascinating and inimitable essence of life material, the biomimetic chemical–physical characteristics of synthetic hydroxyapatite nanocrystals can render themselves *in vitro* and *in vivo* spontaneously mineralizable. The main guides for biomimetic approaches such as supramolecular organization, interfacial molecular recognition and multilevel processing, are strongly connected to the nano-sized dependent chemistry of apatite crystals. Pursuing the aim to mimic more and more the characteristics of bone tissue, the synthesis of biomineral-inspired hydroxyapatite nanocrystals is a reality that is becoming transferable into the preparation of technologically innovative biomedical devices. The synthesis of nanostructured biomimetic bone substitutes resembling the complex hierarchical structure of the biological tissue is an attractive field of research that is achieving the promised results. Moreover, the ability to functionalize the surfaces of apatite nano-crystals with bioactive molecules makes them able to transfer information and to act selectively on the biological environment. Furthermore, this approach offers a promising route to the construction of hierarchically ordered biomaterials based on the principle of controlled nanoparticle self-assembly, allowing us to consider inert mineral materials as templates for life.

### Acknowledgments

We thank MIUR (Cofin 2004-032118) and University of Bologna (funds for selected research topics) for financial support, and Bologna University Laboratory of

Environmental and Biological Structural Chemistry (LEBSC) research group and Bristol University Mann's research group for fruitful discussions.

# Magnetic Nanoparticles for Tissue Engineering

*Akira Ito and Hiroyuki Honda*

### 8.1

#### Introduction

Magnetic nanoparticles, from nanometer to submicron size, have been developed for medical applications by many researchers [1, 2]. Since magnetic nanoparticles have unique magnetic features not present in other materials, they can be applied to special medical techniques. Magnetic particles are attracted to high magnetic flux density and this feature is used for drug targeting [3] and bioseparation [4–6], including cell sorting [7]. A comprehensive review on the use of magnetic particles in clinical applications was given by Häfeli et al. [8]. In these applications, magnetic particles are given various names, e.g. magnetic microspheres, magnetic nanospheres, and ferrofluids, among others. Here, we use the general term “magnetic nanoparticles”, and review and discuss their new applications in tissue engineering.

Magnetite ( $\text{Fe}_3\text{O}_4$ ) particles are being used in an increasing number of biological and medical applications, including cell sorting. To add an affinity and target ability to cells, we applied the concepts involved in drug delivery systems (DDSs) to magnetite nanoparticles and developed functionalized magnetite nanoparticles. We developed magnetite cationic liposomes (MCLs), which are cationic liposomes containing 10-nm magnetite nanoparticles, to improve accumulation of magnetite nanoparticles in target cells by taking advantage of the electrostatic interaction between MCLs (positively charged) and the cell membrane (negatively charged) [9–11]. Since MCLs are designed to interact with target cells via electrostatic interaction, there is the risk of non-specific interaction between MCLs and various non-target cell types. A promising technique is the use of antibodies raised against target cells to isolate them from the other cells. We developed antibody-conjugated magnetoliposomes (AMLs) for use in cancer-targeted therapy [12–14]. The AMLs were made from magnetoliposomes (MLs) consisting of neutral lipids, to reduce electrostatic interaction with target cells. Target cells can be magnetically labeled by the functionalized magnetite nanoparticles (MCLs or AMLs), via uptake of magnetite nanoparticle into the cells (Fig. 8.1).

The loss or failure of an organ or tissue is one of the most frequent, devastating,

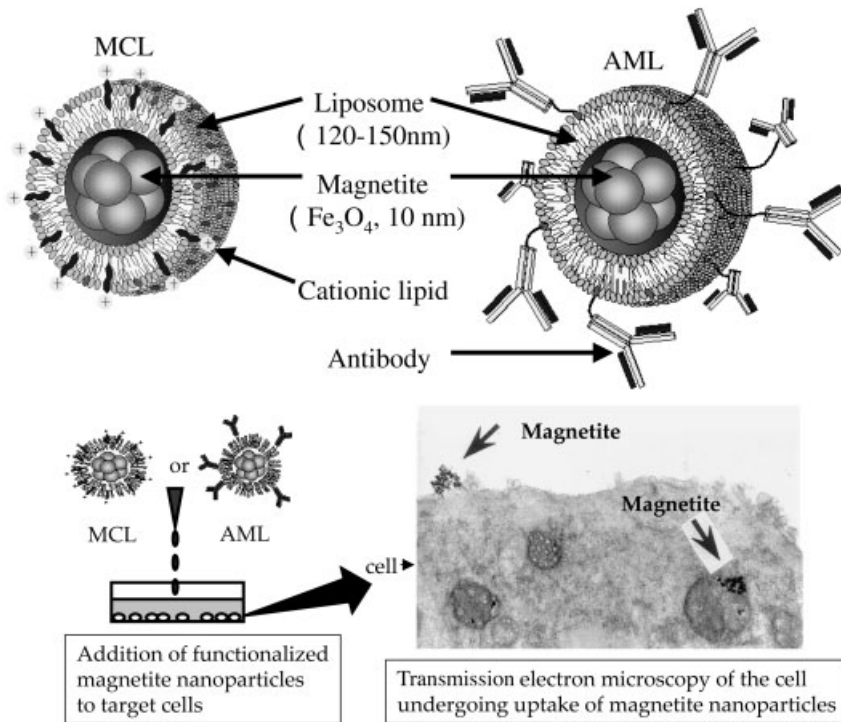

Fig. 8.1. Schematic of functionalized magnetic nanoparticles.

and costly problems in human health care. Tissue engineering applies the principles of biology and engineering to the development of functional substitutes for damaged tissue. Langer and Vacanti laid the foundations of this interdisciplinary field in 1993 [15], and worldwide interest in tissue engineering was initiated. The following decade saw growing enthusiasm for tissue engineering, and tissue engineering has been a promising technology for overcoming the organ transplantation crisis resulting from donor organ shortage. In general, tissue engineering consists of the following processes: (a) Target cells are isolated and expanded to the required cell number; (b) cells are harvested and reseeded into three-dimensional (3D) biodegradable scaffolds, allowing 3D cell culture; and (c) the cultured 3D constructs are implanted into patients.

Although an overall technology of these processes in tissue engineering has been established, there is still room for improvement in each process. From the point of view of bioprocess engineering, development of a methodology of “physical manipulation of target cells” is essential for tissue engineering in the next few decades. We selected magnetic force as a physical force, and manipulated target cells labeled with magnetite nanoparticles using DDS techniques. Thus, we have developed a novel cell-manipulating technology using functionalized magnetite nanoparticles and magnetic force, which we have designated “Mag-TE”. The pres-

ent chapter focuses on Mag-TE that has been applied to the processes in tissue engineering: (a) Magnetic isolation and expansion of mesenchymal stem cell (Section 8.2); (b) magnetic cell-seeding into 3D biodegradable scaffolds (Mag-seeding, Section 8.3); and (c) construction of 3D tissue-like structure by using magnetic force (Section 8.4).

## 8.2

### Mesenchymal Stem Cell Isolation and Expansion

Bone marrow-derived mesenchymal stem cells (MSCs) can differentiate into osteoblasts, chondrocytes, adipocytes, muscle cells or nerve cells *in vitro* and *in vivo* [16–19]. Since MSCs can easily be obtained by bone marrow aspiration, transplantation of bone marrow MSCs may provide a new treatment for regeneration of mesenchymal tissues [18]. However, marrow aspiration of too great a volume causes damage and pain to the donor. Thus, it is difficult to obtain the large number of MSCs required for regeneration of injured tissues. Expansion of MSCs *in vitro* is a necessary step in the clinical application of MSCs.

Despite the great interest in MSCs, there is still no well-defined protocol for isolation and expansion of MSCs in culture. Most experiments have been conducted using MSCs isolated primarily from bone marrow aspirates by their tight adherence to plastic dishes, as described by Friedenstein et al. [20]. However, this method for isolating cells does not help increase the number of MSCs, as there is only a small number of MSCs in bone marrow aspirate. Pittenger et al. reported that only a small percentage (0.0001–0.01%) of bone marrow aspirate cells that attached to the culture dishes were MSCs [16]. In addition, culture volume inevitably becomes large, since there are numerous nonadherent cells such as hematopoietic cells that must be diluted and removed by washing and changes in medium, resulting in low-density culture of MSCs. Under such low-density culture conditions, MSCs do not proliferate immediately, and require much time to develop into colonies as growth factors, including autocrine [21–24], paracrine [24], and juxtacrine [25] factors, play an important role in cell growth. Therefore, we developed a new method for producing high-density culture, using magnetic nanoparticles to promote expansion of MSCs.

#### 8.2.1

##### MSC Expansion using MCLs

We have developed MCLs that have been used as carriers to introduce DNA into cells [26], and as heat generating mediators for cancer therapy [27–31]. Here, in this study [32], magnetic forces were used to move MSCs labeled with MCLs, to hold them *in situ*, and to culture them at high density. First, we investigated the applicability of this combined methodological approach to the enrichment and proliferation of MSCs using MCLs. Figure 8.2 illustrates a schematic of MSC expansion using MCLs.

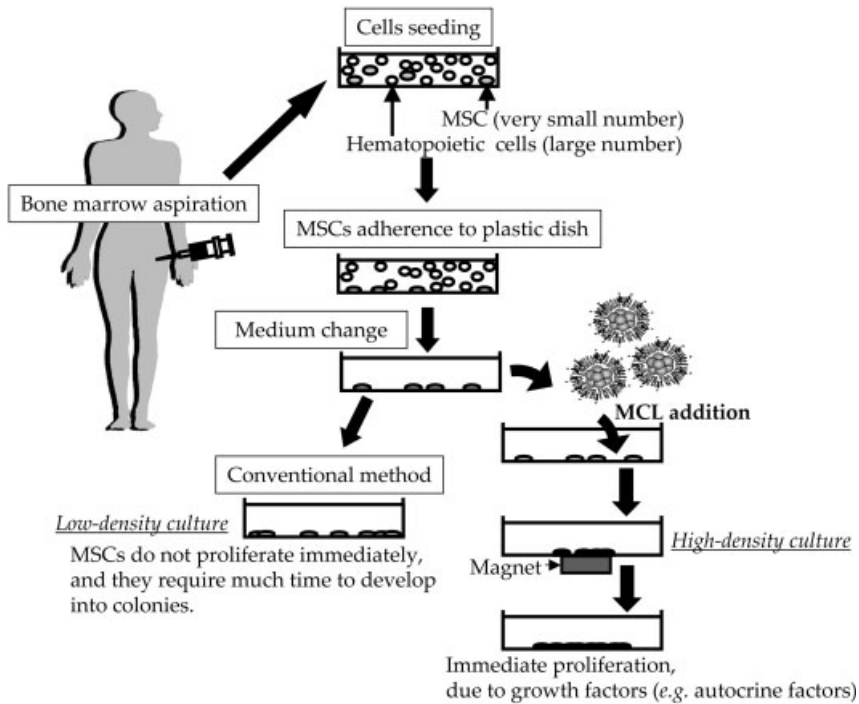

Fig. 8.2. Schematic of the expansion of MSCs using MCLs.

Expansion of MSCs using MCLs was investigated as follows. At 4 h after addition of the MCLs, 1000 human MSCs (a very small cell number corresponding to the MSCs in 1 mL of bone marrow aspirate) were seeded into a 100-mm cell culture dish with 10 mL of cell culture medium; a cylindrical neodymium magnet (diameter, 2.2 cm; height, 1 cm; 4000 Gauss) was then placed under the dish to provide magnetic force vertical to the dish.

When the MCLs were added to human MSCs at 100-pg magnetite per cell, uptake of magnetic nanoparticles began rapidly and maximum uptake ( $20 \text{ pg cell}^{-1}$ ) was achieved at 4 h after addition. Subsequently, the amount of magnetite per cell decreased due to dilution as a result of cell growth. Growth of MSCs in medium containing MCLs (MCL(+))MSCs) was compared with growth of MSCs in medium without MCLs (MCL(-))MSCs). MCLs did not inhibit nor stimulate growth of MSCs. Furthermore, no effects of MCL addition on MSC differentiation were observed. Osteogenic differentiation of MCL(+))MSCs transferred into osteogenic medium was attained 17 days after transfer. MSCs incubated in osteogenic medium changed shape from fibroblastic (undifferentiated MSC) to polygonal, and formed calcium nodules. Adipogenic induction of MCL(+))MSCs was attained after culturing in adipogenic medium, as indicated by accumulation of lipid-rich vacuoles within cells and the presence of Oil red-O-positive cells. Thus, we observed no tox-

**Fig. 8.3.** Cultures of MSCs produced by Mag-TE (A), compared with conventional means (B), have a high density (C).

icity against MSC proliferation or differentiation when the magnetite concentration was  $100 \text{ pg cell}^{-1}$ .

MCL(+)MSCs accumulated circumferentially along the edge of the magnet at the center of dish where the magnet was positioned (Fig. 8.3A), while MCL(-)MSCs formed scattered colonies throughout the dish (Fig. 8.3B). Since magnetic particles are attracted to high magnetic flux density, MCL(+)MSCs were attracted to where the magnetic density was highest (Fig. 8.3C). The growth area regulated by the magnetic force was approximately  $1 \text{ cm}^2$ , as indicated by image analysis. These results suggest that the MCL(+)MSCs were seeded at  $1000 \text{ cells cm}^{-2}$ , which was a much higher concentration than that of MCL(-)MSCs ( $18 \text{ cells cm}^{-2}$ ;  $1000 \text{ cells per } 55\text{-cm}^2 \text{ dish}$ ). A total of  $2.2 \times 10^4$  cells were counted on day 7, corresponding to the number of cells in  $1 \text{ cm}^2$  of confluent culture (approximately  $2 \times 10^4 \text{ cells cm}^{-2}$ ). This was five-fold greater than the number obtained for MCL(-)MSCs using the conventional method.

Methods for expansion of MSCs are in great demand for clinical applications. One approach to expansion of MSCs is identification of growth factors involved in self-renewal of MSCs. Tsutsumi et al. reported that fibroblast growth factor-2 (FGF-2) increases the growth rate of rabbit, canine and human bone marrow MSCs [33]. However, the mechanism by which FGF-2 maintains proliferation without differentiation is unknown, and clinical applications of cytokines should be pursued

with caution due to the unknown functions of cytokines. Alternatively, growth factors such as cytokines are produced by cells themselves and act as autocrine factors. Huss et al. reported that autocrine factors such as stem cell factor (SCF) and interleukin-6 (IL-6) are involved in proliferation and differentiation of a canine bone marrow-derived cell line, and that an increase in local cell concentration is associated with cell viability [34]. In addition, Gregory et al. reported that conditioned medium from cultures of human MSCs increases the rate of proliferation of freshly plated cultures of human MSCs; secretion of high levels of dickkopf-1 (Dkk-1), an inhibitor of the canonical Wnt signaling pathway, was involved in the reentry of MSCs into the cell cycle in lag phase because of low cell density [35]. These results prompted us to use magnetic force for MSC separation. As mentioned above, when MSCs were seeded at high density using MCLs, the number of cells obtained was five-fold greater than the number obtained from culture without MCLs. These results suggest that growth factors, including autocrine, paracrine, and juxtacrine factors, are involved in the proliferation of MSCs. “High-density culture” using magnetic nanoparticles provides a new methodology for expansion of MSCs.

### 8.2.2

#### MSC Isolation and Expansion using AMLs

As mentioned in Section 8.2.1, we used magnetic force to move MSCs labeled with MCLs and to culture them at high density, and demonstrated the feasibility of magnetic force-based high-density culture for proliferation of MSCs *in vitro*. Because MCLs were designed to interact with target cells via electrostatic interaction, there is the risk of non-specific interaction between MCLs and various non-target cell types. The MCLs were mixed with purified MSCs that had been isolated from bone marrow aspirates.

A promising technique is the use of antibodies raised against MSCs to isolate MSCs from bone marrow aspirates. We previously developed antibody-conjugated magnetoliposomes (AMLs) for use in cancer therapy [12–14]. The AMLs were made from magnetoliposomes (MLs) that consisted of neutral lipids, to reduce electrostatic interaction with target cells. Recently, many researchers have used antibodies to isolate or characterize MSCs [36–38]. Barry et al. reported that CD105 (endoglin), which is the TGF (transforming growth factor)- $\beta$  receptor I/III present on endothelial cells, macrophages, and connective tissue stromal cells, is a useful surface antigen for isolation of MSCs [36]. Therefore, we investigated whether magnetic force-based high-density culture of MSCs, using anti-CD105 antibody-conjugated magnetoliposomes, is an effective method for expansion of MSCs [39]. Figure 8.4 illustrates a strategy for MSCs expansion using AMLs.

Magnetic separation of human MSCs from bone marrow aspirates using anti-CD105 antibody-conjugated magnetoliposomes was performed as follows. After obtaining informed consent, an average of 10 mL of iliac and maxillofacial bone marrow was collected from donors. These bone marrow aspirates were mixed with 20 mL of cell growth medium, and 3 mL of that mixture was combined with 7 mL of

Fig. 8.4. Schematic of the separation and expansion of MSCs using AMLs.

medium containing AMLs, after which bone marrow aspirates with AMLs were placed in 100-mm tissue culture dishes. A disk-shaped neodymium magnet (diameter, 2.2 cm; 4000 Gauss) was then placed under the 100-mm dish to expose the aspirate to magnetic force vertical to the bottom of the dish. After every 3 to 4 days of culture, the nonadherent cells were removed and the medium was replaced.

The immobilization density and average particle size of  $\alpha$ CD105-AMLs were 47.7  $\mu$ g-antibody/mg-magnetite and 136.7 nm, respectively. As shown in Fig. 8.5, 85% of the human MSCs were magnetically separated using  $\alpha$ CD105-AMLs, which was a significantly higher percentage than the values obtained using magnetoliposomes not conjugated to antibody (MLs; 30%).

In the initial state of cell culture after the magnet was placed under the culture dish, the AMLs accumulated at the center of the dish along the edge of the magnet. At 1 day after the start of culture, when the medium was replaced, nonadherent cells and excess AMLs were removed, and very few cells with fibroblastic morphology were found to have adhered to the dish. In the control dishes, cultured using the conventional method, none or very few colonies were observed. In contrast, in the  $\alpha$ CD105-AML cultures, cells accumulated at the center of dish along the edge of the magnet, followed by development of those cells into variously sized colonies at the periphery of the magnet, resulting in high-density cell culture. On day 7, the number of viable cells was assayed (Fig. 8.6). In  $\alpha$ CD105-AML culture of iliac bone marrow aspirate, an average of 246 cells were detected per dish, which

Fig. 8.5. Separation of MSCs using anti-CD105 AML or non-antibody-conjugated MLs.

was 24-fold greater than the numbers obtained with control cultures. No viable cells were detected in the control maxillofacial bone marrow culture. In contrast, an average of 138 cells per dish was detected in the  $\alpha$ CD105-AML maxillofacial bone marrow culture.

In this study, we used AMLs to create a “high-density MSC culture” from bone marrow aspirate. A net bone marrow aspirate of 1 mL was used as a model for expansion of MSCs from an extremely small number of cells. In this model, few or no cells were detected in cultures obtained from iliac and maxillofacial bone marrow aspirates using conventional methods based on the plastic-adherent tendencies of cells. In contrast, after 7 days of culture with  $\alpha$ CD105-AMLs, 246 cells were

Fig. 8.6. MSC separation and expansion from bone marrow aspirates using anti-CD105 AMLs (Mag-TE) or without AMLs (a conventional method).

detected in iliac bone marrow culture and 138 cells were detected in maxillofacial bone marrow (Fig. 8.6). These results suggest that this method, which we have termed “Mag-TE”, is an effective method for expansion of MSCs from very small initial numbers of cells. Typically, only a small number of cells can be obtained from bone marrow aspirates; this is especially true for maxillofacial bone marrow. However, we achieved efficient expansion of MSCs from maxillofacial bone marrow using  $\alpha$ CD105-AMLs and a magnet.

### 8.3

#### Mag-seeding

One approach to tissue engineering is to seed the cells in 3D porous biodegradable scaffolds that allow the cells to form a continuous structure via cell adhesion, proliferation, and deposition of ECM. Although cell-seeding into scaffolds at a high density is closely associated with enhancement of tissue formation in 3D constructs (e.g., cartilage [40], bone [41] and cardiac tissue [42]), effective and high-density cell seeding into 3D scaffolds is difficult to achieve. Technical difficulties in cell-seeding are caused by the complicated structure of the scaffold [43–46], and insufficient migration into the scaffolds due to their pore sizes and materials, which may cause crucial prolongation of the culture period due to a shortage of initially seeded cells. Therefore, numerous methodologies for effective cell-seeding into 3D scaffolds have been investigated [47], and novel methodologies have been also highly sought.

One conventional cell-seeding methodology (static-seeding) involves cell suspension being seeded onto small scaffolds using small volumes of highly concentrated cell suspension, as such a large number of cells cannot be obtained from Petri dish culture [47]. Here, the inevitable problem arises, namely that the cell suspension seeded onto the scaffold flows away along with medium flow, and only a small number of cells remains on the scaffolds. Mag-TE could help overcome this problem, as magnetic force would attract seeded cells that had been magnetically labeled to prevent them from flowing away, with the result that numerous cells could be seeded onto the scaffolds.

We applied a Mag-TE technique to a tissue engineering process in cell-seeding, (termed “Mag-seeding”), and investigated whether Mag-seeding enhances cell-seeding efficiency into 3D porous scaffolds for tissue engineering [48]. NIH/3T3 fibroblast cells (FBs) were used as the model, along with six kinds of scaffold: five were collagen sponges, each of a different pore size (50–600  $\mu$ m), while the other was a D,D-L,L-poly(lactic acid) (PLA) sponge. Mag-seeding was performed as follows: FBs were incubated with culture medium containing MCLs, while scaffolds were hydrated in culture medium and then placed in the well of tissue culture plates. A magnet was placed on the reverse side of the tissue culture plate to provide magnetic force vertical to the plate, and aliquots (100  $\mu$ L) of the magnetically labeled cell suspension then poured onto the top of the hydrated scaffolds. Figure 8.7(A) illustrates a schematic of Mag-seeding.

## A. Schematic of Mag-seeding

## B. Cell-seeding effect of Mag-seeding by pore size

Fig. 8.7. Mag-seeding (A) and its cell-seeding efficacy (B).

The cell-seeding efficiency of Mag-seeding was compared with that of static-seeding. As shown in Fig. 8.7(B), the cell-seeding efficiency for all scaffolds was enhanced by Mag-seeding. Accompanying an increase in pore size, the number of cells in the scaffold increased, and then reached a plateau; approximately 5000 cells mm<sup>-3</sup> for static-seeding and 12 000 cells mm<sup>-3</sup> for Mag-seeding. Since the apparent size of the scaffold was particularly small in a collagen sponge with a pore size of 600  $\mu\text{m}$ , very few cells were detected when the cells were seeded by static-seeding. This is because the poured cell suspension onto the scaffold flowed away. Conversely, a substantial number of cells was detected when the cells were seeded by Mag-TE, suggesting that the magnetic force facilitated cell-seeding.

The effects of magnetic force intensity on cell-seeding efficiency were examined. Two kinds of magnet (magnetic field intensity; 4 and 10 kG) were used in this experiment. The seeding efficiency by Mag-seeding using the 10-kG magnet was significantly higher than the efficacy by static-seeding or by Mag-seeding using the 4-kG magnet (Fig. 8.7B).

In conclusion, we demonstrated that a large number of cells can be seeded into scaffolds by Mag-seeding. Magnetically labeled cells are attracted by magnetic force and consequently numerous cells remain in the scaffold across the medium flow. The cell-seeding efficiency depends on the pore size of the scaffolds. In static-seeding, cells seeded onto scaffolds may enter into the scaffold due to natural precipitation by gravity. For scaffolds with small pore size, most of the cells poured onto the scaffold cannot enter, and thus only a small number of cells are seeded within the scaffold. By Mag-seeding, a significantly larger number of cells enter the scaffold, regardless of pore size (50–600  $\mu\text{m}$  tested). Moreover, cell-seeding efficiency is enhanced by the use of a magnet with higher magnetic induction. These results indicate that Mag-seeding is an easy and reliable cell-seeding technique. In addition, since cells labeled with MCLs can be easily manipulated using magnetic force, automation of cell-seeding for tissue engineering is a distinct possibility, which could aid industrial engineered-tissue production.

## 8.4

### Construction of 3D Tissue-like Structure

Currently, tissue engineering is based on seeding cells onto 3D biodegradable scaffolds, which allows the cells to reform their original structure [15]. However, some problems remain with this approach, e.g., insufficient cell migration into the scaffolds and inflammatory reactions due to scaffold biodegradation, and thus novel approaches for achieving 3D tissue-like constructs are required. We applied Mag-TE to the construction of “scaffold-less” 3D tissue-like structures.

#### 8.4.1

##### Cell Sheet Engineering using RGD-MCLs

A major difficulty obstructing the fabrication of *in vivo*-like 3D constructs without the use of artificial 3D scaffolds is a lack of cell adherence in the vertical direction via cell–cell junctions. This non-adherence is caused by enzymatic digestion of adhesive proteins. To overcome this, Okano et al. employed a thermo-responsive culture surface grafted to poly (*N*-isopropylacrylamide) (PIPAAm) [49–51]. Cells adhered to and proliferated on the thermo-responsive surface, as well as on tissue culture polystyrene dishes. Furthermore, confluent cells on the PIPAAm dishes were expelled as intact contiguous sheets by decreasing the temperature to below the lower critical solution temperature (LCST) of PIPAAm. Kushida et al. recovered monolayer cell sheets from a surface grafted with PIPAAm and then deposited extracellular matrices (ECMs); digestive enzymes were not used and the ECMs

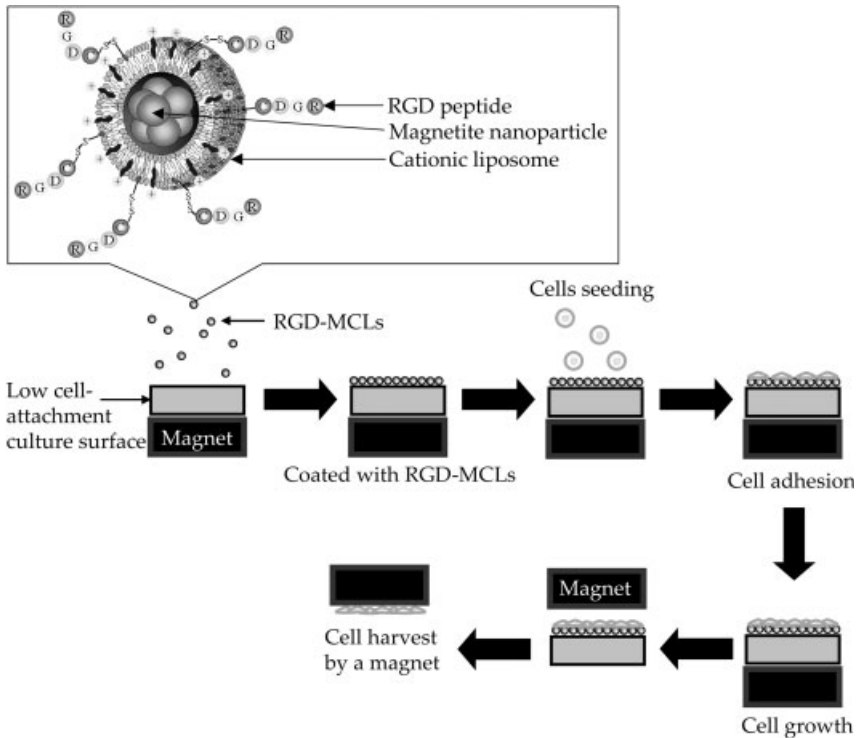

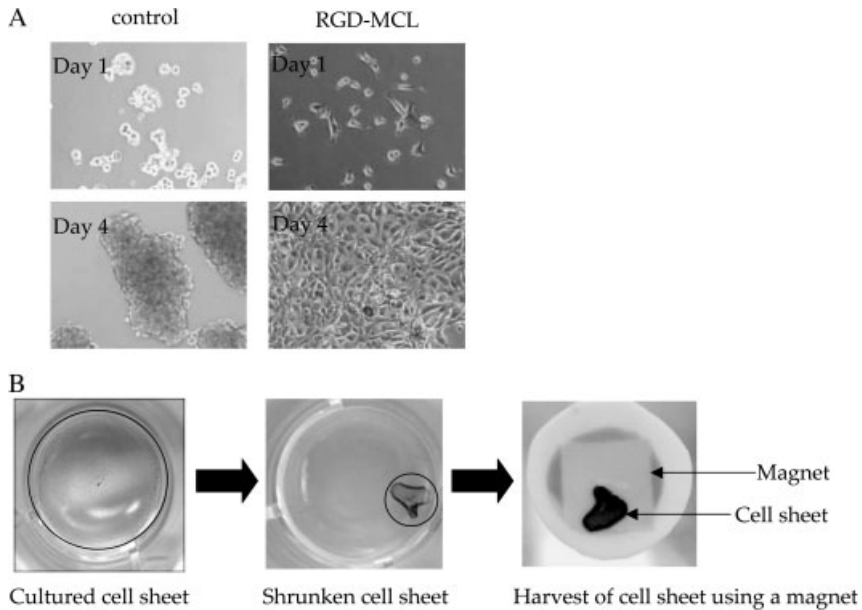

Fig. 8.8. Schematic for Mag-TE using RGD-MCLs.

remained to enhance cell–cell attachment [52]. These engineered cell sheets could be layered to construct multi-layered 3D cell sheets, and Okano et al. proposed the concept of “cell sheet engineering”.

We have developed a new biomaterial and methodology for Mag-TE. The RGD (Arg-Gly-Asp) sequence, an integrin recognition motif found in fibronectin [53, 54] and one of the most extensively studied cell adhesion peptides, was conjugated with magnetite cationic liposomes (RGD-MCLs) [55]. Figure 8.8 illustrates the RGD-MCLs.

RGD-MCLs, which contained magnetite nanoparticles that possessed a positively charged cationic lipid surface and were coupled covalently with the cell adhesion peptide RGD (Arg-Gly-Asp-Cys), were constructed according to the method of Gyongyossy-Issa et al. [56] with slight modifications. The average particle size of the RGD-MCLs was 243 nm. The density of the immobilized peptides in RGD-MCLs was 0.226 mg peptide/mg magnetite.

The new technique using RGD-MCLs consists of the following processes. RGD-MCLs are pre-seeded onto a low cell-attachment culture surface, consisting of a hydrophilic and neutrally charged covalently bound hydrogel layer, and a magnet is set on the underside of the well to attract the RGD-MCLs to the well surface. Target

**Fig. 8.9.** (A and B) Formation of cell sheets by Mag-TE using RGD-MCLs.

cells are then seeded into the wells, which are coated with RGD-MCLs, and are then incubated until confluency. The magnet is removed to detach the cell sheets from the well, after which the cell sheets are harvested using a magnet inserted into the well. Figure 8.9 gives a schematic of Mag-TE using RGD-MCLs.

When NIH/3T3 cells, which are anchorage dependent, were cultured in low-attachment plates, the cell number did not change during the 4 day incubation period. For RGD-MCLs, apparent cell proliferation was observed and the cells proliferated to confluency during the 4 day incubation period. Figure 10.8(A) shows photomicrographs of NIH/3T3 cells cultured on the uncoated surface (Control), and that coated with RGD-MCLs for 1 day or 4 days. When the cells were cultured in low-attachment plates, the cells floated in the media and no cells were observed to be attached to the plate. Subsequently, the cells aggregated and formed spheroid constructs on day 4. Conversely, when the cells were cultured on the surface coated with RGD-MCLs, NIH/3T3 cells had adhered and spread by day 1, and had proliferated to confluency by day 4.

The NIH/3T3 cells grown to confluency on RGD-MCLs were subjected to a novel fabricating and harvesting method using a magnet. After 4 days of incubation on RGD-MCLs, the magnet placed on the underside of the low-attachment plate was removed. When the medium was gently pipetted to cause medium flow from the periphery of the cell sheets, the cell sheet detached from the bottom of the plate and shrank, thus resulting in the formation of a contiguous cell sheet-like construct. The cell sheets fabricated by Mag-TE were black-brown due to the magnetite

nanoparticles, and we investigated whether these cell sheets could be harvested using magnets. The cylindrical neodymium magnet positioned on the underside of the low-attachment plate was removed. A hydrophilically treated membrane was pasted to the head of a cylindrical alnico magnet, and the magnet moved into the well toward the surface of the culture medium. Due to the magnetic force, the cell sheets floated up to the surface of the culture medium and without disruption, stuck to the membrane (Fig. 8.9B).

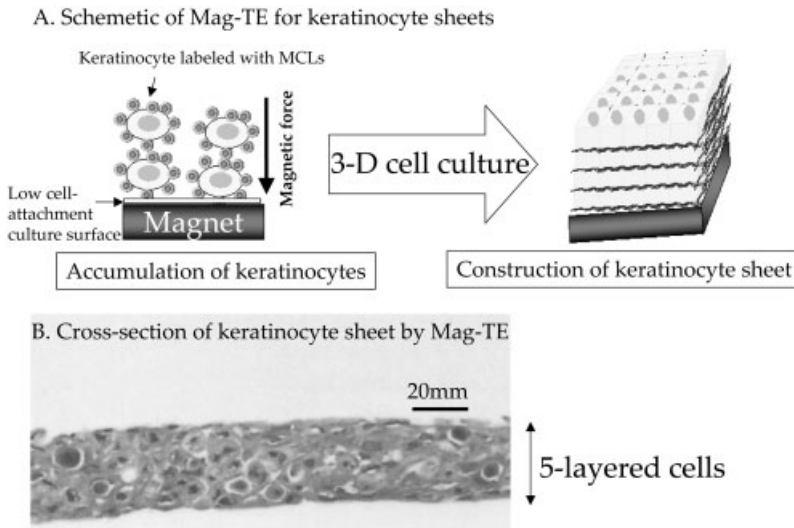

In this study, cell integrin ligand RGD peptides were covalently coupled to cationic liposomes containing magnetite nanoparticles, and we used these RGD-MCLs as a novel biomaterial for tissue engineering. RGD-MCLs have two possible active effects on cell adherence; one is positive charge of the cationic liposomes, and the other is the RGD peptide on their surface. When cells were cultured on the surface of neutrally charged magnetoliposomes, the cells floated in the media and no cells were observed to be attached to the plate. Conversely, cells attached onto the culture surface coated with MCLs, thus suggesting that the positive charge due to cationic liposomes facilitated cell attachment to the culture surface. However, few NIH/3T3 cells spread and proliferated on MCLs. In contrast, when NIH/3T3 cells were cultured on a surface coated with RGD-MCLs, the cells adhered, spread, and proliferated, thus suggesting that RGD peptides strongly promote cell adhesion. These data encourage further development of tissue engineering techniques using magnetite cationic liposomes coupled with cell adhesion peptides, such as KQAGDV (Lys-Gln-Ala-Gly-Asp-Val) peptide for smooth muscle cells [57] and YIGSR (Tyr-Ile-Gly-Ser-Arg) peptide for neurons [58].

In cell sheet engineering, methodologies for handling cell sheets are needed because grafts fabricated by cell sheet engineering are easily damaged by handling. We proposed a novel methodology for handling cell sheets using RGD-MCLs and magnetic force; the Mag-TE method enabled us to handle cell sheet-engineered grafts. Because cell sheets constructed by Mag-TE contain magnetite nanoparticles, NIH/3T3 cell sheets can be recovered and handled using a magnet. This feature is not present in cell sheets produced using other methodologies, such as the use of a PIPAAm-grafted surface. These results also suggest the possibility of developing a “tissue-engineered graft delivery system” using Mag-TE, while Mag-TE could also be applied to industrial tissue engineering because magnetic force could greatly simplify the recovery step of cell sheet production. This recovery step could be automated by substituting the magnet used to harvest cell sheets with an electromagnet, which can immediately release the sheets from the surface of the magnet via electrical control. These findings indicate that RGD-MCLs are potent tools for industrial tissue engineering.

#### 8.4.2

##### **Construction of a Keratinocyte Sheet using MCLs**

The epidermis is one of only a few tissues for which it is possible to culture its principal cell (the keratinocyte) and to use these cultured cells to reconstitute stratified and differentiated human tissue [59, 60]. These skin equivalents have been

**Fig. 8.10.** (A) Scheme for the construction of a keratinocyte sheet by Mag-TE; (B) cross-section of a keratinocyte sheet so-produced.

used clinically to repair burns and wounds [61, 62]. In this study [63], MCLs were used to label human keratinocytes magnetically, and we investigated whether magnetically labeled keratinocytes could be accumulated using a magnet, and whether stratification is promoted by magnetic force to form a sheet-like 3D construct by Mag-TE (Fig. 8.10A).

In this case, MCLs were added to keratinocytes, to manipulate cells magnetically in a similar way to that described in Section 8.2.1. MCLs-labeled keratinocytes ( $2 \times 10^6$  cells, corresponding to five-fold confluency in 24-well plates) were seeded into 24-well low-attachment plates, to investigate whether five-layered keratinocyte sheets can be constructed by the accumulation of cells by magnetic force. A 30 mm neodymium magnet (4000 G) was placed under the plate. Keratinocytes without MCLs or with MCLs in the absence of a magnet did not attach to the plates. In contrast, keratinocytes labeled with MCLs at  $50 \text{ pg cell}^{-1}$  accumulated on the low-attachment plates in the presence of the magnet. Keratinocytes labeled with MCLs formed a sheet-like construct in the presence of the 30 mm magnet. Phase-contrast microscopy of the cross-sections of the sheets (Fig. 8.10B) revealed that keratinocytes labeled with MCLs formed five-layered sheets.

Notably, when keratinocytes were seeded onto monolayer keratinocytes cultured on tissue culture plates they did not form a sheet-like construct. Moreover, when keratinocytes were seeded onto the low-attachment plates, they did not attach to the surface of the plates and did not form sheets. When protease (trypsin) was used for preparation of keratinocyte suspension, the ECMs may have been digested. As a way to enhance layered cell–cell interactions, we took a physical

approach, using magnetic attraction. Keratinocytes magnetically labeled with MCLs evenly accumulated onto the low-attachment plates in the presence of a magnetic force. Keratinocytes magnetically labeled with  $50 \text{ pg cell}^{-1}$  MCLs formed 5-layered keratinocyte sheets. We speculate that the cell–cell adhesion was caused by the very close placement of cells by the magnetic force.

In our experience, if epithelial sheets fabricated by the method of Rheinwald and Green [64] have five or more cellular layers, they are sufficiently strong for recovery and transplantation [65]. Therefore, in this study, magnetically labeled keratinocytes of five-fold confluency against the culture area were seeded to construct five-layered keratinocytes. As a result, keratinocyte sheets with five layers were constructed. The sheets fabricated by Mag-TE consisted of undifferentiated keratinocytes, which apparently differs from the epidermal sheets fabricated by the method of Rheinwald and Green [64]. To the best of our knowledge, this is the first time that multilayered “undifferentiated” keratinocyte sheets have been constructed. Undifferentiated keratinocytes in keratinocyte sheets produced by Mag-TE may have greater effects on wound healing than cornified and anucleate keratinocytes fabricated by inducing terminal differentiation.

Yamato et al. have reported that thermo-responsive culture dishes grafted with PIPAAm allow the intact harvest of keratinocyte sheets without damage caused by protease (e.g. dispase) treatment [66]. Dispase, a neutral protease from *Bacillus polymyxa*, is widely used to harvest multilayered keratinocyte sheets from culture dishes [67]. In clinical use, extensive washing to remove dispase from keratinocyte sheets is required before they can be applied to wounds, because residual dispase is harmful to the wound site. In industrial production of keratinocyte sheets, this washing is laborious, and is a technological barrier to automation of the process. In our method, we used low-attachment plates, to harvest keratinocytes from the plate without enzymatic treatment after removing the magnet, because the keratinocytes did not adhere to the plate surface. Bioreactors automated for successive culture for epithelial sheet generation have been developed [68, 69]. Because Mag-TE does not require washing of the keratinocyte sheets, which is a laborious step, it allows automation of tissue engineering. Moreover, we used magnetic force to make the recovery step easier, which could aid industrial production of keratinocyte sheets. For automation of this recovery step, the magnet used to harvest keratinocyte sheets may be substituted with an electromagnet, which can release the sheets from the surface of the magnet when switched off. Together, these findings indicate that MCLs are potent tools for industrial engineered-tissue production.

#### 8.4.3

##### **Delivery of Mag-tissue Engineered RPE Sheet**

Age-related macular degeneration (AMD) is an eye disease and a major cause of blindness [70]. The most severe form of AMD is characterized by choroidal neovascularization (CNV), which causes rapid visual loss. When CNV is surgically excised from patients with AMD, the retinal pigment epithelium (RPE) is also removed along with CNV. Since RPE cells play a critical role in assisting photoreceptors in

vision, RPE cell transplantation into the sub-retinal space, from where these cells are surgically excised, is one possible approach [71]. RPE cells in suspension have been injected into the sub-retinal space of animal models and AMD patients. While some success has been achieved in animal models, with recovery of vision [72, 73], the results have been limited in humans [74, 75]. The poor outcomes are due to two major factors; limitations in obtaining autologous RPE cells and difficulty in RPE cell delivery.

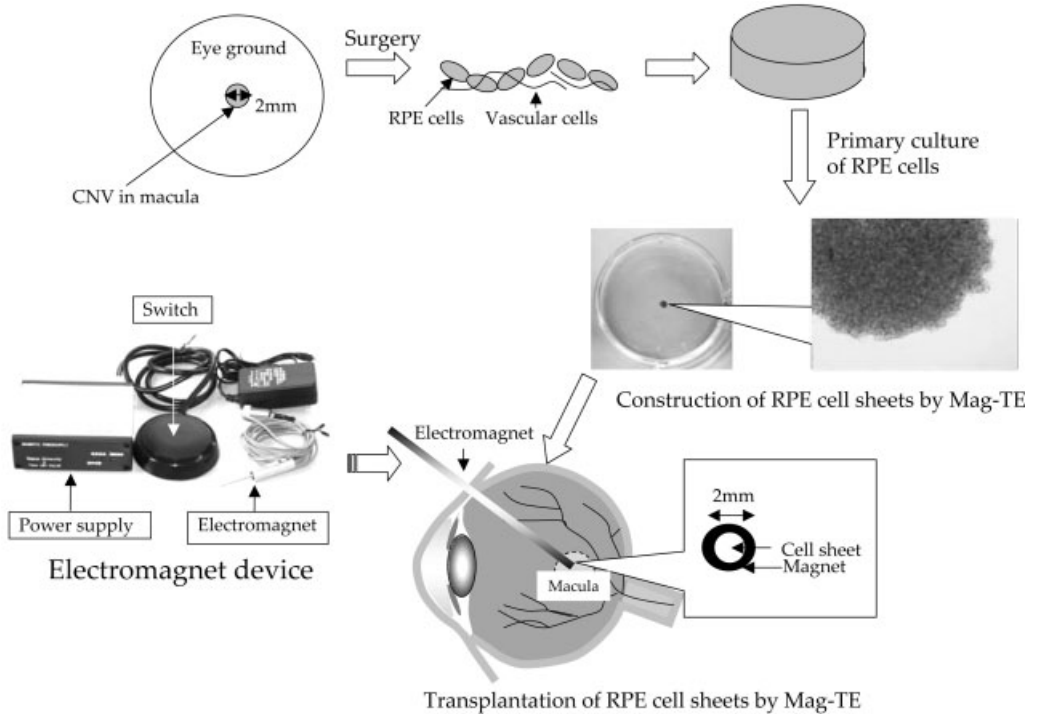

Tissue engineering is a possible technology for solving the above-mentioned problems. Conventionally, tissue engineering has been based on two steps: expanding autologous cells *in vitro*, and seeding the cells onto 3D biodegradable scaffolds to reform their native structure [15]. First, a method for cultivating RPE cells from CNV specimens that have been surgically removed from patients with AMD has been developed [76]. The use of autologous RPE cells can overcome immune rejection, and the expansion of RPE cells may resolve donor shortage. Conversely, the use of biodegradable scaffolds poses problems, such as insufficient cell migration into the scaffolds and inflammatory reaction due to the biodegradation of the scaffolds. Particularly for tissue engineering of RPE, since RPE constructs desired for transplantation are of very small size (1–4 mm<sup>2</sup>) and also inflammation is a complicating factor in eye diseases, an autologous cell sheet-like structure without artificial scaffolds may be more suitable. However, since cell–cell interactions are difficult to manipulate, assembly of a 3D cell construct without scaffolds remains a challenge. Moreover, the difficulty faced constructing RPE cell sheets is in the handling of such small tissue-engineered grafts for transplantation. To the best of our knowledge, there are few reports on tissue-engineered graft delivery systems.

In one study [77] we investigated whether RPE cell sheets could be constructed using Mag-TE. Thus, MCLs were used to label RPE cells magnetically, and we investigated whether magnetically labeled RPE cells could be accumulated to form RPE cell sheets, instead of artificial scaffolds, using a magnet. Moreover, since the RPE cell sheets constructed by Mag-TE contained magnetite nanoparticles, we investigated whether these cell sheets could be handled with a magnet, and assessed the feasibility of using a tissue-engineered graft delivery system by Mag-TE *in vitro*.

ARPE-19 cells, used in this study, are a spontaneously arising human RPE cell line with normal karyology [78]. Figure 8.11 illustrates a schematic for the construction and transplantation of RPE cell sheets using MCLs and magnetic force (Mag-TE).

To produce small RPE cell sheets, less than 4 mm<sup>2</sup>, a cloning ring of 2.4 mm caliber (inner area, 4 mm<sup>2</sup>) was used. A cloning ring was placed at the center of a 24-well low-attachment plate and a 22 mm neodymium magnet was placed under the plate. Magnetically labeled ARPE-19 cells ( $8 \times 10^3$  cells mm<sup>-2</sup>, which corresponds to a 10-fold concentration of confluency) were seeded into the cloning ring to investigate whether multilayered RPE cell sheets less than 4 mm<sup>2</sup> can be constructed via accumulation of cells by magnetic force. ARPE-19 cells without MCLs or with MCLs in the absence of the magnet did not form cell sheets, and the cells were dispersed when the cloning ring was removed. In contrast, ARPE-19 cells labeled with MCLs formed an approximately 1 mm<sup>2</sup> sheet-like construct in the

**Fig. 8.11.** Scheme for the construction and transplantation of RPE cell sheets by Mag-TE (the apparatus used is shown on the bottom left of the figure).

presence of a magnet. The cross-sections of the layers revealed that the ARPE-19 cells labeled with MCLs formed 15-layered sheets with a thickness of 60  $\mu\text{m}$  each.

Next, we investigated whether these magnetically labeled RPE cell sheets could be harvested and delivered using a magnet. When the cloning ring and the cylindrical neodymium magnet positioned on the reverse side of the 24-well low-attachment plate were removed, the RPE cell sheets detached from the bottom of the well. As a device for delivery of the magnetically labeled tissue, an iron wire was attached magnetically to the cylindrical neodymium magnet. The magnetic flux density at the tip of the iron wire was 1100 Gauss. The tip of the iron wire was then positioned at the surface of the culture medium. Due to the magnetic force, the RPE cell sheets floated up to the surface of the culture medium without disruption, and stuck to the tip of the iron wire. As a model for transplantation, we investigated whether the RPE cell sheets constructed by Mag-TE could be delivered onto the bottom of the tissue culture dish containing 10 mL of medium. When the magnet was removed from the iron wire and the wire was tapped gently, the cell sheet detached from the tip of wire and sank onto the tissue culture surface. After incubation for 1 day, the cell sheets had attached to the tissue culture dish. Subse-

quently, the cell sheets were further incubated. ARPE-19 cells growing from the cell sheets were observed after a 16 day incubation period, suggesting that the transplanted cells had retained their activity.

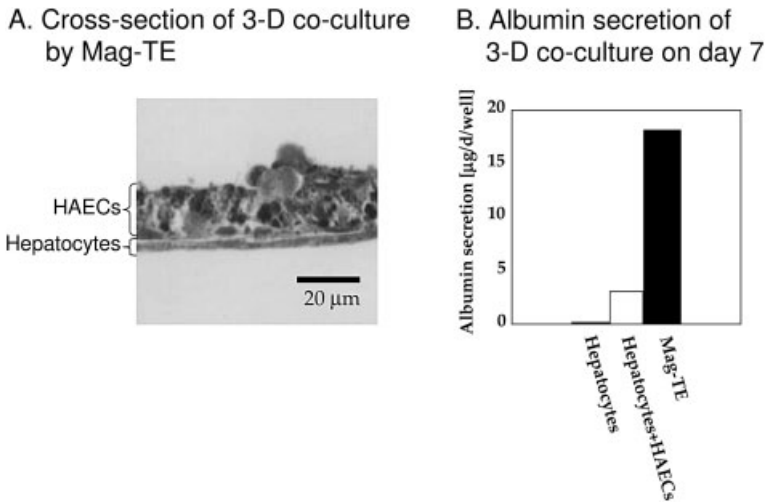

The Mag-TE method enabled us to handle the tissue-engineered grafts using magnetic force. We showed that the small RPE cell sheets constructed by Mag-TE could be recovered and delivered using magnetic force. Due to the magnetic force, the RPE cell sheets labeled with MCLs floated up to the surface of the culture medium and stuck to the tip of the iron wire on the magnet. To deliver the RPE cell sheet into the sub-retinal space of AMD patients, the cell sheet must be sufficiently strong so as not to break in the intraocular space, in which a balanced salt solution is added during surgery to adjust intraocular pressure. Furthermore, the cell sheets should not disperse into unintended spaces in the eye during transplantation. In our study, the RPE cell sheets were transplanted into the tissue culture dish containing 10 mL medium, as an *in vitro* model. In this experimental model, the RPE cell sheets were successfully transferred into another dish and released from the tip of iron wire by detaching the magnet and nullifying the magnetic effect of the iron wire. In the near future, we intend to study the feasibility of Mag-TE in animals and clinical trials. Presently, we have developed a tissue delivery device for Mag-TE, which is an electromagnet device that enables on-off control, to manipulate Mag-tissue engineered grafts (Fig. 8.11).

#### 8.4.4

#### **Construction of a Liver-like Structure using MCLs**

Tissues and organs *in vivo* often consist of several types of cell layers. Cell–cell interactions among these layers are important in maintaining the normal physiology of organ systems, such as the vasculature (smooth muscle and endothelial cells [79]), skeletal muscle (myocytes and peripheral nerves [80]), and liver (hepatocytes and sinusoidal endothelial cells [81]). However, cell–cell interactions are difficult to manipulate in co-culture systems with two or more cell types, even in 2D cultures. Moreover, the assembly of 3D tissues containing various cell types remains a challenge.

Heterotypic interactions play a fundamental role in liver function. Since the liver is formed from endodermal foregut and mesenchymal vascular structures, it may be functionally mediated by heterotypic interactions [82, 83]. Liver-specific functions in isolated hepatocytes that require nonparenchymal cells disappear in homotypic cultures [84]. Various 2D co-culture systems of hepatocytes and nonparenchymal cells have been investigated, including those using microfabrication [85] and 2D patterning [86]. However, novel technologies are required to reconstruct the liver to function as it does *in vivo*. This would require a 3D construct containing various types of cells that could thrive beyond the cell type limitations of co-culture. This study [87] uses magnetic force to precisely place magnetically labeled cells onto target cells and to promote heterotypic cell–cell adhesion to form a 3D construct. Here, we magnetically labeled human aortic endothelial cells (HAECs) using MCLs. We then investigated whether the labeled HAECs could be placed onto

**Fig. 8.12.** (A and B) Construction of liver-like structure by Mag-TE.

a rat hepatocyte layer using magnetic force, and whether magnetic force promotes the adhesion of heterotypic cells.

We seeded  $1.2 \times 10^5$  HAECs (the number of cells required to reach confluence in 24-well cell culture plates) onto hepatocyte monolayers and manipulated a 22 mm magnet to form double cell layers throughout the wells. HAECs labeled or not with MCLs did not attach to hepatocytes in the absence of a magnet. Conversely, in the presence of the magnet, HAECs evenly attached to the hepatocyte layer throughout the wells. The hepatocyte layer expressed albumin under the HAEC monolayer that stained positively with Berlin blue, indicating the presence of MCLs (Fig. 8.12A). We measured hepatic albumin expression to determine cellular function in the layered co-culture system by Mag-TE (Fig. 8.12B). Albumin secretion in homotypic hepatocyte culture was undetectable on day 7. Hepatic albumin secretion was slightly enhanced in co-cultures of HAECs, even when the magnet was not present. Conversely, layered co-cultures in the presence of a magnetic force maintained a high level of albumin secretion on day 7.

Two major difficulties obstruct fabrication of an *in vivo*-like 3D construct for 3D tissue engineering including heterotypic cells. One is non-adherence to heterotypic cells caused by the cell type limitation of co-culture. Okano et al. have developed double layered co-cultures using a thermo-responsive surface of grafted PIPAAm to overcome this difficulty [49–51]. Harimoto et al. [88] reported that whereas trypsinized single endothelial cells do not attach to hepatocytes, endothelial cell sheets fabricated by cell sheet engineering would attach to hepatocyte monolayers. However, the assembly of heterotypic cells into complex tissues such as duct-like constructs also presents a challenging technological barrier, even for cell sheet engineering. Another difficulty is to spatially control the positioning of target cells. Mironov et al. [89] have developed a computer-aided jet-based cell printer that

could place cells at specific sites on thermo-responsive gels, and termed this “organ printing”. This technology seemed to overcome the difficulties with spatial control. However, printed cells can only form monolayers, which must be stratified layer-by-layer to assemble 3D organs. Here, we developed a new method using magnetite nanoparticles and magnetic force, which we refer to as Mag-TE, to overcome these difficulties.

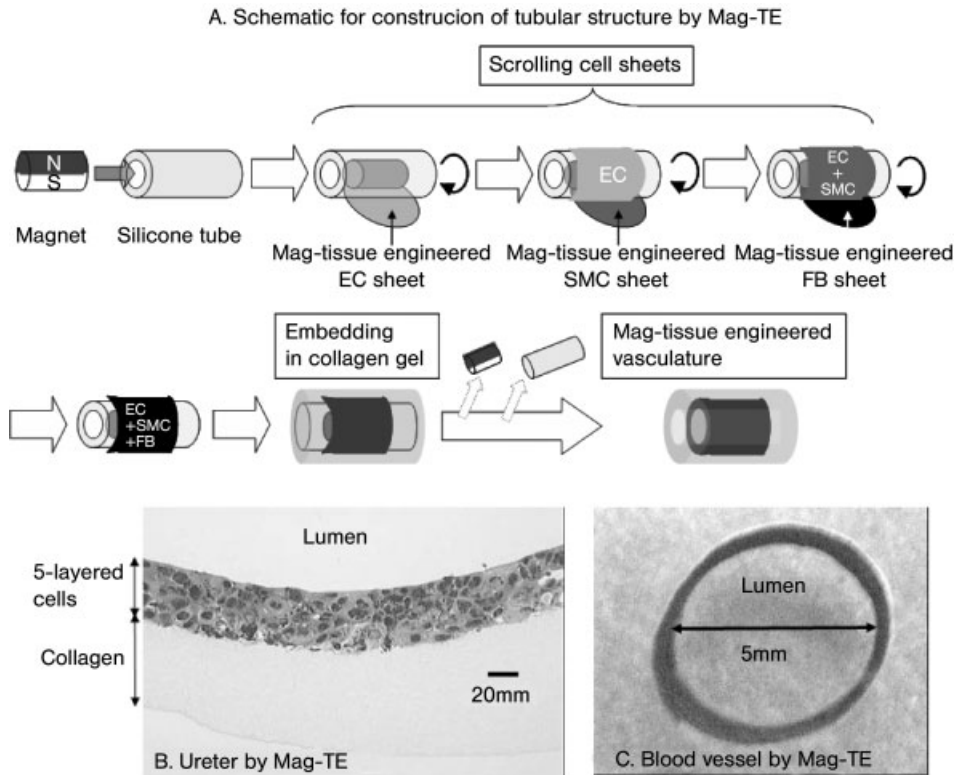

Co-culture systems with nonparenchymal cells maintain hepatocyte functions for long periods [90–92]. To examine the feasibility of the layered co-culture system using magnetic force, we used the liver model of hepatocytes and endothelial cells. We seeded  $1.2 \times 10^5$  HAECs, which corresponds to the number at confluence in 24-well cell culture plates, onto hepatocyte monolayers and positioned a 22 mm magnet that could apply 4000 G uniformly throughout the plates. This caused an almost uniform upper layer of HAECs. Albumin secretion by hepatocytes was enhanced in this double-layered co-culture system. The precise mechanisms that regulate increases in liver-specific function in hepatocyte co-cultures have not been elucidated. Bhandari et al. [93] have reported that 3T3 fibroblast cells persist in co-cultures with hepatocytes, but 3T3 cell conditioned medium could not substitute for viable co-cultured 3T3 cells in preserving hepatocyte function, suggesting that cell–cell interaction is essential for modulating hepatocyte functions. Potential mediators of cell–cell interactions include soluble factors such as cytokines [94] and insoluble cell-associated factors such as ECMs [95]. We surmise that the tight and close interaction of overlaying HAECs and monolayer hepatocytes using magnetic force caused ECMs and cytokines to be deposited between the layers, thus powerfully enhancing liver function. In contrast, cellular interaction was very weak in co-cultures without the magnetic force and HAECs hardly attached to the hepatocytes. The mechanism by which close cell–cell distance enhances cell to cell interaction, such as gap junction formation, remains to be elucidated.

#### 8.4.5

#### **Construction of Tubular Structures using MCLs**

Tissues and organs *in vivo* have unique shapes, and are often composed of several types of cell layers required to maintain the normal physiology of organ systems. In one study [96] we investigated whether we could use Mag-TE to form tubular structures such as ureters (which consist of monotypic urothelial cell layers) and blood vessels (which consist of heterotypic layers of aortic endothelial cells, smooth muscle cells, and fibroblasts).

First of all, Mag-tissue engineered cell sheets were constructed. After incubation with MCLs, human aortic endothelial cells (ECs), human aortic smooth muscle cells (SMCs), mouse NIH/3T3 fibroblasts (FBs), or canine urothelial cells (UCs) were seeded into low-attachment plates. A cylindrical neodymium magnet (diameter, 30 mm; magnetic induction, 4000 G) was then placed on the reverse side of the low-attachment plates to provide magnetic force vertical to the plate, and the cells were cultured for 24 h. Figure 8.13(A) illustrates the procedure used to construct tubular structures. A cylindrical magnet with magnetic poles on its curved surface

**Fig. 8.13.** (A) Scheme for the construction of tubular structures by Mag-TE. (B and C) Ureter and blood vessel, respectively, produced by Mag-TE.

was used (diameter, 3 mm; length, 10 mm; magnetic induction, 1300 G). The magnet was inserted into a silicone tube (outer diameter, 5 mm; inner diameter, 3 mm; length, 25 mm). The 5 mm outer diameter was chosen to construct small-diameter blood vessels (inner diameter, <6 mm). The cylindrical magnet in the silicone tube was then rolled over the magnetically labeled cell sheet. To construct a tissue-engineered ureter, a UC sheet only was used. To construct a blood vessel, an EC sheet was used first, followed by addition of an SMC sheet and an FB sheet. Collagen was injected and allowed to gelate around the cell sheets, to support the cell constructs.

When the cylindrical magnet in the silicone tube was rolled over the magnetically labeled UC sheet, UCs were attracted onto the silicone tube by magnetic force. UCs ultimately covered the entire surface of the silicone tube. The sheets formed from ECs, SMCs and FBs in the construction of blood vessels were thicker than the UC sheets. When the silicone tube and magnet were removed, we obtained tubular constructs of tissue engineered urothelial and vascular tissue. Histo-

logical observation revealed that the constructed urothelial and vascular tissues formed contiguous tubular structures with a lumen of 5 mm; Fig. 8.13(C) shows a macroscopic view of the vascular tissue. The urothelial structure consisted of five- to seven-layer monotypic urothelial tissue that formed on the collagen gel (Fig. 8.13B).

In this study, for the construction of magnetically labeled cell sheets using magnetic force, four types of cells (UCs, ECs, SMCs, FBs) were used. In general, it is difficult to fabricate 3D tissue constructs without using 3D scaffolds, due to the lack of cell adherence via cell–cell junctions, particularly in the vertical direction. We developed a novel methodology for fabrication of cell sheets, which we have termed “Mag-TE”.

For clinical applications, tubular constructs of urothelial and vascular tissue can be cultured for long periods in tubular tissue-oriented bioreactors, such as those that provide biomechanical stimuli similar to those that occur *in vivo* [97–99], to induce these cells to express differentiated phenotypes. For cultivation using bioreactors, because the tubular tissues constructed by Mag-TE contain a sufficient amount of suitably placed cells, culturing for cell proliferation may not be required. Consequently, only culturing for expression of differentiated phenotypes and deposition of ECMs (e.g., collagens and elastins of vascular tissues [100]) would be required. This suggests that use of tubular constructs created using Mag-TE can shorten the culture period required before treatment. In this study, collagen gel was used as a support to reinforce the mechanical strength of tubular tissue constructed by Mag-TE; there has been no quantitative analysis of the mechanical properties of such tissue constructs. Several groups are working to improve the mechanical properties of collagen-gel-based vascular grafts. Control of collagen gel fibril orientation has been investigated in an effort to maximize the mechanical strength of collagen-gel-based scaffolds [101, 102].

## 8.5

### Conclusion

In this chapter, we have only been able to highlight magnetic nanoparticles and Mag-TE as “metallic nanoparticles for tissue engineering”. These techniques for tissue engineering are based on biochemical engineering, cell biology, magnetism, nanotechnology, and many other scientific fields. Currently, magnetic techniques complement other methods presently used in medical applications, and this combination therapy should result in more effective medical treatment, including tissue engineering and regenerative medicine. Greater understanding of the properties of magnetic particles will increase their potential for medical application.

When considering the use of metallic nanoparticles, toxicity is an important issue in clinical applications. For magnetite nanoparticles, no toxic effects against proliferation of several cell types were observed within the range of magnetite concentrations tested (e.g., human keratinocytes, <50-pg magnetite/cell; human endothelial cells, human smooth muscle cells, mouse fibroblast cells, canine urothelial

cells, human mesenchymal stem cells [MSCs],  $<100 \text{ pg cell}^{-1}$ ), and no effect on the differentiation of MSCs was observed. Moreover, in a preliminary study [103], we investigated the toxicity of systemically administered MCLs (90 mg, i.p.) in mice; none of the 10 mice injected with MCLs died during the study. Transient accumulation of magnetite was observed in the liver and spleen of the mice, but the magnetite nanoparticles had been cleared from circulation by hepatic Kupffer cells and/or fixed macrophages in the spleen by the 10th day after administration [103]. However, further study is required to assess the toxicity of residual magnetic nanoparticles in grafts before Mag-TE can be used for clinical applications.

## 9 Applications and Implications of Single-walled Carbon Nanotubes in Tissue Engineering

*Peter S. McFetridge and Matthias U. Nollert*

### 9.1 Introduction

The discovery of single-walled carbon nanotubes (SWNT) by Iijima in 1991 [1] initiated a surge of interest that continues to grow as our understanding of these unique materials evolves. The extraordinary mechanical [2, 3] and electrical properties [4] of SWNT have fueled continued interest as the spectrum of potential applications grows that can take advantage of these unique nano-scaled materials. Applications encompass a wide range of composite materials from electrically conducting polymers and biopolymers, and nanoelectronics, to biosensors and materials that interface directly with biological systems [5–7].

A rapidly growing discipline that may take advantage of SWNT unique properties is the area of regenerative medicine in the field of tissue engineering [8]. The broad concept, as the name implies, is the regeneration of diseased or damaged tissues such that complications of using transplant tissue can be avoided. Central to this theme is the use of 3D scaffolds that provide support for adhesion-dependent cells in a manner that guides tissue regeneration by the host, or other transplanted cells. The aim is that the preformed scaffold (in the shape of the end product) will guide cellular regeneration to result in the development of neo-tissue. Importantly, not only the physical parameters of the scaffold are critical to allow the correct structural and biochemical development, but also the environment in which the cells are cultured. It is the combination of these factors that are fundamentally important if fully functional tissue is to be developed.

Although the number of peer reviewed published articles on SWNT has been increasing dramatically (both in terms of material processing and its applications) as interest grows, there has been little published in the area of tissue engineering. In this chapter we will discuss general applications of SWNT in the field of tissue engineering, paying particular attention to the preparation of these nano-materials and how they interact with cells. We first review some of the history behind the electrical stimulation of cells and the reasoning behind the use of SWNT as a conductive material to support or promote organ regeneration. We then review

purification and preparation processes, and then take a closer look at cellular interactions, and how functionalizing or modifying SWNT surface chemistry can modulate cell function. The chapter concludes by reviewing specific applications of SWNT in tissue engineering and the current pertinent literature.

## 9.2

### Electromagnetic Fields for Tissue Regeneration

The particular attributes of carbon nanotubes that are of special interest to regenerative medicine are their mechanical and electrical properties. The importance of electrical properties in modulating biological processes has been recognized since the mid-1700s. In fact, by the end of the eighteenth century the injury potential, which is a direct current voltage gradient induced within an injured tissue space by current flowing into and around an injured nerve, had been recognized and measured. In recent times, these currents have been shown to be essential for regeneration [9, 10]. Within a hundred years of the early work of Galvani and Volta in describing and characterizing electric currents and fields, many others promoted bioelectricity for a wide variety of dubious medical applications [11], including insomnia, migraine and baldness among others. The dubious scientific work and downright charlatanism from this period tainted perceptions that last to this day regarding bioelectric phenomena.

There are now several systems that clearly demonstrate that electrical field modulation promotes tissue regeneration, for which the unique properties of carbon nanotubes may be exploited to develop improved therapeutic options. One such area is in nerve regeneration. The seminal work demonstrating the influence of electrical fields on nerve growth was by Borgens et al. [12]. They showed that injury currents carried by  $\text{Na}^+$  and  $\text{Ca}^{2+}$  ions were driven into the cut ends of severed lamprey spinal cord axons. Increased branching and faster regeneration of the axons was observed in the presence of a steady electric field of opposite polarity. This work has been extended to a guinea pig model in which the spinal cord was severed and significantly greater axonal growth was observed in the presence of an applied electrical field compared with the case where no electrical field was present [13]. In another study, improvements in nerve function were also observed with an applied electrical field [14].

Another area that has seen extensive work on the interaction between electrical fields and biomedical applications is in bone growth. Pulsed electromagnetic fields (PEMF) stimulation has been in clinical use for nearly 30 years on patients with delayed fracture healing and nonunion and has been demonstrated in a multitude of clinical case reports [15–17]. Double-blinded studies have confirmed the clinical effectiveness of pulsed electromagnetic fields stimulation on osteotomy healing [18, 19] and delayed union fractures [20]. Brighton et al. [21] conducted a multi-center study of the nonunion and reported an 84% clinical healing rate of nonunion with direct current treatment. Recently, Schaden et al. [22] reported 76% of

non-union or delayed union patients treated with one time extracorporeal shock wave therapy resulted in bony consolidation with a simultaneous decrease in symptoms.

Both of these applications have led investigators to develop electrically conducting materials that have favorable biocompatibility characteristics. The most widely studied conducting biomaterial is the polymer polypyrrole. The biocompatibility properties of this material were first studied by Wong et al. [23]. They showed that extracellular matrix proteins could adsorb on a thin film of polypyrrole and could support attachment and spreading of cells. In the presence of an electrical potential, cell growth and DNA synthesis were altered. A range of inherently conducting polymers has been developed and they have been reviewed [24]. Potential applications of polypyrrole based electrically conducting biomaterials include glucose biosensors [25, 26], neural prosthetics [27, 28], and bone tissue engineering [29–31]. Taken together, these studies demonstrate that there is great potential in developing novel biomaterials and biomedical devices with the capacity to be electrically conducting. Since carbon nanotubes can act as conductors, there is immense interest in exploring their potential in biomedical applications.

### 9.3

#### Tissue Engineering

As a discrete discipline, tissue engineering is little more than a decade old; however, growth of cells on synthetic materials as a means to improve the performance of implantable materials dates back to the 1970s [32–35]; in particular, in the development of small diameter vascular prosthetics where it became obvious that these materials need to be more than just immunologically inert, rather they need to functionally integrate with surrounding tissues to enhance performance. As such, there has been continuous development of these materials to understand and improve interactions with cell systems.

In addition to the many biological molecules that enhance cellular interactions, such as growth factors and adhesion peptides, magnetic and electrical stimulation (as described above) has a strong influence on cellular growth, cellular phenotype, and tissue regeneration [36–42]. As such, designer materials that allow modulation of mechanical, electrical and thermal properties may produce materials that can be fine-tuned to suit specific applications. For example, when a diseased and occluded blood vessel is to be excised and a prosthetic tube implanted, if the mechanical compliance between a patient's existing blood vessel and the new implant do not match, the chance of graft failure increases significantly [43]. By varying the concentration of SWNT within an appropriate polymer a wide range of compliance values can be obtained, then specifically matched to each patient. Although most polymer additives will allow control over the material's bulk mechanical properties, few materials offer the combined influence of mechanical and electrical modulation.

Incorporating conductive additives into a bulk material allows the gross conduc-

tive properties to be modulated such that electrical stimulation can be used to enhance tissue repair and/or regeneration [44]. One distinct advantage that SWNT have over other conductive additives is the dual capability of varying the material's conductivity *and* enhancing the material's mechanical properties. One biopolymer that has seen a wide range of clinical successes is the extracellular matrix (ECM) molecule collagen [45–49]. Typically collagen is hydrolyzed and stored in an acidic solution that is returned to a neutral pH to initiate polymerization. Unlike most synthetic polymers this method allows living cells to be added during the polymerization step, to produce preformed, homogenous, cell dense materials. This is particularly important as it reduces the time and cost of construct development. By starting with a cell dense material one can avoid having to wait several weeks for the cell populations to proliferate and fully populate the matrix. The earlier work of Weinberg and Bell, who developed the first collagen-based *de novo* blood vessel in 1986 [50], had shown the potential of these natural polymer scaffolds; however, the major draw back was poor mechanical strength and stability. Collagen in its natural form is composed of similarly repeating amino acids, where glycine is repeated every third amino acid, with many of the remaining amino acids being proline and hydroxyproline. As collagen is hydrolyzed, collagen bundles dissociate creating a mass of disorganized fibers that absorbs a significant amount of water to form what is called a hydrogel. Cells remodel the collagen and these disorganized fibers are realigned back into their original form as functional tissue is created. As the fibers realign, a significant amount of shrinkage occurs as the fibers condense and water is expelled.

The most common method used to enhance mechanical properties of collagen-based hydrogels is the addition of chemical crosslinks that bind, strengthen and minimize enzymatic digestion of the long-chain polymer [51–54]. Many crosslinkers, such as glutaraldehyde, are toxic and often leave residual toxins in the scaffold after processing. A further drawback of this approach is that it renders the material impervious to cellular infiltration. The barrage of ECM degrading and remodeling enzymes, secreted by cells, have little effect on many of these chemically induced crosslinks, and as such there is little cell penetration or remodeling of the scaffold. The result is stable, but inert, materials. From a tissue engineering perspective, cell migration into the scaffold and subsequent remodeling are fundamentally important if functional neo-tissue is to be formed. By using conductive additives, which also enhance the material's mechanical characteristics, the opportunity exists to develop off-the-shelf, high-performance materials that may improve repair and regeneration of diseased tissues.

However, with the current state of technology, single-walled carbon nanotubes (SWNT) cannot be used for medial applications straight from the production plant. In general the production of SWNT results in a high percentage of contaminants that must be removed prior to application. Purification technologies are diverse, and often change the surface chemistry of the SWNT, which in turn changes the way biological systems respond to the presence on SWNT. As often is the case with nano-scale materials, the particle's surface chemistry dominates the interactions between the nanotube and the surrounding environment. Changing func-

tional groups on the surface of SWNT can dramatically alter the way in which they interact with hydrophobic and hydrophilic materials; we can use this property to improve dispersion and function within various different polymers. In the next section we discuss the purification and dispersion of SWNT in relation to tissue engineering scaffolds for tissue regeneration.

#### 9.4

##### **SWNT Preparation: Purification and Functionalization**

As a potentially implantable material, not only will the SWNT be exposed to the body, but also any contaminants from the manufacturing process not removed through purification processes. If a SWNT composite is non-degradable with nanotubes bound within the material, any negative biological effects of the nanotubes will likely be minimized compared with materials that degrade over time. As in the case with degradable tissue engineering scaffolds, SWNT and contaminants would come into direct contact with host tissue at higher concentrations. Consequently, compatibility with cells and surrounding tissue is crucial, particularly if the SWNT are not eliminated through normal bodily function. For these new materials to be successful they must be biologically, mechanically, and chemically compatible with the host tissue, and, as such, a comprehensive understanding of how SWNT interact with living systems is required. This is important from not only a materials perspective, but also as an airborne contaminant, or any other interaction these nano-materials may have with biological systems.

Various different methods are used to produce SWNT, including chemical vapor deposition, laser pyrolysis, pulse laser vaporation, and carbon arc-discharge. Each of these methods results in differing qualities of nanotubes with yields containing different types and amounts of production contaminants. Different production methods will result in a different elemental composition, and as such the efficiency of purification techniques will have a strong bearing on biological interactions. By understanding these processes we can gain insight into what the dominant mode in which SWNT (or production contaminants) interfere with cell function. This may lead to determining the critical parameters of SWNT preparations that must be modulated to improve cell interactions and thus develop enhanced biomaterials.

To date, few investigations have assessed SWNT–cell interactions and those that have shown a toxic response by cells and tissues [55–59]. A study by Warheit et al. (2004) observed the formation of a series of multifocal granuloma in rats when SWNT were instilled intratracheally [59]. Interestingly these results were not dose-dependent as other studies have shown. Oberdörster et al. (2004) found that oxidative stress was induced when juvenile Largemouth Bass were exposed to C<sub>60</sub> fullerenes within brain tissue, with the fullerenes localizing in lipid-rich regions such as cell membranes [57]. Schuler et al. (2004) expressed concern that, due to the small dimensions of nanoparticles, they might penetrate the skin and possibly reach the brain by eluding the immune system [60]. Similarly, in a study by Shvedova et al. (2003), using unpurified SWNT produced by the HiPCO process with a

30% iron mass, (NASA-JSC, Houston TX), caused changes in cell ultrastructure and morphology, a loss of cell integrity and apoptosis, accelerated oxidative stress, an accumulation of peroxidative products, and depletion of antioxidants in immortalized human epidermal keratinocytes (HaCaT) [61].

Although the exact mechanism that causes these deleterious interactions with cell systems is unknown, a comprehensive understanding of how SWNT interact with living systems is, clearly, required. By understanding the mechanism(s) that causes these effects on cell function (such as production contaminants, mass transfer limitations, hydrophobic interactions etc.) it will be possible to modulate SWNT chemistry to improve SWNT–cell interactions, and as such develop improved materials.

A recent publication by Nimmagadda et al. (2006) describes how purification and SWNT surface chemistry variation effects the function and viability of 3T3 fibroblasts [62]. In these investigations SWNT were obtained from CarboLex Inc. (Lexington, KY), manufactured by a modified electric-arc technique. In this method a plasma discharge is induced at high temperatures onto a cathode containing graphite powder, metal catalysts, and adhesives. The deposit that forms contains the SWNT. This process results in 40–60% amorphous carbon, as well as non-carbon contaminants including, Ni, Y, Co, and others [63–65]. The study aimed to determine if SWNT themselves, or the production contaminants, were responsible for the toxic responses observed, and to assess if variation in SWNT surface hydrophobicity would improve cellular interactions. Three different preparations of SWNT were assessed, including “as purchased” nanotubes (AP-NT), nanotubes purified by acid washing to remove catalyst residue (PUR-NT), and purified nanotubes functionalized with the small hydrophilic carbohydrate, glucosamine (GA-NT). SWNT that were purified by nitric acid oxidation resulted in dissolution of much of the metal contaminants, but also functionalized the damaged (or defect) ends of the SWNT with carboxylic acid groups reducing the material’s hydrophobicity. With the additional functionalization step of added glucosamine, a small sugar molecule, to the SWNT, the overall hydrophobic nature of these NT is further reduced.

An assessment of the effects of these different SWNT preparations has shown a dose-dependent relationship between the viability of mouse 3T3 fibroblasts and concentration of SWNT, where increasing concentrations of SWNT resulted in decreased cell viability. The effects of “as-purchased” SWNT on 3T3 mouse fibroblasts are similar to other reported data, where cell viability was significantly diminished [55, 58, 66]. The observed effects are strongly influenced by contaminants in the preparation, as well as by soluble and non-soluble components. Improved cell viability occurs with PUR-NT and GA-NT over AP-NT preparations (at a given concentration), emphasizing that purity alone (and thus production method) plays an important role in biocompatibility of SWNT. These investigations have shown significant variation of 3T3 fibroblasts viability and metabolic function (after three days in culture) compared with control values. At the lowest concentration of AP-NT (0.001% w/v), cell viability was reduced to 55% of control values (Fig. 9.1a). In the same cell cultures 3T3 fibroblasts demonstrated dramatic changes in their met-

**Fig. 9.1.** (a) AP-NT/3T3 cultures demonstrated a negative dose-dependent relationship with increasing AP-NT concentration. At the lowest tested concentration of AP-NT (0.001%) only 55% of fibroblasts remained viable ( $p < 0.05$ ). (b) At lower concentrations, cells in AP-NT preparation reduced Alamar Blue dye as much as 200% more than the cells under control conditions ( $0.78 \times 10^{-4}$  fluorescence units). No metabolic activity was observed at and

above 0.0625% NT ( $n = 3$ ). (c) SEM displayed spherical bodies dispersed throughout AP-NT/3T3 cultures. These were hypothesized to be detached cells encased with nanotubes, where cells may have coalesced to form the larger spherical bodies. In this analysis 3T3 cells were cultured with an AP-NT concentration of 0.0625% NT (wt./vol.), with a cell viability of 19.65% compared with control values (100%) [62].

abolic activity (Fig. 9.1b), illustrating a nonlinear effect dependent on NT concentration. The variation observed in metabolic activity is consistent with results from a recent study by Cui et al. (2005) [55]. In their study, the ability of human HEK293 cells to adhere and proliferate when cultured in the presence of SWNT was also diminished. Cui et al. also assessed gene expression profiles for several specific genes and showed that variation in metabolic activity could in part be explained by the variation in gene expression profiles. Unfortunately, neither the elemental composition nor the purification process (if any) of the nanotubes purchased from Carbon Nanotechnologies, Inc. was described. As such the effect, or comparative effect, of residual contaminants was not assessed.

SEM analysis of 3T3 cells cultures in AP-NT, gives further insight into cellular interactions with NT, where spherical bodies ranging from 5 to 15  $\mu\text{m}$  in size

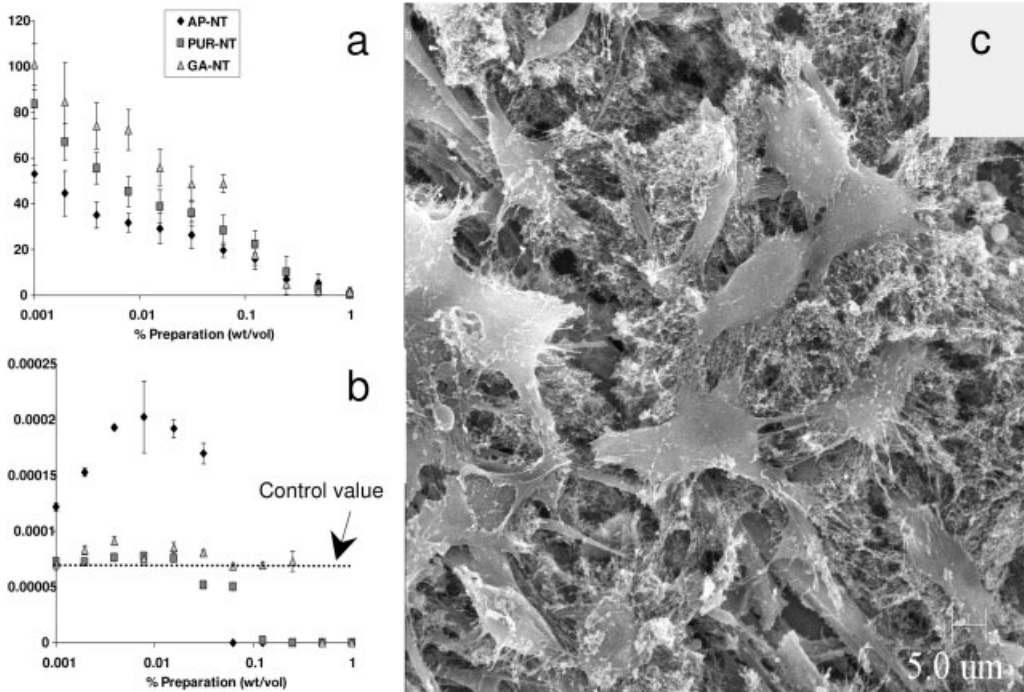

have been observed (Fig. 9.1c) [62]. These spherical bodies were hypothesized to be detached, or semi-detached, cells encased in nanotubes that may, in some cases, have coalesced to form the larger spherical structures.

Purification and functionalization of AP-NT reduces the negative effect on cell viability and metabolic activity, demonstrating that as-purchased NT contain impurities/contaminants that may be responsible for the variation in cell viability and function seen in Fig. 9.1. The effect of these components was assessed by acid washing and chemical surface modification of AP-NT. This suggests that the removal of production contaminants and SWNT hydrophobicity both play an important role in cell-SWNT interactions. The overall trend shows cells incubated in GA-NT preparations having a higher cell viability with less deviation in metabolic activity (from control values) compared with cell/PUR-NT cultures. This suggests the surface properties of SWNT may have a profound effect on cell function. However, the dose-dependant relationship still exists as increasing concentrations of both PUR-NT and GA-NT preparations still reduce cell viability (Fig. 9.2).

At the concentration of 0.0625% w/v 3T3 fibroblasts cultured in the presence of glucosamine functionalized SWNT (GA-NT) for 6 days were found to migrate to the upper surface of the GA-NT to form sheets of cells over the nanotube preparation. Figure 9.3(a) shows an enlargement of Fig. 9.2(c) (incubated for 3 days), compared with sheets of cells seen spreading over the surface of the nanotube preparation after 6 days in culture (Fig. 9.3b).

Because of the small size of these particles, the surface properties dominate the overall chemistry of the molecule and, as such, the addition of functional moieties can dramatically alter the manner in which these particles interact with the surrounding solution. The basic structure of SWNT is a graphene sheet of carbon atoms linked by non-polar covalent bonds. Since electrons are equally shared there is no charge separation and these molecules cannot enter into a charge interaction with water [67]. They are therefore hydrophobic, resulting in minimal solubility in aqueous media. In an investigation by Nimmagadda et al. all NT preparations aggregated to some degree, although the purified nanotubes with carboxylic acid groups and the SWNT functionalized with glucosamine displayed varying degrees of solubility [62]. SEM analysis of AP-NT (the most hydrophobic of the three NT preparations) cultured with 3T3 fibroblasts displayed spherical structures encased in NT-like particles. This led us to the hypothesis that the hydrophobic NT were penetrating, and aggregating within the hydrophobic cell membrane leading to cell rupture (Fig. 9.1c). These effects were not seen with NT functionalized with glucosamine where the hydrophobic nature of SWNT was reduced.

Evidence for the translocation of nanotubes through cell membranes has been confirmed by fluorescence imaging, with [68, 69] and without [70] functionalized markers or molecules. These studies clearly show the nanotubes entering cells, and the potential of nanotubes localizing in hydrophobic regions of the cell membranes. A study by Cherukuri et al. (2004) using a pluronic surfactant that disperses the nanotubes suggests an active mechanism of SWNT uptake. In this study, mouse peritoneal macrophage-like cells were used whose function is the active uptake of targeted particles. However, this may be a secondary uptake path-

**Fig. 9.2.** (a) Cells incubated with GA-NT showed the highest viability followed by cells/PUR-NT cultures, and cell/AP-NT cultures have the lowest viability at SWNT concentrations below 0.125%. Preparations and concentrations below 0.125% NT (wt./vol.) show a statistically significant difference ( $p < 0.05$ ), with the exception of concentrations above 0.125%, where no significant difference between each preparation was

found ( $n = 3$ ). (b) 3T3's in GA-NT and PUR-NT preparations show metabolic activity similar to 3T3's in control cultures. There was no significant difference ( $p < 0.05$ ) between preparations or concentrations between 0.5 and 1.0% NT (wt./vol.). (c) SEM displays 3T3 cells dispersed throughout the 3D GA-NT matrix. No spherical bodies were observed as seen with 3T3 cells incubated with AP-NT [62].

way, whereas in normal stromal cells uptake may be passive translocation driven by hydrophobic/hydrophilic interactions. The results presented by Cherukuri et al. (2004) do not show any toxicity effects at SWNT concentrations of  $3.8 \mu\text{g mL}^{-1}$ , where they estimated an uptake rate of 1 nanotube per cell per second (total of 70 000 nanotubes ingested) over the incubation period of approximately 20 h [70]. By comparison, at the lowest SWNT concentrations assessed by Nimmagadda et al. [62], 0.000976 w/v, or  $9.76 \mu\text{g mL}^{-1}$ , fibroblast viability was reduced to  $50.08 \pm 3.74\%$  for “as purchased” nanotubes (AP-NT), with  $83.58 \pm 6.22\%$  viability with “purified” nanotubes (PUR-NT). Only glucosamine functionalized nanotubes (GA-NT) had no effect on cell viability at these concentrations (Fig. 9.2).

Cherukuri et al. have shown a 40% reduction of SWNT internalization when incubated at  $27^\circ\text{C}$  compared with  $37^\circ\text{C}$ , which is consistent with the temperature

**Fig. 9.3.** (a) 3T3 fibroblasts cultured in the presence of GA-NT at 0.0625% (w/v) for 3 days, showing an enlargement over Fig. 9.2(c). (b) Similar magnification of 3T3 cells cultured under the same conditions for 6 days that have migrated to the upper surface of the GA-NT to form sheets, with (c) (inset) showing a lower magnification of cells covering the surface of the nanotube preparation [62].

dependence of phagocytosis [71]. By contrast, Pantarotto et al. (2004) used amino-modified SWNT functionalized with the fluorescent probe fluorescein isothiocyanate (FITC) and SWNT functionalized with a peptide responsible for G-protein function (also covalently bonded to FITC) to show that uptake by human 3T6 and murine 3T3 fibroblasts was not affected by temperature variation or the use of endocytosis inhibitors. They concluded that the method of translocation appeared similar to cell penetrating peptides, which is not associated with the endocytosis pathway, but the exact mechanism was unclear [72, 73]. Recently, Monteiro-Riviere et al. (2005) have shown that multi-walled carbon nanotubes (MWCNT) were present in cytoplasmic vacuoles of human epidermal keratinocytes [56]. Our investigations have shown that, depending on the hydrophobicity state of the SWNT, these nano-particles appear to aggregate on the surface of cell-like structures. Although several different mechanisms of SWNT translocation are likely, we hypothesize that due to the hydrophobic nature of these nano-particles they tend to aggregate within hydrophobic regions of the lipid bilayer to form focal points. As yet there is no clear evidence that hydrophobic nanotubes move from the lipid bilayer and back into the aqueous environment (either cytoplasmic or extracellular) and as such there is some question as to whether these nanotubes remain within hydrophobic lipid membranes or as postulated enter the cells aqueous environment. The fluidity of these lipid membranes, which interact with other cell membranes, may transport SWNT into the cell, though not necessarily out of the lipid membranes. From our observations, as concentrations increase, the likelihood of the small focal aggregations enlarging in size increases; it is therefore quite possible that, at sufficiently high concentrations, SWNT interfere with membrane integrity, resulting in rupture and cell death.

In our investigations SWNT within each preparation settled out of solution over

**Fig. 9.4.** Images (A–C light microscopy, D–F SEM) displaying SWNT preparations dispersed in aqueous cell culture media inoculated on 3T3 fibroblasts after 3 days incubation. (A) AP-NT displaying large aggregates of nanotubes, (B) SWNT aggregates are progressively dispersed through purification steps (PUR-NT), and (C) further reduced hydrophobic interactions of SWNT within the aqueous environment by functionalization with glucosamine. Lower SEM images show (D) AP-NT, (E) PUR-NT and (F) GA-NT surface topography as the SWNT become less hydrophobic, with improved dispersion.

the 3 day incubation period to form layers directly on the cell cultures. Light microscopy illustrates how the differentially treated nanotubes tend to aggregate as a function of hydrophobicity, GA-NT layers appeared more dispersed compared with AP-NT and PUR-NT preparations (Fig. 9.4a–c), with SEM images showing variable surface topography as NT dispersion increases (Fig. 9.4d–f). The presence of glucosamine molecules functionalized on the surface of SWNT improved SWNT interactions with the aqueous media, allowing SWNT bundles to disperse more uniformly with less aggregation [74].

It is unlikely that tissue engineered scaffolds would be made solely of SWNT, rather they will be formed as a composite material where the bulk polymer will be chosen for selected characteristics pertinent to its endpoint application. Materials designed for use in soft tissue repair applications will be vastly different from bone, or artificial limbs, and as such properties such as elasticity, biocompatibility, porosity, charge, etc. need to be considered.

From a materials perspective, carbon nanotubes used as an additive within a bulk polymer need to be dispersed uniformly, ideally as aligned, individual tubes rather than large random aggregates. Without uniform dispersion we will not be able to take full advantage of the unique properties of SWNT, and as such is a critical issue. Significant effort has focused on full-length SWNT and MWNT disper-

sion, with several approaches being taken to improve dispersion and alignment. Both chemical and mechanical dispersion methods have been used, including, but not limited to, sonication, surfactants, and functionalization with different moieties or macromolecules. Improving alignment of SWNT has been equally challenging and several methods have been investigated, including mechanical shear [75, 76], anisotropic flow [77], and magnetic fields [78, 79].

As discussed, the surface chemistry of these nano-particles dictates the manner in which SWNT are prepared to interface appropriately with the bulk polymer. Clearly, SWNT dispersion within aqueous hydrogels requires a different approach than dispersion in non-polar polymers. Sennett et al. (2003) mixed both SWNT and MWCT in molten polycarbonate (PC) using a twin-screw extruder to disperse the nanotubes, then used a melt-spinning technique to align the NT with the PC fibers. MWCT and SWNT displayed different dispersion characteristics, with larger individual MWCT dispersing uniformly; however, SWNT dispersion was limited to bundles of nanotubes rather than single tubes [76]. This effect will in part be due to the mixing characteristics of different sized particles but dispersion will again be dominated by the nano-particle's surface chemistry. MWCT and SWNT that are produced using different production methods will have different contaminants and will require different purification strategies, most of which can alter the surface charge/chemistry. As such the two materials will likely behave very differently under similar solution conditions.

Other methods of dispersion include functionalization of nanotubes to alter their surface chemistry and/or provide secondary chemical bonding sites. These functional moieties range in chemistry and function, and include (amongst others) biological polymers, including DNA and other large macromolecules. One of the more common methods to functionalize nanotubes is the formation of carboxylic acid groups as either a final process or as an intermediate in a process called defect functionalization using a strong oxidant such as nitric acid ( $\text{HNO}_3$ ) [80–83]. Fu et al. (2002) functionalized SWNT with oligomeric poly(ethylene glycol) to solubilize SWNT and MWNT in aqueous solutions. They then added serum albumin using surface-bound ester linkages, citing an ester to amide transformation as the mechanism of adsorption [83]. These preparations were shown to have a high solubility in water and suggested this method to conjugate fragile biological species. Of the biological polymers used, Zheng et al. (2003) have shown effective dispersion of SWNT in water when sonicated in the presence of single stranded DNA (ssDNA), suggesting binding through  $\pi$ -stacking of ssDNA wrapping in a helical fashion around the SWNT [84]. Baker et al. (2002) oxidized SWNT to form carboxylic acid groups then reacted with thionyl chloride and then ethylenediamine to generate a terminal amine group to which (after several intermediate steps) single-stranded DNA oligonucleotides were functionalized to the SWNT. These investigations have shown the ability of DNA to be covalently bound to SWNT, then for complementary DNA sequences to hybridize with minimal interaction from non-complementary sequences [81]. Bianco et al. (2005) have discussed several strategies for using, and functionalizing, nanotubes in biomedical applications. The paper focuses on nanotube functionalization for specific applications in drug, vac-

cine, and gene delivery and provides an excellent overview of different functionalization strategies [85].

As a material with potential biomedical applications the absorption pattern of these and other molecules to the surface of SWNT is important to further our understanding of how SWNT are likely to interact with not only the bulk polymer but with surrounding cells and tissues. The inherent hydrophobic nature of SWNT has been hypothesized to play a dominant role in the non-specific molecular binding of various molecules to the surfaces of SWNT [69, 72, 86–88]. In addition to these direct effects of SWNT on cells, it is also possible that SWNT aggregates may indirectly alter cell function by limiting mass transfer of substances either to or from the cell surface. We investigated this possibility by examining the interactions of differentially functionalized SWNT on glucose and protein transfer through SWNT membranes [62]. These investigations were designed to assess any mass transfer limitation that might occur as the SWNT settled onto the cell layer and potentially affected cell function. At sufficiently high concentrations, all SWNT preparations (AP-NT, PUR-NT and GA-NT) resulted in a reduced rate of glucose transfer, compared with controls. However, because the glucose mass transfer rate was still in excess of cellular demand it was concluded that there was no inhibition of cell function. Although no conclusions can be drawn regarding glucose adsorption from the data available, the three preparations clearly had a different topography and porosity (Fig. 9.4), which would be the likely cause of variation in mass transfer rate. Similarly, protein (balanced salts with 10% serum) transfer through the membrane displayed mass transfer variation, indicating inhibition. At lower concentrations of SWNT there was no significant variation in mass transfer across any of the three SWNT preparations. At higher SWNT concentrations (0.25% and 1%) a significant decrease in protein transfer was noted across the PUR-NT preparation compared with AP-NT and GA-NT preparations (Fig. 9.5b) [62].

The results of this study clearly demonstrate that chemical composition and nature of nanotube preparation is of fundamental importance for biological applications. Furthermore, choice of supplier, manufacturing method, and the effectiveness of NT purification will strongly influence the overall composition, including contaminants within the raw material. These impurities will have a range of effects on cellular viability and metabolism, depending on the contaminants involved and their concentration; however, the mechanism by which either the contaminants or the SWNT alter cell viability or metabolism is yet to be resolved. SWNT purification is therefore a critical step and it is important to note that these processes can alter the surface chemistry of the nanotubes and thus their interactions with cells and tissues. We have hypothesized that when SWNT remain strongly hydrophobic (AP-NT and PUR-NT preparations) these nanoparticles interfere with the lipid bilayer of the cell membrane by aggregating within these hydrophobic regions and disrupting cell membrane. Although other mechanisms presumably also occur, SEM evidence points strongly to these hydrophobic interactions as playing a dominant role in early cell failure.

The nanotubes used in the above investigations showed significant effects on *in vitro* cellular function that cannot be attributed to one factor alone, but are likely

**Fig. 9.5.** (a) A decrease in glucose transfer rate was observed at higher concentrations of NT preparations (1%). From the transfer rates observed and the cell consumption rate ( $1.368 \times 10^{-6} \text{ mg dL}^{-1} \text{ h}^{-1} \text{ cell}^{-1}$ ), no apparent mass transfer limitation is likely to

have occurred. (b) Analysis of total protein (human plasma) transfer through NT layers showed no significant difference ( $p < 0.01$ ) between AP-NT, GA-NT and control values, whereas PUR-NT layers displayed a significant reduction at higher concentrations [62].

the result of several unfavorable interactions. These interactions were significantly reduced by comprehensive purification processes, and by modifying NT surface chemistry to reduce hydrophobicity and/or the introduction of functional groups. With high purity SWNT the end application will dominate the requirement to modify NT surface chemistry.

## 9.5

### Specific Applications of Carbon Nanotubes in Tissue Engineering

Carbon nanotubes offer a unique potential to develop smart materials that can be tailored to meet specific mechanical and electrical properties. These properties can be optimized to suit specific applications in areas such as bone development where materials must be rigid yet retain a degree of elasticity. The ability to alter the material's conductivity also provides the opportunity to modulate cell interactions/function by applying electrical fields. The same process can be used for most tissues, especially those that respond in a positive way to electrical stimulation. Some of the more obvious applications include bone, nerve, and cardiac tissue engineering; however, other areas, including skin wound healing, have been shown to respond to electrical fields and are thus candidates for SWNT scaffolds.

There are three primary drivers for the use of SWNT as additives in tissue engineering scaffolds: first is to fine tune scaffold mechanical properties (application specific); the second is to use the NT conductive properties to modulate the materials electrical properties so electrical fields can be used to stimulate the growth and development of tissue engineered constructs; and the third is to promote phenotype specific cellular regeneration by varying the scaffold's conductivity and modulating an applied electrical field. Clearly, a significant amount of basic research is required to verify these goals, but the potential is there given the current status of our knowledge.

In this last section we review several recent publications that focus directly on tissue applications using NT as a component of scaffold materials. Due to the relative infancy of this research area, publications are limited but they clearly show the direction and potential of these novel materials. In a series of investigations interfacing structural biological polymers with SWNT, MacDonald et al. (2005) have assessed the interactions between cell-loaded collagen hydrogels dispersed with varying concentrations of SWNT (0.2, 0.4, 0.8, and 2.0 wt.%) (Fig. 9.6). Figure 9.7 shows progressive enlargements of the composite scaffolds using SEM image analysis of the cartoon given in Fig. 9.6 [89].

The overall goal of these investigations is to enhance the mechanical and functional properties of these hydrogels for potential use in areas such as orthopedic, cardiac and neuronal tissue engineering. Collagen hydrogels have been used in a wide variety of medial implants with excellent results; however, from a purely structural perspective these gels lack the mechanical stability that more demanding applications such as blood vessels and bone replacement require.

The potential to improve the material's mechanical attributes while at the same time adding functionality to the matrix will undoubtedly prove to be a productive avenue of research for both hard and soft tissue replacement or repair. As one of the few investigations that use a degradable polymer with NT dispersed at concentrations as high as 2.0 wt.% it is promising that the authors show no loss in cell viability (rat aortic smooth muscle cells) over the 7 day culture period. Although there was a general reduction in cell number at day 3, by day 7 there was no statis-

**Fig. 9.6.** Diagrammatic representation of the process by which CNT can be incorporated firstly into collagen fibrils then form a collagen–CNT composite material [89].

tical difference in total cell number between controls (hydrogels less NT), and NT treated constructs [89].

This data contrasts the reduced cell viability seen in our own investigations [62] where at 1.0 wt.% SWNT no cells were viable. In our investigations the SWNT were dispersed directly in the cell culture media, eventually coming out of suspension, and as such where in direct physical contact with cells. The increased cell viability in the studies by MacDonald et al. (2005) is likely due to the interaction between NT and collagen fibers, where collagen fibers may bind the NT, reducing the direct interactions/contact with cells seen in our investigations. This adds weight to our hypothesis that non-bound hydrophobic NT localize in hydrophobic regions of the cell membrane, resulting in mechanical disruption of the cell membrane (Fig. 9.1).

Not surprisingly, bone and neuronal engineering have been an early focus for several tissue engineering groups. In one of the earliest publications using NT in a tissue engineering application, Supronowicz et al. (2002) assessed cellular interactions with NT composite materials. In these investigations the interactions of

**Fig. 9.7.** Progressive enlargement of the same section of a composite scaffold (A–C), using scanning electron microscopy, showing examples of nanotubes and nanotube bundles incorporated into the collagen fibrils, identified by their typical banding pattern [89].

murine osteoblasts seeded onto poly(lactic acid) (PLA)/MWNT composites were assessed while stimulating cells with alternating current. PLA, normally an insulator, was made conductive with the addition of 20% (w/w) NT, resulting in a resistivity of 0.2 ohms ( $\Omega$ ). Osteoblasts seeded at a density of 7500 cells  $\text{cm}^{-2}$  were exposed to an alternating current of 10  $\mu\text{A}$  at a frequency of 10 Hz with a 50% duty cycle. Results show a significant increase in cellular proliferation, type I collagen deposition, and calcium content although no expression of alkaline phosphatase or bone sialoprotein was recorded. Using only the MWNT/PLA composite, samples were either subjected to the alternating current, or not. Unfortunately, there was no control using PLA alone (no MWNT additive), and as such we cannot determine whether the effects noted were the result of the applied current or the presence of MWNT [90]. The translation of this polymer composite to a tissue engineering scaffold requires a degree of porosity be built into the initial material; however, at such high MWNT concentrations (20% w/w) the structural properties may be negatively effected.

A different approach by Zhao et al. (2005) used differentially functional SWNT as a scaffold template aiming to mimic collagen fibrils at the nanoscale such that nucleation is initiated and crystallization of hydroxyapatite (HA) occurs to encourage bone formation. Various functional groups were explored to expose negatively charged surfaces that are believed to promote supersaturation of local ions leading to mineralization. Unlike carboxylic acid functionalized SWNT, the paper shows that sulfonate- and phosphonate-functionalized nanotubes lead to nucleation of HA on their surfaces [91]. This is a promising approach to a complex issue where the defined orientation of HA in natural mineralization processes may be mimicked using SWNT to enhance the regeneration capacity of newly formed bone.

The mechanical and rheological properties of poly(propylene fumarate) (PPF)/SWNT composites were investigated by Shi et al. (2005) as a potential injectable scaffold for bone repair. This work again draws attention to the importance of SWNT dispersion within any polymer matrix. Although the mechanical properties were enhanced at lower concentrations (0.02, 0.03, 0.05 wt.%), higher concentrations (0.1 and 0.2 wt.%) resulted in air bubble formation and SWNT aggregates within the polymer matrix [92]. Interestingly, functionalization of the NT or the addition of surfactants did not improve dispersion in PPF, underscoring our earlier observation that NT surface chemistry may need to be specifically tailored for improved dispersion in this particular polymer.

A second area of specific interest in SWNT composite materials is as a substrate for neuronal growth and development [93, 94]. Lovat et al. (2005) describe the use of MWNT neural signal transfer whilst supporting cell adhesion and dendrite elongation. These results show adhered hippocampal neuronal cells spontaneously fire action potentials with an increased frequency. The authors suggest that growing neuronal circuits on NT substrates promotes an increase in network operation [95]. Also using NT as substrates for neuronal growth, Hu et al. (2005) have prepared polyethyleneimine (PEI) functionalized SWNT films deposited on glass surfaces as a copolymer to assess hippocampal neuron function. These investigations assessed neurite outgrowth and branching as a comparative investigation to sub-

strates of PEI (a widely used substrate for neuronal culture) and as-purchased MWNT. Results show that neuronal cells cultured on SWNT-PEI substrates produce outgrowths and branching intermediate between PEI (alone) and as-purchased MWNT, suggesting that the ratio of NT to PEI could be titrated to produce neurons with specific characteristics [96]. In an earlier paper, Webster et al. (2004) showed the potential of carbon nanofiber reinforced polycarbonate urethane (PU) as a scaffold to promote adhesion and growth of cell-specific phenotypes compared with cells grown on glass or 100% PU substrates. Using different cell types on increasing concentrations of NT (NT with a diameter 60 nm), it was shown that the adhesion of astrocytes and fibroblasts generally decreased with increasing concentrations of NT (ratio of PU:NT wt.%); conversely, osteoblast adhesion increased under the same conditions [97]. The authors see the potential of either PU/NT coated or bulk materials being used that offer reduced fibroblast adhesion, and thus reduce the soft tissue formation on orthopedic implants, while at the same time increasing the opportunity for osteoblast adhesion leading to new bone growth. Correa-Duarte et al. (2004) have discussed the generation of thin films of MWNT to form 3D sieve architectures [98]. Using specific treatments and lengths of NT, SEM analysis shows NT forming in perpendicular alignments, pyramid-like formations, and also honeycomb structures. In addition to scaffold surface treatments to modulate cell function, this technology would also be useful in determining the effect of physical patterning and cell adhesion at the nanoscale with identical materials with different structures.

## 9.6

### Conclusions

Clearly, cell survival on a biomaterial is not adequate, in itself, for functional tissue regeneration. The use of NT offers several unique opportunities to develop nano-textured surfaces, variably conductive materials, and materials with adjustable mechanical properties that can be tailored to meet specific design considerations. As these investigations continue to test and further understand cell interactions at macro, micro, and nano-scales the promise of smart, functional materials will become a reality. Ultimately, it is likely to be a combination of multiple stimuli, including mechanical, chemical, and electrical factors that will enhance the development of new functional tissue engineered devices.

# Nanoparticles for Cell Engineering – A Radical Concept

*Beverly A. Rzigalinski, Igor Danelisen, Elizabeth T. Strawn,  
Courtney A. Cohen, and Chengya Liang*

### 10.1 Introduction and Overview

Nanotechnology holds great promise for the treatment of disease through cellular engineering. Engineering has made substantial advances in materials science and construction of nanoscale devices over the last decade. Movement of this emerging technology into the realm of cell biology and medicine involves applying these advances to biological systems, providing novel opportunities to intervene in the progression and pathology of disease. To accomplish this, scientists must develop the ability to work and reason in a manner that merges previously distinct disciplines; applying the principles of physics and engineering to cell biology and physiology. This chapter is directed towards achieving this goal.

It is of critical importance to address this merging of disciplines in our written discussions of nanotechnological inroads into the biomedical sciences. The present chapter discusses such a progression in an interdisciplinary manner for the first time, by examining the role of engineered nanoparticles as free radical scavengers at the cellular level and their potential use as pharmacological agents for free radical-mediated disorders.

We begin with a brief discussion of free radicals and their role in cellular function and dysfunction, followed by examination of the role of oxidative stress in aging and disease. The current pharmacology of oxidative stress will be addressed along with its limited efficacy. Comparisons will be made regarding free radical processes in biological vs. industrial and chemical processes. Next, we will examine an alternative, nanotechnological approach to oxidative stress at the cellular level and examine the emerging potential for the utilization of different nanoparticles in the treatment of disease.

## 10.2

### Free Radicals and Oxidative Stress

Free radicals are highly reactive compounds, lacking the full complement of electrons necessary for molecular stability. In biological organisms, unstable free radicals can strip electrons from cellular macromolecules, rendering them dysfunctional. Free radical species encountered within the cell include superoxide ( $O_2^-$ ), the hydroxyl radical ( $OH^\cdot$ ), nitric oxide (NO), peroxynitrite ( $ONOO^-$ ), lipid hydroperoxides, and others [1–5]. Importantly, many free radical reactions in the cell are self-propagating [6]. An example of this is the lipid peroxidation chain reaction, initiated by the hydroxyl radical ( $OH^\cdot$ ). The reaction is initiated by interaction of the hydroxyl radical with a membrane lipid (L):

In the second phase of the propagation process:

1.  $LH^\cdot + O_2 \rightarrow LHOO^\cdot$
2.  $LHOO^\cdot + LH_2 \rightarrow LHOOH + LH^\cdot$

Thus, the free radical species is regenerated to propagate the peroxidation reaction. In hydrophobic areas such as the plasma membrane, chain reactions of lipid peroxidation can damage membrane structure and induce cell death [6–8]. One of the end products of peroxidative damage to cellular lipids is the destructive aldehyde 4-hydroxy-2-nonenal (4HNE), a highly reactive electrophile that interacts with protein constituents such as cysteine, histidine, and lysine [9, 10]. 4-HNE has been implicated as a damaging factor in many human disease states, by virtue of disruption of protein function. Formation of prostaglandin-like compounds, termed isoprostanes, by free radical-mediated lipid peroxidation has also been implicated in numerous pathological conditions [11]. In addition to lipid peroxidation, cellular sugars and proteins can also undergo free radical mediated oxidation, which may induce loss of catalytic function, destruction of cellular architecture, increased degradation or accumulation of damaged cellular constituents, as occurs in many neurodegenerative, ischemic, diabetic, and other disorders (Table 10.1). Engineering and materials science readers should note that these biological free radical processes are similar to those encountered in industrial and materials science applications – the players are somewhat different but the game remains the same.

#### 10.2.1

##### Sources of Intracellular Free Radicals

Free radicals arise from many sources within the cell, as described in several good reviews [5, 12–16]. Mitochondria and the oxidative phosphorylation process are considered to be a primary site of free radical production, giving rise to superoxide

**Tab. 10.1.** Human disease states that generate oxidative stress or of which oxidative stress is a known component.

Organ system	Disease
Brain, CNS, PNS	Alzheimer's, Parkinson's, Huntington's, Multiple Sclerosis Trauma, Stroke, Ischemia, Other Neurodegenerative disorders
Circulatory	Atherosclerosis, Hyperlipidemia, Cardiovascular diseases Vascular disorders, Hypertension
Endocrine	Diabetes, Metabolic Syndrome
Musculoskeletal	Arthritis, Physical injury, Joint disorders
Immune	Allergic disorders, Autoimmune disorders, Inflammatory disorders
Respiratory	Asthma, emphysema, COPD, Bronchitis
Digestive	Inflammatory bowel disease, Crohn's disease

radicals during the passage of electrons through the electron transport chain [17–19]. Free radicals are also formed at sites of inflammation, released by neutrophils and macrophages to destroy invading bacteria [1, 18]. However, cells of the immune system also generate free radicals in inflammatory disorders such as Alzheimer's disease, arthritis, and cardiovascular disease, where they initiate or propagate tissue damage [5].

Free radical production is also a by-product of certain normal cellular enzymatic reactions. The cyclooxygenase enzyme produces free radicals during prostaglandin synthesis [20, 21]. NADPH oxidase and xanthine/xanthine oxidase are also intracellular enzyme systems associated with generation of free radicals during normal metabolic function [1, 6, 21]. NO is a free radical produced by nitric oxide synthase (NOS) and is commonly utilized in cell signaling in the nervous and cardiovascular systems [22]. However, overproduction of NO in inflammatory and disease states such as atherosclerosis can result in formation of the highly reactive peroxynitrite radical (ONOO<sup>•</sup>), which can subsequently induce nitrosylation of critical cellular proteins and damage their function.

In addition to endogenously generated free radicals, organisms are exposed to numerous exogenous sources of free radicals and free radical generating agents during a typical life span. These include environmental toxins such as pesticides, radiation, pharmacological agents, industrial pollutants, food additives, cigarette smoke, and many others. In summary, the typical cell is exposed to numerous free radicals from both endogenous and exogenous sources during a lifetime. Such free radical exposure, if unchecked or excessive, may induce considerable damage to cellular constituents necessary for survival and function.

## 10.2.2

**Oxidative Stress**

Healthy cells are able to counteract the damaging effects of free radicals via innate, natural, enzymatic or molecular mechanisms. Superoxide dismutase (SOD) catalyzes the conversion of the superoxide radical into  $\text{H}_2\text{O}_2 + \text{O}_2$ . Although  $\text{H}_2\text{O}_2$  is also damaging to biological systems, catalase and glutathione peroxidase enzymes convert  $\text{H}_2\text{O}_2$  into  $\text{O}_2 + 2\text{H}_2\text{O}$ . Other endogenous reductants that ameliorate cellular free radicals include *n*-acetyl cysteine, vitamin E, vitamin C, carotenes, melatonin, and lipoic acid derivatives, and are the subject of many recent reviews [1, 23–27].

Although excessive free radical production can be damaging, production of free radicals in low amounts is necessary for normal cell function and signaling. For example, the free radical NO is necessary for normal signal transduction pathways in the vasculature [28] and neurotransmission in the brain [23]. Phagocytic cells routinely utilize free radicals for destruction of invading bacteria or cells infected with viruses. Regulation of cell signaling pathways such as phosphatase activity, calcium signaling, and transcription factors have all been implicated in having regulatory links with free radical production within the cell [22, 29, 30]. Hence a low amount of free radicals appears to be important to normal cell function and the healthy cell achieves a biological balance between free radical production and degradation.

Cellular havoc arises when the production of free radicals exceeds the capacities of cellular defense mechanisms or when cell defense mechanisms are compromised by aging and other pathological states, disturbing the biological balance. In this case, production of free radicals far exceeds their normal signaling functions and damage to cellular macromolecules ensues. The burden of free radicals imposed upon a cell in such a situation is termed oxidative stress, and often arises as a prerequisite or result of aging or disease states. For an example of this, let us return to the subject of the NO free radical. NO is an important neurotransmitter in regulated, low, amounts. However, when produced in overabundance due to neuronal damage or in the presence of hydroxyl radicals, oxidative stress can be imposed upon the brain. The damaging ONOO<sup>-</sup> radical is formed under these conditions, which can induce lipid peroxidation and nitration of protein tyrosine residues [31]. Tyrosine nitration inhibits phosphorylation of tyrosine residues in proteins, an important signaling mechanism in cell regulation. Other free radicals may catalyze formation of carbonyl groups on proteins, which can interfere with tertiary conformation and inhibit or reduce their function [30, 32, 33]. The end result of such cumulative damage is cell dysfunction or demise.

Within the cell, there is a balance between the rate of free radical production and the capacity of cellular defense mechanisms to mitigate free radical damage. When cellular mitigating systems are compromised, high levels of oxidative stress can do extensive cell damage. Cellular pathologies associated with free radicals include lysosome and proteasome dysfunction leading to cell death [34–36], loss of signaling cascades mediated by phosphorylation [32, 37], oxidation of DNA bases [38, 39],

destruction of the membrane lipid environment [40, 41], loss of vascular tone and responsivity [32, 42], aberrant neurotransmission [16, 43, 44], mitochondrial dysfunction [1, 13, 14], and initiation of cell death pathways [12, 16, 45].

### 10.2.3

#### **Oxidative Stress and Disease**

A multitude of disease pathologies are caused or otherwise related to oxidative stress, including Alzheimer's disease, inflammatory disorders, Parkinson's disease, diabetes, atherosclerosis, hypertension, and mechanical injury, which are summarized in Table 10.1 and are the subject of numerous works [1, 18, 25, 43, 46–49]. As with Alzheimer's disease, free radical production is often not the ultimate causative factor, but is a byproduct of cellular malfunction initiated by amyloid beta peptide. Aberrant free radical production by damaged cells can lead to destruction of uninjured “bystander” tissue, thereby propagating the damage. In Alzheimer's disease, excessive free radical production in damaged neurons and inflammatory activation of microglia leads to free radical injury of healthy, neighboring neurons [37, 44, 50]. Similar pathologies have been associated with atherosclerosis, arthritis, and other inflammatory disorders that are prevalent in aging organisms [1, 6, 51–54].

Of particular interest to us all has been the role of free radicals in aging and age-associated disorders. As described by Harman [55], aging began with the origin of life, and represents the accumulation of diverse deleterious changes in cells and tissues that increase the risk of disease and death. Although there are several theories on aging, the “Free Radical Theory of Aging” appears to have the most biochemical support [23, 50, 55]. According to this theory, aging is associated with accumulation of macromolecular free radical damage to lipid membranes, mitochondria, protein, and DNA, promoting cell dysfunction and death. Numerous lines of evidence support this hypothesis and are the subject of several excellent reviews [1, 45, 49, 50]. Aging is accompanied by an increase in the level of oxidative damage such as carbonyl groups and tyrosine nitration of cellular proteins, a general index of free radical damage [32, 33, 56]. Late onset Alzheimer's is characterized by an accumulation of oxidatively modified proteins [32, 57]. The antioxidant spin trap *n*-*t*-butyl- $\alpha$ -phenylnitron improved spatial memory of aged rats relative to untreated controls, and also decreased the level of oxidative damage to cellular macromolecules in the brain [32]. Lipid peroxidation products have also been shown to increase with age [58], suggesting that membrane damage accumulates over the course of a lifespan.

Quality of life, not only life span, is important in the aging process. Once again, the free radical hypothesis maintains that free radical production is associated with cognitive deficits, neuronal dysfunction, atherosclerotic conditions, and inflammatory conditions associated with aging. Neural tissue has the highest ATP and oxygen utilization of all the organs in the body. It follows that neural tissue is therefore exposed to some of the highest levels of oxidative stress in neurodegenerative diseases and aging. Several reviews [59–61], suggest that free radical scavengers

may be useful therapeutic adjuncts in treatment and prevention of age-associated disorders, improving the quality of life.

Given the widespread involvement of free radicals in aging and disease, the use of free radical scavengers or antioxidants as pharmacological therapy has been reported in many disorders (reviewed in Refs. [25, 27, 52, 54, 59–61]). Free radical scavengers such as vitamin E, vitamin C, *n*-acetyl cysteine, melatonin, SOD mimetics, 21-aminosteroids, 2-methylaminochromans and nitrosone spin traps have been utilized to lessen the severity of disorders associated with free radical production. However, many of these free radical scavengers have met with only limited clinical success. For example, SOD and poly(ethylene glycol)-conjugated SOD showed promise in the treatment of traumatic head injury, where superoxide radical production contributes to disease pathology [59, 61, 62]. Yet clinical trials of these agents yielded far from promising results, likely due to lack of cell or tissue penetration. On the whole, pharmacological use of free radical scavengers has several problematic aspects. The first is lack of penetration to the site of radical production, as may be the case with exogenous SOD mimetics. Similarly, vitamin C is also a free radical scavenger, yet it is thought to function only in aqueous environments and has difficulty crossing the lipid membrane of the cell. Additionally, due to its chemical structure, high concentrations of vitamin C are also reported to act as free radical generators, so proper dose is critical to antioxidant function. The second problematic issue is the requirement for repeated dosage. Many of these scavengers require repetitive daily dosing to replace molecular species that were utilized in free radical reduction. In the case of vitamins C or E and other antioxidants, one molecule of antioxidant is utilized for each free radical detoxified, and regeneration is low or non-existent in the case of exogenous agents such as spin traps and 21-aminosteroids. In summary, although supplementation with free radical scavengers has shown to be beneficial in several disease states, the overall success has been limited at the clinical level.

### 10.3

#### A Nanotechnological Approach to Oxidative Stress

Up to this point, our discussion of free radicals and oxidative stress have focused on events from a biological standpoint. However, if we examine the basic chemistry of free radical mechanisms, the engineer will realize that the cellular processes underlying biological oxidative stress are encountered in many non-biological instances. Let us take, for example, the processes involved in three-way catalysis for improved combustion and removal of environmental contaminants from engine exhaust. These processes have much in common with the biological concept of redox reactions and antioxidants from a chemical and physical standpoint. Likewise, the role of coatings in reduction of metal oxidation involves chemical principles similar to those associated with prevention of oxidation of biomolecules, intracellularly. Nanoparticle formulations added to such industrial catalytic systems often serve the role of a catalysis promoter or a stabilizer, to improve the efficiency

of the catalyst. However, looking at this issue from a cross-disciplinary standpoint, the actions of enzymes and cofactors involved in biochemical reactions can be defined in a similar manner, in that they act at catalysis promoters that are unchanged by the reaction they catalyze. From an engineering standpoint, nanotechnology has provided dramatic improvement in industrial applications related to efficiency of redox reactions. Cross-disciplinary application of these processes to cellular redox reactions occurring on the nano-scale intracellularly may provide a new basis for pharmacological treatment of many diseases related to oxidative stress.

Three of the most-studied nanoparticle redox reagents, at the cellular level, are rare earth oxide nanoparticles (particularly cerium), fullerenes and their derivatives, and carbon nanotubes. In the following sections, we discuss the chemistry and biological properties of these nanoparticles and their potential use in preservation of cellular redox status and treatment of disease.

### 10.3.1

#### Rare Earth Oxide Nanoparticles – Cerium

Rare earth oxides of cerium, neodymium, praseodymium, and ruthenium have been utilized in three-way catalysts for enhancement of fuel combustion, removal of soot from engine exhaust, removal of environmental free radical contaminants such as NO and SO from fuel exhaust, removal of organics from wastewater, promoters of catalysis in environmental clean up, and in development of fuel cell technologies [75]. These applications are all related to the high redox capabilities of rare earth oxides; that being their ability to serve as free radical scavengers. Out of the lanthanide series of elements, oxides of cerium (ceria,  $\text{CeO}_2$ ) nanoparticles are reported to have several unique properties that make them highly efficient redox reagents (Fig. 10.1). To date, on the intracellular level, ceria has been the most-studied of this nanoparticle group.

As a rare earth element of the lanthanide series, cerium oxide has a characteristic fluorite lattice structure. Lanthanides exist in the earth's crust at about 100 ppm,

**Fig. 10.1.** Electron micrograph of cerium oxide nanoparticles. (Courtesy of Nanophase Inc., Romeoville, Illinois.)

with cerium making up approximately 24 ppm [63]. However, cerium has several unique properties among the rare earths, established by examining microcrystalline cerium oxide structures [65]. First, cerium has two partially filled subshells of electrons, 4f and 5d, with 14 excited sub-states of cerium predicted [66]. The cerium atom can exist in either the +3 (fully reduced) or +4 (fully oxidized) state, and may readily flip-flop between the two in a redox reaction [66–68]. Both the crystal lattice size and the bond length change when alterations in redox state occur. It is hypothesized that cerium oxides make excellent oxygen buffers with high oxygen storage capacities, because of their high redox capabilities [64]. In addition to alterations in cerium redox state, cerium oxide also exhibits oxygen vacancies, or defects, in the lattice structure, by loss of oxygen and/or its electrons [66, 67]. Formation of each defect removes a subgroup of ions from the lattice structure. Thus, creation and annihilation of oxygen vacancies occurs in the cerium oxide lattice during redox reactions [65]. Cerium and its oxides are also unique, among the rare earths, in that there is a high hydrogen absorbing capacity on the surface, providing for ease of reactions with  $H_2$ ,  $O_2$ , or  $H_2O$ , as compared with other rare earths.

The valence and defect structure of cerium oxide is dynamic and may change spontaneously or in response to physical parameters such as temperature, pH, presence of other ions, and oxygen partial pressure [67–69]. Several groups have examined the use of cerium oxide particles as metal coatings to reduce oxidation and as coatings for catalytic converters, to enhance oxidation of carbon monoxide and hydrocarbons, and reduce nitrogen oxide emissions [70, 71]. A primary role of cerium oxide under these conditions is to act as an oxygen storage and release component [69]. The chemical reactions of cerium oxide have been reviewed [68, 72–75] and include oxygen atom transfer and absorption, oxidation of unsaturated hydrocarbons, electron transfer to hydrocarbon radicals, high catalytic activity in redox reactions, and reduction of nitrogen oxide. One cannot avoid noting the similarities between these uses and the properties necessary for a good cellular antioxidant. Thus, the chemistry of cerium oxide further supports a potential role as either a biological free radical scavenger or antioxidant.

The atomic and molecular properties of materials at the nanometer scale change in ways we are just beginning to comprehend. The chemical behavior of cerium oxide nanoparticles may reflect the chemical properties of its macromolecular structure to some extent, but altered characteristics are likely at the nanoscale. For example, Raman spectra of cerium oxide nanoparticles are very different from microparticles [68]. Creation and annihilation of oxygen vacancies is reported to occur more rapidly in nano-ceria, making it a more efficient redox center in industrial applications. Guo and Waser have reported that the electrical conductivity of nanocrystalline  $CeO_2$  is several orders of magnitude higher than its microcrystalline form [76]. Several other groups report that nanocrystalline cerium oxide shows enhanced electrical conductivity as grain size decreases below 100 nm, due to a decrease in the enthalpy of oxygen defect formation [67–69]. Thus, oxygen vacancies are likely to form more readily at the nanoscale, increasing the number of sites available for free radical scavenging. Additionally, the surface area of cerium oxide

particles (grain boundary) is dramatically increased at the nanoscale, so greater oxygen exchange and redox reactions may occur over the increased surface area [71]. It is precisely these proposed alterations in cerium oxide nanoparticles that may impart cellular biological effects. Several reports indicate that ceria and its oxides are the only rare earth elements capable of undergoing redox transformations at ambient temperatures, such as those encountered in the intracellular environment [77, 78]. However, the chemical properties of cerium oxide nanoparticles under physiologically relevant parameters remain unknown, as most studies to date utilize temperatures and pressures well above the physiological range. Thus, there is a distinct need to further study the chemistry and physics of ceria nanoparticles at physiological temperatures and in medium with ionic composition similar to the intracellular and interstitial fluid environment.

#### 10.3.1.1 Biological Effects of Cerium

Biologically, cerium has been utilized most often in the form of nitrates or chlorides of cerium. In China, cerium chlorides and nitrates are used in fertilizers, to increase harvest [74]. Aged rice seed treated with cerium nitrate showed an enhanced respiratory rate and increased activities of superoxide dismutase, catalase, and peroxidase, enzymes associated with reduction of oxidative stress and free radicals [79].

Cerium has been found in humans and other animals, with amounts varying from several parts per billion to parts per million. In a feeding study conducted in pigs, feed containing rare earth elements (38% La, 52% Ce, 10% other) increased weight gain and feed conversion ratios [80], thereby enhancing biomass production. No negative health effects were observed. Serum cholesterol, triglycerides, total protein, albumin and ionic composition were normal and concentration of rare earths in the tissues was below 52  $\mu\text{g}$  per kg dry weight. Cerium nitrate has been used in treatment of burns, and improved the outcome of burn patients [81, 82]. Improved outcome was associated with a reduction in the systemic inflammatory response observed in burn victims and improved capacity for tissue repair. Rare earths in general have potent anti-atherosclerotic, anti-arthritis, and anti-inflammatory activity. Histologically, the chloride form of cerium has been used to identify subcellular sites of free radical (superoxide,  $\text{H}_2\text{O}_2$ ) production [83, 84]. It has also been used to study the location of xanthine/xanthine oxidase in rat liver cells, an enzyme associated with free radical production [22]. Although these studies involve the use of nitrates and chlorides of cerium, they support a distinct role for cerium in interaction with cellular free radicals.

From the few existing reports, cerium is relatively inert from the biological standpoint of toxicity – but reports are scarce and do not address oxides of cerium, much less nanoparticles. However, some negative biological effects have been reported, particularly at high concentrations. One report of inhalation pneumoconiosis was identified, occurring in a lens grinder exposed to prolonged high inhaled concentrations of rare earths [85]. Millimolar solutions have been shown to aggregate erythrocyte membranes *in vitro*, through disulfide bond crosslinks [86]. At high concentrations and non-physiological pH, cerium chloride served as a catalyst

for DNA and peptide hydrolysis [87]. Cerium chloride given to rats at 0.2–20 mg kg<sup>-1</sup> increased the oxygen affinity of hemoglobin by alteration of the secondary structure [87]. Based on its redox activities, it appears likely that cerium interacts with proteins such as hemoglobin and cytochrome P450, which contain heme-iron centers at the active site. However, once again, these reports represent the activity of cerium in the chloride or nitrate form, at millimolar concentrations. The biological properties of cerium oxide nanoparticles are likely to substantially differ.

#### 10.3.1.2 Biological Effects of Cerium Oxide Nanoparticles

The previous section describes the biological effects of cerium in general; however, cerium oxide nanoparticles, although having some similar properties, appear to be quite different on the whole. At the cellular level, cerium oxide nanoparticles have several potent properties, notably at extension of cellular longevity and as regenerative antioxidants.

In several studies, the Rzigalinski laboratory has demonstrated that nanoparticles of cerium oxide, of the size range of 6–20 nm, prolong the lifespan of mixed brain cell cultures, by 6–8-fold [88–90]. Ceria nanoparticles of greater than 20 nm were without effect at prolongation of life span, as were ruthenium, titanium, and neodymium oxide nanoparticles. In these experiments, cerium oxide nanoparticles were added directly to the tissue culture medium on day 10 *in vitro*, allowed to remain in the medium for 48 h, followed by replacement with fresh medium. Thus, a 48 h period was allowed for particle uptake. The optimal particle dose was 10 nM in the tissue culture medium. Figure 10.2 shows representative light micrographs of mixed brain cell cultures treated with cerium oxide. Importantly, neurons present in these aged cultures demonstrated signaling characteristics similar to their younger, untreated counterparts, demonstrating that normal neuronal function was also preserved in ceria nanoparticle-treated cultures [88–90].

Based on the industrial uses of ceria nanoparticles in redox reactions, it was hypothesized that the cellular effects of ceria nanoparticles were due to a free radical scavenging activity. To examine the mechanism of action further, cell cultures were exposed to free radical generating conditions of UV light,  $\gamma$ -radiation, H<sub>2</sub>O<sub>2</sub>, and trauma [88, 90–93]. Cultures treated with ceria nanoparticles showed dramatic resistance to these forms of oxidative stress, and survival exceeded that observed with the biological free radical scavengers vitamin E, melatonin, and *n*-acetyl cysteine.

Of critical importance is the dosing regime used in these studies. First, cultures were only treated once, on day 10 *in vitro*. At this time in culture, a confluent astrocyte monolayer covers the bottom of the tissue culture well, with neurons, microglia, and oligodendrocytes loosely attached to the astrocyte layer. Little cell division occurs at this time, and most of the cells in culture are terminally differentiated. A single dose of ceria nanoparticles was responsible for the dramatic extension of lifespan observed in these cultures. Further, a single dose on day 10 demonstrated enhanced protection against oxidative stressors through the extended lifespan of the cultures. This suggests that the antioxidant capacity of ceria nanoparticles in the cell may be, unlike many free radical scavengers, regenerative. The known

**Fig. 10.2.** Light micrograph of control and nanoparticle treated rat cortical mixed cell cultures. (A) 27-day-old organotypic culture near the end of its *in vitro* life span. Note the lack of confluent astrocyte monolayer in the background and low numbers of remaining, processed neurons. (B) 27-day-old culture

treated with 10 nm cerium oxide nanoparticles once, on day 10 *in vitro*. Note the healthy, confluent astrocyte monolayer and abundant neurons with robust processes. (C) 123-day-old culture treated with 10 nm cerium oxide nanoparticles on day 10 *in vitro*. Total magnification 800 $\times$ .

chemistry of ceria nanoparticles appears to support this hypothesis. Ceria undergoes rapid, reversible reduction and oxidation and can readily take up and release oxygen, alternating between  $\text{CeO}_2$  and  $\text{CeO}_{2-x}$  [64, 68, 94]. Therefore, it is a redox cycling agent that does not in itself generate free radicals in the process. Based on reports from the materials science field, we can only speculate on the actions of ceria nanoparticles in the physiological milieu. In aqueous medium, it appears likely that formation of adsorbed OH groups occurs on the surface of the ceria, with a concomitant reduction of the Ce atom from +4 to +3 (Fig. 10.3). This change in cerium valence alters the structure of the oxide lattice, creating oxygen vacancies and expansion of the lattice [95, 96]. This electron shuffling in the lattice, along with the oxygen vacancies generated, provide redox potential for free radical scavenging [76, 97]. After the scavenging event, the original lattice structure may be regenerated by  $\text{H}_2\text{O}$  and the cerium atom returned to the +4 state [98]. However, we would point out that the precise mechanisms responsible for lattice regeneration in the intracellular environment can only be speculated (Fig. 10.3). Thus,

**Fig. 10.3.** Hypothesized intracellular mechanism(s) of action of ceria nanoparticles (see text for description).  $\text{FR}^\bullet$  = free radical.

the redox properties of ceria appear to make it possible for the nanoparticles to both oxidize and reduce molecules, depending on the conditions in the surrounding milieu and the level of oxidative stress.

Why then, are micro-sized ceria particles ineffective or weakly effective as biological free radical scavengers? First, and probably most obvious, micro-ceria is unlikely to enter the cell due to its size. As shown in Fig. 10.4, nano-ceria readily enter mixed brain cell cultures and other cells [99], and hence are able to carry out redox reactions. Figure 10.4 shows brain macrophage or microglia that has phagocytosed one nanoparticle, with possibly a second in the process of consumption. Figure 10.5 is an electron micrograph taken from mixed brain cell cultures, demonstrating the presence of nanoparticles in the cytoplasmic space. Second, nano-ceria has a dramatically increased surface area as compared with micro-sized particles, thereby increasing the available redox sites. Last, nano-ceria is capable of redox behavior at far lower temperatures than its micro-sized counterparts, and has more oxygen vacancies for scavenging electrons, which may allow for redox cycling in physiological environs [96, 98, 100].

**Fig. 10.4.** Electron micrograph of intracellular cerium oxide. Note that one particle appears to already have entered the cell (first arrow), while a second may be in the early stages of phagocytosis (second arrow).

**Fig. 10.5.** Electron micrograph of mixed cortical cultures, showing intracellular accumulation of ceria nanoparticles (arrow).

#### 10.3.1.3 Other Oxide Nanoparticles

Materials science has utilized other oxides of the lanthanide series for redox reactions, including neodymium, ruthenium, praseodymium, lanthanum, and titanium. In many cases, ceria nanoparticles are doped with these compounds to enhance redox activity or stability. Although pure nano-oxides of these rare earths were without the life extension and radical scavenging abilities of ceria, mixtures of ceria-doped nanoparticles remain to be further examined for biological effects. The stability of ceria nanoparticles within the cell and the persistence during repetitive challenges of oxidative stress are presently unknown, and dopants may improve the intracellular half-life. Toxicities of these oxides have not been noted, with the exception of ruthenium, which can interfere with mitochondrial function [101]. However, there remains much work to be done regarding biological properties of ceria-doped nanoparticles.

Nanoparticles of zinc oxide and iron oxide have also received much attention at the biological level. Zinc oxide nanoparticles are routinely used as UV-absorbing agents in sunscreens. Their effects as intracellular antioxidants and lifespan extenders remain to be examined. Iron oxide nanoparticles have several emerging applications for drug delivery and biomedical imaging. However, problematic issues arise in that iron oxides may produce free radicals via the Fenton reaction, and hence may have damaging effects on cells. In this case, the addition of ceria nanoparticles to iron oxide nanoparticle preparations utilized in drug delivery may serve to abrogate deleterious effects of Fenton-reaction generated intracellular free radicals.

#### 10.3.1.4 Fullerene Derivatives and Carbon Nanotubes

Ceria nanoparticles are not the only nanoparticles that have future potential as free radical scavengers. Although experiments on cell lifespan are lacking, numerous reports suggest that fullerenes and carbon nanotubes may also act intracellularly as potent free radical scavengers. Corona-Morales et al. [102] have demonstrated that the water soluble carboxylic acid derivative of fullerene, carboxyfullerene, prolonged survival of adrenal chromaffin cells exposed to the free radical generating

neurotransmitter dopamine. In a series of papers, Dugan et al. [103–105] showed that carboxyfullerenes acted as free radical scavengers and dramatically reduced neuronal death induced by excitotoxic doses of NMDA, amyloid beta peptide, and  $H_2O_2$ , suggesting a role in neuroprotection. Carboxyfullerenes out-performed several other groups of free radical scavengers, including 21-aminosteroid compounds, vitamin E analogs, and spin trap agents. The extensive double bond system in fullerenols has led Krusic et al. to characterize them as a “free radical sponge” [106]. In rats, carrying the mutant SOD gene responsible for amyotrophic lateral sclerosis, carboxyfullerenes infusion delayed both functional deterioration and death [105]. Additionally, carboxyfullerene prevented the iron-induced oxidative injury in the nigrostriatal dopaminergic system of rats by acting as an antioxidant and suppressing free radical damage [107], suggesting potential use in Parkinson’s disease-like disorders. The mechanism of action of fullerenes has been hypothesized by Jain [108], in which a free radical forms a bond with fullerene creating a stable, non-reactive fullerene radical. Taken together, these reports suggest that like ceria nanoparticles, fullerene derivatives hold great potential in treating oxidative-stress related degenerative conditions, such as those associated with aging. Their role in aging, however, remains to be investigated.

The free radical scavenging and generating activities of carbon nanotubes have also been a subject of great debate. Unpurified single-walled carbon nanotubes (SWCNT) were shown to stimulate production of free radicals in human keratinocytes and bronchial epithelial cells [109, 110]. However, the free radical generating activities of SWCNT appeared to be due, in part, to metal contamination during particle synthesis. Muller et al. [111] reported that multi-walled carbon nanotubes (MWCNT) induced inflammatory and fibrotic reactions in rat lung after intratracheal instillation. They hypothesized that the mechanism of action was via free radical generation. In a recent subsequent study, Fenoglio et al. [112] directly examined the effect of MWCNT on free radical generation via electron spin resonance and found that MWCNT did not generate free radicals in physiological buffers. In contrast, they found that MWCNT were excellent scavengers of free radicals, including hydroxyl and superoxide radicals. In support of a role for CNT as free radical scavengers, one must consider that functionalization and polymer grafting onto CNT involves reactions similar to radical addition to the carbon framework [113, 114].

#### 10.4

##### **Nano-pharmacology**

Substantial evidence suggests that nanoparticles comprise a class of materials that may be potent antioxidants and intracellular redox reagents. However, treatment at the organismal level is confounded by the need for establishing the behavior of nanoparticles within the pharmacological parameters of ADME – absorption, distribution, metabolism, and excretion. Given the novelty of nanotechnology and the requirement for alternative ways of thinking about chemistry and physics in

the realm of the very small, traditional pharmacological parameters will no doubt require additional adjustments.

#### 10.4.1

##### Absorption

For a nanoparticle to be utilized in pharmacotherapy, absorption into the system is generally one of the first hurdles to be met. Several reviews address the study of nanoparticle-assisted drug delivery [115, 116] but much work remains in this realm, particularly for rare earth nanoparticles such as ceria and carbon derivatives such as CNT and fullerene compounds. It has been well established that various nanoparticles can enter an organism via skin absorption, digestive tract, and parenteral administration. Many even cross the blood–brain barrier. Our laboratory has conducted experiments injecting ceria nanoparticles into the tail vein of the mouse (Fig. 10.6). We found that injection of a 90 nmol total over 3 days via tail vein resulted in an increased accumulation of tissue cerium in brain, heart, and lung at 3 months post injection (Fig. 10.6). Interestingly, these three tissues are the most highly oxidative organs of the body. During the 3 month post injection period, no overt toxicological effects were noted in these experiments; however, histological assessments were not conducted (most of the tissue available was utilized to mea-

**Fig. 10.6.** Distribution of cerium in mouse tissues. Mice were injected with CeO<sub>2</sub> nanoparticles in saline via the tail vein (10  $\mu$ L, 3 mM stock), every other day for a total of

three injections. Mice were sacrificed 3 months post injection. Tissues were collected, ashed, and analyzed for cerium content by inductively coupled mass spectrometry.

sure tissue cerium levels). As measured by ashing followed by inductively coupled plasma mass spectrometry, tissue cerium levels were approximately doubled, but remained in the ppb range (Fig. 10.6). Six months post injection, tissue cerium levels were similar. These studies suggest that ceria nanoparticles are readily absorbed by tissues and tend to accumulate and persist in highly oxidative areas. One particular difficulty in administration was noted during intravenous injection in that injection of stock solutions higher than 3 mM appeared to agglomerate at the site of injection, blocking circulation and resulting in necrosis at the tail. Thus, agglomeration may be problematic in nanoparticle delivery. Additionally, notably, the long-term effects of accumulated ceria have not yet been examined and metabolic parameters such as excretion in urine and feces are unknown.

#### 10.4.1.1 Agglomeration

Agglomeration appears to be a primary issue in dosing, as mentioned above. Ceria, as well as other nanoparticles, have a high propensity for agglomeration, particularly in physiological medium. Agglomeration increases particle size and may block cellular or tissue uptake mechanisms. At the organismal level, systemic agglomeration of nanoparticles may block capillary circulation, lymphatic vessels, alveoli, or kidney perfusion. Thus, the use of dilute, well dispersed solutions of nanoparticles is critical. In our studies, care was taken to eliminate pre-administration agglomeration of nano-ceria by avoiding phosphate buffers and the use of rigorous sonication prior to delivery [88]. Poorly dispersed ceria solutions or solutions prepared in phosphate buffer, result in poor intracellular delivery of nanoparticles. However, as can be seen in Figs. 10.4 and 10.5, it appears likely that some agglomeration occurs in the cells themselves, since the particle size in electron micrographs appears to be somewhat larger than that in the stock solutions and intracellular particles shown in Fig. 10.5 appear to be associated. In lung cells, Stark et al. also found agglomerates of ceria [99], which appeared to be localized to vacuole-like structures.

In addition to agglomeration, contaminants from synthesis of nanoparticle preparations may also cause a range of effects and must be carefully controlled in cellular and animal studies. Metal contaminants from synthesis of carbon nanotubes may promote free radical generation and toxic effects. Likewise, tailing surfactant in nano-ceria preparations synthesized via micro-emulsion techniques have also proved damaging to the cell. Therefore, an assessment of preparation purity is a critical step that must be considered prior to biological use.

#### 10.4.1.2 Dose

Dose is also a parameter that needs to be addressed in a somewhat non-traditional pharmacological manner. Traditional pharmacology generally expresses dose in a molar or  $\text{mg kg}^{-1}$  manner. However, nanoparticles are engineered “mini-reactors”, and dose via mass or molar number may be an inappropriate descriptor, since each individual particle appears to be an entity unto itself. For example, in nano-ceria or fullerenes, the radical scavenging effect is primarily due to surface area reactions, which are enhanced at the nano-scale. Based on this premise, Oberdorster et al.

[117] propose that dose be described in terms of surface area, rather than mass. Other groups have utilized the descriptor of number of nanoparticles delivered per cell for *in vitro* experiments, which works well for nanoparticles of discrete size. Until further experimentation provides adequate guidelines, both these types of dose descriptors appear useful for experimental analysis and comparison. In the cases of carbon nanotubes, additional parameters of particle length and circumference need to be considered.

#### 10.4.2

#### **Distribution, Metabolism, and Excretion**

Distribution, metabolism, and excretion are parameters that also must be addressed as nanotechnology moves into the realm of conventional pharmacology. This area is one in which research is decidedly scarce. Studies with ultrafine particulates have shown that inhaled doses reach the systemic circulation and penetrate the blood–brain barrier, and this scenario is likely for many forms of nanoparticles [118, 119]. However, progress in this area has been hindered by our lack of ability to detect nanoparticle distribution and excretion. In the case of fullerenes, chemical detection in tissues is confounded by the fact that carbon is a ubiquitous backbone of all organic molecules. With cerium oxide and other rare earth nanoparticles, assessment of distribution is hindered by our ability to extract cerium oxide from tissues and the lack of chemical assessment of its presence. Of course, it is certainly possible to measure rare earths in tissue by inductively coupled mass spectrometry, but this only measures the rare earth element itself, and not the presence of oxides or other derivatives. Current research directed to the use of fluorescent tags may improve our ability to track the distribution of nanoparticles in living cells and tissues. Additionally, nanoparticles synthesized with heavy metal cores may permit localization via CT or MRI in the whole animal.

### 10.5

#### **Nanoparticle Antioxidants and Treatment of Disease**

Research to date suggests that nanoparticles may provide the field of medicine with effective, long lasting antioxidants for the treatment of diseases associated with free radical production (Table 10.1). Neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, multiple sclerosis, amyotrophic lateral sclerosis, and traumatic and ischemic brain injury all have free radical mediated components [1, 3, 5, 6, 120, 121]. Efficient nanoparticle free radical scavengers may hold great potential in abrogating the functional deficits associated with many of these neurological disorders. Using an *in vitro* model for traumatic brain injury [122–125], our group has shown that pre-treatment of brain cell cultures with ceria nanoparticles prior to injury, reduces cell death and neuronal dysfunction after injury [91, 92]. Importantly, ceria nanoparticles were effective at reducing neuronal death and dysfunction even when delivered up to 3 h post injury – an effect not

reproduced by other free radical scavengers. These effects were due, in part, to a reduction in the inflammatory reactions in brain microglia [92]. Other work also supports a role for fullerene derivatives in mediation of free radical damage in the nervous system [102–106].

Cardiovascular disorders are another realm in which nanoparticle free radical scavengers may hold great promise. Development of atherosclerotic lesions is promoted by free radical-mediated vascular damage and free radical generation to the vessel wall increases and promotes the subsequent inflammatory processes. Hence, effective administration of nanoparticle antioxidants may blunt this process, particularly in susceptible populations. Percutaneous transluminal angioplasty (PTCA) is a widely used procedure in treatment of acute and chronic ischemic heart disease. One of the most serious and reoccurring complications of PTCA is re-stenosis, leading to further blockage and occurrence of new ischemic events. The pathophysiology of re-stenosis is multifactorial and consists of inflammation, smooth muscle cell migration, proliferation, extracellular matrix remodeling, and free radical damage. Poly(ethylene glycol)-based core shell nanoparticles (NK911) loaded with the antineoplastic drug doxorubicin were able to prevent re-stenosis after balloon angioplasty in animal models [126]. It appears the core shell nanoparticles directed the doxorubicin to the damaged vascular epithelium. Incorporation of free radical scavenging nanoparticles into the core shell of such preparations may lead to further enhancement of endothelial function and reduction in future damage. Similarly, the use of coronary stents in treatment of chronic and acute coronary occlusion is also complicated by the occurrence of in-stent re-stenosis [127] and is a clinical problem treatable only by coronary artery by-pass. Stent re-stenosis is a result of continuing inflammatory reactions within the vascular walls, of which free radical production is an important component. Coating of vascular stents with ceria or other nanoparticles may aid in reducing inflammation around the site of stent insertion and decrease the incidence of re-stenosis.

Oxidative stress and free radical production are also a primary component of inflammatory disorders such as arthritis. Accumulation of activated inflammatory cells within the arthritic joint release high levels of free radicals that promote destruction of tissue within the joint. An as-yet unexplored possibility lies in the use of ceria and other antioxidant nanoparticles in reduction of damage to the arthritic joint, by direct delivery to the joint itself or via coating of implantable materials. In support of this potential usage, our laboratory has found that treatment of activated microglia and macrophages with ceria nanoparticles reduces release of free radicals from these cells and protects bystander cells from damage from activated immune cells [88, 92, 93]. Further, work by our collaborators, Drs. S. Olgun and C. Reilly, suggests that treatment of lupus mice with ceria nanoparticles decreases disease severity and inflammatory cell activation (Olgun, Reilly and Rzigalinski, unpublished results).

Of importance to us all is the association between oxidative stress and aging and age-related disorders. Can nanoparticles be the fountain of youth long sought by Ponce de Leon? Although promising, the utility of nanoparticles in retarding aging are far more complex than to venture an answer to such a question. Ceria nanopar-

ticles, and possibly others, certainly hold promise for extension of lifespan and abrogation of age related disorders. However, much work is necessary to move the current work in cellular studies, to the level of organism longevity. In preliminary studies in the fruit fly, we have found a 30% increase in lifespan in flies fed cerium oxide nanoparticles, dosed at 10–100 nM in the food. However, doses above 1 mM appeared to result in a decrease in lifespan. Hence, total cumulative dose to the organism is likely to be an important parameter. Also, the effect of dosing throughout the lifespan vs. dosing for a limited time period needs to be examined. Although excessive free radical production contributes to cell damage, free radicals, as discussed in Section 10.1, also have beneficial effects on survival – particularly in the vascular and nervous systems. Thus, blockade of free radical production may reach the level of “too much of a good thing”. For example, NO radicals are critical to maintenance of vascular tone and endothelial function. Satoh et al. [128] have shown that fullerene nanoparticles interfere with NO-mediated vasodilation and may have deleterious effects on the vasculature at high concentrations. For ceria nanoparticles, the vasoactive actions of NO may also be rendered non-functional at certain concentrations, resulting in disruption of the normal vascular response *in vivo*. Thus the question arises as to how much free radical scavenging is too much, and at which point these highly efficient nanoparticle scavengers interfere with normal cell function. Further engineering of nanoparticle structure may provide a solution to this problem. However, much work is needed to assess these parameters.

An additional paradox arises when one considers the increased incidence of neoplasia with age. If resistance to free radical damage is conferred to normal cells by nanoparticles, might not cancerous cells or dysfunctional cells destined for apoptosis also receive a degree of protection when nanoparticles are delivered? Such events might potentially counteract the tumor killing effects of radiation or chemotherapy, both of which may act through free-radical mediated cell death. Alternatively, if such nanoparticles could be delivered to healthy cells surrounding the site of a radiation dose, they may afford protection to healthy bystander cell injury associated with radiation therapy. Again, further engineering and targeting of nanoparticles may provide solutions to these issues. Nonetheless, such avenues remain to be explored before the full medicinal capabilities of nanoparticles can be put to use.

## 10.6 Toxicology

Despite the beneficial potential of antioxidant nanoparticles in the treatment of disease, there remains a major hurdle that must be surpassed before progress can be made in this area. Toxicological data is seriously lacking. Presently, there are only scant reports on the effects of nanoparticles in general on organism metabolism and function. As discussed in Section 10.3, some nanoparticles appear to have the potential to induce free radical formation and damage, which may be due to con-

taminants from synthesis procedures [109, 110, 119]. Several studies have reported that SWCNT and MWCNT induce granulomas and fibrosis in the lung during intratracheal or inhalation exposure [110, 129]. Oberdorster et al. [130] have reviewed the potential toxicological effects of fullerenes as free radical generating agents, particularly after exposure to light. Kamat et al. [131] also report significant lipid peroxidation due to photosensitized C60. Hussain et al. have reported that oxide nanoparticles of molybdenum, aluminum, iron, and titanium were toxic, albeit at high doses [132]. Ueng et al. [133] demonstrated that certain fullerene derivatives suppressed microsomal enzymes and mitochondrial oxidative phosphorylation *in vitro*, although the compounds were able to scavenge free radicals in brain tissue [134, 135]. Chen et al. report that SiO<sub>2</sub> nanoparticles were taken up into the cell nucleus, where they caused aberrant clustering of nuclear proteins and inhibited replication and transcription [136]. Thus, although highly promising, antioxidant nanoparticles are certainly not a magic bullet as yet and the road ahead is likely long – but equally likely one worth traveling.

## 10.7

### Summary

Free radicals and oxidative stress are associated with a broad spectrum of human diseases. Despite their prominence in pathological conditions, antioxidant therapy has met with only limited success. Nanoparticle technology encompassing rare earth oxides, fullerene derivatives, and carbon nanotubes show great promise in antioxidant therapy in a myriad of disease conditions. However, much work is needed to fully realize their capacity in nanomedicine.

## 11 Nanoparticles and Nanowires for Cellular Engineering

Jessica O. Winter

### 11.1 Introduction

The use of nanostructures (e.g., nanoparticles and nanowires) has increased dramatically in the last decade. Most applications have exploited the unique optical properties of mesoscale materials for imaging applications, both *in vivo* and *in vitro*. More recently, nanostructures have been investigated as components of actuating systems that can interact directly with the cellular environment. Because of the complementary size-scale of nanostructures and biological components, these systems provide the opportunity to precisely manipulate cells and proteins. This ability will produce greater insight into cellular function and pave the way for novel therapies.

This chapter discusses applications of nanostructures, including nanoparticles and nanowires, to cellular engineering. While several authors discuss specific aspects of nanomaterial interactions with cells (e.g., cell adhesion), this chapter is one of the first comprehensive investigations of the role of nanoparticles and nanowires in manipulating specific cellular components. Most of these approaches are in nascent stages, and therefore much of this chapter is focused on *potential* opportunities. Discussion is confined to semiconductor, metallic, silica, and magnetic materials, as carbon-based materials, polymeric nanostructures, and protein nanoparticles are discussed elsewhere. This chapter is divided into several subsections. Section 11.2 describes the motivation for using nanostructures to explore the biological milieu, their synthesis, and modifications required for biocompatibility. Section 11.3 examines nanostructures that interact with the cell exterior. Methods for modifying cell adhesion, migration and for manipulation of the cytoskeleton are discussed. Section 11.4 explores techniques for nanostructure delivery to the cell interior. Upon contact with cells, nanostructures enter the endocytosis pathway. Methods for eluding this fate are evaluated. Additionally, applications in intracellular tracking and sensing are considered. Section 11.5 describes nanostructure transport using the cytoskeletal system, including actin- and myosin-based approaches. Potential use for internal cytoskeletal manipulation and cargo delivery are evaluated. Section 11.6 considers the use of nanostructures for biomolecule

delivery, including drug delivery and gene therapy. As applications in the area of drug delivery are vast, nanotherapeutics for cancer therapy are presented as examples. Section 11.7 examines the potential of nanostructures to manipulate proteins, membrane bound receptors, and ion channels. Finally, concluding thoughts and a look to the future are presented in Section 11.8.

## 11.2

### Biological Opportunities at the Nanoscale
